composite to have a combination of desirable piezoelectric properties in addition to having lower density and higher flexibility than sintered PZT. Pioneered by Robert Newnham's group at Penn State University, PZT–polymer composites with 0–3, 1–3, and 3–3 connectivities have been intensely studied and are widely used in ultrasonic imaging and hydrophones. The superior properties of such composites over their monolithic counterparts arise from the macroconnectivity of the stiff, high-permittivity PZT elements in the compliant, low-permittivity polymer matrix. The polymeric matrices used include PVDF, PVA, PVC, and epoxy resins. The presence of the polymer reduces the dielectric constant and the density, leading respectively to a larger voltage output and lower acoustic impedance. Recently, hot-pressed 0–3 PZT–PVDF (50/50 volume fraction) has been found to show reasonably high d_{33} and good mechanical properties [93]. There are several studies of ceramic–ceramic nanocomposites as well. For example, Cheung et al. [94] prepared a dispersion of $BaTiO_3$ nanoparticles in a sol–gel matrix, also of $BaTiO_3$. Films having this composite structure were made by spin coating. Similar 0–3 ceramic–ceramic nanocomposites were also formed using PZT [95] and some of these may find application as ultrasonic transducers. Explicit formulas are available for calculating the effective piezoelectric coefficients of 0–3 composites of ferroelectric particles in a ferroelectric matrix in terms of the composition and the constituents' piezoelectric, dielectric, and elastic properties [96].

Even though the largest hydrostatic figures of merit for biphasic PZT–polymer composites have actually been obtained from 3–n types of structure, such as 3–3 [97], 3–2, and 3–1 [98], most of the older techniques used for

the synthesis of these architectures are laborious and result in poorly controlled structures. Recently Smay et al. [99] have made use of a robotic direct-write deposition technique ("robocasting") to fabricate a range of such 3–n structures and have presented a systematic study of the piezoelectric and dielectric properties as a function of connectivity and PZT/polymer ratio.

7.2. Dielectric Properties

A proper choice of composite architecture can lead to a substantial enhancement in the dielectric constant. Recently, a dielectric constant of over 130 has been observed [100] in a 0–3 $BaTiO_3$–cyanoresin composite (51/49 volume fraction), while the dielectric constant of the pure polymer is only 21 (at 1 kHz). This is one of the highest dielectric constants observed so far in $BaTiO_3$-based polymer composites. Bai et al. [101] have recently reported large enhancements in the dielectric constant of a 0–3 composite where the matrix was an *irradiated* copolymer. High-energy irradiation converted the polymer from a normal ferroelectric to a relaxor ferroelectric, leading to a reduction in the *P–E* hysteresis at high fields. The dispersed ferroelectric phase was $Pb(Mg,Nb)O_3$–$PbTiO_3$, which is itself a relaxor ferroelectric with a high room temperature dielectric constant. Such a composite showed a weakly temperature dependent dielectric constant of over 250. At optimal composition, the breakdown strength too was very high (120 MV/m), leading to a very large energy storage density of 15 J/cm^3. However, the value of the ceramic content in this case is so high that the material probably loses its flexibility.

Dang et al. [102] have recently reported a three-phase composite with a dielectric constant above 500. The composite consists of an insulating polymer matrix and a homogeneous distribution of small particles of $BaTiO_3$ and Ni. Such a three-phase polymer–matrix composite is flexible and can be easily fabricated into various shapes at low processing temperatures. The electrical properties of such composites can be analyzed by percolation theory when the metallic filler concentration is close to the percolation threshold. Similarly, the incorporation of metallic Ag particles into SBN [103] and Pt particles in PZT [104] leads to significant improvements in the dielectric properties and also to lower processing temperatures. Kundu et al. [105] observed a drastic increase in the dielectric constant of a PZT/glass composite on introducing 4–15 nm PbS particles. In samples with PbS volume fraction varying between 0.07 and 0.14, the dielectric constant ranges between 900 and 3500 (at 1 kHz).

The glass ceramic composite has also been used as a vehicle for basic studies of size effects in ferroelectrics. Thus, McCauley et al. [106] have grown dispersed nanometer-sized $BaTiO_3$ particles in a residual glass matrix. They find that the T_C, ε_{max}, and the width of the ε–T curve all scale systematically with the mean size of the $BaTiO_3$ crystallites. The extrapolated critical size for the destabilization of ferroelectric order was found to be 17 nm.

7.3. Pyroelectric Properties

Ferroelectric–polymer composites also show excellent pyroelectric properties such as the figure of merit p/ε, where p is the pyroelectric coefficient and ε is the dielectric constant.

For example, the value of p/ε for a PZT/polymer composite has been reported to be up to six times higher than in monolithic PZT [107]. Similar results have also been reported for polymer composites involving $PbTiO_3$, $BaTiO_3$, and TGS. Taking the depolarization of the ferroelectric particles into consideration, Wang et al. [108] have derived a general formula for the pyroelectric coefficient of a composite in terms of the dielectric constant of the two components, the volume fraction and the depolarization coefficient. Ploss et al. [109] studied the pyroelectric coefficient of a 0–3 $PbTiO_3$/PVDF–TRFE composite as a function of the relative polarizations of the ceramic and the copolymer. They find that the composite with the ceramic and the copolymer polarized in the same direction exhibits the strongest pyroelectricity but relatively weak piezoelectricity.

7.4. Optical Properties

Several ferroelectric oxides such as $BaTiO_3$, $(Pb, La) \cdot TiO_3$, $LiNbO_3$, and $KNbO_3$ have useful nonlinear optical (NLO) properties because of their polar crystallographic structure. Transparent TeO_2-based glasses containing dispersed ferroelectric crystallites are promising NLO glass candidates. The advantage of using a TeO_2-based glass as matrix is that its refractive index is close to that of several ferroelectric crystals, which leads to low scattering losses at the glass-ceramic interface. Other types of glasses have also proved useful. Transparent glass–ceramic composites in which ≈ 40 nm $SrBi_2Ta_2O_9$ particles were dispersed in lithium borate glass appears to be a promising candidate for NLO applications [110]. At room temperature, the system shows a pronounced second harmonic generation (at 532 nm) and a ferroelectric hysteresis with a low dielectric loss.

From a calculation of the electro-optic Kerr constant of a composite containing nonlinear, centrosymmetric dielectric microcrystals, it has been shown that the nonsphericity of the microcrystals may lead to an enhancement of the Kerr constant provided the permittivity of the glass ceramic phase is much smaller than that of the inclusions [111].

7.5. Magnetoelectric Properties

The magnetoelectric (ME) effect is characterized by the appearance of an electrical polarization (magnetization) on applying a magnetic (electric) field. A material with a high ME coefficient should find application as magnetoelectric sensors in radioelectronics, microwave electronics, and optoelectronics. Other than the "intrinsic" ME effect shown by many single phase materials (Cr_2O_3, yttrium iron garnets, rare earth ferrites, etc.), an "extrinsic" ME effect may be exhibited, for example, by a ferrite/piezoelectric (ceramic/ceramic) composite, so-called since neither of the two components is individually a ME system. Thus, when a magnetic field is applied to such a composite, the ferrite particles change shape due to magnetostriction, and the strain is passed on to the piezoelectric phase, which results in an electric polarization. The ME effect has, in fact, been observed in composites such as $CoFe_2O_4$/$BaTiO_3$, (Ni–Co–Mn)ferrite/PZT, etc. Theoretical calculations of the ME effect in composites have been made using Green's function

techniques and considering linear and nonlinear coupling between piezoelectric and piezomagnetic particles. Interestingly, a giant linear ME effect is predicted in, for example, a composite of ferromagnetic rare earth iron alloys filled with a ferroelectric polymer such as PVDF [112]. Nan et al. [113] have studied a three-phase multiferroic composite consisting of particles of Tb–Fe–Dy alloy (Terfenol-D), dispersed (with a volume fraction f) in a mixture of PZT and PVDF. The ME response of such a composite is due to the large magnetostriction of Terfenol-D and the large piezoelectricity of PZT, and the coupling between the two through a flexible matrix. The percolation threshold for such a system (as measured from dielectric, piezoelectric, and ME properties) occurs at $f_T \approx 0.12$. For $f < f_T$, the system exhibits increasing piezoelectric and ME response. But these quantities drop sharply as f_T is approached and vanish at f_T, above which volume fraction the composite only shows magnetostriction. The expected giant ME effect remains unrealized as yet.

8. SYNTHESIS OF NANOCRYSTALLINE FERROELECTRICS

A wide variety of chemical techniques have been successfully used for synthesizing nanocrystalline ferroelectrics with controlled mean size and size distribution (see [114] for a recent review). These include sol–gel, co-precipitation, spray-pyrolysis, freeze-drying, microemulsion-mediated reactions, hybrid dry–wet processes, etc. Conventional "dry" powder-mixing processes are usually unsuitable because the temperatures involved are often too high—resulting in grain growth and a broad size distribution. Some of the more useful wet techniques are briefly described.

8.1. Sol–Gel Process

A *sol* is a dispersion of solid particles (less than ≈ 100 nm in size) in a liquid, while a *gel* is a rigid (or semisolid), porous interconnected network. The sol–gel process [115, 116] consists of the following generic steps (also described schematically in Fig. 13):

(i) preparation of a homogeneous solution of the precursors (e.g., metal alkoxides) in an organic solvent miscible with water [or with the reagent used in step (ii)]
(ii) conversion of this solution into a sol by treatment with suitable reagents
(iii) gelation of the sol via polycondensation
(iv) shaping the gel (or viscous sol) into the desired form (granular, spherical, thin film, fiber, etc.)
(v) low temperature sintering (usually <500 °C) of the shaped gel into the final nanocrystalline product

The precursor metal alkoxides, $M(OR)_n$ (where M is the metal and R is an alkyl group) can be synthesized by reacting the corresponding metal chloride with an alcohol in the presence of a base such as ammonia. The general reaction is

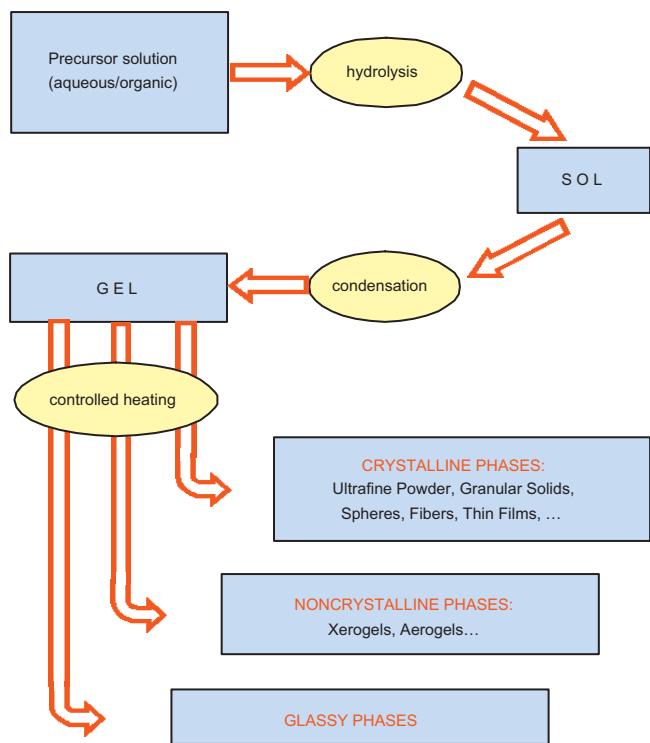
$$MCl_n + nROH + nNH_3 = M(OR)_n + nNH_4Cl$$


Figure 13. A schematic flow chart of the sol–gel process for the synthesis of low-dimensional oxide/ceramic materials.

The metal alkoxides can then be hydrolyzed to yield oxides, hydrated oxides, and hydroxides in the amorphous, crystalline, or nanocrystalline form. A number of ferroelectric oxides have been successfully synthesized using the basic sol–gel process as well as its many variations. Ozaki [117] has given a detailed discussion of the preparation of a variety of ultrafine Ba and Pb based perovskite compounds and their solid solutions. Jo and Yoon [118] have provided a comparative study of the advantages of the sol–gel technique over the conventional oxide–mixing route in the case of ferroelectric $(Ba_{0.2}Pb_{0.8})TiO_3$. Fukui et al. [119] have used complex alkoxides to prepare submicrometer $Pb(Zr_{1-x}Ti_x)O_3$. Zhong et al. [23] have prepared $PbTiO_3$ fine particles by the basic sol–gel technique. They dissolved lead acetate in 2-ethylhexanol at 80 °C and added a stoichiometric amount of titanium n-butoxide to the solution, which was then hydrolyzed by adding water. The resulting precipitate was washed, filtered, and dried. $PbTiO_3$ fine particles of different average size in the 20–200 nm range were obtained by calcining the dried precipitate at different temperatures between 550 and 700 °C. Earlier, Ishikawa et al. [21] had achieved similar results starting from a stoichiometric mixture of titanium tetra-isopropoxide and lead isopropoxide, both dissolved in isopropyl alcohol. Several hybrid techniques based on the basic sol–gel have also been successfully used. Chattopadhyay et al. [26] synthesized nanocrystalline $PbZrO_3$ by using NH_4OH to co-precipitate Pb^{2+} and Zr^{4+} ions from an aqueous solution of $Pb(NO_3)_3$ and $ZrOCl_2 \cdot 8H_2O$. The mixed precipitate was converted to a stable sol by ultrasonication and gelated using 2-ethyl hexanol in presence of a surfactant. The gel was dried and calcined to obtain nano-$PbZrO_3$.

8.2. Co-Precipitation and Complexation

In this process, it is essential to achieve conditions that allow simultaneous and not sequential or selective precipitation of the relevant cations. This would ideally allow a molecular level mixing of the components and may be expected to lead to a totally homogeneous product. However, even in this case the resulting precipitate would be a mixture of different phases, probably with different particle sizes. The formation of the final product would then proceed via solid-state atomic diffusion among these particles, resulting in particle growth and a relatively broad size distribution. Wherever possible, it is preferable to form a *complex* of all the cations that would *directly* lead to the desired phase on thermal decomposition. The decomposition temperature should obviously be optimized to minimize particle growth.

As a simple example, we consider the synthesis of nanocrystalline $PbTiO_3$ by coprecipitation from $Pb(NO_3)_2$ and $TiCl_4$ [25]. $TiCl_4$ (dissolved in HCl) was precipitated as $Ti(OH)_4$ by adding NH_4OH before being converted to soluble $Ti(NO_3)_4$ by adding con. HNO_3. The presence of NH_4NO_3 in the solution prevents the formation of insoluble $PbCl_2$ during the subsequent step. An aqueous solution of $Pb(NO_3)_2$ was added to the $Ti(NO_3)_4$ solution in stoichiometric proportion. The cations were co-precipitated as hydroxides by adding the solution to NH_4OH while keeping the pH controlled at 9–10. The mixed hydroxide precipitate was heated to various temperatures between 460 and 850 °C to produce $PbTiO_3$ nanoparticles in the size range 20–200 nm.

Co-precipitation from organometallic precursors has been used to synthesize ultrafine $BaTiO_3$ [120]. Potassium titanyl oxalate solution was slowly added to a barium acetate solution, being continuously stirred. The precipitate was dried and calcined at 550 °C to produce $BaTiO_3$. A similar technique (using strontium nitrate instead of barium acetate) can be employed to produce $SrTiO_3$.

8.3. Microemulsion-Mediated Reactions

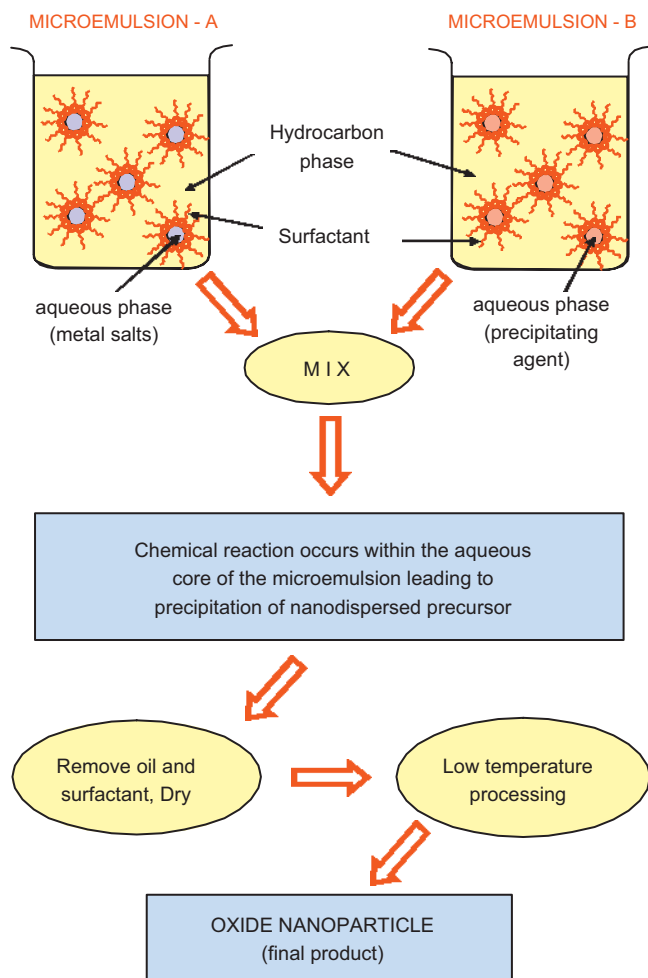
A microemulsion is a thermodynamically stable, optically isotropic dispersion of two immiscible liquids (usually water and oil) consisting of nanosized domains of one liquid in the other, stabilized by an interfacial layer of surface active molecules (surfactant). A water-in-oil microemulsion consists of essentially monodispersed droplets (10–100 nm in size) of an aqueous phase in a continuous hydrocarbon phase. The dispersed aqueous phase can be used as nanoreactors for the precipitation of uniform-sized nanoparticles of a variety of metals, oxides, halides, etc. [121, 122]. Typically, the two reactants are confined within the aqueous cores of two different suitably chosen microemulsion systems. On adding the two, the reactants come into contact in a controlled manner since the aqueous droplets continually collide, coalesce, and exchange contents. The resulting precipitated species remains confined within the core of the microemulsion and is subsequently separated, dried, and heat-treated—if necessary—to obtain the nanoparticulate solid (Fig. 14). The droplet size, and hence the particle size of the final product, is controlled essentially by the water/surfactant ratio, in addition to other microemulsion parameters.


Figure 14. Schematic diagram of the conventional scheme used for microemulsion-mediated precipitation of oxide nanoparticles.

Figure 15. Schematic diagram of the microemulsion-mediated sol–gel reaction for producing oxide nanoparticles.

Herrig and Hemplemann [123] have reported a microemulsion-mediated sol–gel process for the synthesis of perovskite oxides such as $BaTiO_3$, $BaZrO_3$, $SrTiO_3$, and $SrZrO_3$ in the form of ultrafine particles stabilized as colloids in an organic solvent. The metal alkoxide solution was prepared by refluxing Ba or Sr in isopropanol at 125 °C under dry N_2. The Ba/Sr isopropylate was cooled to room temperature and equimolar quantities of $Ti(nprop)_4$ or $Zr(nprop)_4$ added to it. Immediately thereafter, a water-in-cyclohexane microemulsion with Brij-30 (polyoxyethylene-4-laurylether) as surfactant was poured into the solution. This results in a transparent solution consisting of nanodispersed metal precipitates. The alcohol, cyclohexane, and water were removed from the solution by vacuum evaporation and the residue was washed in acetone using a centrifuge. The dried precipitates were sintered at various temperatures to obtain 9 nm $BaTiO_3$ (at room temp.), 18 nm $SrTiO_3$ (700 °C, 1 h), 11 nm $BaZrO_3$ (800 °C, 1 h), or 19 nm $SrZrO_3$ (900 °C, 1 h). A flow chart of the process is shown in Figure 15.

Lu and Wu [124] used a water–oil emulsion to synthesize 100 nm (and larger) $PbTiO_3$ microparticles. The aqueous phase contained a solution of equimolar lead nitrate and titanium oxynitrate (produced by hydroxide precipitation

from $TiCl_4$ using NH_4OH, and dissolving the precipitate in HNO_3) dispersed in n-octane with 1 wt% SPAN-80 as surfactant. Due to the nature of the surfactant as well as the low surfactant/water ratio used, the resulting mixture is an *emulsion* (which phase-separates spontaneously with time) rather than a microemulsion. The advantage of this technique is that an additional precipitation step is unnecessary and the $PbTiO_3$ fine particles are obtained directly by removing the solvents and subsequent thermal treatment. The disadvantage of not using a microemulsion is that the resulting particle size was rather large: 100–200 nm for samples calcined at 700 °C.

8.4. Hydrothermal Reactions

Hydrothermal synthesis generally involves water as a catalyst as well as a component and is used to describe reactions at temperatures above 100 °C and pressures above 1 atm. This route offers certain important advantages such as ease of use, high product purity, good control over particle size, and low process cost. For example, $BaTiO_3$ powder has been synthesized by a low temperature, low pressure hydrothermal route [125] based on the reaction of TiO_2 (anatase) powder in an alkaline aqueous solution of

Ba(OH)$_2$ at 90 °C. Hydrothermal routes generally involve the processing of an aqueous solution or suspension of the precursor gel powder at somewhat elevated temperatures and pressures. Such precursor gel powders are usually nm-sized gels containing precipitated metal salts (such as chlorides, sulfates, and nitrates) or metal alkoxides. However, spherical gel powders have also been used in hydrothermal synthesis. Thus Choi et al. [126] have synthesized spherical nanoparticles of PbTiO$_3$, BaTiO$_3$, and SrTiO$_3$ from spherical TiO$_2$ gel powder, while spherical nanoparticles of PbZrO$_3$ and Pb(Zr,Ti)O$_3$ where prepared from spherical gels of ZrO$_2$ and ZrTiO$_4$, respectively. The TiO$_2$ and ZrO$_2$ spherical gel powders were first synthesized by the thermal hydrolysis of TiCl$_4$ and ZrOCl$_2$, respectively, while the spherical ZrTiO$_4$ gel powder was obtained from thermal hydrolysis of a mixture of TiCl$_4$ and ZrOCl$_2$ in an alcohol–water solution. The sources for the *A*-site cations of the perovskite compounds were Pb(CH$_3$COO)$_2$·3H$_2$O, Ba(OH)$_2$·8H$_2$O, and Sr(OH)$_2$·8H$_2$O. The most interesting point about this process is that the spherical precursor gel powders retain their shape during the hydrothermal treatment to produce rather large (400–800 nm) but perfectly spherical particles of the perovskite oxide product.

Since the hydrothermal technique leads to considerable energy savings due to relatively low processing temperatures, several modifications of the basic process have been investigated. Komarneni et al. [127] have used a combination of microwave and hydrothermal techniques to synthesize a number of ultrafine perovskite such as BaTiO$_3$, SrTiO$_3$, (Ba,Sr)TiO$_3$, PbTiO$_3$, Pb(Zr,Ti)O$_3$, Pb(Mg,Nb)O$_3$, etc. The use of microwaves enhances the reaction kinetics by one or two orders of magnitude over the conventional hydrothermal process. Since the reaction vessel is sealed during the process, the synthesis of Pb- and Bi-based systems, for example, is environmentally safer. The microwave-hydrothermal process typically uses a microwave digestion system operating at 2.45 GHz and 600 W and at a maximum pressure of 200 psi. As a typical example, the authors prepared BaTiO$_3$ from a solution of Ba(NO$_3$)$_2$, TiCl$_4$, and KOH at 20 psi. The product consisted of spherical, unagglomerated particles having a size in the range of 100–200 nm.

9. DEPOSITION OF FERROELECTRIC THIN FILMS

During the past couple of decades, major advances have taken place in the techniques for the deposition of uniform, homogeneous, device-quality thin films. Several different techniques have been successfully employed for the synthesis of high quality ferroelectric thin films suitable for basic studies as well as device applications. A process for depositing ferroelectric thin film based devices should generally possess the following characteristics [128]:

(1) possibility of integration with metallic or conductive oxide electrode layers with physicochemical properties different from the ferroelectric material,
(2) compatibility with integrated device processing with specific microstructure on specific substrates,
(3) production of highly oriented as well as polycrystalline films and heterostructures with specific properties,

(4) ability to produce patterned structures, superlattices, and layered heterostructures,
(5) perfect reproducibility of the deposition process,
(6) economical with high deposition rates.

The three most successful techniques that satisfy most of these criteria are pulsed laser ablation deposition (PLAD), metal-organic chemical vapor deposition (MOCVD), and plasma/ion-beam sputter deposition (PSD/IBSD). Here we provide brief descriptions of these processes. It is relevant to note that these techniques can also be suitably modified to produce nanocrystalline thin films of various materials (metals, oxides, nitrides, sulfides, etc.) with controlled grain size in the 5–100 nm range [129]. Some of the other techniques that have been used with varying degrees of success for producing ferroelectric films are chemical vapor deposition, metal-organic deposition, liquid source mist deposition, and sol–gel.

9.1. Pulsed Laser Ablation Deposition

The main advantage of PLAD is that it allows rapid and *stoichiometric* deposition of multication as well as multicomponent oxide films. A typical PLAD system requires an excimer laser (such as a KrF laser operated at 248 nm, with an output power density of ∼1 J cm^{-2}, and a repetition rate of 1–10 Hz), a rotating target holder, and a substrate holder that can be heated to about 800 °C. The process allows considerable control over the composition, microstructure, and properties. The process parameters that mainly determine these quantities are the ambient gas (usually O$_2$) pressure, the substrate temperature, the target-to-substrate distance, the laser energy, and wavelength.

9.1.1. Recent Applications

SBT films were grown by PLAD as a part of a metal–ferroelectric–insulator–semiconductor FET structure (SBT/SiON/Si) by Sugiyama et al. [130]. Nakaiso et al. [131] deposited ferroelectric Sr$_2$(Ta$_{1-x}$Nb$_x$)$_2$O$_7$ films on Pt/Ti/SiO$_2$/Si and SiO$_2$/Si(100) substrates. Excellent ferroelectric properties were observed [132] in (Pb,La)(Zr,Ti)O$_3$ deposited directly on metal surfaces. PZT thin films deposited on different substrates (Au coated Si, Al$_2$O$_3$, Corning glass, etc.) by reactive pulsed laser (Nd-YAG) deposition show good piezoelectric and ferroelectric properties [133]. Cillessen et al. [134] have shown that the coercive field in PLAD-deposited thin-film ferroelectric capacitors consisting of PZT sandwiched between La$_{0.5}$Sr$_{0.5}$CoO$_3$ electrodes is comparable to bulk ceramic values. Textured thin-film capacitors with a columnar microstructure were found to show lower switching voltages than epitaxial films. High quality BaTiO$_3$ thin films were epitaxially grown on SrTiO$_3$ (100) substrates from a single crystal target [135]. The authors also grew BaTiO$_3$/YBa$_2$Cu$_3$O$_7$ bilayer structures on LaAlO$_3$ (100) substrates. Jia et al. [136] deposited Ba$_{0.5}$Sr$_{0.5}$TiO$_3$ thin films on conducting RuO$_2$ [grown epitaxially on (100) LaAlO$_3$], which showed pure (111) orientation normal to the substrate surface and exhibited dielectric constant above 600 and dielectric loss of 0.03–0.05 at 100 kHz under zero dc bias. Palkar et al. [137] were able to deposit perfectly *c*-axis oriented, single phase, ferroelectric PbTiO$_3$ films directly on (100) Si.

9.2. Metal-organic Chemical Vapor Deposition

MOCVD outstrips all other techniques as far as compositional control, large-area film uniformity, and compatibility to ULSI fabrication technology are concerned. Since it is extensively used in commercial IC fabrication, the process parameters and instrumentation are understood extremely well. However, the major disadvantage still faced by this technique in the processing of ferroelectric oxides is the nonavailability of some of the metal-organic precursors with acceptable purity, vapor pressure, and chemical stability. A typical experimental setup (used for the synthesis of $PbTiO_3$ and PZT thin films) [138] consists of a cold-wall reactor with horizontal flow design using a resistively heated inconel susceptor. The system is equipped with three temperature and pressure controlled liquid-source stainless steel bubblers containing the organometallic precursors (for Pb, Ti, and Zr). In the case of low vapor pressure solid precursors, one directly sublimes the solid or evaporates the melt into the carrier gas, which is usually N_2, He, or Ar. For most materials, better thickness and compositional uniformity can be achieved when the processing occurs at pressures below about 100 Torr.

9.2.1. Recent Applications

The application of MOCVD to the synthesis of ferroelectric thin films has been reviewed very recently [139]. Many common ferroelectrics such as SBT, BST, PZT, etc. have been successfully grown by MOCVD and there is substantial volume of literature on the subject. In MOCVD-grown $BaTiO_3$ films on (100)Pt/(100)MgO substrates, the grain size was found to be strongly affected by $p(O_2)$ and showed a maximum when $p(O_2)$ was between 66 and 93 Pa. The dielectric constant increased from 93 to 640 with increasing grain size from 20 to 130 nm, showing a broad peak at 350–380 K [140]. Leedham et al. [141] have addressed the important issue of new, single source MOCVD precursors for SBT, SBN, and SBTN. It is clear that MOCVD remains the most promising technique for ferroelectric thin film based device fabrication and integration.

9.3. Plasma Sputter Deposition

There is extensive work on the PSD of ferroelectric thin films using multiple element targets as well as multicomponent oxide targets. The target (cathode) is connected to a dc or rf power supply (100 V to few kV) while the substrate (anode) may be grounded, electrically floating, or at small dc bias and is typically heated to a few hundred °C. After evacuating the chamber, a gas (typically a few millitorr of Ar) is introduced and serves as the medium in which the plasma discharge is initiated and sustained. It is advantageous to confine the plasma magnetically using a magnetron system. When a visible discharge is maintained between the electrodes, there is a flow of current accompanied by a deposition on the substrate. The process parameters that control the composition, microstructure, and film quality include the gas pressure, the substrate temperature, the target-substrate geometry, and the applied dc/rf voltage. Thus, oriented and epitaxial films can usually be grown when conditions are

such that the mean kinetic energy of the sputtered atoms is rather low when they arrive at the substrate. The use of elemental metallic targets in the deposition of PZT films with controlled stoichiometry and properties has been demonstrated [142]. The authors used a disc-shaped target with several unequal sectors of Pb, Zr, and Ti. They suggest that such a process is governed by three factors: (a) the formation of a reproducible oxide layer on the target surface, (b) the stability of the oxide species during transport through the plasma, and (c) the nucleation and growth of the film on the substrate.

9.3.1. Recent Applications

Remiens et al. [143] recently deposited PZT (and Nb substituted PZT) films on Si by rf-magnetron sputtering and studied the effect of process parameters on dielectric, ferroelectric, and piezoelectric properties. Kikuchi et al. [144] deposited ferroelectric PLZT thin films on 200 mm diameter $Pt/Ti/SiO_2/Si$ substrates in a multichamber production system. Using rf-magnetron sputtering from elemental targets, highly oriented (111) $PbTiO_3$ films were deposited on amorphous sapphire for optical studies [145]. SBT films have been deposited by rf-magnetron sputtering on a $Pt/Ti/SiO_2/Si(100)$ structure between 500 and 600 °C. The maximum remnant polarization value ($2P_r$) of the SBT film was 15 $\mu C/cm^2$ [146]. BST films have been grown on $SrTiO_3$, $LaAlO_3$, MgO, α-Al_2O_3, and $Y_3Fe_5O_{12}$ by rf sputtering [147]. In recent times, many other ferroelectric thin films have also been grown using this technique.

The IBSD technique typically uses an Ar^+ beam directed at 45° to the target normal. In a more successful modification, multiple ion beams have been used, where each beam is directed at different elemental targets such as Pb, Ba, Zr, and Ti [148].

10. LOCAL PROBE MEASUREMENTS

Clearly, it is essential to understand the basic phenomena governing size effects in ferroelectric nanomaterials if we want to apply them to the next generation of high density electronic devices and microelectromechanical systems. In addition to some of the important studies described in the preceding sections, a number of new and interesting results have started arriving from various types of high-resolution, local probe measurements such as scanning force microscopy (SFM). These techniques allow us to directly visualize the ferroelectric domain structure and dynamics. SFM-based methods for ferroelectric domain imaging make use of either the piezoelectric property of ferroelectrics or the presence of surface charge associated with the presence of the spontaneous polarization [149]. The two basic modes of the SFM can be utilized in the following ways. (a) *Noncontact Mode*: In the noncontact (attractive) mode, the SFM can be employed as an electrostatic force microscope (EFM), which can be used to detect the static surface charge—proportional to the normal component of the electrical polarization. The surface charge induces an opposite image charge on the probe tip, such that the resulting force gradient depends only on the magnitude but not the sign of the surface polarization. It follows that oppositely oriented

180° domains would present the same contrast in EFM and only domain walls would be clearly seen due to a variation in the charge density in their vicinity. A contrast between opposite domains can be introduced with the help of an external bias voltage. (b) *Contact* (*Piezoresponse*) *Mode*: When the probe tip is in contact with the ferroelectric sample, the domain structure can be observed in the SFM piezoresponse mode by monitoring the local electromechanical oscillation of the sample caused by an ac voltage applied through the probe tip. The sample vibration due to an ac signal of frequency ω also has a second harmonic component at 2ω due to the electrostrictive effect and the dielectric response.

Studying the piezoelectric properties of individual grains in relaxor ferroelectric films [solid solution of $PbTiO_3$ and $Pb(Mg,Nb)O_3$] by SFM, Shvartsman et al. [150] observe a clear correlation between the values of the effective piezoelectric coefficients and the grain size. Larger grains show stronger piezoelectric behavior, spontaneous polarization, and coercivity. A contrasting result was reported by Buhlmann et al. [151], who deposited PZT films by reactive sputtering on conductive $Nb:SrTiO_3$ and patterned features down to 50 nm by e-beam lithography. Piezoelectric sensitive SFM in the contact mode revealed a strong *increase* of the piezoelectric response for feature sizes with lateral dimensions below 300 nm (in 200 nm films). This behavior is believed to be due to vanishing *a*-domains.

Higgins et al. [152] have used scanning piezoresponse microscopy to show that in a ferroelectric thin film that has been depoled using the shrinking hysteresis loop method (similar to degaussing a ferromagnet) the zero-field, zero-polarization state actually consists of an array of up and down polarized domains, and each domain is roughly the size of the grains in the sample. Gruverman et al. [153] have studied the microscopic correlation between the crystallinity, domain arrangements, and switching behavior of SBT thin films deposited by PLAD and flash MOCVD. They show that the domain contrast of an individual grain and its switchability are strongly dependent on the grain orientation.

Scanning probe techniques have also been used to demonstrate that single, 10 nm wide nanowires of $BaTiO_3$ are ferroelectric [154]. These nanowires, synthesized by a solution-based method, are essentially single crystalline, defect-free ferroelectrics. Due to their one-dimensional structure, they should serve as the building blocks for fabricating a variety of nanoscale functional devices. Electrical polarization can be reproducibly induced on such nanowires but is retained only for a few days.

It appears safe to anticipate that in the next few years, many of the fundamental problems in nanoferroelectrics would be addressed and resolved using scanning probe techniques.

GLOSSARY

Antiferroelectric   A solid with an antiparallelly ordered array of local dipoles, resulting in a net zero polarization.

Coercive field (E_C)   The external electric field required to reverse the macroscopic polarization of a ferroelectric.

Displacive ferroelectric   A type of ferroelectric in which the elementary dipoles strictly vanish in the paraelectric phase. The atomic displacements in the low-temperature (ferroelectric) phase with respect to their corresponding positions in the high-temperature (paraelectric) phase are small compared to the inter-nuclear distances.

Ferroelectric   A solid that exhibits a spontaneous, field-reversible dielectric polarization, for $T < T_C$, the Curie temperature.

Order–disorder ferroelectric   A type of ferroelectric in which the elementary dipoles are non-vanishing but thermally average out to zero in the paraelectric phase. The atomic displacements on both sides of T_C are comparable to the inter-nuclear distances.

Piezoelectric effect   Development of electrical polarity on the application of stress. This effect and its converse (the development of strain on applying an electric field) are both linear in nature, a reversal in the stimulus resulting a reversal of the response.

Pyroelectric effect   Change in the spontaneous polarization with temperature.

Relaxor ferroelectric   In such systems, the temperature dependence of the dielectric constant (ε) displays a broadened peak. Unlike a normal ferroelectric, it obeys a modified Curie-Weiss law in which the inverse dielectric constant varies as some power (between 1 and 2) of the temperature.

CONTENTS

1. FIELD EMISSION AND FIELD-EMISSION MATERIALS

Field emission—also called Fowler–Nordheim tunneling [1]—is a process where electrons tunnel through the surface potential barrier of a metal–vacuum interface and float in the vacuum region during the presence of an extremely high electric field (Fig. 1). This quantum-mechanical tunneling of electrons is an important mechanism for thin surface potential barriers, just like those in heavily doped semiconductor–metal junctions. Different from thermionic emission, electron field emission occurs without emitter heating (cold cathode). As a result, a field-emission electron source has several prominent advantages: less power consumption, low thermionic noise, high current density (typically 100 A/cm^2 for field emission, 0.5 A/cm^2 for thermionic emission), high coherence, low energy spread, miniature volume, and so on [2].

The Fowler–Nordheim model describes the tunneling current I as a function of the voltage between the cathode and anode V:

$$I/V^2 = a \exp(-b/V) \tag{1}$$

where $a = (\alpha A \beta^2/1.1\phi) \exp[B(1.44 \times 10^{-7})/\phi^{1/2}]$, $b = 0.95B\phi^{3/2}/\beta$, $\beta = E/V$, $A = 1.54 \times 10^{-6}$, and $B = 6.87 \times 10^7$. α is the apparent emission area, β is the surface local field enhancement factor (geometric field enhancement factor), E is the electric field intensity at the surface, and ϕ is the electron work function of the emitter. All these parameters characterize electron field emission.

Metals, semiconductors, and graphite have electron work functions of a few electron volts (Table 1), and therefore field emission will not occur until the electric field exceeds 5×10^7 V/cm [2]. In practice, however, it is impossible to build up such an electric field uniformly over any area larger than 10^{-8} cm^2. Field emission always occurs in some tiny protruding areas (10^{-15}–10^{-8} cm^2) associated with a reduced electric field ($<10^6$ V/cm). The reason for this simply is a local enhancement of the electric field in those tiny protruding areas, which dramatically decreases the field intensity needed for field emission. For large-scale, uniform field emission, an array comprising many molybdenum microtips was proposed and developed by Spindt in 1968 [3] (Spindt cathode, TFFEC). The Spindt cathode realized a 1–10 μA/tip field-emission current at 300 V gate bias (60 nm spacing between the gate and tip) [4]. Subsequent improvements in process have enabled the Spindt cathode to produce a current over 100 μA/tip at the gate voltage below
Figure 1. Energy band diagram model for metal. E_F: metal Fermi level, E_{VAC}: vacuum level at metal surface, e: electrons in conduction band, A: metal atoms. Dashed line represents the band diagrams in the electric fields applied to metal, $E_1 < E_2$.

100 V [4]. Following the Spindt cathode, various configurations of emitters in pure and compound materials have been studied in the past three decades, and a continuous effort is still being devoted to achieving cathodes of high performance.

An ideal material for the field emitter should have a high mechanical strength and melting point, excellent electrical conductivity and thermal conductivity, a low work function and stable chemical properties, and be inexpensive and easy to process. From the engineering point of view, field emitters should be able to deliver a high current density at a low electric field. Molybdenum shows not only a high hardness, but also a high melting point and good electrical conductivity (Table 2). Head and shoulders above other materials, molybdenum microtips (Spindt cathode) exhibited an availability of 100–1000 A/cm² emission current [2]. However, the inherent features of double evaporation (a technique for fabricating molybdenum microtips) restrains the microtip array from being scaled up. Silicon and polysilicon are prevalent materials in the semiconductor industry.

Table 1. Work functions of metals, silicon, and graphite.

Material	Work function	Material	Work function
Mg	3.61	In	3.97
Al	4.19	Sn	4.43
Ti	3.83	Sb	4.56
Cr	4.44	Ba	2.48
Mn	4.08	Ta	4.20
Fe	4.65	W	4.55
Co	4.79	Pt	5.40
Ni	5.15	Au	5.21
Cu	4.59	Pb	4.04
Mo	4.21	Si (P)	4.30
Pd	5.17	Si (N)	3.30
Ag	4.42	Graphite	4.6–5.4

Table 2. Melting point and resistivity of materials commonly used for field emission.

Material	Melting point (°C)	Resistivity ($\mu\Omega \cdot cm$)
Mo	2617	5.17
W	3410	5.6
Si	1410	$100–10^{11}$
C	3550	1375

Arrays of silicon and polysilicon microtips can be potentially scaled up, and the fabrication is also compatible with up-to-date integrated-circuit techniques. Despite a great effort with silicon and polysilicon microtips through the 1980s and 1990s [5–11], the uniformity issue with array scale up and the high cost involved remained. In addition, silicon and molybdenum microtips require a working condition of ultrahigh vacuum and high voltage. Therefore, their current density and stability are limited [12–14, 72–74]. As a potential field-emission material, diamond drew great attention to its negative electron affinity (NEA), and excellent performance in high-speed, high-temperature, and high-power applications [14–23, 68–71]. Negative electron affinity can contribute an intensive electron beam at a low electric field. Unfortunately, diamond fails to benefit from this virtue due to a small concentration of electrons in its conduction band (wide bandgap material). It has been proven that shallow-level n-type doping of wide-bandgap materials is extremely difficult. The shallow donors such as P, Li, and Na showed a very low solubility and activity in diamond [24]. Moreover, the chemical vapor deposition process for diamond is not completely compatible with the fabrication techniques of integrated circuits.

2. FIELD EMISSION OF CARBON NANOTUBES

Since the discovery of carbon nanotubes in 1991 [25], they have been regarded as a new generation of materials for field emission. The carbon nanotube, a seamless small carbon tube formed by rolling up a single or several pieces of graphene sheets, is predicted to have numerous advantages as a field emitter: (1) high chemical stability and high mechanical strength, (2) high melting point and reasonable conductivity, (3) high aspect ratios (10–100) with very small tip radius (5–50 nm) to greatly enhance the local electric field, (4) large-scale production at low cost, (5) an extremely low electron work function, and so on (Tables 2, 3) [13, 26–30].

2.1. Electron Work Function

The electron work function is an energy threshold where electrons start to be emitted into vacuum from a metal conduction band, that is, the difference of energy between vacuum and the Fermi levels (Fig. 1). The work function varies with different metals, and ranges from 2 to 6 eV (Table 1). The modified Fowler–Nordheim equation $(I/V^2) = (a\beta/\phi)\exp(-b\phi^{3/2}/\beta V)$ shows clearly that the field-emission current I is reversely proportional to the electron work function ϕ. For practical applications, therefore,

the emitter with a small work function is preferred. Since the emission current I and the voltage V can be measured experimentally, the work function ϕ is determined by the Fowler–Nordheim equation if the local field enhancement factor β is known. Nevertheless, ϕ usually is not well identified due to an ambiguity in both the effective emission area (smaller than apparent emission area) and the local field enhancement factor.

Sinitsyn et al. [26] experimentally estimated the electron work function of carbon nanotubes. Two kinds of carbon nanotubes were used: 10 nm thick bundles comprising 8–11 Å diameter single-wall carbon nanotubes (SWNTs), and 10 nm diameter multiwall carbon nanotubes (MWNTs). They calculated the β using the Fowler–Nordheim equation (FN equation) for field emission and the Schottky equation for thermal emission, respectively. By the I–V characteristics measured (FN curves), they found that both SWNTs and MWNTs exhibited extremely low work functions, 1.1 eV for bundled SWNTs and 1.4 eV for MWNTs. Obraztsov et al. [31] assessed MWNT ϕ using a simplified approximation of $\beta \approx H/R$ (H is the nanotube height, and R is the radius of the nanotube tip). They calculated a ϕ in 0.2–1.0 eV for MWNTs. These values are much smaller than the work functions of metal, silicon, and graphite (Table 2). No theoretical model has explained such a low work function for pure carbon nanotubes so far, but some possible explanations have been proposed in different aspects. One explanation highlights the role of imperfections in the tubular structure [26]. The theoretical study reveals that imperfections in the nanotube structure may cause dramatic reductions in the ionization potential and work function compared to those defect-free tubules. For instance, taking away one carbon atom from a C_{60} molecule will result in a 0.4 eV decrease in its ionization potential. On the other hand, numerous experimental observations verified that imperfect and uncapped tubular structures do exist in SWCNTs and MWCNTs. In agreement with this explanation, MWNTs generally include more impurities and defects, so they show a lower work function than SWNTs. Another explanation is associated with the curvature of graphene sheets that form a nanotube [32, 33]. When the graphene sheets are bent, the atomic bonding shows more sp^3 character than sp^2. The character change from sp^2- to sp^3-like hybridization will produce some sp^3-like atom lines along the nanotube surface, and consequently lead to a decrease in the work function and effective surface barrier. A similar case to carbon nanotubes is diamond, which totally consists of sp^3-hybridized carbon. The sp^3 hybridization endows the diamond surface with negative electron affinity, which dramatically reduces the height of the surface potential barrier.

In other studies, the work function of carbon nanotubes was measured by photoelectron emission (PEE) and field-emission electronic energy distribution (FEED). Shiraishi et al. [34] used PEE to investigate SWNT and MWNT work functions, and obtained 5.05 eV for SWNT and 4.95 eV for MWNT. Fransen et al. [35] measured the work function of an individual MWNT mounted on a tungsten tip by FEED associated with the I–V characteristic curve. Their measurement showed a 7.3 ± 0.5 eV work function for MWNTs. Obviously, these values are inconsistent with those calculations from the FN curve slope. Some are inclined to

believe FEED and FEE measurements rather than the calculation by the FN curve slope due to the indefinite field-enhancement factor and effective field-emission area in the FN equation. Clearly, the electron work function for carbon nanotubes is more complicated than for metal, diamond, and graphite. The structure, defect, and surface state of carbon nanotubes (specifically, cap nature, the edge structure of graphene sheet in an open end, etc.) strongly affect the value of the work function. Therefore, they should be taken into consideration together. Our current knowledge about the work function of carbon nanotubes is limited. A comprehensive understanding still awaits more detailed studies.

2.2. Field-Enhancement Factor

The local field-enhancement factor β (also called the geometric enhancement factor) reflects the enhancement of an electric field at the emitter surface by an electrode configuration. It is represented as $E_{local} = \beta\, dE_{macro}$, where E_{local} is the local field intensity, E_{macro} is the macroscopic field intensity, and d is the distance between the cathode and anode. A perfectly planar surface should have a unitary field-enhancement factor.

The field-enhancement factor β is obtained by either the slope of the FN curve or the aspect ratio of the emitter. The FN equation is modified as $I/V^2 = (a\beta/\phi)\exp(-b\phi^{3/2}/\beta V)$. From the slope $(-b\phi^{3/2}/\beta)$ of the logarithmic NF equation ($\log(I/V^2)$ versus $1/V$), the field enhancement factor β is easily worked out if the work function is known. As the effective emission area and the work function for carbon nanotubes usually are difficult to be determined, β only can be estimated by the slope. For typical vertically aligned carbon nanotubes, they can be treated as whisker-shaped emitters, and thus the local field-enhancement factor β is approximated as a simple function of the nanotube aspect ratio:

$$\beta \approx H/R \qquad (2)$$

where H and R are the height and radius of the carbon nanotube tip, respectively [28]. It should be noted that Eq. (2) excludes the screening effect (see Section 2.5), so it is suitable for single and low site density carbon nanotubes. On the other hand, the radius R in Eq. (2) for field emission could be much smaller than the actual radius of the nanotube tip because field emission may come from a few spots instead of the whole tip. As a result, the β from Eq. (2) could be much smaller than that from the slope of the FN curve.

There have been numerous experimental studies to assess MWNT and SWNT local field-enhancement factors [13, 35–39]. The values reported range from 500 to 7,600,000, which is 10–10^4 times larger than the field-enhancement factor of allotropic diamond. The maximum value is comparable to the field-enhancement factor of molybdenum and silicon (Table 3). Clearly, such a strong field enhancement directly benefits from the extra high aspect ratio and the tiny tip size of carbon nanotubes. Field enhancement is also related to carbon nanotube alignment and site density. Bonard et al. [37] estimated the field-enhancement factors of SWNTs and MWNTs by the slope of the FN

Table 3. Comparison of the field-emission characteristic of silicon, carbon nanotubes, diamond, and molybdenum from the cited references.

	Turn-on field intensity (V/μm)	Emission current	Field-enhancement factor (1/cm^{-1})	Work function (eV)
Silicon tips	40–400 [90–92]	10–100 μA ($\sim$100 V/μm) (100 tips) [90–92]	100–400,000 [90–92]	4.30 Si (P) 3.30 Si (N)
Carbon nanotubes	<15 V/μm (SW) [26] 1.5 V/μm [31]	100 mA/cm^2 (30 V/μm) [26]	1300 (max), 500–800 [13]	1.1 (MW) 1.3 (SW) [26] 5.05 (SW) 4.95 (MW) [34]
			7,600,000 [35]	7.3 ± 0.5 (MW) [35]
	1.0 V/μm (SW) [36]	90 μA/cm^2 (3 V/μm) [36]	17,000–33,000 [36]	0.2–1.0 (SW) [36]
	1.5–4.5 V/μm (SW) [37]	10 mA/cm^2 (SW, 3.9–7.8 V/μm) [37]	1000–3000 (MW) 2500–10,000 (SW) [37]	
	0.7 V/μm (MW) [38]	1 mA/cm^2 (3.0 V/μm) [38] 0.1–1.0 × 10^6 A/cm^2 (capped) 10–100 A/cm^2 (uncapped) [39]	80,000–190,000 [38] 20,000–40,000 (capped) 60,000–300,000 (uncapped) [39]	
	1.34–1.45 V/μm (65% MW) [40]	3–7 mA/cm^2 [40]		
Diamond	15 (0.01 A · m/cm^2, B-doped) [14] 0.2–0.3 (N$^+$-doped polycrystal) [87]	10 mA/cm^2 (30 V/μm, B-doped) [14]		5.0–5.3
	20–50 (B-doped polycrystal), 5–11 (undoped nanocrystal) [88]	1 mA/cm^2 (20–80 V/μm) [88]	70–203 (B-doped polycrystal) 223–745 (undoped nanocrystal) [88]	
		0.5 mA/cm^2 (5–8 V/μm) [89]		
	15 (N-type T-amorphous) [90]			
Metal tips (Mo, Spindt cathode)	Above 10–100 V/μm [2]	100–1000 A/cm^2 [2]	100,000–500,000 [2]	4.21

curve in the low-current regime ($d = 125$ μm, $\phi = 5$ eV). The β ranged from 2500 to 10,000 for SWNTs, and 1000–3000 for MWNTs. It is easy to understand that, for the smaller tip size, SWNTs normally showed a higher local field-enhancement factor than MWNTs. Kim et al. and Saito and Uemura [36, 39] reported the even higher field-enhancement factors of 17,000–33,000 (SWNTs) and 60,000–300,000 (MWNTs), respectively. It is noted that the field-enhancement factors from different reports vary within a wide range. Besides the obscure effective emission area and work function, the variation may also be attributed to the different experimental conditions, such as electrode configuration, carbon nanotube morphology, structure, site density, and so on. For example, capped and uncapped MWNTs showed a substantial difference in the field-enhancement behavior [39]. The β for uncapped MWNTs could be several times larger than it is for capped MWNTs (Table 3).

2.3. Turn-On Field Intensity

Turn-on voltage is an important parameter for field-emission devices. It represents the ability to work at low voltage. To avoid taking an electrode configuration into consideration, the turn-on electric field intensity is used instead of the turn-on voltage. It is defined as a macroscopic field needed to draw a specific current density (usually 10 μA/cm^2) [37]. Experimentally, the turn-on field intensity is also identified as a voltage where the I–V characteristic ($\log(I/V^2)$–$1/V$

curve) begins to deviate from the Fowler–Nordheim model [40]. For a material, the turn-on field strongly depends on its work function and field-enhancement factor.

Turn-on field intensity is also a function of the structure, morphology, and geometry of carbon nanotubes, particularly the alignment, length, diameter, cap, defects, and so on. With a low work function and an extremely high field enhancement factor, carbon nanotubes demonstrate a turn-on field intensity between 0.1–5 V/μm, 10–100 times smaller than the turn-on field intensities of metal, silicon, and diamond (Table 3). The carbon nanotube therefore is a material especially suited for those field-emission devices that are expected to work at low voltage. Theoretically, SWNTs should have a lower turn-on field intensity compared to MWNTs due to the smaller size and uncapped end. In experiments, conversely, MWNTs show a lower turn-on field intensity than SWNTs because the impurities and defects in MWNTs lead to a change of work function, and then a decrease of the turn-on field intensity. On the other hand, the effect of carbon nanotube caps on the turn-on field has not been completely clarified yet. Saito and Uemura [39] found that uncapped carbon nanotubes not only emitted at a lower voltage, but also kept a higher current in comparison with those capped nanotubes, whereas Bonard et al. [41] claimed that uncapped nanotubes emitted at twice the voltages needed for capped nanotubes. Apparently, these totally different results of Saito and de Pablo's experiments also include a conflict of the work functions and

field-enhancement factors between capped and uncapped carbon nanotubes.

2.4. Field-Emission Mechanism and Characteristic

Carbon nanotube behavior strongly depends on its structural properties. It cannot be simply treated as a metallic tip in field-emission behavior and mechanism. Metal tips, for instance, have a monotonic work function of ∼5.0 eV, whereas carbon nanotubes show a wide range of work function (0.2–7 ± 0.5 eV) due to the impurity in their structure, carbon bonding sp^3 hybridization, and so on. Therefore, the field-emission behavior and mechanism for carbon nanotubes are also more complicated.

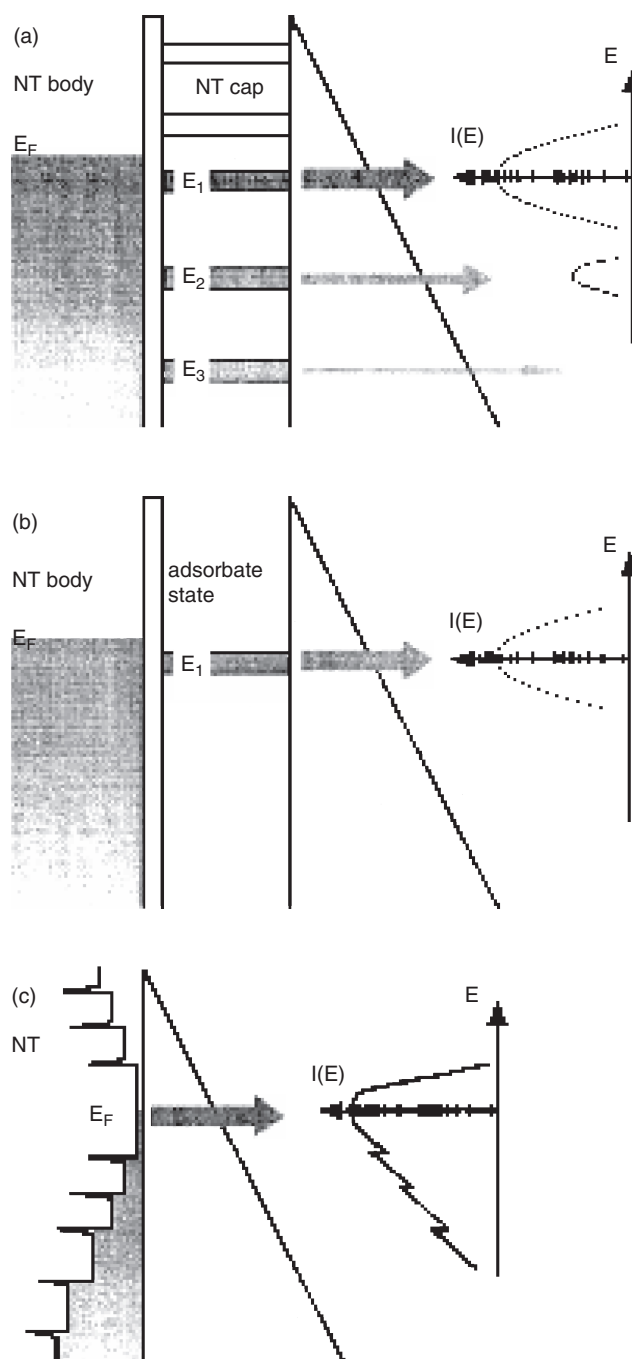
Field-emission electron energy distribution is efficient tool for the study of field-emission characteristics and mechanisms. For metal tips, the emitted electrons originate from the conduction band, that is, around the Fermi level. The work function simply is the difference between the vacuum level and metal Fermi level (∼5.0 eV) (Fig. 1), and the electronic density of state (DOS) in the energy band follows Fermi–Dirac statistics [Fig. 2(c)]. Correspondingly, a single peak in FEED spectra appears around the Fermi level, and the typical full width at half maximum (FWHM) of FEED is fixed at 0.45 eV [42]. For carbon nanotubes, a multiple-peak FEED spectra was observed [35, 43, 44]. The multiple peaks in FEED reflected that field-emission electrons originate from several states of energy levels, that is, nonmetallic electronic states. Fransen et al. [35] studied the multiple-peak spectra from an individual MWNT mounted on a tungsten tip, and found that some peaks with a larger FHWM (0.21–0.71 eV) were shifting linearly with the applied electric field. The shifted peaks were distinguished as arising from the field penetration into nanotubes or a voltage drop in the ohmic resistance of nanotubes and the contacting resistance between the nanotubes and tungsten tip. The other peaks with a smaller FWHW (0.17 eV), corresponding to the resonant states from a nanotube tip, did not shift with applied field [Fig. 2(a)]. From an individual SWNT at room temperature, Dean et al. [43] observed a peak corresponding to adsorbate states (3.0 eV above Fermi level), and no peak shift was shown in FEED spectra with applied electric field. When the temperature increased to 900 K, the emission current decreased an order of magnitude from its initial value, which indicated adsorbate shifting. As the temperature increased further, additional peaks appeared in the FEED spectra (above the Fermi level), and the adsorbates and adsorbate tunneling states were removed, leading to an abrupt drop in emission current [Fig. 2(b)]. In another study [45] of a single SWNT, Dean and Chalamala found different regimes associated with temperature and applied electric field. The first regime corresponds to the adsorption (at low fields and low temperatures) and desorption (at either high fields and high currents or temperatures above 400 °C) through resonant tunneling (adsorbates). The other regimes correspond to intrinsic field emission from a clean nanotube, and have a far lower emission current at comparable voltages. All of the studies show that nonmetallic electronic states play a key role in the emission mechanism


Figure 2. Energy band models of the field emission from the carbon nanotubes with (a) cap, (b) adsorbate resonant tunneling, (c) metallic behavior. of carbon nanotubes, and strongly affect the field-emission characteristic.

Regarding the geometric position of carbon nanotubes for field emission, field-emission microscope patterns reveal that the emitted electrons originate from the edge rings of graphene layers for uncapped MWNTs and from the caps for both capped MWNTs and SWNTs [39, 41, 44, 46–50].

Rinzler et al. [49] previously proposed that emitted electrons came from an unraveled linear carbon chain at the graphene edge of uncapped MWNTs. Saito and Uemura proved Rinzler's assumption by the field-emission microscopy (FEM) patterns taken from uncapped MWNTs [39]. The FEM patterns show a "doughnut-like" annular bright ring and a black spot in the central region, which corresponds to the cavity of an uncapped nanotube. Through another two patterns taken from capped MWNTs with clean surface and absobates, Takakura et al. [44] further verified that emitted electrons arose from the whole cap of capped nanotubes. Apparently, those patterns contain six bright spots, and each spot exhibits the shape of a pentagonal ring. Moreover, the six spots are also fivefold symmetrized [Fig. 3(a) and (b)]. All of the symmetries in the patterns completely agree with the structure of a nanotube cap. According to the theory of nanotube capping, any nanotube cap must include six pentagonal carbon rings, and they are isolated from each other [51–53].

Figure 4 shows a typical field-emission characteristic of carbon nanotubes (I–V and $\ln(I/V^2)$–$1/V$). The I–V curve in Figure 4 can be divided into three sections with the voltage from low to high, that is, nonlinear–linear–nonlinear distribution. In the low-voltage region, the current increases slowly, and then switches to a sharp linear rise following the turn-on voltage. In the high-voltage region, the current begins to increase slowly again until saturation. The measurement of the field-emission electron energy distribution associated with the I–V characteristic curves [35, 54] revealed that, at low voltages and currents, the emitted electrons came from the energy levels close to the Fermi level, which corresponds to the linear section in the $\ln(I/V^2)$–$1/V$ curve. The I–V linearity exhibited an intrinsically metallic field-emission characteristic as predicted by the Fowler–Nordheim theory. As the peak position in the V–FEED spectra shifted forward to lower kinetic energies (E–E_F) at high voltages and current densities, the I–V curve correspondingly became linear. This indicated that the energy of electrons had changed. Electron energy levels were moving away from the Fermi level. Simultaneously, the I–V characteristic showed an ohmic behavior.

Saturation is an important aspect in the limit of field-emission current. Several mechanisms leading to current saturation have been proposed [35, 45, 54–56]. Vacuum space charges, one of the mechanisms, occurs when an extra high electric field (over 7 V/nm) is applied. Considerable emitted electrons distribute in the space between two electrodes, and create an additional electric field opposite the applied field. Overlapping the additional field, the intensity of the applied field will be cut down, and thus the field-emission current will also be limited. Since the intensity of the additional field is directly proportional to the applied field, the emission current eventually shows saturation with a gradual increase of applied field. Another mechanism for current saturation is solid-state transport, that is, the serial resistance of the emitter and the contacting resistance of the emitter and substrate. The ohmic resistances play the key role of limiting the current at high voltage and current density. These two mechanisms of space charges and solid-state transport are well understood through studying metal emitters.
Figure 3. Field-emission patterns from an MWNT with (a) clean surface obtained just after heat cleaning at about 1300 K, and (b) two adsorbates onto pentagons. Reprinted with permission from [44], A. Takakura et al., *Ultramicroscopy* 95, 139 (2003). © 2003, Elsevier Science.

Adsorbates and adsorbate tunneling enhancement, one kind of current mechanism found in semiconductors, is another mechanism to limit the emission current of carbon nanotubes. Dean and Chalamala [45] introduced adsorbates to a clean individual SWNT by exposing them to H_2O at a partial pressure of 10^{-7} torr for 5 min. The adsorbates caused an increase in field-emission current by a factor of 200 (at 1400 V), and the I–V curve with adsorbates showed a strong current limit between 100 and 300 nA, in sharp contrast to the behavior of an SWNT without adsorbate (clean carbon nanotubes). An individual carbon nanotube

the *I–V* characteristic shows a reversible behavior between the up and down sweeps of the applied field. Besides vacuum space charges and solid-state transport, adsorbate and adsorbate tunneling should be taken into consideration for the current-limiting mechanisms of carbon nanotubes.

2.5. Site Density of Carbon Nanotubes—Field-Screening Effect

The field-screening effect was observed by Nilsson et al. [57] on a carbon nanotube film. That is, the electric field on each nanotube is shielded by nearby neighboring nanotubes, and thus it restrains the field penetration. Nilsson et al. simulated the screening effect, as shown in Figure 5. In their scanning field-emission measurement, they clearly showed that a decreased site density of carbon nanotubes would reduce the screening effect and increase the emission site density and emission current, as in Figure 6. The authors predicted that an intertube distance of about two times the height of nanotubes would optimize the emitted current per unit area. Several other groups also reported similar results [58–62].

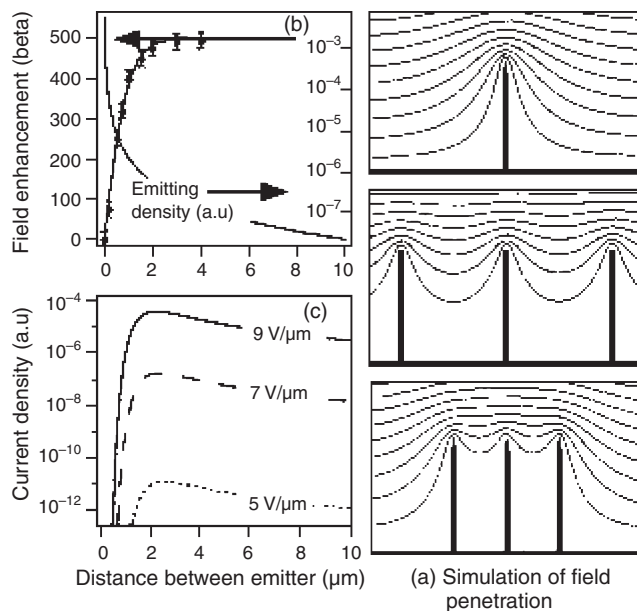
To control the site density of carbon nanotube film, several methods have been proposed. Nilsson et al. [57] used microcontact printing to deliver an Fe-containing catalyst solution to a substrate. By changing the Fe concentration, the site density of carbon nanotubes in film can be changed. However, the carbon nanotubes are randomly oriented. Ren et al. [63–67] used electron-beam lithography to make a catalyst array of Ni nanoparticles, and then grew well-aligned nanotubes on the nickel nanoparticles by plasma-enhanced chemical vapor deposition (PE–CVD).


Figure 5. (a) Simulation of the equipotential lines of the electrostatic field for tubes of 1 μm height and 2 nm radius, for distances between tubes of 4, 1, and 0.5 μm, along with the corresponding changes of the field-enhancement factor β and emitter density (b), and current density (c) as a function of the distance. was selected for the study to highlight the current-limiting effect and avoid any interaction with the neighboring nanotubes. The emission current in this experiment was also kept at a comparable low level (2 μA) so as to rule out vacuum space charges. This study clearly demonstrates that, similar to the case of semiconductors, the current saturation for carbon nanotubes can arise from adsorbates. The adsorbates are removed from adsorbate tunnels with increasing of applied electric field and emission current, which decreases the adsorbate-tunneling enhancement, and finally induce the saturation of the field-emission current. The adsorbates can also return to the nanotube surface (adsorbate tunnels) when the applied electric field is reduced. Correspondingly,

The films were produced with ethanolic inks of 10(a), 40(b), and 60 mM $Fe(NO_3)_3 \cdot 9H_2O$. The FE maps were taken under identical conditions using 100 V in constant voltage mode. The color scale corresponds to 0–10 μA/pixel for images (d), (e), and to 0–1 μA/pixel in image (f). Reprinted with permission from [57], L. Nilsson et al., *Appl. Phys. Lett.* 76, 2071 (2000). © 2000, American Institute of Physics.

Furthermore, the carbon nanotubes were precisely positioned on a substrate (Fig. 7). Due to the expensive equipment used and the extensive labor requirement, this method cannot be used for mass production.

Recently, Tu et al. [68] applied pulse-current electrochemical deposition to prepare different site densities of Ni nanoparticles by changing the deposition current and duration time. Aligned carbon nanotube arrays with a site density from 10^6 to 10^9 /cm^2 were grown from the Ni nanoparticles using PE–CVD, as shown in Figure 8. Field-emission properties were improved for the CNT array with low site density and long length [61].

Another method that used nanosphere lithography to fabricate Ni nanoparticles in a periodic array was developed by Huang et al. [69]. A monolayer of self-assembled polystyrene spheres was coated on a silicon substrate as a mask (Fig. 9). By Ni deposition, a certain thickness of nickel went through the interspaces of polystyrene spheres to form Ni nanoparticles in a honeycomb array. The polystyrene layer was washed away, and only the Ni nanoparticles remained on the silicon substrate. Aligned carbon nanotubes were grown
Figure 7. SEM images of aligned carbon nanotubes grown from Ni nanoparticle arrays of *e*-beam photolithography with controllable diameter, site density, and site position. (a) 200 nm thick nanotubes in 1 and 3 μm spacings. (b) 100 nm thick nanotubes in 1.5 μm spacing.

from the honeycomb array of Ni nanoparticles by PE–CVD (Fig. 10). The carbon nanotubes can have an intertube distance between 0.1 and 5 μm, depending on the size of the polystyrene spheres. Correspondingly, the site density is varied around 10^7–10^8 nanotubes/cm^2.

2.6. Field-Emission Stability

A stable field emission is imperative for practical devices. The residual gases in vacuum influence the field-emission stability dramatically. It has been found that metal and silicon emitters are very sensitive to residual gases. Various residual gases originate from the components that constitute a device, such as a cathode, anode, sealing frit, spacer, and so on. Although pumped out in outgassing process and absorbed by getters after sealing, the residual gases are difficult to remove completely. They can evolve and further increase the pressure during device operation. The residual gases not only react with emitters, changing the surface properties, but also ionize under an electric field to bombard the emitters and modify the tip radius, which leads to field-emission instability and even device failure. It was found that unstable field emission and irreversible degradation occurred with the Mo and Si emitters exposed to O_2,
Figure 8. SEM images of aligned carbon nanotubes with site density of (a) 7.5×10^5 cm^{-2}, (b) 2×10^6 cm^{-2}, (c) 6×10^6 cm^{-2}, (d) 2×10^7 cm^{-2}, (e) 3×10^8, and (f) a single standing carbon nanotube. CO$_2$, and H$_2$O during operation. The reason is that the formation of metal oxides and silicon dioxides changes the surface barrier width, surface conductivity, and tip radius [70, 71]. For a stable field emission, Mo and Si emitters have to work at a pressure below 10^{-9} torr, which is an impractical pressure for any static vacuum system.

Carbon nanotubes have exhibited a chemical inertness and a tolerance to ion sputtering, so they are stable over a wide range of pressure. Sinitsyn et al. [26] investigated the pressure influence on the field-emission characteristics of SWNTs and MWNTs at 291 K. Field emission was obtainable from 10^{-7} to 10^{-2} torr for both SWNTs and MWNTs, and a stable emission remained until up to 10^{-5} torr pressure. Moreover, pressure-induced current degradation was also restorable with the pressure decrease. Other experiments [36, 37, 39, 48, 72, 73] showed similar results in the field-emission stabilities of SWNT and MWNT. The stable emission currents from 0.01 to 20 mA/cm^2 remained for 1 h to thousands of hours. Noticeably, Saito and Uemura [39] used MWNTs with a cathode ray tube (CRT) to replace a conventional thermionic cathode. In their CRT dc-driving lifetime test, a constant field-emission current of 210 μA at 12 kV anode voltage and 10^{-8} torr pressure was sustained over 8000 h without degradation.

An individual carbon nanotube and a group of carbon nanotubes showed different behaviors in current stability. Saito and Uemura [39] traced a probe current emitted

from an individual MWNT. Some stepwise fluctuations were recorded at low currents, and large steps appeared in the high-current region. The stepwise fluctuation was attributed to intrinsic field-emission characteristics. In contrast, the total current from a group of comparable MWNTs showed no stepwise fluctuation. The stable current without fluctuation was interpreted as a macroeffect from a group of MWNTs, that is, individual fluctuations were averaged in the macroeffect.

Emission current stability is also correlated to the current density [37, 74]. Bonard et al. [37] studied the dependence of current fluctuation with time in different current regimes. In a low-current regime ($\leq$10–25 $\mu A/cm^2$), the frequency and amplitude of the fluctuation increased with the current increase, and the maximum amplitude was 1–10 $\mu A/cm^2$. The emission current became stable gradually as the current increased to near saturation (above 10–25 $\mu A/cm^2$) (Fig. 11).

Residual gases are also responsible for the field-emission instability of carbon nanotubes. Exposed to H_2, H_2O, Ar, CO, N_2, and O_2, respectively, carbon nanotubes showed different behaviors. The experimental result and discussion are given in Section 2.7.

2.7. Field-Emission Degradation and Failure

Field-emission degradation is a sustained decrease of emission current while the applied voltage remains constant. It includes reversible and irreversible degradations. Field-emission failure occurs after an evolutional degradation of field emission or disastrous damage to the field emitter. Field-emission degradation and failure generally arise from physical and chemical modifications, such as surface absorption and oxidation, Joule heating, gas ion bombardment, defects, and so on.

Reversible degradation normally involves a reversible V–I characteristic of field emission. Dean and Chalamala [45] proposed that the reversible V–I characteristic of carbon nanotubes resulted from surface adsorption. They investigated a reversible V–I characteristic from individual SWNTs using a field-emission microscope, and found an evident hysteresis between the V–I curves of the "up" voltage
sweep and the "down" voltage sweep in a clean 10^{-9} torr vacuum, as shown in Figure 12. In a 10^{-7} torr unbaked vacuum (unclean), however, the hysteresis disappeared, that is, the I–V curves became reversible (Fig. 13). On the other hand, FEM images revealed that adsorbates shifted from enhanced tunneling states to induce a current decrease over time between voltage steps during the up sweep (behind the saturation point), and reoccupied the enhanced tunneling states with a higher tunneling enhancement leading to a current increase over time between voltage steps during the down sweep (Fig. 14). The study has solidly proven that adsorbate-tunneling enhancement results in a reversible V–I characteristic and reversible degradation.

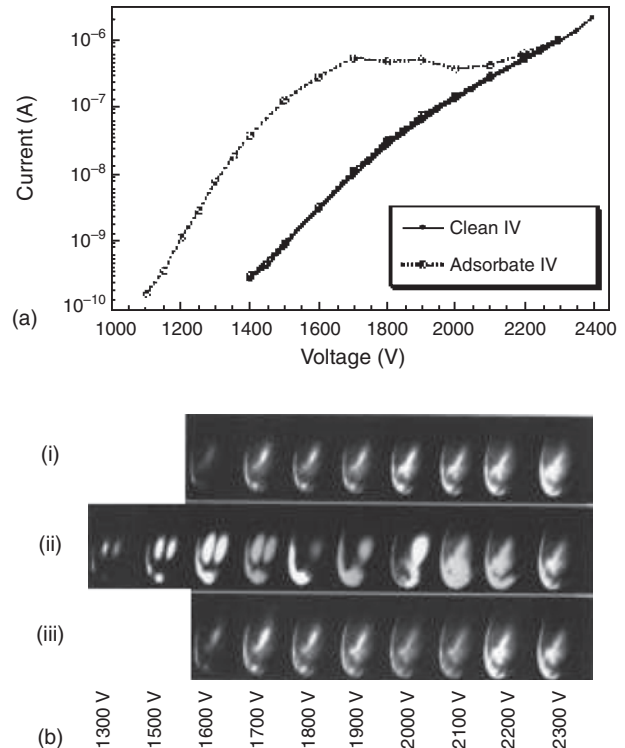
The observation of SWNT and MWNT degradation has been reported in a number of papers [13, 26, 36, 37, 39, 48, 72–76]. Kim et al. [36] observed the field-emission stability of an SWNT-based flat panel display at 1.0 mA current (1.5 mA corresponded to 90 $\mu A/cm^2$) for 10 h. In the initial stages of field emission, no degradation occurred, but only <10% fluctuations were found over a 4.5 in panel. The <10% fluctuations were interpreted as a field stress effect because the field-emission current showed a high stability in the extended stage.


Figure 12. (a) Field-emission characteristics of a single SWNT with and without adsorbates. [(b)(i)] The FEM pattern of a clean SWNT is stable over the voltage sweep, but [(b)(ii)] the FEM pattern of the same nanotube with an adsorbate changes during the I–V sweep concurrent with the onset of current saturation. [(b)(iii)] At 2300 V, the adsorbate effects disappear, resulting in a clean nanotube field-emission pattern. During the downward I–V sweep, the images match those of the clean SWNT shown in [(b)(i)]. Further, Zhu et al. [48] assessed the field-emission durability of an SWNT with different current densities. The durability was tested by the measurement of an electric field needed to maintain the current density as a constant until the SWNTs were destroyed. One test at 20 mA/cm^2 current density supported by a field of 5.5 V/μm (10 μA current, 250 μm anode-emitter distance) was sustained for 75 h. The other test at a higher current density of 500 mA/cm^2 (100 μA current, 100 μm anode-emitter distance) ran for 25 h, and the field needed for the current density increased from 16.5 to 20 V/μm. This result clearly shows that faster degradation and failure usually occurs at the higher current density where more Joule heating has been produced. More discussions on Joule heating are given in [76].

Nilsson et al. [76] observed the field-dependent and current-dependent degradations of a carbon nanotube thin film in different current regions. For field-dependent degradation, it typically occurred at the first scan of the field and low current levels. The electrostatic force removed loosely adhered carbon nanotubes, and the nanometer-sized amorphous carbon allotropes from the nanotube tip apex to lower the emission site density and lead to field-emission degradation. The field-induced modifications on carbon nanotubes have been experimentally verified in a number of reports [37, 77, 78] by scanning electron microscope (SEM) and transmission electron microscope (TEM) observations. For current-dependent degradation, it occurred at high current levels. The current for Nilsson's study (>0.3 μA), however, is not considered to be at the level (>3 mA) that can cause a substantial heating dissipation in the solid transport through a nanotube body. Therefore, Nilsson et al. attributed the current-dependent degradation to a poor contact between the carbon nanotubes and the substrate, that is, in those poor contacting areas, the electron transport from the substrate through nanotubes to vacuum can produce enough heat to burn the nanotubes and substrate away. SEM examination has clearly shown some melted regions in the silicon interface without the coverage of nanotubes. For a stable emission and high current density, it is necessary to improve the contact of carbon nanotubes and substrate.

Bonard et al. [37] compared SWNT and MWNT degradations at 150 μA/cm^2 current density and 10^{-7} mbar pressure. First, a gradual degradation and a monotonic decrease in the
Figure 14. Changes in current with time during an *I–V* measurement. Step changes in current correspond to the steps in applied voltage. (a) The up sweep shows consistent drops in current over time between the voltage steps above the saturation onset. (b) The down sweep shows an increase in current over time when measured in nonideal vacuum (10^{-7} torr, unbaked phosphor). Reprinted with permission from [45], K. A. Dean et al., *Appl. Phys. Lett.* 76, 375 (2000). © 2000, American Institute of Physics.

field-enhancement factor were observed for both SWNTs and MWNTs through the experiment. Second, a fast degradation occurred to the SWNTs, and the current density decreased more than 50% from its initial value within 10 h. By SEM observations, it was found that the SWNT site density was substantially reduced after the experiment. Compared with SWNTs, MWNT degradation was much slower, only a 5–10% decrease of current density from its initial value in the same period (Fig. 15). It is easy to understand that the single shell of SWNTs is more sensitive to ion bombardment and residual gas. SWNTs thereby are easily modified and deformed, whereas the multishells of MWNTs are more tolerant to those influences.

In other studies [13, 36, 39, 72], no degradation occurred to MWNTs except for some small fluctuations. de Heer [13]
Figure 15. Long-term field-emission stabilities of SWNTs (left scale) and MWNTs (right scale) at constant voltage and 10^{-7} mbar pressure. Reprinted with permission from [37], J. M. Bonard et al., *Appl. Phys. Lett.* 73, 918 (1998). © 1998, American Institute of Physics.

et al. tested an MWNT-based electron gun at a 30 $\mu A/mm^2$ current density for 48 h. Only 10% current fluctuations were measured, and the fluctuations could be decreased to 2% by a feedback system. Wang et al. [72] observed a similar result on their matrix-addressable diode flat panel display. A stable current of 76 $\mu A/mm^2$ (fluctuation <8%) was tested for 12 h. Saito and Uemura [39] recorded a time trace of MWNT at an average current of 110 μA over 8000 h, and no degradation was measured (4% fluctuation).

For the field-emission failure of carbon nanotubes, de Pablo et al. [79] proposed an electrical failure model induced by defects. They used a nanocontact scanning force microscope to examine an MWNT rope where both ends were connected to a voltage ramp. While a voltage was repeatedly applied to this MWNT rope, every $I–V$ curve and corresponding change in rope morphology were recorded in turn until an electrical failure occurred. Eventually, de Pablo et al. located the electrical failure at a small region of a single nanotube where a 4 nm protrusion had originally stuck out from surface before the experiment. The diameter of apparent protrusion was 62 ± 5 nm. At such a scale, the irregular region can be identified as a defect. Accordingly, they further proposed that defects could be a mechanism of emission current limit for carbon nanotubes, especially for SWNTs.

Dean and Chalamala, Wadhawan et al., and Hata et al. [73, 80, 81] investigated H_2, HO_2, Ar, CO, N_2, and O_2 influences on the field-emission characteristic and degradation of carbon nanotubes. Dean and Chalamala [73] found that SWNTs operated at 3–4 μA current and 10^{-9} torr pressure for 350 h without substantial degradation. In addition, no degradation (some small fluctuations) was found when SWNTs operated for 80–100 h under the following conditions: (1) 1 μA current and 10^{-7} torr pressure with HO_2 exposure (HO_2 partial pressure 0.036 torr), and (2) 3–4 μA current and 10^{-7} torr pressure with H_2 and Ar exposures, respectively (H_2 partial pressure 0.15 torr, Ar partial pressure 0.015 torr). However, an irreversible degradation occurred when SWNTs operated at 3–4 μA current and 10^{-7} torr pressure with H_2O_2 and O_2 exposures (Fig. 16). After 48 h, the currents reduced by 25% for H_2O and 75%

for O_2. These experimental results demonstrated clearly: (1) that SWNT degradation depends on current level, and (2) the fast, irreversible degradation in oxygen and the different percents of current drops between H_2O and O_2 highlighted carbon nanotube sensitivity to oxygen and oxygen concentration. As a result, Dean and Chalamala proposed that, in poor vacuum, SWNT emitters were more stable than unballasted metal emitters because SWNTs never showed any protrusion growth, sputter-induced mobile atoms, and an arcing process that metal emitters did. Although SWNTs are susceptible to damage in oxygen, they can operate in a high-vacuum water environment and comparably low current. Therefore, carbon nanotubes are among the best materials for field-emission devices. Similar to Dean and Chalamala's observation, Wadhawan et al. [80] found no significant change in the field-emission characteristics for both the SWNTs and MWNTs exposed to Ar and H_2 gases. O_2 exposure temporarily increased the turn-on voltage of SWNTs by 22%, and decreased the field-emission current by two orders of magnitude. The degradation was completely reversible by operating in ultrahigh vacuum for 40 h. For MWNTs, the operation in O_2 at a higher voltage (compared to SWNTs) caused a 43% increase in turn-on voltage and a decrease of three orders of magnitude in emission current. The degradation on MWNTs was only partially reversible. Recently Hata et al. [81] studied the field emission from MWNTs in the ambient gases of H_2, CO, N_2, and O_2. The experimental result obtained is also in agreement with Dean and Chalamala's conclusion on SWNTs.

From those investigations in this section, one can conclude that the field-emission degradation and failure for carbon nanotubes arise from high current density (Joule heating), the nature of carbon nanotubes, structure defects, adsorbate state and gas absorption, oxygen concentration, ion bombardment, working pressure, and so on.
Figure 16. Operation of a single SWNT emitter under several gas ambiences. Total exposures were 0.15 torr (150,000 L) for H_2 and 0.015 torr (15,000 L) each for H_2O, Ar, and O_2. 3. FIELD-EMISSION APPLICATION OF CARBON NANOTUBES AND FLAT PANEL DISPLAY

Practical applications require different field-emission current densities. Flat panel displays call for a uniform current density of 1–10 mA/cm^2 over a large area, whereas microwave amplifiers demand a current density above 500 mA/cm^2 for a high power gain at 1–10 GHz. Presently, the available current density for carbon nanotubes approximates 0.1–100 mA/cm^2 (individual reports claimed 1–4 A/cm^2), much larger than silicon and diamond. Carbon nanotubes are suitable for those applications in modest current density.

Carbon nanotubes are applied to field emission in two ways: (1) an individual nanotube for a point electron source, and (2) multiple carbon nanotubes for a parallel electron-beam source.

An individual nanotube on a probe for a scanning tunnel microscope and an atomic force microscope is the typical application of a point electron source. Schmid and Fink [82] demonstrated that individual carbon nanotubes can behave as a coherent electron source. They mounted a single nanotube onto the tungsten tip of a low-energy electron point source microscope, and recorded the in-line holograms for a 7 nm wide carbon fiber that was used as a scattering object. This single nanotube electron source operated at low voltage, and could show an interference pattern with the same order of fringes as those shown by a conventional tungsten atomic point source. In addition, carbon nanotubes are relatively–chemically inert and tolerant to ion sputtering. These properties associated with the high coherence of emitted electrons and the low operating voltage make individual carbon nanotubes a unique point electron source.

In parallel electron-beam applications, most of the attention has been given to field-emission flat panel displays (FEDs) because flat panel displays have a giant market and demand a moderate current density [36, 40, 72, 83–86]. Moreover, carbon nanotubes can be produced in large scale, and can easily be built into composite materials for FED purposes. Rapid progress has been made in the past decade. In 1998, Saito et al. demonstrated an MWNT lighting element structured inside a cathode ray tube (CRT) [83]. The MWNTs were grown on graphite disks by dc arc discharge. Baked at 450–500 °C in air to treat a silver paste and remove a cylindrical mold, these graphite disks attached with carbon nanotubes were mounted onto a cathode ray tube to replace a conventional filament cathode. By applying a voltage to the lighting elements, the green, blue, and red fluorescent screens mounted on three CRTs were lighted, respectively. Right after Saito, Wang et al. [72] built a 32×32 matrix-addressable flat panel display by patterning carbon nanotube-epoxy (on a cathode) and phosphor-coated ITO film (on an anode, i.e., screen) into 32 straight lines, respectively. The nanotube-epoxy lines and the phosphor-coated ITO lines cross over each other perpendicularly. Addressable pixels were formed at every intersection of nanotube-epoxy lines with phosphor-coated ITO lines. When the voltage addresses a nanotube-epoxy line and an ITO line, the pixel at the intersection will be excited. In 2000, Kim et al. [36] successfully assembled and characterized a 4.5 in,

128-line matrix-addressable flat panel display. This prototype showed an unusually high brightness (1800 cd/m^2) at a lower voltage (740 V, 0.25 duration, 15.7 kHz frequency) compared to a Spindt-type FED (300 cd/m^2 at 6000 V). Further, a fully sealed 128-line addressable FED in the color mode also was experimentally fabricated. Although these diode-type flat panel displays are only able to display letters and stationary images, they have clearly demonstrated carbon nanotube feasibility for flat panel displays. Recently, a great breakthrough in 5 in triode-type FEDs was made by Jung et al. [84]. The triode-type display for the first time realized a full-color display in the moving-image mode [Fig. 17(c)], and the brilliant image was displayed at a resolution of 240 × 120 lines [Fig. 17(d)]. A matrix-addressable circuit was used to drive this FED. To form a triode structure, backside photolithography associated with photosensitive SWNT paste was initially introduced to protect the surface properties of SWNT paste from the interruption of a subsequent process [Fig. 17(a)]. The adoption of a thick gate wall suppressed the diode effect and color cross in subpixels [Fig. 17(b)]. With the decrease of spacer thickness and gate hole size, the turn-on voltage and anode voltage of the triode-type display reduced to 40–45 and 400–800 V, respectively. The breakthrough demonstrates that carbon nanotubes are compatible with current FED fabrication. The remarkable achievements outline the prospect of carbon nanotubes in field-emission applications.

4. CONCLUSION

A constant topic for vacuum microelectronics is how to achieve a cathode of high performance because the cathode is the core of a field-emission device. A cathode of high performance should exhibit not only a high current density at low operating voltage, but also a stable field emission in harsh environments. Accomplishing this purpose depends on the developments of theory, technology, and material. It has been theoretically and experimentally proven that carbon nanotubes are an inherent good material for field emission. The low electron work function and unique geometry endow the cathode with the features of low turn-on voltage and high local field enhancement, which make the field-emission device able to work at high current density and low voltage. Their chemical inertness, strong carbon bonding, and sputter etching-free feature lead to field emission with reduced environmental dependence.

Carbon nanotubes have shown great potential to fulfill the demands for field-emission applications. In the past decade, rapid progress had been made in carbon nanotube synthesis, field-emission mechanism, and field-emission characterization. The control over the carbon nanotube diameter, alignment, and site density have improved field-emission properties. The initial experiments and analysis in field-emission stability, degradation, and failure also have been carried out. The present barriers to commercialization include field-emission uniformity, reliability, and lifetime. The imperative task is establishing a comprehensive theory and model to control carbon nanotubes in both morphology and structure, developing the ability to manipulate one single nanotube, and better understanding the field-emission mechanism, including various defects and surface-state properties. More detailed studies should be devoted to the electron work function, the interface property of nanotubes and substrate, the degradation and failure mechanism, and so on. With the development of theory and technology, one can expect that various field-emission devices of carbon nanotubes will be commercially available in the near future.

GLOSSARY

Absorbate states Absorbates on semiconductor surface bring in electronic states in energy band and impact on the electrical behavior of semiconductor. These electronic states are called absorbate states. Absorbrate states can be removed or replaced with the status change of semiconductor surface, leading to an unstable and deviant operation of devices.

Band gap In a semiconductor material, the minimum energy necessary for an electron to transfer from the valence band into the conduction band, where it moves more freely.

Conduction band A vacant or partially occupied set of many closely spaced electronic levels resulting from an array of a large number of atoms forming a system in which the electrons can move freely or nearly so. In reference to the conductivity in semiconductors, it is the band that accepts the electrons from the valence band.

Donor An atom that is likely to give off one or more electrons when placed in a crystal.

Electron Particle with spin 1/2 and carrying a single negative charge (1.6×10^{-19} Coulomb).

Fermi–Dirac statistics Fermi–Dirac statistics provides the probability that an electron in thermal equilibrium with a large system occupies energy level E. Fermi-Dirac distribution function is given by:

$$f(E) = \frac{1}{1 + e^{(E-E_F)/kT}}$$

The system in thermal equilibrium is characterized by its temperature T and its Fermi energy E_F.

Fermi level For metals, the highest occupied molecular orbital in the valence band at absolute zero temperature ($T = 0$ K). In insulators and semiconductors, the valence and conduction bands are separated. Therefore the Fermi-Level is located in the band gap. Based on Fermi-Dirac distribution function, the probability for an electron to occupy Fermi level is one half.

Gate Electrode of a field emission transistor, which controls the current from the emitter.

Impurity A foreign atom in a crystal.

Interface Boundary between two materials.

Ionization The process of adding or removing an electron to/from an atom thereby creating a charged atom (i.e. ion).

I–V curve Current versus voltage characteristics.

I–V measurement Current versus voltage measurement.

Negative electron affinity Electron affinity is defined as the energy required removing an electron from the bottom of conduction band to a distance far from the material surface, i.e. to vacuum level. Hence no energy barrier prevents low-energy electrons from escaping into the vacuum if vacuum level lies below the conduction band minimum. In this case the surface has a negative electron affinity.

Quantum mechanics Theory that describes particles as a wave function.

sp^3 hybridization The phenomenon of mixing up of different orbitals of same energy level of an atom to produce equal number of hybrid-orbitals of same energy and identical properties is known as hybridization. A hybrid orbital contains maximum two electrons with opposite spin. The process of hybridization in which one s-orbital and three p-orbitals overlap to produce four hybrid-orbital is known as sp^3 hybridization. These hybrid-orbitals are not only identical in shape and energy but also at an angle of 109.5° from each other (tetrahedral fashion).

Static vacuum system A closed vacuum system without exhaust.

Substrate The material in which a device is embedded or on to.

Surface barrier Increased potential at the surface of a material.

Thermionic emission Process where electrons are emitted across a confining barrier. The driving force of this process is the thermal energy that provides a non-zero density of electrons at those energies larger than the barrier.

Tunneling Quantum mechanical process where a particle can pass through a barrier rather than having to go over the barrier.

Valence band Made up of occupied molecular orbitals and is lower in energy than the so-called conduction band. It is generally completely full in semiconductors. When heated, the electrons from this band jump out of the band across band gap and into the conduction band, making the material conductive.

Filling of Carbon Nanotubes

Pawan K. Tyagi, Manoj K. Singh, D. S. Misra

Indian Institute of Technology, Mumbai, India

CONTENTS

1. INTRODUCTION

The discovery of carbon nanotubes by Ijima [1] in 1991 started the onset of activity in this novel class of materials. Carbon nanotubes are tubules of very narrow (1.4–50 nm) diameter. It might be justified to say that the nanotubes are another allotrope of carbon, diamond, graphite, and buckminster fullerenes (C_{60}, C_{70}, etc.) being the others. Out of these allotropes only graphite has planar structure and graphite planes truly are the building blocks of the carbon nanotubes. Nanotubes have strong potential for applications due to the interesting electrical, mechanical, and chemical properties they possess. In addition, the interesting possibility of filling of the tubes with different materials enables us to make nanostructures in a controlled fashion. The filling of nanotubes has recently been discussed in a few excellently written reviews [2–5]. The confined existence of the material inside the tubes might introduce interesting new properties in these materials and show physical phenomena which have not yet been seen.

Initially nanotubes were synthesized by the arc discharge method [6–9]. Later on, however, a host of other techniques [10–13] were exploited for the synthesis of nanotubes. Currently plasma arc jet [13], laser ablation, chemical vapor deposition (CVD) [10, 11] pyrolysis, electrolytic conversion [12], and arc discharge are the most popular methods for the synthesis of the nanotubes. The filling of the carbon nanotubes received immediate attention because of the known existence of the metal particle entrapped by the fullerene

[11, 12]. Nanotubes are either single walled or multiwalled as shown in Figure 1a and b. Single walled tubes are divided into three categories depending on their structure as shown in Figure 2a–c. In multiwalled tubes the concentric shells of the graphite planes are held together by weak van der waals forces. Single walled tubes mostly exist in bundles.

1.1. Structure of Carbon Nanotubes

It is convenient to describe the structure of a single walled carbon nanotube in terms of a honeycomb lattice of a single plane of graphite (a graphene layer). The basic unit cell of a honeycomb lattice is a two-dimensional (2D) parallelogram with a two-atom basis. The unit vectors of a graphene layer are shown in Figure 3b. In general a tube is defined in terms of its chirality. The axes of the graphene layer are along a_1 and a_2, respectively (i.e., the two directions termed as zigzag). The bisector of these two axes is called the "armchair" axis. Chiral vector is defined as a vector C_h drawn from its origin to a point on a honeycomb lattice defining chirality of the tube. As the coordinates of points on a zigzag axis are $(m, 0)$ the chiral angle of zigzag type tubes is zero. Likewise the chiral angle (θ) of a tube along the armchair direction is 30°. Any other type of tube falls in between these categories and the chiral angle lies between $0 < \theta \leq 30°$. The structure of various tubes is described in Figure 2a–c. Various structure parameters of the tubes are listed in Table 1.

2. SYNTHESIS

2.1. Multiwalled Carbon Nanotubes

Carbon nanotubes are readily prepared by striking an arc between graphite electrodes in ~500 torr of helium, which is considerably higher than the pressure of helium used for the production of fullerene soot. A current of 60–100 A across the plasma with potential drop of about 25 V gives high yields of carbon nanotubes. The arcing process can be optimized such that the major portion of the carbon anode is deposited on the cathode in the form of carbon nanotubes and graphitic nanoparticles [6]. Carbon nanotubes have been produced in large quantities by using plasma arc jets [13] by optimizing the quenching process in the arc between
Figure 1. (a) Bundles of single walled carbon nanotubes. (b) Multi-walled carbon nanotubes.

Figure 2. Structural models of (a) armchair, (b) zigzag, and (c) a general tube. The chiral angle (θ) lies between 0° and 30° for a general tube. Reprinted with permission from [3b], M. S. Dresselhaus et al., *Carbon* 33, 883 (1995). © 1995, Elsevier Science.

2.2. Aligned Carbon Nanotube Bundles

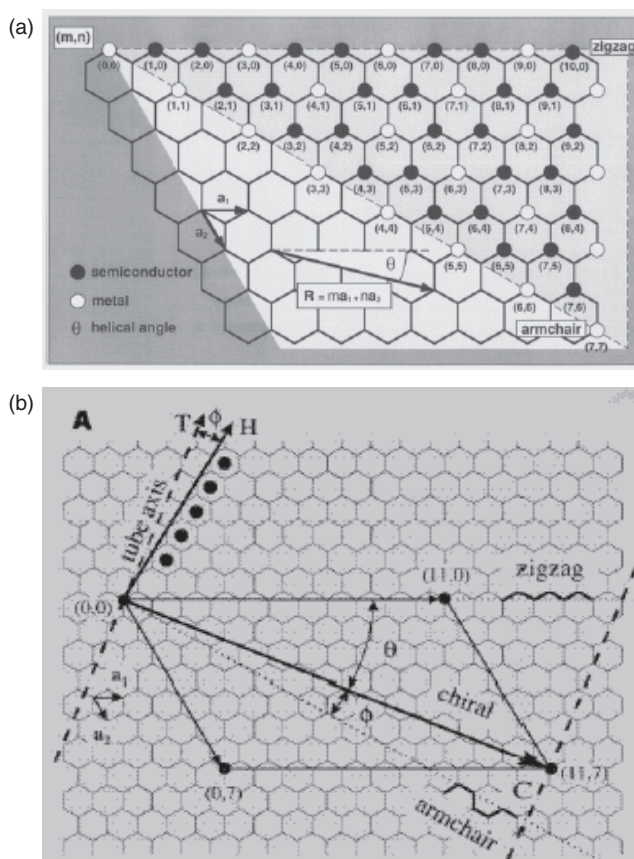
Carbon nanotubes are potential candidates for use as field emitters [23]. The synthesis of aligned nanotubes bundles is of particular relevance to this application. Aligned nanotube


Figure 3. (a) Graphene layer and unit vectors of a single walled carbon nanotube and (b) chiral vector and chiral angle of a (11,7) tube. Reprinted with permission from [103], J. W. G. Wildoer et al., *Nature* 391, 59 (1998). © 1998, Macmillan Magazines Ltd.

a graphite anode and a cooled Cu electrode [14]. Studies with scanning tunneling microscopy reveal that the deposition of carbon vapor on cooled substrates of highly oriented pyrolytic graphite gives rise to tubelike structures [15]. Electrolysis in molten halide salts with carbon electrodes under Ar atmosphere also yields carbon nanotubes with high concentration [16]. Besides the conventional arc-evaporation technique, carbon nanotubes are produced by the decomposition of hydrocarbons, such as acetylene, under inert conditions around 700 °C over iron/graphite [17], cobalt/graphite [18], or iron/silica [19] catalysts. The presence of transition metal particles is essential for the formation of nanotubes by the pyrolysis process and the diameter of the nanotubes is determined by the size of the metal particles [20]. Sen et al. [21] prepared carbon nanotubes and metal-filled onionlike structures by the pyrolysis of ferrocene, cobaltocene, and nickelocene under reductive conditions, where the precursors act as a source of the metal catalyst as well as carbon. It was also shown that the pyrolysis of benzene in the presence of ferrocene or [Fe(CO)$_5$] gives high yields of nanotubes. The diameter of the nanotubes depends on the concentration of the carbon source and size of metal precursors [22].

Table 1. Parameters of carbon nanotubes.

Symbol	Name	Formula	Value
a_{C-C}	carbon–carbon distance		1.421Å
a	length of unit vector	$\sqrt{3}a_{c-c}$	2.46 Å
$\mathbf{a_1}, \mathbf{a_2}$	unit vectors	$\left(\frac{\sqrt{3}}{2}, \frac{1}{2}\right)a, \left(\frac{\sqrt{3}}{2}, -\frac{1}{2}\right)a$ in (x, y) coordinates	
$\mathbf{b_1}, \mathbf{b_2}$	reciprocal lattice vector	$\left(\frac{1}{\sqrt{3}}, 1\right)\frac{2\pi}{a}, \left(\frac{1}{\sqrt{3}}, -1\right)\frac{2\pi}{a}$ in (x, y) coordinates	
C_h	chiral vector	$C_h = na_1 + ma_2 = (n, m)$ n, m: integers	
L	circumference of nanotube	$L = |C_h| = a\sqrt{n^2 + m^2 + nm}$ $0 \leq |m| \leq n$	
d_t	diameter of nanotube	$d_t = \frac{L}{\pi} = \frac{\sqrt{n^2+m^2+nm}}{\pi}a$	
θ	chiral angle	$\sin\theta = \frac{\sqrt{3}m}{2\sqrt{n^2+m^2+nm}}$	
		$\cos\theta = \frac{2n+m}{2\sqrt{n^2+m^2+nm}}$ $0 \leq |\theta| \leq 30°$	
		$\tan\theta = \frac{\sqrt{3}m}{2n+m}$	
	SWNTs of chirality (n, m) are		
	(i) semiconducting if $(n - m)$ is not a multiple of 3		
	(ii) metallic otherwise		
d_R	the highest common divisor of $(2n + m, 2m + n)$		
$\mathbf{T}$	translational vector of 1D unit cell	$T = t_1a_1 + t_2a_2 \equiv (t_1, t_2)$ t_1, t_2: integers	
T	length of T	$T = \frac{\sqrt{3}L}{d_R}$	
N	number of hexagons per 1D unit cell	$N = \frac{2(n^2+m^2+nm)}{d_R}$ $2N \equiv n_C$/unit cell	
$\mathbf{R}$	symmetry vector[a]	$\mathbf{R} = pa_1 + qa_2 \equiv (p, q) p, q$: integers[a]	
		$d = mp - nq, 0 \leq p \leq n/d, 0 \leq q \leq m/d$	
$\mathbf{M}$	number of 2π revolutions	$\mathbf{M} = \frac{[(2n+m)p+(2m+n)q]}{d_R}$ M: integer	
		$N\mathbf{R} = MC_h + dT$	
R	basic symmetry operation	$R = (\Psi|\tau)$	
Ψ	rotation operation	$\Psi = 2\pi\frac{M}{N}, \left(\chi = \frac{\psi L}{2\pi}\right)$ Ψ: radians	
τ	translation operation	$\tau = \frac{dT}{N}$ τ, χ: length	

[a] $\mathbf{R}$ and R refer to same symmetry operation.

bundles have been obtained by chemical vapor deposition over transition metal catalysts embedded in the pores of mesoporous silica or the channels of alumina membranes [24, 25]. Terrones et al. [26, 27] prepared aligned nanotubes over silica substrates, laser patterned with cobalt. Ren et al. [28] employed plasma-enhanced CVD on nickel-coated glass with acetylene and ammonia mixtures for this purpose. The mechanism of the growth of aligned nanotubes by this method and the exact role played by metal particles in alignment are not clear, although a nucleation process involving the metal particles is considered to be important. Fan et al. [29] have obtained aligned nanotubes by employing CVD on porous silicon and plain silicon substrates patterned with iron films. Here again, the exact roll of iron particles in alignment of the tubes is not known. The work of Pan et al. [30] shows that the tip growth mechanism might be responsible for alignment.

Aligned nanotubes can be obtained by pyrolysis of mixtures of organometallic precursors and hydrocarbons [21, 22]. One would expect that the transition metal nanoparticles, produced *in-situ* in the pyrolysis, may not only nucleate the formation of carbon nanotubes but also align them. This aspect has been examined by carrying out the pyrolysis of metallocenes along with additional hydrocarbon sources in a suitably designed apparatus [31–33].

A ferrocene–acetylene mixture appears to be ideal to prepare large quantities of compact bundles of aligned carbon nanotubes. Andrews et al. [34] have carried out the pyrolysis of ferrocene–acetylene mixtures to obtain aligned carbon nanotubes. The advantage of this procedure is that the aligned bundles of nanotubes can be produced in one step at relatively low cost without prior preparation of the substrates. Pyrolysis of iron(ii)phthalocyanine also yields aligned nanotubes [35]. Hexagonally ordered arrays of the tubes are produced using alumina templates with ordered pores [36]. By employing catalytic chemical vapor deposition, Mukhopadhyay et al. [37] obtained large quantities of quasi-aligned carbon nanotubes using metal-impregnated zeolite templates.

2.3. Single Walled Carbon Nanotubes

The nanotubes generally obtained by the arc method or hydrocarbon pyrolysis are multiwalled and have several graphitic sheets or layers. Single walled nanotubes (SWNTs) were first prepared by metal-catalyzed dc arcing of graphite rods [7] under helium atmosphere. The graphite anode was filled with metal powder (Fe, Co, Ni) and the cathode was of pure graphite. SWNTs are generally formed in the material deposited behind the cathode. Various metal catalysts

have been used to make SWNTs by this route. Dai et al. [38] prepared SWNTs by the disproportionation of CO at 1200 °C over molybdenum particles of a few nanometers diameter dispersed in a fumed alumina matrix. Saito et al. [39] compared SWNTs produced by using different catalysts and found that a cobalt or an iron/nickel bimetallic catalyst gives rise to tubes forming a highway-junction pattern. Nickel catalyst yields long and thin tubes radially growing from the metal particles. SWNTs are also prepared by using various oxides (Y_2O_3, La_2O_3, and CeO_2) as catalyst [40]. The arc-discharge technique, although cheap and easy to implement, leads to low yields of SWNTs. Journet et al. [41] obtained an ~80% yield of SWNTs in the arc by using 1 atomic yttrium and 4.2 atomic nickel as catalyst.

Arc evaporation of graphite rods filled with nickel and yttria under helium atmosphere (660 Torr) gives rise to weblike deposits of SWNT bundles [33] on the chamber walls near the cathode. SWNTs have been produced in more than 70% yields by the condensation of a laser-vaporized carbon–nickel–cobalt mixture at 1200 °C [42]. These SWNTs are nearly uniform in diameter and self-assemble into ropes consisting of 100 to 500 tubes in a 2D triangular lattice. Under controlled conditions of pyrolysis, dilute hydrocarbon–organometallic mixtures yield SWNTs [33, 43–45]. Pyrolysis of a nickelocene–acetylene mixture at 1100 °C yields SWNTs [43]. Pyrolysis of ferrocene–thiophene mixtures also yields SWNTs but the yield appears to be somewhat low. Laplaze et al. [46] have demonstrated that concentrated solar energy can be employed to vaporize graphite to synthesize SWNTs. Nikloaev et al. [47] obtained SWNTs using a gas-phase catalytic method involving the pyrolysis of $[Fe(CO)_5]$ and CO. The decomposition of CO on a silica-supported Co/Mo catalyst also yields SWNTs [48]. Colomer et al. [49] obtained SWNTs in high yield by passing a H_2/CH_4 mixture over a transition-metal deposited MgO substrate. Flahaut et al. [50] have synthesized SWNTs by passing a H_2/CH_4 mixture over transition-metal oxide spinels, obtained by the combustion route. Zeolites containing one-dimensional channels have also been investigated toward the synthesis of monosized SWNTs [51].

3. VARIOUS ROUTES FOR FILLING THE TUBES

3.1. Filling MWNT

3.1.1. Capillary Filling by Chemical Routes [52]

The idea that the carbon nanotubes could be filled with a variety of metals to prepare the nanowires of metals was very appealing. One has to, however, make sure that the tubes are open ended. This is because in general the tubes are closed at both ends. The ends are also the weakest spot in the structure as they contain pentagons of carbon atoms. The opening of the tube ends can be achieved by boiling the suspensions of nanotubes [53] in aqueous nitric acid for several hours at 150 °C. This generally results in the opening of the ends of about 80–90% tubes. We describe the methodology of filling the tubes using the **wet chemical route**.

One Step Method for Filling the Tubes [54]   A sample of closed nanotubes (0.5 g), azeotropic nitric acid (68% ca., 100 cc), and soluble nitrate (0.5–1 g) was heated to reflux for 4.5–12 h. The nitric acid was decanted off subsequently. The filtered residue was dried at 60 °C. When the resulting powder is calcined at 450 °C in Ar flow, about 60% of the nanotubes contain oxide nanocrystals of 3–5 nm diameter and 10–30 nm length. Using this technique it is possible to fill the oxides of **Ni, Co, Fe, U** [53], **Nd, Eu, La, Ce, Pr, Y, Zr, and Cd** [54], **Mo** [55], and **Sn** [56, 57].

Two Step Method for Filling the Tubes [54]   In the two step process, the nanotubes are opened by refluxing in azeotropic HNO_3 for 8–24 h. The filtered residue is heated to 900 °C to remove the acidic groups attached to the surface of the tubes. Subsequently the sample of the tubes is mixed with the metal complexes. The filtered residue is dried and later on calcined at 450 °C in Ar flow. The two step method is useful for systems that do not dissolve in nitric acid. In particular this is found to be useful for filling the tubes with **Rh, Ru** [58], **Pd** [59], **Co, Au** [60, 61], **and Ag** [61, 62]. For filling of the tubes with **Au** and **Ag** the nanotube powder is mixed with solutions of $AuCl_3$ and $AgNO_3$, respectively. This results in filling of tubes with $AuCl_3$ and $AgNO_3$. Further reduction of the mixture to 300–400 °C in H_2 flow leads to filling of the tubes with Au and Ag [54].

SnO [56]   The filling of the tubes with **SnO** is achieved by heating 100 mg of nanotube powder with 0.8 g of $SnCl_2$ in 2 ml of hot concentrated hydrochloric acid. The pH of the solution has to be raised slowly to 10.2 by dropwise addition of Na_2CO_3. The resulting mixture was dried at 160 °C for 3 h. Multiwalled tubes contained **SnO** in the core region.

3.1.2. Filling with Molten Solid Route

The filling of the carbon nanotubes by heating them in the presence of molten metal was immediately explored after the discovery of the tubes when Ajayan and Ijima [52] attempted to fill the tubes with **Pb** in a sealed quartz ampoule. Various elements that have been filled using these techniques are discussed.

Eutectic Mixture of UCl_4 and KCl [63]   **UCl_4** and **KCl** are mixed in different molar ratios and are mixed with opened multiwalled tubes. The mixture is then heated in a sealed quartz ampoule at a temperature 150 °C greater than the liquid temperature of each eutectic [63]. Using this technique the surface tension of the composite material is suitably adjusted to achieve the filling.

Filling the MWNTs with Pb, Se, Sb [52]   Lead (**Pb**) was evaporated on carbon nanotube samples using e-beam evaporation techniques. When the tubes were heated to 400 °C, the melting temperature of lead, the filling took place. Similar results were obtained for **Sb** and **Se**.

As discussed the capillary filling of the MWNTs has been achieved using two dominant routes. In the first case, the tubes are mixed with chemical solutions containing nitrates and halides salts (wet chemical route) of the filler material. In the second case the powder of the tubes is mixed and heated with the filler itself. In the majority of the cases the

compound of the filler material has to be reduced in the flow of either Ar or H_2 gas at sufficiently high temperature. That raises the question whether the filling is of pure intended solid or a mixed phase of the two. So far the evidence shows that the complete reduction of the salt has occurred. One should, however, not rule out the presence of the localized nonhomogeneity of the starting compound. The limitation of the wet chemical route is the limited availability of the salts, less or no control of the composition of the resulting filler, and process based impurities.

In the filling with molten route capillary action, surface tension, and wetting play important roles in the process [64, 65]. Generally the filling of the nanotubes by capillary action is restricted to low surface tension metals such as **Bi**, **Cs**, **S**, and **Se** [65, 66]. When filling the nanotubes two competing phenomena, the rise of the molten liquid in the capillary and the wetting of the walls accompany each other. If the diameter of the tube is too small, generally the wetting of the tube surface results. This is one of the main reasons for the poor efficiency of the filling of SWNTs. The capillary action to fill the nanotubes by the forces of surface tension is governed by the contact angle (θ) between the liquid and solid interface [67]. If the θ is more than 90°, the filling of a liquid inside a capillary can only be achieved by applying the pressure difference. On the other hand if the value of θ is less than 90° the liquid gains energy by rising in the capillary. Figure 4 shows the cases of different contact angles.

As discussed, the open-ended multiwalled nanotubes (MWNTs) are filled with **Pb**, **Bi**, **Cs**, **S**, and **Se** [52, 65–67] by heating with molten metals. It has been concluded that the filling in this case is limited to only the low surface tension substances (with $T < 180$ mN/m). This, however, requires much more serious attention because the surface tension decreases steeply with temperature. One should also not discount the carbonaceous impurities affecting the surface tension of the molten metal. Table 2 shows the surface tension of various elements popular for filling the tubes. The data are represented at the melting point of the materials. To circumvent the threshold value in a few cases the mixtures of the compounds have also been used for filling the tubes [68–73].

Another important parameter for filling the tubes with heating in the molten state of the materials could be the viscosity of the material. It may be difficult to fill the tubes with a highly viscous metal.
Table 2. Surface tension at melting point of some of the materials used for filling the tubes.

Elements/compounds	Surface tension (mN/m)
HNO_3	43
Sulphur	61
Cesium	67
Selenium	97
Vanadium oxide	80
Lead oxide (PbO)	132
Bismuth oxide (Bi_2O_3)	200
Tellurium	190
Lead	470
Uranium oxide	513
Nickel	1856
Indium	568
Uranium	1653

3.1.3. Filling by Arc Discharge

Arc discharge experiments have also been used for filling the materials inside the MWNTs [74]. In this method the holes are drilled in the graphite anodes that are packed with the metal to be filled inside the tubes. With this arrangement, the filled MWNTs are deposited on cathodes. The important work in filling of the nanotubes using this route was perfected by Guerret-Piecourt et al. [74]. Figure 5 shows the filling of the tubes by the arc discharge technique. A correlation is observed between the efficiency of a filling material (filler) and the incomplete shell structure of some of the elements. It is speculated that the elements with incomplete shells are efficient fillers. Clearly a lot more experimentation is essential to confirm this result. It has been reported that in all 41 elements are inserted inside the MWNTs: some partially and some fully. A variety of elements such as transition elements (**Cr**, **Ni**, **Re**, **Au**), rare earths (**Sm**, **Gd**, **Dy**, **Yb**), and covalents (**S**, **Ge**, **Se**, **Sb**) are filled nearly continuously and **Mn**, **Co**, **Fe**, **Pd**, **Nb**, **Hf**, **Os**, **B**, **Te**, and **Bi** are filled partially with small gaps in between [74–78]. The procedure of filling the tubes is discussed.

Filling the MWNTs with Ge, S, Se, and Sb [74–78] For filling of the multiwalled tubes with these elements the arc discharge method was used. The anode and cathode were graphite rods of diameter 9 mm and lengths 38 and 72 mm, respectively. A 6 mm diameter hole was drilled in the anode to a depth 38 mm and was filled with graphite and element powder. The ratio of the graphite and the element in the mixture was 70% and 30%. The electric arc conditions were 100–110 A, 20–30 V and He pressure was 0.5 bar. The same technique is also used for filling the tubes with **Cr**, **Ni**, **Re**, **Au**, **Sm**, **Gd**, **Dy**, and **Yb**.

Filling TaC and CeC₂ inside MWNTs [79, 80] Tantalum powder filled graphite rods are used in an arc discharge apparatus as the positive electrode (anode). The negative electrode (cathode) is pure graphite. The powder filled rod is initially heated to 2000 °C to form carbide and is then used for deposition. The analyses of the tubes show that there are no oxide impurities and the fillings are either pure carbide or pure metal.

Figure 4. (a) Description of the contact angle of liquid and wall of a capillary tube. (b) and (c) The contact angle for concave and convex surface, respectively.
Figure 5. Filling of the core region of multiwalled tubes using arc discharge with (a) Cr, (b) Ni, (c) Dy, (d) Yb, and (e) Cr. Reprinted with permission from [74], G. Guerret-Piecourt et al., *Nature* 372, 761 (1994). © 1994, Macmillan Magazines Ltd.

It was concluded by these studies that the elements with incomplete outer electronic shells perhaps have the best chance of filling the tubes fully. However, only one such study has been reported and more data are required before it can be used as a rule of thumb. It has also been reported that a small concentration of S impurity helps considerably in filling the tubes. Using this method carbides such as LaC_2 [79, 80], YC_2 [81, 82], CeC_2 [79, 83], Gd_2C_3 [74, 84], TiC [74, 85], ZrC [86], TaC [80, 83, 87], HfC [88], MoC [87, 89], and others [90] have been inserted in the MWNTs. This technique is disadvantageous because in the high temperature environment of the arc discharge it is rather easier for elements to convert to the carbide form and only a few elements are inserted without carbide formation.

3.1.4. Catalytic Filling of MWNTs [10, 11]

Another technique for generating filled MWNTs is to use the catalyst itself to fill the tubes at the time of synthesis. In this process an electroplated **Ni** layer is used as a catalyst for the growth of nanotubes by a CVD technique [10]. The copper substrates are subjected to NH_3 treatment for the production of the nanocatalyst and used as templates for nanotube growth. The method has been adopted to fill Ni and NiPt [11] inside the tubes and can be easily used for filling **Cr**, **Co**, **Fe**, and **Pt** inside the MWNTs. The transmission electron microscope (TEM) image of the nanorods of diameter ~40 nm and length ~0.5 μm nanorod and therefore the structure of the **Ni** rod may have interesting features that

were not seen earlier. In Figure 6 one can clearly see the uniform and dense **Ni** filling inside the tube. The diameter of the **Ni** nanorod is approximately 40 nm and its length is 500 nm. It is also evident that the symmetry of the end cap of the tube is enforced on the end of the tube.

To understand the microstructure of the Ni nanorods inside carbon nanotubes, a nanodiffraction study was performed at various locations of the tubes. Typically the size of the area chosen for nanodiffraction was 15 nm. The locations were (a) inside the Ni nanorod, (b) near the tip of the tube, (c) near the lower tip of the tube, and (d) on the walls. The nanoarea diffraction patterns at all four locations are shown in Figure 7. Narrow diffraction spots observed from face-centered cubic, Ni nanorods in the case of Figure 7 indicate that the structure of the rods is perfectly crystalline in this region. No evidence of another phase, such as Ni_3C, is found at this location. Closer to the tip (Fig. 7b), the diffraction pattern becomes intensely blurred with thicker

Figure 7. Electron diffraction patterns of the Ni nanorods inside the multiwalled carbon nanotubes prepared in our laboratory. The diffraction pattern was recorded at different locations of the tubes. It is observed that the nanorods are crystalline and of pure phase in the core region. Near the walls graphite and Ni_3C phases are seen. Reprinted with permission from [11], M. K. Singh et al., *J. Nanosci. Nanotech.* 3, 165 (2003). © 2003, American Scientific Publishers.

spots, implying that the structure now may not be perfectly crystalline. Figure 7c shows the nanodiffraction observed near the lower tip of the tubes. It shows diffraction spots corresponding to superposition of several phases. The dominant spots belong to the (110) and (112) planes of graphite, (110) and (220) planes of Ni, and (306) and (113) planes of Ni_3C. Similarly the nanoarea diffraction (Fig. 7d) within the walls of the tubes indicates the presence of (112), (002) planes of graphite structure and some evanescent patterns of (113), (220) planes of the Ni_3C phase that are possibly present at the interface between the graphite walls and the Ni filling.

The disadvantage of the previous technique may be that it is restricted to filling by only those elements that can be used as the catalyst for the growth of the nanotubes. Similarly **Fe** filling of the multiwalled tubes has been accomplished using catalytic decomposition of cyclohexane [91]. This technique also relies on *in-situ* filling of the tubes at the time of synthesis.

3.2. Filling SWNTs

Filling of SWNTs has been attempted using the previous techniques also. However, the additional constraint in case of SWNTs is their small diameter and as a result the capillary action may not be as efficient. An excellent review on filling of the SWNTs was published by Monthioux [3a]. The filling of SWNTs is all the more important because

the dimensions are much smaller and the chances of seeing quantum effects due to the reduction of the size will be high in this case. Following the work of David Luzzi, several studies have been published on the filling of the SWNTs with fullerenes [92]. This structure is known as a "peapod" [93]. Remarkable behavior is reported for C_{60} molecules when encapsulated in ~1.4-nm-diameter SWNTs during *in-situ* electron-beam irradiation within an electron microscope, including dimerization [94, 95], coalescence [95–97], and diffusion [94]. The latter is probably more spectacular because it may lead to applications where motion and transport are required, such as the electronics industry (e.g., nanodevices) or biochemistry and medicine (e.g., nanopipes or nanosyringes). It is also possible to attach a foreign atom to the fullerene cage and then insert it in SWNTs. Research in this direction is being carried out vigorously by various groups [94, 97–100]. Actually, the synthesis of "endotubular metallofullerenes" such as GdC_{82} [98–100], LaC_{82}, La_2C_{82}, SmC_{82} [100], La_2C_{80} [101, 102], and $Er_xSc_{3-x}NC_{80}$ SWNTs [102] is already achieved. Some of these are described.

3.2.1. Filling of SWNTs with Halides of Lanthanides (La, Nd, Sm, Eu, Gd, Tb, and Yb)

As-prepared SWNT powder (30 mg) was mixed with the anhydrous halides of these elements in dry box conditions. The samples of the mixture were sealed in a quartz ampoule under vacuum and placed in a tube furnace. The temperature of the furnace was raised to 10–50 °C above the melting points of the respective lanthanides (Table 3) at the rate 3–5 °C min^{-1}. The sample was held at a high temperature for one hour and then furnace cooled to room temperature.

The seminal work on filling of SWNTs was carried out by Meyer et al. [72] at Oxford who showed the actual 2D nature of the KI crystals inside the SWNT. In this work the image of single atoms arranged in a truly 1D crystal lattice inside the nanotube of 1.6 nm diameter is produced. A clear arrangement of alternate K and I atoms is evident in the TEM image. The spectacular result (Fig. 8) is that the coordination number of the atoms of the 1D crystal is different from the bulk and the lattice appears to be distorted. The normally square lattice is distorted more along the $\langle 100 \rangle$ direction than along $\langle 110 \rangle$ resulting in a "pseudo square" lattice having the circular symmetry of a nanotube. The distortion corresponds to a "Poisson ratio" of 0.293. The Oxford team has also succeeded in filling halides such as $(KCl)_x (UCl_4)_y$ and $AgCl_xBr_y$ [104], CdI_2 and $ThCl_4$ [104],

Table 3. The melting point and the filling temperature of lanthanide [71].

Material	Melting temperature	Filling temp.
$LaCl_3$	860	910
$NdCl_3$	784	834
$SmCl_3$	686	706
$EuCl_3$	850	860
$GdCl_3$	609	659
$TbCl_3$	588	638
$YbCl_3$	854	904

(a)

(b)

CdCl$_2$ [69, 104], **TbCl$_3$** [69], **TiCl** and **PbI$_2$** [70], **KI** [69, 72, 105, 106], **ZrCl$_4$** [96], and **AgCl$_x$I$_{1-x}$** [107].

3.2.2. Filling with AgCl, AgBr, and AgBr$_{0.2}$Cl$_{0.8}$

Filling with these halides was achieved by the previously discussed route. The halides of Ag and Br were mixed and ground with SWNT powder. The mixture was sealed in a silica tube under vacuum and then heated to temperatures higher than the melting temperature of the halide. The heating temperatures, respectively, for **AgCl**, **AgBr**, and **AgBr$_{0.2}$Cl$_{0.8}$** were 833, 800, and 783 K.

Other halides such as **MoCl$_5$** and **FeCl$_3$** [108] have also been filled inside SWNTs. Recently the insertion of chromium oxide in SWNTs was achieved by Mittal et al. [109–111] using a simple chemical process to be described. Another example of filling **Sb$_2$O$_3$** was reported recently [63, 112, 113]. Generally speaking, filling SWNTs with oxides has rarely been attempted so far.

3.2.3. Filling with Sb$_2$O$_3$ [113]

As-prepared powder (0.03 g) of SWNTs is mixed and ground with 0.15 g of **Sb$_2$O$_3$** powder. The mixture is sealed in a quartz ampoule and heated at a rate 1 K min^{-1} to 1033 K [113] and slowly cooled to room temperature.

3.2.4. Filling with Pt, Au, and Pd [59, 61, 62]

Platinum and gold are filled inside the single walled carbon nanotubes by mixing a purified powder (5 mg) of SWNTs with approx. 10 mg of AuCl$_4$ · xH$_2$O. The mixture was dried at 373 K for 2 h and then heated to 643 K in vacuum (10^{-3} Torr). For the preparation of **Pt** filled tubes H$_2$PtCl$_6$ · 6H$_2$O was mixed with purified powder of single walled tubes. The mixture was heated to 773 K in vacuum in a quartz ampoule. The **Pd** filling of the tubes is achieved by heating the purified nanotube powder with PdCl$_2$ in a sealed quartz ampoule at 873 K [59, 62].

3.2.5. Filling Single Chain Compound of ZrCl$_4$ in SWNT [96]

ZrCl$_4$ powder was mixed with SWNTs in a 1:1 mass ratio under dry box conditions. The mixture was ground thoroughly and then the sample was sealed in a quartz ampoule and heated at 2 K/min to 350 °C and kept at that temperature for one hour. The samples were furnace cooled to room temperature.

3.3. Fullerene Cages Inside SWNTs

The most interesting supermolecules which can be filled inside SWNTs are **C$_{60}$**, **C$_{70}$**, **C$_{84}$**, etc. Fullerene cages appear to fill the SWNTs almost naturally. The efficiency of fullerene filling can easily be termed highest. It is very likely that the van der Waals force between the fullerene cages and tubes is responsible for this. Because of the attraction force between the wall and cages the fullerene molecule is in an energetically favorable position and remain stable.

3.3.1. Making "Peapod" Structure with C$_{60}$ Inside SWNTs

For making peapod (**C$_{60}$** and **C$_{70}$** inside SWNTs) structures pulse laser deposited SWNTs are used. The sample of purified SWNTs is heated with fullerene powder at 650 °C for two hours inside an evacuated quartz ampoule. It is observed that the fullerenes fill the SWNTs with high density. Filling of the SWNTS with the fullerenes occurs spontaneously when the tubes are heated with the fullerene powder. Arrangement of fullerene cages inside the SWNTs is shown in Figure 9.

3.3.2. Filling of Gd@C$_{82}$ Inside the SWNTs [98–100]

Gd@C$_{82}$ doped with a range of metallic elements such as **Gd**, **La**, **Sm** etc. is being filled inside the SWNTs as shown in Figure 10. For this purpose carbon soot containing
Figure 9. Filling C$_{60}$ inside SWNT "peapod" structure. Reprinted with permission from [94], B. W. Smith et al., *Chem. Phys. Lett.* 315, 31 (1999). © 1999, Elsevier Science.
Figure 10. (a) and (b) are high resolution TEM (HRTEM) images of the isolated and bundles SWNTs containing the Gd@C$_{82}$ fullerenes. Dark spots seen on the fullerene cages correspond to encapsulated Gd atoms that are oriented randomly with respect to tube axis (bar = 5 nm). (c) The computer model of Gd@C$_{82}$ in the nanotube. Gd@C$_{82}$ and other metallofullerenes was generated with gadolinium containing graphite rods in a dc arc deposition apparatus. Subsequent to the understanding that the fullerenes fill the nanotubes spontaneously, the fullerene cage C$_{82}$ was carried out in a multistage high performance liquid chromatography apparatus. The purified SWNT powder was refluxed in HNO$_3$ for 12 hours at 140 °C prior to the experiment. The filling of the **Gd@C$_{82}$** was achieved by heating the mixture of **Gd@C$_{82}$** and SWNT powder at 500 °C for 12 hours. A similar procedure was adopted for filling the inner core of SWNTS with other metallofullerenes such as **La@C$_{82}$SWNT**, **La$_2$@C$_{82}$SWNT**, **Sm@C$_{82}$SWNT** [100], **La$_2$@C$_{80}$SWNT** [101, 102], and **Er$_x$Sc$_{3-x}$N@C$_{80}$SWNT** [102].

3.3.3. Filling Sc$_2$@C$_{84}$ Inside SWNTs [92]

Sc$_2$@C$_{84}$ powder is mixed with SWNT powder and heated at 650 °C in ampoule. This sample procedure results in an extremely high density of fullerene molecule inside SWNTs, confirming our earlier statement that C$_{60}$ is a natural

filler for SWNTs. As shown in Figure 11 the density of **Sc$_2$@C$_{84}$** inside SWNTs is very high. The interatomic distance between atomic positions of Sc inside C$_{84}$ in SWNTs is 0.35 nm.

3.3.4. Chemical Solution Route for Filling CrO$_x$ in SWNTs

Recently Monthioux et al. proposed two solution phase chemistry-based methods for filling SWNTs with **CrO$_x$**. The first method was originally developed to tentatively intercalate SWNT ropes with **CrO$_3$**. As-prepared SWNTs from a Y/Ni-anode electric arc method were soaked into HCl together with CrO$_3$ in large excess. The mixture was left at room conditions (temperature, light) in open air at various times ranging from 3 h to 1 month. Evidence for filling was obtained via TEM after 3 h, with an optimum in yield (~30%) obtained after 2 days of soaking time. From microprobe EDX analysis and nanoprobe electron energy loss spectroscopy, it was concluded that CrO$_x$ fills inside SWNTs, while some Cl (in addition to C, Cr, and O) was found in SWNTs gathered into ropes.

4. STRUCTURE AND PROPERTIES OF THE NANOMATERIALS INSIDE THE TUBE

In spite of the tremendous progress made in fabrication of the single walled as well as multiwalled carbon nanotubes, the properties of the materials filled inside the tubes have not received as much attention. This is probably mainly due to the technical difficulties related to the complete filling of the tubes and the uncertainties about the purity of the tubes. However, there have been some results on the characterization of the filled material. HRTEM and the electron diffraction patterns of nickel filling inside the nanotubes have been studied by Singh et al. [10] in some detail. X-ray diffraction
Figure 11. (a) HRTEM image of various orientations of Sc$_2$@C$_{84}$ molecules inside SWNTs. (b) Simulation models for molecules observed in SWNTs. Reprinted with permission from [92], K. Suenaga et al., *Phys. Rev. Lett.* 90, 055506-01 (2003). © 2003, American Physical Society.

(XRD) studies show that the **Ni** nanorods inside the multi-walled tubes are under tensile stress and all XRD peaks are downshifted toward lower 2θ values as compared to the bulk **Ni**. The compression of the lattice inside the nanotubes has also been studied by computer simulation and the results are interesting [89]. It is also observed by Singh et al. that the **Ni** nanorods inside the tubes are highly cylindrically symmetric. The cylindrical cap of the **Ni** nanorod may have an entirely different crystalline structure than otherwise obtained. The results of encapsulation of **La$_2$C$_3$** inside the nanotubes, on the other hand, show that the nanotube end cap follows the symmetry of the carbide itself, while Mn$_3$C encapsulation inside the nanotubes follows the cylindrical symmetry of the nanotubes. It is also reported that the Ni$_3$C phase is mostly present at the interface of the filling and the carbon nanotube walls [11].

For the multiwalled carbon tubes filled with Fe there are reports by Grobert et al. [114] that the coercivity of the filling inside the tubes is much higher than the bulk iron and even higher than the **Ni** and **Co** [114]. Similarly γ Fe filled tubes show interesting hysteresis shifts in magnetization studies [115]. A large body of work is available by Loiseau et al. in studying the scanning tunneling microscopy (STM) of **Cr** filled nanotubes. They suggest that there is a strong interaction between the **Cr** filling and carbon nanotubes. Interesting features are observed in STM studies as a function of biasing voltage. Theoretical estimates of the Raman signal enhancement by **Ag** filling of the carbon nanotubes are also reported.

The observation of the quantum effects due to the confinement of the materials inside the tube has not received sufficient attention. This is mainly because the filling of the SWNTs where the confinement effects are most likely to be present has been achieved only in a limited fashion. To see the confinement effects one has to achieve efficient filling of material inside the single walled tubes. At least complete filling of the material inside the tube length of 100 nm and a uniform high density of such filled tubes must be achieved to effectively see the influence of confinement effects. The size of the tubes has to match the parameters corresponding to the confinement one is envisaging. For instance the diameter of the tubes must be of the order of the electron mean path if the confinement effect is to be seen in resistivity of the filled material. Similarly, to observe the confinement effects on the bandgap of the materials one has to use the size of the tubes of the order of a few lattice constants. For silicon the diameter of the tube required may be 1.5 nm. Interesting magnetic confinement effects might be possible to observe if the number of atoms confined in the tube is really small (50–100). This has not been achieved so far and controlled filling of the tubes is still a bit distant.

On the other hand, very interesting structural properties and characteristics of the filled tubes are already evident. For instance, structural modifications of filled material are reported for **ZrCl$_4$** filled tubes. It is observed that under the electron beam of 300 kV of a transmission electron microscope the continuous filling converts to clusters of **ZrCl$_4$**. Clusters as small 1 nm can be easily formed inside the nanotube. In addition it is observed that the walls of the nanotubes are not affected by the interaction with the beam. The image contrast reveals clear images of Zr atomic

sites and it is speculated that the Cl content of the clusters decreases continuously with the beam interaction as a function of time. Similar observations are also reported for the Bi filled inside the SWNTs. In that case, however, the electron irradiation of the tubes results in Bi loss through the defects in the walls. The "peapod" and "endofullerenes" also show interesting properties as function of electron irradiation. It is reported that these materials have a chain structure inside the tubes and can move or diffuse in the tube freely. This remarkable behavior was reported for **C$_{60}$** molecules when encapsulated in 1.4-nm-diameter SWNTs during *in-situ* electron-beam irradiation within an electron microscope, including dimerization [94, 95, 116], coalescence [95–97], and diffusion [94].

A truly one-dimensional lattice of **Gd@C$_{82}$** is observed inside SWNT using reflection high energy electron diffraction analysis [98]. **C$_{82}$** molecules with entrapped Gd atoms are located in a one-dimensional arrangement with interatomic distances 0.105 ± 0.05 nm. It would be of huge interest to perform magnetic measurements on such one-dimensional arrangements of atomic moments.

5. SUMMARY OF FILLING OF TUBES USING VARIOUS TECHNIQUES

Table 4. Multiwalled carbon nanotube.

Elements/material	Technique	Ref.
MoO$_3$	heating	[117]
Ni, NiS	arc discharge	[77, 118, 157]
Cr, CrS	arc discharge	[77, 157]

GLOSSARY

C_{60} A structure consisting of 60 carbon atoms connected in a network of closed hexagons and pentagons.

Capillary A tube with very fine diameter.

Carbonaceous impurities The impurities such as amorphous carbon particles, graphite particles and other carbon based particle.

Catalyst chemical vapor deposition (CCVD) In which the gas precursors are decomposed over a catalyst.

Chemical vapor deposition (CVD) process In this process the environment of gas precursors is used for the deposition of the films.

Confinement The phenomena of restricting or limiting the motion or otherwise of the atoms or molecules in an enclosure.

Electron energy loss spectroscopy A technique based on electron energy loss very sensitive for characterizing the graphite structure.

High-resolution transmission electron microscopy (HRTEM) Used for deciphering the structure of the materials. The technique is extremely useful for studying the nanomaterials.

Nanodiffraction When electron diffraction pattern is studied from a nanometer size area of a sample it is termed as nanodiffraction.

Peapods The structure containing fullerenes inside the carbon nanotubes is called peapods.

Pyrolysis A high temperature process in which the gas precursors are decomposed in a high temperature zone.

Fivefold Twinned Nanoparticles

H. Hofmeister

Max Planck Institute of Microstructure Physics, Halle, Germany

CONTENTS

1. INTRODUCTION

Twinning is widespread in crystalline materials of various origin and nature. Basic concepts and definitions of twinning are treated in many textbooks and review papers [1–3]. A description of the crystallographic fundamentals of twinning can be found in the *International Tables for Crystallography*, Volume D: "Physical Properties of Crystals" [4]. Twins may form as a result of erroneously attaching atoms or molecules to a growing crystal such that two crystals appear to be growing out of or into each other. Character and rule of twinning can be understood by considering the sequence of atomic layers added to a crystal during growth. Stacking of close-packed planes in face-centered cubic crystals is possible in three different positions denoted **A**, **B**, and **C** leading to a regular growth sequence **ABCABCABCABCA**. If, for example, the central **A** layer of this sequence is followed by a layer of misplaced atoms assuming the wrong position **C**, upon which a regular stacking appears again, then the following sequence will form: **ABCABCACBACBA**. In this way the crystal lattice is mirrored at the central layer **A**, which is easier to see if the central letter **A** is replaced by a vertical line | representing a mirror or twin plane: **ABCABC|CBACBA**. There are two general types of twin style: contact and penetration [5, 6]. The one considered here is contact twins that have a composition plane, the twin plane, that forms a boundary between the twinned subunits.

Twinning often has a serious effect on the outward shape and symmetry of a crystal, in particular in the case of repeated twinning. Two types of repeated twinning are known: lamellar and cyclic. Lamellar twinning forms from parallel contact twins repeating continuously, one after another. Cyclic twinning requires nonparallel coplanar composition planes. If these twin planes enclose an angle being an integer part of 360°, then a complete circle can be formed by cyclic twinning. Some classic minerals like cassiterite (SnO_2), wurtzite (ZnS), and rutile (TiO_2) form cyclic twins called "trilling," "fourling," "sixling," or "eightling" quite according to their twin angles of 120°, 90°, 60°, or 45°, respectively. Cyclic twinning is also found in minerals of the spinel ($MgAl_2O_4$) group whose specific rule of twinning bears its name, the spinel twin law. Here a twin plane is parallel to one of the octahedral habit planes enclosing an angle of 70.53°, which is close to $2\pi/5$. Repeated cyclic twinning according to this twin law does not form a complete circle, but leaves a small gap. Nevertheless, it enables the formation of "fivelings" of a number of crystals.

Actually, repeated twinning, also called polysynthetic twinning, or multiple twinning, is rather common in natural minerals and crystalline materials. There are also known examples of twin compounds composed of cyclicly arranged twin pairs [7]. However, it is the type of fivefold twinning on alternate coplanar twin planes in small particles, creating "fivelings" of unique morphology, for which the term "multiply twinned particles" (usually abbreviated as MTPs) was applied. The term MTP will herewith be used for such particles, otherwise, for example, for fivefold twinning in thin films, the term "fivefold twinned structures" is used. The unique morphology of MTPs and the unusual symmetry of the arrangement of building units are essential structural features, mostly at dimensions of a few nanometers, but fairly often also up to micrometer or even millimeter dimensions.

Fivefold twinning in thin films and nanoparticles of nanometer dimensions is in itself a whole class of materials, the origin of widespread structures resulting from a great variety of substances and fabrication processes involved. These are introduced in this chapter together with the issues of synthesis, formation mechanisms, and stability and lattice defects. Various illustrative examples are aimed at emphasizing the importance of this phenomenon in the area of nanostructured materials. It always has attracted the attention not only of crystal growth and crystallography research,

but also of cluster physics, physical chemistry, surface science, thin film growth, and materials research. The occurrence of quintuples of twins and local fivefold structures includes also quite different materials systems ranging from biological materials to minerals, such as proteins [8], polyoxometalates [9], viruses [10], surfactant bilayers [11], natural diamond [12], and self-assembled metal nanoparticle superlattices [13]. Within the minerals, even particular diamond species of extraterrestrial origin, which were contained in meteorites, are found [14]. Appropriate examples will be mentioned when discussing various aspects of fivefold twinning. This chapter is accompanied by an almost complete list of references that makes available results and experiences of previous work in a greater context.

1.1. Crystallographic Characteristics

The characteristics of materials that favor MTP formation are: (i) face-centered cubic (fcc) or diamond cubic (dc) crystals, (ii) low twin boundary energy, and (iii) a surface energy anisotropy with, for example, $\sigma\{111\} < \sigma\{100\}$, where $\{111\}$ and $\{100\}$ are the indices of surfaces of lowest energy for cubic crystals. However, any other crystal allowing repeated cyclic twinning with twin angles of about $2\pi/5$ would fit as well, if the twin boundary energy is not exceedingly large. The structural peculiarities of such particles comprise the following characteristics: (i) They are composed of equisized subunits of tetrahedral shape, (ii) the subunits join together on adjacent bounding faces (twin planes), (iii) the subunits enclose an angle of $\sim 2\pi/5$, and (iv) the involved tetrahedra share common axes of fivefold symmetry. Shape and composition of particles formed according to the above construction scheme are (i) the decahedron (pentagonal bipyramid), consisting of 5 tetrahedra with 1 fivefold axis, bounded by 10 triangular faces, and (ii) the icosahedron, consisting of 20 tetrahedra that share 6 fivefold axes and one common point at the center, bounded by 20 triangular faces. Composition and shape of the decahedron (point group symmetry D_{5h}) and the icosahedron (point group symmetry I_h) are schematically shown in Figure 1. As tetrahedral subunits of regular fcc or dc lattice, respectively, cannot form a complete space-filling structure, there remains an angular misfit (resulting in a gap of 7.35° for the decahedron), which is not considered in the drawings. Strictly speaking, the fivefold axes in such materials are only of pseudo-fivefold symmetry, unless there is some rearrangement of the lattice.
For single crystalline particles of most of the materials (cubic crystals) considered here, the common growth form is that of a cuboctahedron that is bounded by triangular octahedron faces, or $\{111\}$, and square cube faces, or $\{100\}$. This semiregular or Archimedian solid is drawn as a hard sphere model in Figure 2. Different from that, MTPs such as the icosahedron (Platonic solid), also drawn in Figure 2, are bounded by triangular faces of equal type, or $\{111\}$, only. This octahedron face is energetically favored for fcc and dc crystals because of the surface energy anisotropy of most of these materials, according to the above mentioned condition (iii) of MTP formation. That is how MTPs minimize their surface energy by approaching a spherical shape, which is most effectively achieved with the icosahedron.

1.2. Modes of Appearance

The mode of appearance of fivefold twinned particles depends on both their orientation with respect to a planar substrate (or a matrix) and the evolution of their surface morphology as influenced by the growth conditions. With respect to a planar substrate, there are four possible high symmetry orientations for both types of MTPs. Decahedra may be situated (i) with their fivefold axis perpendicular to the substrate plane, as in "fivefold" orientation or (011); (ii) with the fivefold axis parallel to the substrate plane, as in "parallel" or (001); (iii) with one tetrahedral bounding face resting on the substrate, as in "face" orientation or (111); and (iv) with the common edge of two tetrahedra resting on the substrate, as in "edge" orientation or (112). As can be seen from Figure 3, this gives as projection on the substrate (or imaging) plane a regular pentagon, a rhombic, a shortened pentagon, or a slightly less shortened pentagon, respectively. Icosahedra may be situated (i) with the common edge of two tetrahedra resting on the substrate and two fivefold axes parallel to it, as in "edge" orientation or (112); (ii) with one corner resting on the substrate and one fivefold axis parallel to it, as in "parallel" orientation or (001); (iii) with one fivefold axis perpendicular to the substrate, as in "fivefold" orientation, or (011); and (iv) with one tetrahedral bounding face resting on the substrate, as in "face" orientation or (111). Figure 4 shows the corresponding projections on the imaging plane giving a hexagon shortened along a diagonal, a hexagon elongated along a diagonal, a regular decagon, or a regular hexagon, respectively. The assignment of orientations in terms of crystal axes indices (in braces)

Figure 3. Orientation of decahedra on a substrate: "fivefold" (011), "parallel" (001), "face" (111), and "edge" (112).

concerns one, two, or five tetrahedra situated in the corresponding orientation.

The growth conditions are usually described by a growth parameter α that relates the rates of growth along different crystal directions. For fcc or dc materials, it is given by $\alpha = \sqrt{3v_{100}/v_{111}}$, where v_{100} is the growth velocity of cube faces and v_{111} is that of octahedron faces. The effect of α on the crystal morphology is a continuous variation starting, for example, with a perfect cube shape for $\alpha = 1$, via the cuboctahedron shape shown in Figure 2 for $\alpha = 1.5$, which corresponds to thermal equilibrium growth, to the octahedron shape for $\alpha = 3$. Under thermal equilibrium, the growth morphology may also be described by a parameter β relating the surface free energies ε_{100} and ε_{111} of the lowest energy surfaces. However, crystal growth usually is far from thermal equilibrium; thus the shape evolution is not characterized by minimizing the surface energy, but rather the growth rate of each face as determined by the kinetics. For MTPs this may lead to deviations from the ideal shapes introduced above, which range, for example, for the decahedron from a star-shaped (A) to a strongly faceted (B) and a prism-shaped specimen (C) corresponding to a variation of growth parameters from 3 to 2 and 1.5, respectively, as shown in Figure 5. Shapes B and C are named
Figure 5. Deviations from the ideal shape of decahedra: (A) star-shaped, (B) faceted (Marks), and (C) prism-shaped (Ino).

"Marks decahedron" [15, 16] and "Ino decahedron" [17] by those who first introduced the corresponding models. An example of the formation of re-entrant edges, where twin boundaries emerge to the surface, as well as faceted dimples at the emergence points of fivefold axes, represents the Cu decahedron in Figure 6. Accordingly, re-entrant edges, faceted dimples, and pyramidal capping of triangular faces may occur at icosahedra [18].

1.3. Features of Fivefold Twinning

1.3.1. Natural Origin

Fivefold twinning, being a widespread habit of nanoparticles and nanostructured materials, actually is not only found in synthetic materials, but also in structures with a natural origin. As a most striking example, one may mention the polyhedral forms of certain viruses and their pentagonal aggregation. This was predicted in 1956 by Crick and Watson [19] and was confirmed in 1958 and later, mainly by electron microscopy means [10, 20–23]. Another example from biology is the hollow icosahedron configuration *in vivo* of
Figure 4. Orientation of icosahedra on a substrate: "edge" (112), "parallel" (001), "fivefold" (011), and "face" (111).
Figure 6. Early findings of fivefold twinning (fivelings) of natural occurrence.

certain protein supermolecules [8]. In the course of studying the presolar history of matter, fivefold twinned diamonds of extraterrestrial origin have been found in meteorites [14, 24]. By far, the most numerous and earliest examples of natural occurrence of fivefold twinning are known from the field of mineralogy. In former centuries, an essential part of the contemporary materials science was developed by mineralogists, mining engineers, and metallurgists. Thus it is understandable that in the first half of the 19th century the natural formation of "fivelings" in some minerals was known and therefore reported subsequently in textbooks and shape catalogues [25–29].

It was as early as 1831 that Rose [30] reported the observation of a strongly faceted decahedron of gold, the schematic drawing of which, shown in Figure 6, is an astonishing precursor of the Marks decahedron given in Figure 5B. Next to gold, fivefold twinning was also frequently observed in diamond of natural origin. This was reported for the first time by von Waltershausen [31]. Besides slightly faceting at the twin boundary tips, the original drawing, shown in Figure 6, contains a gap between subunits o^{IV} and o^{V}, corresponding to a defect caused by the lack in space filling with five tetrahedra. The first finding of a copper fiveling was reported 1882 by von Lasaulx [32]. This multiply twinned crystallite, also shown in Figure 6, is characterized by a nearly star-like shape and pentagonal dimples at the emergence of the fivefold axis. The indication of a $7°20'$ gap between subunits O_1 and O_5 is based on theoretical considerations rather than on experimental observation. The MTPs of natural origin usually exhibit sizes around 1 to 2 mm. Further findings of natural fivefold twinned crystallites including, besides the already mentioned Au, diamond, and Cu, also Ag, sphalerite (ZnS), marcasite (FeS_2), magnetite (Fe_3O_4), and spinel ($MgAl_2O_4$), are presented together with the year of first mention of the corresponding mineral and related references in Table 1. One particular observation was reported by von Rath in 1877 [33] concerning an approximately 2 mm long pentagonal needle of gold whose shape corresponds to an elongated form of the prism-shaped decahedron in Figure 5C. This way, all essential shape variations of decahedra as introduced in Figure 5 were known by the end of the 19th century. The formation of fivefold twin junctions by cyclic twinning in naturally occurring substances, as confirmed by continued observations in the first half of the 20th century, was supported from a theoretical crystallography point of view by Herrmann [34]

Table 1. Natural occurrence of fivefold twinned structures.

Matter	(First mention) Refs.
Au	(1831) [26, 28, 30, 33, 397, 398, 423]
Ag	(1944) [29]
Cu	(1882) [29, 32]
C (dc)	(1863) [7, 12, 14, 24, 25, 27, 29, 31, 424, 425]
ZnS	(1882) [7, 27, 32]
FeS_2	(1977) [426]
$MgAl_2O_4$	(1877) [427]
Fe_3O_4	(1984) [428]
virus	(1958) [10, 20–23]
protein	(1997) [8]

who introduced the noncrystallographic point-groups D_{5h} of the decahedron and I_h of the icosahedron. A description of simple forms of these noncrystallographic classes was given by Niggli [35].

1.3.2. Synthetic Origin

The investigation of fivefold twinned structures in synthetic nanoparticles and thin films started in the second half of the 20th century by Segall [36] with the observation of pentagonal grains of pyramidal shape in cold rolled Cu upon thermal etching in 1957. This was followed in 1959 by the observation of pentagonal whiskers (i.e., rod-like shape) of Ni, Fe, and Pt grown from the vapor phase on W substrates by Melmed and Hayward [37] who also explained the peculiar shape by assuming five twinned fcc subunits with only slight lattice distortions. Mackay [38] presented in 1962 a hard sphere model of icosahedra, described them as being made up of 20 tetrahedra, discussed their characteristics, calculated the density of closed shell icosahedra, and demonstrated a mechanism of transition to the fcc structure. In the same year Schlötterer [39–41] reported on fivefold twinned pyramidal grains of Ni grown by electrodeposition, and one year later Wentorf [42] described fivefold twinned crystallites of synthetic diamond with indications of a small-angle grain boundary accommodating the angular misfit. In 1964 Faust and John [43] reported on Si and Ge fivefold twinned grains grown from the melt. Skillman and Berry [44] found fivefold twinned particles of AgBr grown from solution. Ogburn et al. [45, 46] communicated the observation of pentagonal dendrites of Cu grown from the vapor phase. Schwoebel [47, 48] reported pentagonal pyramids of Au grown in fivefold orientation on Au(110) and Au(100) surfaces, and Gedwill et al. [49] obtained fivefold twinned grains of pyramidal shape in the deposition of Co by hydrogen reduction of $CoBr_2$, respectively. Similarly, in 1965 De Blois [50, 51] found the formation of pentagonal shaped whiskers of Ni by hydrogen reduction of $NiBr_2$. In the same year Bagley [52–54] proposed a model of pentagonal decahedra made up of five twinned tetrahedra whose orthorhombic lattice only slightly deviates from the fcc crystal lattice. In 1966 Downs and Braun [55] found fivefold twinned grains in the plating of Ni by thermal decomposition of nickel carbonyl.

The discovery of decahedral and icosahedral particles of Au and Ag formed in the early stage of thin film growth on alkali halide and mica substrates as well as by evaporation in inert-gas atmosphere in 1966 [56–64] is connected with extended availability and improved capabilities of electron microscopes at this time, which favored focusing on fivefold twinned structures of nanometer dimensions. This way, already in the first ten years of exploration, broad experimental evidence of the phenomenon, correct nomenclature, clear models, and reasonable insight in formation mechanisms was achieved. Since then a continuous and even increasing interest in fivefold twinned structures in nanoparticles and thin films produced a more than linear increase (from 1 in 1957 to 25 in 2001) of publications per year and was more and more devoted to technologically important materials like diamond, semiconductors, and Ni. The fivefold twin structure could be made visible, in particular, by

HREM as it is shown in Figure 7 by the example of a deca-hedron of Rh [65]. The HREM image (left) of the MTP situated in fivefold orientation (twin boundaries marked by arrow heads), that means with the fivefold twin junction perpendicular to the image plane, together with the corresponding diffractogram (right) give a clear representation of its symmetry as well as spacings (e.g., of {111} and {200} planes) and angular relations of the lattice of the tetrahedral subunits involved. Utilization of dedicated experimental techniques like cluster source equipped molecular beam devices for synthesis [66] and real-time video recording equipped electron microscopes for characterization [67–71] enabled elucidating new models and mechanisms of MTP formation as well as uncovering a rich variety of new materials having such structures. The appeal of fivefold symmetry was tremendously encouraged with the disclosure of icosahedral quasicrystals and related phases [72–75] and with the invention of the quasilattice concept to describe these structures basing on local icosahedral packing of atoms contained in tetrahedrally close-packed and related phases of intermetallic compounds [76–79]. Between both fields there are certain relations from a structural point of view, such as via decagonal twinned crystalline approximant phases [79–82].

2. MATERIALS SYNTHESIS AND FORMATION MECHANISMS

2.1. Materials Overview

Fivefold twinned structures may be found in any crystalline material that allows twinning on alternate coplanar twin planes enclosing an angle of about $2\pi/5$. Favorite materials throughout the periodic table of elements are the transition metals Fe, Co, Ni, Cu, Ru, Rh, Pd, Ag, Ir, Pt, Au; the lanthanide's Sm and Yb; as well as the group II element Mg, group III elements Al and In, and group IV element Pb, that have fcc crystal lattice, at least for the modification present in multiply twinned particles. Additionally, the group IV elements C, Si, and Ge with dc crystal lattice contribute to the MTPs. Further, multiply twinned structures are known from a number of alloys like Au-(Fe, Co, Ni, Cu, Pd), Al-(Li, Cr, Mn, Fe, Cu, Zr), Ni-(Zr, Ti), Pt-(Fe, Rh), and Si-Ge. There exists also a considerable list of binary and ternary compounds from which MTPs have been reported, including AgBr; the nitrides and carbides BN, TiN, TiCN and
BC, Cr_2C_{2-x}, SiC; the oxides Fe_2O_3, Fe_3O_4, SnO_2, $BaTiO_3$, and B_6O; and further the compound semiconductors GaP, $CuInSe_2$, CdSe, and CdTe. The list of materials, to which even the molecular crystals fullerite C(60) and C(76) must be added, as well as supramolecular polyoxometalates and surfactants, is still increasing.

A summary of these materials together with their main characteristics and the routes of synthesis applied is given in Table 2, where elements, alloys, compounds, and composite materials with fivefold twinned structures are listed. For each entry, the table contains the year of first mention and a number of representative references. This summary must be completed by composite materials consisting of MTPs embedded in a matrix like Ge, Si, or Si-Ge precipitates in Al alloys [83–88]; Cu precipitates in Ni-Zn-Cu alloy [89]; and Au, Ag, or Co precipitates in polymer or glass matrix [90–96]. As an example of matrix-embedded MTPs, Figure 8 shows a decahedral particle of Ag grown by precipitation in glass [97]. The HREM image (left) of the particle (twin boundaries marked by short lines) clearly shows its nearly spherical shape determined by the metal-matrix interface energy. The accompanying diffractogram (right) reveals symmetry, lattice plane spacings, and angular relations according to the approximately fivefold orientation. Another class of materials should be finally mentioned, namely colloidal crystals or self-assembled superlattices consisting of two- or three-dimensional arrangements of metal nanoparticles that form fivefold twinned structures quite according to those previously described [13].

2.2. Routes of Synthesis

2.2.1. Vapor Phase Techniques

The synthesis of fivefold twinned nanoparticles and thin films may be proceeded by a large number of various processes and specific techniques. Generally, they differ by the state of the material applied in the synthesis. We distinguish synthesis (i) from the vapor phase, (ii) from the liquid phase, and (iii) from the solid phase. Vapor phase synthesis (i) includes (a) heterogeneous nucleation and growth of particles and thin films by various methods of either physical or chemical vapor deposition on substrates, and (b) homogeneous nucleation and growth of particles by aggregation within an inert-gas atmosphere. Most of the early work on metal MTPs has been done according to the process scheme given in (a) by thermal evaporation of the metal within an evacuated chamber and condensation of the metal vapor on appropriate substrates [57, 60, 98–111]. Physical vapor deposition was also applied in the formation of multiply twinned nanoparticles and thin films of Ge [112–121], SnO_2 [122], Fe_2O_3 [123], and C(60) or C(76) [124–128]. Chemical vapor deposition has been used for formation of multiply twinned nanoparticles and thin films, for example, of diamond [18, 129–132] (particles) and [133–146] (thin films), or Si and Si-Ge [147–149], TiN [150–152], TiCN [153, 154], SiC [152], GaP [155], and BN [74, 132] from precursor molecules, the decomposition or reaction of which provides the species deposited. The inert-gas aggregation technique (b) was successful in producing MTPs of most of the metals [64, 101, 156–167] and Si and Ge [168, 169], as well as alloys of

Table 2. Materials with fivefold twinned structures: (A) elements, (B) alloys, (C) compounds, and (D) composites.

Materials	Synthesis	Characteristics	Refs.
A. Elements			
Mg (1981)	inert-gas aggregation, cluster beam expansion	decahedra, closed shell icosahedra	[160, 242]
Fe (1959)	PVD, inert-gas aggregation	decahedral whiskers, decahedra	[37, 101, 158, 159, 293]
Co (1964)	solid-phase reduction, inert-gas aggregation	decahedra, icosahedra	[49, 64, 293, 430]
Ni (1959)	PVD, electrodeposition, inert-gas aggregation, colloidal synthesis	hollow whiskers, icosahedra, decahedra, thin films, rod-shaped decahedra	[37, 39, 157, 159, 165, 190, 200, 202, 204, 206, 208, 431]
Cu (1957)	electrodeposition, inert-gas aggregation, colloidal synthesis, PVD, e-beam	thin films, rod-shaped decahedra, icosahedra	[36, 39, 45, 98, 100, 157, 159, 178, 193, 231, 363, 388]
Ru (1988)	colloidal synthesis	structural fluctuations	[71]
Rh (1981)	solid phase reduction, PVD, colloidal synthesis, electrodeposition	decahedra, icosahedra	[65, 108, 226, 371, 374, 410, 435, 436]
Pd (1966)	PVD, inert-gas aggregation, electrodeposition, colloidal synthesis	decahedra, icosahedra, double icosahedra	[56, 63, 64, 99, 101, 107, 159, 161, 174, 198, 249, 438, 439]
Ag (1966)	PVD, inert-gas aggregation, electrodeposition, colloidal synthesis, e-beam	decahedra, icosahedra, rod-shaped decahedra	[60, 63, 98, 105, 157–159, 166, 174, 205, 207, 211, 217, 230, 255, 258, 291, 292, 349, 354, 440, 441]
Ir (1997)	electrodeposition	decahedra, icosahedra, shape variations	[210, 216]
Pt (1959)	PVD, inert-gas aggregation, colloidal synthesis, electrodeposition	decahedral whiskers, shape variations, decahedra, icosahedra	[37, 104, 161, 191, 210, 376, 411, 444]
Au (1964)	PVD, inert-gas aggregation, colloidal synthesis, electrodeposition, solid-phase reduction	decahedra, icosahedra, rod-shaped decahedra, double icosahedra; self-assembled nanoparticles superlattice	[13, 40, 47, 57–59, 61, 62, 64, 105, 106, 157–159, 161, 173, 182, 189, 210, 212, 237, 239, 240, 254, 259, 324–327, 335, 365, 366a, 378, 382, 387, 400, 407, 411, 447–450]
Sm (1992)	inert-gas aggregation	decahedra	[66]
Yb (1993)	inert-gas aggregation	decahedra, icosahedra	[162, 452]
Al (1997)	e-beam irradiation	decahedra, icosahedra	[232]
In (1999)	physical vapor deposition	decahedra, tetragonal lattice sub-units	[109, 111, 340]
C (dc) (1963)	high-pressure melt synthesis, CVD, dynamic-shock synthesis	decahedra, misfit faults, icosahedra, thin films, star-shaped & rod-shaped decahedra	[18, 42, 129–132, 138, 139, 141–143, 145, 350–352, 456, 457]
Si (1964)	melt growth, matrix precipitation, CVD, PVD, inert-gas aggregation	decahedra, misfit faults, thin films, star-shaped decahedra	[43, 147, 149, 168, 169, 185, 186, 234, 266, 270]
Ge (1964)	melt growth, matrix precipitation, PVD, inert-gas aggregation, solid phase crystallization, ion implantation	star-shaped & rod-shaped decahedra, thin films, decahedra	[43, 96, 112–116, 120]
Pb (2000)	inert-gas aggregation, PVD	decahedra, tetragonal lattice sub-units	[110, 164]
B. Alloys			
Au-Fe (1999)	PVD, electrodeposition	decahedra, icosahedra	[213, 385]
Au-Co (2002)	electrodeposition	decahedra, icosahedra	[213]
Au-Ni (2002)	electrodeposition	decahedra, icosahedra	[213]
Au-Cu* (1997)	inert-gas aggregation, electrodeposition	decahedra, icosahedra, rod-shaped decahedra	[170, 210, 215, 432]
Au-Pd (1990)	colloidal synthesis	decahedra of rounded shape	[428]
Fe-Pt (2002)	colloidal synthesis, inert-gas aggregation	decahedra, icosahedra, ordered phase transition	[171, 434]

Au-Cu and Fe-Pt [170, 171]. The process scheme given in (b) mainly enables particulate mass production of the corresponding material [159, 169, 172–174] and investigation of unsupported particles [164, 175–178]. The vapor phase route also includes modern techniques of materials synthesis such as pulsed laser deposition [179–181] and sputtering [95, 182, 183]. A typical example of growth from the vapor phase is given in Figure 9. The rhombic profile of the decahedral Rh particle [108] shown in the HREM image (left) is due to the (001) orientation of the base tetrahedral subunit relative to the electron beam. The accompanying diffractogram exhibits spots originating from {111}, {200}, and {220} lattice plane fringes of the (001) oriented base and two (112) oriented top tetrahedra marked by squares and circles, respectively. Additional spots marked by open arrows result from Moiré type contrast features in the particle center due to superposition of subunits of both orientations [166].

2.2.2. Liquid Phase Techniques

Liquid phase synthesis (ii) includes (a) growth from the melt and (b) growth from solution via precipitation by chemical means (b1) or by electrodeposition (b2). High-pressure melt growth was used for diamond [42] and B_6O [184] synthesis. Precipitation from alloy melt was utilized for the growth of Si and Ge MTPs [43, 185, 186]. Most of the quasicrystalline phases and their approximants have been produced by rapid cooling of Al-Mn and similar alloy melts [74, 187, 188]. The solution route (b1), or colloidal synthesis, has been frequently used for wet chemical formation of multiply twinned AgBr [44] and metal particles of Au, Ag, Cu, Pt, Pd, Ni, and
Figure 9. Decahedral particle of Rh in parallel orientation grown by vapor deposition on NaCl.

Ru, as well as Pt- alloys [91, 189–198]. The solution route (b2), or electrodeposition, is widely utilized for fabricating protective coatings, mostly of Ni, whose appearance depends on grain size and texture, which may be controlled by the electrode potential. Fivefold twinned grains are the main constituents of films with ⟨110⟩ texture. Multiply twinned structures have been reported for Au, Ag, Cu, Pt, Pd, Ni, Ir, Rh, and Cu- alloys deposited as films [40, 199–204] or particles [45, 205–213]. As it was mainly revealed by the work of Da-ling Lu [209, 210, 214–216], the crystal habit of fcc metal particles is controlled by the electrode potential in solution, that means icosahedra and decahedra are formed at lower potential, whereas at higher potential less or no MTPs occur. Typical examples of MTPs grown from solution can be found in Figure 18 where HREM image contrast features of icosahedral Ag particles formed by hydrolysis of a mixed solution of tetraethoxy orthosilicate and silver nitrate in ethanol plus water [217] are presented.

2.2.3. Solid Phase Techniques

Solid phase synthesis (iii) includes several subroutes: (a) precipitation from solid solutions in crystalline or glassy hosts, (b) solid phase crystallization from the amorphous phase, (c) solid phase reduction by reactive gases like H_2 or CO of highly disperse metal compounds, and (d) irradiation-assisted processing by electron beam or ion beam impact applied to induce particle formation in a matrix or on a substrate. Precipitation of fivefold twinned nanoparticles in crystalline matrix was reported for Au, Ag, Cu, Ni, Al-Li, Si, Ge, and Si-Ge [83–89, 181, 182, 186, 218, 219] where shape deviations, such as rod-like particle shapes, depending on orientation relations between precipitate and matrix as well as on the respective interface energy, were frequently observed. Precipitation of MTPs in glassy hosts was observed for Ag in soda lime glass, doped by ion exchange, upon thermal processing [90, 94, 220–222] and for Si in SiO_x by thermal decomposition of SiO [223]. Ag decahedra formed in glass matrix keep their structural peculiarities even when stretching the glass at elevated temperatures results in elongation of the previously spherical particles [220]. The amorphous-to-crystalline phase transition according to process scheme (b) has been studied intensively for thin films of Ge [113–117, 119, 224] and powder particles of Si [147, 148], which exhibit a distinct tendency to fivefold twinned structure formation. Solid phase reduction, or process scheme (c), has been used for decades to fabricate highly dispersed, supported metal particles, such as for application in heterogeneous catalysis. MTPs of Au, Ag, Cu, Rh, Co, and Ni are reported for this subroute [49, 50, 55, 217, 225–227] to occur on appropriate carriers. In recent years, a number of techniques for irradiation-assisted processing was developed to produce new nanoparticles and nanoparticulate composites. These techniques include electron beam irradiation to induce particle formation by reduction and aggregation of precursors where MTPs have been observed for BN, Ag, Cu, Al, Si, and Ge [95, 96, 228–234], as well as ion beam irradiation to introduce, that means to implant, dopants like Ag or Ge in a matrix so as to enable particle formation. MTPs originating from the latter technique were found for Ag and Ge in glassy hosts [94–96].

Finally, as a further route to fivefold twinned nanostructures, one should mention here the self-assembly of ligand-stabilized metal nanoparticles into superlattices of two or even three dimensions [13] that exhibit fivefold twin junctions similar to the pentagonal aggregations of virus particles [22]. When using a micelle route to preferentially create multiply twinned metal particles [235, 236], one could compose in this way a fivefold twinned superlattice of MTPs.

2.3. Formation Mechanisms

2.3.1. Nucleation-Based Formation

The formation of MTPs and fivefold twinned structures is an important issue, since understanding of the relevant mechanisms may help to control conditions for preferred formation or prevention of such structures. The great variety of materials and processes involved cannot be attributed to only one mechanism of formation. In general, we distinguish (i) nucleation-based and (ii) growth-mediated formation of fivefold twins. The nucleation (i) or noncrystallographic packing of atoms, is complemented by layer-by-layer growth in the course of which the noncrystallographic arrangements transform to quintuples of twins. The growth-mediated formation (ii) may proceed by cyclic twinning operations due to (a) misstacking of atoms (growth twinning) or (b) mismatch of lattices (deformation twinning) during growth.

MTPs are observed in the nucleation stage (a) of thin film growth on substrates via physical [237–240] and chemical vapor deposition [18, 129, 130], as well as in inert-gas aggregation [159, 161], melt growth [241], solution growth [189], electrodeposition [201], and solid phase crystallization [116]. Sometimes the noncrystallographic nature of the nuclei formed is emphasized by the name "paracrystalline nuclei" [201]. The preferred formation of closed shell structures with icosahedral arrangement is confirmed by the observation of magic numbers in the mass spectra of transition metal clusters [242–248]. Fcc metal clusters obey the building plan of Mackay icosahedra [38] as it has been shown for five-shell Pd clusters of 561 atoms by direct imaging [249]. The first steps of evolution for such clusters, starting from a 1 shell nucleus, by shape maintaining layer-by-layer growth, contain 13, 55, 147, 309, 561, ... atoms as schematically drawn in Figure 10. Likewise, pentagonal decahedra may evolve from a nucleus of decahedral shape whose initial growth sequence contains 7, 23, 54, 105, 181, ... atoms. During growth the noncrystallographic packing of atoms is transformed to a fivefold twinned arrangement of translationally ordered subunits whose small size enables compensation of the angular misfit [92].
The nucleation of fivefold symmetry in dc materials proceeds, according to their bonding characteristics, via cage rather than closed shell structures having pentagonal dodecahedron (20 atoms) and truncated pentagonal bipyramid (15 atoms) shapes, which are analogues of icosahedron and decahedron, respectively. The first steps of a layer-like growth sequence of decahedral shape, containing 15, 60, 140, 265, 490, ... atoms are illustrated in Figure 11. With the dodecahedron nucleus, a growth sequence of 20, 100, 292, 568, 994, ... is obtained when its 12 pentagonal faces are decorated by truncated pentagonal bipyramids. Always three of these attached cages of the first layer share one atom, at which formation of a tetrahedral subunit of a dc lattice may start in the course of further layer-like growth [250, 251]. In the above cluster models, the tetrahedral bond is preserved with bond angles and bond lengths only slightly differing from that of bulk dc crystals. The outer atoms have dangling bonds that may be saturated, for example, by hydrogen. 15 atoms and 20 atoms hydrogenated carbon cage clusters correspond to the hydrocarbon molecules hexacyclopentadecane and dodecahedrane [252], respectively, which are assumed to be effective in the nucleation of diamond MTPs by methane decomposition [129]. The formation of fivefold twinned structures of Ge was proposed to originate from a 15 atoms nucleus formed in the amorphous phase [116]. A 100 atoms cluster first has been proposed to explain defect structures in the heteroepitaxial growth of Si on spinel [250].

2.3.2. Growth-Mediated Formation

If not nucleated from the beginning, MTPs also may form during growth by repeated cyclic twinning. The main source of growth twinning is misstacking of atoms at faces of low growth rate so as to produce reentrant edge configurations, which enable accelerated growth along a twin boundary [43, 117, 120, 186, 253]. In the particle stage of growth, twinning may proceed by the formation of primary, secondary, and tertiary twins on pre-existing tetrahedra as shown schematically in Figure 12. This process is found to operate not only to form decahedra, but also icosahedra by successive stacking of tetrahedra. Rather soon after the nucleation mechanism has been introduced, alternatively the tetrahedra stacking mechanism began to be discussed [57, 93, 169, 205, 254–257]. First it was observed during *in-situ* investigation of the epitaxial growth of Au on MgO [258] and was later confirmed by an *ex-situ* study on the growth of Au on

AgBr [259]. The formation of multiply twinned structures by successive twinning on alternate cozonal twin planes also has been found in thin film growth of Ni, Ge, and SnO$_2$ [117, 122, 134, 202, 260]. In all cases, the formation of triple twin junctions is a decisive step in favor of fivefold twinning. Frequently, networks of interlinked threefold and fivefold twin junctions are observed in these films. Local fivefold twinned structures have been considered as essential growth stimulating constituents of preferred fcc growth of van der Waals crystals [261–263].

In addition to misstacking of atoms during growth as one possible origin of repeated twinning, the intersection of stacking faults and twin lamellae, introduced into the lattice of growing thin films because of plane strain deformations, must be considered. Deformation twinning may serve as a means of relaxing plane strains. The ability of fivefold twinned structures to accommodate large interfacial strains due to lattice misfit and thermal expansivity differences is known from the heteroepitaxial growth of semiconductors on insulating substrates [155, 264–266]. Strain-induced twin formation starts with the introduction of 90° Shockley partial dislocations passing through the strained lattice [267–270]. Successive penetration of a strained lattice by dislocations on alternate twin planes consequently will lead to the crossing of twins. A simple case of twin intersection, the penetration of a stacking fault **SF** through a twin **T**, observed in the solid phase crystallization of Ge thin films [117, 220], is shown in Figure 13. In the crossing region, a secondary twin is formed. At the intersection of stacking fault and twin boundary, five-membered rings occur resulting from dislocation reactions [270]. The latter will act as seeds of prospective fivefold twin junctions upon propagation of additional dislocations on adjacent planes and will also lead to an extension of the secondary twin.

Sometimes, the origin of a certain fivefold twinned structure cannot be attributed to only one of the above discussed formation mechanisms, but may result from an interplay of growth twinning and deformation twinning. At various stages of thin film growth, extended structures containing several individual multiple twins may occur. During thin film growth of Au and Ag, decahedral and icosahedral
MTPs have been observed to form polyparticles via coalescence preserving almost completely their previous structures [271, 272]. Networks of interlinked fivefold and threefold twin junctions have been found in electrodeposited Ni films having ⟨110⟩ texture [202, 204, 260]. Similar networks occur at advanced stages of the solid phase crystallization of amorphous Ge [114, 119, 120, 224, 253, 273] as well as in the chemical vapor deposition of diamond [134, 136, 139] and Si [149]. In the applied range of temperature and film thickness, it is generally assumed that kinetic factors dominate the growth that has been described as "solid-like growth" by Marks [272]. However, the formation of MTPs has also been discussed as being due to transformation to a higher symmetrical arrangement [274].

3. STABILITY AND PHASE TRANSITIONS

3.1. Stability of Fivefold Twins

Frequently, MTPs and fivefold twinned structures do not exist separately, but in coexistence or even competition with structures that exhibit regular crystal lattice without twins. Their stability is an intriguing issue mainly because of the discrepancy between noncrystallographic packing of atoms and its extension in three-dimensional space. Experimental and theoretical investigations of clusters, a few atoms up to several hundreds or even a few thousands of atoms in size, aimed at determining stable forms and their size limits, have been mostly done on rare-gas [262, 275–281] and transition metal [243, 246, 282–289] clusters produced in supersonic beams during gas expansion. Atomistic studies, using data from electron diffraction [164, 176–178, 276–278, 290–292] and mass spectrometry [242–244, 293, 294], by means of molecular dynamics and Monte Carlo simulations employing various pair interaction potentials [245, 247, 279, 280, 287, 295–297], revealed a wealth of knowledge on magic numbers and growth sequences [242, 244–248], thermal stability, shape and structure [246, 282, 284, 296, 298–307], phase transitions [248, 262, 289, 297, 308–316], and melting behavior [288, 310, 317] of clusters of icosahedral, decahedral, fcc crystalline, or disordered structure. However, there has been predicted not a global minimum of potential energy for a multitude of structural motifs and cluster configurations, but very small energy differences such that clusters do not

necessarily have a single stable structure at realistic temperatures [282, 309, 317, 318]. Moreover, there has been found not a single sequence of phase transitions like icosahedral to decahedral to single crystalline fcc and its dependence on size and temperature, but also a reversal of this sequence [311] as well as a gradual instead of immediate transition [297, 308]. In addition, from molecular dynamics simulations there has been predicted, besides the layer-by-layer growth, also a certain probability of misstacking of atoms leading to island growth in twin position, which enables transition of decahedral to icosahedral shape by growth as it was experimentally observed on a much larger size scale [259]. Finally, experimental magic numbers associated with structures based on Mackay icosahedra have been classified by atomistic simulation to be of kinetic origin [319]. Even if the intermolecular potential disfavors the icosahedral structure, it occurs frequently due to potential characteristics that enhance kinetic trapping effects. The existence of such kinetic effects suggests that it will be possible to control structures of clusters and nanoparticles by tuning external parameters to enable design of nanomaterials properties.

The above findings are analogous to the configurational instabilities inherent to particles of sizes smaller than 8 nm [320, 321]. Real-time video recording of HREM investigations on very small metal particles revealed fast changes between a number of structures including cuboctahedra (single crystal), single twinned cuboctahedra, fivefold twinned decahedra, and icosahedra [67–71, 89, 322–327]. Some of these structures may be understood as result of a fivefold twin junction (also described as wedge disclination [328] or line disclination [329]) entering into and moving through a particle [330, 331]. Steps of this movement will include also asymmetric decahedra like the one of Ag shown as example in Figure 14. An eccentric position of the fivefold twin junction can be observed more often the smaller the particles are. The structural transformations observed along with a much higher rate of particle rotations in the presence of an electron beam may be understood in terms of statistical fluctuations with the probability of a particular configuration depending on size and temperature [320, 321].

MTPs consisting of regular fcc or dc subunits contain spatial discontinuities that introduce inhomogeneous strains. Additional strain and twin energy resulting from the specific composition of MTPs may be balanced by a reduction of surface energy up to a certain size above which trans-

formation to single crystalline particles of cuboctahedral shape was expected. Strain relief by structural modifications such as homogeneous lattice distortions or the introduction of lattice defects as inhomogeneous lattice distortions may extend the range of stability. Energy balance considerations including cohesive, surface, adhesive (i.e., concerning particle/substrate interaction), elastic strain, and twin boundary energy aimed at calculation of stable size regions for MTPs of transition metals in comparison to their single crystalline counterparts [16, 17, 332] provide stable and quasistable size limits around 30 and 300 nm for icosahedral and decahedral MTPs of Ag, respectively. Transitions from multiply twinned structures to single crystalline fcc have been observed for very small metal particles in gas expansion experiments by electron diffraction techniques from which crossover sizes of 3.8 nm have been derived for Cu [333], whereas in comparable experiments a size-independent transition was found for Ag [178] and a dependence on the type of inert gas was found for Pb [164]. On the other hand, experimental studies on MTPs gave evidence of their extension to sizes far above the size limits derived from stability considerations (see Section 4.2.). One of the reasons for this behavior is that they may undergo lattice transformations and in many cases exhibit lattice defects.

3.2. Lattice Transformations and Defects

The lack in space filling that results when composing MTPs of regular fcc tetrahedral subunits raises the question of whether the lattice of some or all of these subunits may adopt a slightly changed state of uniform distortion. To allow for the absence of spatial discontinuities in MTPs, some kind of structural modification or lattice defect is needed. This may be brought about by elastic strains acting on the tetrahedral subunits as first described by S. Ino to calculate their stability [17]. A slight, uniform distortion, for example, transforms the tetrahedral subunit fcc lattice into one having body-centered orthorhombic (bco) point group symmetry so as to enable a Bagley decahedron with twin angle 72° [52–54]. Figure 15 shows the fcc unit cell of lattice parameter **a** inside which a bco unit cell of lattice parameters **a**, **b**, **c** is drawn. As long as $\mathbf{a} = \sqrt{2}\,\mathbf{b}$ and $\mathbf{b} = \mathbf{c}$ (i.e., the nearest neighbor distance), the inscribed tetrahedron has fcc characteristics. The required uniform distortion is achieved

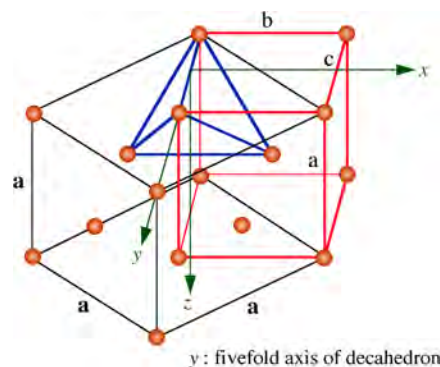
Figure 14. Asymmetric decahedral MTP of Ag grown by physical vapor deposition on alumina with eccentric position of the fivefold junction.


Figure 15. Tetrahedral twin subunit of a decahedron transformed from fcc to bco lattice.

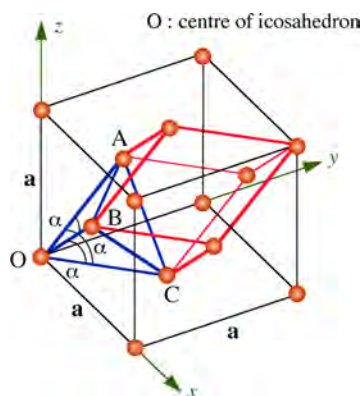
by applying a biaxial stress to elongate **c** (**c** = 1.0515 **b**) and to shorten **a** (**a** = 1.3764 **b**) [334]. This transformation preserves the close packing, but widens the angle between the triangular faces meeting at the *y*-axis from 70.52° to 72°. Another uniform distortion transforms the tetrahedral subunit fcc lattice into one having rhombohedral (rho) point group symmetry so as to enable a Mackay icosahedron with twin angle 72° [38]. Figure 16 shows the fcc unit cell of lattice parameter **a** inside which a rho unit cell of lattice parameters **b** is drawn. As long as the rhombohedral cell angle is $\alpha = 60°$, the inscribed tetrahedron has fcc characteristics. By applying an uniaxial stress along the cube diagonal direction close packing is preserved in the icosahedron with a rhombohedral structure, but α is enhanced to 63.43° [334]. The nearest neighbor distance however is different now for interplane atoms (**b** = OA, OB, OC) intraplane atoms (**c** = AB, AC, BC) with **c** = 1.0515 **b**. Consequences of these model considerations for lattice characteristics, diffraction patterns, and image contrast features have been demonstrated by crystallographic and electron microscopy studies on Au particles [334–338].

Accommodation of the angular misfit by transformation to the rho lattice has been reported also for Al-Mn multiple twins [339]. Contrary to the above examples where lattice distortions are assumed uniformly throughout all tetrahedral subunits, there are also reports about tetragonal lattice distortions in only one or two subunits while the remaining tetrahedra exhibit fcc lattice. This behavior has been observed for decahedral MTPs of In [109, 111, 340] and Pb [110]. The lattice of In bulk metal usually has base-centered tetragonal (bct) point group symmetry and adopts fcc structure only in multiply twinned nanoparticles, whereas the lattice of Pb bulk metal usually has fcc point group symmetry and adopts bct structure not only in MTPs, but also in single crystalline and single twinned nanoparticles. Icosahedral MTPs of the Fe-Pt intermetallic phase have been assumed to adopt the $L1_0$ superstructure, which was not found in untwinned nanoparticles of this material [171]. Interestingly, the $L1_0$ superstructure has not only promising magnetic properties, but also enables formation of perfect decahedra without any need of distortion. Based on this structural characteristic, an icosahedron model has been proposed that consists of two such $L1_0$ decahedra, having


one common vertex and their fivefold axes in line, completed by a "belt" of ten slightly distorted tetrahedra [171]. It should be noted here that, similar to chemically ordered $L1_0$ decahedra of Fe-Pt, icosahedra of a few materials have been found that do not require elastic straining to close the angular gap, because their lattice characteristics already fit to the condition that the tetrahedron angle α amounts to 63.43°. This has been reported for MTPs of C(76) having monoclinic lattice [127], for B_6O where oxygen atoms are three-coordinated to icosahedral B(12) clusters in a rho lattice [179, 180, 184, 241, 341], as well as for BC with rho lattice [167]. Although clusters having fivefold symmetry are well known as entities in crystal structures [342–344], up to now only the above mentioned B(12) have been found to be arranged in hierarchical packing from which icosahedral MTPs may form.

Elastic strains in fivefold twinned structures of fcc and dc materials determine not only the general structural characteristics [16, 17, 275, 328, 332, 345, 346], but also that of the twin boundaries involved [347]. At sizes distinctly above 10 nm, inhomogeneous elastic strains [348] allow rather large reductions of the strain energy stored in MTPs such that stress relief processes may occur involving the formation of lattice defects [332]. Typically, planar defects such as stacking faults and secondary twin boundaries are observed [115, 321, 349]. A particular stress-relieving configuration observed in fivefold twinned structures of Si and Ge [115, 117, 169] is shown in Figure 17. It consists of regular arrays of tetrahedrally arranged stacking faults emerging at stair-rod dislocations. Such stacking of fault arrays results in an angular lattice dilatation in the respective twin subunit, while the neighboring subunits remain undistorted. Two pairs of stacking faults are sufficient to accommodate the angular gap at the length scale of the particle shown here. More extended arrays in combination with small angle boundaries have been observed at Si particles of larger dimensions. Localized strains, defects, and misfit faults, which often simply consist of a small angle boundary, are by far the most reported inhomogeneities in MTPs and fivefold twinned structures of diamond [27, 129, 350–352], Si [169], TiN [151], and $CuInSe_2$ [353]. Individual dislocations

[105, 349, 354] and point defect agglomerations [107, 348] are rather scarcely observed.

4. STRUCTURAL CHARACTERIZATION

4.1. Characterization Methods

4.1.1. Electron Microscopy and Diffraction Methods

Electron diffraction as employed to the study of cluster beams using refined methods of diffraction peak analysis [164, 176–178, 277, 278, 290–292], similar methods have been applied in XRD studies [305, 355], enabled one to distinguish between MTPs and single crystal structures on a scale of only a few nanometers or even less. The importance of electron microscopy for structural characterization of MTPs and fivefold twinned structures in synthetic materials from the very beginning has already been pointed out in Section 1.3.2. This essential role results from the submicrometer size scale at which the phenomenon of multiple twinning mostly was found, thus being the actual domain of electron microscopy structural characterization. Utilization of a considerable number of methods and techniques ranging from simple shadow casting [10, 40] to state-of-the-art investigations devoted to, for example, observation under ultrahigh vacuum and at low temperature conditions [111], revealed many of structural characteristics that otherwise could not have been elucidated. Within the continuously increasing number and quality of electron microscopy studies, there have been employed electron diffraction pattern recording of individual MTPs and calculation of such patterns [337, 356–362], *in-situ* experiments to follow growth and transformation processes inside the electron microscope [234, 255, 258, 355, 363], weak-beam dark-field and related imaging modes for visualizing the internal structure of MTPs [259, 335, 336, 364, 365], HREM [105, 109, 191, 217, 273, 325, 326, 349, 354, 366–373] and corresponding image contrast calculation [121, 174, 175, 347, 362, 369, 372, 374–391], tilt series to study how external shape and internal structure of MTPs change with their orientation to the electron beam [166, 190, 192, 362, 392], real time observation of fast processes such as structural fluctuations or particle coalescence [67, 70, 322, 323, 325, 326, 381, 393], and combination of XRD or X-ray absorption spectroscopy investigations with TEM or HREM studies [194, 355, 394].

4.1.2. Selected Area Electron Diffraction

Special attention is devoted to selected area electron diffraction (SAED), from which fivefold symmetry may be recognized in a direct manner, and HREM, from which unique "fingerprints" may be obtained. Actually, before and besides HREM imaging, it is the SAED pattern of an individual decahedron in fivefold orientation, one of the first was published 1964 by Schlötterer [40] and another striking example 1972 by Ino et al. [395], which is directly convincing and allows one to examine with high accuracy the symmetry as well as spacings and angular relationships of multiply twinned particles. To illustrate the capabilities of this method, Figure 18 shows as an example the SAED pattern of a decahedral Ni grain in fivefold orientation within an
Figure 18. Selected area electron diffraction pattern of a decahedral Ni grain (fivefold orientation) within an electrodeposited thin film.

electrodeposited thin film having ⟨110⟩ texture. This grain of about 400 nm extension in a plane perpendicular to its fivefold axis exhibits secondary twin boundaries in two of the tetrahedral units. Accordingly, in the diffractogram a slight splitting of related spots of {111} and {222} type can be seen, which indicates an inhomogeneous relaxation of elastic strains due to the space filling gap. For the sake of clarity, no assignment of spots has been added to the SAED pattern, but two circles are drawn enclosing the innermost spots of {111} and {200} type. From this rather complex electron diffraction pattern, it can be clearly seen that not one single crystal, but a grain consisting of five subunits in well-defined orientation relationship are transmitted by the electron beam. Likewise, diffraction patterns from regions of 1 nm size of multiply twinned Au nanoparticles obtained by means of a microdiffraction equipment operated in the scanning transmission mode [396] confirm the particle composition of twinned subunits.

4.1.3. High Resolution Electron Microscopy

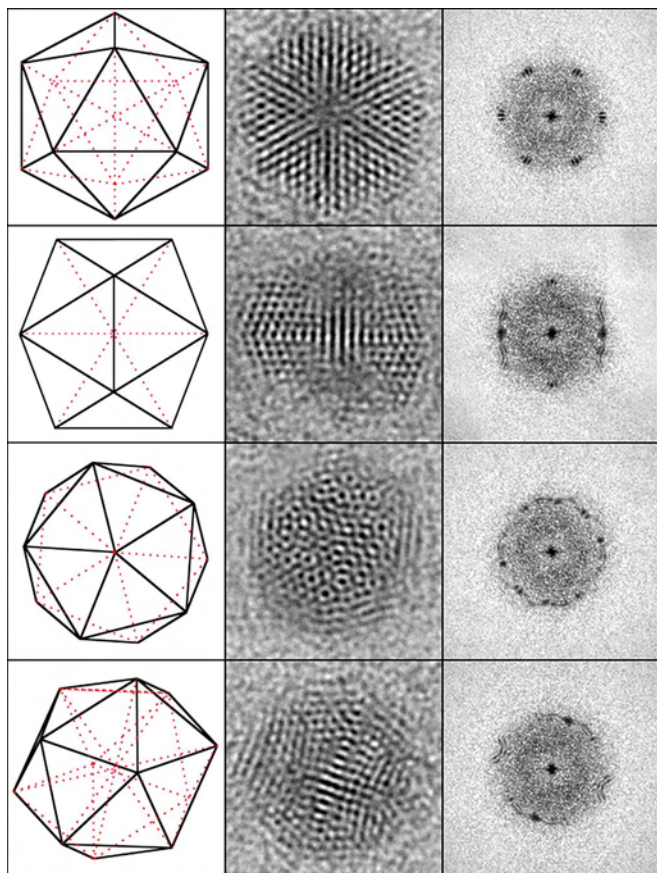
Imaging of lattice plane fringes by high resolution electron microscopy of MTPs frequently reveals, in combination with diffractogram analysis and image contrast calculation, a clear signature of particle shape and internal structure [166, 382, 384, 385, 390]. This is demonstrated in Figure 19 for Ag icosahedra arranged in various orientations with respect to the electron beam. It comprises HREM image, diffractogram, and particle model of the particles in "face" orientation, "edge" orientation, "fivefold" orientation, and one tilted around 10° out of "edge" toward "fivefold" orientation (from top to bottom). The edge length of the HREM images corresponds to 4.8 nm. These image contrast features depend on the configuration of tetrahedral subunits that are oriented such as to give rise to lattice plane contrasts. In the "face" oriented icosahedron, for example, there are six twin planes parallel to the electron beam, or the axis of observation, leading to six sets of {111} lattice plane fringes. However, there must be considered superposition of lattice plane fringes where tetrahedral units are stacked one above another. That is why the image details cannot be straightforwardly interpreted in terms of lattice planes and increasingly become more complicated the more superposition occurs. The highly complex contrast patterns in HREM images of icosahedral particles due to superposition of various lattice segments cause corresponding complex spot patterns in the diffractogram. However, the frequently observed


Figure 19. HREM "fingerprints" (edge length 4.8 nm) of icosahedral Ag particles in various orientations: "face," "edge," "fivefold," and tilted around 10° out of "edge" toward "fivefold," from top to bottom, together with diffractogram (right) and model (left).

diffractogram spot splitting, as shown in Figure 19, is no direct evidence of angular misalignment or spatial mismatch of the lattice of twinned subunits. Actually, the shape of image regions of equal lattice plane fringe arrangement is reflected in the diffractogram fine structure [390], which is related in a certain way to the electron diffraction spot fine structure of polyhedral crystallites observed earlier [397]. The fine structure of diffractogram spots also is found for calculated HREM images of icosahedra assuming a rho pointgroup symmetry without any lattice defects. By Fourier transform processing of various projections of tetrahedral subunit model images, the interference nature of the phenomenon has convincingly been demonstrated [390].

4.2. Size and Shape

The additional strain and twin energy associated with the formation of MTPs may be balanced by a reduction of surface energy up to a certain size (see Section 3.1), above which transformation to single crystalline structures is expected. Experimentally observed fivefold twinned structures however, not only frequently exceed the size limits based on thermodynamic considerations, but also exhibit distinct deviations from the nearly spherical shape into various types of rod-like or even star-like particle shapes. One reason for

this behavior is the accommodation of angular misfit by the introduction of lattice transformations or lattice defects (see Section 3.2). Another reason is that obviously certain growth conditions not only favor deviation from the ideal MTP shape (see Section 1.2), but also enable exceedingly large particle size. Besides the two examples of Figures 20 and 21, which show a large decahedral MTP of Pd in "fivefold" orientation and a large icosahedral MTP in "parallel" orientation, the most impressive examples of extremely large MTPs of various materials (i.e., those having micrometer size and above) are compiled in Table 3. These include decahedral particles of the molecular C(60) crystal fullerite [125] exceeding the millimeter scale of size, and icosahedral particles of boron suboxide B_6O [341] with sizes around 40 μm. While most of the MTPs on the micrometer scale are of decahedral shape, the above-mentioned extraordinary large icosahedra forming material exhibits a rhombohedral structure with a rhombohedral unit cell angle of $\alpha = 63.1°$ being very close to the one for ideal icosahedral twinning.

Multiply twinned rod-like particles may form from decahedral nuclei by preferential growth along the fivefold axis. First observations were made within Au crystals of natural occurrence [33, 398–400]. Different from regular decahedra, these particles exhibit extended prism faces of {001} type. Their multiply twinned nature is revealed most easily from tilting experiments in the electron microscope, as has been shown recently for rod-like silver particles grown by inert-gas evaporation technique [166]; this reference also sums up the literature about MTPs of rod-like shape in synthetic materials. As may be concluded from the model shown in Figure 5C, rotation around the long axis of the particle, situated perpendicular to the electron beam, is found to produce two characteristic image contrast patterns, separated from one another by 18° rotation, both having rotational periodicity of 36°. According to a rather recent publication, decahedral nanorods have also been fabricated via a bioreduction route [401]. Elongation of icosahedral MTPs toward rod-like shape may be achieved not simply by growth, but by successive growth twinning, this way reaching beyond the shape of complete icosahedra. As shown by the model in Figure 22, particles of elongated shape can be formed by stacking two icosahedra into each other such that they share five tetrahedra grouped around a common fivefold axis, as in a decahedron. Characteristic image contrasts of triple rhombic shape result from positioning one of the fivefold axes
Figure 20. Decahedral particle of Pd in fivefold orientation grown on KI substrate by vapor deposition.

of these particles, being their long axis, parallel to the substrate, or perpendicular to the electron beam [387]. Hence the three decahedral regions involved show {111} lattice plane fringes within rhombic areas (shaded in Figure 22). In addition, these decahedra in "edge" orientation exhibit {220} lattice plane fringes within square areas (hatched in Figure 22). From atomic-scale simulations of copper polyhedral nanorods [391, 402], both types of rod-like MTPs have been found as stable geometrical structures. Multiply twinned particles of star-like shape may form, as deviation from the decahedron shape, by reduced growth rate along the five twin boundaries of the tetrahedral subunits. Hence,

Table 3. Size extrema found in fivefold twinned materials.

Material	Approx. size	Type	(Year) Ref.

these tetrahedra exhibit {111} truncations at their peripheral corners resulting in a star decagon projection when viewed in "fivefold" orientation. Star-like MTPs first have been reported for Cu of natural occurrence [32] and later for synthetic materials such as diamond [18, 42], Ge and Si [43, 88, 185], BN [132, 403], colloidal gold [212, 404], TiN and SiC [151, 152], Al-Cr-Si alloy [82], and also C(60) [405]. Finally it should be mentioned that a number of multiply twinned structures are hollow, that means they exhibit an external shape of fivefold symmetry but an internal void of variable extension. Hollow fivefold twinned structures are mainly found in whiskers of pentagonal cross-section [50, 51, 406] and in organic materials such as proteins or surfactant bilayers [8, 11].

5. PROPERTIES AND APPLICATIONS

5.1. Structure-Sensitive Properties

Physical and chemical properties of materials assembled of fivefold twinned nanoparticles may differ from materials consisting of untwinned nanoparticles in a variety of aspects according to their respective structural characteristics. These differences concern properties sensitive to the surface energy, the lattice symmetry, the internal structure, and the surface structure, and they may cause changes, such as of the melting point, magnetic moment, electronic transition, and chemical reactivity, respectively. For MTPs embedded in a matrix of foreign material instead of the surface structure, the interface structure has to be considered, which via particle-matrix interaction may influence the elastic properties of the composite. In studies devoted to the properties of multiply twinned nanoparticles mostly the influence of their real structure on heterogeneous catalysis is stressed [65, 108, 156, 163, 217, 226, 363, 371, 374, 407–412] since adsorption and reactivity are highly structure-sensitive properties. In a very recent investigation, Au MTPs have been found to lower selectivity and activity in the partial hydrogenation of unsaturated aldehydes with respect to the desired product allyl alcohol [227]. That means MTPs of Au are not useful for this reaction path. For separated Au(55) clusters of closed shell composition, an extraordinary high resistance against oxidation has recently been reported [413] that most probably is due to their icosahedral morphology. Tetrahedral subunits with the rho lattice of B_6O perfectly fit together at a common vertex without dislocations needed to accommodate an angular gap, thus enabling the

growth of rather large icosahedra of boron suboxide [179, 180, 184, 241, 341]. Consequently, glide planes are locked in these particles that may result in a low density material of extraordinary hardness. Quite similar is the situation with massive icosahedral crystals of boron carbide, for which the well known hardness of this compound could be further improved because of being multiply twinned with icosahedral symmetry [167]. Precipitation hardening in structural alloys of AL-Si-Ge is dependent on the precipitate morphology, which is largely determined by twinning [87]. Multiply twinning completely changes the interface with the matrix, and consequently the strengthening effect of these precipitates in the metal matrix is reduced. Since the formation of multiple twin junctions apparently promotes the growth of Si nanowires in the oxide-assisted route [414], it will be interesting to see to which extent this structure may influence the optoelectronic properties of the material.

5.2. Symmetry-Dependent Properties

The appearance of spontaneous ferromagnetic order in Pd nanoparticles of about 6.8 nm size has been explained by a transition from single crystalline to multiply twinned structure with decreasing size [313]. The icosahedral symmetry is considered to contribute to the onset of ferromagnetic ordering or to the increase of an already existing magnetic moment. The main driving force in this transition has been shown to be the strong surface anisotropy of fcc single crystals being replaced by the energetically more stable icosahedral arrangement below the above size [313]. Stoichiometric Fe-Pt nanoparticles of 3 to 6 nm in size are found to preferentially exhibit icosahedral structure upon appropriate thermal processing [171]. Icosahedral MTPs of this alloy are assumed to be stabilized by transition to the $L1_0$ ordered phase, which exhibits large magnetocrystalline anisotropy [171]. This may be the basis for future magnetic materials with nanometer dimensions. For studying their physical properties the Raman, Brillouin, and elastic tensors of materials that exhibit fivefold point group symmetry have been calculated [415–417]. Concerning the optoelectronic properties of nanoparticles there is a very recent report on an excellent combination of fluorescence spectroscopy and HREM of isolated semiconductor nanoparticles allowing both methods to be applied to the same specific particle [418]. This way changes not only in size, but also in structural as well as morphological characteristics can be correlated to fluorescence properties of isolated nanoparticles. First results of the investigation of CdSe nanoparticles on transparent Si_3N_4 substrate indicate that the emission of strong fluorescence is not restricted to single crystalline particles of about 8 nm size, since icosahedral MTPs of slightly smaller size also show such emission [418]. More and systematic studies are needed to ascertain the role of the respective structural characteristic in this behavior.

6. SUMMARY

The aim of this chapter is to emphasize by illustrative examples and comprehensive references the importance of the widespread habit of fivefold twinning in nanostructured materials and to shed some light on the multitude of its

facets. In particular, it shall enable us to link synthesis and processing of technologically promising or even important materials, their fivefold twinning characteristics, and their physical and chemical properties. This also includes the issue of comparing nanoparticulate materials, which preferentially have fivefold twinned structure to those being mainly in the untwinned state (see, e.g., [227]). For more detailed reading about this fascinating and rather complex phenomenon, some review articles concerning experimental as well as theoretical work in this field may be recommended. These are "Structure of Small Metallic Particles," by M. Gillet [419]; "Noble Metal Clusters" by R. Monot [420], "Comparison Between Icosahedral, Decahedral, and Crystalline Lennard–Jones Models Containing 500 to 6000 Atoms," by B. Raoult et al. [279]; "Phase Instabilities in Small Particles," by P. M. Ajayan and L. D. Marks [320]; "The Energetics and Structure of Nickel Clusters: Size Dependence," by C. L. Cleveland and U. Landman [284]; "Experimental Studies of Small Particle Structures," by L. D. Marks [421]; "Growth and Structure of Supported Metal Catalysts," by P. J. F. Harris [411]; "Preferred Structures in Small Particles," by N. Doraiswamy and L. D. Marks [321]; "Shells of Atoms," by T. P. Martin [294]; "Crystallography of Clusters," by J. Urban [384]; "Pentagonal Symmetry and Disclinations in Small Particles," by V. G. Gryaznov et al. [328]; and "Structure, Shape, and Stability of Nanometric Sized Particles" by M. J. Yacaman et al. [422]. The review "Forty Years Study of Fivefold Twinned Structures in Small Particles and Thin Films," by H. Hofmeister [220], gives a comprehensive record of four decades work (1957–1997) on fivefold twinned structures in small particles and thin films. The present chapter shall not only make available models and experimental findings of previous investigations in a greater context, but also stimulate future studies on this phenomenon.

GLOSSARY

Dislocation A line defect in a crystal, along which the lattice is displaced by a certain amount perpendicular or parallel to the dislocation line.

Ferromagnetic order Chemical order in a crystal that exhibits interaction at the atomic level, causing the unpaired electron spins to line up parallel with each other in a domain where a magnetic moment results.

Fluorescence The emission of light by a substance immediately after the absorption of energy from light of usually shorter wavelength.

Glide plane A low index crystal plane along which translation of one part of a crystal relative to the other part may proceed by the movement of dislocations.

Pair interaction potential Intermolecular potential describing the interaction between pairs of atoms derived from empirical models of interatomic bonding, used for computer simulation of bond energy and atomic structure of clusters.

Point group symmetry A method of denoting the combination of symmetry elements that a crystal contains.

Stacking fault A planar defect in a crystal where one part is displaced relative to the other part, such that the displacement does not correspond to a translational symmetry operation.

CONTENTS

1. INTRODUCTION

The growth of epitaxial insulators shows a potential for applications in microelectronics devices such as semiconductor-on-insulator (SOI) structures, monolithic integrated circuits, improved gate insulators in metal–insulator–semiconductor field effect transistors (MISFETs), and passivation layers of compound semiconductor devices [1].

Fluorides have attracted much attention particularly by their ability to grow epitaxially on semiconductor crystalline substrates in opposition to other dielectrics, such as SiO_2 and SiN_x, which are mainly amorphous. In particular, group IIA fluorides such as CaF_2, SrF_2, and BaF_2 show many desirable properties such as low vapor pressure, easy molecular sublimation with the right stoichiometry, and good insulating behavior at room temperature.

The small lattice mismatch between CaF_2 and Si (+0.6%) at room temperature allowed various applications for CaF_2 thin films, the most important being on SOI devices. The integration of metals on CaF_2/Si heterostructures is equally well used in MIS devices, resonant tunneling diodes, and resonant tunneling transistors. We note that the availability of devices based on CaF_2/Si structures has sped up research in this interesting field in the past few years.

Progress in thin films on insulators and semiconductors is demanded by large scientific and business-related interests. The most significant support for these investigations of magnetism in thin films arises from the magnetic recording industry.

This review describes not only one specific class of metallic films integrated on silicon owing to CaF_2 epilayers, but also prototypical ferromagnetic thin films widely used in many applications. More general subjects are also discussed in this review such as magnetism, magnetotransport, and the mechanical behavior of thin films, thin-film technology, and surface-sensitive measurements.

This review is divided into four main topics, with three of them focused on CaF_2-based heterostructures, that is, CaF_2/Si(111), Fe/CaF_2 heterostructures, and metals/CaF_2/Si(111). An original contribution about the initial growth of Fe on CaF_2(111) has been included in Section 3. The focus on CaF_2(111) epitaxially grown on Si(111) is due to experimental results that clearly pointed to the (111) plane as the best experimental choice. An overview of the results obtained for different metals epitaxially grown on CaF_2 is discussed in Section 4. In Section 5, we address the reports involving Fe and metallic alloys grown on fluorides in general as well as multilayered and granular thin films. Finally, the role of physical properties on the overall behavior of the systems and the potential areas of technological application are discussed.

1.1. CaF_2

Calcium fluoride, or fluorite, is a very important industrial mineral with many different applications. It is used as a flux in steelmaking, as a source of fluorine in fluorinated water, as a precursor to hydrofluoric acid industrialization, and as a prime material for special optical lenses.

Fluorite is a popular mineral and is mined worldwide. It can be found in a variety of colors, depending on the hydrocarbon impurities. CaF_2 belongs to the halide mineral group,

is brittle with a hardness of 4 on the Mohs scale, and cleaves easily along [111] planes.

Fluorite is an isometric mineral with a face-centered cubic structure, $Fm3m$ symmetry, and lattice parameter of $a_0 = 0.5462$ nm. Its density is 3.18 g/cm^3 at 20 °C, and the refractive index is between 1.43 and 1.44 for the visible spectrum. The crystal structure of CaF_2 is shown in Figure 1.

The electronic structure of fluorite is dominated by a wide gap of 12.1 eV at room temperature, making it a very good insulator. Calcium fluoride is clearly ionic with the strongly electronegative fluorine capturing two electrons from the cationic calcium valence shell. Its valence band is dominated by fluorine p states, whereas, on the contrary, the conduction band is formed mostly by strongly mixed calcium s and d states [2].

CaF_2 is considered the ideal material by researchers working on semiconductor-on-insulator (SOI) devices due to both its crystal structure and its insulating characteristics [3].

1.2. CaF$_2$/Si

The use of naturally grown silicon oxide on silicon for insulating purposes has been a natural choice employed over and over. The problem with silicon oxide is its amorphous structure, which precludes postgrowth of heteroepitaxial films. In fact, in several areas of scientific and technological interest, the growth of crystalline epitaxial insulators is preferred: SOI structures, gate insulators, three-dimensional structures, metal–insulator–semiconductor (MIS) structures, and the integration of magnetic films onto silicon are among those that should be mentioned. For the demanding optoelectronics, electrical transport, and magnetic devices, high-quality epitaxial insulators are needed in combination with sequential metal, semiconductor, or magnetic epitaxial layers.

Surveying the potential epitaxial insulators on silicon, the group IIA fluorides arise as natural candidates [1, 3], and, among these, fluorite is by far the most studied material.

The lattice match of face-centered cubic fluorite with silicon (cubic $Fd3m$ diamond structure) is very good, but for growth by molecular beam epitaxy (MBE), epilayer strain is unavoidable in the process. This is, in fact, produced in the cooling cycle after CaF_2 growth, due to the large difference in thermal expansion coefficients between CaF_2 and Si [1], which eventually induces cracking in thick epilayers [3].
Figure 1. Crystal structure of CaF_2.

Furthermore, the growth of good-quality heteroepitaxial films of CaF_2 on Si(111) substrates has been demonstrated, leading to structures grown layer by layer with adequate smoothness. This aspect and the optimal growth and thickness conditions of epitaxial fluorite will be reviewed in Section 2.

1.3. Fe/CaF$_2$/Si

Several different metals such as Cu, Pt, Al, Co, and Fe, among others, have been deposited with reasonable epitaxial results. Here we stress the magnetic Fe heteroepitaxial epilayers deposited on CaF_2/Si(111).

The driving force behind such studies of MIS structures concerns the production of hybrid ferromagnetic–semiconductor devices. The last decade has seen tremendous development of solid-state electronics and optoelectronics, while the circuit elements involving magnetic materials have been under-researched. This trend is changing rapidly due to the discovery and application of the giant magnetic resistance (GMR) effect, together with the upcoming spintronics field, where the conduction electron spin can be manipulated [4, 5].

The direct deposition of ferromagnetic transition metals on silicon produces unwanted silicide formation even at room temperature [6]. The operation of this hybrid structure at higher temperatures could lead to irreversible structural and phase changes. An alternative solution would be the growth of a diffusion blocking layer between the silicon and the magnetic metallic films, with CaF_2 displaying the required properties for moderate temperature growth and operation.

In the last decade, several works were published on the structural, thermal, electrical, magnetic, and mechanical aspects of epitaxial Fe deposited on CaF_2/Si. These efforts will be reviewed in Section 3.

An overview on the other metals successfully grown on CaF_2 are described and discussed in Section 4.

1.4. Fe on Other Fluorides

Although the bulk of this review is selective with respect to the more common research of Fe epitaxially grown on CaF_2/Si(111), we include a discussion of other fluoride substrates with characterizations that can be found in the literature.

The deposition of Fe thin films on LiF crystals was investigated in the 1970s without the tools actually required for interface characterization that are currently employed in surface physics and materials science. More recently, the initial growth stage of Fe on group IA fluorides (LiF, KF, RbF, . . .) has been investigated by numerous methods, revealing rather poorly defined interfaces together with a strong interfacial chemistry. The growth of Fe films and clusters on group IIA fluorides (MgF_2, CaF_2, BaF_2, . . .) reveals, on the other hand, well-defined interfaces and, due to this, they have received more attention.

Chemical sensitivity, particularly to atmospheric exposure, precludes the investigation of some fluoride compounds such as CdF_2 as suitable substrate materials.

Certainly the most interesting fluoride compounds are the transition metal fluorides of the form MF_2 (M = Mn, Fe, Co,

Zn, . . .), which have been used as model systems to study finite-size and other phase transition phenomena because of their well-known Ising-like magnetic interaction and well-defined magnetic and crystalline structures. Perhaps the most interesting system is Fe/FeF_2, which has received much attention due to a number of novel and surprising magnetic properties. Another very interesting system consists of magnetic clusters embedded in a MgF_2 matrix, which has been pointed to as the granular system with the largest tunneling magnetoresistance. All of these topics, together with their detailed literature references, will be described and discussed in Section 5.

1.5. Technological Perspectives

The growth of heteroepitaxial $Fe/CaF_2/Si$ structures has been shown to be feasible. Less successful seems the tailoring of Fe/CaF_2 multilayers where the growth of CaF_2 on Fe represents the major difficulty. This alternate deposition of Fe and CaF_2 multilayers leads to granular films of iron and calcium fluoride, even at room temperature, with intermixing at the interfaces. This process is followed by the formation of several FeF_3 compounds involving Fe^{3+} ions.

The basic research aspects of heteroepitaxial $Fe/CaF_2/Si$ structures have been advanced in the last decade, but so far no device has been produced to our knowledge. The technological perspectives nevertheless look bright for this type of MIS system in the future.

Many other fluorides such as LiF, MnF_2, and FeF_2 have been successfully used as substrates for the deposition of high-quality Fe thin films. Each can provide useful information, but the best candidates are MnF_2 and FeF_2 because of their high crystal quality in combination with a promising avenue for prototypical spin-based device exploration.

2. EPITAXIAL CaF_2 ON Si(111)

In 1989, Schowalter and Fathauer [3] published a complete review of the growth of CaF_2 on Si(111) where various aspects of the epitaxial growth of films were analyzed, such as the crystalline quality of epitaxial layers of CaF_2, the surface energy, the cracking of epitaxial layers, and the CaF_2/Si interface.

With the democratization of surface study techniques and spectroscopic and structural techniques based on synchrotron radiation in the 1990s, it was rapidly possible to obtain a deeper understanding of the initial growth stages of the epitaxial films of CaF_2 on Si single-crystal substrates. However, the most studied subsystem to date is $CaF_2/Si(111)$. Two main reasons can be pointed out for this choice among others. First, the (111) plane of both CaF_2 and Si is the densest plane, facilitating epitaxial growth. Second, the surface energy of the (111) CaF_2 plane is lower, in comparison with planes of other directions [3], thus helping the condensation. CaF_2 films grown on the Si(111) surface have smoother surfaces and a better crystalline quality than those grown on the Si(100) surface.

In virtue of this scenario, the initial growth stages and structural quality of epitaxial films of CaF_2 on Si(111) have been extensively studied, while only a few reports are found for Si surfaces with different orientation.

Sugiyama and Oshima [1] have published a review on the MBE growth of fluorides where the initial growth stages, the growth mode, and the type of epitaxy are extensively discussed in the light of techniques such as X-ray photoelectron spectroscopy (XPS), X-ray photoelectron diffraction (XPD), near-edge X-ray absorption fine structure (NEXAFS), medium-energy ion scattering (MEIS), X-ray standing waves (XSW), scanning tunneling microscopy (STM), atomic force microscopy (AFM), and low-energy electron microscopy (LEEM). The interfacial structures of $CaF_2/Si(111)$ have been studied by high-resolution transmission electron microscopy (HRTEM) and X-ray diffraction.

Next, we will briefly describe the initial nucleation stage of CaF_2 on Si(111) for two of the most important growth conditions.

2.1. Initial Growth at Low Temperature

Two types of epitaxies are reported for CaF_2 films grown on Si(111), depending on the substrate temperature [7]: type A below 500 °C and type B above 500 °C. Type A epitaxy is characterized by the coincidence in the surface plane between the $[1\bar{1}0]$ and $[\bar{2}11]$ axes of the CaF_2 and Si, whereas, for type B, these axes are exchanged between film and substrate, which corresponds to a 180° film rotation with respect to type A epitaxy. The two distinct epitaxial relations are shown in Figure 2.

Denlinger et al. [8] have shown by *in-situ* XPS, XPD, and low-energy electron diffraction (LEED) that, for CaF_2 films grown at 450 °C, a fraction of the CaF_2 molecules are dissociated and can consequently induce reactions between Ca—Si and Si—F at the interface. It has also been observed that the Si—F bonds inhibit the lateral growth of the first monolayer, resulting in nucleation centers for the second monolayer. The second monolayer grows preferentially on the first one, even if it remains discontinuous, promoting a three-dimensional (3D) growth that results in worse epitaxial quality as reported by Wollschläger and Meier [9].

More recently, Wang et al. [10] have shown by AFM that the deposition at 410 °C leads to the coexistence of type A and type B epitaxies. In summary, the growth of CaF_2 films on Si(111) at substrate temperatures below 500 °C is initially
(a) Type A   (b) Type B

Figure 2. Schematic drawings of the two distinct epitaxial relations of the CaF_2 on Si(111): (a) type A orientation in which the orientation of the film is identical to that of the Si; (b) type B orientation in which the orientation of the film is rotated by 180° about the surface normal of the substrate.

two dimensional (2D), with the increase in the thickness becoming 3D-like with a predominant type A epitaxy.

2.2. Initial Growth Stage at High Temperature

Denlinger et al. [8] have also studied the initial growth of CaF_2 films on Si(111) at higher substrate temperatures and concluded that, for substrate temperatures above 600 °C, Ca—Si bonds and CaF occur at the interface as a consequence of the CaF_2 dissociation. Another interesting result is the nucleation of the second monolayer, which only starts after the Si surface is totally covered. In contrast with low-temperature experimental findings, no Si—F bonds were observed, corroborating the hypothesis that Si—F bonds reduce the diffusion length at the surface. Additionally, X-ray photoemission diffraction results show that the type B epitaxy of the successive layers is associated with Ca—F bonds.

Huang et al. [11] elaborated a structural model for the CaF_2/Si(111) interface with an intermediate monolayer of $CaSi_2$ between the substrate and the CaF_2, owing to high-resolution grazing incidence X-ray diffraction and X-ray reflectivity measurements performed at synchrotron radiation. This completely agrees with the results of Denlinger et al. [8] for high substrate temperatures; that is, the formation of Ca—Si bonds and CaF occurs at the interface as a consequence of the CaF_2 dissociation.

LEED, XPS, and STM measurements were recently employed by Sumiya [12] to study the phase evolution of the CaF_2 surface reconstructions as a function of the temperature of the substrate during growth and thermal annealing with STM images showing these surface reconstructions. XPS also indicates that the surface at high temperatures consists of CaF. The STM images are clear and disclose the formation of a structure of CaF rows at 700 °C. Surface analyses show that the surface of the islands at 640 °C possesses a (1×1) reconstruction and the rows are proceeding from a (3×1) reconstruction.

Thus, a type B epitaxy of CaF_2 on Si(111) is found under low CaF_2 growth rates and at high deposition temperatures (>600 °C) due to the dissociation of the CaF_2 to CaF at the Si surface. This promotes the formation of a CaF/Si interface with Ca directly bonded to Si to form a $CaSi_2$ compound. For CaF_2 films grown above 700 °C, the row structure is observed, resulting in better structural quality. These results show the influence of the morphology of the surface on the quality of the films [1, 12].

2.3. CaF_2/Si(111) Interface

The initial stage of epitaxial growth of CaF_2 on Si(111) has been studied by several techniques. Although the reported results are partly inconsistent with each other, it is clear that the chemical reaction at the initial coverage of CaF_2 on Si(111) and the interface structure depend strongly on the deposition conditions (see [1] and references therein).

There is a consensus that both Ca and F bond to Si at the interface at high deposition temperatures (>600 °C). The proposed structural model of a stoichiometric CaF_2/Si(111) interface is based on the existence of Si—Ga and Si—F bonds. However, it is thought that the dissociation of CaF_2

molecules to CaF at the interface may promote a predominance of Si—Ca bonds and the resulting depletion of F atoms. The Ca atoms are mainly situated at the T4 bonding sites; that is, Ca is located on the threefold site on top of a second layer of Si atoms [1]. The CaF_2/Si interface is atomically abrupt since a single layer of film forms on the Si surface until the atomic terraces have been filled. The nucleation of the second layer only starts after the completion of the first layer. The epitaxial film has a predominant type B orientation. When the growth is performed below 500 °C, there is both more F and more disorder at the interface. It is also generally stated that at a lower substrate temperature the critical size of the one-layer CaF_2 island is rather small, so that the Si substrate is not fully covered when nucleation of the second layer starts.

There is no conclusive report on the structural changes occurring at the interfaces during postdeposition annealing of the CaF_2/Si heterostructures.

3. Fe/CaF_2 HETEROSTRUCTURES

The number of publications on Fe/CaF_2 heterostructures grown on Si(111) in the last years attests to the growing interest in this system. In this section, the growth process, with special emphasis on the importance of the deposition temperature on microstructure, on chemical stability, and on magnetic behavior, will be drawn.

3.1. Growth and Epitaxy

Epitaxial α-Fe films grown by the electron beam evaporation technique on a CaF_2 epilayer on Si(111) substrates show the [110] orientation along the growth direction. The structure of nanometer-thick Fe films has been studied using several X-ray diffraction techniques and scanning and transmission electron microscopy as well [13].

Grazing incidence diffraction χ-scans confirm that the growth of α-Fe films on CaF_2(111) proceeds along the [110] direction with an in-plane relation such that the α-Fe[1$\bar{1}$0] direction is parallel to the CaF_2[1$\bar{2}$1] direction, meaning a 30° rotation of α-Fe(110) planes with respect to CaF_2(220) ones. Two main defects could be identified in the epilayers. First, twins are clearly apparent for samples deposited above room temperature. Second, regular dislocation lines appear on some sample regions. Scanning electron microscopy micrographs of the shiny metallic surface of the samples reveals a regular geometric pattern, which constitutes isosceles triangles interpreted as dislocation lines emerging at the surface. The planes normal to the α-Fe(110) plane, which have a mutual angular relationship, were identified as being due to the following Miller indices: [1$\bar{1}$2], [1$\bar{1}$2], and [1$\bar{1}$0]. Thus, the regularity of dislocation lines emerging at the film surface strongly suggests the structural quality of the epitaxial Fe films.

By using geometrical arguments, the $[110]_{\alpha\text{-Fe}} \| [111]_{CaF_2}$ and $[1\bar{1}0]_{\alpha\text{-Fe}} \| [1\bar{2}1]_{CaF_2}$ epitaxial relations could be explained as a particular case of the Nishiyama–Wassermann epitaxy [14]. Taking into account only the lattice parameter, one readily would expect the same orientation for Fe grown on Si and on CaF_2. This is not verified, and despite the lattice parameter of CaF_2 and Si differing by only 0.6% at room

temperature, α-Fe grows on Si(111) with the [111] axis along the growth direction [15].

After Schowalter and Fathauer [3], the difference in surface free energy, estimated at 0.45 J m^{-2} for CaF$_2$(111) and at 1.24 J m^{-2} for Si(111), can be used to explain these two distinct orientations of Fe films on both materials. Another argument that can be equally used to explain this difference is the formation of a silicide interlayer between Fe and Si by a solid-state interdiffusion [4, 16], even at room temperature (RT). This interfacial chemistry can help to accommodate the large lattice misfit.

Over the last few years, the initial growth of metallic Fe on CaF$_2$, notably over thin CaF$_2$(111) epilayers on Si(111), has been extensively studied [17, 18]. According to ultrahigh vacuum scanning transmission electron microscopy with nanometer resolution, the initial growth of Fe proceeds by three-dimensional islanding on CaF$_2$ substrates. A very high nucleation density has been observed on both bulk and thin CaF$_2$ epilayers and this for a wide range of substrate temperatures, from 20 to 300 °C. This indicates a limited surface diffusion with nucleation occurring at defect sites (notably fluorine sites) with a high trapping energy ($\sim$1 eV). Although the Fe island distribution is correlated to chemical or defect dominating growth, Fe is not expected to form compounds with CaF$_2$. The analyses of particle size revealed an almost monodisperse distribution of Fe islands on CaF$_2$(111) surfaces with no statistical differences between diameters and spatial distribution of islands for growth from RT up to 300 °C. More than 85% of the population of Fe islands have a diameter of 2.0 nm. The number of Fe islands per unit area was found to be 7×10^{12} islands/cm^2 with an average separation between Fe island centers around 3.7 nm. The stage of Fe island nucleation on CaF$_2$/Si(111) surfaces held at room temperature occurs at least for coverage between 0.4 and 1.3 ML Fe (1 ML = 7.7×10^{14} atoms/cm^2). Another interesting result concerns the coalescence and/or coarsening that have a weak influence on secondary nucleation which seems to occur via surface diffusion and incorporation in the sides of preexisting islands. A more in depth analysis of the Fe initial growth stage will be given later with recent unpublished results.

A set of samples has been prepared in an MBE multigrowth chamber. First, a 100-nm-thick CaF$_2$ epilayer has been grown on a hydrogen-terminated Si(111) surface. These CaF$_2$(111)/Si substrates were introduced in the growth chamber and annealed at 250 °C for 4 h to promote structural ordering. The substrate temperature was decreased to 150 °C, and once the temperature was stabilized, Fe was deposited at a rate of around 0.1 nm/min. In order to check the chemical stability, Fe films were also prepared with substrate temperatures of 450 °C, which is higher than the decomposition temperature of CaF$_2$.

In-situ X-ray photoemission spectroscopy (XPS) has been used to probe the core levels of the chemical species (Mac II spectrometer). At several stages of deposition, the samples were cooled to room temperature and transferred to an XPS chamber under ultrahigh vacuum (UHV). As expected, the slow increase in the Fe/Ca and Fe/F intensity ratio indicates that the initial growth of Fe proceeds by islanding on the CaF$_2$ surface.

In-situ reflection high-energy electron diffraction (RHEED) measurements were performed using a variable-incidence Staib RHEED system operating at 12 keV under grazing angle. For quantitative analyses, the diffraction pattern was recorded and analyzed using a high-sensitivity charge-coupled device (CCD) camera linked to a computer image-processing system. Figure 3a and c shows the RHEED diagrams of the CaF$_2$(111) surface taken along the [$2\bar{1}\bar{1}$]$_{CaF_2}$ and [$1\bar{1}0$]$_{CaF_2}$ azimuths, respectively, immediately prior to the start of Fe growth. These two directions, which differ from each other by 30°, reveal a flat and well-structured CaF$_2$(111) surface. Figure 3b and d shows the RHEED pattern diagrams along the [$2\bar{1}\bar{1}$]$_{CaF_2}$ and [$1\bar{1}0$]$_{CaF_2}$ azimuths, respectively, after the growth of 1.8 nm equivalent thickness of Fe deposited at 150 °C. The beginning of the Fe growth is characterized by a two-dimensional diffraction that fades into an increasing background. Once the Fe coverage increases, the Fe spots become visible and more elongated with thickness, within a complex RHEED pattern that is associated with small fractions of aligned epitaxial regions.

Partial indexing of the Fe diffraction spots of the RHEED diagram, taken along the [$2\bar{1}\bar{1}$]$_{CaF_2}$ and [$1\bar{1}0$]$_{CaF_2}$ azimuths, is given in Figure 3b and d. According to the RHEED diagram taken along the [$2\bar{1}\bar{1}$]$_{CaF_2}$ azimuth shown in Figure 3b, the initial nucleation of Fe on CaF$_2$(111) exhibits two domains with the same epitaxial relationship along the growth direction [110]$_{\alpha\text{-Fe}}\|$[111]$_{CaF_2}$, but with two distinct in-plane matching planes: [$1\bar{1}0$]$_{\alpha\text{-Fe}}\|$[$2\bar{1}\bar{1}$]$_{CaF_2}$ and [$1\bar{1}2$]$_{\alpha\text{-Fe}}\|$[$2\bar{1}\bar{1}$]$_{CaF_2}$.

The RHEED diagram taken along the [$1\bar{1}0$]$_{CaF_2}$ azimuth shown in Figure 3d reveals twinning domains with a [111]$_{\alpha\text{-Fe}}\|$[111]$_{CaF_2}$ epitaxial relationship along the growth direction and two distinct in-plane matching planes: [$1\bar{1}0$]$_{\alpha\text{-Fe}}\|$[$1\bar{1}0$]$_{CaF_2}$ and [$\bar{1}10$]$_{\alpha\text{-Fe}}\|$[$1\bar{1}0$]$_{CaF_2}$. As usual, in the case of Fe epitaxied directly on a Si(111) substrate [19], it can adopt two different stacking sequences along the (111) direction during growth: one aligned (type A) and the other rotated by 180° with respect to the surface normal of the substrate (type B). The symmetry of the diffraction of each crystal domain is clearly shown in Figure 3d. These two α-Fe domain orientations have a twinning epitaxial relationship.

Therefore, the RHEED pattern diagrams reflect a complex situation, including multidomain epitaxy. There are at least three epitaxial modes of the α-Fe on CaF$_2$(111). We summarize the domain epitaxial relationships at low Fe coverage as follows [20]:

Type A epitaxy:

[111]$_{\alpha\text{-Fe}}\|$[111]$_{CaF_2}$ along the growth direction
[$1\bar{1}0$]$_{\alpha\text{-Fe}}\|$[$1\bar{1}0$]$_{CaF_2}$ in-plane matching of planes

Type B epitaxy:

[111]$_{\alpha\text{-Fe}}\|$[111]$_{CaF_2}$ along the growth direction
[$\bar{1}10$]$_{\alpha\text{-Fe}}\|$[$1\bar{1}0$]$_{CaF_2}$ in-plane matching of planes

Type C epitaxy:

[110]$_{\alpha\text{-Fe}}\|$[111]$_{CaF_2}$ along the growth direction
[$1\bar{1}2$]$_{\alpha\text{-Fe}}\|$[$2\bar{1}\bar{1}$]$_{CaF_2}$, [$1\bar{1}2$]$_{\alpha\text{-Fe}}\|$[$1\bar{1}0$]$_{CaF_2}$, and [$1\bar{1}2$]$_{\alpha\text{-Fe}}\|$[$2\bar{1}\bar{1}$]$_{CaF_2}$ with in-plane matching of planes
It is worth noting that the RHEED analyses along both $[2\bar{1}\bar{1}]_{CaF_2}$ and $[1\bar{1}0]_{CaF_2}$ directions reveal a so-called type C epitaxy with three in-plane matching planes rotated 30° from each other. This type C epitaxy becomes predominant when the Fe coverage increases, as will be shown later.

The in-plane lattice parameter evolution of the growing Fe film has been equally monitored through the RHEED profiles using a high-sensitivity CCD camera. Streak positions and distances have been measured as a function of time by making intensity profiles along a predefined region. The in-plane lattice parameter evolution along the $[1\bar{1}0]_{CaF_2}$ azimuth is presented in Figure 4 as a function of the equivalent Fe coverage (deposition time is given in the top axis). The streak spacing between $CaF_2(0,\bar{1})$ and $(0,1)$ has been used as reference lattice parameter to extract the misfit for deposition at 150 °C. From the beginning of the growth, a slow evolution from $(1/\sqrt{2})a_{CaF_2} = 0.3863$ nm to a value of $a_{interface} = 0.4129$ nm is observed, followed by a smooth decrease to a value of $a_{bulk} = 0.4084$ nm, which is 0.8% greater than the Fe bulk value $\sqrt{2}a_{\alpha\text{-Fe}} = 0.4053$ nm.

When the Fe coverage increases, the domains formed by the stacking of planes with higher atomic density overcome the twinned domains, leading to large crystallites (mosaic crystals) with the $[110]_{\alpha\text{-Fe}}$ orientation axis aligned along the $[111]_{CaF_2}$ growth axis. Figure 5 shows a conventional θ–2θ scan in Bragg–Brentano geometry of the (110) Bragg reflection of the samples protected with a 10-nm-thick amorphous ZnSe cap layer to prevent reaction with air.

In summary, structural and XPS analyses do not indicate the existence of a relevant interfacial chemistry. Indeed, the multidomain epitaxial regions are still observed. The characteristic growth process and structural relaxation of the Fe on $CaF_2(111)$ seems to be controlled not simply by Fe film thickness, but instead by the balance between the intrafilm interaction strength and the Fe–CaF_2 interaction strength. These features may strongly affect the magnetic response at low coverage of Fe. A more detailed study is necessary to clarify these questions.

3.2. Thermochemical Stability

Chemical reaction between Fe and CaF_2 is commonly rejected based on thermochemical considerations [18]. The formation of iron silicides promoted by pinholes in the thin CaF_2 epilayer has been suggested to occur rather than a chemical reaction between Fe and CaF_2. However, recent results on multilayered and granular Fe thin films and fluorides (CaF_2 and LiF), grown at room temperature, have

Figure 3. RHEED patterns of the 100-nm-thick $CaF_2(111)$ surface taken along (a) $[2\bar{1}\bar{1}]_{CaF_2}$ and (c) $[1\bar{1}0]_{CaF_2}$ azimuths, respectively. The RHEED patterns taken along the same azimuths as (a) and (c) but after the deposition 1.8 nm equivalent Fe coverage are shown in (b) and (d), respectively. Single-crystal spot diffraction patterns of the epitaxial domains were indexed by following the in-plane matching planes according to the notation: $[1\bar{1}2]_{\alpha\text{-Fe}}\|[2\bar{1}\bar{1}]_{CaF_2}$ (white) and $[1\bar{1}0]_{\alpha\text{-Fe}}\|[2\bar{1}\bar{1}]_{CaF_2}$ (black) for type C epitaxy with $[2\bar{1}\bar{1}]_{CaF_2}$ azimuth, and $[2\bar{1}\bar{1}]_{\alpha\text{-Fe}}\|[1\bar{1}0]_{CaF_2}$ (black) for type C epitaxy, $[1\bar{1}0]_{\alpha\text{-Fe}}\|[1\bar{1}0]_{CaF_2}$ (white with subindex A), and $[\bar{1}10]_{\alpha\text{-Fe}}\|[1\bar{1}0]_{CaF_2}$ (white with subindex B) for the epitaxies A and B, respectively, with $[0\bar{1}1]_{CaF_2}$ azimuth.
Figure 4. Lattice parameter evolution during growth of a small amount of Fe at 150 °C as visualized by RHEED. The reference was taken along the $[1\bar{1}0]_{CaF_2}$ azimuth on in-plane lattice parameter of CaF_2.

shown the intermixing at the interfaces and the formation of imperfect compounds involving Fe^{3+} ions [21, 22].

The chemical mechanism of compound formation is still elusive. However, it seems that CaF_2 films in contact with a moist atmosphere with subsequent adsorption of small molecules (O_2, H_2O, CO_2, N_2, etc.) are important agents for causing a degenerative effect on CaF_2 epitaxial films and subsequently promoting the chemical reaction between Fe and CaF_2. Recent experiments on CaF_2(111) surfaces damaged by radiation with low-energy electrons have shown that the damaged surface is highly reactive with O_2 and CO_2 [23]. In general, the structure of the fluorine-terminated surface is almost free of defects. Exposing this surface to an oxygen dose of some hundred langmuir, however, produces defect formation, each one occupying an ionic site that has been interpreted as hydroxyl groups substituting surface fluorine ions [24]. Therefore, these studies seem to indicate that a perfect fluoride surface is chemically inert and will not be degraded by exposure to oxygen or water, but preexisting surface defects in the form of vacancies or F centers can play an important role in surface reactivity.
Figure 5. X-ray diffraction pattern in θ–2θ scan of the (011) Bragg reflection of the samples protected with a 10-nm-thick amorphous ZnSe cap layer.

Now, let us address the dependence of the crystal quality on the Fe deposition temperature. According to θ–2θ diffraction experiments performed for 30-nm-thick Fe films, the α-Fe(110) reflection increases in intensity steadily with deposition temperature up to 450 °C, whereas the α-Fe(200) signal becomes weaker. Concomitantly, the full width at half-maximum associated with the Fe(110) reflection decreases from 5.9° to 2.1° (or 64%) when the deposition temperature increases from 150 to 450 °C, respectively. This clearly indicates that the crystal quality increases with temperature. The best crystalline quality concerning grain size and stress release is found for samples deposited at 450 °C [25].

The thermochemical stability of the material obtained by sequential deposition of discontinuous Fe and CaF_2 thin layers at room temperature definitely plays an important role. The reactivity of Fe and F is well documented [26–30] and the intermixing of Fe and CaF_2 at the interfaces is also strongly demonstrated [21, 22, 31].

Composite films were deposited as multilayers onto 40-nm CaF_2(111) epilayers previously grown on HF-etched Si(111) wafers in BALZERS UMS 500P electron beam equipment with a base pressure of 2×10^{-8} mbar. For comparative analyses, 30-nm-thick Fe films were grown at 450 °C on CaF_2(111)/Si(111). The samples discussed here follow the convention where the subindices placed after the parentheses indicate the repetition number of Fe and CaF_2 layers in each sample. Such samples are denoted as follows:

Sample A. (CaF_2 3.4 nm/Fe 1.5 nm)$_{20}$/CaF_2(111) 40nm/ Si(111)
Sample B. (CaF_2 3.4 nm/Fe 3.2 nm)$_{10}$/CaF_2(111) 40 nm/Si(111)
Sample C. Fe 30 nm/CaF_2(111) 40 nm/Si(111)

Transmission electron microscopy (TEM) reveals that sample A is composed almost entirely of isolated Fe-rich granules with an average size of 20 nm, dispersed in a disordered CaF_2 matrix. For sample B, the plan-view micrographs show Fe-rich granules forming a percolation network where magnetic closure structures are readily facilitated. Selected-area electron diffraction (SAED) of samples A and B exhibits diffraction patterns consisting of rings that correspond to ferric trifluoride (FeF_3) reflections together with a $Ca(OH)_2$–CaF_2 mixture. Several crystalline forms of FeF_3 are present in these samples: rhombohedral FeF_3 (r-FeF_3) and hexagonal tungsten bronze FeF_3 (HTB-FeF_3) species, namely, anhydrous HTB-FeF_3 and HTB-$FeF_3(H_2O)_{0.33}$ [28–30]. TEM analyses of sample C reveal an excellent structural quality with respect to the first two samples with predominant reflections of α-Fe(110) planes stacking along the growth direction.

In this way, the complex chemical reactions involving ferric trifluoride by-products must be taken into account when considering future applications of Fe/CaF_2 structures.

3.3. Magnetic Properties

3.3.1. Epitaxial Fe on CaF_2

The magnetic properties of Fe films on CaF_2(111) were investigated by both *in-situ* and *ex-situ* methods. It has been demonstrated, for example, that *in-situ* surface magnetooptic

Kerr effect (SMOKE) measurements are unsuitable for the detection of a ferromagnetic signal in the island array. The ferromagnetic response cannot be observed for a maximum applied field of 1 kOe if the island diameter is smaller than 2.8 nm. Besides, the SMOKE analyses cannot distinguish between superparamagnetic and nonmagnetic behavior. An alternative approach was to cover the Fe island array with a protective silver capping for *ex-situ* magnetic measurements. In these measurements, a superparamagnetic response was observed [32].

To clarify the magnetic response in a better way, we have performed magnetic measurements on the set of samples discussed in Section 3.1, which were cooled to room temperature after deposition and capped with a 10-nm-thick amorphous ZnSe layer to prevent reaction with air. This procedure has been tested as being efficient to protect samples for several weeks in air. As an additional precaution, samples were stored in a N_2-saturated atmosphere and quickly prepared to the measurements in an alternating gradient force magnetometer as well as in a SQUID magnetometer. This amorphous cap layer is less constrained to the Fe islands than the Ag cap layer from the point of view of mechanical relaxation and strain-induced effects.

Figure 6 shows the saturation magnetization moment per square centimeter (m_s) versus the Fe thickness for a set of three samples grown at a deposition temperature of 180 °C as well as for one sample grown at 450 °C. The same deposition rate of about 0.1 nm/min has been used for all samples. Figure 6 shows that m_s increases linearly with thickness and one can find a slope ($M_s = 1700$ G) that is in very good agreement with bulk Fe magnetization at room temperature ($M_s = 1710$ G). The extrapolation of this line intercepts the thickness axis at a value of 0.48 nm. A crude interpretation will lead to the existence at the interface of a magnetically dead layer, which includes a number of Fe atoms corresponding to a 0.48-nm-thick layer. The deposition performed at the higher temperature of 450 °C also suggests the presence of an equivalent dead layer. Since the slope extracted from the data is quite close to the bulk Fe
value, the dead layer may result from a less accurate thickness calibration, from a surface chemistry with an interfacial phase, or from a superparamagnetic behavior induced by islanding at the CaF_2 surface. Another possibility is that magnetization is being lost by strain induced in the Fe epilayer by the lattice mismatch between Fe and CaF_2 at the interface.

Transmission electron microscopy has been equally used to confirm the thickness calibration. In fact, while the effective Fe thickness remains a difficult parameter to determine, the equivalent Fe coverage depends only on the shutter time control for a given deposition rate. The thickness of 0.48 nm is very close, however, to the thickness registered by RHEED (∼0.5 nm) for the Fe structural relaxation process (see Fig. 4).

Figure 7 shows the magnetization versus the field measured with the applied field in plane for the sample set of Figure 6. No appreciable magnetic anisotropy was observed for magnetic fields applied along different directions in the film plane. By increasing the Fe layer thickness, both the remanence and the coercivity increase. The higher deposition temperature strongly reduces the coercive field, H_c, whereas the saturation magnetization is only slightly affected. This suggests a structural relaxation in the sample. Also, the magnetic results point to the existence of misaligned epitaxial regions and multiphase domains at low Fe coverage more than to the existence of an interfacial compound. It is worth noting, however, that both assumptions lead to a loss of magnetization as inferred from the magnetic measurements.

By remembering that the Fe nucleation proceeds by three-dimensional islanding on CaF_2, a superparamagnetic response at low Fe coverage is expected. However, the structural results concerning the formation of misoriented epitaxial domains presented in Section 3.1 require a much more careful analysis. The evidence of different orientations of α-Fe at the interface imply a complex magnetic response, strongly dependent on the relaxation of the in-plane lattice parameter, which persists up to 1-nm-thick Fe coverage. Our present results demonstrate the importance of an

Figure 6. Saturation magnetization moment per square centimeter (m_s) versus Fe thickness for three samples deposited at 180 °C. Result of one sample deposited at 450 °C is also shown. A linear fit (dashed line) of the samples deposited at 180 °C leads to $M_s = 1700$ and a magnetic dead layer thickness of about 0.48 nm.
Figure 7. Magnetization versus magnetic field curves for samples with $T_s = 180$ °C; $t_{Fe} = 14$ nm, $H_c = 451$ Oe (solid circles); $T_s = 180$ °C, $t_{Fe} = 4.7$ nm, $H_c = 172$ Oe (open circles); $T_s = 450$ °C, $t_{Fe} = 4.7$ nm, $H_c = 49$ Oe (open squares); and $T_s = 180$ °C, $t_{Fe} = 2.4$ nm, $H_c = 40$ Oe (solid squares).

in-situ characterization of the early stages of Fe growth on CaF_2 to understand the magnetic properties of Fe/CaF_2 heterostructures.

3.3.2. Fe/CaF$_2$ Multilayers

The structural and magnetic properties of Fe/CaF_2 multilayers have been investigated by Mosca et al. [21] and Kita et al. [22]. Both reports indicate that discontinuous multilayered structures are formed. Discontinuous multilayers are an intermediary structure between an ideal multilayer thin film and a granular system as shown in Figure 8.

Discontinuous multilayered structures consisting of Fe/CaF_2 present interesting magnetic behavior of a cluster-glass phase with the presence of short-range antiferromagnetic ordering within Fe-rich granules. Magnetic irreversibility occurs mainly due to frustration of the antiferromagnetic interactions in the magnetic structure of Fe^{3+} ions. Sample A, described in Section 3.2, presents the irreversibility (branching of field cooling (FC) and zero field cooling (ZFC) curves) commonly observed in spin-glass systems. The irreversibility temperature, T_{irr}, associated with the bifurcation in the ZFC/FC curves, can be attributed either to magnetic clusters or to frustration of antiferromagnetic interactions. FC magnetization curves exhibit a broad maximum around 100 K that is progressively attenuated by increasing the applied field. The magnetic response of sample B differs markedly from that of sample A. The direct-current (dc) data suggest a ferromagnetic behavior coexisting with frustrated antiferromagnetic interactions in the percolated network of magnetic particles. According to Hansen and Morup [33], T_{irr} is dependent on the size distributions of the assembly of magnetic particles. Thus, the large value of T_{irr} indicates an increase in the size of the magnetic particles in sample B.

Mössbauer spectra of samples A and B measured at room temperature and zero field reveal that ferromagnetic order is not present in sample A, as expected for a composite sample consisting of granules, whereas the characteristic α-Fe sextets are observed for sample B, which depicts ferromagnetic behavior at room temperature. For sample A, three different Fe sites could be identified: $HTB\text{-}FeF_3(H_2O)_{0.33}$, FeF_2, and a singlet that can be ascribed to small superparamagnetic Fe clusters dispersed in a CaF_2 matrix. For sample B, the same Fe sites plus a sextet corresponding to α-Fe were identified. It is clear that the contributions due to $HTB\text{-}FeF_3(H_2O)_{0.33}$, FeF_2, and the small Fe clusters come from the reaction between Fe and CaF_2 at the interfaces.

A possible explanation for these magnetic results is that frustrated random antiferromagnetic interactions exist in the assembly of granules consisting of antiferromagnetic ferric trifluorides FeF_3 [28–30]. According to Ferey et al. [28], the magnetic structure of the crystalline forms of FeF_3 consist of a tetrahedral subnetwork of Fe^{3+} cations where the number of magnetic interactions involved in the square and triangular platelets of the cationic subnetwork gives rise to the frustrating topology of the structure.

We believe that our aforementioned results are consistent with a chemical reaction between Fe and CaF_2, implying Fe^{3+} antiferromagnetic compounds rather than a frustrated random superparamagnetic phase. The magnetic behavior of sample A is consistent with an almost complete reaction of Fe with CaF_2 at room temperature, forming FeF_3 compounds. Sample B shows a ferromagnetic behavior that implies that nonreacted Fe still exists in this film where three-dimensional, rather than bidimensional, Fe islanding occurs during the growth stage. Sample C, consisting of a continuous and homogeneous Fe film grown at 450 °C, also exhibits a small magnetic irreversibility at moderate high temperatures.

Magnetic measurements of samples A and B annealed at 450 °C for 1 h in vacuum [31] reveal a strong magnetic irreversibility, which can be explained by the spatial distribution of antiferromagnetic aggregates consisting of crystalline forms of FeF_3 with a Néel temperature around 140 K.

Magnetoresistance measurements [34] using the standard alternating-current (ac) four-point method of samples A and B before and after annealing reveal a small negative magnetoresistive effect ($<0.2\%$) at room temperature. Up to 10 kOe, the resistivity systematically decreases as a function of the applied field without evidence of saturation.

As discussed in the last paragraph of Section 3.2, experimental efforts are still needed to clarify the magnetic and magnetotransport properties of Fe/CaF_2 structures.

3.4. Self-Assembled Fe Nanowires on CaF$_2$

Linear arrays of Fe stripes regularly spaced 15 nm can be obtained by photolysis of ferrocene that is selectively adsorbed between CaF_2 stripes that were self-assembled on a stepped Si(111) surface [35]. These self-assembled Fe nanowires represent a very interesting type of magnetic nanostructure for patterned storage media and related applications. To date, there is no work on the magnetism for the samples fabricated by this method.

3.5. Mechanical Properties

Nanomechanical tests of $CaF_2/Si(111)$ and $Fe/CaF_2/Si(111)$ samples were made with a Nanoindenter IIs (Nano-Instruments Co.) using a Berkovich diamond indenter tip [25, 36]. Nanoscratch tests were performed using the available scratch option for the nanoindenter to measure the tangential forces during the scan of the lateral face of the inverted triangular pyramid of the Berkovich tip. Typical parameters of the nanoscratch tests used were relative speed of 5 μm/s, scanning distance of 400 μm, and load in the range of 20–4000 μN.

The nanoscratch tests with 40-nm-thick CaF_2 films on Si(111) clearly show a pronounced plateau at the friction coefficient curves. For the macroscopic roughness of the 20-nm-thick sample and depth profiles during the scratch tests limited to 40 nm, the friction coefficient varies from 0.15 to 0.25. A similar behavior has been verified on samples as grown at 300 °C (polycrystalline) and subsequently
Figure 8. Schematic drawings of (a) multilayered film, (b) discontinuous multilayered film, and (c) granular film.

rapidly thermal annealed (RTA) at 450 °C for 1 min (mosaic crystal), with the exception of a secondary plateau, present in the RTA sample, which can be related to the Ca silicide layer formed at the interface between CaF_2 and Si [36].

Nanomechanical properties of epitaxial 30-nm-thick α-Fe films grown on CaF_2/Si(111) at deposition temperatures ranging from 30 to 450 °C were also reported in the literature [25]. The results show dependence for in-plane residual strain with hardness and nanoscratch measurements. For example, the nanoindentation results show an increase in the pop-in events in the load versus penetration curve upon increasing deposition temperature, indicating a correlation of film crystal quality with mechanical behavior. The biggest nanoscratch resistance was achieved for a sample deposited at 150 °C, which has larger hardness and better adhesion.

Delamination of the Fe film from the CaF_2 support was observed at a load of about 1200 μN. The load value where the delamination occurs for a tip penetration smaller than the thickness of the bilayer Fe/CaF_2 is defined as the critical load for adhesion, and the ratio of the critical load with the contact area is defined as the critical stress [37]. By using these definitions, a two-order-of-magnitude increase in adhesion has been observed for the sample deposited at 150 °C with respect to room temperature deposition. The samples deposited at 150 °C were also qualitatively harder, showing a smaller plastic deformation. It is worth noting that the crystalline quality of the Fe films is enhanced by increasing the deposition temperature from 20 to 450 °C, whereas the relative strain of the Fe plane spacing parallel to the surface displays a minimum at a deposition temperature of 150 °C [25]. These results indicate that an Fe deposition temperature of about 150 °C minimizes the internal strain relaxation of the Fe films and, consequently, favors better adhesion of the Fe films to the CaF_2 substrate.

4. OTHER METALS ON CaF₂/Si(111)

Besides ferromagnetic iron, several metals have been deposited on epitaxial CaF_2, leading to interesting three-dimensional device structures.

Although the lattice parameter of Al is approximately three-quarters the lattice parameter of CaF_2, Cho et al. [7] have succeeded in growing epitaxial CaF_2 films on Al and vice versa, thus fabricating a technically sound epitaxial metal/insulator/metal structure on Si.

Cuberes et al. [38] demonstrate the successful deposition of Au/CaF_2 structures on the reconstructed (7 × 7) Si(111) surface. These authors characterized the interfaces using the ballistic electron emission microscopy (BEEM) technique, showing that the spectral features of the density of states depend on the CaF_2 epitaxial thin film.

Mattoso et al. [39] have shown that Cu grows epitaxially on CaF_2/Si(111) with the following epitaxial relationships: $Cu(111)\|CaF_2(111)\|Si(111)$ along the growth direction and $Cu[1\bar{1}0]\|CaF_2[1\bar{1}0]\|Si[1\bar{1}0]$ for the in-plane matching. Despite a mismatch of about 34% between Cu ($a_0 = 0.36150$ nm) and CaF_2 ($a_0 = 0.54626$ nm), a geometric coincidence between three Cu lattices and two lattices of CaF_2 brings the misfit to only 0.74%. This geometric

argument was used to explain the heteroepitaxy of Cu on CaF_2.

The most promising structure of all reported up to now seems to be the $CoSi_2$/CaF_2 heterostructure on silicon. In a series of papers, the group at the Tokyo Institute of Technology demonstrated the feasibility of the growth of metal-like cobalt silicide on a CaF_2 insulator. Since 1992, Saitoh et al. [40] have shown devices presenting quantum interference of so-called hot electrons. This group reported on the first hot-electron transistor, the resonant tunneling diode, and the resonant tunneling transistor, establishing a very successful line of research followed by many scientists worldwide thereafter.

In 1998, LaBella et al. [41] demonstrated the hot-electron transport properties in ultrathin Pt/CaF_2/Si(111) MIS heteroepitaxial structures.

More recently, Shusterman et al. [42] have reported on successful epitaxial growth of Al on CaF_2/Si(111), as well as Cu/Al(3 nm)/CaF_2/Si(111) structures, indicating the same relationships described by Mattoso et al. [39] for Cu/CaF_2/Si(111) structures.

In summary, beyond magnetic Fe a few other metals such as Au, Pt, Al, and Cu as well as Co silicides can be epitaxially grown on CaF_2/Si heterostructures. Geometric relationships have been applied to explain the epitaxy of metals on CaF_2, but very few studies exist on the initial growth stages of these metals and their dependence on the deposition parameters. Such studies can extend the possibility of future applications beyond those already reported.

5. Fe AND THEIR ALLOYS ON FLUORIDES

Several fluorides grow epitaxially on semiconductor substrates, opening many possibilities for new electrical and optical devices. Further progress in fabricating novel and attractive devices using fluorides could be achieved by the integration of epitaxial metals on fluoride/semiconductor heterostructures. In this section, we address several kinds of fluorides that were epitaxially grown on semiconductors, especially on Si substrates.

Next, we describe the epitaxial growth, structural characterization, and magnetic properties of Fe and their alloys on fluorides. However, there have been very few reports on this subject, except for FeF_2 and LiF substrates.

Finally, nanostructured multilayer films and nanogranular thin films consisting of ferromagnetic 3D metals and fluorides are described and discussed.

5.1. Fluorides on Semiconductors

The epitaxial growth of alkali metal fluorides, such as KF and RbF, is a very difficult task since they are dissociatively adsorbed due to the reaction of halogen atoms with Si dangling bonds [43]. Concomitant with this fact, the fluorination of the Si surface exposed to fluorine leads to spontaneous surface etching at room temperature [44, 45].

LiF on Si is another interesting system because LiF is the material with the most extreme ultraviolet (UV) transmission of all, and therefore it is largely used for special UV and X-ray optics.

Cosset et al. [46] have reported on the deposition of textured crystalline LiF film on a monocrystalline Si(100) substrate. They found that LiF is almost site equivalent for adsorption on the Si surface and tends to form clusters for all growth conditions. From 300 to 550 °C, reactions between the LiF adsorbate and the substrate occur as a consequence of the dissociation of LiF and fluorination of the surface [47]. Similar results were obtained for LiF on Si(111) substrates with evidence of the formation of SiF_x and Li—Si complexes at temperatures higher than 300 °C [48]. Thus, good heteroepitaxial growth of LiF on Si(100) or Si(111) can be ruled out.

Prior work on epitaxial CaF_2 on Si can be extended to MgF_2 and CdF_2, which both have a smaller lattice parameter than that of Si. Although a CdF_2 crystal has the same fluoride structure as CaF_2, CdF_2 possesses a rather lower chemical stability [49]. An appropriate combination of MgF_2 and CdF_2 fluorides with CaF_2 could allow better lattice matching with Si. The optical coating applications of MgF_2 as infrared optical components of, for example, windows, mirrors, lenses, and prisms, make this an attractive alternative.

The most useful studies of the epitaxial growth of fluorides using an MBE apparatus have been done mainly with respect to group IIA fluorides such as CaF_2, SrF_2, and BaF_2 [50–52]. These cubic fluoride structures are closely related to the diamond structure of Si, thus giving high-quality crystalline thick films. Although the thermal expansion coefficients close to the room temperature of the fluorides $(10–30 \times 10^{-6} \text{ K}^{-1})$ are comparatively larger than those of

Si $(2.33 \times 10^{-6} \text{ K}^{-1})$, suggesting that the cubic fluorides do not exhibit completely crack-free epitaxial growth on Si, the cubic fluorides are ionic solids with many desirable properties, such as large free energy of formation, low vapor pressure, simple molecular sublimation in UHV, and ease of growth as stoichiometric compounds [52].

Some rare earth lanthanide trifluorides, such as LaF_3, CeF_3, and NdF_3, can also be grown epitaxially on Si(111) substrates [53]. These trifluorides have a smaller linear thermal expansion coefficient compared to those of the group IIA fluorides. The trifluorides have a water-insoluble nature and possess a hexagonal crystal structure, which was successfully used as a template for epitaxial growth of rare earth metals [54]. A quasi-stoichiometric GaF_3, which has a rhombohedral crystal structure, can also be obtained by sublimation under UHV [55]. Yttrium fluoride, YF_3, produces low-index film layers on glass that exhibit good transparency in the UV through infrared (10 μm) regions.

The properties of some fluorides are briefly reviewed in Table 1. More data on the MBE growth of fluorides on semiconductors such as GaAs, Ge, and InP can be found in [1].

5.2. Fe on FeF_2

It is easily recognized that the growth of Fe on FeF_2 is currently an active area of research with goals that range from the fundamental understanding of the exchange anisotropy phenomena [62, 63] of such a system to its potential application to the magnetic domain stabilization

Table 1. Fluoride properties.

Compound	Crystalline structure	Lattice parameter (nm)	Lattice mismatch with Si at room temperature (%)	Energy bandgap (eV)	Antiferromagnetic Néel temperature T_N (K)	Ref.
LiF	Cubic NaCl	0.4026	−26.0	12	—	[56]
KF	Cubic NaCl	0.5348	−1.5	11	—	[1, 3]

in magnetoresistive (MR) heads [64] and spin-valve-based devices [65]. Next, we address the research activity on the magnetic fluorides.

FeF$_2$ is a magnetic insulator with a body-centered tetragonal crystal structure where Fe^{2+} ions sit at the unit cell center ordering antiferromagnetically with the ions at the corners. The interaction between the Fe^{2+} ion spins is the superexchange interaction via F$^-$ ions and is sensitive to a change in distance. When the distance between Fe^{2+} ions decreases, the exchange integral increases, resulting in a concomitant increase in the Néel temperature, T_N. FeF$_2$ is a uniaxial antiferromagnet material with a large uniaxial magnetocrystalline anisotropy along the c axis [66]. Therefore, the FeF$_2$(110) surface has equal numbers of spins from the two antiparallel sublattices and is called compensated, whereas the FeF$_2$(100) surface is uncompensated since its surface plane contains spins that point in a single direction.

Nogués et al. [66, 67], using conventional electron beam evaporation, have successfully grown (110)- and (100)-oriented Fe thin films on FeF$_2$ previously grown on MgO and Al$_2$O$_3$ substrates. Highly textured (110)- and (100)-oriented Fe thin films were also grown by electron beam evaporation on the (100) and (110) crystal faces of FeF$_2$ using the Bridgman–Stockbarger method [58].

The magnetic characterization of these Fe/FeF$_2$ bilayer structures has shown a number of novel and interesting properties such as a large exchange bias [67], a positive exchange bias [66, 68], a perpendicular ferromagnetic–antiferromagnetic coupling between Fe and FeF$_2$ [58], and an asymmetric magnetization reversal in the Fe exchange-biased layer [69, 70].

Exchange bias (EB) is a phenomenon that occurs in systems where a ferromagnet (FM) is in direct contact with an antiferromagnet (AFM). When a sample with an FM/AFM interface is cooled below T_N (assuming that the Curie temperature is larger than T_N) in the presence of a magnetic field, the center of the magnetization loop of the FM/AFM bilayer shifts away from the zero field. The magnitude of this shift is known as the exchange bias field H_{EB}. Since the discovery of this phenomenon by Meiklejohn and Bean [62, 63], extensive efforts have been devoted to its full understanding because of both its fundamental interest and its importance in technological applications [71].

Currently, technological interest is focused on the unidirectional anisotropy, or exchange bias field produced in an FM film that is coupled to an appropriate AFM film. Berkowitz and Takano [72] reviewed the experimental characterization and theoretical models for a variety of metallic and oxide film couples. Almost all the reported investigations with insulating AFMs involve the monoxides NiO, CoO, and (Ni$_x$Co$_{1-x}$)O. Typically, the exchange couples with metallic AFM films involve Mn-based AFM films such as FeMn (30–55 at% Mn), which is currently in use in most commercial exchange-biased MR read heads. However, the crystal structure of metallic AFMs often deviate more strongly from cubic symmetry than do the structures of the insulating AFMs.

The simple crystal and spin structure of FeF$_2$ (as well as MnF$_2$) make it a prototype system for understanding the EB phenomenon and for investigating practical problems such

as the unwinding of the magnetic domain state and the annihilation of domains with field cycling.

There have been reports on the growth of Fe on the transition metal fluorides such as FeF$_2$, MnF$_2$, and ZnF$_2$, which have similar crystal and spin structures but very different anisotropies, a crucial parameter to investigate and control the exchange bias phenomenon in an FM/AFM interface [73].

Furthermore, the bilayers consisting of Fe deposited on the (110) crystal face of FeF$_2$ and MnF$_2$ exhibit an unconventional EB phenomenon [66]. The main feature of normal EB is the displacement of the hysteresis loop to fields that point opposite to the applied cooling field. Nogués et al. [66] applied strong cooling fields to the same samples where normal (or negative) exchange bias has been measured in weak cooling fields and discovered positive exchange bias in Fe/FeF$_2$ and Fe/MnF$_2$ systems, that is, a shift to the right of the hysteresis loop ($H_{EB} > 0$). The role of magnetic domains in the ferromagnet in positive exchange-biased bilayers was recently investigated by Kiwi et al. [74, 75]. Indeed, the fundamental physics of exchange bias coupling continue to excite considerable research [76, 77]. The synthetic layout of FM/AFM exchange-biased bilayers and magnetization loops with negative and positive exchange bias is shown in Figure 9.

Perpendicular coupling between the Fe spins and the ordered FeF$_2$ spins was discovered by studying the freezing field dependence of the exchange bias in Fe films on (110) and (100) FeF$_2$ surfaces [58]. Similar perpendicular anisotropy was also found in uniaxial FeF$_2$–CoPt heterosystems [78, 79].
Figure 9. Schematic drawings of the crystal structure of FeF$_2$ and FM/AFM exchange-biased bilayer structure where the crystalline orientation of the AFM layer is reflected in the periodic alternating pattern of three rows. Scheme of the FM magnetization loops with negative and positive exchange bias observed in the exchange-biased structures with AFM fluoride.

Although the perpendicular anisotropy is strongly related to the domain configuration at the FM/AFM interface, the spin wave excitation also plays a crucial role. For instance, Mössbauer effect studies of Fe(110) surfaces covered by MnF_2 show that surface magnetic effects persist for at least 10 monolayers of the (110) Fe sample below T_N, indicating that the classical framework of spin wave models must be taken into account [80].

5.3. Fe and their Alloys on Other Fluorides

Several studies have demonstrated that crystalline thin films of ferromagnetic metals and alloys can be grown on LiF crystal substrates.

At the beginning of the 1970s, different groups in the former Soviet Union worked on the structural, magnetic, and magnetooptical properties of Fe—Co and Fe—Ni alloy thin films, as well as on double-layer ferromagnetic films, deposited on LiF crystal substrates, but many of these references are difficult to access [81–83]. According to these reports, the ferromagnetic thin films have good crystal quality and exhibit magnetic properties similar to those of the bulk material. Detailed information on the interfacial chemistry is not available in these studies since all the thin films that were described have a thickness of several tens of nanometers.

More recently, X-ray rocking curves and transmission electron microscopy analyses have been used to show that the epitaxial growth of some cubic metals such as Ag, Al, Cu, Cr, Fe, V, and Mo on rock salt substrates is improved markedly by covering the air-cleaved rock salt with a LiF intermediate layer [84]. Also, the structural properties of ferromagnetic Fe—Pd and Fe—Pt alloy thin films on LiF crystals are improved significantly in comparison to MgO crystals and glass substrates [85].

In a recent work, epitaxial (100) Fe films grown on the cleaved LiF substrates present unidirectional anisotropy and displaced hysteresis loops explained by a possible interfacial antiferromagnetic layer between the film and the substrate [86].

Surprisingly, there have been only a few reports on the growth of Fe and its alloys on other fluorides, except $(Fe_xZn_{1-x})F_2$, which is an Ising antiferromagnet commonly obtained using coevaporation of FeF_2 and ZnF_2 sources.

McChesney et al. [87] have studied the epitaxial thin films of $(Fe_xZn_{1-x})F_2$ grown on $MgF_2(100)$ substrates by coevaporation of FeF_2 and ZnF_2 sources. Such $(Fe_xZn_{1-x})F_2$ single-crystal thin films with fixed Zn concentration exhibit high quality and were used to study the magnetic phase diagram of dilute magnets. Shi et al. [88] have used $(Fe_xZn_{1-x})F_2$/Co bilayers grown on MgO(100) substrates to demonstrate that antiferromagnetic–ferromagnetic interface exchange bias can be controlled by diluting antiferromagnetic FeF_2 with nonmagnetic ZnF_2. In particular, a neutron scattering study of the random-field Ising film $Fe_{0.5}Zn_{0.5}F_2$ near the percolation threshold has been performed [89, 90] and modeled [91, 92].

It is worth noting that during the last 20 years dilute antiferromagnetic systems such as $(Fe_xZn_{1-x})F_2$ and $(Fe_xMn_{1-x})F_2$ have been extensively used as model systems to study the spin dynamics and phonon relaxation associated with local magnon modes [93–99].

5.3.1. Fe/Fluoride Multilayered Films

The interfacial chemistry between Fe and the fluorides was recently investigated in Fe/MgF_2, Fe/CaF_2, and Fe/LiF multilayered thin films and granular systems. In contrast to the interface between Fe and MgF_2 and CaF_2, which is markedly abrupt at relatively high temperatures under UHV, the Fe/LiF structures exhibit interface mixing and compound formation.

Ferromagnetic 3D metal/fluoride structures are commonly obtained by alternating deposition in conventional UHV evaporation systems as well as by codeposition using UHV evaporation or radiofrequency (RF) sputtering.

The interfacial phenomena of ferromagnetic Fe and nonmagnetic fluoride insulators (LiF, CaF_2, and MgF_2) have been investigated by means of Mössbauer spectroscopy, ferromagnetic resonance, and magnetization measurements [22, 100–102].

Kita et al. [22] investigated multilayered thin films of Fe and fluorides (CaF_2, LiF) produced by UHV electron beam evaporation. They found that mixing occurs at the interfaces, forming imperfect compounds. Mössbauer studies show that Fe and the fluorides are mixed at their interface and confirm the presence of ionic Fe atoms at the interfaces with hyperfine field contributions similar to that of FeF_3. The chemical mixing is more pronounced at the Fe-on-LiF interface than at the LiF-on-Fe interface. Unidirectional anisotropy due to an exchange anisotropy in both Fe/CaF_2 and Fe/LiF is also observed in both multilayered thin films. It is suggested that exchange anisotropy is due to magnetic exchange coupling between ferromagnetic and antiferromagnetic parts in the films, that is, the presence of an antiferromagnetic layer. The thickness of the antiferromagnetic layer was estimated to be less than 4 nm, which is the thickness of a fluoride layer.

Differently from the Fe/LiF, the Fe/MgF_2 interface is chemically stable and enhancement of the hyperfine field was observed in Fe/MgF_2 multilayered films deposited on Kapton and Si(111) wafer substrates [102]. The enhancement of the hyperfine field indicates that the fluoride causes a large electronic and magnetic modulation at the interfaces. Multilayer structures are clearly observed in films with Fe layer thickness greater than 3 nm, whereas with Fe layer thickness less than 2 nm a granular-like structure appears to be present in these films. The Fe atoms form clusters small enough to exhibit superparamagnetic characteristics. It is worth noting that this island structure in the Fe/MgF_2 is responsible for the tunneling magnetoresistance found in the same system [103].

5.3.2. Fine Magnetic Particles in Fluoride Films

Large spin-dependent tunneling magnetoresistance (TMR) in insulating nanogranular systems consisting of metallic ferromagnetic particles embedded in an insulating host was first found in Co—(Al—O) by Fujimori et al. [104, 105] and since then TMR has been investigated for many kinds of insulating nanogranular systems [106]. These granular films are easily obtained in systems consisting of a combination of a ferromagnetic 3D metal (such as Fe, Co, and Ni) and an oxide that has a large heat of formation. Fluorides such as MgF_2, BaF_2, and CaF_2 have also a large heat of formation

and are chemically stable. Some nanogranular structures have already been obtained such as Fe—(Mg—F) [107, 108], Co—(Mg—F) [108], and (Fe—Co)–(Mg—F) [109] films.

Granular thin films composed of Fe or Co metal or Fe_xCo_{1-x} alloy and MgF_2 have been investigated by XRD and transmission electron microscopy (TEM) which confirm the nanogranular structure consisting of bcc Fe or Fe—Co alloy and network-like crystalline Mg—F with MgF_2 intergranules. The largest value ever reported in insulating nanogranular TMR thin films has been obtained in the FeCo–(MgF) system [109]. This large TMR effect is attributed to spin-dependent tunneling associated with superparamagnetic Fe or FeCo nanogranules separated by tunnel barriers consisting of MgF insulating intergranules. More recently, large tunneling magnetoresistance effects of Co clusters embedded in a MgF_2 matrix have been reported [110]. A possible explanation for the enhanced spin polarization of the tunneling electrons is the dominated d-electron tunneling due to Co(3d)–F(2p) hybridization.

6. FINAL REMARKS

The objective of this review was to resume the state of the art of research on the metal/CaF_2/Si heteroepitaxial growth with a short incursion into other fluoride systems. The feasibility of several MIS structures shows that this area of research has gained maturity. The heteroepitaxial growth of CaF_2 thin films on Si is clearly dominated as shown in a number of publications. Although still not completely understood, it has been shown that the electrical properties and epitaxial relations of CaF_2/Si(111) depend on the growth conditions. Many research groups have used CaF_2/Si(111) as a prototypical system for studying the atomic and electronic structure at the ionic/covalent interface. The problem now is found centered in the successful deposition of metal films on CaF_2. Using the newly available deposition and characterization techniques, an effort has to be made to study the different metal/CaF_2 interfaces. These interfaces clearly influence the quality of the heteroepitaxial structures and films as well as their transport, magnetic, or optical behavior and quality. Useful and attractive devices using the properties of CaF_2 will be realized when the interfacial atomic structure and chemical reactions can be controlled on the atomic level. The future for these types of MIS and multilayer structures seems as interesting as ever.

GLOSSARY

Epitaxial growth Deposit of a crystalline layer onto a single-crystal seed layer, maintaining the spatial coherence at the interface between crystal lattices.

Epitaxial relationship Preferential parallelism of the lattice planes of two crystal structures spaced by an interface.

Exchange bias Exchange interaction across the interface between antiferromagnets and ferromagnets with pinning of the ferromagnet magnetization.

Field cooling Magnetization procedure in which a magnetic field is applied when the sample is cooling down.

Giant magnetoresistance Phenomenon associated with an appreciable decrease in the resistance when a applied magnetic field, strong enough to magnetically saturate the system, brings the magnetization of all magnetic entities into alignment.

Magnetic anisotropy Preferential alignment of the magnetization along a certain direction of a material under a given magnetizing field.

Superexchange interaction Long-range indirect magnetic coupling between localized magnetic moments mediated by atoms with pairing of electrons.

Superparamagnetism Magnetic behavior observed above a certain blocking temperature in the systems consisting of non-interacting single-domain magnetic particles with diameters below a certain critical size.

Zero-field cooling Magnetization procedure in which the magnetic field is switched off when the sample is cooling down.

Focused Ion Beam Nanofabrication

Andrei V. Stanishevsky

University of Alabama at Birmingham, Birmingham, Alabama, USA

CONTENTS

1. INTRODUCTION

The development of fabrication processes of materials and devices at nanoscale is one of the major challenges of nanotechnology. Among the nanofabrication techniques available, focused ion beams (FIB) have become a popular tool for surface modification of materials and functional structure prototyping at the micro- and nanoscale. Focused ion beams have a diameter less than 1 μm and are produced by using electrostatic lenses to focus the image of a point source, usually a liquid metal ion source, onto the substrate, and to deflect it in a precise fashion [1]. A schematic representation of a FIB apparatus is given in Figure 1.

FIB systems producing a few picoamperes ion beam probes with a diameter down to 100 nm were reported as early as the 1960s. An imaging resolution of 50 nm was demonstrated in 1974 with the ion systems based on gas phase field ionization sources. The liquid metal ion source was invented in 1975. Hitachi pioneered the use of FIBs for integrated circuit cross-sectioning for failure analysis in 1985 [1]. According to Melngailis [2], there were about 35 FIB machines in the world by 1986, and now the number is several hundred.

The past decade has seen many advances in FIB tools including improvements in both ion optics and tool automation. Ion beam optics has improved rapidly to the point where the beam size and profile are no longer the limiting factors in many applications of FIBs ranging from failure analysis to prototype nanodevice manufacturing. Most FIB equipment on the market today uses gallium liquid metal ion sources (LMIS) with the service life of up to 2000 μA-h and accelerating voltages in the range of 10–50 kV. Other LMISs have typically much shorter service lives, and they include AuPdAs, Si, Co, $Au_{77}Ge_{14}Si_9$, $Co_{36}Nd_{64}$, etc.

Over the last two decades, focused ion beams have emerged as one of the important tools for both scientific research and industrial applications. Commercially available FIB systems have reached resolutions close to electron beam systems (about 5 nm), but micro- and nanoengineering with FIBs is a sequential process. It is therefore much slower than the parallel processes of optical or electron beam lithography and it should not be expected to provide a technology for mass production of nanosize structures and devices any time soon. FIB technology has already found applications in the semiconductor industry as a complement to other processes for certain operations on individual chips on the wafer such as failure analysis, rewiring, and defect repair. FIB will find, probably, its niche in the fabrication of small series of specific nanoscale devices—for example in a research environment—or in customization of unique devices. Examples of current FIB applications include micro- and nano-optical components, samples for transmission electron microscopy, scanning microscopy probes, microtools, semiconductor devices, surface nanodevices, and three-dimensional (3D) nanostructures and components of microelectromechanical systems.

Principles of focused ion beam equipment design, generation of ion beams, and the method applications are thoroughly discussed in numerous reviews [1–10]. Several other reviews outline specific applications of FIBs for microfabrication [11], nanomachining [12], two-dimensional and three-dimensional shapes, ion lithography, and the preparation of site-specific specimens [13].

FIBs are used mostly for defect repair of optical and X-ray masks, circuit modification, device modification, failure analysis of circuits and devices, circuit and device cross-sectioning, transmission electron microscopy (TEM) sample preparation, ion microscopy, secondary ion mass spectroscopy, and experiments on direct maskless implantation of devices. Since the incident ions produce both
Figure 1. A schematic of a focused ion beam column. A photograph of a gallium liquid metal ion source and an example of beam raster are shown in inserts.

secondary electrons and ions, images formed from either are possible. FIB provides results superior to other techniques in fabrication of cross-sections in materials and devices for failure analysis. Figure 2 gives an example of the image of the FIB polished cross-section in a Cu-metallized test structure in comparison with the same area after mechanical polishing. Grain structure of Cu layer is clearly visible in FIB polished cross-section. An example of FIB fabricated lamellae for TEM studies is shown in Figure 3. The thickness of the lamellae of less than 40 nm can be achieved.

The main applications of FIB processes today are mostly concerned with local ion sputtering or modification of the material. The sputtering yield is usually 1–3 atom/ion. A number of factors determine the micromachining results, including ion beam diameter, current and mass, angular effects caused by edges or depth variations across the
Figure 2. FIB secondary electron images of the cross-sections of copper plated electron beam patterned PMMA. Top: cleaved and mechanically polished. Bottom: the same area after FIB polishing.
Figure 3. FIB fabricated lamella for TEM studies at 60° tilt (top) and top views (bottom). The lamella's thickness is between 60 and 100 nm.

pattern, and redeposition of sputtered material. The ion beam diameter determines the resolution of the ion-milled structure. To enhance the sputter yield by a factor between 2 and 30 and to suppress redeposition of sputtered material, an approach called FIB gas assisted etching (GAE) is often used.

FIB is a very useful, ultra-high-vacuum compatible tool for a maskless, direct, and local implantation of dopant ion species in semiconductors. Due to the small lateral straggling, the still increasing resolution in the further development of the instruments and the flexibility of the writing schedule programming for a step and repeat mode FIB can gain importance in the field of nanoscale semiconductor devices.

This chapter is not intended to describe FIB principles and equipment in detail but rather to show current results and potential opportunities for FIB fabrication at the sub-100 nm scale. The FIB fabricated structures presented in photographs in this chapter were prepared by the author using a Micrion FIB-2500 machine capable of operating at up to 50 kV accelerating voltage and with a Ga^+ ion beam diameter down to 5 nm.

2. FOCUSED ION BEAM (FIB) SPUTTERING AND IMPLANTATION AT NANOSCALE

2.1. FIB Implantation

FIB implantation takes place in conditions of much higher local ion currents than conventional implantation. Compared to the fundamental meaning of the damage production by ion irradiation, however, there exist only a few systematic investigations concerning high current density irradiations with a focused ion beam. For nanoscale patterning the appropriate level of interaction between ions and solids is translated toward low dose effects. In this case local defect injection now plays a major role due to the small thickness of active layers used, and to the high sensitivity of many materials and structures to ion bombardment.

The dramatic changes of magnetic, ferroelectric, optical, electric, and mechanical properties of FIB implanted materials have been observed. The effects of a high ion current during the FIB process on the implant distribution profiles, defect formation and annealing, chemical composition modification, and phase transformations are not studied in detail, especially at the sub-100 nm scale. It is obvious that the lateral straggling effect during implantation is a limiting factor in nanoscale applications. Some approaches to fabricate functional nanoscale FIB implanted structures will be given in Section 4, and this technique has yet to be optimized.

Shinada et al. [14] utilized FIB optics in single-ion implantation, which enables one to implant dopant ions one-by-one into a fine semiconductor region until the necessary number is reached. The authors have optimized the process in order to improve the controllability of dopant atom position to within 100 nm. The average aiming precision of 60 nm was achieved in one-by-one ion implantation of 60 keV Si ions into CR-39 (a fission track detector). Mitan et al. [15] have demonstrated formation of $CoSi_2$ lines using FIB implantation of 200 keV As^{2+} ions through the surface $Si/Co/SiO_2$ layers into the underlying Si substrate followed by the removal of the surface layers and annealing. The authors believe that the linewidth below 100 nm can be achieved.

Most FIB machines operate with Ga^+ ions at accelerating voltages of 30–50 kV, and this results in implantation and damage depths of less than 100 nm. This surface layer becomes structurally and chemically modified. For example, the exposure of a ferroelectric $Pb(Zr,Ti)O_3$ (PZT) material to the 50 kV Ga^+ ion beam dramatically changes the composition of a surface layer [16]. Auger electron spectroscopy reveals ~26–57 at% Ga in the 5 nm thick surface layer depending on ion dose. Oxygen concentration is significantly reduced when compared with a nondamaged film, while lead is practically lost. The composition of the surface layer at the dose of 6.24×10^{16} ion/cm^2 was found as $Ga_{0.53}Zr_{0.13}Ti_{0.21}O_{0.13}$. The annealing increases the amount of oxygen to 50–60 at%. The distribution of gallium in the damaged layer is not uniform. It was observed that gallium has a strong tendency to segregate in nanosize droplets (<50 nm) on the PZT surface during FIB milling. The FIB exposed 100 nm thick PZT films were found to lose the ferroelectric properties becoming dielectric after thermal annealing.

When a 50 kV Ga^+ FIB was applied to bulk diamond and so-called "tetrahedral amorphous carbon" (ta-C) films, the formation of Ga-rich amorphous graphitic layer was observed, as well as strong surface swelling due to the Ga implantation and substrate phase transformations [17]. Surface swelling is a common effect during conventional ion implantation. Huey and Langford [18] observed such an effect during low dose FIB irradiation of silicon surface. Surface protrusions with a height as small as 1 nm can be fabricated in an ordered manner. Dotsch and Wieck [19] have shown that the insulating lines in GaAs can be created using 100 kV Ga^+ FIB implantation. Roshchin et al. [20] noticed that thin magnetic films are extremely sensitive to ion irradiation even at 10^{12} cm^{-2} ion doses although Xiong et al. [21] found no effect of ion-induced damage on the magnetic properties of the magnetic nanoelements.

2.2. Sputtering

The majority of FIB applications employ physical sputtering of a substrate material to form either trench or protrusion patterns with various outlines. The precise shape of the sputtered region produced by FIB depends on the size of the region, the ion dose, the profile of the beam, and the beam scan parameters (scan strategy, time the beam is present in a spot or dwell time) [2, 4, 7]. The slope of the sidewalls of a sputtered region depends on the inverse gaussian profile of the ion beam current density. Both the speed and direction of scan are found to play a role in determining the results of material removal. The redeposition of a material sputtered from the bottom of the milled region causes a distortion of the sidewall profile. In a case of a narrow sub-100 nm groove or hole the redeposition effects will be the most important for the sidewalls of the structure. Furthermore, the reflected ions on the sidewalls (glancing incidence angle) will also have an effect on the ion-milled structure. At the base of the nearly vertical sidewalls a deep trench is formed (self-focusing effect) [2, 7]. Other observed effects such as an enhancement of the sputtering yield with increasing ion incident angle, precipitation of implanted species, and surface morphology changes can also play a significant role at nanoscale.

Campbell et al. [12] produced 60 nm wide and 120 nm deep trenches with nearly vertical sidewalls in Si using a 30 kV Ga^+ FIB process. Damage of silicon consisted of amorphization up to the depth of 80 nm, and possible gallium implantation up to depth of 50 nm according to TEM studies. Gallium precipitation was suggested at higher ion doses. Gierak et al. [5, 22] designed a 30 kV Ga^+ FIB machine and demonstrated a ~8–10 nm trench width in $AlF_3/GaAs$ multiplayer samples and a hole diameter down to 10 nm in 10 nm thick SiC membranes. Sub-100 nm FIB sputtered patterns in both diamond and ta-C films were prepared by Stanishevsky et al. [17, 23, 24]. Using the lowest available beam current (2–5 pA) and an optimized beam scanning procedure, submicrometer tips with heights of ~800 nm and radii of ~40 nm at the top were milled in both a 1 μm thick ta-C film and chemical vapor deposition (CVD) diamond microcrystals. A minimum size of the milled through trench of ~30 nm has been achieved at these

ion currents in 1 μm CVD diamond crystallites. A beam diameter of ~10 nm was estimated for the beam current of 3 pA. It was found that the effects of material swelling and redeposition hinder the trench formation at short dwell times. Similar trench sizes in ta-C film have been reported. An example of a narrow trench FIB milled in a ta-C film is shown in Figure 4. The depth of this 20 nm wide trench was estimated at ~400 nm.

Taniguchi et al. [25] and Russell et al. [26] have demonstrated the FIB fabrication of field emitter tips with a radius of less than 100 nm in a diamond crystal by sputtering the area around the central mesa. Olbrich et al. [27] proposed the FIB milling procedure to fabricate high aspect ratio diamond tips for atomic force microscopy. Kuball et al. [28] used FIB sputtering for the fabrication of GaN nanopillars. GaN pillars as small as 20 to 30 nm in diameter were fabricated. Using secondary electron imaging, the quality of the GaN pillars was investigated as a function of the gallium ion beam current used for the sputtering. Ion beam currents as low as 1 to 4 pA are needed to fabricate such a nanometer-size GaN structure, which makes the process very long.

Besides the grooves and pillars, it is also possible to fabricate metal wires with a nanosize width by the direct sputtering of a metal layer as shown in Figure 5. The 300 nm thick Ni wires with widths of ~80 nm and lengths of several hundred micrometers have been made by sputtering the Ni film on SiO$_2$ substrate using an optimized FIB scan procedure. The gap separating the nanowire from the remaining Ni film was found to be insulating despite the ion induced damage.

The ability of FIB to form narrow grooves in a thin metal layer was investigated as a key approach in the fabrication of novel structures for observation of such phenomena as single electron tunneling and giant magnetoresistance. Using a finely focused beam, narrow line patterns with narrow spacings were delineated on a Ge/nitrocellulose double layer resist [29]. It was shown that the line spacing and the length are limited mainly by the process of

Figure 5. Direct FIB patterning of nanowires with a width down to 80 nm in 300 nm thick Ni film on quartz.

peeling off the Ge layer during the FIB sputtering. FIB was applied to form narrow grooves in magnetic and nonmagnetic metal films using Ge/nitrocellulose double layers as self-development resist and nanopatterns were formed to reveal the usefulness of FIB direct write processes for the fabrication of magnetic microdevices. To show the effectiveness of the present method for fabricating nanoscale grooves using a finely focused beam, 40 or 60 nm wide and 7.8 μm long grooves with a spacing of 500 nm were fabricated. Of course, much smaller structures can be currently fabricated as demonstrated in Figure 6. Nanogaps and nanobridges with widths down to 20 nm have been fabricated in Ni/Cu two-layer thin film heterostructures on SiO$_2$. The electrical

Figure 4. FIB milled 20 nm trench in ta-C film. Two areas of 200 nm depth were originally milled, and the trench connects these areas. The ion dose used for the trench formation was a priori found to provide a depth of ~400 nm. The spread of the redeposited material is visible at the both ends of the trench.
Figure 6. Nanobridges in Ni(10 nm)/Cu(50 nm) film on SiO$_2$/Si substrate. The bridge width is ~20 nm.

properties of such structures have not yet been investigated to date. It is unclear if there are effects of ion implantation, damage, and precipitation of implanted atoms on the electric properties of such nanostructures.

The observations of Ga precipitation in the FIB fabricated structures have been made [16, 30]. This effect may have serious consequences in FIB prototyping of nanostructures. In recent experiments [30], a focused ion beam was used to implant an array of spots in a silicon host. The FIB was programmed to inject a 1 mm^2 area with ion doses of 2×10^{10} ions/spot at a spot spacing of 10 μm. It was shown that the regions around the edges of the drilled holes do contain fine Ga precipitates with a size of $\sim$5 nm. This proof-of-principle experiment conclusively demonstrated that the FIB can produce ordered spots on a substrate and that it is even possible to produce precipitates around the edges of the ion-drilled regions. Another observation of Ga precipitation during the FIB milling of a doughnut-like trench in quartz is shown in Figure 7. Relatively large (70–100 nm) droplets of Ga are formed along the edges of the sputtered region in some cases.

The effect of the ripple formation during the FIB sputtering is observed on tilted surfaces [24, 31]. This effect may become important when prototyping three-dimensional nanostructures, for example, optical lenses and emitter tips. Figure 8 shows the surface morphology changes of a ta-C film FIB sputtered at 60° incident angle. The height (30–40 nm) and period (150–400 nm) of the ripples are in the nanoscale range, and they depend little on the ion beam scan procedure. Understanding ripple formation on surfaces created by ion bombardment is of both fundamental and technological interest. Although there is a general consensus about the evolution of ripple structure as being due to competition between surface roughening introduced by sputtering and smoothing created by various processes, all the ripple formation mechanisms are yet to be identified. Candidates include pure thermal diffusion, viscous flow,

Figure 8. FIB secondary electron (left) and atomic force microscopy (right) images of ripples formed on the surface of ta-C film during 60° tilted FIB irradiation. The beam scan parameters were the same for all three areas in left image. The ion dose increases from the top to bottom area.

ion-enhanced or -inhibited diffusion, and preferential sputtering without actual mass movement.

The redeposition of sputtered material during the FIB patterning process seems to be the most important when dealing with nanosize structures. One problem associated with this effect is the need for much higher ion doses to fabricate, for example, a sub-100 nm diameter hole with certain depth when compared to a few micrometer diameter hole of the same depth. This is demonstrated in Figure 9. In this case, square 1-μm wide through apertures were FIB milled in a 2 μm thick silicon membrane with increasing ion doses. The image contrast variations at the edges of the apertures appear when the dose increases indicating the formation of a redeposited layer on the sidewalls. When the ion beam breaks through the membrane, the aperture width

Figure 7. Gallium nanoparticles formed around a 50 keV Ga$^+$ FIB milled 100 nm deep doughnut-like trench in quartz.
Figure 9. Redeposition effect of sputtered material onto the sidewalls during the membrane fabrication in 2 μm thick Si substrate. The ion dose increases from (a) to (i). The ion beams breaks through the substrate in the area (f).

is much smaller than expected (Fig. 9f). It requires an ion dose twice as high to remove the redeposited layer and to reach the size close to preset one (Fig. 9i). The fabrication of smaller through apertures requires even larger ion doses and, respectively, a very long process time. The redeposited material is much more difficult, if possible at all, to remove in the case of deep nanowide holes and trenches in a bulk substrate.

The diameter of the through apertures can be controlled by using a controlled endpoint termination technique. In this technique a Faraday cup is placed underneath the membrane and the transmitted ion current is measured *in-situ* during FIB milling. The milling can then be terminated, by blanking the ion beam, once a defined ion current is passing through the emerging hole in the membrane. The ordered arrays of through apertures with diameters down to <20 nm in 500 nm thick gold membranes have been successfully fabricated [32]. The size of such apertures can be further reduced employing the interesting effect recently described in [33, 34]. According to the authors, when a whole membrane containing 60 nm nanoholes is additionally irradiated by 3 keV Ar^+ ions, the diameter of a nanohole reduces to nanometer size until it collapses. Figures 10 and 11 demonstrate this effect for a case of additional irradiation of the area containing the arrays of FIB fabricated nanoholes in Si_3N_4 coated gold membrane with the same 50 kV Ga^+ FIB. One can see the shrinkage of the 100 nm holes down to 30 nm diameter after low dose irradiation (Fig. 10). Surprisingly, much larger holes shrink in the same way (Fig. 11). This cannot be currently explained by the theory proposed in [33, 34], and further investigations of this effect are of great interest. The shape of the initially cylindrical cross-section of the hole can be changed during the hole shrinking, and this can affect the nanoscale optical properties of such structures [32].

2.3. FIB Gas Assisted Etching

The introduction of a reactive gas can enhance or reduce the sputtering rate of a particular material and provide higher selectivity between different materials. The redeposition

Figure 11. The effect of FIB low-dose irradiation of a 30 μm × 30 μm area of a 400 nm thick Si_3N_4 coated gold membrane on the changes of a 300 nm diameter through holes. Left image—as-milled holes, Right—after the low-dose exposure. Note the contrast change inside and around the holes.

effect can also be substantially reduced. The principle of ion beam gas assisted etching (GAE) is to adsorb suitable precursor gas molecules on a substrate and expose them to an ion beam. The ion beam causes a reaction between the adsorbed gas molecules and the substrate atoms, forming volatile compounds and thus an enhanced removal of material. The gases used in GAE applications should not react spontaneously with the substrate. Reactive gases commonly used in a FIB GAE processes are XeF_2 for SiO_2, Si_3N_4, and W etching, Cl_2 and I_2 for aluminum and silicon, O_2 for photoresists, H_2O for diamond, and Br_2 for chromium. Other gases or gas mixtures are under investigation [35, 36]. There are currently no reports on the application of FIB GAE to the fabrication of sub-100 nm structures. One reason for that is the requirement of a very short time period (dwell time) of the beam interaction with the adsorbed gas molecules to produce a greater enhancement of the sputtering rate. It has been shown that the yield of the reaction depends linearly on the surface coverage with gas molecules. When the focused ion beam moves along the surface, it consumes the adsorbed molecules, and a certain time (often called the "refresh time") is needed for the adsorbed layer to recover. If the size of the FIB exposed area is very small, for example, for making a nanohole, the beam is present in this area for too a long time or returns to the same spot quickly. This prevents formation of the adsorbed layer of the gas molecules, therefore diminishing the effect of GAE. Possibly only when the pattern size is large (or when a relatively big number of nanostructures is patterned simultaneously) can one benefit from the FIB GAE.

3. THREE-DIMENSIONAL NANOSTRUCTURES

The patterns of nanosize trenches or protrusions produced by the FIB sputtering give one example of possible three-dimensional nanostructure fabrication in a FIB process. Two other approaches to fabricate nanoscale structures using FIB induced deposition and FIB irradiation combined with chemical etching are described.

3.1. FIB Induced Deposition

In the case of FIB induced deposition, the incident energetic ions cause a fragmentation of the adsorbed molecules of a suitable gaseous compound leaving behind a deposit. FIB induced deposition enables the fabrication of complex three-dimensional shapes with overhanging features. A variety of gaseous precursors can be used, although few were utilized to date. FIB induced deposition has been used to fabricate layers of W, Au, Pt, Cu, C, and SiO_2. An example of the SiO_2 pillars formed by FIB deposition using TEOS and O_2 as the precursor gases is shown in Figure 12. Even at the smallest beam diameters, the size of the deposited structures is relatively large. The size of the deposited structures can be reduced by the FIB trimming using physical sputtering process as shown in Figure 13, but this is not always convenient.

The most successful work in truly nanoscale 3D direct deposition has been done by Matsui et al. [37]. This group fabricated 80 nm spirals of up to several micrometers tall using 30 kV Ga^+ FIB induced carbon deposition from an aromatic hydrocarbon precursor. Microcoil, drill, and bellows with 0.1 μm dimensions were also fabricated. That three-dimensional nanostructure fabrication process is illustrated in Figure 14. In this process, the beam is scanned at digital mode. First, a pillar is formed on the substrate by fixing a beam position. After that, the beam position is

Figure 13. SiO_2 pillar with the tip diameter less than 100 nm after FIB trimming.

moved within a diameter of a pillar and then fixed until the deposited terrace thickness exceeds an ion range, which is a few tens of nanometers. This process is repeated to make three-dimensional structures. The key point to make three-dimensional structures in this approach is to adjust a beam-scan speed to avoid the sputtering of the deposited terrace, while providing the conditions for the growth of the overhanging part of the terrace. The growth conditions in x and y directions are controlled by ion beam deflectors. The growth of the z direction is determined by a deposition rate; that is, the height of structure is proportional to the irradiation time when the deposition rate is constant.

Figure 12. FIB induced deposition of SiO_2 nanopillars using tetra-tetraethylorthosilane (TEOS) and oxygen.
Figure 14. Fabrication process for three-dimensional nanostructure by FIB induced deposition proposed by Matsui et al. [37].

It was concluded from the experimental results that FIB direct write deposition processes may become interesting tools for the fabrication of micro- and nano-systems in the field of electronics, mechanics, optics, and biology.

FIB deposition of other materials, particularly W and Pt, has not yet been realized to fabricate sub-100 linewidths [38]. Direct write metallization is an important approach for circuit modification and prototyping. It was proposed that the FIB induced deposition starts with the nucleation of nanoscale metal deposits scattered over the substrate surface. Despite local impacts of the ion beam within the irradiated area of the substrate the localization of the nucleation spots is not correlated to the scan path of the ion beam. The nanoscale tungsten particles preserve their position and typical shape during further deposition. Only after merging of the particles into a contiguous tungsten layer does the second regime of growth characterized by deposition of tungsten on a tungsten surface set in. In this regime the deposition process is determined by the total ion dose and the average current density the sample was subjected to.

There is a need in more theoretical studies of FIB induced deposition for nanoscale structures. The effect of much faster growth of a deposit inside the trenches than on a flat surface is commonly observed in FIB induced deposition, but the comparison of the composition and the properties of the deposits in these two situation has not yet been reported. This effect is demonstrated in Figure 15. The substrate containing FIB sputtered narrow grooves was first coated with a ~500 nm thick SiO_2 layer, which also filled the whole depth of the grooves. After that, the FIB sputtering was used again to mill narrower grooves into the FIB-deposited SiO_2 layer. The ~150 nm thick layer of tungsten was finally deposited. The tungsten deposit filled also the whole depth of the grooves, resulting in the ~50 nm feature size at the groove tip. Although this structure outlines the possible nanoscale design of FIB fabricated nanovias and interconnects for nanodevice prototyping, the properties and stability of these nanodeposits have yet to be investigated.

Another major problem in FIB induced deposition is the presence of the ion beam tail. This leads to a substantial deposition around complex patterns as shown in Figure 16. Although this tungsten microheater is not a nanostructure, it indicates the common problem of excessive deposition in unwanted areas in the FIB induced deposition process. One approach to overcome this problem is to use FIB GAE with suitable reactive gases to clean the fabricated structure as shown in the bottom picture in Figure 16. Other precursor compounds and beam scan strategies also have to be investigated.

3.2. Etching of FIB Exposed Surface

It is well known that a high concentration of p^+ doping in Si drastically reduces its etch rate in certain chemical etchants such as KOH and hydrazine. The FIB irradiation of selected regions on Si substrate leads to the same result. The exposure to Ga^+ FIB with ion doses $>10^{15}$ cm^{-2} of selected

Figure 15. FIB induced deposition of SiO_2 dielectric layer and tungsten-plug in nanovias.
Figure 16. Ion beam tail effect on the deposited pattern. Top: as-deposited tungsten meander microheater; Bottom: the same structure after GAE cleaning.

areas reduces the etching rate of such areas to a negligible value when compared to bulk Si (100). This approach has been utilized to fabricate various micro- and nanoscale three-dimensional structures. Koh et al. [39] demonstrated formation of ordered arrays of nanopyramids by wet etching of a 60 kV Si^+ FIB irradiated Si (100) surface in a hydrazine solution for 15 s at 115 °C. An example of similar arrays initially patterned by 50 kV Ga^+ FIB with an ion dose of $\sim 1 \times 10^{15}$ cm^{-2} and subsequently etched in 10% KOH solution at 80 °C is shown in Figure 17. The thickness of the insoluble layer in Si is $\sim$100 nm at these FIB parameters. When a much larger ion dose is used to irradiate the substrate this results in a pattern similar to that shown in Figure 17; the deep holes are formed due to sputtering of the substrate material. The KOH etching removes unexposed material leaving funny three-dimensional structures because the ion-damaged sidewalls of these holes are stable to the chemical etching (see, for example, Fig. 18). The thickness of the walls in such structures depends on the ion species and their energy, the substrate material and the beam scan strategy. Using the described approach many other complex 3D micro- and nanostructures can be fabricated. Figure 19 shows an array of FIB delineated bridges with lengths of $\sim$30 μm. The narrowest bridge has a width of $\sim$100 nm. The bridge with the preset width of 50 nm did not survive the etching/rinsing process. The minimum width of nanocomponents produced in this approach has yet to be determined. Complex shape cantilevers with a width of $\sim$100 nm produced by FIB and KOH etching were also demonstrated

Figure 18. There-dimensional glasslike structures on KOH wet-etched Si, roughly representing damage profile produced by FIB at large ion doses.

[40]. It is possible to create other quite complex structures in such an approach, like gridlike membranes with $\sim$100 nm component width as shown in Figure 20. These structures may have attractive mechanical properties for prototyping micro- and nanomechanical components. However, the contamination of the fabricated structures with Ga or other ion species can be a limiting factor.

FIB induced surface modification can also have the opposite effect and enhance the rates of chemical or reactive ion etching processes depending on the reactive compound. Enhanced etching of FIB exposed InP in HF was observed [41]. The FIB fabricated patterns were applied

to create index coupled feedback gratings in GAInAsP/InP laser structures. The width of the pattern elements was ~100 nm. Koshida et al. [42] fabricated 40 nm wide refractory Mo and W metal lines on Si substrates by FIB exposure of MoO_3 and WO_3 inorganic resists, development, and subsequent reduction in dry hydrogen gas.

Titanium and TiO_2 nanowires for potential chemical sensor applications with lengths up to 100 mm were produced by etching FIB exposed Ti and TiO_2 films on SiO_2 with appropriate chemical solutions. An example of TiO_2 100 nm single-grain wide nanowire is shown in Figure 21.

An interesting approach to produce nanosize channels in alumina membranes was proposed by Liu et al. [43]. The
surface of polished Al was irradiated by FIB followed by anodization of the surface and removal of the remaining Al substrate. It was found that concaves as shallow as a few nanometers can effectively guide growth of the nanochannels to an aspect ration of ~100. A pore size of 20–50 nm seems to be achieved.

4. FUNCTIONAL SUB-100 nm STRUCTURES

A variety of working nanostructures has been produced using FIB sputtering and implantation processes. Formation of narrow grooves is a key process in fabrication of novel structures for observation of such phenomena as single electron and photon tunneling, Coulomb blockade, and giant magnetoresistance. The ability to fabricate nanometer-wide trenches and holes was used to make novel Josephson junction devices [44–47], nanosize shadow masks in silicon membranes [48] to subsequently deposit InGaN quantum dots and quantum wires by metal organic CVD. Ochiai et al. [49] demonstrated wedge emitter fabrication using focused ion beam physical sputtering. The emitter–collector gaps of various widths ranging from 10 to 1000 nm were produced as shown in Figure 22. The formation by FIB sputtering of a nanohole in a metal layer was followed by the chemical etching of underlying SiO_2 to remove the ion induced damage in the emitter structure.

The FIB implantation is increasingly used to fabricate numerous magnetic nanostructures [20]. It was found that thin magnetic films are extremely sensitive to ion irradiation even at 10^{12} cm^{-2} ion doses. Reducing the lateral dimensions of patterns in magnetic materials to the level of certain critical parameters (exchange length, domain wall width, Barkhausen jump length) can lead to new insights into nanomagnetic applications such as ultrahigh density recording.

Figure 22. Fabrication process for a Mo field emitter with a lateral wedge. (a) Sample cross-section of a Mo/SiO_2/Si structure with FIB sputtering for the production of an emitter–collector gap. (b) Subsequent wet etching for the suppression of the structural damage.

Anders et al. [50] have fabricated magnetic nanostructures using focused ion beams to pattern perpendicular media. The perpendicular granular media consisted of a 20 nm $Co_{70}Cr_{20}Pt_{10}$ magnetic film protected by 5 nm of CN sputtered onto a Cr–Ta (1 nm)/Ni–Al (6 nm) underlayer structure grown on glass substrates. Arrays of square islands with sizes ranging from 50 to 730 nm and periods from 70 to 750 nm were fabricated and studied using atomic force microscopy (AFM) and magnetic force microscopy. Small islands with periods of 130 nm are single domain while larger islands show multidomain states similar to the unpatterned film. The smallest islands exhibit a thermal stability far superior to the continuous media (about three orders of magnitude higher). The high thermal stability of the nanoislands can be explained, in part, by a substantial reduction in the demagnetizing fields caused by the FIB patterning.

Similar experiments by Xiong et al. [21] have demonstrated that very high quality magnetic nanostructures can be fabricated by FIB milling even in thin films of soft magnetic materials such as permalloy. No evidence was found for ion-induced damage to the magnetic properties of the nanoelements. The length scales of 100 nm achieved using the FIB fabrication method are suitable for single-domain magnetic devices. This finding allows a high-throughput rate of device prototyping and could even be significant for the future commercialization of certain niches of magnetic nanotechnology and magnetoelectronics.

FIB implantation of B^+ ions into *n*-type doped silicon yields lateral *npn* junctions [51] producing white luminescence. It was found that the actual ion beam size plays only a small role because optical radiation originates from nanoclusters only in depleted regions of about 100 nm in width. These junctions emit light from their nanoscale depletion regions if operated in reverse biased breakdown mode, depending on voltage polarity on either side of the implanted area. Bacher et al. [52] realized luminescent structures based on CdTe/CdMnTe quantum dots using 100 kV, 30 nm Ga^+ ion beam diameter. The maximum of photoluminescence shifts from 1.69 to 1.77 eV with the ion dose increase from 10^{13} to 5×10^{13} cm^{-2}. Kuball et al. [53] fabricated pillars with a lateral size down to 30 nm in GaN/AlGaN heterostructures. Although the larger ($\sim$300 nm) GaN/AlGaN HFETs fabricated by FIB exhibit photoluminescence despite the FIB induced damage, the results for smaller structures have not been reported.

Kondo et al. [54] fabricated Si MOSFETs with a nanoscale channel by changing the effective channel lengths from 27 to 82 nm using FIB implantation and SiO_2 implantation masks with very narrow widths (see Fig. 23), and they have investigated Coulomb blockade phenomena in such structures. Coulomb blockade oscillations were observed in the temperature range from 4.2 to 13 K. Kim et al. [55] used FIB techniques utilizing both lithographic and nanoparticle formation processes to fabricate a single-electron transistor that can operate at room temperature. The results for the drain current as a function of the gate voltage at different source voltages at room temperature clearly showed Coulomb oscillations indicative of Coulombblockade effects. These results indicated that FIB fabricated single electron transistor structures operating at room

temperature hold promise for potential applications in ultrahigh-density memory devices.

Another kind of a nanotransistor structure was proposed by Dotsch and Wieck [19] who defined insulating lines in two-dimensional electronic layers in GaAs using a 100 kV Ga^+ ion beam with a diameter of 30 nm. A lateral so-called in-plane-gate field-effect transistor-like structure was demonstrated.

FIB patterning of thin film multilayer stacks to form ferroelectric PZT capacitor heterostructures was conducted [16, 56] to investigate the effect of scaling on such structures. It was found that the thermally annealed FIB patterned working nanocapacitor (Fig. 24) consists of a dielectric (sidewall layer) and ferroelectric (bulk) parts. The thickness of the sidewall damaged layer is $\sim$5–10 nm. The contribution of this sidewall layer is significant in sub-100 nm structures, and it will affect the results of the measurements of the capacitor characteristics. The volume of the dielectric part in a 70 nm capacitor reaches $\sim$50%, and the actual lateral size of the ferroelectric part is $\sim$50 nm.

Nanofabrication of charge density wave (nano-CDW) sub-100 nm structures by applying a hydrogen focused ion beam to the one-dimensional conductor, molybdenum blue bronze ($K_{0.3}MoO_3$) crystal [57, 58], was reported. The nano-CDW
Figure 24. FIB   fabricated   Pt/La(Sr$_{0.5}$Co$_{0.5}$)O$_3$/Pb(Nb$_{0.04}$Zr$_{0.28}$Ti$_{0.68}$)·O$_3$/La(Sr$_{0.5}$Co$_{0.5}$)O$_3$/Pt/SiO$_2$ ferroelectric nanocapacitor structure with a lateral size of 70 nm (top) and its piezoelectric hysteresis loop (bottom).

structures show negative resistance above the threshold fields, which monotonously increased with decreasing temperature. The one-dimensionality of electrons has been confirmed by negative magnetic resistance, whose magnitude reduces with decreasing dimensionality.

Several functional sensor nanostructures have been also proposed. Sandhu et al. [59] fabricated bismuth Hall-effect nanoprobes by FIB trimming with dimensions of 120 × 120 nm for direct imaging of magnetic materials using scanning Hall probe microscopy. These nanoprobes were used for room temperature imaging of crystalline garnet films and strontium ferrite permanent magnets. The Hall coefficient and magnetic field sensitivity of the Bi nanoprobes were 3.3×10^{-4} $\Omega\,G^{-1}$ and 7.2 G/Hz$^{1/2}$, respectively, at driving current of 40 μA. Puers et al. [60] fabricated a miniature "Pirani" pressure sensor. Although the minimum lateral dimension of that sensor is ∼1 μm, it is worth mentioning this device here. The sensor's working principle is that of Pirani-type vacuum sensors. However, unlike most Pirani sensors, the working range of the device is around atmospheric pressure. The device active area was fabricated by FIB induced deposition of W, followed by FIB trimming to fabricate a suspended W bridge of ∼10 × 1 μm size. The structure was encapsulated in a FIB deposited SiO$_2$ cage (protective cap). The electric resistivity of W was 180 $\mu\Omega$ cm, and it was able to withstand a current density of 7.5×10^9 A/m^2.

AFM cantilevers with integrated nanoelectrodes were proposed by Lugstein et al. [61]. Such a scanning probe is capable of simultaneously measuring topography and local electrochemistry at a sample surface. Nanosize electrodes were patterned directly on cantilevers for scanning probe microscopy by FIB trimming.

The emerging area where the FIB finds numerous applications is micro- and nano-optics. Naghski et al. [62] have proposed the modification of optical structures by FIB patterned grooves. Optical channel waveguides formed by FIB implantation-induced mixing of AlGaAs multiple quantum well structures and subsequent oxidation of the mixed regions have the potential of significantly reducing the size of integrated photonic waveguide structures. The calculations presented for the submicrometer channel waveguides show that reductions in size by at least an order of magnitude are possible for directional couplers and other structures involving curved channel waveguide sections. Such size reductions would allow the realization of significantly higher levels of device integration than those currently possible.

The FIB capability to produce nanoholes with a high aspect ratio is useful in fabrication of the apertures in near-field scanning optical microscopy (NFSOM) tips [63, 64]. Danzebrink et al. [64] used FIBs to fabricate slit-shaped apertures that show a polarization dependent transmission efficiency and a lateral resolution of <100 nm at a wavelength of 1064 nm. These slits were fabricated in metallized silicon cantilevers. Lehrer et al. [65] realized the NFSOM aperture probes with the actual hole diameter down to 60 nm. These aperture probes are based on metal-coated AFM sensors. Apertures with circular and rectangular shape with dimensions below 100 nm were fabricated. Optical near-field measurements (wavelength of light 1064 nm) were used to demonstrate the functionality of these probes with a resolution down to 60 nm (1/17 of wavelength). The properties of NFSOM aperture probes can be further improved by realizing the subwavelength surface plasmon full-eye structures as shown in Figure 25.

Observation of photon tunneling gated by light at a different wavelength in the FIB created array of nanometer scale cylindrical channels in a thick gold film has been demonstrated [32]. In these experiments the rectangular arrays of nanometric cylindrical holes have been patterned into a freestanding 400 nm thick gold membrane using focused gallium ion beam milling. To avoid stress in the gold membrane, the gold film is supported by 50 nm thick Si$_3$N$_4$ membrane with a 5 nm intermediate Cr layer. Since there is no glass/metal interface, milling artifacts such as redeposited material can be avoided leading to better-defined structure geometry. Relatively large areas (50 μm × 50 μm) of the gold membranes were patterned, creating nanosized holes with dimensions down to 20 nm. The diameter of the hole can be monitored by using a controlled endpoint termination technique. A drop of poly-3-butoxy-carbonylmethyl-urethane (3BCMU) polydiacetylene solution in chloroform was deposited onto the gold membrane surface. After solvent evaporation polydiacetylene film was left on both the top and the bottom surfaces of the perforated gold membrane. Such 3BCMU polydiacetylene films hold the current record for the largest fast nonresonant optical $x^{(3)}$ nonlinearity. Polarization properties of gated light provided strong proof of the enhanced nonlinear optical mixing in nanometric channels involved in the process. This suggests the
Figure 25. FIB milled optical ring structure with ∼80 nm linewidth in 300 nm thick Ag thin film on quartz.

possibility of building a new class of "gated" photon tunneling devices for massive parallel all-optical signal and image processing. More complex nanostructures (see, for example, Fig. 26) for nanophotonic applications are currently under investigation.

The formation of nanocrystals in FIB irradiated materials has been observed. Tarumi et al. [66] found this effect for amorphous Ni–P alloy where the crystallographically oriented nanocrystals were formed. The FIB induced formation of arranged nanocrystal regions in optical materials may have a great impact on design of new optical nanodevices.

An interesting approach to locally electrochemically deposit metal structures was shown by Spiegel et al. [67]. In this study the Cu conductive lines with a width down to 300 nm were grown on a FIB irradiated Si surface. Although

this is much larger than 100 nm, this approach is interesting to explore. The copper nanostructures were deposited on p-type silicon (p-Si) by means of a selective electrochemical reaction. P-type Si was implanted with Ga^+ ions at ion energy of 30 keV with different ion fluences, 1.0×10^{12} to 1.0×10^{16} cm^{-2}. In a second step Cu was deposited selectively at the implantation sites at different cathodic potentials and for different exposure times. Deposition time, as well as potential, strongly affects the morphology of the Cu deposit. Extended polarization leads to overgrowth of the initial defect patterns resulting in a loss of lateral growth control. By adjusting the implant and electrochemical conditions it was possible to obtain deposits as fine as 300 nm (width), which is also the lateral resolution of the FIB process used (i.e., corresponds to the ion beam distribution).

5. SUMMARY

Each technique that can be utilized for nanofabrication, such as laser NFSOM, scanning probe microscopy, electron beam lithography, and FIB patterning, has its own excellent features.

The focused ion beam is a powerful tool for engineering at nanoscale. The main benefits are the high flexibility of the nanostructure designs that can be realized. The slow processing is the main drawback of the FIB. This technique is best suited for prototype structures and nanodevice fabrication.

Future tasks for researchers dealing with FIBs for nanoengineering are to explore novel applications of the high-resolution ion beams thereby opening new niche markets for this technology. A breakthrough in FIB technology applications will be the demonstration of potential mass production capacity.

GLOSSARY

FIB induced deposition Based on the dissociation of adsorbed molecules of a metal organic or another gaseous precursor by incident ions, which results in a deposited layer. Growth rate is proportional to the reaction yield and the ion flux.

Focused ion beam (FIB) A method for a high-vacuum micro and nano-machining based on a liquid metal ion source (LMIS), which produces an optically bright beam of ions that are accelerated focused to sub-100 beam diameter, and rastered over a surface in a desired pattern, causing implantation and sputtering of the target.

Gas assisted etching (GAE) The enhancement of removal of material from a certain area in FIB processing. When a gas is introduced near the surface of the sample during FIB milling, the sputtering yield can selectively increase depending on the chemistry between the gas and the material. The etchant is selected based on its ability to react with the sputtered material to form volatile molecules that do not bond to the sample material. GAE ion beam induced reaction kinetics is based on an assumption that the yield of the reaction depends linearly on the density of the adsorbed gas molecules.

Liquid metal ions source (LMIS) Uses the quantum mechanical field emission/field evaporation mechanism, appearing at high electric field strengths, for ionization of metal ions. The molten metal covers a sharp emitter tip, which has several kV potential with respect to an extraction electrode aperture. The high field strength at the emitter tip enables the metal atoms to evaporate and ionize. Ions are extracted through the extraction aperture and can be further accelerated.

CONTENTS

1. INTRODUCTION

The notion of generating systems with plenty of interfacial areas was first perceived and suggested by Turnbull [1] and Gleiter [2]. By "plenty," it means that the ratio, interfacial-area/volume $\sim 10^7$ cm^{-1}. Physically, there would be just about as many atoms residing at the grain boundaries as there are in the bulk. These interfacial atoms would manifest themselves in novel physical and chemical behaviors, as described in a number of reviews [3–6], which are not found in conventional polycrystalline materials of coarse grain size (grain size > 10 μm), of which the ratio, interfacial-area/volume, is negligibly small. For instance, the Hall-Petch (H-P) relation says that the yield strength of a material is inversely proportional to the square root of its grain size, r. But the H-P relation is explained on the basis of dislocation pile-ups at grain boundaries [7]. On reducing the grain size of a grain to a few nanometers, confining a dislocation in it would become more and more difficult. It is apparent that the conventional model may have to be revised, providing opportunities in both fundamental research and applications. Magnetic nanostructured material provides another example. A well-known synthesis technique involves annealing an amorphous material at an elevated temperature [8]. Nanocrystals then emerge with the amorphous phase serving as the background. The system exhibits attractive, soft magnetic properties. There are other preparation methods besides devitrifying a glassy specimen, but the interesting magnetic properties at very small grain size, $r \sim 15$ nm, remain [9].

The attractive mechanical and magnetic properties of nanostructures render them important functional materials in industrial applications. In the electronic industry, thin nanostructured specimens can very often serve these purposes. However, nanostructures only in their bulk form are applicable in many other areas. There is therefore a pressing need for the synthesis of bulk nanostructures. By "bulk," we mean that the dimension of a specimen in any direction is >1 mm. In this review, the focus is on the synthesis of bulk nanostructures.

2. TECHNIQUES OF SYNTHESIZING NANOSTRUCTURED ALLOYS

2.1. Gas Condensation and Powder Compaction

The first attempt to produce bulk nanostructured materials is by a method that involves condensation and compaction [10, 11]. In the experiment, metals are evaporated onto a cold finger (cooled by liquid nitrogen) to form very fine powders in an ultra-high vacuum (UHV) chamber. The cold finger acts as a collector for the fine powders, which are subsequently scrapped off by a device made of Teflon®. The scrapped powders are led into a compaction device, also located inside the UHV chamber, for a fusion/bonding process. The *in-situ* compaction process provides a clean environment for the nanometer-sized powders to avoid contamination. Although the synthesis process is done using great precaution, an actual nanostructured specimen unavoidably contains flaws [5], which include micropores; trapped gas and the size of the constituent grains is not uniform. In fact, an as-pressed specimen has a density about 90% of its bulk density or theoretical value.

The flaws can be, and in many cases, proved fatal to the promising properties of the nanostructured materials. For example, a pore behaves like a crack, causing premature failure under tensile stress. Sanders et al. [12, 13] introduced warm compaction, which is very effective in driving out absorbed and trapped gases, bringing the density of a compact to $\geq 98\%$ of the theoretical value, albeit some micropores are still there. Since the compaction takes place at an

elevated temperature, grain growth is expected, but not serious. Most importantly, it turns out that the mechanical properties of these heat-treated compacts improve significantly.

The processing of nanostructured materials by means of a UHV method is costly and slow, but the powders so produced are clean. Driven by economic considerations, other modified techniques of producing nanometer-sized powders were introduced. Mechanical alloying or ball milling [14–16] is a notable one in which a large amount of fine powders can be produced in a relatively short period. Besides, it is capable of manufacturing exotic powders that are not accessible by other means. During ball milling, the materials are more open to contamination. This problem is also common to the other methods for the mass production of ultra-fine powders, such as sol–gel synthesis [17] and spray conversion processing [18]. Consequently, even though these modified methods are less costly, the defective nature of the nanostructured compacts can only be worse than before.

2.2. Severe Plastic Deformation

In this method [19], metallic materials are subjected to a very large degree of plastic deformation. There are two major experimental arrangements. First, two channels made of special die are joined to each other at an angle ϕ. A metallic billet is then repeatedly forced through the device to bring about plastic deformation. This process is called equal channel angular (ECA) pressing. An as-fabricated specimen can be rod shaped with a diameter of ≤ 20 mm and a length in the range of 70–100 mm. Second, an anvil with a cylindrical hole (flat base) on its surface is used as a support. A metallic ingot is put into the hole. A second anvil or a cylindrical plunger that just fits into the hole of the first anvil is placed above the ingot. The two anvils are then pressed against each other very hard. Meanwhile, the plunger is allowed to rotate. The surface friction induces surface shear on the ingot, causing serious straining. This process is termed severe torsion straining. The specimens prepared by this method are usually disk shaped with a diameter of 10 to 20 mm and a thickness of 0.2 to 0.5 mm.

The grain size, r, of an as-treated specimen can be of nanometer dimension, with $r \sim 20$ nm in the case of high carbon steel. The grain boundaries are high angled, but wavy as observed under TEM. There is huge stress in the grains, arising partly from a large number of dislocations located near the grain boundaries. TEM does not detect any cracks or pores, an improvement over those nanostructures synthesized by powder compaction.

Cold rolling can also bring about severe plastic deformation. Recently, Wang et al. [20] were able to produce nanocrystalline Cu by severely cold rolling commercially available pure Cu. It is interesting that an as-prepared specimen exhibits high tensile ductility in sharp contrast to its coarse-grained counterpart.

2.3. Electrodeposition

Electrodeposition techniques can be employed to produce bulk nanocrystalline materials [21, 22] with a thickness that can be as large as ~ 2 mm. It turned out that an as-prepared specimen contains negligible porosity. The constituent grains can be either textured as illustrated by the commercially available nanocrystalline Ni or equiaxed [23]. If the experimental conditions are carefully adjusted, the grain-size distribution can also be narrow.

By an electrodeposition technique, Lu et al. [24] were able to synthesize nanocrystalline Cu, which displays superplasticity in a rolling experiment. A conventional coarse-grained Cu specimen on cold rolling breaks when its thickness is reduced by about a factor of 8. The factor on the other hand increases to 50 for nanostructures synthesized by the electrodeposition technique.

3. UNDERCOOLED LIQUIDS AND BULK AMORPHOUS ALLOYS

3.1. By Nucleation and Growth

3.1.1. Introduction

A few terminologies are first introduced to facilitate the discussions below. The thermodynamic melting temperature (or liquidus) of an alloy is denoted by T_1. As an alloy melt is cooled to a temperature T below its T_1, it is called an undercooled melt with an undercooling, ΔT, defined as $\Delta T = T_1 - T$. On crystallization or solidification, the undercooled molten ingot turns into a solid called undercooled specimen, which can be a crystal, an amorphous solid, a quasi-crystal, or a mixture of them.

Physically, as an alloy melt is undercooled below its T_1, hardening occurs, that is, the liquid becomes more and more difficult to flow. The hardening takes place homogeneously throughout the entire undercooled melt. A quantitative measure of the hardening is its viscosity, η. It increases only slowly when ΔT is small. However, at large ΔT, the hardening process picks up speed and η increases by some orders of magnitude to 1×10^{12} poise in a narrow temperature range. At $\eta \sim 1 \times 10^{12}$ poise, the hardened molten alloy is termed an amorphous solid. The temperature at which $\eta \sim 1 \times 10^{12}$ poise is called the glass transition temperature of the alloy system. Therefore, an amorphous solid is a frozen liquid. Please refer to [25, 26] for an excellent review on undercooled liquid.

Most often, the continuous hardening process of an undercooled melt can be interrupted by crystallization, transforming it into a crystalline solid(s). In the transformation process, a nucleus of the stable crystal forms in the undercooled liquid, creating a liquid-solid interface. This is called nucleation. Next, the liquid-solid interface advances into and consumes the undercooled melt, completely transforming it into a solid. This step is called growth.

3.1.2. Formation of Bulk Glasses

It is clear that in order for a melt to become an amorphous solid on continuous cooling, the nucleation and growth process must be bypassed. Klement et al. [27] demonstrated that Au-Si could be quenched into an amorphous solid with a cooling rate estimated to be on the order of 10^6 K s^{-1}. It is, however, not certain whether the glass formation is primarily due to the suppression of nucleation, that of growth or both. On the more fundamental aspects, Chen and Turnbull [28] demonstrated the kinetic glass transition by calorimetry.

Turnbull and Cohen [29–31] introduced a free volume model to explain the glass transition.

Since the synthesis involves rapid quenching or rapid solidification, one dimension of the as-prepared amorphous alloys is thin to facilitate heat removal [27]. This limits the potential applications of amorphous alloys, which exhibit attractive mechanical and magnetic properties. The search for bulk glass is therefore an urgent matter.

Nucleation can be brought about by two different origins. First, the surfaces of impurities provide a periodic potential for the attachment of the atoms from the metastable phase, helping nucleation. This type of nucleation is called heterogeneous nucleation. Second, in the absence of impurities, a pure undercooled melt can form a nucleus by structural fluctuation. This kind of nucleation is termed homogeneous nucleation. Experience [32] indicates that homogeneous nucleation rarely occurs.

To form bulk glass, one approach is to remove potent nucleation impurities from a melt and this is demonstrated in the case of Pd-Ni-P [33], in which a wholly amorphous ingot of diameter ∼1 cm was prepared by a fluxing technique. The technique was extended to Pd-Cu-Ni-P [34], leading to the formation of an amorphous rod specimen of diameter 72 mm.

The second approach to bulk glass formation is to search for systems that resist nucleation or growth or both when quenching through the undercooling regime at slow cooling rates, typically 1 K s. The earlier bulk glasses formed by this method, to name a few, are La-Al-Ni [34], Zr-Cu-Ni-Al [35, 36], and Zr-Ti-Cu-Ni-Be [37]. To summarize, Inoue [38] introduced three empirical rules for the search of bulk glass formation systems (extracted from [38]):

1. multicomponent system consisting of more than three elements;
2. significant difference in atomic-size ratios above 12% among the main constituent elements;
3. negative heats of mixing among their elements.

3.1.3. Formation of Nanostructured Bulk Amorphous Alloys

When bulk glass is annealed at an elevated temperature, crystallization proceeds by the advancement of the crystal-amorphous or crystal-liquid interface [39]. After a volume that is amorphous is swept by the crystal-amorphous interface, it is turned into a crystalline solid. Very often, even if the dimension of the microstructures of the crystallized solid is of nanometer size [40], it becomes extremely brittle, rendering it useless for applications. When such an amorphous phase is crystallized in a differential scanning calorimeter (DSC), the thermogram would display one or two closely overlapped crystallization peaks [40].

On the other hand, if an amorphous specimen is only partially crystallized into nanocrystals that disperse themselves uniformly in the remaining amorphous phase, a process called nanocrystallization by Inoue [38] occurs. The physical properties are enhanced. In particular, the ductility and high strength associated with the amorphous phase is further improved. When such a glass is subjected to thermal scan in a DSC, there would be two crystallization peaks, the first one corresponding to the emergence of the nanocrystals while the second one corresponds to the crystallization of the amorphous matrix.

To bring about nanocrystallization, Inoue et al. [41] added certain impurities into a bulk glass former. They are chosen in such a way that the three empirical rules for bulk glass formation stated above are somewhat violated. For instance, it is suggested that to form bulk glass, the heats of mixing are negative among the constituent elements. The added impurities are then purposely chosen such that when mixed, there would be negative heats of mixing, zero heats of mixing, and positive heats of mixing. This alteration generates microscopic homogeneity that eventually leads to a primary crystallization and then a crystallization event for the remaining amorphous matrix. The following four criteria are proposed by Inoue [42] to achieve nanocrystallization (extracted from [42]):

1. multistage crystallization processes;
2. existence of homogeneous nucleation sites in an amorphous phase;
3. suppression of growth reaction caused by segregation of a solute element with low atomic diffusion at the nanocrystal/amorphous interface; and
4. high thermal stability of the remaining amorphous phase by the enrichment of solute elements from the primary crystalline phase.

To illustrate it, Inoue added Ti to $Zr_{58}Al_{12}Ni_{10}Cu_{20}$ to change its composition to $Zr_{53}Al_{12}Ti_5Ni_{10}Cu_{20}$. Ti has a zero heat of mixing against Zr. The single stage crystallization then becomes a two-stage crystallization process (criteria 1 and 2). Since the reaction during the first peak is not polymorphic, that is, the composition of the nanocrystals is different from that of the amorphous phase, in this case Al atoms are rejected to the crystal/amorphous interface, stabilizing the amorphous phase and slowing down the diffusion motion or growth velocity (criterion 3). Finally, the crystal/amorphous interface stop moving when more Al builds up in the rest of the amorphous phase (criterion 4). The nanocrystals emerged during nanocrystallization appear to be spherical (homogeneous nucleation in criterion 1) and have a grain size of 10–15 nm.

3.2. Formation of Bulk Metallic Nanostructured Alloys Involving Spinodal Mechanism

3.2.1. Introduction

A typical phase diagram of a binary eutectic alloy of elements A and B is shown in Figure 1. Let ε_{AA}, ε_{BB}, and ε_{CC} be the bond energies between A-A atoms, B-B atoms, and A-B atoms, respectively. Then $1/2[\varepsilon_{AA} + \varepsilon_{BB}] < \varepsilon_{AB}$. There are two interesting considerations. First, if the crystal structures of A and B are different, the free energy curves of this system at a temperature above its eutectic temperature T_E is shown in Figure 1b(i), in which the free energy curves for the crystalline phases do not join to each other smoothly. On the other hand, the liquid phase, which does not have to meet any long-range order, can be represented by a single, smooth, free-energy curve. Moreover, owing to the large entropic term in $G_1 = H_1 - TS_1$, where G_1 is the Gibbs
Figure 1. A typical phase diagram of a binary alloy of A-B.

Figure 3. (a) The development of a hump in the liquid free-energy curve shown in Figure 2a at a temperature well below T_{E}. (b) The development of a hump in the liquid free-energy curve shown in Figure 2b at a temperature substantially below T_{E}.

free energy, H_1 is the enthalpy, T is the temperature in K, S_1 is the entropy, and the subscript 1 stands for the liquid phase, it concaves upward. Second, if A and B have the same crystal structure, the corresponding solid free-energy curves, again at a temperature above T_{E}, may be depicted as the one shown in Figure 2b. The one for the liquid phase is also a single, smooth curve and concaves upward, again for the same reasons. From now on, we would focus only on the free-energy curves of the liquid phase in both cases.

We assume that the condition $1/2[\varepsilon_{\mathrm{AA}} + \varepsilon_{\mathrm{BB}}] < \varepsilon_{\mathrm{AB}}$ persists in the liquid state at all ΔT. Then, as a binary eutectic melt of composition, $\mathrm{A}_x\mathrm{B}_y$ is cooled from above, its liquidus, T_1, to a temperature T, which is below T_{E}; it is metastable with an undercooling, $\Delta T = T_1 - T$. On further cooling or at low values of T, the entropic term in $G_1 = H_1 - TS_1$ becomes less dominant and H_1 begins to take charge, which brings about metastable liquid phase separation. So far, the discussion has been limited to $\mathrm{A}_x\mathrm{B}_y$, a fixed composition of the A-B alloy. On relaxing this condition to include the entire composition range, we will see a hump emerging on the liquid free energy curve as the temperature is lowered well below T_{E} as shown in Figure 3a and 3b. A free-energy diagram describes the behavior of various phases at a fixed temperature. When the free-energy curves are considered

as a function of temperature, it culminates in a metastable liquid phase miscibility gap in a phase diagram (please refer to Fig. 4).

In general, a liquid miscibility gap does not have to lie below all the solid phases, for example, the one in a monotectic phase diagram [43]. On the other hand, consider a eutectic alloy in which the solid and the liquid phase share the same composition range. Since $H_s < H_l$ and $S_s < S_l$, where the subscript s stands for the solid phase, the liquid miscibility gap as described above would lie below the eutectic temperature, T_{E}.

There are two decomposition reactions in the metastable liquid miscibility gap, namely, by liquid nucleation and growth (metastable), and by liquid spinodal decomposition (metastable). In the former, on quenching, a homogeneous undercooled melt decomposes by first forming a nucleus of a more stable liquid phase. The transformation continues by the advancement of the liquid-nucleus interface. The morphology in the absence of coarsening is island-like. A typical example is shown in Figure 4 of a liquid of composition x_{NG}, which on reaching T decomposes into two liquids of compositions x_1 and x_2. In the latter case [44–46], an original homogeneous undercooled melt undergoes local composition fluctuation, characterized by uphill diffusion.
Figure 2. (a) Free-energy curves of the binary A-B alloy at a temperature $T > T_{\mathrm{E}}$ (eutectic temperature). Assume that A and B have different crystal structures. (b) Free-energy curves of the binary system A-B alloy again at a temperature $T > T_{\mathrm{E}}$. Assume that A and B have the same crystal structure.
Figure 4. The metastable liquid miscibility gap below T_{E} for the A-B binary alloy.

There is no sharp interface during the incipient stage of the decomposition. But as the uphill diffusion process continues, the composition gradient sharpens and at the end it turns into a steep interface. In Figure 4, on reaching the spinodal regime, a homogeneous melt of composition x_{SD} continues to build up the concentration gradient until the compositions of its split components—both liquids—reach x_1 and x_2, leaving behind sharp interfaces. The transformation does not start out from certain points in the melt, as in the case of the decomposition by nucleation and growth, but occurs simultaneously throughout the entire specimen. Consequently, the decomposed melt is filled with interpenetrating networks of characteristic wavelength, λ. Cahn [43] and Hilliard [46] predicted that the system would evolve to a characteristic wavelength λ_m. As a result, the microstructure is quite uniform. A diagram showing the network morphology of undercooled $Pd_{80}Si_{20}$ is shown in Figure 5. Cahn [43] and Hilliard [46] also predicted that $\lambda \propto [(T_{CS} - T)/T_{CS}]^{-1/2}$, where T_{CS} is the temperature of the chemical spinodal of the liquid. Since $(T_{CS} - T)$ scales with ΔT, if we can undercool the melt to a very large ΔT, forcing λ into the nanometer regime, it becomes a nanostructure on crystallization.

The decomposition, either by nucleation and growth or by spinodal decomposition, results in the formation of multiple metastable/undercooled liquids. The structures can be described as island-like liquid droplets embedded in another liquid matrix or liquid networks interpenetrating each other. The crystallization kinetics, in the presence of plenty of interfaces, can be different from that of conventional systems.

3.2.2. Nanostructures from Bulk Glassy Alloys I

Chen and Turnbull [47] found that when amorphous $Pd_{78}Au_6Si_{16}$ is rapidly heated to a temperature just above its glass transition temperature, T_g, for a few minutes, two interconnected amorphous phases of different electron density emerge. There are only tiny traces of nanometer crystalline inclusions in one of the decomposed amorphous phases. They suggested that the transformation follows the course:

Glass $\rightarrow$ melt $\rightarrow$ (phase separation) 2 melt phases

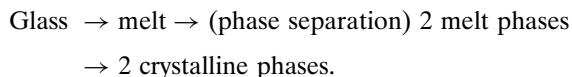
$\rightarrow$ 2 crystalline phases.


Figure 5. Typical morphologies of a system that has undergone a spinodal mechanism.

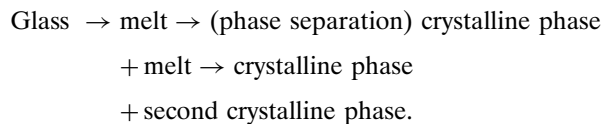
Chen and Turnbull [47] studied the crystallization kinetics of amorphous $Pd_{80}Si_{20}$ in a similar manner. The experimental results suggested that the transformation follows the course:

Glass $\rightarrow$ melt $\rightarrow$ (phase separation) crystalline phase

$+$ melt $\rightarrow$ crystalline phase

$+$ second crystalline phase.


The heats of mixing the pure liquid metals are negative, leading the authors to suggest that the two liquids formed from the homogeneous liquid have a high degree of unique local order. Hence, the overall energy is lowered.

Since the interconnected amorphous microstructure observed in thermally annealed $Pd_{78}Au_6Si_{16}$ alloy is similar to that exhibited by phase-separated silicate glasses, Chou and Tumbull [48] proposed that it is the spinodal mechanism that leads to the interconnected morphology in amorphous $Pd_{78}Au_6Si_{16}$ upon annealing. They went further to conduct the small-angle X-ray scattering (SAXS) experiments. together with large-angle X-ray scattering and calorimetry on various alloys. The SAXS is a suitable tool for the study of the composition segregation in a material, thereby on the evolution of spinodal decomposition, which exhibits continuous composition variation. Experimentally, the behavior of the incipient decomposition was generally consistent with the predictions of Cahn's spinodal theory. The authors then suggested that the following transformation courses for various amorphous systems were rapidly heated to just above their respective T_g and annealed for a short period:

$Pd_{82}Si_{18}$

Glass $\rightarrow$ (T_g) melt $\rightarrow$ homogeneous fcc solution

$Pd_{80}Au_{3.5}Si_{16.5}$

Glass $\rightarrow$ (T_g) melt $\rightarrow$ phase separation

$\rightarrow$ crystalline phase $+$ melt

$\rightarrow$ second crystalline phase $Pd_{74}Au_8Si_{18}$

Glass $\rightarrow$ (T_g) melt $\rightarrow$ (phase separation) 2 melt phases

$\rightarrow$ 2 crystalline phases.
Most of the phase-separated specimens studied by Chen and Turnbull [47], and Chou and Turnbull [48] were annealed at temperatures just above their respective T_g. Tanner and Ray [49] were able to prepare amorphous phase-separated specimens in the Zr-Ti-Be system by quenching the melts at cooling rates of 10^5–10^7 K s^{-1}. The two amorphous phases, which are of nanometer size, mix up in two different ways. In the first, discrete, separated particles embed themselves in an amorphous matrix. In the second, a characteristic interconnected structure appears in the system of $Zr_{36}Ti_{24}Be_{40}$. Calorimetry confirms that there are two glass transition temperatures However, the nature of the phase-separation process is not known. The experimental results indicate that at cooling rates of 10^5–10^7 K s^{-1}, there is enough time for liquid-phase separation to take place and complete, but too short even for crystallization to start. The specimens prepared by Tanner and Ray [49] were not bulk nanostructured alloys due to the necessity of fast quenching rates.

3.2.3. Nanostructures from Bulk Glassy Alloys II

Peker and Johnson [37] found that $Zr_{41.2}Ti_{13.8}Cu_{12.5}Ni_{10.0} \cdot Be_{22.5}$ is an excellent bulk glass former. To understand why it forms glass so readily. Johnson's group studied in detail the crystallization kinetics of Zr-Ti-Cu-Ni-Be by using a high vacuum electrostatic levitation (HVESL) method [50], which enables the heating, melting, and cooling/undercooling of roughly a 3 mm-diameter drop. The themogram is obtained by means of a pyrometer. Undercooled specimens of various degrees of undercooling were prepared this way.

In the experiment, an undercooled $Zr_{41.2}Ti_{13.8}Ni_{10.0}Be_{22.5}$ melt is cooled to a temperature T, which is just below 800 K. As soon as it reaches T, the heat treatment process is changed to an isothermal condition. A small hump will first appear on the thermogram, to be followed by two overlapping, but distinct crystallization peaks. Both peaks are very large compared to the small hump preceding them. On the contrary, on skipping the prolonged isothermal run and allowing the melt to cool continuously to a temperature close to or below T_g, the molten drop can become an amorphous solid.

When subjected to field ion microscopy and atom probe techniques [51], an as-prepared amorphous specimen displays composition inhomogeneities of nanometer size. Some of the regions are Be rich while the others are Be poor, but both are amorphous. There is an amorphous phase separation. Compared to the themogram recorded earlier [50], the authors suggested that the small hump is due to the heat released during phase separation. Since the hump occurs at a temperature way above T_g, it is a liquid state phase separation. The undercooled liquid components eventually are frozen to amorphous state on further cooling.

The two phases in the amorphous phase separated specimen have different compositions or different T_g. In a reheating experiment that brings the temperature of the specimen to a value that is intermediate between the two glass transition temperatures, the phase with lower T_g crystallizes, leaving the other one in the amorphous state. The final morphology then becomes a bulk specimen with nanocrystals embedded in an amorphous matrix. Busch and Johnson [52] found that $Zr_{46.2}Ti_{8.8}Cu_{7.5}Ni_{10}Be_{27.5}$, on the other hand, does not exhibit any decomposition reaction, even though its composition is very close to $Zr_{41.2}Ti_{13.8}Ni_{10}Cu_{12.5}Be_{22.5}$. The peculiar behavior arises from the fact that its chemical spinodal is below its T_g. This is not surprising for, in general, the chemical spinodal line of a miscibility gap changes steeply with composition.

The introduction of a metastable miscibility gap also helps explain another dilemma. $Zr_{41.2}Ti_{13.8}Ni_{10.0}Cu_{12.5}Be_{22.5}$ is a bulk glass former. Accordingly, during its cooling from a melt to become a bulk glass and even if the as-formed glass is reheated to a temperature near the glass transition temperature, nucleation events should be sparse. It [53] was found, to the contrary, that as the bulk glass is reheated to a temperature somewhat above T_g, plenty of nanocrystals emerge, embedding themselves in the amorphous matrix. Additionally, they are very small, indicating that the glass-forming ability of $Zr_{41.2}Ti_{13.8}Ni_{10.0}Cu_{12.5}Be_{22.5}$ is likely to be crystal growth limited. The amorphous phase separation in

undercooled $Zr_{41.2}Ti_{13.8}Ni_{10.0}Cu_{12.5}Be_{22.5}$ and the behavior of $Zr_{46.2}Ti_{8.8}Cu_{7.5}Ni_{10.0}Be_{27.5}$ in the undercooling regime illustrate that the glass-forming ability of Zr-Ti-Ni-Cu-Be is not necessarily crystal growth limited.

Schneider et al. [53, 54] attempted to unveil the nature of phase-separation process by employing small-angle neutron scattering (SANA). The experimental data is generally consistent with the predictions of Cahn's theory on spinodal decomposition.

Liquid $Mg_{62}Li_3Cu_{25}Y_{10}$ [55] specimens were cast into strip form with a thickness of 1 mm by means of copper molds. The as-quenched specimens were then studied by high-resolution transmission electron microscopy (HRTEM). By phase contrast, there are two apparently amorphous regions in a HRTEM image. Crystallization has started to take place in one of the phase-separated regions. The authors then suggested that a phase separation occurs in the liquid state during quenching. The one that is Mg-Li-rich one undergoes incipient crystallization.

3.2.4. Nanostructures from Bulk Undercooled Molten Alloys

It was found that when an alloy melt is immersed in an oxide flux at an elevated temperature, preferably about 200 K above the liquidus, T_1, of the alloy, impurities can be effectively removed from the melt into the flux. When free of potent heterophase impurities, the alloy melt can be undercooled substantially below its T_1. There are now two unique experimental procedures that this molten alloy can offer. First, it can be cooled down from its T_1 to a temperature deep in the undercooling regime with very slow cooling rates, sometimes less than 1 K s^{-1}, until it is interrupted by crystallization. This enables the formation of a large piece of undercooled specimen with various degrees of undercoolings. For example, molten $Pd_{40}Ni_{40}P_{20}$ [33] can be directly quenched to its glassy state bypassing crystallization with a cooling rate of ~1 K s^{-1}. The as-formed amorphous ingot can have a diameter >1 cm. Second, a continuous cooling cycle can be modified to include intermediate isothermal annealing periods [56]. If crystallization events take place during isothermal runs, the initial bulk undercooling of an undercooled specimen just before crystallization is well defined, simplifying microstructural analysis.

It is not clear why the fluxing technique is so effective in obtaining large undercooling for an undercooled melt. Presumably the flux, itself an oxide, helps absorb heterophase impurities in the molten alloy, which are mostly oxides, into itself. For those homophase impurities, the high temperature fluxing forces them to homogenize with the bulk melt. Physically, the large undercooling of a melt below its T_1 is attributed to its very different short-range order from a crystalline phase [32]. Phenomenally, the interfacial free energy, γ_{lc}, between the liquid and crystalline phases assumes a large value, leading to large ΔT or large, free-energy change between the liquid and crystalline phases for transformation.

In subsequent experiments, Lee and Kui [57, 58], and Yuen et al. [59, 60] employed a fluxing technique with a slow cooling rate of 8 K s^{-1} to study the crystallization kinetics of undercooled molten alloys that crystallized at different ΔT. AS a result, the microstructures of undercooled $Pd_{80}Si_{20}$

[57, 58] and $Pd_{40.5}Ni_{40.5}P_{19}$ [59, 60], both eutectic alloys, were recorded as a function of ΔT. Since a slow cooling rate was used, the initial bulk undercooling just before crystallization could be measured with precision, that is, the established relationship between microstructure and ΔT is relevant and reliable. Based on the experimental results, it can be concluded that there is a metastable liquid miscibility gap for each of them. In fact, the entire metastable liquid miscibility gap of Pd-Si [61] was determined experimentally. In the following, undercooled $Pd_{80}Ni_{20}$ will be the leading example with occasional references to undercooled $Pd_{40.5}Ni_{40.5}P_{19}$.

AT $0 < \Delta T < 190$ K, the microstructures consist of long dendrites (pure Pd_3Si without any inclusions) embedded in a eutectic matrix as shown in Figure 6a, similar to that of a typical solidified metal. At $190 < \Delta T < 220$ K, there is a sudden microstructural change. The long dendrites disappear and are replaced by island-like structures (Pd_3Si). Pd particles are often found, dispersing themselves either inside or at the periphery of the islands as shown in Figure 6b. The background matrix is Pd_9Si_2. At $\Delta T > 220$ K, it is an interconnected network, consisting of two subnetworks. The one with a lighter color is Pd_3Si. Again, there are Pd inclusions but the population of Pd particles at the periphery of the Pd_3Si subnetwork increases over the one with $190 < \Delta T < 220$ K. The dark subnetwork has a composition of Pd_9Si_2 (Fig. 6c).

The microstructures revealed in undercooled specimens in the undercooling regimes of $190 < \Delta T < 220$ K and $\Delta T > 220$ K provide a clue to the transformation mechanisms in undercooled $Pd_{80}Si_{20}$. The microstructures have three characteristics. First, the microstructures shown in $190 < \Delta T < 220$ K are island-like, whereas those in $\Delta T > 220$ K are intertwining networks. Second, the phases in both undercooling regimes remain unchanged, but there is a sudden refinement in grain size by as much as 30 times, as one crosses over from $\Delta T < 220$ K to $\Delta T > 220$ K. Third, the island-like structures in $190 < \Delta T < 220$ K become connected after a long period of annealing. The microstructures versus ΔT are therefore generally consistent with the predictions of a miscibility gap (Fig. 4). In the nucleation and growth regime, the characteristic microstructures should be island-like, while those inside the chemical spinodal are network-like. Seward et al. [62] showed that a network-like morphology is not a sufficient condition for spinodal mechanism as they demonstrated that a system of spherical particles becomes interconnected on annealing. To remove any doubt about the origin of the network structure, an undercooled melt with $\Delta T = 210$ K at an undercooling just above the chemical spinodal, was annealed for a prolonged period (>30 min). The spherical structures coarsen, building up a somewhat connected morphology, which is distinctively different, however, from that in Figure 6c. Therefore, the network structure shown in Figure 6c, which takes place at a larger undercooling, results from a spinodal mechanism. There is additional evidence indicating that the microstructure shown in Figure 6c indeed comes from spinodal decomposition. The sudden grain refinement transition observed boosts a spinodal mechanism for undercooled molten Pd-Si. There are a number of models [63–70] proposed to explain the phenomenon of grain refinement in metals at large ΔT.
Figure 6. (a) Typical microstructures of undercooled $Pd_{80}Si_{20}$ specimens with $\Delta T \leq 190$ K. The needle-like structures are dendrites of composition Pd_3Si. It generally requires that the crystal growth velocity be very large when a grain refinement process takes effect. In undercooled $Pd_{80}Si_{20}$ melt, the crystal growth velocity is slow at $\Delta T \approx 200$ K, a condition that is only favorable to a spinodal mechanism.

There is an important question left. Does the metastable liquid miscibility gap occur in the solid state or in the liquid state? A thermocouple was used to record the thermal history of a molten Pd-Si ingot as it was cooled below its T_1 and crystallized. There were only crystallization peaks, excluding any solid-state reaction that took place in the undercooled specimen. When a spinodal decomposition reaction occurs in a binary solid, the two emerging solids should have the same crystal structure. The Pd_3Si subnetwork and the Pd_9Si_2 subnetwork found in undercooled Pd-Si have very different crystal structures. They do not form the right couple for spinodal decomposition. On the other hand, as a liquid undergoes spinodal decomposition, only short-range order has to be matched, which is readily met in the liquid. Therefore, it is concluded that there is a metastable liquid miscibility gap in Pd-Si alloy.

The crystallization kinetics of two undercooled spinodals intermixing with each other are of interest. It was found that their respective crystallization processes could be quite independent of each other. As crystallization proceeds in one, the other spinodal can stay in the liquid state.

The characteristic wavelength, λ, of undercooled Pd-Si near but below its chemical spinodal is ~ 1 μm. According to Cahn [43], it decreases rapidly as the temperature of the undercooled liquid moves away from the chemical spinodal. The formation of bulk nanostructured alloy is then one step away. Two different experimental approaches were employed for this goal. In the first, undercooled molten specimens were crystallized at well-defined ΔT for quantitative results. Accordingly, Guo and Kui [71] prepared, again by a fluxing technique, a series of undercooled $Pd_{82}Si_{18}$ specimens. The largest ΔT achieved was ~ 360 K. The measured λ versus ΔT is shown in Figure 7a, which depicts a rapid decrease of grain size against ΔT at small ΔT, but leveling off at $\Delta T \geq 300$ K. The smallest λ is 50 nm, occurring at $\Delta T = 360$ K. A morphological transition appears and is marked in Figure 7a. The microstructures obtained in undercooled specimens with $\Delta T < 320$ K are interconnected (Fig. 7b), but changes to more or less equiaxed grains for $\Delta T > 320$ K (Fig. 7c). It appears that the driving force for this transition is due to surface tension, as demonstrated in the case of undercooled Pd-Ni-P ingots [72]. For specimens with $\lambda \geq 180$ nm, the networks are interconnected. On the other hand, for $\lambda \leq 180$ nm, the networks are prone to break up into droplets to reduce surface areas.

An as-prepared undercooled ingot, taking the one with $\Delta T = 360$ K as an example, enjoys three privileges. First, its diameter can be as large as 1 cm, so it is a bulk nanostructured alloy. Second, micropores are absent. Third, the microstructures are uniform, which is a result of the spinodal mechanism.

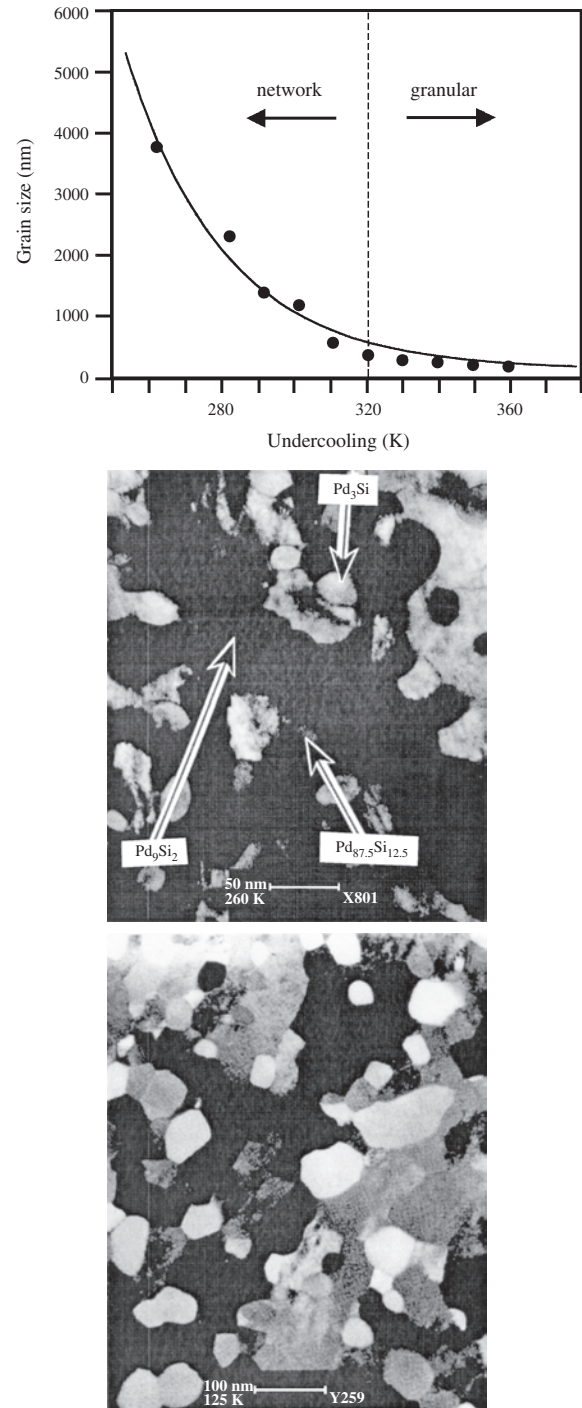
The second approach to bulk nanostructured alloys formation involves rapid quenching. In the experiment, a fluxed molten specimen inside an evacuated fused silica tube was directly quenched in water. The undercooled specimen was


Figure 7. (a) A plot showing grain size versus ΔT. There is a morphological transition at $\Delta T > 320$ K, at which the network morphology ($\Delta T < 320$ K) changes to granular structure ($\Delta T > 320$ K). therefore in rod shape, but still a bulk sample for its diameter is ≥2 mm. It is estimated that the quenching rate is a few hundred degrees per second. The maximum ΔT achieved in this situation is certainly larger than that under isothermal conditions. As a result of the rapid solidification, λ versus ΔT is not available and the structure is even farther away from equilibrium. The microstructures can basically be divided into three categories. In the case [73] where the relative cooling rate is the least but larger than that in [71], there are still two crystalline networks intermixing with each other, but λ can be as small as 5–6 nm (Fig. 8a). The grains are equiaxed indicating that during water quenching, the liquid spinodals with very small λ still found time for network breakup (please see that the electron diffraction in the insert of Fig. 8a is ring, made up of diffraction spots). Also, the grain size distribution is very sharp, consistent with the predictions of Cahn's spinodal theory (Fig. 8b). In the case where [73] the relative cooling rate is somewhat faster, there are again two networks, but one is amorphous while the other one remain crystalline (Fig. 8c). The diffraction pattern, shown as an insert in Figure 8c, reveals an interesting feature. It resembles that taken from a single crystal. But the pattern was actually taken from an area with a diameter >100 nm. Inside that region, there are plenty of the crystalline spinodals all contributing to the diffraction spots and yet the final pattern is that of a single crystal. A plausible explanation is that during quenching. $L \rightarrow L_1 + L_2$ by spinodal decomposition. Although L_1 crystallizes, the quenching rate is able to freeze L_2. It is apparent that the quenching rate is slow enough for the spinodal mechanism to proceed, but was not long enough for the liquid spinodals to break up. As crystallization starts out from one place (heterophase impurities), it grows epitaxially along the L_1 network until it completely crystallizes. L_2 is immune to what happens in L_1. In the case that the relative quenching rate is the fastest, it is expected that both spinodal would be amorphous. This does not occur in undercooled Pd-Si, but takes place in undercooled Pd-Ni-P [74]. Unfortunately, transmission electron microscopy (TEM) cannot resolve the two amorphous phases using the phase contrast method. Presumably, the composition difference between the two amorphous phases is not large enough or the wavelength is too small to be resolved by the TEM.

The rapid quenching rate does not destroy the three privileges as previously mentioned. An as-prepared specimen is still in bulk form, free of micropores and uniform grain size.

The bulk nanostructured alloys so far prepared by spinodal mechanism are still not large enough for precision mechanical testing and direct industrial applications. In a recent attempt, again by a fluxing technique, Ng and Kui [75] were able to prepare a bulk Pd-Si rod of diameter 8 mm and length 80 mm. The grain size is not as uniform as the one in [71], ranging from 50 nm to 100 nm. Micropores are absent, but there is a groove or cavity running along the length of the undercooled specimen, which originates from the volume change as the molten rod crystallizes at very large undercooling.

GLOSSARY

Bulk metallic glass   An amorphous solid with a physical dimension ≥ 1 mm in any direction.

Bulk nanostructure   A 3-dimensional nanostructure with a physical size ≥ 1 mm in any direction.

Dendrite   Branched crystal with the appearance of trees.

Dislocation   A line defect in a crystal, distorting it from being a lattice of regular periodicity.

Hall–Petch equation   It states that the yield stress σ_y is inversely proportional to the square root of grain size D. Mathematically, $\sigma_y = \sigma_o + k(D)^{-1/2}$, where σ_o is a frictional stress required to move dislocations and k is the Hall–Petch slope.

Heterogeneous nucleation   The nucleus (or nuclei) forms with the help of foreign particles in a nucleation and growth process.

Homogeneous nucleation   The nucleus (or nuclei) forms by an intrinsic structural fluctuation in a nucleation and growth process.

Liquid phase separation   When undercooled into a liquid miscibility gap, a homogeneous liquid splits into liquid components.

Liquidus   The thermodynamic melting temperature of an alloy, denoted by T_1.

Metastable liquid miscibility gap   A miscibility gap for liquids, which are at a temperature below their respective T_1.

Miscibility gap   A phase boundary separating single-phase field from that of mixtures.

Nucleation and growth   One type of phase transformation in which a nucleus of the stable phase forms first in a less stable phase. Then crystal growth starts out from the nucleus, consuming the less stable phase.

Phase diagram   A diagram describing the distribution of the thermodynamic equilibrium phases of an alloy at different temperatures and compositions.

Polymorphic transformation   It occurs in single component systems when different crystal structures are stable over different temperature ranges.

Spinodal decomposition   One type of phase transformation in which nucleation barrier is absent (no need for the formation of nucleus). It is best described by uphill diffusion of the like species.

Undercooled molten alloy   An alloy melt at a temperature below its T_1.

Undercooled specimen   An alloy that had solidified at a temperature T, which below its T_1. However, T is not specified.

Undercooled specimen with ΔT   An alloy that had solidified at an undercooling of ΔT.

Undercooling   The notation for undercooling is ΔT. Mathematically, $\Delta T = T_1 - T$, where T_1 and T are the liquidus and the temperature of an alloy melt under the condition that $T_1 > T$.

Viscosity   The degree of resistance to flow when a liquid or solid is under a shear stress.

Formation of Nanostructured Polymers

Beinn V. O. Muir, Christine K. Luscombe, Wilhelm T. S. Huck

University of Cambridge, Cambridge, United Kingdom

CONTENTS

1. INTRODUCTION

Nanotechnology has received a tremendous amount of interest over the last decade, not only from the scientific community, but also from the business sector and the general public [1, 2]. Although nanotechnology is still a relatively new science [3], it has already shown great potential for exciting technological innovations, with an enormous impact on areas as diverse as information technology, medicine, and energy supply [4, 5]. The miniaturization of components, and consequently the devices themselves, would increase the speed of devices and information storage capacity. More importantly, nanotechnology should lead to completely new functional devices since nanostructures are small enough to have fundamentally different physical properties that are governed by quantum effects. If nanometer-sized features are fabricated in materials that are currently used in electronic, magnetic, and optical applications, quantum behavior should lead to unique properties. The interaction of nanostructures with biological materials is also unexplored, and this is certain to be another important area of research in the future [6].

Polymers have played a vital role in the development of man from prehistoric times. Since ancient times, biopolymers such as wood, wool, and starch have been used as a construction material, clothing, and thickening agent, respectively. In the early 20th century, polymers, including plastics, synthetic rubbers, and elastomers, were synthesized for use in many applications. Recently, electrically conductive and light-emitting polymers have been discovered [7], paving the way for visual display units constructed from a flexible polymer film. Polymers are showing increasing versatility in a large number of applications, including electronic devices [8], medicine [9], and in the rapidly advancing field of nanotechnology.

A polymer is a macromolecule constructed from a collection of covalently connected monomers. For example, poly(styrene) (PS) $(-CH_2-CH(C_6H_5)-)_n$ is built from the combination of styrene monomers $CH_2=CH(C_6H_5)$ with the monomeric unit $CH_2-CH(C_6H_5)$. The simplest polymers are linear polymers, and there are other possible forms, such as branched or star shaped (see Fig. 1). In solution, polymers can form spheres, random coils, and helices. There are two main methodologies used for polymer synthesis. One method is chain polymerization, where compounds with multiple bonds act as monomers. The most common functionality used for polymerization is the alkene group, with carbonyl and alkyne groups also being utilized occasionally. The activated intermediate (a radical, carbocation, or carboanion) adds across the multiple bond to form a new, and larger, intermediate which then adds across a new monomer. Another method is step (condensation) polymerization. This uses bifunctional monomers which undergo standard condensation reactions to form long chains. Suitable reactions include esterification, amidation, and etherification, as well as many organometallic coupling reactions [10].

Protein engineering, which allows the design of new proteins with novel functions, is a very powerful tool that can be used to fuse the biological and synthetic world. However, as it is currently impossible to predict the folding of unknown protein sequences, and even harder to design, express, and harvest *de novo* proteins, it is clear that other building blocks are required. Inspired by these biological examples, it is clear that polymers could be ideal components for man-made nanostructures because of their natural 5–100 nm length scale, ease of synthesis, and rich chemistry. Unfortunately, it is presently impossible to design and fabricate arbitrary polymers with a well-defined shape and functionality. If we are to bridge the gap between the biological world and nanofabrication, major advances in the control over polymeric materials at the nanometer level are necessary.

In this chapter, we will look at a number of different strategies to synthesize or fabricate polymers with well-defined nanoscale dimensions. The text is structured around
Figure 1. The upper section is a schematic drawing of linear, branched, and star polymers, including their possible shapes in solution. The lower section shows the structures of the polymers discussed in this chapter.

Figure 2. Overview of nanostructure fabrication technologies, illustrating the top-down and bottom-up approaches.

four main themes: top-down techniques, molecular self-assembly, chemical synthesis, and structures using biological materials. The top-down approach involves subtractive or lithographic techniques, where bulk material is structured into small features. In contrast, a bottom-up approach can be achieved via self-assembly or self-organization, processes which rely on the formation of noncovalent linkages between the building blocks (see Fig. 2). This alternative to conventional lithography uses molecular assembly, starting with molecular (Ångström-sized) building blocks, and linking them together into larger and larger structures. Nanosized structures can also be built up via the chemical synthesis of new covalent bonds between atoms. This leads to a diverse array of functionalized nanoparticles. Finally, polymers form the basis of biological function, and great inspiration can be obtained through the study of polymeric structures in biology. Research into the structure of such biological nanomachines will have important consequences on the fabrication of future nanosized devices. There is a growing interest in the use of biological polymers as building blocks for nonnatural structures. DNA is an obvious candidate, but protein engineering is beginning to make a sufficiently large impact, allowing the use of proteins as building

blocks. These developments will be discussed at the end of this chapter.

2. TOP-DOWN TECHNIQUES

The continuing drive in the semiconductor industry to fabricate smaller structures using top-down techniques will soon require dimensional control at sub-100 nm length scales, comparable to the size of polymers. State-of-the art photolithographic techniques can now more or less routinely fabricate features with dimensions below 100 nm, and at best can produce structures as small as 10 nm. Although patterned polymer films are used as sacrificial etch resist layers which are not present in the finished structure, it is clear that polymers are an integral part of these techniques. In a number of other lithographic methods, classified as soft-lithographic techniques, polymers are shaped into submicron structures, and form a more integral part of the final structure or patterning procedure. These alternative methods have the common feature of not using light or other short-wavelength energy sources to generate patterns, but rely on printing, imprinting, molding, or other mechanical processes instead. Before discussing nanoimprint lithography and a number of soft-lithographic techniques, we would like to illustrate the different uses of polymers in techniques such as *e*-beam and extreme ultraviolet (EUV) lithography.

2.1. Chemically Amplified Resist Materials

Over the last 15 years, silicon-based microelectronic devices have seen a dramatic increase in performance, due to the capability to produce smaller and smaller features, and to increase their surface density. Chemically amplified resist (CAR) materials, developed by Fréchet et al. at IBM, have been the main driving force behind this miniaturization [11, 12]. In particular, research has focused on positive tone photoresists consisting of polymers with acid-labile pendant protective groups, photoacid generator molecules, and additives [13]. Upon exposure to radiation, the photoacid generator molecules undergo a chemical reaction that generates a low amount of acid. During the postexposure bake, this acid diffuses and cleaves off the acid-labile protective groups. This deprotection step converts the insoluble polymers into soluble polymers, which can be washed away in the developing step. Their sensitivity relies on the chemistry of the photoacid catalysis, whereby a single radiation event (which generates the acid) can induce the chemical transformation of hundreds of molecules. The ultimate resolution of these resists is dependent on the interplay between a number of complex functions, including acid mobility and deprotection rate kinetics. Recent work uses X-ray and neutron reflectivity measurements to study the reaction front of the acid deprotection step into the polymer film [14]. The next generation of CAR materials needs to be capable of imaging feature sizes well below 100 nm, using deep-UV (DUV—248 nm), extreme UV (EUV—13.4 nm), or e-beam radiation sources. The development of these resists requires an enormous combined effort of all of the major resist manufacturers and end users [15]. EUV resists need to be applied in very thin films (<100 nm), as every organic material absorbs high amounts of short-wavelength radiation. Langmuir–Blodgett (LB) techniques have been proposed to prepare ultrathin, defect-free resist layers of poly(N–alkylmethacrylamide), although their use as EUV resists has not been shown [16]. Current resists are based on linear polymers, but it is conceivable that chain entanglement might eventually limit the minimum resolution. Recently, Fréchet and co-workers synthesized a range of dendrimers bearing thermally labile t-Boc end groups which could be used for sub-100 nm lithography [17]. Using both DUV and e-beam lithography, features as small as 50 nm with aspect ratios of 2.5:1 were achieved. Dendrimers combine the advantages of high molecular weights (and hence good processing properties) with low entanglement. In an attempt to make the lithographic process more environmentally friendly, Fréchet also reported the synthesis of water-soluble photoresists based on the photo-cross-linking of poly(methacrylates) containing sugar groups [18]. CAR resists do not have to rely on photoacids; it is also possible to use photogenerated bases and styrenic copolymers which are susceptible to base-catalyzed β elimination [19] or decarboxylation [20].

The high sensitivity of chemically amplified resists makes them ideal candidates for overcoming the low throughput in e-beam lithography, and to make fast e-beam writing possible. Negative e-beam resists are generally based on the epoxy-cross-linking chemistry of novolac polymers (glycidyl ethers) [21], with added phenylcarbinols [22] or calixarenes [23] for acid-hardening strategies.

The molecular weight of the polymers used as resists is extremely important. Poly(methylmethacrylate) (PMMA) has been the standard high-resolution positive tone resist for e-beam lithography since it was first introduced in the early 1980s [24]. The polymer undergoes chain scission, and shows a reduction in M_w upon exposure. The developer is strongly selective toward the dissolution of the low-molecular-weight components [25]. When high M_w PMMA is used (>500 kD), the fabrication of high-density nanostructures becomes very difficult as the irradiated polymer chains form a gel in the developer solution [26]. The development can be aided by sonication and a careful choice of developing solution, which contracts the radius of gyration of the PMMA inside the nanosized features. The highest resolution achieved with e-beam lithography is now about 3–4 nm [27, 28]. There is also some concern that high M_w polymers are too large compared to the structures to be resolved, which might lead to irregular features. Studies have found 20–40 nm nodes in both high and low PMMA [29]. It is therefore likely that these are caused by polymer aggregates, which will adhere to the sidewalls of the polymer features formed after developing [30].

In a fairly recent development, supercritical CO_2 ($scCO_2$) has been introduced as an alternative to developing in aqueous base [31]. It was shown that both silicon-containing [32] and a novel class of fluoropolymers containing acid cleavable tetrahydropyranyl groups [33] were good photoresists in combination with $scCO_2$ developing, facilitating the formation of 200 nm features [34].

2.2. Nanoimprinting

One of the major problems of e-beam lithography is its low throughput, which makes it a very costly technique. A viable methodology would involve the creation of nanomasters using lithographic techniques such as e-beam, focused ion beam, or extreme UV, which can then be replicated into other materials using inexpensive techniques. Over the last years, nanoimprinting has developed into a very powerful technique to generate nanometer scale features in both polymeric [35] and inorganic substrates [36]. Imprinting or embossing is a well-known technique used to introduce microstructures into hard polymers by pressing a master with surface relief features into a thermoplastic polymer film that is heated close to [37] or above its T_g [38]. This process is the basis for many commercial products, perhaps the best known of which are compact disks [39]. Chou and co-workers have demonstrated that features as small as 25 nm, extending over remarkably large areas, can be generated [40]. Nanoimprint lithography (NIL) has the potential of high throughput due to parallel processing. It does not require sophisticated tools, and allows nanoscale replication for data storage [41, 42]. Furthermore, nonplanar surfaces can be imprinted via the use of planarization layers. Multiple layers of imprinted features can then be prepared [43]. Large areas can be patterned by rolling a cylindrical mold over a flat polymer film; however, this process has not been demonstrated with sub-100 nm features [44]. A prototype "nano-CD" with 10 nm features and 400 Gbits/in^2 has been fabricated as a demonstration of the power of the nanoimprint technique

[45]. NIL is also compatible with conventional device processing techniques [46], and has been used to prepare a number of nanoelectronic devices, including GaAs metal–semiconductor–metal photodetectors [47]. When polymer films doped with dye molecules were imprinted in the submicron range, polymer films with anisotropic optical properties due to molecular alignment of chromophores [48] were formed. Similarly, organic light-emitting devices were imprinted with 200 nm gratings, which is a first step toward the fabrication of photonic crystals or lasers [49].

The quality of the nanoimprinting process depends on a number of experimental parameters, such as T_g, viscosity in the melt, and adhesion of the polymer to the mold [50]. PMMA has been most widely used as the imprintable material, but a range of thermoplastic and thermosetting polymers is under investigation to optimize the imprinting and subsequent etching steps [51, 52]. As a first step toward the integration of biological systems and nanotechnology, the interaction of cells with nanoembossed polymers has been studied [53]. Surprisingly, it was found that cells can detect nanosized "spikes," and do not adhere to these surfaces. Surfaces created in this way could have important applications in tissue engineering [54].

2.3. Soft Lithography

Soft lithography is a term coined by Xia and Whitesides [55] to describe techniques which allow the patterning of surfaces without the use of the expensive "traditional" lithographic techniques described in the previous section. These techniques are based on self-assembly and molding as low-cost alternatives for micro- and nanopatterning.

The most widely used soft-lithographic technique is microcontact printing (μCP) [56]. In this technique, a patterned elastomeric stamp formed from poly(dimethyl siloxane) (PDMS) is coated with a chemical ink (see Fig. 3). A monolayer is then transferred when the stamp is brought into conformal contact with the substrate. Submicron surface relief structures can easily be introduced in PDMS by curing the polymers against a lithographically prepared master. The advantage of μCP is the ability to pattern surfaces *chemically* at the submicron level. The fabrication of sub-100 nm surface relief features has proven to be much more difficult as nanoscale structures easily collapse [57, 58].
Figure 3. Soft-lithographic techniques using PDMS stamps.

Researchers at IBM have made considerable progress by systematically changing the cross-linking density and molecular weights of the PDMS, in addition to using a variety of nano-sized filler materials to improve the stiffness of the polymer materials [59, 60]. It must be ensured that the Young's modulus of the PDMS does not exceed a certain value; otherwise, the stamps formed will be too stiff to come into intimate contact with the surface. The specific shape of the features on the stamp is also very important. Recently, Huck and co-workers replicated PDMS stamps against 200 nm gratings in InP [61]. On the stamps, 135 nm wide and approximately 100 nm high protruding lines were separated by 65 nm wide gaps. It was found that even hard PDMS with additional amounts of cross linking did not always accurately reproduce these gratings. The attractive (van der Waals) forces between the two polymer surfaces at either side of the 65 nm gaps are sufficiently large to make the lines collapse. Mere scanning with an AFM tip was sufficient to cause this collapse. An interesting way to achieve stamps with nanometer-sized features is via anisotropic etching of Si(100) substrates. The fast etching along the preferred crystal planes generates extremely sharp etch pits or grooves. Replicating these pits or grooves into soft PDMS immediately yields stamps with a feature size in the sub-50 nm range without the need for expensive lithographic equipment [62]. Commercially available Sylgard 184 PDMS (which is most commonly used for microcontact printing) is not stiff enough to replicate these sharp features accurately. The minimum feature sizes that can be obtained with this soft elastomer are in the 100–200 nm size range. By exploiting a multilayer strategy of hard and soft PDMS, Whitesides and co-workers recently succeeded in producing composite stamps with sub-50 nm features, which were still sufficiently deformable to enable printing over large areas [63, 64]. The elastomeric nature of the PDMS can be exploited using mechanical compression of the stamp to generate smaller features. New masters can be fabricated through stamp compression, and subsequent replication of the compressed features into a hard poly(urethane) polymer [65]. After a number of cycles, PDMS stamps with sub-100 nm features were obtained [66].

A major problem which becomes significant at the 100 nm level is the rapid diffusion of the small molecules that are commonly used as inks. This limits the resolution and reliable reproduction of features using μCP to approximately 100 nm [67]. The spreading of the ink has been exploited in the fabrication of very narrow lines. By leaving the stamp on the surface for an extended period of time, the gap between two adjacent printed lines eventually narrows to approximately 100 nm [68]. Although lateral feature sizes below 100 nm are very difficult to achieve, it is possible to combine μCP and the assembly of ultrathin polymer films with nanometer precision [69, 70]. Such films can be used to amplify the initial printed pattern, and greatly enhance the etch resistance of the monolayer underneath [71]. It has been shown that polymers can be used as inks, and present a solution toward diffusion-limited feature resolution [72]. In recent work, dendrimers were used as inks to pattern silicon wafers into 135 nm wide dendrimer lines on a 200 nm pitch [61].

Replica molding (REM) is a soft-lithography technique initially used to fabricate polymer microstructures with controlled structures on planar or curved surfaces. The process

involves molding a prepolymer onto a previously fabricated master, followed by polymer curing and replica removal. The technique was subsequently extended to produce nanostructures using a PDMS stamp as the mold [65]. The soft elastomeric stamp reduces the stresses involved in the separation of the master and the replica, and therefore reduces any potential damage to the master and replica. Whitesides and co-workers have demonstrated the replication from a PDMS master of an array of 60 nm wide features into polyurethane (PU). Multiple copies were made without any noticeable reduction in the PU replica pattern fidelity [73].

The next soft-lithography technique to be discussed here is micromolding in capillaries (MIMIC), which was also developed by Whitesides and co-workers [74]. When a patterned PDMS stamp is brought into contact with a substrate, which may also be structured, an empty network of capillaries is formed. When a sufficiently fluid prepolymer is placed in contact with network openings, the liquid fills the cavities via capillary action. The prepolymer can then be cured and the PDMS stamp removed to yield polymeric patterned structures with sub-100 nm feature dimensions [75]. Through careful selection of the capillary surface energy, the exact structure of the final polymer film can be fine tuned [76]. An important advantage of MIMIC over standard lithographic techniques is that pattern formation can be carried out in a single step, a valuable characteristic for any microfabrication technique.

Phase-shift lithography is a technique which combines photolithography with soft lithography to form features at or below 100 nm [77]. The process involves the exposure of a thin layer of photoresist to polychromatic ultraviolet light passing through an elastomeric stamp which is in conformal contact. This allows standard photolithography to be carried out in the near field, with relatively simple and convenient apparatus. Whitesides and co-workers have used composite PDMS stamps to further reduce the minimum feature size possible with phase-shift lithography [64]. This work describes the fabrication of high-density arrays of ring-like structures with edge lengths down to 30 nm. These nanowells can be used as containers for the growth of inorganic nanocrystals

3. SELF-ASSEMBLY

A self-assembly, or bottom-up, approach to nanostructured polymer films is fundamentally different from the top-down lithographic techniques described in the previous section. Instead of locally destroying or deforming material to generate features, bottom-up approaches rely on the formation of covalent or noncovalent bonds between basic building blocks to generate larger structures [78, 79]. The main advantages of this approach are the ease of reaching the nanometer domain and the low capital expenditure on equipment. One of the main drawbacks of this method is the difficulty in making arbitrary features, as one relies heavily on thermodynamically defined structures. These limitations, which will become apparent below, will need to be taken into account in any device design.

3.1. Phase Separation of Block Copolymers

Block copolymers comprised of two (or more) flexible, chemically incompatible, and dissimilar blocks, for example, poly(styrene) and poly(isoprene), can microphase separate into a variety of morphologies with nanometer-scale dimensions [80, 81]. This self-assembly process is driven by an unfavorable mixing enthalpy and a small mixing entropy, while the covalent bond between the two blocks prevents macrophase separation. The microphase separation can form various morphologies, including spheres, lamellae, inverse spheres, and several more complex shapes, depending on the polymers used and on their volume fractions [82, 83]. If the morphology can be controlled [84, 85] and turned into a useful structure, phase separation of block copolymers could be a powerful tool for fabricating nanostructures without additional lithography and processing steps [86].

Phase separation of polymers into lamellar structures has been used to generate 50–100 nm thick periodic layers with different refractive indexes, which can be used as photonic crystals. Solution cast films of symmetrical poly(styrene)–poly(isoprene) (PS–PI) diblock copolymer films showed single, well-defined reflectivity peaks in the visible wavelength region [87]. The peak reflective wavelength could be tuned from 350 to 600 nm by adding homopolymers to the block copolymers, which increased the thickness of the lamellar layers [88]. By blending a triblock copolymer such as poly(styrene)–b–poly(butadiene)–b–poly(t–butyl methacrylate) (PS–PB–PBMA) with a PS–PBMA diblock copolymer, noncentrosymmetric lamellar phases were obtained with three different alternating layers [89]. Other morphologies are easily accessible by varying the two polymers in the diblocks. Dense periodic arrays of holes and dots have been fabricated by exploiting the microphase separation of poly(styrene)–poly(butadiene) (PS–PB) or PS–PMMA diblock copolymer films [90]. After microphase separation, one of the polymer components can be selectively etched and rinsed away. A typical example shows 20 nm holes, separated by 40 nm and extending over very large areas. The phase-separated structures were transferred into an underlying silicon nitride film via selective etching of one of the polymer blocks, and subsequent reactive ion etching (RIE) into the inorganic substrate. Alternatively, the pattern can be transferred into a thin poly(imide) film on a silicon substrate. Subsequent *e*-beam evaporation of metals and lift off of the poly(imide) mask results in dense arrays of metal dots [91].

Porous membranes have been formed from the diblock copolymer poly(t–butyl acrylate)–b–poly(2–cinnamoylethyl methacrylate) (PBA–PCEMA). The PCEMA block can be cross linked photochemically, while the PBA block contains the t–butyl group which may be cleaved by hydrolysis. The PBA block undergoes cylindrical phase formation, which can then be used to create thin films with regularly packed and uniformly sized nanochannels with diameters less than 20 nm. Films prepared in this way may serve as the skin layers for membranes with channels tunable both in size and in the functional groups within the cavity [92]. The long-range lateral order of the microdomains can be improved using chemically [93] or topographically patterned

substrates [94–96], the interplay between crystallization and microphase separation [97], and epitaxial growth on crystalline substrates [98].

A prerequisite for the successful use of block copolymers as nanoscopic templates is the control over the orientation of the microdomains. In particular, for cylindrical microdomains, an orientation normal to the substrate is required. This thermodynamically stable orientation can be achieved in thin polymer films by controlling the surface energy of the substrate, choosing the right solvent for drop or spin casting of the block copolymer and thermal annealing. Electrical poling can also be used to orient the microdomains [99]. The alignment of cylindrical domains and the subsequent removal of one of the components of the diblock copolymers leads to a nanoporous structure. The porous film can be filled via electrodeposition, which leads to the formation of nanowires (∼15 nm in diameter) in a polymer matrix [100]. The unfilled, nanoporous film yields a nanoelectrode array, which at low scan rates behaves like a macroelectrode, but at high scan rates, the nanoelectrodes act independently [101].

When the surface is patterned into areas of different surface tension, phase separation can be driven to follow the underlying pattern [102, 103] (see Fig. 4). A thin film of a poly(styrene) and poly(vinylpyridine) (PS/PVP) blend was spun cast on top of alternating hydrophobic and hydrophilic stripes. As the two polymers are strongly incompatible, demixing takes place during spin coating. After the solvent has completely evaporated, the topography of the polymer film mimics the underlying surface energy pattern. Rinsing the films with cyclohexane selectively removes one of the polymers (PS), leaving patterns of PVP behind. Recently, results have been published which indicate that control over phase separation can be extended to the sub-100 nm size regime [104]. Further developments in this direction could lead to the generation of functional patterns of various designs in microphase-separated structures. However, the kinetic pathways through which the equilibrium-phase-separated states are reached delicately depend on the particular pattern, its size, and overall film thickness [105], and in practice, this means that it is quite difficult to obtain a well-defined phase-separated structure that follows the underlying pattern.

3.2. Polymer Nanotubes

Polymeric nanotubes have received considerable attention recently as potential "molecular wires" and replacements for carbon nanotubes which are difficult to functionalize. Polymers with suitable electronic and optoelectronic properties have been structured into nanofibers as it was envisaged that they would be used in nanoscale devices. Polymer structures were produced within the pores of

nanoporous membranes [106] or zeolites [107]. Specifically, well-defined poly(p–phenylene vinylene) (PPV) fibers have been produced inside hexagonally ordered templates formed from liquid crystalline materials [108]. The formation of nanowires without the use of templates is also possible, although there is only limited control over the shape, dimension, and orientation of the fibers [109]. Nonetheless, impressively regular polypeptide nanotubes show the potential of this kind of approach [110]. The formation of individual nanosized objects from block copolymers is also possible, although the design parameters are less well understood. A number of general concepts have been described. Amphiphilic block copolymers, for example, poly(stryrene)–block–poly(acrylic acid), form so-called crew-cut aggregates [111] when they are first dissolved in a good solvent and water is slowly added, leading to controlled aggregation of the hydrophobic blocks [112]. Similar nanostructures can be formed based on the thermoreversible dissolution of block copolymers in single solvents [113]. The amphiphilic properties of the blocks can be tailored via hydrogen bonding with small surfactant molecules. These occupy polar or charged sites on one of the blocks, leading to a controlled, shielded assembly of individual crew-cut aggregates [114]. A disadvantage of these methods is the sensitivity toward the dissolution–precipitation process and the instability of the objects formed. "Freezing" the self-assembled nanostructures can be achieved by incorporating photochemically cross-linkable groups or blocks [115]. The cross-linked fibers can subsequently be "sculptured" by selectively dissolving or degrading one of the blocks, and are stable enough to be suspended in other solvents [116]. An inverse approach can also be used to form organic–inorganic mesoporous materials, where self-organized surfactant phases form templates for the mineralization of a variety of inorganic minerals [117]. Instead, the block copolymers aid in the controlled, nanostructured mineralization of aluminosilicates [118], which are subsequently removed, to render individual polymeric "hairy objects" [119]. An elegant approach toward polymeric nanostructures has been explored by Steinhart et al. [120]. By simply placing a polymer melt or solution on a nanoporous surface, monodisperse polymer nanotubes form after the polymers wet the inside of the pores. Wall thickness, composition, length, orientation, and ordering of the polymeric nanotubes can be easily controlled by varying the polymers used, the surface energy, and the pattern of the mold. Instead of wetting the inside of capillaries to create hollow nanofibers, one can also coat the outside of ultrathin fibers, and subsequently remove this template [121]. The templates are formed via electrospinning [122] of easily degradable polymers, and fibers with diameters as small as 100 nm can be prepared [123]. Interestingly, fibers with surprisingly regular elongated pores in the 200 nm region were obtained by electrospinning dichloromethane solutions of poly(L–lactide) [124]. It is thought that spinodal phase separation as a result of very rapid solvent evaporation, followed by solidification of the polymer fibers, leads to the formation of these structures. Using a sol–gel coating technique, these fibers can also be used as templates for nanoporous TiO_2 tubes, which could have important catalytic properties and applications in solar cells [125].

Figure 4. Phase separation of block copolymers leading to well-organized nanoscale surface features.

4. POLYMER NANOPARTICLES

Thus far, we have discussed numerous examples where polymers are structured at the nanometer level via lithographic methods or by the exploitation of self-organization and phase separation. Nanoparticles have been fabricated using a variety of synthetic techniques, for example, via miniemulsion polymerization, which has been optimized to yield particles ranging from 20 to 50 nm [126]. Landfester and co-workers have exploited the miniemulsion process to prepare semiconducting polymer nanospheres, which can be deposited via spin coating from aqueous dispersions [127, 128]. Miniemulsions are understood as stable emulsions consisting of stable droplets with a size of 20–500 nm created by shearing a system containing oil, water, surfactant, and a highly water-insoluble compound [129, 130]. Polymer particles are formed by polymerizing monomers that are dissolved in the oil phase [131], or by evaporating the solvent, leaving polymer residue behind [132]. Miniemulsions also allow the formation of hollow particles that can be used as nanocapsules [133]. It has also been possible to form inorganic microcapsules filled with organic liquids or polymers [134], chitosan-grafted biopolymer nanocapsules [135], molecularly imprinted polymer nanospheres for use as affinity receptors [136], and semiconducting polymer nanospheres [137].

Polymeric nanostructures are more commonly prepared via a bottom-up approach by synthesizing polymers with well-defined shapes (see Fig. 5). Synthesis can be carried out on assemblies that are spatially constrained to form novel structures [138]. Functionalized polymeric nanoparticles have a huge potential in a range of nanotechnological applications, ranging from vectors for drug-delivery systems [6] to templating agents for nanoporous microelectronic materials [139].

4.1. Dendrimers

Dendrimers, with their perfectly branched architectures, are the best known examples of spherical nanoparticles consisting of single molecules [140, 141]. Their highly branched structure gives rise to interesting properties which are different from those exhibited by linear polymers with similar molecular weights [142–147]. Dendrimers can be synthesized via divergent [148–155] or convergent [156–158] pathways, leading to full control over the placement of every monomer in the ever-growing molecule. There is no need to discuss dendrimers in great detail here, as they have been the topic of numerous books and review articles over the last few
years [159–170]. As a result of their branched architecture, the shell of the dendrimers can be made denser than the inside (core). This has been exploited to make molecular containers [171, 172] large enough to encapsulate up to five large dye molecules [173, 174]. It is possible to produce dyes with modified properties via the synthesis of dendritic chromophores which consist of a fluorescent core attached to a dendrimer [175–181]. Polyamidoamine (PAMAM) dendrimers have shown promising results as delivery agents in DNA transfection studies [182]. The full control over the synthesis enables the placement of functional groups at any position. For example, redox-active metal porphyrins in the center of large dendrimers can become completely shielded from the environment, altering the redox potential [183]. A number of other redox-active moieties have been investigated, including tris(bipyridine) ruthenium (II) complexes [184], fullerines [185], ferrocenes [186–189], oligothiophenes [190], oligonaphthalenes [191], and 4,4′–bipyridinium [192]. Research has shown that the dendritic structures have an insulating effect on the redox sites [193]. Even more elaborate structures contain light-harvesting groups at the periphery of the dendrimers, combined with electroactive cores, as a first step toward molecules that are able to transform solar power into electrical energy [194–199]. Conjugated dendrimers have also been synthesized for use in light-emitting devices [200–203]. The shielding of the dendrimer core from the environment has been used to introduce simple catalytic functionality [204–214]. Photochemically responsive cores have been incorporated into dendritic structures so that they may potentially be used as molecular switches [215]. Azo linkers which can undergo a photochemical cis-trans isomeration have also been investigated [216–222]. Dendrimers with hydrophilic outer rims and hydrophobic interiors provide an ideal microenvironment for reactions that proceed via apolar transition states. The reactants (which do not react significantly in the polar solvent in which the dendrimer is dissolved) diffuse toward the interior, with its more apolar "climate." The reaction then proceeds to yield polar products, which are subsequently expelled from the interior and diffuse back into the solvent [223]. One of the major problems associated with dendrimer use is the daunting synthesis of these large (M_w over 10,000) molecules with numerous functional groups. Instead of making molecularly perfect structures, considerable effort has been devoted to the facile synthesis of structures that have a similar construction, but are far easier to synthesize.

4.2. Cross-Linked Micelles

Discrete nanoparticles may also be synthesized via new methodologies such as intramolecular chain collapse, as demonstrated in a recent elegant example by Hawker and co-workers [224]. First, linear chains with benzocyclobutene (BCB) coupling groups were synthesized using a controlled radical polymerization. The monodisperse polymers that were obtained assumed a spherically shaped random coil in solution. Collapse of these chains, followed by intramolecular cross linking, leads to the formation of discrete nanoparticles [225]. This strategy allows the synthesis of polymeric nanoparticles on a multigram scale with minimal difficulty.

Figure 5. Selection of polymer nanoparticles with different molecular architectures.

Instead of intramolecular cross linking of single chains, a number of groups have utilized intermolecular cross linking of preassembled polymer chains, to synthesize well-defined spherical nanoparticles, known as polymer micelles. These polymer micelles are prepared through the self-assembly of amphiphilic block copolymers in aqueous solutions [226, 227]. The particles have diameters ranging from 20 to 200 nm, and are generally spherical. Other shapes have also been observed, including fractal structures consisting of toroidal networks, worm-like micelles [228, 229], and vesicles [230]. Polymer micelles only exist above critical micelle concentrations, and show a strong dependency on solvent polarity and salt concentration.

Covalent cross linking of the chains stabilizes the structures, forming cross-linked dendrimer-like nanospheres [231, 232], polymer brushes [233], and shell cross-linked knedel-like (SCK) structures. SCKs combine the features of a hard shell with a fluid cavity, block copolymer micelles, and dendrimers. These amphiphilic copolymer micelles consist of a rigid, but permeable cross-linked outer layer and a mobile uncross-linked interior. It is believed that these types of structures will find applications in phase-transfer reactions, drug delivery, and industrial support catalysts [234]. The resulting materials, consisting of nanoparticles embedded in an insulating matrix, have semiconducting properties which are independent of the type of DNA used [235].

A large range of different structures is possible through the careful design of each block within the diblock copolymer. Nanofibers may be created, where one block is the cross-linked core and the second block forms the concentric shell [236, 237]. Hollow nanospheres [238, 239] can be formed by varying the segments of the block copolymers used [240], and by postfunctionalization of the cross-linked nanoparticles [241]. Pore generation within nanospheres was carried out via the introduction of a porogen (a short chain polymer) into the micelle core. The core structure was locked in shape through cross linking, and the porogen could then be removed. These cavities were then used to estimate the thymine–adenine binding constant within the pores [242].

5. BIOLOGICAL POLYMERIC ASSEMBLIES

This chapter has thus far focused on synthetic polymers that have well-defined nanoscale dimensions or polymers that self-assemble and self-organize into nanostructures. As explained in the Introduction, polymers are ideal nanoscale building blocks, and are widely used in the natural world as part of the cellular machinery. Much of the inspiration for the research reviewed in this chapter has come from biological macromolecules and macromolecular assemblies. There are many hundreds of examples of biological polymers and their nanoscale functionality, and as a result, we would like to focus on the only real biopolymer that can be designed and synthesized from molecular building blocks: DNA. DNA has found its way into nanotechnology because of its unique self-assembly and recognition properties, in addition to its ease of synthesis. Here, we illustrate the wide range of research that has exploited DNA, including the organization of nanoparticles and the direct assembly into nanostructures. This section will conclude with the very few examples of protein engineering which give a hint of future developments involving complex proteins in well-defined nonbiological devices.

Nature uses polymers such as DNA, proteins, and a range of biopolymers as building blocks to form working nanoscale devices, including viruses, bacteria, and ultimately, the cells of higher organisms. The ribosome contained within cells is constructed from two subunits of RNA and protein. Their function is to utilize the information coded within DNA to fabricate polypeptides within the cytoplasm. This is a perfect example of a polymeric device used to manufacture new polymeric structures. Muscle contraction is another example where nanostructures feature in biological function. The globular protein actin can polymerize into long fibers which are widely distributed within cells. In muscle, these actin fibers are interdigitated with myosin aggregates, and it is the relative movement of these two sets of fibers which gives the molecular basis of muscle contraction.

5.1. DNA Structures

The bottom-up approach toward structurally well-defined nanoarchitectures needs a molecular toolkit that allows the facile assembly of molecular building blocks into two- and three-dimensional structures [243]. DNA is potentially one of the most versatile and well-understood "glues" available to the biologist, chemist, and materials scientist [244, 245]. For this reason, a number of groups have utilized DNA to generate nanostructured materials [246–248] or to arrange nanoparticles [249, 250]. The main reason for the attractiveness of DNA as a nanoscopic building block is the hybridization of complementary single strands into a double helix. This hybridization is based on the formation of multiple hydrogen bonds between the matching bases in each strand. The process is very robust, and leads to stable structures, but more importantly, it is a very selective process: only complementary strands are able to form the double helix. This allows the "programming" of all assembling processes, which is an almost unique property for any "assembler" in the nanometer-size scale [251]. Nanoparticles coated with different strands of DNA (via a thiol linker) will recognize each other in solution and aggregate [252]. The aggregation leads to a color shift of the nanoparticle solution [253], and can be used as a colorimetric detection of specific DNA sequences [254, 255]. This strategy can also be used to induce the formation of binary or ternary nanoparticle networks, combining large and small particles [256]. The aggregation is not limited to gold or silver nanoparticles, but can be extended to incorporate semiconductor quantum dots such as CdSe [257]. The aggregation has almost exclusively been studied in solution, but is also very effective in the layer-by-layer build up of DNA and gold nanoparticle composites [258]. An elegant example of the programmable hybridization is the use of DNA as a molecular ruler that governs the exact distance between two metal nanoparticles [259]. A single strand of DNA with a number of recognition sites has been decorated with 1.4 nm nanoparticles containing different short complementary sequences. The length of the DNA that interconnects the particles can simply be tailored by synthesizing longer sequences. An even more complex experiment used the combined molecular recognition powers of DNA/RNA and of streptavidin–biotin to organize 1.4 nm Au

nanoparticles in yet more complicated patterns [260]. DNA has also been used as a template to grow nanometer-scale conducting silver wires. Instead of linking two nanoparticles together, a 16 μm long single strand of λ DNA was used to bridge the gap between two electrodes, both functionalized with short DNA strands. Silver ions were then deposited onto the organic DNA double-helix bridge, which were reduced to form metallic silver. Overall, 100 nm wide, 12 μm long metallic wires were fabricated [261]. Although these are only crude proof-of-principle experiments, they nonetheless demonstrate the power of self-assembly of macromolecules in nanofabrication.

All of these strategies use DNA as a programmable assembler to connect inorganic building blocks. Perhaps the most stunning structures that have been formed from DNA have been synthesized by Seeman and [262, 263]. In that work, DNA is the material from which complicated 2-D and 3-D molecules are built, entirely relying on the hybridization of complementary strands [264, 265]. The first innovation was the use of three- or four-arm junctions through appropriate sequence design, hybridization conditions, and annealing procedures [266, 267]. These junctions later served as corners in more complex structures, by combining the "sticky ends" of the junctions with short rigid pieces of double-stranded DNA. Three-arm junctions were combined to form triangular [268] or square grids [269], or even cubes [270]. It is important to note that this DNA cube does not actually resemble a cube when in solution; its structure is based on the topology, or interconnectivity, that is equivalent to a cube. The synthesis of these molecules is extremely complicated, and a solid-phase strategy was adopted to increase both yields and the amounts of nucleotides that can be introduced [271] (see Fig. 6).

To improve the structural rigidity of the nanostructures, double crossovers (DX) were introduced, which fuse two double helices together [272, 273]. These DNA structures do yield recognizable structures in solution compared to the DNA structures described above. Amazingly, triangles can be hooked up to a longer chain, leading to a necklace pattern that can be visualized with AFM [274]. The spacing between the triangles can easily be tailored via the supporting strand. By designing DX building blocks with "sticky ends" that were linked to form 2-D crystalline networks, periodic arrays as large as 2×8 μm were formed, and the network repeat units could be characterized by AFM [275]. The stiff, essentially linear DX double double helices form dense mats or porous networks, completely following the self-assembly designs that are programmed into the polymers [276].
Figure 6. Self-assembled DNA structure.

5.2. Biological Nanomachines

So far, we have discussed a wide range of different nanoscale structures that were assembled from polymeric building blocks. However, almost all of these structures are very far from actual working devices; in fact, the only process where polymers are used to fabricate devices is in the (conceptually) old-fashioned process of lithography. Yet, as we have briefly discussed in the Introduction, polymers are the building blocks for devices in the biological world. For example, the ribosome forms one of the most impressive pieces of cellular "machinery," and consists of two large subunits. Each subunit, in turn, consists of RNA and over 20 proteins. These proteins unwrap DNA, read the information it contains, assemble proteins from amino acids, and rewrap the DNA again [277, 278].

These are the kind of truly astonishing devices that will need to be developed if nanotechnology is going to make a huge impact on fields such as medicine, chemistry, and materials science. Over the last decade, considerable progress in this direction has been made. One of the most impressive examples involves harnessing motor proteins into powering inorganic devices. The rotary nature of the ATPase enzyme was conclusively demonstrated by Noji et al., with the attachment of actin filaments to the motor protein. They showed that the work performed by the enzyme was almost 100% efficient [279]. Montemagno and co-workers [280] fabricated tiny biomolecular motors constructed from three elements: lithographically produced nickel posts with a height of 200 nm and a width of 80 nm, a recombinant F_1–ATPase enzyme anchored to the nickel posts via histidine tags, and an individual silicon nanopropellor attached to each enzyme. These silicon rotors were functionalized with a biotinylated histidine-rich peptide to facilitate attachment to the F_1–ATPase enzyme. The addition of Na_2ATP caused the rotors to rotate in an anticlockwise direction at speeds of up to 8.3 r/s. The motion of the propellers could be stopped by the addition of sodium azide, a potent ATPase inhibitor. This conclusively demonstrated that the movement was due to the F_1–ATPase motors. Research has also focused on harnessing the movement of kinesin, another motor protein powered by the hydrolysis of ATP. Kinesin acts by moving along tubular protein filaments, known as microtubules, and the drive of this research has been to restrict the movement of microtubules along predefined pathways. In recent work by Uyeda and co-workers, lithographic techniques were used to create embedded glass tracks which confine the movement of the microtubules [281]. Their novel approach overcame the common drawbacks of systems involving motor proteins, including the loss of filaments over track boundaries [282, 283] and bidirectional movement [284]. The system developed by Uyeda and co-workers displayed linear unidirectional movement through the incorporation of arrowheads along the tracks. This allowed the fabrication of so-called microtubule circulators, and enabled the active transport of tubules from a randomly distributed configuration to one in which only one of two sides is populated. It is possible that future devices will be constructed from a combination of microtubules and conventionally fabricated silicon structures.

6. SUMMARY

The range of examples reviewed in this chapter illustrate how control over polymers and polymeric materials can aid the fabrication of nanoscale devices. Synthetic routes designed to control polydispersities and molecular weights of polymers were essential in the development of photoresists that can now be used in extreme UV lithography to create patterns in the 150 nm, and ultimately in the sub-100 nm, regime. Alternative techniques exploiting contact printing, molding, and embossing or imprinting all rely on the nanostructuring of polymers to replicate nanoscale features in an economically viable way. At the same time, synthetic capabilities have expanded to give perfect control over the phase separation of block copolymers, which is another rapidly expanding field of research. Nanoparticles can also be obtained by synthesizing polymer molecules with increasingly large dimensions, while maintaining control over their three-dimensional shape and functionality. Examples include dendrimers, hyperbranched polymers, cross-linked micelles, and core–shell particles. These have great potential as nanoreactors, delivery vehicles, transfection agents, and rheology modifiers. Natural systems are unmatched in their controlled three-dimensional shape and their ability to perform work at the molecular level, as the examples of the motor proteins surely show. Slowly but surely, however, synthetic polymers are approaching a level of complexity that can finally result in the mimicking of biological polymers. The field of polymers in nanotechnology will continue to show a diverse array of developments, leading to increasingly complex structures and the incorporation of these synthetic polymers into nanoscale devices.

GLOSSARY

Biological polymers Polymers which exist in nature e.g. DNA, proteins, polysaccharides, gums, and resins.

Block copolymers A copolymer where each type of monomer is arranged in substantial sequences or blocks. ~AAAAABBBBBAAAAA~

Copolymer A polymer which is composed of two or more types of monomer unit.

Cross-linked micelles Discrete nanoparticles formed by the cross-linking of polymer to achieve spherical shapes.

Dendrimer A unique type of polymer which is a highly branched three-dimensional macromolecule with highly controlled structures, a single molecular weight, and the flexibility for tailored functionalization.

Deoxyribonucleic acid (DNA) A double-stranded helix of nucleotides which carries the genetic information of a cell. It encodes the information for proteins and is able self-replicate.

Microcontact printing (μCP) A type of soft-lithographic technique which involves the use of a patterned elastomeric stamp formed from poly(dimethyl siloxane) (PDMS) with a chemical ink to transfer monolayers on to a substrate when the stamp and the substrate are brought into contact.

Molecular weight (M) The weight average molar mass of the molecules present in the polymeric mixture.

Molecular wires Molecular wires are single chain conducting molecules which have their ends attached to electrodes.

Monomer A small molecule which can be joined together to form larger molecules such as dimers, trimers or polymers.

Phase separation When there are two or more components in a system which are immiscible then the components separate into their respective phases.

Photolithography A process of transferring geometric shapes on a mask to a surface using radiation commonly UV, extreme UV, *e*-beam, or X-ray. A layer of photoresist is placed on the surface using spin-coating, and parts of it are removed during the lithographic process to transfer the shapes.

Photoresist Organic substances (monomeric or polymeric) which are sensitive to light. There are two types of photoresists: positive and negative. Positive photoresists are often polymeric material which have photolabile groups which cause the material to become soluble in the developer on exposure to light. Negative photoresists are often monomeric material which polymerize on exposure to light.

Polymer A large molecule constructed from many smaller structural units called monomers.

Self-assembly Self-assembly is a thermodynamic process by which molecules come together to build desired supramolecular structures due to specific intermolecular interactions. Examples of self-assembly are often seen in nature.

Soft lithography A lithographic technique which allows the patterning of surfaces with the use of expensive traditional photolithographic processes. Different types of soft lithographic techniques include phase shift lithography, microcontact printing, nanoimprinting, and micromolding.

Spin coating A process to form thin films of material by placing a solution of the material on the center of a disc and spinning very rapidly allowing the material to spread out evenly and thereby forming a thin film.

Synthetic polymers Man-made polymers which were synthesized either by chain polymerization or step (condensation) polymerization.

CONTENTS

1. INTRODUCTION

The experimental preparation of supported, oriented monolayers of polyfunctional organic molecules with a variety of molecular structures was first achieved in the early 1980s [1–5]. This technique involved the adsorption of disulfides on zerovalent gold substrates, which spontaneously organized into films. These films have come to be known as self-assembled monolayers (SAMs). Several types of SAM systems have been developed and characterized, including organosilicon–oxide, carboxylic acid–metal oxide, and organosulfur–noble metal (Au or Ag). Because self-assembly is a viable means of controlling the physical and chemical properties of solid surfaces, many studies have been devoted to the development of thin films of functionalized molecules for optical, electronic, mechanical, or biochemical applications [6–8]. Of all of the monolayer systems, the thiol SAMs on Au(111) have received the most extensive experimental [9–21] and theoretical examination [22–39].

Technological applications, such as microelectromechanical systems (MEMS) [40–44] and magnetic storage devices [45–47], have piqued interest in the potential use of organic films for boundary layer lubricants. In these applications, the thickness of the lubricating film is on the order of a monolayer. At these thicknesses, adhesion of the molecules to the substrate is of paramount importance, particularly in applications that involve the relative motion of solid surfaces in contact. Thus, monolayers formed from self-assembly, which are covalently bonded to the substrate, such as alkanethiols and alkylsilanes, are good candidates for boundary layer lubricants. As a result, the mechanical and tribological properties of self-assembled monolayer materials have been studied a great deal using scanning probe microscopies [48–71].

The atomic force microscope (AFM) provides a unique and powerful means of directly investigating the tribology of atomic-scale contacts. However, interpretation of data obtained from AFM experiments is notoriously difficult for a number of reasons: absolute quantitative measurements are often not possible, the structure of the AFM tip may not be known, nor is its structure necessarily preserved during the course of an experiment, and the preparation and characterization of samples can be difficult, and involves many uncertainties [65].

Molecular dynamics (MD) simulation is a useful tool that can be used to model atomic-scale probes in sliding contact with SAMs, providing information that would otherwise be unavailable [72, 73]. Like AFM experiments, MD experiments are faced with a number of difficult challenges, most notably problems of scale. Despite the exponential growth in computing power, it will be quite some time before the time and length scales of laboratory experiments can be approached. Computational groups that have undertaken MD investigations of the tribology of SAMs have often taken very different approaches. Broadly, the differences can be addressed by a number of basic questions: How are atomic-interactions modeled? How are the initial SAMs and the initial probing tips designed? How are external forces used to control load and temperature? How are the challenges of length and time scales handled? These questions are not independent of one another. However, they do provide a useful framework within which the work in this field can be understood. This review focuses on work by groups that have undertaken computational studies aimed at complementing AFM or surface force apparatus (SFA) tribology experiments with SAMs. This review does not provide an exhaustive discussion of the modeling work that deals with the structure and dynamics of monolayer films. The reader is referred to the original papers for such a detailed discussion. In this work, the structure is discussed because it is a starting point for the MD studies of the tribology of SAMs. This work is intended to discuss MD simulations that focus on the tribology of SAMs, highlighting some significant issues associated with these studies (and MD simulations in general), as well as indicating some possible future directions.

2. THE UNITED-ATOM MODEL

The works of Hautman and Klein [22, 23] are among the earliest MD studies concerned with the structure and dynamics of long-chain molecules on metallic substrates. Although these are not tribological studies, they are particularly relevant because they employ a basic molecular model that has been subsequently adopted by most groups undertaking computational studies of alkanethiol SAMs. More recently, the structure [22–39], compression [74, 75], and the friction [76, 77, 79–92] of alkanethiol monolayers have been the subject of considerable theoretical examination. In addition, the particular system under investigation, $SH(CH_2)_{n-1}CH_3$ chains anchored onto a gold surface, represents a type of sample that has been extensively examined in AFM friction studies of SAMs.

The classical empirical model utilized by Hautman and Klein is the united-atom potential [93, 94]. This model has been used in MD studies of the structural and dynamical properties of a variety of complex molecular systems such as solid alkanes [95, 96], layers of long-chain molecules [97–100], and organic liquids, including thiols [101, 102]. Hautman and Klein adopted the basic model of these studies, and extended it to model the interaction of chain groups with a gold substrate.

In the basic united-atom model, the CH_2 groups, the terminal CH_3 group, and the anchoring sulfur atom are represented as spherical pseudoatoms. This allows for computational efficiency and fewer parameters at the expense of some realism. Essentially, the pseudoatom represents an average over the motions of hydrogen atoms attached to the carbon atom of interest. To eliminate the time scale issues associated with high-frequency vibration, bonds between pseudoatoms are held rigid [103]. By constraining the system to evolve only through the low-frequency angular deformations of chain backbones, the equations of motion can be evolved using relatively large time steps, for example, time steps on the order of 5 fs.

The intramolecular potential includes a harmonic angular-bending potential, where the angle is that formed by three consecutive Pseudoatoms. Also included is a torsional potential that is a function of the dihedral angle associated with four consecutive pseudoatoms (the middle two atoms define the axis perpendicular to the plane containing the dihedral angle). pseudoatoms in the same chain that are farther apart than fourth nearest neighbors, and pseudoatoms from different chains, interact through Lennard–Jones potentials. This qualitatively characterizes the model of atomic interactions utilized by most groups that have undertaken computational studies of the structural [22–39], mechanical [74, 75], and tribological [76, 77, 79–92] properties of alkanethiol SAMs.

To describe the interactions between pseudoatoms and the metallic substrate, a straightforward approach would be to integrate the 12–6 interactions over the half space describing the substrate. The resulting form, however, does not accurately describe basic properties, such as binding energy, distance above the surface, and dispersion coefficient [104, 105]. Instead, Hautman and Klein utilized a 12–3 form for the surface potential. Coefficients for the CH_2 and CH_3 pseudoatoms are fixed using a combination of scaling arguments to connect with Lennard–Jones parameters and existing fits to Kr on Ag(111) [105]. Parameters for the S–Au surface interaction were fixed using thermal desorption and electron energy loss spectroscopy measurements for dimethyl disulfide on Au(111).

In their initial study, Hautman and Klein equilibrated arrays of 90 $SH(CH_2)_{15}CH_3$ (hexadecanethiol) chains at room temperature, with periodic boundary conditions imposed to model infinite monolayer surfaces [22, 23]. The use of periodic boundary conditions is a standard tool utilized in all of the theoretical studies discussed in this review. Two model systems, referred to as models I and II, were investigated for comparison. Both models make use of the potential outlined above. Model I leaves the angle between the S–C bond and the surface normal unconstrained, while Model II imposes a harmonic bond-bending potential with a potential minimum at an angle of 100° with respect to the horizontal. The force constant is taken to be the same as for the bond-bending potential describing the hydrocarbon chains. These two models represent limiting behaviors.

After equilibration, Model I shows an ordered all-*trans* arrangement of chains uniformly tilted with respect to the surface normal. There were very few gauche defects, and they were confined primarily to the ends of chains. As expected, Model II shows very different characteristics near the head groups. Due to the extra constraint causing the

S–C bond to lie approximately parallel to the gold substrate, nearly every chain exhibits a gauche defect near the head group, causing the chains to take on a characteristic "L" shape. Far from the head groups, however, the chains take on an ordered uniformly tilted arrangement as in Model I. Although Model I is somewhat more ordered, the models are very similar in the region far from the head groups. This ordered uniformly tilted arrangement appears to be a general property at this packing density, and does not appear to be sensitive to the details of how the chains are anchored to the underlying substrate. This structure has been observed in many simulations of anchored long chains using a number of potential energy functions [106–113]. The similarity between Models I and II, in the regions far removed from the gold substrate and chain-head groups, suggests that the tribology of these systems may not be very sensitive to the details of the substrate–chain interaction. It is likely that the structure of the interface between sliding surfaces will be of paramount importance, and these limiting models investigated by Hautman and Klein show no significant difference in this region.

3. STRUCTURE OF ALKANETHIOL SAMs

There have been many theoretical studies of the structure of long-chain molecules on substrates [22–39, 106–115]. By far, the majority of the theoretical work has focused on the structure of model alkanethiols. Experimental studies of the structure of alkanethiol SAMs on Au(111) have shown a slightly distorted $(\sqrt{3} \times \sqrt{3})R30°$ triangular lattice structure corresponding to a chain–chain spacing of approximately 5 Å and an area of 21.6 Å^2 per chain [9–21]. The hydrocarbon tails self-organize into a well-ordered monolayer with chains tilted uniformly toward their next-nearest neighbors. Additional experimental studies of the structure of alkanethiol SAMs at low temperatures (50 K to room temperature) revealed a $c(4 \times 2)$ superlattice structure [116–118] (four chains per unit cell, with two types of chains whose carbon backbones are oriented differently from one another). Hautman and Klein pointed out that several phases might exist in SAMs over the accessible temperature range [22, 23]. In addition, multiple structures might exist for chains of different lengths at a given temperature [18]. Few of the theoretical studies on this system have been able to reproduce the superlattice structure. Only two papers to date have produced a superlattice structure [31, 37]. In what follows, we discuss a cross section of the theoretical papers dealing with the structure of alkanethiol monolayers.

In one of the earliest works [24] on the structure of alkanethiols, the collective tilt behavior of chains containing 20 psuedoatoms and 20 carbon atoms as a function of density was examined using the united-atom potential and an all-atom potential [93, 94]. Bond lengths were constrained in the simulations using both potentials, between pseudoatoms in the united-atom simulations, and C–C and C–H bonds in the all-atom simulations. Simulation cells contained 90 molecules in a triangular lattice with periodic boundary conditions imposed.

Conformational, or gauche, defects were most often present at the ends of the chains. This phenomenon has been observed in earlier simulations [22, 23] and subsequent simulations of alkylsilane monolayers [110], long-chain alcohol molecules [108], and monolayers composed of alkane chains [109, 122]. Karaborni [106, 107] utilized an anisotropic united-atom model to model the approach and separation of opposing monolayers. Simulations were performed by compressing 128 molecules, with 19 CH$_2$ segments and a COOH head group, evenly distributed on two plates (25 Å^2 per molecule) at 7 m·s^{-1}. These simulations also showed that increasing the tilt angle of the molecules decreased the number of gauche defects in the midsections of both monolayers. This same link between tilt angle and gauche defects was observed in the simulation of long-chain alcohols [108].

Bareman and Klein determined that the average tilt angle increases with increasing area per chain (density), and that the molecules are in a rotator phase (molecules rotating about their molecular axis) at 300 K for both potential models [24]. However, the backbone orientation distribution functions and the reorientation relaxation times differed depending upon the potential used. Use of the proper all-atom parameters led to monolayers that exhibited the collective tilt angle and density behavior observed in experiments, while the united-atom potential did not. Lastly, the united-atom parameters, which were fit to the bulk properties of short alkane chains, were shown to significantly underestimate the effective diameter of the C$_{20}$ chains studied. This study, and another by Klein and co-workers [25], showed that the inclusion of hydrogen atoms has a significant impact on the structure of the SAMs. In fact, stable next-nearest neighbor configurations could not be obtained using the united-atom potential. In simulations of crystalline n–alkanes, the explicit treatment of hydrogen atoms was essential to obtain the proper packing structure [28, 39]. Thus, there remain some unanswered questions regarding the validity of the united-atom potential for simulations of SAMs [22–24, 28, 30, 31].

Garrison and co-workers used MD and the united-atom potential to do an exhaustive search of the phase space of chain orientations and tilt directions to determine possible candidates for the $c(4 \times 2)$ superlattice [31] of alkanethiol SAMs. The simulation systems were composed of 64 chains placed over eight layers of Au to form the $(\sqrt{3} \times \sqrt{3})R30°$ structure. The top three layers of Au atoms were allowed to move according to Newton's equations of motion, the four intermediate layers were coupled to a thermostat, and the bottom-most layer was rigid. In contrast, in all previous simulations of alkanethiols on Au, the S–Au attachment to the surface was fixed [22–30, 32–39].

One structure for the $c(4 \times 2)$ superlattice for chains with 4–6 carbon atoms and three structures for chains with 12 or more carbon atoms were obtained. None of these structures contained chains that were in a perfectly perpendicular herringbone arrangement, as depicted by most theoretical papers [22–30, 32–39]. Rather, a skewed herringbone structure was obtained with the interplanar angle different from 90°. However, only two of the proposed structures were stable with respect to time at temperatures below 100 K. The remaining two structures (for long chains) only survived several hundred picoseconds before the chain backbones reoriented themselves. This process typically involved

a small amount of untilting (1–5°). The authors speculated that this might be the preferred mechanism for monolayers to undergo structural changes, and that adding bulky groups to the chains might prevent this reorientation.

One of the most recent investigations of alkanethiol self-assembly on gold was conducted by Goddard and co-workers [37]. The goal of that work was to develop a force field that would be capable of predicting the $c(4 \times 2)$ super-lattice structure which was stable over a wide temperature range with no disulfide bonds to the substrate. For a model to be able to predict the superlattice structure, it appears that an accurate force field for the S–Au interaction must be used. Early studies of alkanethiol structures on gold, where the sulfur–psuedoatom interaction within the united-atom potential and the surface was modeled as a continuum interacting with pseudoatoms via a structureless potential, were unable to predict the superlattice structure. In contrast, by using mobile S atoms and dynamic Au atoms, Bhatia and Garrison identified four possible $c(4 \times 2)$ superlattice structures for different length alkanethiols, which were all unstable [31].

Goddard and co-workers [37] performed quantum mechanical calculations on Au clusters of 15 atoms and periodic systems of two Au layers. Both of these systems showed that the *fcc* bonding site had the lowest energy. Then a force field was developed by using the results of the quantum calculations on the periodic system. Using the developed force field, MD simulations on monolayers with chain lengths from C_1 to C_{18} were conducted. The $c(4 \times 2)$ superstructure was reproduced at 300 K. Simulations on C_{12} chains between 50 and 400 K showed that the tilt angle decreased and the monolayer thickness increased as the temperature increased.

A small number of theoretical studies have also examined the structure of hydrocarbon chains attached to silica [29, 111]. For example, the structure of monolayers containing a hydrocarbon chain with azobenzene surrounded by other pure hydrocarbon chains was examined [29]. The simulation cell was an (8×8) square lattice that corresponded to a 21 Å^2/chain surface density. Two configurations, *cis* and *trans*, of the azobenzene chain were examined. The main difference in the monolayers studied was that the *cis* monolayers had looser packing, and the *cis*–azobenzene chains were shorter than the surrounding hydrocarbon chains. The *trans*–azobenzene chains were higher than the surrounding monolayers.

4. OPPOSING MONOLAYERS

The earliest computational studies of SAMs that examined tribology are those of Tupper and Brenner [75, 76] and Glosli and McClelland [77]. Both groups utilized the united-atom potential model [91, 92] to simulate the monolayer chains. Glosli and McClelland [77] focused solely on the friction between identical, ordered monolayers, which models the geometric setup found in SFA experiments [78]. Each monolayer consisted of 36 tightly packed SH(CH$_2$)$_5$CH$_3$ chains, physically pinned to the substrates by a force constant of 50 K/Å^2. The chains were arranged in a two-dimensional triangular lattice with a spacing of 4.44 Å. This

resulted in an area of 17.1 Å^2/chain. The short length of the chains, six carbon units long, and the small spacing between chains resulted in the chains being perpendicular to the substrate rather than tilted (the spacing and the area per chain on gold is 4.99 and 21.9 Å^2, respectively). This eliminates gauche defects, and provides a symmetric computational cell. As mentioned previously, the united-atom method was utilized, with an LJ 6–12 potential for interactions between chains and a smoothing function for nonbonded interactions. The simulation temperature was ramped from 20 to 300 K, with weak and strong interfacial attractions applied to investigate the effect on shear stress. Although this system is not exactly the type of system examined in the AFM experiments of the friction of alkanethiols on gold, a number of features are nonetheless noteworthy. The commensurate geometry of the identical layers led to clear organized behavior during sliding. Layers responded in a synchronized fashion such that the instantaneous shear stress showed a very clear periodic variation, exhibiting steep drops to large negative shear stresses.

Chandross et al. [110] recently performed simulations that examined the adhesion and friction of identical alkylsilane SAMs attached to silicon dioxide substrates (Fig. 1). Systems with chain lengths of 6–8 carbon atoms with 100–1600 molecules on each surface were examined. One hundred chains per monolayer corresponds to a surface that is 43 Å × 50 Å. These simulations showed that large negative instantaneous shear stress results with system sizes up to hundreds of chains. However, in monolayers comprised of 1600 chains, all chains were not precisely synchronized. Thus, the instantaneous shear stress of the entire system exhibited much less severe variations as groups of chains slipped at slightly different times. While the 1600-chain system never exhibited a negative instantaneous shear stress, the local slipping behavior was the same as in much smaller systems of 400, and even 100 chains.
Figure 1. Two alkylsiloxane monolayers composed of C$_8$ chains attached to silicon dioxide (SiO$_2$) substrates, which are 4 oxygen atoms thick. The system is being sheared at a velocity of 1 m · s^{-1} under a load of 200 MPa. Oxygen, silicon, carbon, and hydrogen atoms are colored red, yellow, blue, and light gray, respectively. This figure is based on the work described in [110] by M. Chandross, G. S. Grest, and M. J. Stevens at Sandia National Labs.

The analysis by Glosli and McClelland of their slides, conducted under a variety of conditions, revealed two separate mechanisms for the dissipation of energy. The first mechanism was an abrupt, almost discontinuous, plucking mechanism, where the layers jump between potential maxima. This mechanism was most evident at low-temperature and high-head-group interaction strengths. Because of the strong interfacial attraction, the friction force was found to be independent of the velocity of the slide. Because bond lengths were held fixed, vibration in these studies refers to modes associated with angular variations along chain backbones. The second mechanism was also a thermal mechanism, where vibrational excitations helped the chains to slide over potential maxima. This latter mechanism was most evident at high-temperature and low-head-group interaction strengths, where the friction force decreased because of this gliding of the energetic chains over one another.

Similar investigations undertaken by Tupper and Brenner [75, 76] utilized identical alkanethiol monolayers consisting of longer chains, $SH(CH_2)_{15}CH_3$ and $SH(CH_2)_{20}CH_3$, chemisorbed via the sulfur end group to Au(111). The simulation cell contained 64 chains per monolayer attached to gold substrates. In these simulations, a Taylor expansion for the torsional terms was added to the harmonic potential, as well as a harmonic term to model bond bending. Interchain interactions were modeled with an LJ 6–12 term, and the rigid-bond constraint was replaced by a modified Hautman and Klein harmonic bond-stretching potential for modeling compression. Consequently, the time step was shortened to 0.25 fs, so that fast bond-length oscillations were accurately modeled. In turn, due to computational constraints, a sliding speed of 0.1 nm·ps^{-1} or 100 m·s^{-1} was utilized. This is order of magnitudes higher than experimental speeds, and alarmingly close to thermal speeds. However, simulations of the compression phase at speeds of 0.1 nm·ps^{-1} and 0.01 nm·ps^{-1} showed no noteworthy differences. The recent work of Chandross et al. [110] also confirms this with respect to slides conducted at speeds of 2.0 and 20 m·s^{-1} in a load regime of 0.2–2.0 GPa. This is not to say that the sliding speeds utilized are not a serious concern. Compression (or sliding) speed is one of the compromises that must be made to undertake simulations of this scale. These simulations were done at 300 K using Hoover's algorithm for computing NVT dynamics. The opposing monolayers did not entangle upon compression, but rather experienced a uniform increase in tilt angle. Sliding the upper monolayer relative to the lower caused a change in the tilt angle of 180° during 20 ps of sliding. The authors conclude that energy is dissipated primarily by oscillations in the tilt angle.

Also undertaken by Tupper and Brenner were slides of a single monolayer of $SH(CH_2)_{15}CH_3$ chains, or hexadecanethiol, against a single-layer gold surface [76]. These were the first attempts to investigate a system that resembled systems examined in AFM experiments. These simulations revealed a friction versus load response that remained linear (consistent with Amontons' law), despite the fact that the monolayer exhibited structural changes under compression [76]. It is possible that this is a consequence of the fact that these slides were conducted at fixed height with a flat probing gold surface. In other words, the friction versus load response may reflect more the interaction between the two ordered flat arrays comprised of gold atoms in the probe against the end groups of the chains, rather than the underlying structure of the monolayer.

The studies of Fujihira and co-workers [82–86] also made use of the united-atom potential energy function. In fact, their early studies [82–84] utilized the same computational setup employed by Glosli and McClelland [77], except that the LJ potentials between chains, and within a chain for neighbors more distant than three psuedoatoms, were altered. Bond lengths were also kept rigid during the simulations. Constraining bonds to be rigid may seem like a step backwards; however, the authors make an intriguing suggestion: unless energy fluctuations are strong enough to excite bond-stretching vibrations quantum mechanically, the rigid-bond constraint may be more appropriate in classical models. The implication is that these studies are restricted to weakly interacting systems or systems under low loads. With rigid bonds, it was practical to utilize a sliding speed of 2 m·s^{-1}. Although this was still much faster than experimental speeds, it is clearly separated in scale from thermal speeds in this system. Furthermore, in their recent studies [85, 86], the properties of the cantilever assembly (discussed below) were carefully adjusted to account for the difference between modeled and experimental sliding speeds.

A recurring theme that characterizes the initial studies of Fujihira and co-workers was a clear separation between weak and strong energy modes and their relationship to the work done during sliding. Weak modes include the sum of LJ 6–12 energies between atoms separated by the interface (interfilm potential), the sum of LJ 6–12 potential energies between atoms within the monolayer (intrafilm potential), and the film–substrate potential. Strong modes are composed of the pinning of chains, bond bending, and torsional potentials. While the weak modes exhibited a dramatic build up and release of mechanical energy at slip, the strong modes showed only a weak correlation with stick-slip events. Dissipated energy eventually showed up in all available energy modes including strong modes, although it was the structured build up and release of mechanical energy associated with weak modes that governed frictional behavior. It is possible that the dramatic build up of energy is dependent upon several simulation details, such as load, sliding speed, and probe geometry (in addition, all of these things are intimately linked to the probe–monolayer potential). The strong separation between weak and strong modes is likely due to the fact that the loads probed were very low, and the tip geometry was not commensurate with the sample [72, 120].

5. PYRAMIDAL TIPS

The work of Bonner and Baratoff [79] extended the early studies by adopting a simple model of an AFM cantilever. They modeled the cantilever as a deformable, pyramidal cluster of 285 atoms initially arranged in (001) layers. The cantilever was connected to a rigid support by three orthogonal springs. Relatively soft springs were used for the sliding and loading directions, and a very stiff spring for the transverse direction. Damping was applied to reduce lever response to rapid SAM motions. The gold atoms comprising

the tip interacted with each other through an embedded-atom-model potential. The top two layers of the tip were rigid, the velocities were rescaled at regular intervals to regulate temperature in the next two layers, and no constraints were applied to the remaining atoms. The SAM, comprised of 120 $S(CH_2)_{10}CH_3$ chains was anchored to the deformable gold substrate, that was also partitioned into rigid, thermal, and free atoms.

Due to computational limitations, the radii of curvature of experimental tips (no less than about 15 nm) are far too large to model atomically, although it is commonly suggested that the atomic information extracted from AFM measurements is a reflection of local tip asperities in contact with the sample. Consequently, the model system here may reasonably reflect the appropriate size of a tip asperity in contact with a SAM domain.

Even with imposing the rigid bond-length constraint, the system was at the limit of what was computationally feasible at the time. Consequently, only some general qualitative features were extracted from these simulations. For instance, at low temperature, the same SAM structure previously reported by Hautman and Klein [22, 23] was observed. Increasing the temperature caused the chains to rotate about their tilt axis, to precess about the substrate normal, and to eventually untilt as thermally activated gauche defects preferentially appeared near the methyl end groups. Lateral scans with the tip in contact with the SAM showed a fairly consistent sequence of stick-slip events. Each event involved a few atoms below the tip. These events were sufficient to eventually align the tilt of the SAM with the sliding direction. In its wake, the tip left behind a significant number of gauche defects and a vacancy island. Although the vacancy island quickly disappeared, the gauche defects annealed out only slightly over the duration of the slide.

In the studies of Koike and Yoneya [80, 81], all atoms were modeled explicitly, and comparative studies of the friction of a number of different kinds of monolayers were undertaken. The studies addressed Langmuir–Blodgett (LB) films composed of hydrogenated and fluorinated carboxylic acids. Room-temperature studies of completely hydrogenated or fluorinated chains of the same length, with different packing densities, were conducted. From the simulation perspective, the distinction between LB films and SAMs is minor. Both are modeled as organized long chains in sliding contact with a probing tip. To model individual atoms, including the terminating hydrogen and fluorine atoms, the consistent valence force-field (CVFF) potential, developed for protein structure analysis, was utilized. This potential requires the specification of various parameters that describe the stretching of bonds, bending of bonds, torsional angles, van der Waals interactions, and Coulomb interactions for all atoms.

Using a flat, multilayered SiO_2 tip and sliding at constant load, many of the general trends reported in previous studies were also seen in these studies. With regard to the particular systems studied, the highly fluorinated films exhibited higher friction than the purely hydrogenated films (the friction coefficient is about three times higher). The authors cited a number of experimental studies that reported this dramatic difference. The authors changed the hydrogen and fluorine torsion and bond angle potentials in an effort to change the stiffness of the films, and repeated the friction simulations. They concluded that these contributions to the potential energy could not account for the calculated differences in the friction. A similar analysis, interchanging the intermolecular hydrogen and fluorine potentials, was not carried out because the conformations of the films would have been altered. A particularly interesting analysis showed a correlation between root-mean-square fluctuations in the individual energy modes of the system and friction. The authors asserted that dramatically larger energy fluctuations were apparent in the highly fluorinated system in 1–4 LJ intramolecular interactions in the LB film (and to some extent, also in bond-stretching interactions), and that they were the origin of the difference in friction between the fluorinated and the hydrogenated systems. No strong differences in the root-mean-square energy fluctuations were observed with respect to the bond angles, torsional angles, interfacial, or Coulomb energies.

Fujihara and co-workers [85, 86] also examined a number of tips under positive, zero (but still in contact), and negative loads. The modeled sliders contained harmonic springs, damping, and feedback controls, with the specifications carefully tuned to model basic features of experimental tips, and to account for the mismatch between practical simulation and experimental sliding speeds. Variations in tip structure included incommensurate versus commensurate geometries with respect to the arrangement of chains in the sample, and in the size of molecular-sized tip asperities. The magnitude of the friction, and the frictional dynamics, were seen to be very sensitive to these variations. The authors observed that it was possible to achieve a structured periodic response, reflecting the periodic array of the SAM, by utilizing an incommensurate tip containing an asperity with the thickness of a single atom. Thus, the results of this setup seem qualitatively similar to an experimental AFM's ability to resolve a local sample structure.

A key problem encountered in MD simulation is the time-scale issue. Practical considerations limit atomic simulations to a few nanoseconds with sliding, or indentation, speeds of 1–100 $m \cdot s^{-1}$. Experiments are conducted on time scales that are orders of magnitude larger, and at sliding speeds that are orders of magnitude smaller, than simulation speeds. Therefore, physical pictures obtained from such simulations may be questionable when compared with experimental results. To overcome this problem, Leng and Jiang proposed a temporal–hybrid method to simulate the scanning process over SAMs in the time scale of AFM experiments. In this method, the thermal motion of the individual atoms in the AFM tip is ignored. The tip and cantilever assembly is driven by a support moving at a constant scanning velocity. Molecular dynamics is used to simulate the relaxation of the SAMs, but the motion of the tip is modeled with the harmonic equations plus the interaction between the tip and the SAMs. Two time scales are involved in the simulation: one describing the motion of the tip, and one corresponding to the relaxation of the SAMs. The time scale of the motion of the tip is approximately the same as it is in experiments ($\sim 0.5 \ \mu s$). In contrast, the relaxation of the SAMs is related to all atomic-scale motion; thus, the time step of the integration has to be small ($\sim 1 \ fs$). As the relaxation of the SAMs is supposed to be very fast, within several

picoseconds, the dynamic evolution of the SAMs is a quasistatic process. With this kind of approach, the scanning speed can be as low as $10\ \mu m \cdot s^{-1}$, a practical speed in AFM experiments. All simulations utilizing this temporal–hybrid method were conducted with a rigid tip in contact with a deformable substrate. The relaxation of the atomic substrate leads to the inevitable contact damping that makes surface forces nonconservative.

This method was compared to conventional MD simulations, and results showed that when the resonant frequency of the cantilever was at least one order of magnitude less than that of the atomic substrate, the energy modes of the cantilever and the substrate could be separated. However, the hybrid method did not capture the higher vibrational modes of atoms in the contact area caused by the atomic-plucking motion, which arise from the motion of the slider against the SAM. This did not influence the friction force.

Using this hybrid approach, the indentation and sliding of a rigid (001) Au facet in contact with SAMs of alkylthiolate chains were investigated. The elastic modulus in the film thickness direction was chain-length independent, but the effective shear modulus was chain-length dependent. Longer chains had higher lateral stiffness than shorter chains, leading to lower friction, in agreement with AFM experimental results.

Recently, adhesion and friction in chemical force microscopy were studied using the same method. The scanning tip was modeled by attaching the alkanethiol chains $[-S(CH_2)_7CH_3]_{40}$ or $[-S(CH_2)_7OH]_{40}$ to an Au tip. Interactions between the tip and the SAMs were between the hydrophobic methyl (CH_3) groups or the hydrophilic hydroxyl (OH) terminal groups. Results obtained include force–distance curves, friction curves, friction–sliding-distance curves, interfacial molecular or hydrogen bonding structures, and load distributions among different molecular chains. Results of this study showed that adhesion and friction for the OH–OH contact pairs were much larger than those for the CH_3–CH_3 pairs, due to the formation of hydrogen bonds. The tip position versus cantilever support position curves showed that, during the retraction process of a chemical force microscope (CFM) tip from a surface, the CFM tip was away from the sample surface slightly, while the spring underwent enlongation in the normal direction, before the tip broke away from the surface. Single molecule forces were distributed unevenly at the contact area.

Diestler and co-workers [130, 131] showed that the atomic description of friction of the scanning surface probe device is greatly complicated by wide variations in the temporal regime of the measurement. At one extreme, the system remained in equilibrium for the duration of the measurement, and one can employ statistical thermodynamics to compute friction. However, at the other extreme, the system remained out of equilibrium, and the dynamic history of the system had a strong impact on friction. Obviously, the temporal–hybrid method proposed by Leng and Jiang is based upon treating the sliding as a quasistatic process. Therefore, this method cannot be applied to systems that are far from equilibrium; this includes systems at high loads, systems where there is significant penetration of the tip into the monolayer, and systems undergoing chemical restructuring.

6. ATOMICALLY SHARP TIPS AND INFINITELY FLAT TIPS

Harrison and co-workers developed and used [119–124] a hydrocarbon potential energy function that is one of the few that allows for chemical reactions (with the accompanying changes in atomic hybridization) and long-range interactions [125] to examine the tribology of hydrocarbon monolayers attached to diamond.

Modeling the breaking and forming of chemical bonds is not a straightforward task because it requires the potential energy function to go beyond simple pairwise interactions to include multibodied terms representing the chemical environment. The reactive empirical bond-order (REBO) potential [126, 127] was the first potential developed to model chemical reactions of hydrocarbons, such as those needed to model the chemical vapor deposition growth of diamond from gaseous reactants. In REBO potential, in addition to the terms representing the repulsive and attractive interactions of a bond, there exists a bond-order factor that depends on bond angles, bond lengths, and atomic coordination in the vicinity of the bond. This many-body nature of the bond-order term makes the bond energy dependent on the local environment surrounding the bond, and therefore allows the REBO potential to describe chemical reactions. Harrison and Brenner used this potential in their study of the wear of diamond surfaces in sliding contact, and reported the first case of simulated tribochemistry [128].

Recently, Harrison and co-workers examined the compression and friction of hydrocarbon chains attached to diamond using various probes. The REBO potential lacks the long-range intermolecular and torsional interactions needed to model the organized, tilted structure of SAMs. However, its ability to model chemical reactions is crucial to the simulation of tribochemistry. With that in mind, the REBO potential was modified, and the resulting potential is known as the adaptive intermolecular REBO (AIREBO) potential [125]. In particular, modifications contained in the AIREBO potential include long-range LJ interactions between pairs of atoms that are smoothly turned on and off based on the surrounding chemical environment. Since its creation, the AIREBO potential has been used to undertake a number of interesting mechanical [109] and tribological studies of SAMs [119–124]. In addition, this potential was also used to model the bending of empty and filled single-wall carbon nanotubes [129].

In these simulations equilibrated hydrocarbon monolayers with approximately the same packing density as alkanethiols on gold had an ordered arrangement of chains which were uniformly tilted with respect to the surface normal [109, 120, 122] (Fig. 2). Chains typically had few gauche defects [109], which were primarily confined to the ends of the chains. The position of the gauche defects within the chains was observed in previous simulations by Hautman and Klein [22, 23], and subsequent simulations of alkylsilane monolayers [110]. Karaborni [107] utilized an anisotropic united-atom potential to model the approach and separation of opposing monolayers. Simulations were performed by compressing 128 molecules, with 19 CH_2 segments and a COOH head group, evenly distributed on two plates (25 Å^2/molecule), at $7\ m \cdot s^{-1}$. These simulations showed that
Figure 2. In the upper panel, a monolayer composed of C_{18} *n*–alkane chains in the (2×2) arrangement on diamond (111). This packing is referred to as a tightly packed system. The counterface (probe) is a hydrogen-terminated diamond (111) surface. In the lower panel, C_{14} chains are attached to diamond (111) in a tightly packed arrangement. This system is in sliding contact with a diamond-like carbon probe. This is the ending configuration for the highest load (around 30 nN) investigated for the data reported in Figure 15. In both panels, carbon–carbon bonds appear as green cylinders, and hydrogen atoms as white spheres.

Figure 3. Monolayer of C_{13} *n*–alkane chains shown in yellow (hydrogen atoms are not shown for clarity). The alkane chains are attached to a diamond (111) substrate in the (2×2) arrangement (shown in gray). A capped [10, 10] SWNT is used as the probe (shown in red) [139]. Gauche defects in the C_{13} monolayer are colored green. The tube has slid for 38 Å in the direction of the chain tilt (left to right). In the bottom panel, the view is looking down the long axis of the tube onto the plane that contains the monolayer. In the top panel, the system is rotated away from the viewer, and viewed at an angle.

increasing the tilt angle of the molecules decreased the number of gauche defects in the midsections of both monolayers. This same link between tilt angle and gauche defects was observed in the simulation of long-chain alcohols [108].

The initial studies of Harrison and co-workers utilized tips of two extremes: infinitely flat, hydrogen-terminated diamond counterfaces (Fig. 2, upper panel), which emphasize the friction mechanisms associated with compression of the SAM, and capped carbon nanotubes (Fig. 3), which emphasize penetration into the SAM. Recent studies made use of amorphous carbon tips (Fig. 2, lower panel), which make the monolayer and the probe incommensurate. The compression (indentation) of monolayers composed of *n*–alkane chains of lengths ranging from C_8 to C_{18}, using hydrogen-terminated diamond (111) and carbon nanotube probes, were examined. The chains were attached to a diamond (111) substrate in the (2×2) arrangement because this yields

approximately the same packing density (21.9 Å^2/chain) as alkanethiols on Au(111). These simulations showed that the number of defects formed, and their location, depended upon the contact geometry of the probe, the length of the alkane chains, and the compression speed. For instance, when a hydrogen-terminated diamond (111) probe was used to compress *n*–alkane monolayers [119–123], gauche defects formed primarily on the ends of the chains. Slower compression speeds led to fewer defects being formed. In contrast, when the probe was a capped, single-wall carbon nanotube (SWNT), the majority of the gauche defects formed were localized to the region of the monolayer adjacent to, and under, the nanotube (Fig. 3) [109, 121, 123, 124]. The small radius of the nanotube probe allowed it to "slice" into the monolayer, interacting with a small number of hydrocarbon chains and localizing defects near the tip, irrespective of the length of the *n*–alkane chains [123, 124]. Due to the collective tilt angle of the chains, some chains were pushed closer to the substrate (causing an increase in their tilt angle), some were pushed farther from the substrate (causing a decrease their tilt angle), and some were partially "pinned" under the tube as a result of the indentation. The distribution of defects around the indentation site was not uniform. That is, a larger number of defects were generated on the side of the tube where the tilt angle of the chains decreased.

The effect of probe stiffness on indentation and friction was examined by using rigid, flexible, and multiwall carbon nanotube probes [109, 121, 123, 124]. During indentation, the small contact area of the nanotubes resulted in the number of defects formed being a function of penetration depth into the monolayer. Because a flexible nanotube compresses slightly, and bends a bit to one side as it interacts with the C_{13} monolayer, it does not penetrate a given monolayer as deeply as a rigid nanotube. As a result, for probes in this size range, a flexible tube generates fewer defects than a rigid nanotube as it is pushed into a hydrocarbon monolayer [109]. One important difference between the rigid and the flexible nanotube was that the rigid tube was able to penetrate the monolayer and pin chains against the diamond substrate. Severe indents such as these sometimes led to broken bonds between the chains and the substrate [109, 121].

The elastic modulus of C_8, C_{13}, and C_{22} monolayers was extracted from compression studies of these monolayers using an infinitely flat surface [109]. Plots of stress σ versus strain ε for the compression of these monolayers showed that the elastic modulus of C_8 was approximately an order of magnitude larger than the value determined for C_9 alkanethiols on gold using a quartz crystal microbalance [132]. This is not surprising due to the fact that atomic-scale experiments sample much larger contact areas than those examined in these simulations. Domains and defects are present in the experimental samples which are not present in the simulated systems. The computed elastic modulus of C_8 was the largest, followed by C_{13} and C_{22} [109]. That is, the shorter chains were stiffer in the compression direction (which is perpendicular to the shearing direction). This phenomenon was recently observed during simulations of the compression of opposing alkylsilane monolayers [110].

Harrison and co-workers used various probes to examine the friction of monolayers composed of n–alkane chains with lengths ranging from C_8 to C_{22} [119–124]. The effects of chain length, packing density, sliding direction, probe rigidity, and contact area on friction and wear were all examined. The effect of probe rigidity on friction was examined by using flexible and rigid SWNT probes, and a double-wall nanotube (DWNT) probe, to investigate the friction of C_8, C_{13}, and C_{22} n–alkane monolayers. After penetration into the monolayers, all of these tubes "plowed" through the monolayers, creating gauche defects (Fig. 3) [123, 124]. These defects built up in the wake of the tube, and the number of defects depended upon sliding speed, penetration depth, and sliding direction. The number of defects increased as the penetration depth (and load) increased, as noted earlier. The effect of sliding direction on defect formation was also examined. The total number of gauche defects versus sliding distance is shown in Figure 4 for the case when a flexible DWNT "slices" through a C_{13} monolayer. These two sets of data correspond to different sliding directions. When sliding in the direction parallel to the tilt angle of the chains (left to right in Fig. 3), the number of defects increased with sliding distance (blue line, Fig. 4) until the periodic image of the simulation cell was reached. That is, when the tube passed through an area of the monolayer that had already been perturbed (approximately ten unit cells of sliding), a marked decrease in the number of
Figure 4. Number of gauche defects generated versus sliding distance when a flexible DWNT is in sliding contact with a C_{13} n–alkane monolayer. Data shown in red correspond to sliding along the direction of chain tilt. The black arrow corresponds to the point where the tube slides through an already perturbed area. (That is, the tube is sliding through its periodic image.) Data shown in blue correspond to sliding at a small angle away from the initial sliding direction. The unit cell in the tilt direction is 8.71 Å. The load on the nanotube is 13.8 nN. (See [139] for more details regarding the DWNT.)

defects occurred [124]. Continued sliding through the perturbed region caused the number of defects to decrease almost linearly with sliding distance. This severe decrease in the number of defects did not occur when the tube motion was stopped and the defects were allowed to anneal. In other words, the motion of the tube through an already perturbed region accelerated the rate of defect removal. Adjusting the sliding direction such that it made a small angle with the original sliding direction, and so the tube did not slide over its wake (a previously perturbed region), changed the number of defects created (red line, Fig. 4) during sliding. In this case, the number of defects continued to increase as sliding progressed.

While the motion of the end of the nanotube, or the depth of the tube in the monolayer, is intimately linked to the number of defects formed, the correlation does not appear to be a strong one [124]. Figure 5 shows the depth of the nanotube and the gauche defects generated during sliding with the chain tilt (blue line, Fig. 4). For approximately the first 12 ps (12 Å or ~1.38 unit cells) of sliding, the end of the DWNT (capped region) was "stuck" in the C_{13} monolayer. Because the top of the nanotube was moved, the capped region began to "pull out" of the monolayer (decreasing its depth). There was no appreciable change in the number of gauche defects formed during this time because the capped end of the tube moved little. After the first 12 ps of sliding, the capped end of the DWNT "slipped," and began moving through the monolayer, increasing the number of gauche defects as it moved. The capped end of the nanotube continued this type of weak "stick-slip" motion through the monolayer for the remainder of the simulation. This caused the number of defects to increase monotonically as sliding progressed. Removal of the tube at any time from the monolayer ultimately resulted in the annealing of the gauche defects.
Figure 5. Number of gauche defects (red line) generated when sliding in the direction of chain tilt and the depth of the DWNT (green line) versus sliding time when a flexible DWNT is in sliding contact with a C_{13} n–alkane monolayer. The unit cell in the sliding (tilt) direction is 8.71 Å. The load on the nanotube is 13.8 nN. (See [139] for more details regarding the DWNT.)

Friction versus load data for a flexible and a rigid SWNT sliding through C_{13} monolayers are shown in Figure 6. These data show that, for nanotubes with small contact areas, the flexibility of the probe did not have a marked influence on the measured friction at a given load. The probe rigidity simply limits the loads (penetration depths) that can be examined with a given probe. Sliding through the monolayer caused the flexible nanotube to buckle [123, 124]. Using a DWNT as the probe increased the range of loads that could be examined prior to tube buckling to approximately 15 nN [124].

A number of scanning probe microscope (SPM) experiments reported that the friction of alkanethiols decreases with increasing chain length [58, 60, 63, 64, 67]. After some critical chain length is reached (which is believed

to correspond to a well-packed film), all chain lengths exhibit similar friction versus load behavior. Single-wall carbon nanotubes were used to examine the friction of tightly packed, n–alkane monolayers composed of C_8, C_{13}, and C_{22} chains [123, 124]. Because the diameter of the nanotube probes was approximately 15 Å, the measured friction was a function of the penetration depth into the monolayer. In addition, the experimental trend of longer chains yielding lower friction than shorter chains was not reproduced. Single nanotubes have been used as AFM probes to image very small features on surfaces [133]. However, they have not been used to examine friction. The SPM experiments to date that have examined friction have utilized tips that are one–two orders of magnitude larger than the diameter of the nanotubes used in these simulations. Thus, comparison with experimental data is problematic.

To increase the contact area between the probe and the monolayers, a hydrogen-terminated diamond (111) surface was used as the probe [119, 120, 122, 123]. In this case, the behavior of the friction as a function of load for C_8, C_{13}, $C_{18,}$ and C_{22} chains more closely resembled the trends observed in experimental data. At most loads, the average friction of the shortest chains was generally higher, and that of the longest chains was generally lower. However, subsequent simulations on these systems using the infinitely flat probe have shown that it is very difficult to reduce the error bars sufficiently to separate these curves (Fig. 7). It is likely that the well-ordered nature of the monolayers and the commensurate probe are responsible for this phenomenon. Other, more realistic probes (discussed below) may be able to better reproduce the experimental data. In addition, the majority of the chains moved in a synchronized way during sliding. This resulted in approximate periodicities in a number of quantities associated with sliding, which are discussed below [120].

Figure 6. Friction versus load data when two carbon nanotube probes are in sliding contact with C_{13} n–alkane chains attached to a (111) diamond substrate in the (2×2) arrangement. The sliding direction corresponds to the direction of the chain-tilt angle. Data shown in red and blue correspond to a flexible and a rigid [10, 10] single-wall nanotube, respectively. Error bars correspond to one standard deviation. Each point was calculated from 40 ps slides.

Figure 7. Friction versus load for a hydrogen-terminated diamond (111) surface in sliding contact with n–alkane monolayers. Pink, red, green, and blue lines correspond to data for C_8, C_{13}, C_{18}, and C_{22} carbon atom chains. Error bars indicate minimum and maximum friction values obtained by window averaging the data over unit-cell lengths of sliding (the unit-cell length is from the (2×2) arrangement of chains in the sliding direction). The sliding direction corresponds to the chain-tilt angle. Lines are draw to aid the eye. See [119] and [122] for more simulation details.

Simulations that examined the effects of packing density [119] on friction were motivated by the AFM experiments of Perry and co-workers [50, 51], who examined the friction of a series of spiroalkanedithiols. These simulations examined both tightly and a series of loosely packed monolayers with a hydrogen-terminated diamond probe. The tightly packed system consisted of C_{18} n–alkane chains attached to diamond (111) in the (2×2) arrangement. Loosely packed systems were created by randomly removing chains (20, 40, or 54) from the tightly packed system or by attaching the C_{18} chains to the substrate in a different arrangement, such as (4×4). These systems were equilibrated to 300 K, and compressed with a hydrogen-terminated diamond (111) counterface. The number of gauche defects per chain formed for each system during equilibration and compression is shown in Figure 8. The equilibration phase lasted for approximately 20–25 ps for all systems. It is apparent that removing chains from the tightly packed system, or increasing the space between chains, caused an increase in the disorder of the monolayers. Compressing all but the tightly packed monolayers further increased the disorder.

Friction versus load data for these systems are shown in Figure 9. At moderate to high loads, all of the loosely packed systems (more disordered) exhibited higher friction than the tightly packed (more ordered) system. This result agrees with the experimental findings of Perry and co-workers [50, 51]. A detailed analysis of the quantities associated with sliding was conducted. Those results, in conjunction with data from other studies [119, 120], revealed the following. For tightly packed systems explored with an infinitely flat probe, there are a number of properties that are correlated with the frictional force. Some properties, such as the generation of gauche defects, are correlated with a slight time lag [122].

A C_{13} chain isolated from a tightly packed monolayer is shown in Figure 10. The variation in a number of the

Figure 9. Friction versus load for a hydrogen-terminated diamond (111) surface in sliding contact with C_{18} n–alkane monolayers. Pink and blue lines correspond to the tightly and loosely packed systems of [119], respectively. The systems are the same as those described in the caption of Figure 8, with the omission of the data for the system with 54 chain removed. Error bars indicate minimum and maximum friction values obtained by window averaging the data over unit-cell lengths of sliding. The sliding direction corresponds to the chain-tilt angle. Lines are drawn to aid the eye. See [119] for more simulation details.

quantities defined in Figure 10 with time is shown in Figures 11 and 12. During equilibration and compression, the chains in tightly packed n–alkane monolayers exhibited a right-handed configuration, where the chain circulates counterclockwise starting from the attachment site, or a left-handed configuration. (See [120] for a picture of these chains.) The handedness of the chains may be correlated because groups of chains within the monolayer shared the same configuration. However, not all chains in the simulations shared the same handedness. The fact that two

Figure 8. Number of gauche defects per chain for the equilibration and compression of C_{18} n–alkane monolayers attached to diamond (111). Pink and aqua lines correspond to the tightly and loosely packed systems of [119], respectively. Data represented by the red line is for C_{18} chains attached to diamond (111) in the (4×4) arrangement. All other systems had the chains attached in the (2×2) arrangement. The tightly packed system (aqua line) has 72 chains. 20, 40, and 54 chains have been randomly removed from the surfaces represented by the pink, blue, and green lines, respectively.

Figure 10. Single C_{13} n–alkane chain extracted from an equilibrated monolayer on diamond (111). Azimuthal angle φ (red), tilt angle θ (black), and change in length of the chain ΔL (black) are all defined. Sliding direction (with the tilt angle) is from left to right in the figure. See [120] for simulation details.
Figure 11. Average force on the counterface perpendicular to the sliding direction F_x, average x coordinate on the top carbon atoms of the C_{13} chains, and the azimuthal angle φ as a function of sliding distance. The sliding distance has been divided by the unit cell distance in the sliding direction for the (2×2) packing of the chains on diamond (111). The sliding direction is along the tilt of the chains (positive y in Fig. 10). See [120] for simulation details.

configurations existed may be related to the compression speed; chains became pinned before they could adjust to their neighbors. The fixing of the handedness of the chains by compression broke the symmetry of the system slightly. Analysis of the azimuthal angle φ as a function of sliding distance (Fig. 11) showed that the chains are pushed from side to side as each wave of hydrogen atoms from the countersurface passes over them. (It should be noted that the unit-cell distance of the countersurface was half that of the
monolayer.) All of the chains underwent this synchronized motion. The motion was not symmetric about zero because the chains were preferentially shifted to one side upon compression. This periodicity is also apparent in the average lateral position of the top layer of carbon atoms in the chains (x) and the lateral force (F_x). The sliding direction is along the chain tilt direction, or the y direction (Fig. 11).

This approximate periodicity has also manifested in the trajectory of the carbon atoms at the ends of the chains. Figure 12 shows the motion of these carbon atoms in the sliding (y) and the compression (z) directions. Each wave of hydrogen atoms interacted with the top of the chains, slightly compressing and stretching them. When the countersurface hydrogen atoms passed by, the chains sprang back. Due to the ordered nature of the monolayer, the stretching of the chains ΔL extended throughout the entire chain. In fact, the change in bond lengths between carbon–carbon bonds in the alkane chains is the property that was most strongly correlated with friction [119]. Higher loads led to restricted movement of the chains in the tightly packed system compared to the loosely packed system (labeled $d20$ in Figs. 8 and 9) [119]. Twenty chains were randomly removed from the tightly packed system to form this loosely packed system (d20). In addition, sliding initiated larger bond-length fluctuations in the loosely packed system (d20), which ultimately led to more energy dissipation via vibration [119]. In the tightly packed system, the vibrational energy in the carbon–carbon bonds of the chains was a linear function of the work done during sliding (Fig. 13). Because the countersurface was rigid and sliding at constant velocity, the work was proportional to the friction. Thus, the vibrational energy imparted to the carbon–carbon bonds of the chains had the same behavior with load as friction. The approximate torsional energy, also shown in Figure 13, was calculated by mapping the torsional energy of each set of four consecutive carbon atoms in the chain backbones to the potential energy of an uncompressed butane molecule [119]. This method

Figure 12. Average displacement of the carbon–carbon bonds in the alkane chains ΔL and the average y and z coordinates of the top carbon atoms in the alkane chains (C_{13}) as a function of sliding distance. The sliding distance has been divided by the unit cell distance in the sliding direction for the (2×2) packing of the chains on diamond (111). The sliding direction is along the tilt of the chains (positive y in Fig. 10). See [120] for simulation details.

Figure 13. Vibrational (open squares) and approximate torsional (filled circles) energy as a function of work for a monolayer of tightly packed C_{13} alkane chains. The hydrogen-terminated diamond (111) counterface was held rigid in these simulations. The results of 8 sliding simulations at different loads are shown. Each simulation is divided up into 4 unit cells, and the average energy for each unit cell is plotted. Thus, there are 32 data points. Other simulation details can be found in [119].

of calculating the torsional energy, or the energy associated with gauche defects, implies that the contribution of the torsional energy to energy dissipation plateaus at a given load. Thus, the torsional energy and the friction did not respond the same way to the application of load.

While the creation of gauche defects dissipates energy, their generation may not be the main channel of energy dissipation in these tightly packed systems, as shown in the data presented here. However, there are additional possibilities. First, the torsional energy contribution was mapped to an uncompressed butane molecule. Because the conformation of an individual chain is altered under load, this may not be an appropriate mapping. Furthermore, the result of the formation of a defect with respect to the surrounding region is untreated (changes in the orientation of the chain tip can significantly affect the local order in this region). Finally, the flattening of the torsional angle contribution may be related to the sliding speed. It is possible that the characteristic time for a gauche defect to anneal is longer than the time between subsets of hydrogen atoms on the countersurface interacting with the ends of the chains. If that were the case, the number of defects would continue to increase, eventually reaching some constant level as it does here. In short, the flattening of the torsional energy contribution with load says more about the number of gauche defects than it does about their contribution to energy dissipation. What is clear is that, for these sliding conditions (geometry, sliding speed, etc.), energy dissipation via vibration was determined to be the main channel for energy dissipation. Any variation in simulation conditions, such as probe geometry, sliding speed, or packing density, could open up additional channels of energy dissipation or change the relative importance of existing channels.

When utilizing a commensurate tip in sliding contact with a perfectly ordered monolayer, it may be useful to look at how the friction and load forces are distributed over the set of monolayer chains. Are there trends that manifest themselves in a significant fraction of the individual chains or is there significant variation across the monolayer? In the former case, one could conduct a robust analysis in a comparative study that targets a particular property by way of varying system geometry or simulation parameters over a limited set of simulation runs. In the latter case, more extensive simulations involving independent runs of similarly prepared systems may be required to conduct a statistically significant analysis.

Figure 14 shows how friction and load are distributed across two similarly prepared systems. The systems are linear hydrocarbon chains anchored in a (2×2) arrangement on diamond (111), with a hydrogen-terminated diamond (111) surface serving as the counterface. Starting from the same initial configuration, the counterface was slid against the tilt of the monolayer chains in one system, with the tilt of the monolayer chains in the other. There are 52 chains in the model system. Thus, there are 52 points for each system showing the friction and load attributed to each chain. These forces were calculated by summing all forces between atoms in a single chain and all atoms in the probing counterface. There is clearly a great deal of overlap between the two systems, and also a wide range of variation within individual systems (some chains even have a net effect of pushing
Figure 14. Average friction and load plotted for each chain in a monolayer composed of C_{16} hydrocarbon chains in a (2×2) arrangement on diamond (111). The counterface was a hydrogen-terminated diamond (111) surface. Sliding directions along (positive y) (red circle) and against (negative y) (blue triangle) the tilt angle are given in Figure 10. The monolayer was composed of 52 chains. Sliding speeds were $100 \text{ m} \cdot \text{s}^{-1}$, and the temperature was maintained at 300 K. Other simulations details are as in [119].

the probe along). It is clear that the overall friction was significantly higher when sliding against the chain tilt. However, the higher friction was associated with a subset of the chains (what is going on locally), and not with the monolayer as a whole (what is going on globally). This suggests that additional runs of independently prepared systems would be required to see if this is a consistent trend associated with sliding direction.

The simulations to date have utilized two types of extreme probes: a very small carbon nanotube, and an infinitely flat hydrogen-terminated diamond probe. In an effort to model more realistic probes, Harrison and co-workers have begun making use of amorphous carbon tips with surface roughness. These tips offer several advantages over the previously used probes. First, because their structure is amorphous, many of the issues associated with commensurate contacts will be removed [72]. Second, the irregular structure is likely to resemble the surface of an AFM tip, particularly one coated with a diamond film.

A recent experimental study reported measurements of the structural and friction properties of mixed and single component films of alkanethiols on Au(111) [48]. Two linear regimes were distinguishable in the friction versus load data of the mixed film. At low loads, the mixed film exhibited a very rapid rise in friction. At higher loads, the slope of the curve decreased to a level comparable with the single-component film. The friction versus load data of the single component film was linear over the entire range of loads investigated. With these results in mind, MD simulations of the friction of mixed and pure component SAMs were undertaken. A brief discussion of some preliminary findings follows.

Figures 2 (lower panel) and 15 depict model sliding systems where the probing tip is made from a diamond-like-carbon (DLC) mixture of hydrogen and carbon atoms. Within the bulk, this tip was consistent with some typical benchmark properties of DLC (density, percent hydrogen

content) [134]. The surface structure of the tip exhibited the desired traits of moderate surface roughness and incommensurability with the diamond (111) substrate underlying the SAM. Two systems, referred to as a pure and mixed SAM, were examined. The pure SAM was comprised of 100 linear hydrocarbon chains, each containing 14 carbon atoms (C_{14}) (Fig. 2). The mixed SAM was comprised of an equal mixture of 12-carbon-atom (C_{12}) chains and 16-carbon-atom chains (C_{16}) (Fig. 15). Thus, each of the SAMs contained an equal number of carbon and hydrogen atoms. The chains were anchored to a thin diamond (111) substrate in a (2×2) arrangement.

After equilibrating the systems at 300 K, identical tips were used to indent both systems up to loads near 30 nN. From the indents, a number of system configurations were extracted and used as starting configurations for slides. Figure 16 shows a comparison of friction versus load for these pure and mixed SAM systems. Over the load range investigated, the response of both systems is approximately linear, and the slope of the data for the mixed system is over three times larger than the pure system. This was also observed in AFM experiments that examined alkanethiols of the same lengths [48]. It is likely that this behavior is related to the high degree of disorder in surface structure of the mixed SAM. The relationship between order and friction is well established [50, 51, 72, 119], and the sliding interfaces shown in Figures 2 (lower panel) and 15 are strikingly different in structure.

Initial analysis of energy modes revealed that the thermostats utilized at the top of the tip and the bottom of the sample, to maintain the system at 300 K, are too strong to establish a clear correlation between frictional properties and weak energy modes. Consequently, these systems are being restudied with a weakened thermostat that is applied to all atoms in the system in the dimensions transverse to the

Figure 16. Comparison of the friction versus load for a single-component SAM composed of C_{14} chains versus a mixed SAM with equal numbers of C_{12} chains and C_{16} chains (Fig. 15). Error bars indicate minimum and maximum friction values obtained by window averaging the data over unit-cell lengths of sliding (the unit-cell length is from the (2×2) arrangement of chains in the sliding direction). The sliding direction is along the chain-tilt angle (left to right in Fig. 15). Lines are drawn to aid the eye.

sliding direction. Although thermostats are typically applied only to atoms at the periphery of the system, it has been demonstrated that all nonrigid atoms can be coupled to the thermostat, provided the coupling is weak and not applied in the sliding direction [72].

Because the friction responses of these similar systems are clearly distinct from one another, these preliminary results suggest that further investigation will yield some insight into fundamental friction mechanisms. It will be interesting to extend these investigations to higher loads to see if the slope of the friction versus load curve of the mixed SAM ever matches that of the pure SAM, as is seen experimentally [48].

Recently, there has been much interest in monolayers composed of polydiacetylene. The friction of unpolymerized and polymerized diacetylene monolayers has been measured using the AFM [135]. These authors assert that the presence of the cross-linked molecules in polymerized films alters the structure of the friction versus load data, compared to unpolymerized films, by inhibiting lateral displacement within the monolayers. Moreover, the friction exhibited a directional dependence (anisotropy) in the polymerized films. This is thought to arise from the presence of domains associated with the linear conjugated polymer backbones. Harrison and co-workers have begun to examine the friction in monolayers composed of alkynes, or model unsaturated hydrocarbon layers, using the AIREBO potential. Particular interest was given to the extent to which polymerization, and its position in the chain, affects the lateral stiffness of the film. Careful attention was also given to the way in which these factors might influence the frictional response of the films.

Preliminary results revealed that the application of load initiates a small degree of polymerization, or carbon–carbon bond formation, between chains. Increasing the load generally increased the degree of polymerization. This process

Figure 15. Mixed component SAM in sliding contact with a diamond-like carbon tip. The SAM is a random mixture of C_{12} and C_{16} n–alkane chains. This is the ending configuration for the highest load investigated in Figure 16 (around 30 nN). The tip density is 1.9 g/cm^3. The tip is composed of 38 and 61% sp^3- and sp^2-hybridized carbon atoms, and is 36% hydrogen. Color coding is as in Figure 2. The sliding direction is along the chain-tilt angle (left to right).

was irreversible. That is, when the load was removed, the polymerization remained. When these films were in sliding contact with an amorphous DLC probe, the polymerization continued with increasing sliding distance [136].

7. FUTURE DIRECTIONS

Matching simulation time scales with experimental time scales is one of the most challenging issues related to MD simulations. Experimental sliding speeds are many orders of magnitude smaller than what is currently feasible with MD. The methodology adopted by Leng and Jiang is successful in bridging this gap. However, its use is restricted to systems at very low loads. A more powerful technique is one that could be flexible with respect to the kinds of systems that can be modeled. If phenomena such as wear, chemical restructuring of the tip, or even less dramatic phenomena such as penetration of soft tip asperities into SAM samples, are to be investigated, using fast sliding speeds may be unavoidable in MD simulations. By altering properties of the modeled cantilever assembly, such as the damping of the harmonic springs used to control the motion, mass of the support to which the springs and the tip atoms are attached, and the feedback loop (for regulating the position of the rigid support), it may be possible to reasonably duplicate the essential features of experimental systems using relatively high sliding speeds [87, 88].

Rather than trying to directly model an AFM cantilever, simulations can be conducted in the simpler constant height and constant load modes. In these limits, there is no special tuning of cantilever properties that requires consideration of the sliding speed. It is sufficient to simply use a sliding speed that is separated in scale from thermal speeds. Furthermore, such a simplified approach may help develop fundamental insights into friction mechanisms, particularly if both external force modes (constant height and constant load) are studied together over a wide range of average loads. The wide variety of computational studies undertaken to date hint at a rich variety of physical mechanisms that are relevant to the understanding of friction. However, the large differences in potential models, constraints, and methodologies make it difficult to establish an integrated view of the friction of SAMs.

In addition to the modeling of external forces, care must also be given to the structure of the tip. Comparable experimental and theoretical length scales are thus another challenging problem. The radius of curvature of scanning probe microscope tips is currently no less than about 150 Å. Depending upon the type of potentials used, it is not currently computationally feasible to do MD at this scale. Moreover, it is also not clear that this is the relevant length scale. It is likely that localized asperities from the tip in contact with SAM samples are responsible for the phenomena observed with the AFM. Not much is presently known, theoretically or experimentally, about the surface structure of AFM tips over lengths on the order of angstroms. To what degree is the surface atomically rough? To what degree are there chemically unsaturated atoms at the surface? These are crucial questions that are just beginning to be explored.

This review clearly shows that work in this field is still in its early stages. There are a number of exciting possibilities yet to explore. It is likely that realistic modeling of a variety of systems will require a potential that can address a wide range of phenomena, including the breaking and forming of bonds and nonbonded, long-range interactions. The AIREBO potential discussed above is such a potential, although it is currently limited to the treatment of hydrogen and carbon atoms. Recently, the model was extended to include fluorine, and it is reasonable to expect that other atom types can similarly be added [137]. But there are many kinds of interactions that cannot be addressed within the basic structure of this potential model. For instance, what is the role of humidity and other gases? Most AFM experiments are not conducted in vacuum. What about the chain–substrate interaction? The structure of $SH(CH_2)_{n-1}CH_3$ chains on gold, the most commonly studied SAM, is still an issue of debate. Recent experimental evidence suggests a dimer arrangement as opposed to the adsorption of sulfur atoms at the threefold hollow sites of the gold substrate [138]. It would be a very challenging task to model such a variety of interactions in a consistent manner, although it is likely that this variety is necessary to capture all of the major facets involved with an experimental AFM–SAM system.

While directly connecting with experimental AFM–SAM systems is a long-term goal, there is much room for fundamental studies that elucidate friction mechanisms without necessarily directly modeling experimental systems. The investigations undertaken thus far indicate a rich variety of phenomena. As computational power continues to grow, these investigations will also grow in breadth and in depth.

GLOSSARY

Adaptive integrated reactive empirical bond-order (AIREBO) potential   Based on the REBO potential, this potential energy function is used to model physical and chemical reactions in hydrocarbon systems of all phases.

Alkanethiol   Saturated hydrocarbon chain with a sulfur head group [$-SH(CH_s)_nCH_3$].

Atomic force microscopy (AFM)   Probing a molecular surface using a movable cantilever, and obtaining atomic-scale force and position information.

Langmuir–Blodgett (LB)   The method of applying a single-monolayer thickness of self-assembled alkanethiol-type chains, in an amphiphillic environment, to a substrate using compression of the molecules on a liquid.

Lennard–Jones (LJ) interactions   A model for the repulsive and attractive interactions that occur between non-bonded atoms.

Molecular dynamics (MD)   Computational method that calculates the atomic-scale trajectory of atoms as a function of time that are allowed to move according to Newton's equations of motion.

Nanotube   A nanometer-scale folded carbon sheet, capped or uncapped, used to probe surface structure.

Reactive empirical bond-order (REBO) potential   A potential energy function used to model physical and chemical reactions in gas- and solid-phase hydrocarbon systems.

Self-assembled monolayer (SAM)   A film of hydrocarbon chains that are chemisorbed to a substrate by their sulfur- or silica-containing head groups.

CONTENTS

1. INTRODUCTION

This chapter outlines the main synthesis routes, the structural features, and the physicochemical properties of fullerene dimers. This relatively simple class of materials proved to be rather difficult to study owing, in general, to their low solubility. The interest manifested in these materials is related to their promising electronic and optical properties, and in particular to the intramolecular charge transfer.

The discovery of fullerenes [1] by mass spectroscopy in the mid-1980s attracted wide interest, both from physicists and chemists. Soon thereafter, fullerenes in isolable amounts were obtained by a procedure developed by Krätschmer et al. [2]. This is the point when theoretical works, the prior predominant ones, could be thoroughly checked by experiments. After the initial frenzy when fullerenes were believed to be useful for just about anything, a concept encouraged by the unexpected properties observed for the new entry in the carbon–allotropes family, a more systematic work was started. The properties of fullerenes and derivatives, such

as superconductivity [3], ferromagnetism [4], nonlinear optical properties [5], or even HIV protease blocking [6], are now generally understood as a result of their structure. The famous member of the fullerene family C_{60}, the soccer ball (**1**), was the most analyzed, and this is undoubtedly due to its relatively high abundance, its unique spherical shape, and high symmetry I_h. Fullerene dimers were reported soon after the synthesis of the new monomers. In the search for other properties of fullerene derivatives and an understanding of their structure–properties relationship, systematic synthetic organic chemistry work was done (there are fewer inorganic chemistry works in this field, although several works, for instance by Fagan et al. [7], are famous for proving the electronic nature of C_{60}). The chemistry of fullerenes is today a mature field; the interested reader can consult the works of Diederich and Thilgen [8], Hirsch [9], or Taylor [10, 11]. In spite of sustained research activity in the field of fullerenes, there have not been many fullerene dimers synthesized up to now. This apparent lack of interest in dimeric fullerenes is partly related to the general low solubility of fullerene dimers, and hence, to the difficulty of their synthesis and purification, as well as partly to the difficulty of separating pure samples from the multitude of the isomers obtained. In this sense, experimental methods rarely used by chemists for structural characterization ought to be used, for instance, scanning tunneling microscopy (STM). There is a large variety in the synthesis methods of these molecules, and these will be described along with their structures. We will classify these molecules into two main categories: with one or more direct connections between the fullerene cages, and without direct connections between the fullerene cages. Although this separation seems artificial, it points out the different electronic properties which can be expected from these materials: intercage electronic interaction in one case,

and donor/acceptor electronic transfer in the other. Aside from this classification, we will divide our discussion into other two categories according to the presence or absence of atoms other than the carbon. The latter category is relatively undeveloped, that of all-carbon fullerene dimers, new molecular carbon allotropes [12]. We will also include in our discussion molecules which are not, strictly speaking, dimers, such as C_{119} [13]. However, this is an outstanding example of the synthesis of new molecules starting from a fullerene dimer, and we will detail here all compounds reported in the literature having two fullerene-like cages, even nonequivalent. Most of the compounds synthesized are dimers of C_{60}; only a few examples are known for other fullerenes.
1

We will focus our attention on the all-carbon fullerene derivatives, not only because they might be considered as new allotropes, but also because they may be used for the synthesis of endohedral, higher fullerenes, or even nanotubes by a "coalescence" reaction; these possibilities will be discussed later. Another interesting feature of the dimers is that their electronic behavior should remain largely the same as that of fullerenes, while gaining other characteristics as a result of the intercage couplings. As an example, $C_{120}O$ and other dimers have been found to manifest an electronic communication between the cages [14] (see Section 2). C_{60} dimers also have been claimed to offer a route to the synthesis of endohedral fullerene compounds [15], and *ab initio* and density functional theory (DFT) calculations have been employed to find a reaction path toward the formation of endohedral fullerene compounds. The proposed mechanism involves a [2 + 2] cycloaddition yielding C_{120}, while it allows the formation of a stable "window" through which an atom can enter one of the cages. Finally, fullerene dimers have been sought as proofs for the structures of more complex molecules, for instance, fullerene polymers. In an exceptional example, C_{120} has been shown to be the prototype of a C_{60} polymer, synthesized, and whose structure has been correctly assigned by Rao et al. [16].

As one can see, these molecules have interesting structures, modulable properties, can be used as starting materials for the synthesis of other materials, and can serve as structural prototypes.

2. SYNTHESIS OF FULLERENE DIMERS

2.1. Dimers with Direct Connections Between Fullerene Cages

2.1.1. All-Carbon Fullerene Dimers

Special attention is paid to the all-carbon fullerene dimers because they may be used for the synthesis of higher fullerenes, for instance, by a coalescence reaction [17]

observed to take place under mass spectroscopy (MS) conditions. This reaction was not experimentally proven on a macroscopic scale, but such an opportunity exists and may offer a "rational" approach to the synthesis of higher fullerenes.

In the family of all-carbon dimers with a direct connection between the fullerene cages, the most prominent member is C_{120} (**2**) [18]; synthesized by an unusual mechanochemical reaction, it was rather fully characterized. The synthesis involves milling C_{60} in the presence of a catalyst such as KCN. A possible reaction mechanism is shown in Scheme 1. The method used by Komatsu involved high-speed vibration milling (HSVM), but this dimer can also be obtained by manually grinding C_{60} and lithium under inert atmosphere [19, 20], high-temperature phototransformation [21], hydrostatic pressure [22], or by pressurization of a template compound [23]. By the latter method, with pressurization under 5 GPa at 200 °C of an $(ET)_2C_{60}$ organic molecular crystal, yields of about 80% have been obtained. A detailed analysis of the infrared (IR) signatures of (**2**), the corresponding ultraviolet (UV) polymer, and their assignments by molecular dynamics (MD) calculations have been published recently [24].
2

When the starting material is endohedral[60]fullerene, which is C_{60} encapsulating one or more atoms, the resulting C_{120} will contain one or more atoms in C_{60} cages. Because amounts of the available endohedral[60]fullerenes are very small, a mixture of hollow C_{60} and endohedral[60]fullerenes was used for the synthesis. Thus, only one of the two C_{60} cages of reported endohedral fullerene dimers contains an atom. The reported endohedral fullerene dimers are $^3He @ C_{120}$ [25] and $N @ C_{120}$ [26]. The encapsulated ^3He and N atoms can be used as labeling because the environment of the ^3He and N atoms in the dimers can be monitored by ^3He–NMR (nuclear magnetic resonance) and electron paramagnetic resonance (EPR), respectively.
Scheme 1. Possible mechanism of formation of C_{120}.

There is another recent report on the synthesis of a different kind of dumbbell C_{120} dimer, in which the connection between two fullerenes is made face to face on two hexagons [27], but we believe that there is not enough evidence to prove this structure. This face-to-face dimer would be more likely to give a coalescence reaction, and the authors of this report discussed such a possibility.

Following pioneering work by McElvany et al. [28] who observed a C_{119} cluster by mass spectroscopy, Krätschmer and co-workers [29] isolated two isomers of a different molecule which could be assigned to C_{119} (**3**). Of these two isomers, subtle experimental analysis clearly identified one of the structures of these two compounds as (**3a**). This compound can best be described as a dimer of two 58-atoms clusters, connected through a three-carbon bridge. The synthesis method of (**3**) involved the solid-state heating at 550–600 °C of $C_{120}O$ under argon; hence, presumably, the mechanism involved the elimination of a CO molecule, followed by a reorganization of the C_{119} fragment. This is a nice example of overcoming the high energy barrier required to remove a carbon atom from a C_{60} cluster, and this method could allow the synthesis of other clusters (it has been attempted, unsuccessfully, for the decomposition of $C_{120}OS$) [30]. According to McElvany's work, C_{129} and C_{139} can also be obtained; it is likely that the same solid-state procedure will lead to a mixture of these compounds, but no attempts to obtain these compounds were made until now.

3
Among other possible dimeric structures, theoretical calculations suggest that a pentagon-like linked structure for C_{121} should be stable [31].

2.1.2. Fullerene Dimers Containing Heterogeneous Atoms

As expected, in this category, many more dimers can be included. One of the most interesting compounds in this class is $C_{120}O$ (**4**); it has been used for the synthesis of other compounds, among them the intriguing C_{119}, and it was the first dimer to show an intercage electronic communication. On the other hand, as found by Taylor, this dimer is present as impurity in all samples of C_{60} exposed to light and air. This had major implications on the EPR results published so far, as was clearly demonstrated by Reed and co-workers [32].

4
Independently, Krätschmer and co-workers [33] and Smith et al. [34] obtained $C_{120}O$ by a thermolysis of a mixture of $C_{60}O$ and C_{60} in solid state and in solution, respectively. The two fullerene cages are directly connected, forming a furan-like ring. It is noteworthy that $C_{120}O$ also has been isolated from the as-purchased C_{60} from different providers by Taylor et al. [35]. They also noted that C_{60} "degrades" to $C_{120}O$ under the influence of light, in solid state, in the presence of oxygen. It is likely that this involves the formation of the $C_{60}O$ which is unstable relative to $C_{120}O$.

Using the same procedure, by the thermolysis of $C_{61}H_2$ in the presence of C_{60}, Smith et al. synthesized an analog dimer, $C_{120}CH_2$ (**5**) [34], in which a cyclopentane connects two fullerene cages. It is likely that the same experimental procedure can lead to higher oligomers. A different approach for the synthesis of this dimer was reported by Fujiwara and Komatsu [36] by using a mechanochemical solid-state reaction. The dimer is bridged by a silicon atom (**6**). The mechanochemical reaction was performed on a mixture of C_{60}, dichlorodiphenylsilane, and lithium powder under HSVM conditions. This dimer is sensitive to moisture in solution, which transforms it into C_{60} and $C_{60}H_4$.

5

6
The $C_{60}/C_{60}O/C_{60}O_2$ system was used to synthesize $C_{120}O_2$ (**7**) by Krätschmer et al. [37, 38]. A highly symmetrical $C_{120}O_2$ (C_{2v}) has two furanoid links between the cages, the bridges connecting to 6:6 positions on the fullerene core, and similarly with the $C_{120}OS$ (**8**) structure synthesized by the same solid-state technique [39]. The bridging pattern involves four sp^3 carbons on each of the fullerene cages, and there are several possibilities for obtaining this. The most stable structure is the one having the highest number of double bonds at the 6:6 bond (see the discussion on $C_{122}H_4$ below). Lower symmetry isomers of $C_{120}O_2$ (C_1) have been synthesized by Gromov et al. [40]; a *cis*–1 *syn* compound is shown in Figure 1.

7

8

Scheme 2. Synthesis of $(C_{59}N)_2$.

11

12

Similar in structure to $C_{120}O$ and $C_{120}CH_2$, a new dimer has been isolated from the product of thermolysis of cyclopropane derivatives. The thermolysis of methano[60]fullerenes containing hydrogen atoms such as ethoxycarbonylmethano[60]fullerene (**9**) under inert atmosphere yields $C_{122}H_4$ (**10**) [41]. This dimer has a similar structure to $C_{120}O_2$ and $C_{120}OS$, that is, two direct intercage bonds forming a part of a cyclobutane ring and two indirect intercage links. The cyclobutane edges belonging to C_{60} are located between a five-membered ring and a six-membered ring. The CH_2 bridgehead atoms are connected to the five-membered ring.

9   **10**

Another interesting dimer in this category is $(C_{59}N)_2$ (**11**), which has been obtained by Wudl and co-workers [42]. The dimer was synthesized by "organic chemical methods" (Scheme 2). The first step was the 1,3–dipolar cycloaddition of methoxyethoxymethylazide (MEM–N_3) to C_{60}, followed by the photooxygenation of the as-obtained 6:5–azahomo[60]fullerene; this yields a C_{60}–N–MEM–ketolactam. Finally, the C_{60}–N–MEM–ketolactam was treated with a large excess of *p*–toluenesulfonic acid monohydrate in *o*–dichlorobenzene. From this dimer, hydroroaza[60]fullerene ($C_{59}HN$, **12**) was obtained by irradiation through a Kapton filter in *o*–dichlorobenzene in the presence of tributyltin hydride in argon at 25–35 °C [43]. A recent discussion concerning this dimer is due to Reuther and Hirsch [44]. It is also notable that $(C_{59}N)_2$ can be obtained as a byproduct during the synthesis of a nitrogen endohedral fullerene [45].

One of the earliest directly connected dimers was synthesized by Fagan et al. [46] during the study of a *t*–BuLi addition to C_{60} (Fig. 2). The synthesis of this class of compounds is quite straightforward, as a radicalic coupling of fullerene derivatives (Scheme 3). Several dimers have been obtained by this method [47], and it is notable that these dimers are in equilibrium with the C_{60} radicals [48]. The addition pattern to forming these dimers is, in general, in 1,4 on the C_{60} cage, regardless of the energetically more favorable position on 1,2; this is due to the strong steric interaction favoring the former addition pattern. An interesting topic for the study of these dimers is the energy barrier for the rotation function of the addends; several calculations have been performed on this [49].

Another single-bonded dimer was obtained by Schick et al. [50] by reacting C_{60} in air-saturated benzene with a large excess of morpholine. The obtained precipitate, 50% yield, is a dimer bis–[(4,4′–dimorpholino)–1,4–dihydro[60]fullerenyl] embodying two C_{60} cages directly connected and having two morpholine addends in the 1,4
Figure 2. Molecular structure of $(t$–$BuC_{60})_2$.
Scheme 3. Synthesis of $(RC_{60})_2$.

pattern. The formation of this structural type is also determined by the presence of aminated C_{60} radicals.

2.2. Dimers Without Direct Connections Between Fullerene Cages

2.2.1. All-Carbon Fullerene Dimers

In the family of all-carbon dimers without a direct connection between fullerene cages, we include C_{121} (**13a, 13b**), C_{122} [51] (**14**), and $C_{n(60+5)}$ [52] (**15**). The case of $C_{n(60+5)}$ is very interesting, and its synthesis is ingenious. The authors [52] were interested in the synthesis of molecular carbon allotropes of the fullerene–acetylene hybrid type (**16**). The synthesis involves oxidative coupling of diethynyl-methano[60]fullerene. Limited by the solubility problems, the authors adopted a tether synthesis strategy in which, having attached functional groups to the fullerene core, the solubility problem was avoided.

C_{121} can be described as a dumbbell-like dimer or more appealing as a bis([60]fullerene)methane. A connection of two fullerenes through one carbon atom gives D_{2d} (**13a**) and C_s (**13b**) symmetry fullerene dimers. Similar in structure and formation is C_{122}, in which an ethylene group connects two fullerenes, giving a D_{2h} symmetry molecule. The latter was first reported by Strongin and co-workers [53] by the reaction of an "atomic carbon" with a fullerene. The ingenious idea of making all-carbon allotropes by the reaction of C_{60} with "carbon" is unfortunately impeded by the use of dangerous chemicals.

C_{121}, C_{122}, and other trimers [54] can be obtained by a solid-state decomposition of methano[60]fullerenes. The synthesis of **13a**, **13b**, and **14** is based on the formation of a methanofullerenecarbene as an intermediate, as proposed earlier by Osterodt and Vögtle [55] (Scheme 4). By using the same strategy, higher oligomers of the all-carbon type can also be obtained [54].

X = C(CO_2CH_2CO_2Et)
n = 1, 2
16

2.2.2. Fullerene Dimers Containing Heterogeneous Atoms

This kind of dimer is relatively easy to synthesize, compared with all previous ones, and several such dimers have been characterized. The ease of synthesis is also supported by a rather high solubility, depending on the flexibility of the linkage. According to Mullen and co-workers [56], about 1 g of such a compound can be synthesized and separated in one day on a laboratory scale. Comparatively, in our experience, the isolation of a few milligrams of pure C_{122} requires several weeks. This is one of the reasons for the relative abundance of dimers without a direct connection between fullerenes, similarly called *dumbbells*.

One fullerene dimer in this category, a dyad prepared by the dipolar cycloaddition of a fullerene with N–methylglycine

13

14
Scheme 4. Synthesis of C_{121} and C_{122} based on the formation of a methanofullerenecarbene as an intermediate.

(**17**), has been the object of study for electronic interactions [57]. 1,3–dipolar cycloaddition of N–methylglycine with C_{60} was also used for the synthesis of the fullerene dimer **18** [58]. Significant work also has been done in this area by Rubin and co-workers [59]. They have synthesized a series of "ball-and-chain" systems based on C_{60} in order to study the intramolecular electronic transfer. The synthetic procedures used by the above-mentioned authors involved a diene component in a Diels–Alder reaction with C_{60}. One of the reaction products which we would like to mention here is a fullerene dimer with a dumbbell-like structure (Fig. 3). This dimer has several possible conformations, and they have been compared with a pair of bolas (Fig. 4). Among the three possible conformations of this dimer, the folded–folded one is the most probable, taking into account molecular geometry optimizations. Such a conformation would be based on $\pi-\pi$ attractive interactions between the fullerene cages, and probably imposes consequences in the electrochemical and photophysical properties of this dimer.

17

18
Another dimer formed by the Diels–Alder reaction is the "dumbbell"-like compound (**19**) [60]. The authors improved the solubility of **19** by the introduction of hexyloxyl groups, whose oligomers of up to seven [60]fullerenes were observed by matrix-assisted laser desorption ionization time-of-flight mass spectroscopy (MALDI–TOF MS) and size exclusion chromatography (**20**) [61]. The ^{1}H–NMR of the dimer of **20**

($n = 0$) shows that it can exist either in the *cis* or in the *trans* conformation (Scheme 5).

19

($n = 0 - 5$)

20
Diels–Alder reactions were also performed by solid-state reactions; thus *anti*-bis[60]fullerene adducts of pentacene (**21**) were synthesized by the HSVM reaction of C_{60} with pentacene [62]. The *syn* adduct of the dimer was not obtained by HSVM, while the *syn* derivative of the bis[60]fullerene adducts of 6,13-substituted pentacene (**22**)
Scheme 5. *cis* and *trans* conformers of the bis–hexyloxy-substituted "dumbbell" compound **21** ($n = 0$).

was synthesized in solution [63] when only trace amounts of the *anti* compound were formed.

R = Ph, 4′-hydroxymethylphenyl

21   **22**
An unusually strong electronic communication between two C_{60} cages has been observed for a fullerene–metal sandwich complex formed by reacting $Rh_6(CO)_9(dppm)_2 \cdot (\mu_3-\eta_2, \eta_2, \eta_2-C_{60})$ with C_{60}. The product obtained has a structure like that shown in Figure 5, in which two C_{60} are linked through an octahedral Rh_6 framework [64].

Another metal bridged fullerene dimer is C_{70}–Sm–C_{70}, which is formed in the fulleride $Sm_{2.78}C_{70}$ [65]. While the other reported fullerides are generally van der Waals or ionic crystals, two [70]fullerenes in this fulleride are bridged by an Sm atom with single covalent bonds, whose lengths are 2.49(1) and 2.47(1) Å.

Aside from those, bis–([60]fullereno[1,2–d]isoxazole–3–yl) (**23**) was synthesized by dipolar cycloaddition [66]. More specifically, (**23**) was generated by the double 1,3–dipolar cycloaddition of C_{60} to cyanogen di–N–oxide. The
Figure 5. Molecular structure of $Rh_6(CO)_5(dppm)_2(CNR)(C_{60})_2$. RNC and dppm ligands are omitted for clarity. ($R = CH_2C_6H_5$.)

solubility of this dimer into CS_2, chlorobenzene, and *o*–dichlorobenzene is poor, but it is well soluble in 1–chloronaphthalene/2–chloronaphthalene 9/1(v/v).

23

In the search for molecules having charge separation states, Hudhomme and co-workers [67] developed strategies for the synthesis of C_{60} TTF triads. The idea behind the interest in such a compound lies in the stabilization of the charge separation state $C_{60}^{.-}$ $TTF^{.+}$, as a result of the formation of a heteroromatic 1,3 dithiolium cation upon oxidation. The obtained C_{60}–TTF–C_{60} triad is formed by the reductive elimination of the tetrakis (bromine) TTF in the presence of C_{60}. The compound (**24**) is formed by rigid links of TTF to C_{60}; this approach allows the control of both the relative orientation and the distance between the donor/acceptor groups. As expected, the product is not very soluble, and its thermal instability impeded its purification. Its structure is inferred nonetheless from the synthesis of several soluble derivatives (**25**) in which the C_{60} is cyclopropanated, as well as from MS, UV–vis and electrochemical properties.

24

(R, R′) = ($CO_2CH_2CH_3$, $CO_2CH_2CH_3$)
($CO_2(CH_2CH_2O)_3CH_3$, $CO_2(CH_2CH_2O)_3CH_3$)
(CO_2CH_3, Ph)
25

A recent class of compounds in this category was opened by the synthesis of supramolecular dimers, initially reported by Diederich et al. [68]. Although the chemistry of fullerenes is well developed to date, little work has been done in the area of supramolecular assemblies bearing fullerene units.

The synthesis of a derivative of C_{60} with dibenzo–24–crown–8 ether was accomplished, as well as the one of C_{60} with dibenzylammonium hexafluorophosphate; these form a supramolecular C_{60} dimer (DG = −17.0 kJ in $CDCl_3$:CD_3CN 9:1) (**26**). The hydrogen bonds and ion–dipole interactions led to a structure having the dibenzylammonium component threaded through the cavity of the crown ether macrocycle. As in most of the dimers where there is a large distance between the cages, no electronic interactions between the cages were detected by means of electrochemistry.
26

There is another type of supramolecular dimer, which is based on quadruple hydrogen bonding (**27**) [69]. The non-covalent bonding of this compound is different from that of **26**.
27

Murata et al. reported two C_{60} dimers (**28** and **29**) bridged by a bicyclic framework, both synthesized by solid-state reactions [70, 71]. The dimer **28** was synthesized by heating the solid mixture of C_{60} and 2,3–diazanaphthalene at 150 °C for 2 h. The dimer **29** was synthesized by processing the solid mixture of C_{60} and 4 equivalents of phtalazine using high-speed vibration milling. The interesting point about these compounds is that **28** and **29** were isomerized into **30** and **31**, respectively, by heating in solution.
28
29
30
31

Another dimer that transforms into an isomer with direct intercage bonds, *m*–phenylenebis(arylmethanofullerene) (**32**), was synthesized by Knol et al. [72]. Irradiation in deoxygenated *o*–dichlorobenzene isomerizes about 60% of **32** into **33**. This process is significantly retarded by molecular oxygen. The dimer with direct intercage bonds (**33**) isomerizes completely into **32** by refluxing in *o*–dichlorobenzene. This is the first example of a controlled [2 + 2] cycloaddition process of fullerenes.
R = OC_6H_{13}

32
R = OC_6H_{13}

33

The cage-structured C_{60} dimer (**34**), which consist of four aliphatic chains and two C_{60} end caps, was synthesized by the coupling of two [60]fullerenes and four 1,3–diaminopropanes [73].
34

3. SPECTROSCOPIC CHARACTERIZATION

3.1. Mass Spectroscopy

Mass spectroscopy plays an important role in the characterization of fullerene dimers because this technique requires substantially fewer samples (and machine time) than other analysis methods such as NMR, X-ray diffraction, and so on. However, the fragmentation of fullerene dimers into monomers and the low solubility of fullerene dimers made most of the ionization methods inaccessible for these samples. Typically, only MALDI–TOF–MS gives sufficient mass accuracy and intensity for most of the fullerene dimers. The representative fullerene dimers whose mass spectrum was successfully obtained by MALDI–TOF–MS are $C_{120}OS$ [39], $C_{120}H_4$ [41], C_{121} [76], and C_{122} [76]. All of them were analyzed by using 9–nitroanthracene (9–NA) as a matrix and negative-ion mode. The mass spectra of $C_{120}H_4$, C_{121}, and C_{122} were also obtained by using dithranol as a matrix.

Several ionization techniques were tested to obtain the mass spectrum of C_{120} (**2**) [18]. A signal for C_{120} and C_{60} was obtained by MALDI–TOF–MS and by Fourier-transform ion cyclotron resonance (FTICR). The C_{60} signal was formed by fragmentation of the dimer, which is unavoidable for any of the fullerene dimers reported to date. Fast atom bombardment (FAB), atmospheric pressure chemical ionization (APCI), and electrospray ionization (ESI) in both the positive- and negative-ion modes showed only a peak of C_{60}.

The mass spectra of $C_{120}O$ (**4**) were obtained by MALDI–TOF–MS using 9–NA as a matrix [33] in the negative-ionization mode. In addition to the peaks of $C_{120}O$, the peaks of $C_{120}O_2$, $C_{120}O_3$, $C_{60}O$, and C_{60} were detected in the spectrum. The mass spectra of $C_{120}O$ were also obtained both by negative-ion APCI with N_2 as reagent gas and by negative-ion ESI with N,N,N′,N′–tetramethyl–1,4–phenylenediamine as the electron transfer reagent, but laser desorption ionization (LDI) gives only C_{60} and $C_{60}O$ fragment ions [75].

Not only the molecular ion peak, but also the fragmentation pattern provides information on the molecular structure. For instance, a different fragmentation pattern was observed in the MALDI–TOF–MS observed for the two isomers $C_{120}O_2$ [40].

FAB–MS is usually not suitable for fullerene dimers because the volatility of good solvents for fullerene dimers such as 1,2–dichlorobenzene and 1–chloronaphthalene are too high as a matrix in FAB–MS. In order to solve the problem, Gross et al. [74] applied negative-ion low-temperature FAB–MS to fullerene dimers. In this method, a mixture of 1–chloronaphthalene and 3–nitrobenzyl alcohol and the dissolved sample was frozen with liquid nitrogen. This procedure enabled the use of these solvents in the FAB–MS, and showed high-quality molecular ion peaks for C_{119}, C_{120}, $C_{120}O$, $C_{120}O_2$, and $C_{120}OS$.

3.2. Nuclear Magnetic Resonance

^{13}C–NMR is one of the most powerful tools for the structure analysis of fullerene dimers, and in general was the method of choice. Because few carbon atoms in fullerene cages are bound to protons, there are small differences of relaxation time and of the nuclear Overhauser effect. This makes it possible to quantitatively count the number of carbon atoms of ^{13}C–NMR spectra. Unfortunately, there are some difficulties in obtaining satisfactory ^{13}C–NMR spectra: low solubility of dimers, long relaxation time, as well as the concentration of resonances of fullerene cage atoms in a small domain. For these reasons, many ^{13}C–NMR experiments on dimers required a long acquisition time, relaxation reagent, and a relatively high field NMR. It is not uncommon in this field to have routine spectra acquired for a few days.

A typical example of the structure determined by ^{13}C–NMR is **14** [76]. The ^{13}C–NMR spectrum shown in Figure 6 was measured under the following conditions: instrument: JEOL LNM270 (^1H 270 MHz), solvent: 1–chloronaphthalene with 20% v/v 1–methylnaphthalene–d_{10}, relaxation reagent: Cr(acac)$_3$ 10 mM, flip angle: 90°, pulse repetition time: 10.000 s (acquisition time 3.146 s + pulse delay 6.854 s), number of scans: 34,464. There are other two peaks at 84.71 and 128.90 ppm out of the range of Figure 6. By using a partial ^{13}C-enriched sample, the resonance at 128.90 ppm was detected to originate in the bridging carbon atoms. There are three small resonances, 11 resonances of double intensity, and one resonance of quadruple intensity of the small peaks. The intensity of the resonance at 84.71 ppm is about same as the small resonances. Considering their number and intensity, the only reasonable explanation is that the quadruple intense peak is the overlap of two double intensity peaks, and the symmetry of the dimer is thus C_{2h}. The three small resonances originate in the carbon atoms located in the mirror plane of the molecule.

The structural as well as mechanistic aspects of synthesis of fullerene dimers can be elucidated by using ^{13}C–NMR on partially ^{13}C marked compounds. Thus, the formation of $C_{120}O$ [75] and C_{121} [76] was checked by using ^{13}C partially marked C_{60}. We also note that ^3He NMR studies were performed on the ^3He-incarcerated C_{120} molecules [25, 77].

The experimental conditions of acquisition for some dimers are summarized in Table 1.

Table 1. Experimental conditions of reported ^{13}C–NMR of fullerene dimers.

Molecule	Solvent	[13]C abundance ratio	Cr(acac)$_3$ (mM)	Flip angle (°)	Pulse repetition time (s)	Number of scans	Ref.
C$_{120}$	ODCB–d$_4$	natural	0	N/A	N/A	N/A	[18]
C$_{121}$	1–chloronaphthalene/1–methylnaphthalene–d$_{10}$ (4:1)	natural	10	60	5.146	44,735	[76]
C$_{122}$	1–chloronaphthalene/1–methylnaphthalene–d$_{10}$ (4:1)	natural	10	90	10	34,464	[76]
C$_{120}$O$_2$	CS$_2$/CDCl$_3$ (98:2)	7%	35	N/A	6	36,000	[37]
C$_{120}$O$_2$ (minor)	ODCB acetone–d$_6$ (in capillary)	7%	17.5	90	2.5	92,160	[40]
C$_{120}$OS	ODCB–d$_4$	7%	17	70	2	151,200	[39]

3.3. FT–IR and Raman Spectroscopy

Because of its high symmetry, C$_{60}$ shows only 4 and 11 peaks in IR and Raman spectra respectively, in spite of the large number of carbon atoms. For the case of fullerene dimers whose symmetries are lower than that of C$_{60}$, their IR and Raman spectra show hundreds of peaks. Thus, these spectra must be used in combination with other experimental and theoretical data, and in general have less impact on the structural identification of these compounds. Lebedkin et al. obtained strong evidence for the structure of C$_{119}$ from a comparison of the experimental Raman spectrum and theoretical Raman spectra of several possible isomers [78].

The characteristic vibrations of fullerene dimers are six cage–cage vibrations. One of them is derived from the combination of translations of two C$_{60}$ cages; the others are derived from the combination of rotations of two C$_{60}$ cages. Lebedkin et al. reported the Fourier transform (FT)–Raman spectra of the vibrations of C$_{120}$, C$_{120}$O, and C$_{120}$O$_2$ [79]. The observed wavenumbers for the cage–cage vibrations of C$_{120}$ agree well with the theoretical predictions made by Porezag et al. [80]. In general, the intercage vibrations ("diatomic like") are useful for structural analysis because their frequency can be directly related to the strength of the connection between the cages. The wavenumbers of these vibrations are lower than 200 cm^{-1}, and their intensities are very small. Thus, they are difficult to observe experimentally. In Figure 7, we show the dimer's vibrations modes, as calculated for C$_{121}$ [**13(b)**] [86].

3.4. X-Ray Diffraction

Since the first synthesis of C$_{60}$ by Krätschmer and co-workers [2], it has been observed that C$_{60}$ is difficult to obtain in an ordered single crystalline form. This also has been the case for their derivatives. Luckily, C$_{120}$ (**2**) can be obtained in an ordered single crystalline form; its structure was proven by single-crystal analysis, and consists of two fullerene cages bonded through a four-membered ring at the 6:6 position (i.e., at the connection between two hexagons in a fullerene framework). We note that the cage–cage distance is slightly longer, at 0.1575 nm, than a usual sp^3–sp^3 bond. The shape of C$_{120}$ caused it to be dubbed a *dumbbell*, and this compound is thought to be the repetitive unit of a type of

all-carbon fullerene polymer obtained previously by UV irradiation [16].

Another fullerene dimer analyzed by X-ray diffraction (XRD) was C$_{120}$O; however, due to the disorder, its structure could not be analyzed in detail [81].

4. THEORETICAL CALCULATIONS

In many cases, experimental IR, Raman, and NMR spectra of fullerene dimers were analyzed with the help of theoretical calculations. Theoretical calculations have been employed for the study of fullerenes; several possible structures of fullerene dimers were examined energetically and geometrically.

The three dimers, that is, C$_{120}$O$_2$, C$_{120}$OS, and C$_{122}$H$_4$, are structurally similar; from ^{13}C–NMR data alone, it is difficult to find the correct structure since several structures with the same symmetry are possible. As an example, the three possible structures of C$_{122}$H$_4$ are shown in Figure 8. The differences between them are the location of the two direct intercage bonds and the two methylene bridges. Among these, the most stable ones were determined by quantum chemical calculations, and it was found that their stability
Figure 7. Cage–cage vibrational modes of C$_{121}$ [**13(b)**].
Figure 8. Three possible structures of $C_{122}H_4$.

follows the same rule. The rule is that the most stable structure has the maximum number of double bonds at 6:6 positions, that is, the minimum number of double bonds at 6:5 positions for the dominant Kekule structure [82, 83]. The dominant Kekule structures of three possible structures of $C_{122}H_4$ are shown in Figure 9. Because of mirror symmetry, only one of two C_{60} cages is shown for each structure. The most stable structure is shown in Figure 9(a), and the next is Figure 9(b). The stability is related to the number of double bonds between two six-membered rings: 28, 27, and 24 for (a), (b), and (c), respectively. The same behavior was found for other fullerene derivatives [84].

13(a) consists of two methano[60]fullerenes, while **13(b)** consists of a methano[60]fullerene and a homo[60]fullerene. Generally, a methano[60]fullerene structure is more stable than the corresponding homo[60]fullerene structure [85]. In the case of C_{121}, the computed strain energy of the spiro structure of the bridging atom of **13(a)** is larger than **13(b)**, and this difference compensates for the difference of stability between a methano[60]fullerene and a homo[60]fullerene. Consequently, according to theoretical investigations, Gibbs's free energy of **13(a)** is larger than
Figure 9. π-bonding patterns of $C_{122}H_4$ (a), (b), and (c). The carbon atoms that are connected to a carbon atom of another C_{60} cage and a methylene bridge are marked by an open circle and a closed triangle, respectively.

that of **13(b)** [86]. Actually, it was observed experimentally that **13(a)** and **13(b)** isomerize each other, and the yield for the synthesis of **13(b)** is larger than of **13(a)** [76].

Concerning the properties of **13(b)**, we note that this is the only molecule embodying both types of connection to fullerenes. It has also shown intercage electronic communication; the first reduction potential is close to that of C_{60}, with peak separations for the addition of further electrons. This asymmetry in the structure and electronic properties can explain the asymmetric images obtained by STM [54].

Theoretical calculations have been employed to explore the structure of several all-carbon derivatives [87, 88].

5. PROPERTIES

5.1. Electrochemical Properties

Electrochemical studies have been performed on C_{60} and derivatives since their discovery, mainly to study the abilities of these molecules to be electrochemically reduced. From these studies, it has been found that, in general, C_{60} derivatives are less prone to reduction compared to C_{60} by 50–60 meV. For the fullerene dimers, similar behavior should be observed, with the difference that the two fullerene moieties can interact, thus leading to reduced species having large electronic delocalization. For these systems, one of the most important characteristics was the detection of such electronic communication which would manifest by a splitting between the first and second reduction potentials, third and the fourth, and so on. For a dimeric system in which the two electroactive units are separated (i.e., noninteracting), the first and second reduction potentials should be degenerate. The degree of such "electronic communication" was not ascertained in detail, other than the splitting between the pairs of reduction potentials. One of the most interesting systems to be discussed is C_{120}, and apparently there is no electronic interaction between the fullerene cages in this dimer. Cyclic voltammetry measurements suggest the decomposition to C_{60} after the first electron reduction process [18].

Balch et al. [89] observed an "electronic communication" between the fullerene cages of $C_{120}O$, that is, a stepwise addition of electrons to the fullerene cores. Supported by EPR measurements, they found that the reversible reductions of $C_{120}O$ are sequential: the addition of one electron to one C_{60} cage in a first step changes the reduction potential for the second addition to the other C_{60} cage, that is, a communication between the C_{60} frameworks. In a similar way, although not discussed in detail, in the di–aza dimer $C_{118}N_2$, some degree of interaction occurs [42].

As well as for $C_{120}O$, an electronic communication between the C_{60} cages of silicon-bridged dimer (**6**) was observed by cyclic voltammetry [36].

An interesting system is the unsymmetrical dimer C_{121}. The differential pulse voltammogram of the unsymmetrical C_{121} (C_s) [**13(b)**] shows six distinct peaks located at -1044, -1124, -1436, -1532, -1988, and -2160 mV versus ferrocene/ferricium (Fig. 10) [76]. These six peaks in pairs correspond to each of the first three reductions of the C_{60} cage. The differences between the reduction potential pairs are about 80, 80, and 135 mV, which are larger than the differences between the reduction potentials of isomeric homofullerenes and methanofullerenes. Thus, the splitting arises

not from the difference of the two C_{60} cages of C_{121} (C_s), but from intercage electronic interactions. It is interesting that the first reduction potential of C_{121} (C_s) is slightly more positive than that of C_{60}, while the reduction potentials of C_{60} adducts are expected to be shifted to more negative potentials. That may reflect the unusual electronic structure that involves the coupling of two dissimilar carbon cages: methano[60]fullerene and homo[60]fullerene.

Similarly, intercage electronic communication in $C_{122}H_4$ was detected by means of electrochemical measurements (Fig. 10) [41]. Each of the three electrochemical reduction peaks for C_{60} are split. It is likely that this electronic communication is related to the through-space orbital overlap deduced to exist in HOMO/LUMO for this dimer, by means of electronic calculations. In a similar way, it is likely that $C_{120}O_2$, having a structure similar to that of $C_{122}H_4$, should manifest such intercage interactions.

A remarkable effect was found for $Rh_6(CO)_5(dppm)_2 \cdot (CNR)(C_{60})_2$ (R = $CH_2C_6H_5$), whose cyclic voltammetry experiments showed six well-separated, reversible, one-electron redox waves [64]. The large peak separations for this compound (0.19, 0.24, and 0.29 V) reflect strong electronic couplings between the fullerene cages. In contrast, for other dimers showing electronic communication, the separations between the first two redox waves are about 0.05–0.08 V [41, 76, 89].

The six reduction peaks of a supramolecular C_{60} dimer with quadruple hydrogen bonding (**27**) measured by cyclic voltammetry in toluene/acetonitrile mixture (4:1 v/v) were not split [69]. These results indicate that there is no intercage interaction in the ground state. Like **28**, the split of reduction peaks in the cyclic voltammogram of the dimers

without direct intercage bond, **18** and **22**, was not observed. The cyclic voltammetry of **18** shows four quasireversible reduction waves at potentials rather similar to all 1,2–dihydrofullerenes, that is, slightly more negative potentials than those found for fullerenes [90].

In summary, intercage electronic interactions were observed for the dimers with direct intercage bonds and C_{121}, and not for the dimers without direct intercage bonds. The metal sandwich dimer (Fig. 5), which has no intercage bonds, shows exceptionally strong intercage electronic interactions.

31 and **32** have direct intercage bonds, and thus they are appropriate for studying the influence of direct intercage bonds on intercage electronic communication. Indeed, electronic communication was investigated by electrochemical methods, and the splits between the first and second reduction peaks of **29**, **30**, **31**, and **32** measured by differential pulse voltammograms were 0.06, 0.06, 0.09, and 0.09 eV, respectively. These results showed that the formation of direct intercage bonds enhanced intercage electronic communication.

5.2. Photosensitive Properties

5.2.1. Photostability

One of the important problems is the stability of fullerene derivatives, and particularly their photostability. This problem has not yet been systematically addressed, as far as C_{120} is concerned. Some reports [91–93] concluded that C_{120} is stable under light illumination, while others [94–96] concluded that C_{120} dissociated into two C_{60} monomers in the presence of light. Lebedkin et al. [95] and Bachilo et al. [96], who support that C_{120} is unstable to light, indicated that photodissociation of C_{120} occurs via excited triplet states.

There are fewer reports of photostability of other dimers. Lebedkin et al. reported that $C_{120}O$ and $C_{120}O_2$ did not dissociate under the influence of light [95]. Fujitsuka et al. also reported that $C_{120}O$ is stable under light illumination [97]; this is in agreement with the observation of $C_{120}O$ presence in samples of C_{60} kept in air, as observed by Taylor et al. [98]. Gruss et al. studied the EPR signal of $C_{59}N\cdot$ by pulse laser irradiation (532 nm) of $(C_{59}N)_2$ [99]. The signal intensity did not decrease after more than 10^5 laser pulses, which indicates that the major decay channel of the $C_{59}N\cdot$ is redimerization.

From the available data, most of the dimers are quite stable under the influence of light.

5.2.2. Absorption and Fluorescence Properties

The optical properties of C_{120} have been most intensively studied among the fullerene dimers. The photophysical optical properties of this dimer were reported by Ma et al. [91], and were observed to be rather similar to that of C_{60}. Noticeable is a weaker triplet–triplet absorption in the case of C_{120} comparable to that of C_{60}. All values of C_{120} reported here were determined in toluene. C_{120} has absorption peaks at 434 and 698 nm; this feature is similar to those of other 1,2–dihydro[60]fullerene derivatives (**35**) which have 58π-electron systems. Ma et al. [91] compared the absorption

Figure 10. Differential-pulse voltammogram of C_{121} (top trace), square-wave voltammogram of $C_{122}H_4$ (middle trace), and C_{60} (bottom trace) in *o*-dichlorobenzene with 0.1 M TBAP as supporting electrolyte. For the DPV, the parameters were: scan rate, 20 mV; pulse amplitude, 50 mV; sample width, 17 ms; pulse width 50 ms; and pulse period, 200 ms. For the SWV, the parameters were: pulse step, 2 mV; square-wave frequency, 15 Hz; square-wave amplitude, 10 mV; 256 samples/point for $C_{122}H_4$; pulse step, 4 mV; square-wave amplitude, 25 mV; square-wave frequency, 15 Hz; and 256 samples per point for C_{60}. The first reduction potential of C_{60} is shown by the dotted line. Reprinted with permission from [76], N. Dragoe et al., *J. Am. Chem. Soc.* 123, 1294 (2001). © 2001, American Chemical Society.

spectra of C_{120} and several 1,2–dihydro[60]fullerene derivatives. These spectra showed that the molar absorptivity of C_{120} at the 0–0 absorption band is larger than that of other C_{60} derivatives by a factor of about 2, although they are similar. This indicates that C_{120} can be treated as behaving like a mix of two independent 1,2–dihydro[60]fullerene cages with negligible interactions with regard to electronic transitions. Concerning the absorption properties, fluorescence spectrum, lifetime, and quantum yield, the C_{120} dimer is rather similar to 1,2–dihydro[60]fullerene derivatives than to the parent C_{60}.
35

For the $C_{120}O$ dimer, the absorption peaks of $C_{120}O$ in toluene appeared at 327, 418(sh), 535(sh), and 691 (Fig. 11). This profile is also similar to 1,2–dihydro[60]fullerene and C_{120}, but is different from C_{60}. The fluorescence spectrum and lifetime (1.6 ns) in toluene are also similar to those of 1,2–dihydro[60]fullerenes (1.3–1.5 ns) and C_{120} (1.5–1.6 ns), but different from that of C_{60} (1.2 ns) [97].

Fujitsuka et al. reported the optical properties of C_{121} [13(b)] [100]. The optical properties of C_{121} are interesting because this molecule has two different chromophores, namely, a methanofullerene moiety and a homofullerene moiety. Homofullerenes, which keep a 60π-electron system, have similar absorption spectral profiles as pristine fullerenes, while methanofullerenes, whose number of π electron is reduced to 58, have different absorption spectral features. C_{121} in o–dichlorobenzene shows absorption bands at 689, 425, and 331 nm, with shoulder bands around 600 and 530 nm (Fig. 11). Among them, 689 and 425 nm bands are typical features of methanofullerenes, and 600 and 530 nm bands are typical features of homofullerene, and both of them have a 331 nm band. Consequently, the absorption spectrum of C_{121} is explained by the simple superposition of the spectra of a methanofullerene and
Figure 11. UV/vis spectra of $C_{121}(C_s)$, C_{122}, and $C_{120}O$ in ODCB, determined using solutions of concentrations of 0.1 mg/mL. Reprinted with permission from [76], N. Dragoe et al., *J. Am. Chem. Soc.* 123, 1294 (2001). © 2001, American Chemical Society.

a homofullerene, and no sign of intercage electronic interaction was observed in the absorption spectrum. The fluorescence quantum yield of C_{121} was estimated to be 8.4×10^{-4}. The value is similar to C_{120} (7.9×10^{-4}) and $C_{61}H_2$ (8.7×10^{-4}), and about three times of that of pristine C_{60} (3.2×10^{-4}).

In contrast to C_{121}, C_{122} consists of two identical methanofullerenes without a homofullerene moiety. The absorption spectrum of C_{122} shows similar features as other methanofullerenes like C_{120} and $C_{120}O$, that is, absorption bands at ~420 and ~700 nm [76]. As shown in Figure 11, C_{122} does not have absorption bands typical of homofullerenes (530 and 600 nm), as was the case for C_{121}. In the case of C_{122}, the absorption spectrum is explained by the simple superposition of two methanofullerene spectra.

The absorption spectrum of $(C_{59}N)_2$ is different from both pristine C_{60} and methano[60]fullerenes. The spectrum is similar to that of $C_{59}HN$, and has absorption peaks at ~420, ~600, ~720, and ~800 nm in toluene [101].

5.3. Thermal Properties

Few thermal property experiments have been performed on fullerene dimers. Their importance is related to the feasibility of growing thin films for device and/or transport property studies. Among these studies, it is known that the [2 + 2] photopolymerized polymer reverses to C_{60} upon heating at about 200 °C [102]. Similar in structure, the model molecule C_{120} dissociates quantitatively into C_{60} by heating its o–dichlorobenzene solution at 175 °C for 15 min [18] or by heating in solid state [20]. For other dimers, heating at higher than about 200 °C approaches isomerization or to decomposition, as is the case of C_{121} and C_{122}, respectively [103].

A special case was found for the thermal decomposition of fullerene oxides. While heating a mixture of C_{60} and $C_{60}O$ yields fullerene oligomers, mostly $C_{120}O$ and $C_{120}O_2$, the heating of these species was found to lead to C_{119} [29].

The thermal stability of fullerene dimers was less studied since this method is generally destructive, and requires a relatively large amount of sample (milligram range). However, we speculate that the use of the solid-state reactions will eventually lead to the synthesis of higher fullerenes or small well-defined carbon nanotubes.

6. CHEMISTRY OF FULLERENE DIMERS

The effect of dimerization on chemical reactivity was examined in the case of [2 + 1] cycloaddition to C_{120}. The mono [77] and decakis [104] cyclopropanation of C_{120} by diethyl bromomaronate (Scheme 6) was reported by Fujiwara et al.

The cycloaddition to a fullerene derivative that already has a substituent can take place in nine possible sites (Fig. 12). For the case of bis addition of diethylbromomaronate to C_{60}, which forms bis[di(ethoxycarbonyl)methano][60]fullerene [$C_{62}(CO_2Et)_4$ (**36**)], Hirsch et al. found that the cis-1 isomer was not formed; the relative yields of the other isomers are summarized in Table 2 [105]. In the case of cyclopropanated C_{120} ($C_{121}(CO_2Et)_2$), besides the cis-1 isomer, neither cis-2 nor cis-3 isomers were formed. That is probably due to the larger steric effect of the C_{60} group than that for the diethoxycarbonylmethano group.
Scheme 6. Cyclopropanation of C_{120} by diethyl bromomaronate.

A trans-1 isomer also was not found, probably due to a low yield because of fewer reaction sites than for the other isomers. The trans-1 isomer is also the lowest yield isomer of $C_{62}(CO_2Et)_4$, except for the cis-1 isomer. Aside from the cis- and trans-1 isomers, the orders of yield of isomers of $C_{121}(CO_2Et)_2$ and $C_{62}(CO_2Et)_4$ are the same (Table 2), and hence are governed by the electronic effects on the C_{60} cage.

36
When an excess amount of diethyl bromomaronate (17 equivalents) was used for synthesis, surprisingly, a highly symmetrical decakis-cyclopropanated derivative of C_{120} (**37**) was synthesized in 26% yield. This product was cleaved by light irradiation or by heating, similarly to C_{120}, to give pentakis adducts of C_{60} (Scheme 7). The decakis adduct can be transformed into the eicosa–carboxylic acid derivative in 91% yield (Scheme 7).

GLOSSARY

Carbon nanotube Cylindrical carbon clusters. All carbon atoms in carbon nanotubes are trivalent. The major part of nanotubes consists of a graphene rolled into a cylinder.

Endohedral fullerene Fullerenes encapsulating one or some atoms in their cage.

Fullerene Hollow closed-cage molecules consist of even number of carbon atoms. The number of carbon atoms is equal or greater than 20. All carbon atoms of fullerenes are trivalent.

Higher fullerene Fullerenes that consist of more than 60 carbon atoms.

Homofullerene Fullerene with an methanoannulene moiety in its cage. The methanoannulene moiety is formed by fusion of a five-membered ring and a neighboring six-membered ring for all reported homofullerenes.

Methanofullerene Fullerene with a methanobridge. The methanobridge is at a bond between two six-membered rings for all reported methanofullerenes.

Fullerene Lipid Films

Naotoshi Nakashima

Nagasaki University, Bunkyo, Nagasaki, Japan

CONTENTS

1. INTRODUCTION

The chemistry and physics of fullerenes have received increasing attention by many research groups [1–6]. The solution electrochemistry of fullerenes and the electrochemistry of fullerene films have been widely studied, and are the subject of an intense research focus from both theoretical and experimental approaches [7–10]. Fullerenes with long chain derivatives form a variety of aggregated structures, such as monolayers, self-assembled monolayers (so-called SAM), lipid bilayers, Langmuir–Blodgett (LB) films, and liquid crystals (Fig. 1). The present author [11–27] and others [28–42] have been interested in combining fullerene chemistry and the chemistry of lipid bilayer membranes. Here, we mainly focus on fullerenes with an ordered structure in aqueous systems, and briefly review a lipid bilayer-based aqueous superstructure from fullerene amphiphiles, as well as the structure and electrochemistry of fullerene lipid films and fullerene–lipid composite films.

2. BILAYER-BASED SUPERSTRUCTURES OF FULLERENE–AMPHIPHILES IN WATER

A variety of artificial lipids are known to form liposomal lipid bilayer membranes in water [43–44]. Some of the bilayer aggregates show the growth to superstructures, such as helical bilayers and tubes [45–48]. In this section, molecular bilayer-based superstructure formations from water-soluble fullerenes are summarized. Cassell et al. described that C_{60}-N,N-dimethylpyrrolidinium iodide **1** (Fig. 2) forms supramolecular nanorods (Fig. 3) in dimethyl-sulfoxide with one part water and then adding one part benzene, and that an aqueous solution of the compound treated with ultrasonication and then filtered gives vesicles with diameters of 10–70 nm [49]. Sano and coworkers described the vesicle formation by a bola-amphiphilic fullerene **2** (Fig. 2), although the bilayer structure is not evident [37]. Hirsch et al. revealed by transmission electron microscopy (TEM) of a freeze fracture replica that a C_{60}-carrying globular amphiphile **3** (Fig. 2) forms a vesicular structure in water [34, 38]. Zhou et al. reported that an amphiphile **4** (Fig. 2), a potassium salt of pentaphenylfullerene with charged cyclopentadienide units, forms spherical vesicles in water (Fig. 4) [41]. The average hydrodynamic radius and aggregation number of the vesicle evaluated by laser light scattering were about 17 nm and 1.2×10^4, respectively.

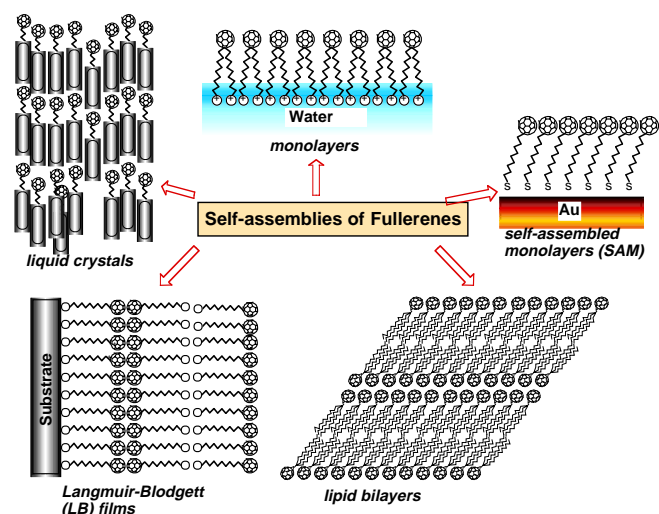
We synthesized a C_{60}-carrying ammonium amphiphile **5** (Fig. 2), which is soluble in DMF, DMSO, hot chloroform, and hot alcohols, but was insoluble in THF, acetonitrile, ethylacetate, hexane, and toluene [17, 20]. Negative-stained transmission electron microscopy (TEM) revealed that the aqueous solution of **5** forms both fibrous aggregates (Fig. 5) and disk-like aggregates with 10–12 nm of thickness. This superstructure is formed via self-organization of **5** in aqueous solution. A possible molecular model for the disk-like aggregate is shown in Figure 6. The wavenumber of the asymmetric and symmetric methylene stretching vibrations in the FTIR spectra of cast films of **5** from both methanol and aqueous solutions appeared at 2922 ± 0.1 and 2850 ± 0.1 cm^{-1}, respectively, over a temperature range of 10–40 °C, indicating that the methylene chain in **5** contains a *gauche* conformation. The UV–visible absorption maximum for an aqueous solution of **5** appeared at 271 nm; this


Figure 1. Schematic drawing of self-assembled fullerenes.

maximum is shifted to longer wavelength by 3 and 5 nm, respectively, compared to those in micellar solutions of hexadecyltrimethylammonium bromide or sodium dodecylsulfate. These shifts are due to the electronic interaction of the fullerene moieties in **5** in an aggregated state.

The phase transition between a crystal phase and a liquid-crystal phase is the most fundamental characteristic of lipid bilayer membranes [50]; however, aqueous aggregates of **1–5** do not possess a phase transition. The results described above indicate that the introduction of a hydrophilic moiety to fullerene enables the formation of bilayer-based assemblies in water. This kind of fullerene-based biomembrane-like carbon nanosuperstructures in aqueous solution is of
Figure 2. Chemical structure of compounds **1–7**.

interest from aspects of both fundamental and biological applications [51]. The construction of electroactive fullerene nanoarchitectures with an ordered structure based on self-assembled molecular organization would possess many chemical and biochemical applications.

3. FULLERENE GEL

Oishi et al. and Ishi-i et al. reported the formation of organic gel from fullerene derivatives in organic solvents [52–53]. They found that a methanol solution of the fullerene-carrying diammonium salt **2** (10–20 mM) transfers gradually

Figure 5. Typical TEM image of an aqueous solution of compound 5. Reprinted with permission from [20], N. Nakashima et al., *Chem. Eur. J.* 7, 1766 (2001). © 2001, Wiley-VCH.

into an organic gel [52]. The TEM image of the gel showed a number of fibrous aggregates with a 10–20 nm diameter. They also reported chirally ordered fullerene assemblies in organic gel systems of a cholesterol-appended C_{60} fullerene 6 (see Fig. 2) [53]. We have described that gel-like films of a tetraoctylphosphonium ion on electrodes provide suitable microenvironments for the electrochemistry of C_{60} [19].

4. STRUCTURE OF FULLERENE THIN FILMS

Cast films of fullerenes with long chains form multilayered structures. By means of X-ray study, cast films of 5 were found to show a molecular bilayer structure (Fig. 7) [21]. Cast films of 2 show sharp, periodical peaks up to order 13, indicating the formation of a well-ordered multibilayer structure [52]. Chikamatsu et al. synthesized compound 7 (*n* = 8, 12, 16) (Fig. 2), and suggested that cast films of 7 form bilayers with interdigitated structures [54]. No phase transition appears for cast films of these compounds.

We reported the synthesis and characterization of self-assembled triple-chain fullerene lipids 8–10 (Fig. 8), where the cross-sectional area of the triple alkyl chain is

Figure 7. Drawing for the molecular-bilayer structure of 5. Reprinted with permission from [20], N. Nakashima et al., *Chem. Eur. J.* 7, 1766 (2001). © 2001, Wiley-VCH.

close to that of C_{60} moiety [11, 15–16, 24]. Compounds 8–10 are not soluble in water and methanol because of the lack of a high hydrophilic moiety in the chemical structure, whereas they are soluble in a variety of organic solvents such as DMF, DMSO, chloroform, benzene, and hexane. They are also soluble in ethanol and isopropanol, although the solubility in the latter two solvents is not high.

Cast films of 8–10 are readily prepared by solvent evaporation. The structure of fullerene lipid bilayer films was investigated by X-ray diffraction. Cast films of 8 form a multibilayer structure with the molecular layer tilting by 42.8° from the basal plane [11, 24]. Cast films of 9 and 10 gave diffraction peaks at $2\theta = 1.97°$ and $2\theta = 2.12°$, respectively, which can be assigned to the (001) plane of these films. These data indicate that the cast films of both 9 and 10 also form multibilayer structures. The X-ray diagrams of the films were temperature dependent. The diffraction peak of the 8-film maintained at temperatures below 35 °C, but it almost disappeared at 50 °C, indicating that the 8-film at the higher temperatures is rather disordered. This temperature dependence is reversible, that is, when the temperature is cycled back to 25 °C, the X-ray intensity of the films is recovered, although aging is required.

5. PHASE TRANSITION OF FULLERENE LIPID FILMS

An interesting feature of cast films of **8–10** is that they show phase transitions [11, 24]. The phase transition of lipid bilayers between the crystalline and liquid crystalline phases is one of the most fundamental characteristics of lipid bilayer membranes, and the lipid bilayer properties depend on the fluidity change of the bilayers [50]. Differential scanning calorimetry (DSC) of cast films of **8** show two endothermic peaks at 35.2 °C (main peak) and 47.0 °C (subpeak) in air, 39.7 °C (main peak) and 47.6 °C (subpeak) in the presence of water, 33.8 °C (main peak) and 47.9 °C (subpeak) in the presence of 0.5 M aqueous tetraethylammonium chloride (TEAC), and 31.5 °C (main peak) and 43.8 °C (subpeak) in the presence of acetonitrile. Interestingly, the phase transition behavior of **8** in various media is not much different, that is, the lipid possesses a similar molecular orientation in the different environments. Retention of the phase transition of lipids in organic solvents is not very unusual [55].

6. SPECTRAL PROPERTIES OF FULLERENE LIPID FILMS

Cast films of fullerene lipids exhibit unique spectral properties [11, 24]. The wavenumber of the asymmetric and symmetric methylene stretching vibrations in the FT–IR spectra of the **8** films changed drastically near 35 °C (Fig. 9a). The shifts of $\nu_{as}(CH_2)$ from 2917.9 to 2922.0 cm^{-1} and $\nu_s(CH_2)$ from 2849.2 to 2851.0 cm^{-1} are ascribable to the *trans-gauche* conformational change of the long alkyl chain [56–57], indicating that the main peak in the DSC thermogram of the **8** films is attributable to the bilayer phase transition typically observed for liposomal and synthetic lipid bilayer membranes. In contrast, no temperature dependence is observed for cast films of **9** and **10** (Fig. 9b, c). From the observed $\nu_{as}(CH_2)$ and $\nu_s(CH_2)$ vibration, both **9** and **10** are found to form *gauche* conformation in the alkyl chains at the measured temperatures; therefore, we detect no main transition for films of **9** and **10**. The origin of the small endothermic peaks is revealed by UV–vis spectroscopy. The UV–vis spectra of films of **8–10** in air at temperatures below 35 °C showed three bands (labeled as bands *A*, *B*, and *C*) with absorption peaks near 215, 262, and 330 nm, respectively (Fig. 10); the peak maxima for bands *A*, *B*, and *C* shifted to longer wavelengths upon increasing the temperature above the small endothermic peaks. Thus, we know that the small endothermic peaks are due to the change in the orientation of the C_{60} moieties in the films. Interestingly, the phase transition of the films regulates an electronic interaction between the C_{60} moieties of lipids **8–10**.

7. A MODEL FOR FULLERENE LIPID BILAYERS

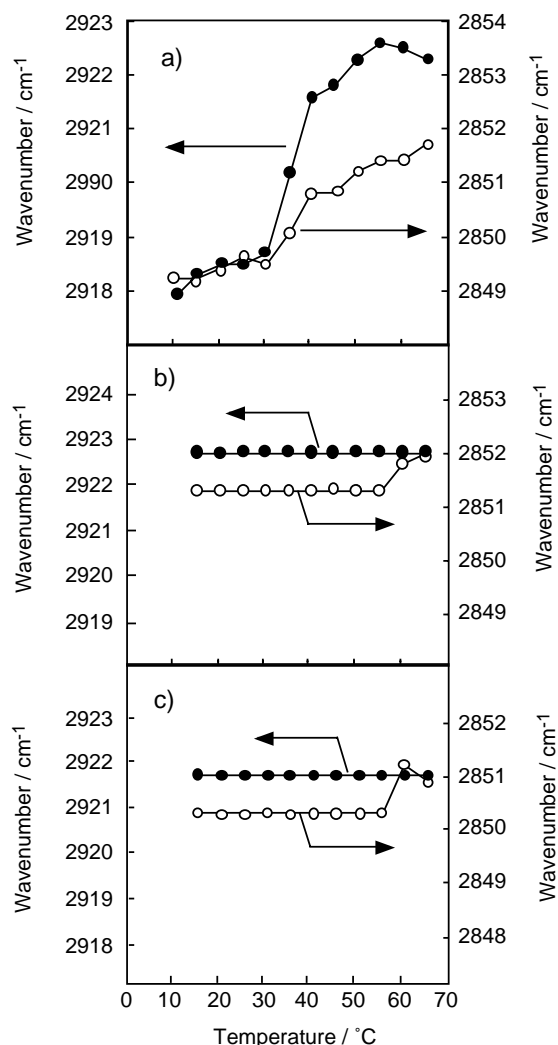
All data obtained from X-ray study, DSC, and spectral measurements suggest a possible schematic model for the structure and phase transition behavior for cast films of **8–10** (Fig. 11). Phase 1 consists of the lipid with a rigid crystalline state, where all alkyl chains form a *trans* conformation. Lipid


Figure 9. Temperature dependence of the wavenumber in the FTIR spectra of cast films of (a) **8**, (b) **9**, and (c) **10**. Reprinted with permission from [24], T. Nakanishi et al., *Chem. Eur. J.* 8, 1641 (2002). © 2002, Wiley-VCH.

8 only forms this state. Phase 2 is a fluid state in which the alkyl chains contain a *gauche* conformation, while the orientation of the fullerene moieties is almost the same as in phase 1. Phase 3 is a fluid state with a less ordered structure than phases 1 and 2 [24].

8. MONOLAYERS AND LANGMUIR–BLODGETT (LB) FILMS OF A FULLERENE LIPID

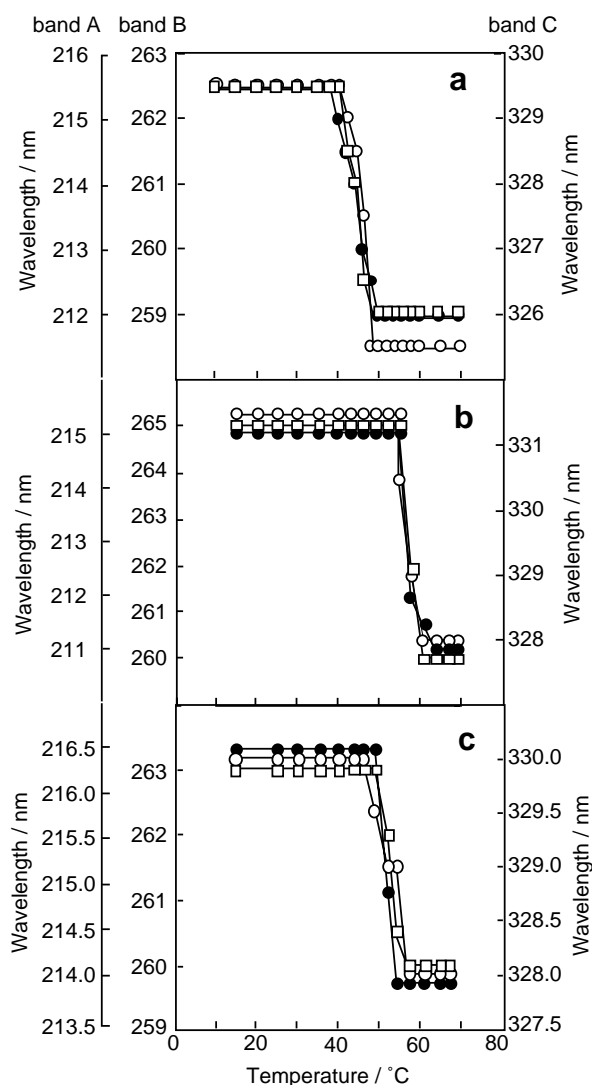
The derivatives of C_{60} and C_{70} form monolayers at the air–water interface, and the formed monolayers can be transferred onto solid substrates [58–70]. Single components of C_{60} and C_{70} form monolayers on water under limited experimental conditions [66–68]. The fullerene lipid **8** forms stable monolayers at the air–water interface [15, 71]. The surface pressure–area isotherm of **8** from the spreading solution of 1.0×10^{-4} M gives a limiting area of 0.27 nm^2/molecule, suggesting the formation of a multiplayer on water. The isotherms from the **8** = 1.0×10^{-5} M


Figure 10. Temperature dependence of peak wavelengths in the UV–vis absorption spectra of cast films of (a) **8**, (b) **9**, and (c) **10**. Reprinted with permission from [24], T. Nakanishi et al., *Chem. Eur. J.* 8, 1641 (2002). © 2002, Wiley-VCH.

solution give limiting areas of 0.78 and 0.98 nm^2/molecule, suggesting the formation of monolayers with hexagonal and the simple square packing, respectively. How is the molecule spatially arranged in the monolayer? An *in-situ* XR technique revealed the nanostructure of the fullerene lipid monolayer on water, that is, the fullerene moiety was in contact with the water surface, and the lipid tail extended to the air (Fig. 12) [71]. The isotherms obtained in the dark and in the light were almost identical; however, deposited LB films in the light or in the dark show different behavior. In the dark or in the light (ca. 190 lux), at a surface pressure of 30 mN/m, the monolayer of **8** was transferred onto a quartz plate.

The LB film fabricated in the light shows structureless electronic spectra with no temperature dependence, whereas the LB film prepared in the dark shows a temperature-dependent UV–vis absorption spectra (Fig. 13). At the lower temperatures, an electronic interaction between the
Figure 11. Possible model for the phase transitions of cast film of **8**–**10**. Reprinted with permission from [24], T. Nakanishi et al., *Chem. Eur. J.* 8, 1641 (2002). © 2002, Wiley-VCH.

fullerene moieties in the LB film prepared in the dark exists. Upon heating over 47 °C, which is identical to the subphase transition temperature of the cast films of **8** [11, 24], the electronic interaction is loosened. The temperature dependence is reversible, that is, the electronic interaction between the fullerene moieties is controllable by the phase change of the film. A light-driven aggregate structural change [72] in the LB film prepared in the light is suggested. Cast films of **8** did not show such a fluorescent light-driven change in the spectra. The molecular orientations of the fullerene moieties of the LB film and the cast film of **8** are not significantly different, that is, the fundamental property of the self-assembled bilayer membrane film is maintained in the LB film prepared in the dark. This is important from the viewpoint of the introduction of bilayer properties of the fullerene lipids to the LB system. This information is useful for designing and constructing new functional supramolecular ultrathin fullerene films at the air/water interface and on solid surfaces.

9. ELECTROCHEMISTRY OF FULLERENE THIN FILMS

The electrochemistry of fullerenes in solution phase and their films on electrode surfaces have been extensively studied, and are the subject of intense research focus. Chlistunoff and coworkers summarized half-wave potentials ($E_{1/2}$) of fullerenes in various media [7]. Supporting electrolyte cations, solvents, and temperature affect the reduction potentials of fullerenes. Dubois and coworkers investigated the correlation between $E_{1/2}$ values of the first three-consecutive one-electron transfer processes of C_{60} and the carbon chain length of tetraalkylammonium perchlorate supporting electrolytes in four different organic solvents [73]. They found a monotonous positive shift of $E_{1/2}$ for the first and second reductions with an increasing chain length. Fawcett and coworkers described the thermodynamics of the reduction of C_{60} in benzonitrile containing tetraalkylammonium salts [74]. They reported that $C_{60}^{\bullet-}$ and C_{60}^{2-} are associated with two or more tetraalkylammonium cations. S.-Guillous et al. quantitatively investigated the ion pairing of tetraalkylammonium cations with C_{60}^{n-} ($n = 1$–4) in four different aprotic organic solvents by cyclic voltammetry at a 10 mm diameter Pt disk microelectrode [75]. Chlistunoff et al. reviewed the electrochemistry of the pristine fullerenes and fullerene thin films in organic solution systems [7]. Echegoyen et al. summarized the redox properties of the pristine fullerenes and their large number of derivatives in an organic solution [9]. In this section, we review the aqueous electrochemistry for electrodes modified with films of: (1) C_{60}, (2) fullerene lipids, and (3) fullerenes (including higher fullerenes and metallofullerenes)–lipid composites (Fig. 14). The aqueous electrochemistry of fullerene films is of importance for both fundamentals and applications in understanding the science and nanotechnology of nanocarbons [16].

9.1. C_{60} Cast Thin Films

The aqueous electrochemistry of C_{60} cast films on electrodes is very unstable and complicated. Szucs et al. assumed that a C_{60} trianion is formed during the reduction in the presence
Figure 14. Schematic drawing for (a) C_{60}, (b) fullerene lipids, and (c) fullerene–lipid composites on electrodes.

of a sodium ion; however, the corresponding cathodic process was not detected [76]. Davis and coworkers reported that two reduction and reoxidation peaks appearing on the cyclic voltammograms (CVs) of C_{60} film-modified electrodes disappear after several cycles [77]. The results indicate that the stable aqueous electrochemistry of C_{60} films on electrodes is not possible. This is in sharp contrast to an organic solution system, in which C_{60} shows six reduction processes leading to the generation of a C_{60} hexaanion [7–10].

Szucs et al. examined the effect of cations, including Li^+, Na^+, K^+, Rb^+, Cs^+, Ca^+, and Ba^{2+}, on the first reduction potential for a cast film of C_{60} on an electrode surface in an aqueous solution, and found that the reduction peaks are shifted to less negative potentials with the decrease of the hydration energy of these cations [78]. This suggests that

the binding of fullerene anions and electrolyte cations determines the formal potentials of the redox reaction. A similar electrochemical behavior is observed for C_{70} film-coated electrodes [79].

9.2. Fullerene Lipid Cast Films

Figure 15 shows a typical cyclic voltammogram of a cast film of **8** on a basal-plane pyrolytic graphite (BPG) electrode, where well-defined redox waves leading to the generation of a fullerene dianion of **8** in the films on the electrodes in water containing 0.5 M tetra-n-butylammonium chloride (TBAC) are evident [24]. The first reduction/oxidation process is stable in the potential cycling, but the second reduction process is unstable (almost disappears after ten scans) because of the formation an electroinactive film of the lipid on the electrode. Similar cyclic voltammetric behavior is observed for the **9**- and **10**-modified electrodes. The formal potentials for **9**- and **10**-modified electrodes in water are not much different; for example, in 0.5 M TBAC aqueous solution, they are −431, −435, and −440 mV versus SCE for **9**- and **10**-modified electrodes, respectively. Electroactive amounts of the fullerene moiety on **8**–**10** increase with a decrease in the alkyl-chain length. About 50% of the C_{60} moieties in the film of **10** on the electrode are electroactive. Interestingly, the fullerene moieties in the films are oriented in such a way as to undergo facile electrochemical communication with the electrodes.

The electrochemistry for **8**–**10** electrodes show thin-layer electrochemical behavior in the scan range of 10–30 $mV \cdot s^{-1}$ and a diffusion-controlled electron transfer in the range of 0.1–3.0 $V \cdot s^{-1}$.

From the analysis of thermodynamics for the binding of electrolyte cations and the electrogenerated radical monoanion and dianion of C_{60} moieties in films of **8**–**10** on electrodes, the electron transfer mechanism for the modified electrodes has been revealed [16]. A theoretical treatment for the binding was made with the following equations (1) and (2):

$$E_{1/2,\,1} = E_1^{0\prime} + \frac{RT}{F} \ln K_1 + \frac{pRT}{F} \ln c \qquad (1)$$

$$E_{1/2,\,2} = E_2^{0\prime} + \frac{RT}{F} \ln \frac{K_2}{K_1} + \frac{(q-p)RT}{F} \ln c \qquad (2)$$
where $E_{1/2,\,1}$ and $E_{1/2,\,2}$ are the half-wave potential for the first and second redox processes, $E_1^{0\prime}$ and $E_2^{0\prime}$ are the standard redox potentials for the two elemental redox processes, p and q are the numbers of electrons involved in the first and second reduction processes, respectively, K_1 and K_2 are the binding constants between the fullerene radical monoanions and the electrolyte cations, respectively, and c is the concentration of electrolytes. The electrolytes used are: tetramethylammonium chloride (TMAC), trimethybenzylammonium chloride (TMBAC), TEAC, tetraethylphosphonium chloride (TEPC), triethylbenzylammonium chloride (TEBAC), tetra-n-propylammonium chloride (TPAC), tri-n-butylbenzylammonium chloride (TBBAC), TBAC, and tetra-n-butylphosphonium chloride (TBPC). Details of the analysis of the binding are described in the literature [16]. Table 1 summarizes p, q, and K_1 values for an **8**-coated electrode. The interesting features are as follows.

1. For all cations used, p is almost 1 and q is almost 2.
2. K_1 shows a strong alkyl-chain-length dependence. This is in sharp contrast to the binding of electrochemically generated fullerene anions in organic solvents with tetraalkylammonium cations, where no alkyl-chain-length dependence has been reported [73, 74]. K_1 values for tetraalkylphosphonium cations are about one order of magnitude greater than those for tetraalkylammonium cations with the same alkyl chain length. The "softness" of tetraalkylphosphonium cations would explain this stronger complex formation since fullerene anions are "soft" anions.
3. For the binding with fullerene radical anions, the introduction of a benzyl moiety to the electrolyte shows a stronger effect than for methyl or ethyl groups, but a weaker effect than for the butyl group.

As shown above, the electrochemistry for electrodes modified with C_{60} and fullerene lipids shows an electrolyte cation dependence, and the formal potential of the fullerene moieties depends on the binding constants between the fullerene anion and electrolyte cations. In contrast, the electrochemistry for fullerene–lipid composite film-coated electrodes shows anion dependence, as shown in the following section.

Figure 15. Typical cyclic voltammogram for a cast film of **8** on a BPG electrode in water containing 0.5 M TBAC at 55 °C. Scan rate, 100 mV/s.

Table 1. Parameters for the binding of the reduced forms of **8** and alkylammonium ions and phosphonium ions at the reduction processes of **8** films on BPG at 328 K.

Electrolyte cation	p	q	K_1/M^{-1}
TMAC	1.03	—	3.80×10
TMBAC	1.08	—	5.24×10^3
TEAC	1.05	—	7.93×10^3
TEPC	1.16	—	5.00×10^4
TEBAC	1.04	—	1.79×10^5
TPAC	1.10	2.15	0.96×10^6
TBBAC	0.97	1.99	1.01×10^8
TBAC	0.97	2.11	1.71×10^8
TBPC	1.06	1.98	1.70×10^9

9.3. Fullerene–Lipid Composite Thin Films

9.3.1. C_{60}–Lipid Composite Thin Films

In sharp contrast to the electrochemistry of C_{60}-coated electrodes [76–78], electrodes modified with films of C_{60}–cationic lipids exhibit stable electron transfer reactions. CVs for a C_{60} embedded in a cast film of an artificial poly(ion-complexed) lipid, ditetradecyldimethylammonium poly(styrene sulfonate) (**11**) on a BPG electrode, show two reversible electron transfers in an aqueous solution, and that the generated radical monoanion and the dianion are very stable (Fig. 16a) [13]. Both the first and second redox couples did not change, even after 50 cycles.

Reversible redox waves leading to the generation of a C_{60} trianion are observed in the cyclic voltammograms of a C_{60}/tridodecylmethylammonium bromide (**12**)-coated electrode (Fig. 16b) [12]. The observed formal potentials are $E_1^{0'} = -0.12$, $E_2^{0'} = -0.74$ and $E_3^{0'} = -1.21$ V versus SCE. Stronger binding between the fullerene anions and tridodecylmethylammonium cations enables the detection of three reduction peaks within the potential window in the aqueous system. The radical monoanion of C_{60} generated in this system is very stable, that is, virtually no change in the CVs for the first redox wave is observed, even after a 30 min hold at -0.5 V. The hold at -1.0 V, where the dianions of the fullerenes are generated, caused a gradual decrease in the current, suggesting the formation of electro-inactive films on the electrodes. The radical trianion generated in this system is not so stable.

The CVs for cast films of C_{60}/**12** on BPG are essentially the same for the measurements in water containing NaCl, KCl, CaCl$_2$, tetraethylammonium chloride, and tetrabutylammonium chloride as an electrolyte. The results suggest that these electrolyte cations are not major counter cations of the fullerene anions; instead, tridodecylmethylammonium acts as the counter cation during the reduction of C_{60}. The CVs for cast films of C_{60}/**12** on BPG show electrolyte anion dependence. The cathodic peak potentials of the electrodes are shifted to a positive direction with an increase of the hydration energy of anions (F$^-$, Cl$^-$, Br$^-$, NO$_3^-$). This is derived from a stronger complex formation of tridodecylmethylammonium and anions with smaller hydration energy, such as NO$_3^-$.

9.3.2. The Higher Fullerene C_{84}–Lipid Composite Thin Films

Reports [10, 80] describing the electrochemical properties of higher fullerenes have been limited due to their low abundance compared with the more readily available C_{60} and C_{70}. From the isolated pentagon rule, 24 isomers of C_{84} are predicted to exist, and two major isomers of C_{84} with molecular symmetry D_2 and D_{2d} have been isolated and used for experiments. In an organic solution, C_{84} has been reported to show four or five reduction processes [81–84], of which the first three reduction processes are stable and the last two are unstable.

The CVs for a cast film of a single component of C_{84} on an electrode gave no well-defined redox current in an aqueous solution. In contrast, well-defined multiple electron transfer reactions for a composite film of C_{84}/tetraoctylammonium bromide (**13**) cast on an electrode occur (Fig. 17). The electrode gives multiple cathodic peaks, together with their corresponding anodic peaks. The formal potentials for the six redox couples estimated from their CVs at 5 mV/s are: $+477$, $+204$, -145, -254, -636, -900, and -1110 mV. Since C_{84} exists as two isomers, the assignment of the multiple redox process is complex. The large positive shift of the formal potentials of C_{84} at the modified electrode compared to those in an organic solution [84] suggests the strong binding of C_{84} anions with a tetraoctylammonium cation in the film [16]. Hydrophobic microenvironments afforded by the tetraoctylammonium matrix contribute to the generation and stability of C_{84} anions.

9.3.3. Metallofullerene–Lipid Composite Thin Films

Metallofullerenes are novel and attractive carbon nanomaterials that encapsulate one or more metal atoms inside the hollow of fullerene cages, and that have been reported to exhibit unique properties that are not seen in empty fullerenes [85–86]. Despite the low abundance compared with the empty-caged fullerenes, researchers have disclosed

Figure 16. Cyclic voltammograms for C_{60} embedded in cast films of (a) ditetradecyldimethylammonium poly(styrene sulfonate) (**11**) and (b) tridodecylmethylammonium bromide **12** on BPG electrodes in water containing 0.5 M KCl at 25 °C. their interesting properties and functions for solid metallo-fullerenes of and metallofullerenes in organic solutions by means of a variety of physical and physicochemical techniques. La@C_{82}-A is the first metallofullerene reported by Smalley and coworkers [87] that was identified to possess C_{2v} symmetry [88–89].

Almost no electrochemistry is observed for an La@C_{82}-A film-coated electrode. In sharp contrast, an La@C_{82}-A/**12**-coated electrode shows well-defined cyclic voltammograms with a major cathodic peak potential at 0.28, -0.69, and -1.0 V (versus SCE) which would correspond to the first, second, and third reductions of La@C_{82}-A, respectively (Fig. 18). The observed cyclic voltammograms were stable for potential cycling. The first reduction process was found to be stable for the negative-end potential hold, while the second and third reduction processes were unstable. The higher stability of the first reduction state of La@C_{82}-A would be due to the formation of a closed shell structure like La@C_{82}-A anion in o-dichlobenzene. La@C_{82} embedded in the lipid film on the electrode is rather stable for dioxygen.

The first, second, and third cathodic peak potentials for La@C_{82}-A in *o*-dichlorobenzene have been reported to be -124, -1103, and -1260 mV versus Ag/AgNO$_3$ [88]. Large positive shifts of the cathodic peak potentials were observed for La@C_{82}-A embedded in the cationic lipid film compared to those in an organic solution. This shift suggests the strong binding of La@C_{82}-A anions with alkyl ammonium cation in these films [16]. Hydrophobic microenvironments afforded by the alkyl ammonium matrices contribute to the generation and stability of the metallofullerene anions.

9.3.4. Electrochemistry of C_{60} in Gel-Like Films

The chemistry and physics of organic gels that have potential applications in the construction of "intelligent" material systems are also an exciting area. Organic gels are known to provide suitable microenvironments for the electrochemistry and regulated electrochemistry of some redox active molecules [90–91]. The CVs for a gel-like membrane of C_{60}/tetraoctylphosphonium bromide (**14**) on a BPG electrode showed three redox couples corresponding to C_{60}/C_{60}^-, C_{60}^-/C_{60}^{2-}, and C_{60}^{2-}/C_{60}^{3-} in the potential window in the aqueous medium [19]. This result shows that the

Figure 18. Typical cyclic voltammograms for La@C_{82}-A embedded in a cast film of tridodecylmethylammonium bromide (**12**) on a BPG electrode in water containing 0.5 M TEAC at 25 °C. electrochemistry of fullerene C_{60} incorporated in a gel-like membrane on an electrode is possible. The formal potentials for the electrochemistry of C_{60} in the membrane were $E_1^{0\prime} = -0.17$, $E_2^{0\prime} = -0.66$, and $E_3^{0\prime} = -1.23$ V, which are close to those for the C_{60}/**13**-coated electrode. The voltammograms were stable for potential cycling over the first two redox waves, leading to the generation of C_{60}^{2-}. These findings afford the opportunity to undergo electrochemical communication of fullerenes and related materials at gel-modified electrode systems that possess many possible applications in a variety of areas.

9.3.5. Aqueous Electrochemistry at a p-Type Semiconductive Diamond Electrode

A *p*-type semiconductive diamond has appeared as a unique electrode material [92, 93] due to the wide electrochemical potential window in aqueous media [94, 95], low background current [96], anticorrosiveness, and fast electron transfer kinetics for outer-sphere redox species [97–98]. Wu et al.
Figure 20. Schematic drawing of the redox switch of fullerenes by a lipid bilayer phase transition.
Figure 21. Schematic drawing of a molecular membrane interface.

observed five reduction steps of C_{60} in a nonaqueous solution using a diamond thin-film electrode [99]. The aqueous electrochemistry of C_{60} incorporated into a cast film of an artificial lipid **12** on a boron-doped p-type semiconductive diamond electrode has been investigated. The electrode shows one quasi-reversible and one sigmoidal wave in a cyclic voltammogram. This is quite different from those using a BPG electrode. The redox mechanism of C_{60} in the film on the diamond electrode is explained using an electron energy diagram. The surface states in the hole transfer processes from the diamond electrode to C_{60} in the lipid film are significant.

9.4. Fullerene Redox Switch

The redox switch is of importance in the design and construction of molecular-switchable devices [100–101]. Osteryoung square-wave voltammetry for BPG electrodes modified with films of fullerene lipids (**8–10**) show a strong temperature dependence. The plots of the reduction current for an **8**-modified electrode show breaks near 35 and 48 °C that are close to the respective main and subphase transitions of **8** films, thus suggesting that the phase transition of **8**-films affects the electrochemistry of the modified electrodes [25]. For **9–10** modified electrodes, some temperature-dependent structural changes of the films that are not detectable by DSC affect the electrochemistry.

The electrochemistry of C_{60} embedded in the artificial lipid film is tunable by the temperature-controlled phase transition of the lipid bilayer films on electrodes [14]. As shown in Figure 19, the electrochemistry for a BPG electrode modified with a film of C_{60}-dihexadecyldimethylammonium poly(styrene sulfonate) (**15**) shows a strong temperature dependence; at the lower temperatures, the electrode gives almost no faradaic current of C_{60} (OFF state). On the contrary, a redox current is evident at higher temperatures (ON state). The break observed near 28 °C is very close to the phase transition of the bilayer films of **15**. This temperature dependence is reversible, that is, the temperature-driven "on–off" switching of C_{60} electrochemistry is possible (Fig. 20).

The construction of fullerene/lipid electrical devices based on the nature of self-organized lipid bilayer membranes would be of interest for the application and utilization of fullerenes.

10. CONCLUSIONS

Fullerenes with an ordered structure in aqueous systems and a lipid bilayer-based aqueous superstructure from fullerene amphiphiles, as well as the structure and electrochemistry of fullerene lipid films and fullerene (higher fullerene, metallofullerene)–lipid composite films, were reviewed. Fullerene-based biomembrane-like carbon nanosuperstructures created in an aqueous solution may be adapted for biochemical and biological use. The discovery that a simple C_{60}-carrying ammonium amphiphile forms both fibrous and disk-like superstructures is of interest since the superstructure is formed through self-organization of the amphiphile in an aqueous solution. The fullerene lipids formed multibilayer structure films that possess phase transitions attributable to the lipid bilayer phase transition typically observed for liposomal and synthetic lipid bilayer membranes and/or to the change in orientation of the C_{60} moieties. We could schematically show the phase transitions of the fullerene lipid films. The aqueous electrochemistry for electrodes modified with films of: (1) C_{60}, (2) fullerene lipids, and (3) fullerenes (including higher fullerenes and metallofullerenes)–lipid composites was reviewed here, and the differences in the electron transfer mechanism are revealed. The aqueous electrochemistry of fullerene films is of importance for both fundamentals and applications in understanding the science and nanotechnology of nanocarbons. We have pointed a factor that plays an important role in the generation of multiply-charged fullerene anions at the electrode devices.

Finally, we would like to emphasize that multibilayer lipid films on electrodes provide hydrophobic microenvironments that are suitable for the facile electrochemistry of fullerene thin films, that is, the lipid films function as a molecular membrane interface that connects the fullerenes and metal electrodes (Fig. 21). Fullerene nanoarchtectures using self-assembled fullerenes are of interest for the construction of nanocarbon-based molecular devices.

GLOSSARY

Cyclic voltammograms Typical electrochemical method that measures electron transfer reactions of electroactive compounds.

Fullerene lipids Fullerene-carrying amphiphiles that form molecular-bilayer structure.

Langmuir–Blodgett films Deposited films on substrates from monolayers on water by the langmuir–Blodgett technique.

Lipid phase transition Phase transition between a crystalline phase and a liquid crystalline phase.

Metallofullerenes Novel carbon nanomaterials that encapsulate one or more metal atoms inside the hollow of fullerene cages.

Fullerene Mechanochemistry

Guan-Wu Wang

University of Science and Technology of China, Hefei, Anhui, China

CONTENTS

1. INTRODUCTION

According to the type of energy source supplied to the system, the different fields of chemistry are classified as thermochemistry, electrochemistry, photochemistry, etc. The term mechanochemistry was proposed by Ostwald as early as 1919 as an energy source for chemical reactions [1]. A narrow field, tribochemistry, was used for reactions initiated by friction during milling of solid reagents [2].

Mechanochemistry involves the transformation of mechanical energy into the driving force for the chemical reactions of solid reagents. Mechanochemistry is generally done in the absence of any solvent. The external dynamic force generated from the mechanical agitation can induce the solid to its vibrationally and electronically excited structures, thus destabilizing the electronic structure of the bonding and making the solid prone to chemical reaction. The activation of the local reaction sites by the mechanical energy caused by the stress, friction, shear deformation, etc., together with the high concentration and closest contact of the reacting species due to the lack of solvation, would be particularly advantageous for the chemical reaction in the solid state.

A recent overview on mechanochemistry by Fernández-Bertrán [3] and an excellent and lengthy review on mechanical alloying and milling by Suryanarayana [4] have appeared. Mechanochemistry was mainly applied to processes related to inorganic materials, such as alloy, ceramics, cermets, ferrites, semiconductors and superconductors, ferroelectrics, mineral fertilizers, catalysts, ceramic construction materials, etc. Fewer examples of mechanochemical reactions by ball milling involving organic compounds have been reported [5–14].

Fullerenes (mainly C_{60} and C_{70}) were first discovered in 1985 [15], and macroscopic amount of fullerenes was made available in 1990 [16]. The discovery and availability in large quantity of fullerenes have stimulated their extensive research in a wide variety of fields such as physics, chemistry, material science, biology, etc. Initially viewed as aromatic and quite chemically inert molecules, fullerenes can actually undergo various chemical reactions characteristic of electron-deficient alkenes. Several review articles [17–21] and an excellent monograph [22] regarding fullerene chemistry have been published.

The solubility of fullerenes in common organic solvents is so low that the use of a large amount of solvents is inevitable in their solution reactions. The reactions of fullerenes in the absence of any solvent have advantages over their solution reactions from the viewpoint of the solubility problem of fullerenes and benign environmental concern by eliminating the usage of harmful organic solvent. Therefore solvent-free reaction of fullerene is an attractive and appealing method to synthesize fullerene derivatives. Fullerene chemistry and mechanochemistry started to merge in the mid-1990s. A review article on the mechanochemical approach to fullerene chemistry at a very early stage of fullerene mechanochemistry was published by Braun in 1997 [23]. Since then, much more work on various solvent-free reactions of fullerenes has been done. The solid-state mechanochemical reaction of fullerene C_{60} based on the authors' own work was reviewed in 1999 [24]. Here a full coverage of fullerene mechanochemistry, including most recent research work in this field, is presented.

2. MECHANOCHEMICAL DEVICES

Different types of mechanochemical devices have been used to provide mechanical activation energy. They differ in their capacity and efficiency, and can be generally classified into two categories: grinding devices and milling devices.

2.1. Grinding Devices

The most convenient and easy method for a mechanochemical reaction is the use of a mortar and pestle, which promotes the reaction through grinding, mixing, and triturating. This method has been widely used by Toda and co-workers to investigate various solvent-free organic reactions [25–27]. A new version of mortar and pestle called Mortar Grinder RM 100 is available from Retsch GmbH & Co. KG; the rotary speed of the mortar is 90 rpm.

2.2. Milling Devices

2.2.1. Shaker/Mixer Mills

Shaker mills such as SPEX mills are most commonly used for laboratory investigations. A shaker mill contains a vial, consisting of the sample and grinding balls, secured in the clump and swung energetically back and forth several thousand times a minute. SPEX mills are manufactured by SPEX CertPrep, Metuchen, NJ. A SPEX shaker mill can process about 10–20 g of the sample at a time.

Most of the reactions described in this article were done with the so-called "high-speed vibration mill." This high-speed vibration mill has almost the same working mechanism as the SPEX shaker mill, and consists of a capsule and a milling ball, which are made of stainless steel (Fe-Cr-Ni with a composition of 74:18:8 wt%). The inner diameter and length of the capsule are 9.0 mm and 26 mm, respectively, and the diameter of the milling ball is 6.0 mm. The capsule containing the sample and milling ball was fixed in a home-built vibrating machine so that the capsule was shaken along its long axis horizontally with a slight fluctuation. The vibration frequency is 3500 cycles per minute [28]. Because of the small size of the presently used capsule, only a small amount (usually not more than 200 mg) of sample can be handled.

2.2.2. Planetary Ball Mills

The planetary ball mill owes its name to the planet-like movement of its vials. These vials are arranged on a rotating support disk and a special drive mechanism causes them to rotate around their own axes. The centrifugal force produced by the vials rotating around their own axes and that produced by the rotating support disk both act on the material and grinding balls in the vial. Because the vials and supporting disk rotate in opposite directions, the centrifugal forces alternately act in like and opposite directions. The material in the vial is ground due to the running down, lifting off, traveling, and colliding of the grinding balls. Planetary ball mills (Pulverisette) are available from Fritsch, GmbH in Germany. Compared to the SPEX shaker mills, Fritsch Pulverisettes are lower-energy mills. A few hundred grams of the sample can be milled in a planetary ball mill at a time.

2.2.3. Attritor Mills

A conventional ball mill consists of a rotating horizontal drum half-filled with small steel balls. In contrast, an attritor consists of a vertical drum with a series of impellers inside it. A powerful motor rotates the impellers. Set progressively at right angles to each other, the impellers energize the steel balls. The operation of an attritor is simple. The material to be ground and the grinding medium are placed in the stationary tank. The mixture is then agitated by a rotating shaft with arms. The laboratory attritor works up to ten times faster than the conventional ball mills. Commercial attritors are available from Union Process, Akron, OH. Attritors are the mills in which a large quantity of the sample from about 0.5 to 40 kg can be milled at a time.

3. MECHANOCHEMICAL REACTIONS OF FULLERENES

The simplest method of mechanochemistry is the use of mortar and pestle, while ball milling is suitable when a prolonged reaction time is required. Various organic reactions have been shown to take place in the solid state when a mortar and pestle is used without solvents [25–27]. In these examples, essentially the same reactions are reported to occur regardless of the presence or absence of solvent. For most of the reactions shown in the following sections, the so-called "high-speed vibration milling" (HSVM) technique is utilized. The stainless-steel capsule is vigorously shaken at a frequency of 3500 cycles per minute. The effective maximum local pressure in the stainless-steel capsule is not less than 15,000 bars during the high-speed milling process [29]. Some solid-state reactions can be totally different from those in the liquid phase under such extreme conditions. Indeed, some novel solvent-free reactions of fullerenes have been observed to occur only under HSVM conditions, and will be discussed in the following sections.

3.1. Nucleophilic Addition of Organozinc Reagent to C_{60}

The nucleophilic addition of amines, organolithiums, and Grignard reagents to C_{60} is one of the most common and widely used reactions to functionalize C_{60}. All these reactions were done in organic solvents such as benzene and toluene [19]. The first application of HSVM technique to fullerene chemistry was the Reformatsky-type reaction of C_{60}. The addition of organozinc reagents to C_{60}, which had not even been attempted in solution, was investigated under solvent-free HSVM conditions. The reactants of C_{60}, zinc powder, and ethyl bromoacetate in a molar ratio of 1:20:5 along with a stainless-steel milling ball were put into a stainless-steel capsule. This mixture was vigorously milled for 20 min by shaking the capsule at the speed of 3500 cycles per minute by the use of a high-speed vibration mill. The reaction mixture was acidified and separated to afford mainly the expected product **1** in 17.2% and some minor side products along with 72.5% recovered C_{60} (Fig. 1) [30]. It was found that longer reaction time increased the yield of compound **3** at the expense of the main product **1**.

3.2. Synthesis of Fullerene Dimers and Trimers

The formation, structure, and characteristics of all-carbon fullerene oligomers and polymers are of particular interest because of their potential application in molecular devices,
Figure 1. Reaction of C_{60} with zinc and ethyl bromoacetate under HSVM conditions [30].

optoelectronics, and nanotechnology. These materials have been prepared by photochemical irradiation [31–37], by alkali metal doping [38–40], and under high-pressure/high-temperature condition [41–45]. However, the insolubility of these materials in any organic solvent has precluded their characterization from the organic chemistry point of view; therefore, their detailed structures remain to be elucidated. It has been suggested that fullerene dimer with [2 + 2] structure is the essential subunit in the fullerene oligomers and polymers. Obviously, the preparation and characterization of fullerene dimers and trimers are of paramount importance for understanding the structure and properties and eventual application of the fullerene oligomers and polymers. Fortunately, fullerene dimers and trimers can be uniquely obtained by mechanochemical reactions.

3.2.1. Synthesis of C_{60} Dimer, C_{120}

The reaction of cyanide ion with C_{60} in a solution of *o*-dichlorobenzene (ODCB)-DMF gives a stable $(CN)C_{60}^-$ anion, which can be quenched with various electrophiles to afford cyanated C_{60} derivatives [46]. In sharp contrast to the reaction in liquid phase, the solid-state reaction of C_{60} with KCN under HSVM conditions for 30 min unexpectedly and selectively afforded the formal [2 + 2]-type dimer C_{120} (**6**) in 18% other than the cyanated C_{60} derivative **5**, along with 70% of unconsumed C_{60} (Fig. 2) [47]. The X-ray crystal structure unequivocally showed that the dumbbell-shaped C_{120} is connected by a cyclobutane ring and this four-membered ring is square rather than rectangular as predicted theoretically. Furthermore, the [2 + 2] structure of C_{120} is stable and does not rearrange to other C_{120} isomers such as those with peanuts-shaped structure.

The amount of KCN need not necessarily be equivalent to that of C_{60}; a small amount such as 0.2 molar equivalent
is enough [28]. Apparently, the solid-state reaction of C_{60} with cyanide proceeds in a quite different reaction pathway from the solution reaction. Formation of C_{120} can also be obtained by the reaction of C_{60} with potassium salts such as K_2CO_3 and CH_3CO_2K, metals such as Li, Na, K, Mg, Al, and Zn, and organic bases such as 4-(dimethylamino)- and 4-aminopyridine [28]. This mechanochemical reaction appears to reach an equilibrium state with a ratio of C_{60} to C_{120} in about 7:3 either starting from a mixture of C_{60} and a chosen reagent or from pure C_{120}. For these reactions, the formation of C_{120} was most probably initiated by electron transfer reaction. Once the radical anion $C_{60}^{\cdot-}$ is formed, it would couple with a neutral C_{60} to give $C_{120}^{\cdot-}$, which would transfer one electron to another C_{60} to afford the neutral C_{120}. Helium-3 labeled C_{60} dimer, $^3He@C_{120}$ (**7**) (Fig. 3), was prepared by the above-mentioned HSVM reaction using a helium-3 labeled C_{60} sample in which the approximate ratio of $^3He@C_{60}$ to empty C_{60} is about 1:1000 [28]. $^3He@C_{120}$ and its derivatives can be monitored by helium-3 nuclear magnetic resonance (^3He NMR) [48]. Similarly, $N@C_{120}$ has been synthesized by the mechanochemical reaction of C_{60} containing approximately 0.01% of $N@C_{60}$ with additives such as KCN, $CuSO_4$, $CaCl_2$, and P_2O_5 [49]. $N@C_{120}$ has been measured by electron paramagnetic resonance (EPR).

[60] Fullerene dimer was also obtained as the main product from the HSVM reaction of C_{60} and C_{70} with 4-aminopyridine, which was designed to synthesize cross dimer C_{130} [50]. Dimerization of C_{60} was also found to occur without the presence of any catalyst. Treatment of C_{60} itself under HSVM conditions resulted in a small amount of C_{120} and a large amount of insoluble C_{60} polymers; the latter was not formed in the reaction of C_{60} and KCN [28]. A similar phenomenon was observed by prolonged mechanical milling in a conventional horizontal ball mill at a rotational speed of 95 ± 1 rpm [51, 52].

Shinohara and coworkers described the preparation of C_{120} in 15% overall yield by simply hand-grinding a mixture of C_{60} and K_2CO_3 [53]. The same research group also reported that C_{120} was obtained as the main product (8%) from a hand-ground reaction mixture of C_{60} and C_{70} with K_2CO_3 aiming to synthesize cross dimer C_{130}, which was isolated in 3% yield [54].

It should be mentioned that C_{120} has been synthesized in high yield (~80%) by squeezing the organic molecular crystal $(ET)_2C_{60}$ at 5 GPa and 200 °C using a wedge-type cubic anvil high-pressure apparatus [55]. While C_{60} powder itself was squeezed in a simple piston-cylinder pressure cell at 1 GPa and ~200 °C for a few minutes, only ca. 3% of C_{120} and mainly insoluble residue of C_{60} oligomers and polymers along with 15–20% unchanged C_{60} were obtained [56]. Longer treatment resulted in a decrease in the yield of C_{120} and an increase in the insoluble portion.

Figure 2. Synthesis of C_{120} from C_{60} and KCN under HSVM conditions [47].
Figure 3. The structure of $^3He@C_{120}$ [48].

3.2.2. Synthesis of Cross Dimer C₁₃₀

Similar to the mechanochemical synthesis of C_{120}, the C_{60}-C_{70} cross dimer C_{130} (**8**) can be obtained by the HSVM reaction of C_{60} with C_{70} in the presence of a catalyst. Reaction of equal amounts of C_{60} and C_{70} with two equivalents of 4-aminopyridine for 30 min under HSVM conditions gave the cross dimer C_{130} (1.5%) in addition to C_{120} (6%), and unreacted C_{60} (46%) and C_{70} (44%) (Fig. 4) [50]. It should be noted that C_{70} dimer, C_{140}, could not be detected in the reaction mixture. The cross dimer C_{130} was found to be a single pure isomer, in which the C_{60} cage is attached to the C_{70} cage at the 1,2-bond in a [2 + 2] fashion. This cross dimerization can even occur by hand-grinding an equimolar mixture of C_{60} and C_{70} with four equivalents of K_2CO_3 in a mortar and pestle for 15 min [54]. Two isomers of the cross dimer C_{130} (3%) along with C_{120} (8%) were obtained (Fig. 4). Again, no detectable quantity of C_{70} dimer, C_{140}, was observed under the reaction condition. These results indicate that dimerization of the C_{60} and C_{70} mixture does not proceed statistically with equal probabilities between the two fullerene units. The formation of the two isomers of C_{130} involves the two most reactive bonds, that is, 1,2- and 5,6-bonds, of C_{70}. The presence of K_2CO_3 appears to be crucial to facilitate the cross dimerization between C_{60} and C_{70} under hand-grinding condition as no reaction was observed in its absence. Furthermore, other reagents that can act as electron donors such as 4-aminopyridine were not effective. The cross dimerization of C_{60} and C_{70} in the presence of K_2CO_3 was proposed to proceed via nucleophilic addition rather than electron transfer reaction [54].

3.2.3. Synthesis of C₇₀ Dimer, C₁₄₀

Effort to obtain C_{70} dimer, C_{140}, by the reaction of C_{70} with various reagents under HSVM conditions was fruitless. However, the synthesis of C_{140} can be realized by hand-grinding a mixture of C_{70} and two equivalents of K_2CO_3 in a mortar and pestle [53]. The presence of K_2CO_3 is crucial for the dimerization. No reaction occurred in the absence of K_2CO_3, and moreover, other reagents such as 4-aminopyridine were ineffective. Five [2 + 2] structural isomers of C_{140} were obtained in a total yield of 8% (Fig. 5). This result is in sharp contrast with the dimerization reaction of C_{70} in high yield (20–30%) under high-pressure (1 GPa) and high-temperature (200 °C) conditions which gave only one single isomer of C_{140} (**10**), a [2 + 2] cycloaddition capto-cap C_{70} dimer with C_{2h} molecular symmetry (Fig. 5) [56]. The reason for not being able to obtain C_{140} under HSVM conditions is not clear. However, it is likely that dimer C_{140} is more labile and much more easily dissociated to monomer C_{70} when compared with C_{120} under the HSVM conditions.

3.2.4. Synthesis of C₆₀ Trimer, C₁₈₀

The effects of various reagents including potassium salts, metals, and aromatic amines on the yield of C_{120} were surveyed to find the optimal reaction condition. It was found that fullerene trimer C_{180} was also formed in these reactions [57, 58]. The analysis of the reaction mixture of C_{60} with one equivalent of 4-aminopyridine for 30 min under HSVM conditions on a HPLC Cosmosil 5PBB column eluted with ODCB showed two small peaks (fractions A and B) of the trimer C_{180}, appearing after major peaks for C_{60} and the dimer C_{120}. The combined components in fractions A and B amounted to 4% yield as C_{180}. Further analysis on a Cosmosil Buckyprep column eluted with toluene revealed that the fraction A is a mixture of at least three structural isomers (**15–18**) while fraction B is a single component with a cyclic triangular structure (**19**) (Fig. 6), as verified by scanning tunneling microscopy (STM) [58].

3.3. [2 + 4] Cycloaddition Reactions of C_{60}

3.3.1. Diels–Alder Reaction of Condensed Aromatics to C_{60}

The [4 + 2] cycloaddition of C_{60} with anthracene is a well-studied reaction in solution [59–61]. The highest yield of the monoadduct is 39% in the conventional thermal conditions [59]. The Diels–Alder reaction of a 1:1.2 mixture of C_{60} and anthracene for 1 h under HSVM conditions was very efficient and gave 55% of the corresponding monoadduct and isomeric mixture of bisadducts in 19% [62]. The reaction appeared to reach an equilibrium state between the reactants and products after a reaction time of about 30 min. The reverse reaction (dissociation) of the monoadduct was found to give a similar component ratio. These results demonstrate that a chemical equilibrium is established under the present solid-state reaction system in spite of the heterogeneous reaction conditions. The HSVM reaction of C_{60} with one equivalent of pentacene afforded the double [4 + 2] adduct **21** (11%) in addition to the symmetrical monoadduct **20** (19%) and positional isomers of bisadducts **22** (15%) (Fig. 7) [62]. Apparently adduct **21** was formed by trapping the thermodynamically less favorable monoadduct **23** by another molecule of C_{60} (Fig. 8). In contrast, the reaction of C_{60} with pentacene in solution selectively gave the monoadduct **20** which has higher thermodynamic stability [63]. Adduct **21** could not be obtained from the solution reaction. Thus, in this particular case, the solid-state reaction appears to be advantageous in trapping the kinetic product. The HSVM treatment of C_{60} with 9,10-dimethylanthracene, tetracene, naphtho[2,3-α]pyrene afforded the corresponding [4 + 2] cycloadducts in fairly good yields.

3.3.2. Diels–Alder Reaction of Phthalazine to C_{60}

When the reaction of C_{60} with one equivalent of phthalazine was carried out in a solution of 1-chloronaphthalene at 255 °C for 1 h, the open-cage fullerene derivative **24** was obtained in 44% yield together with 23% of recovered C_{60} by a one-pot reaction. In contrast, the HSVM reaction of
Figure 8. Structure of less stable [4 + 2] adduct from C_{60} and pentacene [62].

C_{60} with four equivalents of phthalazine for 1 h followed by heating this solid reaction mixture at 200 °C for 2 h afforded dimeric derivative **25** as the sole product in 14% along with 61% of unchanged C_{60} (Fig. 9) [64]. Compound **25** underwent intramolecular [2 + 2] cycloaddition between the two C_{60} cages located in proximity to give a new C_{60} dimer in quantitative yield either upon irradiation with visible light in chloroform or by heating in ODCB.

3.3.3. Diels–Alder Reaction of Di(2-pyridyl)-1,2,4,5-tetrazine to C_{60}

Upon HSVM treatment of a mixture of C_{60} and di(2-pyridyl)-1,2,4,5-tetrazine under HSVM conditions for 30 min, a highly efficient reaction took place and adduct **26** was obtained as a single product quantitatively [65]. The yield of compound **26** obtained by HSVM method is obviously higher than that carried out in refluxing toluene (50–60%) [66]. Compound **26** is highly sensitive to moisture and is transformed by the addition of water molecule followed by an unusual series of rearrangements to give the novel and unexpected 1,2,3,4-tetrahydro-C_{60} derivative **27** (Fig. 10). Other nucleophiles such as alcohols, thiols, and primary and secondary amines react with **26** similarly. The reaction is catalyzed by weak acid catalyst such as silica gel and requires ambient light [67].

The synthesis of dimeric compound **28** was achieved by the HSVM reaction of C_{60} with 0.5 equivalent of di(2-pyridyl)-1,2,4,5-tetrazine, followed by the [4 + 2] cycloaddition of the resultant **26** with C_{60} by heating the solid mixture at 150 °C for 2 h to afford 27% of **28** along with 40% of recovered C_{60} (Fig. 10) [65]. This dimeric compound **28** was obtained only by the solid-state reaction.

Figure 7. Reaction of C_{60} with pentacene under HVSM conditions affording the monoadduct, bisadducts, and C_{60} dimer derivative [62].
Figure 9. Diels–Alder reaction of C_{60} with phthalazine under HSVM conditions and in solution [64].
Figure 10. Reaction of C_{60} with di(2-pyridyl)-1,2,4,5-tetrazine under HSVM conditions and in solution [65–67].

The reaction in solution has been reported to result in only hydrogenation of **26** [66, 67]. A new novel C_{60} dimer with direct intercage bonds was formed quantitatively by the intramolecular $[2 + 2]$ cycloaddition when a solution of **28** in ODCB was irradiated with room light for 3 h [65].

3.4. [2 + 3] Cycloaddition Reactions of C_{60}

3.4.1. 1,3-Dipolar Cycloaddition of Organic Azides to C_{60}

Upon the thermal reaction in solution, it is reported that organic azides and C_{60} give triazoline derivatives only at low temperature and the triazolines are converted to 5,6-open and 6,6-closed azafullerenes by heating the solution at 100 °C [68]. The HSVM reaction of C_{60} and azides for 30 min afforded triazoline derivatives **29** in 62–76%. The triazoline **29b** was then heated in the solid state at 120 °C for 2 h to give the 5,6-open and 6,6-closed azafullerenes **30b** and **31b** in higher yields than in solution (Fig. 11). The fact that triazoline derivative **29b** could not be converted to azafullerenes **30b** and **31b** under HSVM conditions indicates that the temperature in the current HSVM system does not rise up to 100 °C [24].

3.4.2. 1,3-Dipolar Cycloaddition of Diazo Compounds to C_{60}

The HSVM reaction of C_{60} with 9-diazofluorene did not allow the isolation of azo-compound **32** but gave 9,9-fluorenofullerene **33** produced by denitrogenation (Fig. 12) [24].
Figure 11. Reaction of C_{60} with azides under HSVM conditions followed by thermal solid-state reaction [24].
Figure 12. Reaction of C_{60} with 9-diazofluorene [24].

3.4.3. 1,3-Dipolar Cycloaddition of Azomethine Ylide to C_{60} and C_{70}

The 1,3-dipolar cycloaddition of azomethine ylide generated *in-situ* from *N*-methylglycine and paraformaldehyde to C_{60} to give fulleropyrrolidine was reported at a very early stage of fullerene chemistry by Prato and co-workers [69]. The HSVM technique is applied to the Prato reaction of C_{60} under solvent-free conditions. A mixture of C_{60}, one equivalent of *N*-methylglycine, and one equivalent of an aldehyde was vigorously shaken under HSVM conditions for 1 h; the expected fulleropyrrolidines **34a–e** were obtained in moderate yields (Fig. 13) [70].

Similarly, the HSVM reaction of C_{70} with one equivalent of *N*-methylglycine and one equivalent of paraformaldehyde for 1 h gave three monoadduct isomers **35**, **36**, and **37** in 41% yield with a ratio of 47 : 36 : 16 (Fig. 14).

3.4.4. Cycloaddition of Glycines to C_{60} and C_{70} [70]

While working on the Prato reaction of C_{60}, besides the corresponding fulleropyrrolidines, compound **34a** was isolated unexpectedly as a minor product in all reactions of C_{60} with sarcosine and aldehydes. Intrigued by this observation, the novel reactions between fullerenes and *N*-substituted glycines were found. The HSVM reaction of C_{60} with sarcosine (1:1) for 1 h gave **34a** and C_{120} in 19% and 23%, respectively. Furthermore, when sarcosine was substituted by *N*-ethylglycine, the same kind of reaction occurred, and **38** and C_{120} were obtained in 16% and 19%, respectively (Fig. 15).

When a mixture of C_{70} and *N*-methylglycine was treated with HSVM, the reaction gave monoadducts **35** and **36** in total yield of 23% with relative ratio of 1.5:1 (Fig. 16). The reason for the absence of **37** is not known. It should be noted that there is no evidence of the formation of C_{70} dimer, C_{140}, either from the Prato reaction of C_{70} or the direct reaction of C_{70} with *N*-methylglycine. This is consistent with the failure of formation of C_{140} from the reactions of C_{70} with potassium salts, metals, and amines under HSVM conditions.

Figure 18. Reaction of C_{60} with dichlorodiphenylsilane and lithium under HSVM conditions [82].
Figure 19. Formation of inclusion complex of C_{60} and γ-CD by ball milling [83].

3.5. Reaction of Organic Bromides and Alkali Metals with C_{60}

Reaction of C_{60} with organolithiums and Grignard reagents affording alkyl, aryl, or alkynyl C_{60} derivatives is one of the earliest studied reactions in solution [17–22]. A mixture of C_{60}, aryl or alkyl bromide, and metal (Li, Na, K, Mg) in a molar ratio of 1:2 ~ 3:4 ~ 6 was vigorously shaken for 30 min under HSVM conditions. The resulting black reaction mixture was acidified to give the corresponding aryl or alkyl C_{60} derivatives **39** in moderate yield and small amount of C_{120} (Fig. 17) [71]. The HSVM reaction of C_{60} with metals with higher reducing power is known to give a mixture of C_{60} and C_{120} in a 30:70 ratio. The formation of either the C_{60} dimer or the C_{60} polymer is suppressed by the presence of organic bromide. Alkali metals were found effective for these reactions, while the usage of magnesium gave poor result.

3.6. Reaction of Dichlorodiphenylsilane and Lithium with C_{60}

The silicon species such as silylene [72, 73], disilirane [74, 75], and silyllithium [76] have been reported to react with C_{60} to give mono- or disilyl derivatives of C_{60} [72–81]. Unlike the above-mentioned HSVM reaction of C_{60} with alkyl bromide and lithium which gave the alkyl C_{60} derivatives, the HSVM reaction of C_{60} with dichlorodiphenylsilane and lithium powder for 30 min gave 7.5% of adduct **40**, a C_{60} dimer fused with a silacyclopentane ring, together with 67.4% of recovered C_{60} (Fig. 18) [82]. The reaction mechanism is not quite clear yet, but it was assumed that the C_{60} radical anion formed by one-electron transfer from lithium was playing an important role in the reaction.

3.7. Formation of Fullerene Complexes

Braun and co-workers studied the mechanochemical synthesis of the supramolecular host-guest complex of C_{60} and gamma-cyclodextrin (γ-CD) [83]. The equipment used in the mechanochemical investigation was a 50 ml agate ball mill (diameter: 70 mm, height: 15 mm) (Pulverisette, Type 701, Fritsch, Germany). A homogenized mixture of 10 mg of C_{60} and 100 mg of γ-CD was ball-milled for about 20 h at room temperature. A 1:2 C_{60}-γ-CD complex **41** with a bicapped structure was supposed to be formed (Fig. 19). It has been proposed that the mechanochemical enhancement of the reactivity of C_{60} towards γ-CD proceeds via the amorphization of both the originally crystalline phases and guest molecules followed by a solid phase dissolution in amorphous media under vigorous mechanochemical treatment [83]. The C_{60}/δ-CD and C_{70}/δ-CD inclusion complexes have been prepared by the same method [84]. The solid-state inclusion complexation of C_{60} and C_{70} as well as some derivatives of C_{60} with γ-CD, and that of C_{60} and C_{120} with sulfocalix[8]arene, was attained under HSVM conditions more efficiently than classical ball milling [85]. The efficiency of complex formation under HSVM conditions was reflected in the very short reaction time (10 min) for the complexation of C_{60} with γ-CD as compared to about 20 h by classical ball milling [83] or more than 24 h in refluxing

aqueous solution [86], and highest solubility of the formed complexes in water.

Another type of complex, that is, charge transfer complex, was reported to be obtained by grinding 1,4-diazabicyclooctane (DABCO) and C_{60} at room temperature in a dry atmosphere. A number of mixtures were prepared with different mole ratios of DABCO : C_{60}. The formed charge transfer complex was found to dissolve readily in water due to its charge separation and increase in dipole moment. However, the reaction of an aqueous solution of DABCO with C_{60} stirred vigorously for 2 h at 60 °C failed to afford the complex formed in the solid state [87].

4. CONCLUSIONS

Various solvent-free mechanochemical reactions of fullerenes have been investigated. Most of the studied mechanochemical reactions of fullerenes were done by high-energy HSVM technique, and many fewer reactions were done by low-energy ball milling and hand-grinding. It has been found that some mechanochemical reactions under HSVM conditions have the same reaction mechanisms as in the solution reactions, but some other mechanochemical reactions under HSVM conditions undergo quite different reaction pathways from those in the solution reactions and therefore give totally different products. Some fullerene derivatives can be uniquely obtained only under solvent-free and HVSM conditions. The fullerene mechanochemistry is still in its infancy. Even though knowledge of the fullerene mechanochemistry has been accumulated over the past years, many more experiments including more various reactions and the adjustment of variables, such as type of mill, milling speed, milling time, and ball to sample weight ratio, have to be done in order to fully understand the unique mechanochemical behavior and be able to propose a possible theoretical model for the fullerene chemistry under HSVM conditions. Furthermore, the extension of the HSVM technique to more general organic reactions (without the involvement of fullerenes) would be a promising research field to produce some unusual results.

GLOSSARY

Fullerene The third form of carbon, it is a family of caged compounds composed of only carbon element. A fullerene C_n consists of 12 pentagonal rings and any number of hexagonal ones, m, such that $m = (C_n - 20)/2$ (Euler's theorem). The most abundant fullerenes are C_{60} and C_{70}.

Fullerene chemistry The chemistry of fullerenes. Fullerenes undergo various kinds of reactions such as nucleophilic addition, Diels–Alder reaction, 1,3-dipolar cycloaddition, radical addition, oxidation, reduction, etc.

High-speed vibration milling (HSVM) It is a technique used to effectively activate the reaction system by vigorous milling of the reaction mixture with a vibration speed of several thousand cycles per minute.

Mechanochemistry Involves the transformation of mechanical energy into the driving force for the chemical reactions. The activation of the local reaction sites is generated by the stress, friction, shear deformation, etc. Mechanochemistry is generally done under solvent-free condition.

Solvent-free reaction Reaction conducted in the absence of any solvent.

CONTENTS

1. INTRODUCTION

During a series of experiments in 1985 to probe the nature and chemical reactivity of the species produced during the nucleation of carbon plasma, Kroto et al. discovered C_{60} as a stable molecule [1]. This stability is due to geodesic and electronic properties inherent in the truncated icosahedral cage structure. The molecule was named buckminsterfullerene after R. Buckminster Fuller, American architect, engineer, and constructor of geodesic domes. Back in 1966, the possible presence of hollow carbon cages in carbon vapors was indicated [2]. Osawa in 1970 and Bochvar and Gal'pern in 1973 offered unique theoretical studies and proposed the spherical icosahedral-symmetric structure for a C_{60} carbon cage [3]. Subsequent to the paper reporting the discovery of C_{60}, the novel proposal of a truncated icosahedral cage structure did not receive instant universal acceptance. In 1990 Krätschmer et al. confirmed the presence

of C_{60} in arc-processed graphite [4]. They extracted a soluble material, which formed crystals. The X-ray analysis showed the material to consist of 10-Å diameter spheroidal molecules. Subsequent mass spectrometric and infrared data provided the first unequivocal evidence for C_{60} and a host of higher members of the fullerene family, the most prominent one being C_{70} [5]. The extracted C_{60} compound yielded a single ^{13}C nuclear magnetic resonance (NMR) line, which proved that all 60 carbon atoms are equivalent as is expected for the truncated icosahedral buckminsterfullerene structure. The early work on the experimental discovery, properties, and theoretical work on buckminsterfullerene was reviewed in 1991 by Kroto et al. [6].

According to the Euler's theorem, each molecule of the fullerene family (C_n) consists of 12 pentagons and m number of hexagons ($m \neq 1$), conforming to the relation $m = (n - 20)/2$ [i.e., a C_n can be made up of $2(m + 10)$ carbon atoms]. Therefore the 60 carbon atoms of C_{60} are comprised of 12 pentagons and 20 hexagons forming 32 faces. The bonds shared by two hexagons (1.40 Å) (6,6-bonds) (**1**) are slightly shorter than the pentagonal edges (6,5-bonds) (1.46 Å) (**2**) (Fig. 1). All the carbon atoms in C_{60} are equivalent. The carbon atoms are arranged at the 60 vertices of a truncated icosahedron (I_h). Molecules with I_h symmetry, of which C_{60} is the most prominent member (other examples being the smallest fullerene C_{20} stable in its fully hydrogenated form and C_{80}), have the highest degree of symmetry of any known molecule. The point group I_h has three symmetry operations involving the fivefold (C_5) (**3**), the threefold (C_3) (**4**), and the twofold (C_2) (**5**) axes of symmetry (Fig. 2). On the other hand, C_{70} consists of 12 pentagons and 25 hexagons. It has 5 types of carbon atoms (**6**) and 8 different C–C bonds (**7**, **8**) (Fig. 3). It has the shape of a rugby ball (**9**) and has D_{5h} symmetry (Fig. 4). The geometry of the C_{70} polar caps is very similar to that of C_{60}. In contrast to C_{60}, this fullerene has an equatorial belt consisting of 5 hexagons. Like C_{60}, the pentagonal edges are longer bonds, whereas the bond shared by 2 hexagons is shorter. The inner diameter of the C_{60} molecule is determined by NMR experiments to be 7.1 ± 0.07 Å [7]. The outer diameter of the C_{60} molecule is estimated by taking into account the size of the π-electron cloud associated with the carbon atoms. Considering that the interplanar distance between graphite layers is 3.35 Å the outer diameter of C_{60} is estimated as $7.09 \pm 3.35 = 10.34$ Å, where 3.35 Å accounts
Figure 1. The buckminsterfullerene (C_{60}) showing a 6,6-ring junction double bond (**1**) and a 6,5-ring junction single bond (**2**).

for the thickness of the π-electron cloud surrounding the carbon atoms. The C_{70} long axis inner diameter is 7.96 Å and the short axis inner diameter is 7.12 Å [8]. There can be several giant fullerenes such as C_{180}, C_{240}, C_{540}, etc. They represent the higher members of the icosahedral fullerene family. Most studies have been done on C_{60} and C_{70} with few reports on C_{76}, C_{78}, C_{80}, C_{82}, and C_{84} [9]. Some of the important physical constants of C_{60} and C_{70} are listed in Table 1. In C_{60} the highest occupied molecular orbital/lowest unoccupied molecular orbital (HOMO–LUMO) gap is calculated to be 1.5–2.0 eV. The LUMO is triply degenerate and energetically low-lying [10], making C_{60} a good electron acceptor. For C_{70} the LUMO is doubly degenerate. However, the energy separation between the LUMO and the LUMO + 1 is small. From cyclovoltametry (CV) studies, it is found that both C_{60} and C_{70} are capable of having six negative oxidation states in solution. The six electrons completely fill the LUMO level of C_{60}. In the CV the potential separation between any two successive reductions is almost constant ($\sim$450 mV). This result is as expected if the LUMO is triply generate. The choice of the solvent and the supporting electrolyte in the electrochemical cell as well as temperature are important for generating a stable C_{60}^{n-} or C_{70}^{n-} species in solution. For C_{60} a mixture of acetonitrile and toluene is the preferred solvent. The formation and stability of C_{60}^{n-} and C_{70}^{n-} species suggest that the electron transfer reaction with atoms or molecules is possible, which include metals and metal complexes. Reduction potential of C_{60} is 0.99 eV versus saturated calomel electrode (SCE). It accepts six electrons electrochemically, generating up to hexa-anion [11, 12]. Oxidation of C_{60} is relatively difficult (IP + 1.76 eV) [11]. Like C_{60}, C_{70} also displays six easily accessible one-electron reductions.

1.1. Fullerene: Superaromatic or Superalkene?

In the fullerenes the π-bonds are conjugated. The question whether fullerenes have to be considered aromatic
Figure 2. The symmetry axes of the regular truncated icosahedron.
Figure 3. The C_{70} with five types of carbon atoms and eight different C–C bonds, four between 6,6-ring junctions (**I–IV**) and four between 5,6-ring junctions (**V–VIII**).

has remained a debate. A hexagon can be fused to two pentagons in three different ways (Fig. 5). Stable fullerenes have either entirely or predominantly the *meta* orientation of pentagones. The *para* orientation is only found in fullerenes made of 84 carbons or more. In such higher fullerenes strain is less significant due to the lower curvature of the cage surface. C_{60} is the smallest possible fullerene, which obeys the "isolated pentagon rule" [13]. All pentagons in C_{60} are isolated by hexagons. Thus, out of the possible arrangements of a hexagon fused to two pentagons, there is only one structure (**13**) in which there is no double bond on the five-membered rings. A double bond in a five-membered ring increases strain and hence decreases stability. Theoretical calculations indicate that in C_{60}, there can be 12,500 resonating structures [14]. There is only one resonating structure in which all the five bonds of the pentagons are single bonds. In C_{60}, all the double bonds are localized between 6,6-ring junctions (i.e., all the 6,6-ring junctions are double bonds and all the 5,6-ring junctions are single bonds). The hexagons, though seeming to be benzene-like, behave like cyclohexatrienes, and each pentagon has the [5]radialene character. Therefore C_{60} behaves in most of its reactions as a superalkene, rather than a superaromatic. Since there are no hydrogen atoms, substitution reactions are not possible, although substitution of boron for carbon has been observed [15]. Addition reactions are facilitated with considerable ease.

Even though the fullerenes undergo addition reactions easily, the π-bonds are conjugated. There is ample evidence from both experiment and theoretical calculations that fullerenes and their derivatives can sustain ring currents, just like the planar polycyclic aromatic hydrocarbons,
Figure 4. The pentagons superpose when viewed along the D_{5h} symmetry axis passing through the poles.

Table 1. Some important physical constants of C_{60} and C_{70}.

C_{60}		C_{70}	
Physical constant	Value	Physical constant	Value
5,6-Bond length (Å)	1.46	Long axis diameter (Å)	7.96
6,6-Bond length (Å)	1.40	Short axis diameter (Å)	7.12
Inner diameter (Å)	7.10	Number of carbon atom types	5
Outer diameter (Å)	10.34	Number of distinct C–C bonds	8
Binding energy per C atom (eV)	7.40	Binding energy per C atom (eV)	7.42
Heat of formation (kcal/g of C)	10.16	Heat of formation (kcal/g of C)	9.65
First ionization potential (eV)	7.58	First ionization potential (eV)	7.61
Electron affinity (eV)	2.65 ± 0.05	Electron affinity (eV)	2.72

Source: Selected data taken from M. S. Dresselhaus, G. Dresselhaus, and P. C. Eklund, in "Science of Fullerenes and Carbon Nanotubes, Ch. 3, pp. 63 and 67. Academic Press, San Diego, 1996.

as a consequence of the cyclic delocalization of π-electrons. The magnetic properties of fullerenes clearly reflect delocalized character of the conjugated π-electron system. Depending upon the number of π-electrons, within the loops of the hexagons and the pentagons there can occur diamagnetic and paramagnetic ring currents. For neutral C_{60}, for example, the hexagons are diamagnetic whereas the pentagons are paramagnetic. Such ring currents are taken as a measure of aromaticity in planar molecules. The same criterion can be applied to the three-dimensional fullerenes. Due to the presence of both the diamagnetic and paramagnetic ring currents, the fullerenes are described to possess "anomalous aromatic character." The center of each cage feels the combined effects of all ring currents. The best means of study of the overall degree of aromaticity or antiaromaticity is to study both experimentally and theoretically the endohedral fullerenes [16]. Theoretical estimates of heats of hydrogenation based on the reaction $C_{60} + H_2 \rightarrow C_{60}H_{60}$ indicate a stabilization per double bond in C_{60} about one-half that in benzene [17]. Based on several studies, including the heat of hydrogenation, it can be stated that C_{60} exhibits an aromatic stability, which is significantly inferior to that of benzene. The aromaticity of fullerenes is elaborately discussed in a review article [18].

1.2. Structure and Reactivity

Each carbon in fullerenes is sp^2-hybridized but not planar like the ideal sp^2 carbon in graphite. The curvature of the trigonal bonds in C_{60} confers some sp^3 character to the carbon atoms (i.e., each carbon atom is slightly pyramidized).
Figure 5. Three possible ways a hexagon can be fused to two pentagons. In structure **13** there are no double bonds on the pentagons.

The pyramidization angle ($\theta_{\sigma\pi} - 90°$) is 11.6° for C_{60} [19]. This angle is 0° for graphite. Hence the π-bonds on the C_{60} surface are bent. The pentagons are responsible for generating the curved surface of the fullerenes. When a pentagon is surrounded by five cyclohexatrienes sharing the bonds of the pentagon, such that all the double bonds are between 6,6-ring junctions, a curved surface is generated. The pentagon together with its five neighboring hexagons has the bowl shape of a corannulene molecule. However, the shape is not an exact replication of the fullerene polar caps, because corannulene has hydrogen atoms on the boundary carbons of its hexagons. The sp^2 networks of fullerenes have no boundaries, which can be saturated by hydrogen atoms. For C_{60}, a spherical shape distributes the strain as evenly as possible (i.e., the stain energy on a curved surface is minimum) [20]. As the number of carbon atoms in the cage increases, the curvature is reduced, and the chemical behavior should approach that of graphite, with the difference that graphite has dangling bonds at the edges. In C_{70} the polar curvature is same as that of C_{60}; the corannulene subunits have the same type of bond length alternation. The strain calculated per C atom of C_{60} is 10.16 kcal mol^{-1} [21]. Exohedral addition to C_{60} relieves this strain, while endohedral additions cause increase in strain. When isolated nitrogen atoms are inserted into C_{60}, the N atoms do not bond to C atoms. These atoms remain spectroscopically indistinguishable from nitrogen atoms *in vacuo* [22]. Similarly, F atom, methyl radicals are chemically inert when placed inside C_{60} [23].

The driving force for addition is for relieving of strain [24] and a change of the hybridization of carbon atoms involved in addition reaction from sp^2 to sp^3. The change in pyramidization consequent upon hybridization change is clearly seen in the X-ray structures that show distortion upon relieving strain. Addition to fullerene is exothermic due to relief of strain. It is therefore often not possible to stop the reaction at the monoadduct stage. Multiaddition is facilitated with considerable ease. A series of addition sequences ultimately lead to a product with the remaining unreacted six-membered rings, and then further addition is not possible. Since there are a number of double bonds, addition leads to a mixture of mono- and polyadducts. Furthermore, the polyadduct can form regioisomers; the regioselectivity of addition is governed by avoidance of products with a double bond in the 5,6-ring junction.

C_{60} can be viewed as a close cage molecule holding six nonoverlapping pyracylene molecules arranged in an octahedral fashion (Fig. 6). Four pyracylene units are arranged around the belt of the C_{60} molecule, and the remaining two centered on the top and bottom of this equatorial belt (**17**). The six pyracylene units join up in a manner so as to create eight hexagons thus accounting for the 20 hexagons. There is one reactive double bond located in the center of each unit. Many of the addition reactions of C_{60} (and C_{70}) involve the scission of this central double bond in the pyracylene unit. Addition reactions such as cycloaddition, addition of nucleophiles, radicals, including reactions like hydrogenation, halogenations, hydroboration, hydrometallation, and metal complex formations, etc., take place at the 6,6-bonds. Addition at the six 6,6-ring
Figure 6. C_{60} showing six pyracylene units. The six double bonds at the 6,6-ring junctions (**17**, I–VI) are the most reactive ones for addition reactions. Other double bonds are not shown for reasons of clarity. When these six bonds are removed, an aromatic framework of eight benzene rings remains (**18**).

junctions of the six pyracylene units leaves behind an aromatic framework of eight benzene rings (**18**). This is the driving force for octahedral addition. Fullerenes are therefore electron-attracting and reaction with nucleophiles is preferred.

In this chapter, a concise account of the chemical reactions carried out on the curved surface of the fullerenes, specifically of C_{60} and C_{70}, is discussed. Since the literature on fullerenes has grown enormously [25], it is impractical to integrate all the reactions and properties of the products in the limited scope of this chapter. Nevertheless, an attempt is made to cover the important ones as much as possible, keeping the approach overtly simple and coherent. Though comprehensive articles integrating all the developments into one are very few [26], a vast number of up-to-date reviews and monographs on specialized topics are available. These are referred to in each section, which will provide a further link to the original works.

2. ENDOHEDRAL METALLOFULLERENES

Since the face-centered cubic packing structure of C_{60} has two vacant tetrahedral sites and one octahedral site per C_{60} molecule, spheres of radius 1.12 and 2.06 Å, respectively, can be accommodated in these sites. A number of exohedral metal complexes of fullerenes, such as MC_{60}^+, M = Li–Cs, Fe, Co, Ni, Cu, Rh, La, U, and VO, are formed by direct attachment of M^+ with C_{60} by charge transfer [27]. For a C_{60} ternary fulleride like Ba_2CsC_{60}, the fulleride adopts a novel orientation ordering in which the Ba cations occupy the tetrahedral sites and Cs the octahedral sites. Some of the alkali metal exohedral complexes show superconductivity [28]. The C_{60} cavity is roomy enough to accommodate one or more metal ions leading to the formation of endohedral fullerene metal complexes, $M_m@C_n$. The metallofullerene in macroscopic amount is prepared by laser vaporization of a graphite–metal composite in a helium-filled tube-oven at high temperature [29]. Group 3 metals (M = Sc, Y, La), most of the lanthanide series elements, Group 2 metals (M = Ca, Sr, Ba), alkali metals (M = Li, Na, K, Cs), and some tetravalent metals

(M = U, Zr, Hf) have been encapsulated into a fullerene cage to form mono-, di-, and trimetallofullerenes. Mass spectrometry plays a key role in their identification and characterization. The endohedral nature of metallofullerenes, the electronic structures, and properties are determined by synchrotron X-ray powder diffraction and various spectrometric means such as NMR, electron paramagnetic resonance (EPR), ultraviolet-visible near-infrared (UV-vis-NIR), X-ray photoelectron spectroscopy (XPS), and CV. One of the most distinct features of metallofullerenes is their superatom character. They can be viewed as a positively charged core metal surrounded by a negatively charged carbon cage. Several chemical reactions of endohedral metallofullerenes are reported. These novel forms of fullerene-based materials have attracted wide interest not only in physics and chemistry but also in such interdisciplinary areas as materials and biological sciences [30]. The materials have potential application as new types of superconductors, organic ferromagnets, nonlinear optical materials, functional molecular devices, magnetic resonance imaging agents, and biological tracing agents.

2.1. Synthesis

The synthetic method of choice is the arc-evaporation technique in which the arc burns a composite rod made from a metal oxide and graphite in a depressurized He gas. The soot produced contains a number of metallofullerenes and empty fullerenes, which are extracted with solvents such as pyridine, toluene, and carbon disulphide. Laser vaporization of a mixture of C_{60} and La_2O_3 is a convenient method to introduce lanthanum atom [31]. Yttrium atoms are also introduced by laser irradiation of a mixture of graphite and Y_2O_3 [32]. Production efficiency and the species of metallofullerenes increase if metal carbides are used as metal sources [33]. The size of the fullerene cage is also a determining factor. For example, when the cage is C_{82} fullerene, its metallofullerenes are formed and extracted efficiently. A number of methods including high pressure liquid chromatography (HPLC) have been used for isolation of endohedral metallofullerenes [34]. A silica-packed HPLC column in which tetraphenylporphyrin moieties are anchored to the silica surface is used to separate $M@C_{82}$ (M = La, Y) from empty fullerenes [35]. Metallofullerenes like $Ln@C_{80}$, $Ln@C_{82}$, $Ln_2@C_{80}$, $Gd@C_{82}$, and $La@C_{2n}$ are efficiently extracted from the insoluble part of the soot after toluene Soxhlet extraction by way of the high-temperature and high-pressure extraction by pyridine [36]. Aniline is a suitable extraction solvent for a number of metallofullerenes [37].

2.2. Structure

A number of studies by electron spin resonance (ESR), extended X-ray absorption fine structure (EXAFS), scanning tunneling microscopy, transmission electron microscopy, and synchrotron powder X-ray diffraction have strongly suggested that the metal atom(s) are indeed inside the fullerene cages. Since there are many isomers for endohedral metallofullerenes, the determination of structures and symmetries has long been of fundamental interest.

Some metallofullerenes such as M@C$_{82}$ (M = La, Y, Sc), La$_2$@C$_{80}$, Sc$_2$@C$_{84}$, and Sc$_3$@C$_{84}$ have been extensively investigated. For the C$_{82}$ fullerene, there are nine isomers of M@C$_{82}$ (M = La, Y, Sc). For La@C$_{82}$ the observation of two octets in the ESR spectrum suggests two different conformations [38], existing under thermal equilibrium [39]. Like La, M@C$_{82}$ with other trivalent metal atoms like Y, Sc forms several isomers, two of which are dominant. With divalent metal ions (Tm, Ca) three isomers for Tm@C$_{82}$ and four isomers for Ca@C$_{82}$ are known [40]. Theoretical calculations, EPR, EXAFS, and synchrotron X-ray diffraction studies show that M is located off-center in M@C$_{82}$, and M@C$_{82}$ is most stable when M approaches the center of one hexagonal ring [41].

Two metal atoms can even be encapsulated inside the higher fullerene cages forming dimetallofullerenes, M$_2$@C$_{80}$ (M = La, Sc), of which La$_2$@C$_{80}$ is a representative example. C$_{80}$ fullerene has seven isomers. The two La atoms are encapsulated inside the most stable isomers. The two La atoms are located equivalently on the C_2 axis facing the hexagon rings of C$_{80}$. To know whether encapsulated metal atom(s) are rigidly attached to cage carbons or move about ^{139}La-NMR study has been carried out, which confirmed that the metal atoms rotate inside the fullerene cage [42]. For the C$_{84}$ fullerene, there are 24 distinct isomers. Three isomers of Sc$_2$@C$_{84}$ have been isolated [43]. For one isomer only one single ^{45}Sc-NMR signal observed confirms that the two Sc atoms are equivalent. For another isomer the ^{45}Sc-NMR spectra show two distinct signals of equal intensity, indicating that two Sc ions in C$_{84}$ are at inequivalent positions. At about 383 K, however, the two Sc ions move and rapidly exchange their positions, resulting in an equivalent NMR line [44].

The tri-scandium fullerene, Sc$_3$@C$_{82}$, has been characterized by ESR [45]. The results of theoretical calculations show three scandium atoms form an equilateral Sc$_3$ trimer within the C$_{82}$ cage retaining a threefold symmetry axis [46]. The three Sc atoms are in a dynamic state inside the cage. Introducing nitrogen gas into the arc generator during vaporization of the packed graphite rods containing metal oxides has produced high yields of trimetallic nitride endohedral metallofullerenes, Sc$_3$N@C$_{82}$ [47]. The complex can be viewed as a positively charged planar cluster of atoms inside a negatively charged icosahedral carbon cage, [Sc$_3$N]$^{+6}$@[C$_{82}$]$^{-6}$.

2.3. Electronic State

The incorporation of metal atom(s) inside the fullerene results in an electron transfer from the metal atom(s) to the carbon cage under the formation of a stable ion pair (e.g., La^{3+}C$_{82}^{3-}$ for La@C$_{82}$), confirmed from EPR and UV photoelectron spectroscopy (UPS) [48]. Similar measurements for Y@C$_{82}$ indicate the charge-transfer electronic state of Y^{3+}C$_{82}^{3-}$. In studies of Group-2-based samples (M = Ca, Sr, Ba), the resultant structures are M^{2+}C$_{82}^{2-}$. As a result of the transfer of two electrons from each Sc to C$_{84}$ cage, Sc$_2$@C$_{84}$ is also described as (Sc^{2+})$_2$C$_{84}^{4-}$ concluded from the powder diffraction data and XPS studies [49]. C$_{80}$ in M$_2$@C$_{80}$ (M = La, Pr, Ce) acquires the six valence electrons from the two M atoms, forming the same electronic structures, (M^{3+})$_2$C$_{80}^{6-}$. Cyclovoltametry studies indicate that fullerenolanthanides are stronger electron donors as well as stronger electron acceptors than empty fullerenes [50]. The calculated electrostatic potential of the inner surface of empty fullerenes shows that the carbon cage is positive at any position [51]. However, the electrostatic potentials become highly negative for metallofullerenes.

2.4. Reactivity

A large number of experimental studies have been performed on the chemical derivatization of empty fullerenes such as C$_{60}$ and C$_{70}$. Up to now, however, the chemical properties of endohedral metallofullerenes have been studied scantily due to the low yield and separation difficulties. It is of great interest whether endohedral metallofullerenes can also be functionalized and how the endohedral doping of metal atom(s) modifies the reactivities of empty fullerenes. Photochemical cycloaddition of disilacyclopropane with La@C$_{82}$, Gd@C$_{82}$, and La$_2$@C$_{80}$ is one of the earliest chemical derivatizations reactions reported [52]. Under thermal conditions the reaction of these three endohedral fullerenes is observed, though the higher fullerenes, C$_{76}$, C$_{78}$, C$_{82}$ and C$_{84}$ as well as C$_{60}$ and C$_{70}$, do not react thermally with disilacyclopropane. Since the electronegativities of germanium and silicon are similar, it is also found that photochemical and thermal reactions of La@C$_{82}$ with digermacyclopropane afford an exdohedral adduct [53]. The chemical reactions of La@C$_{82}$ and diphenyldiazomethane (Ph$_2$CN$_2$) have been reported and the products (several possible isomers) have been characterized by EPR [54]. Water soluble multihydroxyl endohedral metallofullerols [Gd@C$_{82}$(OH)$_m$ (m = 20) and Pr@C$_{82}$O$_m$(OH)$_n$ (m = 10, n = 10)] are reported [55]. These derivatives are very important and have applications in the field of biomedicine. A symmetric derivative of the trimetallic nitride endohedral metallofullerene, Sc$_3$N@C$_{80}$ with ^{13}C labeled 6,7-dimethoxyisochroman-3-one, is obtained by cycloaddition reaction of the o-quinodimethane intermediate with the endohedral complex [47].

2.5. Potential Applications

Endohedral metallofullerenes with radioactive atoms inside the fullerene cage have potential applications in materials science, biology, and medicine. Promising applications are demonstrated in radiochemical techniques [56]. Radioactive endohedral ^{7}Be@C$_{60}$ can be detected using radiochemical and radiochromatographic methods [57]. Radioisotopically labelled metallofullerenes, such as ^{140}La-labelled La@C$_{82}$ and La$_2$@C$_{80}$, are administered to rats and the distribution of the metallofullerenes in organs is studied. Large portions of La fullerenes are found in liver and blood [58]. Endohedral metallofullerenes such as water-soluble Gd@C$_{82}$(OH)$_n$ can be used as a magnetic resonance imaging (MRI) contrast agent [59]. It is found to be much more effective than the commercially available Gd-MRI contrast agents. Endohedral holmium metallofullerenes have been utilized in a model metallofullerene radiotracer study. The ^{165}Ho metallofullerenes are chemically functionalized to impart water solubility and then neutron activated to ^{166}Ho in order to

determine their biodistribution and metabolism properties. The results have been evaluated for potential applications of lanthanide metallofullerenes as new diagnostic or thera-peutic radiopharmaceuticals [60].

3. ADDITION OF RADICALS

Alkyl and aryl radicals (R$^\bullet$ = Me$^\bullet$, Et$^\bullet$, Ph$^\bullet$, PhS$^\bullet$, PhCH$_2^\bullet$, CBr$_3^\bullet$, CF$_3^\bullet$, Me$_2$CH$^\bullet$, Me$_3$C$^\bullet$, Me$_3$CO$^\bullet$, 1-adamantyl) react with C$_{60}$ to form R–C$_{60}^\bullet$ radical adducts. Single or multiple radical additions are possible depending on the type of rad-ical involved [61]. Addition takes place at the 6,6-double bond of the pyracylene unit, with the creation of new radical center on the C$_{60}$ carbon. Often delocalization of the radical is not possible due to an unfavorable double bond in the pentagonal ring. In such cases two R–C$_{60}^\bullet$ radicals dimerize leading to RC$_{60}$C$_{60}$R. Dimerization does not take place in multiple additions.

A photochemically generated benzyl radical reaction with C$_{60}$ leads to both radical and nonradical adducts R$_n$C$_{60}$ (R = PhCH$_2$, n = 1 to at least 15) [62]. The radical adducts with n = 3 and 5 are stable above 50 °C and have been identified by ESR spectroscopy as the allylic R$_3$C$_{60}^\bullet$ (**22**) and cyclopen-tadienyl R$_5$C$_{60}^\bullet$ (**24**) radicals (Fig. 7). The unpaired electrons are highly localized on the C$_{60}$ surface. The extraordinary stability of **22** and **24** is attributed to the steric protec-tion of the surface radical sites by the surrounding benzyl substitutents. Mass spectrometric analyses of the product from addition of photochemically generated methyl radi-cals to C$_{60}$ show formation of (CH$_3$)$_n$C$_{60}$ with n = 1 to at least 34.

In addition to the benzyl and methyl radicals, a vari-ety of photochemically generated reactive, neutral radicals efficiently add to C$_{60}$ to yield remarkably persistent radi-cal adducts. The photolysis of C$_{60}$ in the presence of donor molecules produces radical anion of C$_{60}$ [63]. The radical anion C$_{60}^{\bullet-}$ is obtained by photolysis of C$_{60}$ solution con-taining benzylic trialkyltin derivatives. Reaction of a num-ber of photolytically and thermally generated alkyl radicals with C$_{60}$ leading to R–C$_{60}^\bullet$ radical adducts (monoadducts) are identified by the proton and ^{13}C hyperfine interac-tions obtained from their electron spin resonance spectra [64]. From ^{13}C NMR spectra it is shown that the unpaired
electron in R–C$_{60}^\bullet$ is mostly confined to the two fused, six-membered rings without delocalization of the unpaired electron over the C$_{60}$ sphere. The ESR spectrum of the (CH$_3$)$_3$C–C$_{60}^\bullet$ is obtained by several photochemical and ther-mal methods including the UV irradiation of a saturated solution of C$_{60}$ in benzene containing *tert*-butyl bromide. The spectrum is remarkably persistent after irradiation and shows a 10-line hyperfine manifold having the binomial intensity distribution appropriate for nine equivalent pro-tons interacting with a single unpaired electron. The tri- and pentabenzyl adducts having allylic and pentadienylic struc-tures found for C$_{60}$-benzyl radical reaction are not observed for *tert*-butyl radical.

ESR spectra of several simple monoalkyl radical adducts of C$_{60}$, studied in solution over a broad temperature range, revealed a substantial barrier to internal rotation about the bond connecting the alkyl substituent to the C$_{60}$ [65]. An analysis of the temperature-dependent shape of the spec-trum of *tert*-butyl-C$_{60}$ affords activation energy for internal rotation of 8.2 kcal/mol. The rotation of the *tert*-butyl group is strongly hindered at low temperatures. Similar barriers exist for other alkyl adducts (except methyl). The alkyl sub-stituents adopt a preferred equilibrium conformation rela-tive to the carbon framework (Fig. 8). Alkoxy radicals RO$^\bullet$ from the photolysis of ROSSOR add to C$_{60}$ yielding RO–C$_{60}^\bullet$ adducts (R = Me, Et, iso-Pr, *tert*-Bu, iso-PrCH$_2$, *tert*-BuCH$_2$) which are detected by ESR spectroscopy [66].

The ability of C$_{60}$ to efficiently react with radicals leads to consideration of C$_{60}$ as a "radical sponge" [67]. This property of fullerenes being a radical scavenger is useful for several practical applications. Antifriction, antiwear, and antiseize properties of lubricating oil are improved in the presence of C$_{60}$, because C$_{60}$ inhibits unwanted polymeriza-tion. The use of a dissolved fullerene catalyst as inhibitor of coking reactions to thereby inhibit formation of coke on a catalyst or catalyst support by elimination of nucle-ating points or growth regions for such coke formation is reported. In the petrochemical and refining industries, the efficient production of many hydrocarbon products is often hindered by fouling resulting from unwitting polymerization of reactive olefins like 1,3-butadiene, isoprene, or styrene. Addition of fullerenes in ppm levels inhibits the thermal polymerization of activated olefins like styrene and butyl methacrylate. The extent of polymerization and the molecu-lar weight of the recovered polymer are strongly dependent on fullerene concentration. Fullerenes apparently inhibit polymerization by scavenging monomer species that propa-gate chain growth.

4. SIMPLE FUNCTIONALIZATION REACTIONS

The π-bonds of fullerenes undergo addition reactions readily. Hydrogenation, halogenation, arylation, and alkylation of fullerenes have been extensively studied and comprehensively reviewed [68]. Since fullerenes contain a number of double bonds multiple addition takes place leading to mixture of isomers. The Schlegel diagrams for C_{60} (**25**) and C_{70} (**26**) with numbering of each carbon atoms is useful in identifying these isomers (Fig. 9). The 6,6-ring junction is the preferable position for 1,2-addition (**27**) (Fig. 10). 1,4-Addition (**28**) leads to introduction of unfavorable 5,6-double bonds and so does the 1,6-addition (**29**). Such additions are preferred only for sterically demanding addends [69].

4.1. Hydrogenation

Hydrogenation of a benzene solution of C_{60} is carried out using hydrogen at just above atmospheric pressure with Pd–C or Pt–C catalysts. However, the hydrofullerene obtained becomes rapidly oxidized to fullerenols. The reduction of the cage is not affected with Raney nickel as the catalyst. Hydroboration, hydrozirconation, or reduction by diimide leads to $C_{60}H_2$ [70]. Since all the 6,6-ring junction π-bonds are equivalent in C_{60}, only one dihydrogen product is obtained. With respect to a hydrogenated π-bond in C_{60}, a second molecule of H_2 can add to any one of the eight regiosymmetrically different double bonds, leading to eight possible tetrahydro derivatives. Indeed the reaction to tetrahydro derivative $C_{60}H_4$ leads to an isomeric mixture and all eight isomers are isolated [70b]. The tetrahydro[60]fullerene mixture consists of 30% of the 1,2,3,4-isomer **30**, shown as the Schlegel diagram (Fig. 11). Isolation of this product in good yields has fundamental significance in relation to the overall chemistry of fullerenes and understanding their aromaticity. The principal tetrahydro product is the one obtained by addition of the second hydrogen molecule to a π-bond in the same ring to which the first H_2 molecule was added. Subsequent addition could have occurred at any of the remaining eight different bonds of C_{60} with equal ease (except for the *trans*-1 double bond which is statistically disadvantaged by a factor of 4:1) had all the π-bonds
Figure 10. Various modes of additions, showing unfavorable 6,5-ring junction double bonds in the 1,4- and 1,6-addition modes.

been localized. The preferential formation of the 1,2,3,4-tetrahydroderivative shows that there is some delocalization of the electron (i.e., the cage is partly aromatic in character). Addition in one hexagon leads the hexagon to lose its aromatic character and hence further addition is favored there.

Unlike C_{60}, all the double bonds of C_{70} are not equivalent. Hence a number of isomeric dihydro[70]fullerenes, in principle, are possible. The reduction of C_{70} by di-imide leads to 1,2- and 5,6-dihydro[70]fullerenes (**31**, **32**) in a 25:1 ratio [70b] indicating that the 1,2-bond is more reactive compared to the 5,6-bond (Fig. 12). The curvature is greater across the 1,2-bond (i.e., the extent of π-bond bending is more in this position and hence addition is favored there). Further reduction of C_{70} by di-imide gives six tetrahydro[70]fullerenes, 1,2,3,4- and 1,2,5,6-isomers (**33**, **34**) each comprising about 25% of the total. This again is due to loss of conjugation upon addition to one double bond in a six-membered ring. The remaining π-bonds of the ring become more reactive for subsequent additions compared to other π-bonds in the molecule.

Higher addition products of C_{60} are obtained by warming a stirred benzene solution of C_{60} with Zn/HCl for 10 minutes. Reduction by Zn–HCl gives $C_{60}H_{36}$ as a major product, which degrades slowly to $C_{60}H_{18}$ (**35**) (Fig. 13) on strong heating. C_{70} gives $C_{70}H_{36}$, $C_{70}H_{38}$, and $C_{70}H_{40}$ [71]. Reduction takes longer time since C_{70} is less reactive than C_{60}. Higher fullerenes such as C_{78} and C_{84} on reduction with Zn/HCl produce $C_{78}H_{36-48}$ and $C_{84}H_{48-52}$ as major components [72]. Formation of stable $C_{60}H_{36}$ (**36**) is a consequence of the four benzenoid rings generated upon hydrogen addition (see Fig. 13). These rings are substantially aromatic due to the removal of strain from the adjacent pentagons [73]. Both $C_{60}H_{18}$ and $C_{60}H_{36}$ can easily be converted into parent C_{60} by action of 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) in refluxing toluene [74].

30
Figure 11. Schlegel diagram for the 1,2,3,4-tetrahydro[60]fullerene.
Figure 12. The di- and tetrahydro derivatives of C_{70}, the major products of diimide hydrogenation.

Reduction using Zn/DCl leads to $C_{60}D_{44}$ and $C_{70}D_{48}$. This higher hydrogenation level is attributed to the greater stabilities of C–D bonds in comparison to the C–H bonds.

4.2. Halogenation

4.2.1. Fluorination

The drive for fluorination of C_{60} was to get a material with properties analogous or superior to Teflon. However, this expectation had one point overlooked, the cage structure, which cannot flex significantly and hence high fluorination levels cannot be achieved. The principal features that dominate fluorination of fullerenes are the addition of fluorine at the 6,6-ring junctions and the tendency to generate aromatic rings in the fluorinated products, as is seen for hydrogenation. A number of fluorinated derivatives are now known [75].

Fluorination is initially carried out using either F_2 or XeF_2 as fluorinating agents at ca. 70 °C. Since these reagents react readily with the solvents used to dissolve the fullerenes (benzene, toluene, dichloromethane, etc.), fluorination is carried out under heterogeneous conditions. Fluorination of the solid fullerenes occurs layer by layer and can be seen by visual swelling of the samples [76]. In contrast to hydrogenation and many other addition reactions, fluorination of solid C_{70} is faster than C_{60}, in which efficient molecular packing restricts lattice penetration [77]. Heterogeneous reaction leads to inefficient fluorination and hence the product consists of a mixture of fluorinated and unreacted fullerenes [78]. Under these conditions, the only pure fluorinated fullerene isolated is $C_{60}F_{48}$. Fluorination of fullerenes by metal fluorides is carried out at high temperatures, ca. 400–500 °C, under vacuum. In this method a mixture
of fluorinated products is obtained which needs extensive HPLC separation. $C_{60}F_{48}$ is a white solid. It exists in two chiral forms (**37**, **38**), the structures of which are determined by two-dimensional (2D)^{19}F NMR (Fig. 14) [79]. $C_{60}H_{48}$ is a concentrated source of fluorine and has been used for fluorination of aromatics [80]. Heating C_{60} with MnF_3 at 330 °C under vacuum and HPLC separation lead to $C_{60}F_{36}$, isolated in two isomeric forms, T and C_3. Addition of 36 fluorine atoms leaves behind benzenoid hexagonal rings, four for T (**39**) and three for C_3 isomer (**40**) (Fig. 15) [81].

Fullerene $C_{60}F_{18}$, a lemon yellow compound, and presumed to be an intermediate in $C_{60}F_{36}$ synthesis, is obtained by fluorination with K_2PtF_6 at 600 K [82]. It is isostructural with $C_{60}H_{18}$. It has an aromatic ring and the bonds in the aromatic rings are shorter than in benzene. The X-ray crystal structure shows the hexagonal aromatic ring at the center of the fluorinated face [83]. $C_{60}F_{16}$ is produced from fluorination of C_{60} with K_2PtF_6 at 465 °C and its structure is confirmed from ^{19}F NMR [84]. $C_{60}F_{20}$, an off-white solid, is formed by fluorinating C_{60} with either a mixture of MnF_3 and KF at 480 °C or Cs_2PbF_6 at 580 °C for 6 h. This compound has a unique structure with flattened poles and an expanded equator. $C_{60}F_2$ is formed in very low yield on fluorinating with K_2PtF_6 at 470 °C. A number of fluorinated derivatives of C_{70} are isolated, though in low yields. The prominent ones are one isomer each of $C_{70}H_{34}$, $C_{70}H_{42}$, $C_{70}F_{44}$, six isomers of $C_{70}H_{36}$, and four isomers of $C_{70}H_{40}$ [85]. Fullerenes $C_{76}F_{36}$, $C_{76}F_{38}$, $C_{76}F_{40}$, $C_{76}F_{42}$, and $C_{78}F_{42}$ are isolated in small quantities from fluorination of C_{76} and C_{78} with MnF_3 at 450–500 °C. Fluorination of C_{82} and C_{84} by MnF_3 at 470 °C leads to fluoro compounds $C_{84}F_{44}$, $C_{84}F_{40}$, and $C_{84}F_{44}$. In view of the low yields, preliminary characterizations of some of the compounds are available [86].

Fluorofullerenes are very reactive toward nucleophilic reactions. Although hydrophobic in the presence of a co-solvent such as acetone, an immediate exothermic reaction takes place with water. Such nucleophilic reaction means that fluorofullerenes would be unsuitable lubricants. Reaction with oxygen traces occurred during fluorination leading to formation of epoxides. For example, $C_{60}F_{18}O$ is isolated by HPLC from the product mixture from reaction leading to $C_{60}F_{18}$. The crystal structure of $C_{60}F_{18}O$ shows the oxygen atom being present in the form of a bridge at the 5,6-ring junction. Three isomers of the compound

are possible, which are isolated [87]. Seven isomers of bis-ethers $C_{60}F_{18}O_2$ are isolated and characterized by 1D and 2D ^{19}F NMR [88].

4.2.2. Chlorination

A reaction of a toluene solution of C_{60} with ICl leads to $C_{60}C_{16}$ (**41**) (Fig. 16), which is a very useful synthon for many phenylated fullerenes and derivatives [89]. Reaction of C_{70} with ICl furnishes $C_{70}Cl_{10}$ (**42**) [90]. Several of the chlorine atoms are in 1,4-positions, leading to two double bonds in the pentagon, which are also conjugated. In $C_{70}Cl_{10}$, pentagon in the center has five exocyclic double bonds. The structure is unique for a halogenated fullerene in having no double bonds in pentagons. The eclipsing adjacent chlorine atoms in both the compounds are regions of high reactivity. The compound $C_{70}Cl_{10}$ decomposes slowly in air, which is attributed to instability arising from the adjacent and eclipsed chlorines. Methoxy groups can replace all chlorine atoms from polychlorinated derivative to give polymethoxy derivatives.

4.2.3. Bromination and Iodination

Bromination of C_{60} in excess bromine gives a quantitative yield of yellow crystals of $C_{60}Br_{24}$ along with some $C_{60}Br_8$ and $C_{60}Br_6$ [91]. The bromine adds on to C_{60} by a 1,4-addition process. The bromo compounds decompose to C_{60} on heating and the stability order is $C_{60}Br_{24} > C_{60}Br_8 > C_{60}Br_6$. The instability of $C_{60}Br_8$ and $C_{60}Br_6$ may reflect the presence of four and two double bonds in pentagonal rings in their respective structures. Further, $C_{60}Br_6$, which is
Figure 16. Structures of $C_{60}Cl_6$ and $C_{70}Cl_{10}$ ($\bullet$ = Cl). Adapted from [89].

isostructural with $C_{60}Cl_6$, contains an eclipsing steric interaction [92]. C_{70} yielded a mixture of products of unknown composition. Iodination of fullerenes does not occur because steric hindrance requires the iodines to be well apart, which requires many double bonds to be on the pentagons.

4.3. Nitration, Sulphonation, and Hydroxylation

Nitration of C_{60} is carried out reacting nitronium ion generated from a mixture of H_2SO_4 and KNO_3 at 95 °C or with nitronium tetrafluoroborate in the presence of alkyl or aryl carboxylic acid in methylene chloride at ambient temperature under atmospheric pressure of N_2 [93]. In the latter reaction instantaneous formation of nitronium alkyl or aryl carboxylate salt is observed. Electrophilic attack of nitronium ion from $RCOO^-NO_2^+$ (R = C_6H_5, p-C_6H_4–Br) to C_{60} forms an intermediate $C_{60}(NO_2^+)_x$ and nucleophilic 1,3- or 1,5-substitution followed by hydrolysis finally gives a polyhydroxy organocarboxylate derivative consisting of an average of 13–15 hydroxyl substituents and 4–5 p-bromobenzoate moieties per C_{60} molecule. This upon hydrolysis gives the corresponding water-soluble fullerols consisting of 18–20 hydroxyl groups per C_{60} molecule. Nitro derivatives are also prepared by reacting C_{60} in the inert CCl_4 solution with conc. HNO_3 and NO_2 gas. The product has the composition $C_{60}(NO_2)_x(OH)_y$. Computation of structures, energetics, and vibrations of $C_{60}(OH)_x$ ($x = 2$–36) and $C_{60}(NO_2)_y$ has also been studied [94]. The computations offer a partial dissociation heat through which thermodynamic stability is measured. $C_{60}(OH)_6$ and $C_{60}(OH)_{18}$ exhibit the best value for partial dissociation heat. C_{60} is sulphonated in fuming sulphuric acid. The reaction involves initial oxidation of C_{60} followed by in-$situ$ trapping of electrophilic C_{60} cation. Reactivity of C_{60} toward oxidative sulphonation reaction induced by H_2SO_4-SO_3 is highly enhanced by P_2O_5, leading to hexacyclosulphated fullerene intermediates, which are converted to dodecahydroxy-fullerenes upon hydrolysis [95]. Hydroxy groups can be added to C_{60} by reaction with BH_3–THF complex followed by hydrolysis with glacial acetic acid, $NaOH/H_2O_2$ or NaOH. The reaction of C_{60} in toluene with potassium and hydrolysis of the product is a convenient route to fullerols. A water-soluble endohedral metallofullerol, $Pr@C_{82}O_m(OH)_n$ ($m \sim 10$ and $n \sim 10$), is synthesized through the reaction of the endohedral metallofullerene, $Pr@C_{82}$, with concentrated HNO_3 and subsequent hydrolysis [96].

4.4. Amination

Neutral nucleophiles such as amines are added to C_{60} to form the corresponding adduct. In this process a maximum of 12 amine molecules can be added to C_{60} nucleus but the most stable one is the adduct which contains six amino groups. The addition takes place across the 6,6-ring junction of the pyracylene unit resulting in an octahedral array. Controlled reactions lead to both 1,2- and 1,4-addition products. The 1,2-addition product is most stable, but depends upon the steric demand of the addend. The reaction of C_{60} with an excess of morpholine or piperidine in benzene in the presence of oxygen leads to isolation of hydrogenated

aminoadducts with a preferred 1,4-addition [97]. If the addend is very bulky, monoamine derivative of fullerene can be isolated. Addition of azacrown ethers in toluene to C_{60} at room temperature results in the monoamine derivative of fullerenes. Monoamination can be efficiently carried out following a titration technique in which addition of the amine to C_{60} solution is carried out in small portions until about 40% of the fullerene remains unreacted.

5. REACTIONS OF HALOFULLERENES

The halofullerenes undergo substitution reactions in the absence and presence of Lewis acid catalysts. When the nucleophile is an aromatic compound, the reaction can be considered an electrophilic aromatic substitution by the halogenofullerene (i.e., fullerenation of aromatics). Pure C_{60} and C_{60}/C_{70} mixtures undergo $AlCl_3$- or $FeCl_3$-catalyzed reaction with aromatics such as benzene and toluene to polyarene units by initial protonation of the cage by the $HAlCl_3OH$ super acid [98]. Ar and H are added across fullerene double bonds. In the products $C_{60}H_nAr_n$, the species with $n = 12$ and 16 are especially obtained when the aromatic group is Ph. The mechanism involves direct fullerenation of the aromatic ring by initial protonation of fullerene to the corresponding fullerene cation and subsequent Friedel–Crafts alkylation. Heating a solution of C_{60}, bromine and $FeCl_3$, in benzene leads to a C_{60} derivative with 12 phenyl groups on the cage [99]. HPLC separation of the reaction mixture leads to $C_{60}Ph_5H$ as the main product, along with $C_{60}Ph_n$ ($n = 4, 6, 8, 10, 12$), $C_{60}Ph_nO_2$ ($n = 4, 6, 8, 10, 12$), $C_{60}Ph_nOH$ ($n = 7, 9, 11$), and a number of other products from spontaneous oxidation of $C_{60}Ph_5H$ [100].

Products with well-defined structures are obtained starting from chlorofullerenes. Reaction of $C_{60}Cl_6$ with $FeCl_3$ in benzene produces $C_{60}Ph_5Cl$, which can be reduced to $C_{60}Ph_5H$ on reaction with PPh_3/H_2O [101]. This is a general reaction for a number of aromatics leading to products of the type $C_{60}Ar_5H$. The mechanism of substitution of the halogen involves an intermediate penta-arylfullerene cation, $C_{60}Ph_5^+$, isolated as the $AlCl_3$ catalyst [102]. Other by-products of the reaction are $C_{60}Ph_2$ and $C_{60}Ph_4$. On exposure to air, both $C_{60}Ph_5H$ and $C_{60}Ph_5Cl$ spontaneously oxidize with elimination of the hydrogen or chlorine attached to the cage and the ortho hydrogen of the adjacent phenyl group, giving a benzo[b]furanyl[60]fullerene; a second oxygen is located in the pentagon that is surrounded by phenyl groups [103]. $C_{60}Ph_5Cl$ reacts with CNBr in the presence of $FeCl_3$ producing a bromoisoquinolino[60]fullerene arising from nucleophilic replacement of the chorine by N≡C-Br, followed by electrophilic substitution into the ortho position of the adjacent phenyl ring. Reaction of bromoisoquinolino[60]fullerene with OH^- ion leads to isoquinolino[3′,4′:1,2][60]fullerene [104]. $C_{60}Cl_6$ reacts with allyltrimethylsilane in the presence of $TiCl_4$ to form a C_s symmetrical, hexaallyl[60]fullerene derivative, $C_{60}(CH_2CH = CH_2)_6$ [105]. The use of $FeCl_3$ as the Lewis acid catalyst in this reaction also produces the same product but in low yields.

Reaction of $C_{70}Cl_{10}$ with $FeCl_3$ in benzene produces $C_{70}Ph_8$ and $C_{70}Ph_{10}$ as the major phenylated derivatives,

along with $C_{70}Ph_9OH$ as a minor component [106]. $C_{70}Ph_8$ gets converted to a bis-lactone, a fullerene with a hole (called a "holey fullerene"), which is a bis-lactone, $C_{70}Ph_8O_4$ [107]. Reaction is light catalyzed and proceeds via insertion of oxygen into [5,6]-bonds followed by oxidative cleavage of the adjacent double bond.

$C_{60}F_{18}$ reacts with benzene/$FeCl_3$ to give the triphenylated compound $C_{60}F_{15}Ph_3$. The structure of the compound is determined from ^1H and ^{19}F NMR studies, which shows that the phenyl groups replaced the three most accessible halogens of $C_{60}F_{18}$ [108].

6. η^5-FULLERENE METAL COMPLEXES

In the exohedral fullerene–transition metal complexes, the fullerenes act as an olefinic ligand and bind the metal center in η^2-fashion [109]. There are several examples of η^5-fullerene metal complexes [110]. For this purpose a cyclopentadiene moiety is generated on the fullerene surface from a pentaadduct, such as $C_{60}Ph_5H$. A number of cyclopentadienyl (Cp) metal complexes (η^5-$C_{60}Ph_5$)MLn (**43**) (MLn = Li, K, Tl, Cu · PEt_3) are synthesized (Fig. 17) using the cyclopentadienyl ring generated through deprotonation of the parent compound $C_{60}Ph_5H$ (**44**) (Fig. 18) [111]. In the process, the carbon atoms bearing the phenyl groups change the hybridization from sp^2 to sp^3. The cyclopentadienide moiety in the penta-adduct **44** appears to be electronically isolated from the bottom 50 sp^2 carbon atoms with the surrounding 5 sp^3 carbon atoms. Theoretical and electrochemical evidence, however, indicates that these two parts show a strong sign of mutual electronic interaction [112]. The η^5-fullerene metal complexes show promise as catalysts and materials of unique steric, electronic, and photonic properties.

Treatment of the pentaphenyl adduct $C_{60}Ph_5H$ with an alkali metal alkoxide such as LiO^tBu, KO^tBu, and TlOEt leads to Li(η^5-$C_{60}Ph_5$), K(η^5-$C_{60}Ph_5$), and Tl(η^5-$C_{60}Ph_5$), respectively. From the ^1H and ^{13}C NMR spectra it is observed that the reaction leads to conversion of the C_s symmetric $C_{60}Ph_5H$ to a new species possessing C_{5v} symmetry. The singlet peak due to the CpH proton ($\delta5.31$ for $C_{60}Ph_5H$) disappears in the formation of the complexes. The synthesis of [Cu(η^5-$C_{60}Ph_5$)(Ph)]$^-$ involves the fivefold addition of an organocopper reagent to C_{60}. This is accomplished by the reaction of C_{60} with an excess amount of organocopper reagent prepared from PhMgBr and CuBr · SMe_2 followed by quenching with aqueous NH_4Cl. The reaction of $C_{60}Ph_5H$

43

**Figure 17.** The pentahaptofullerene metal complexes. Adapted from [110].

Figure 18. Synthesis of the pentaphenyl fullerene adduct $C_{60}Ph_5H$. Adapted from [111].

with $Cu(O^tBu)(PEt_3)$ gives a phosphine-coordinated transition metal complex $Cu(\eta^5\text{-}C_{60}Ph_5)(PEt_3)$. These complexes are sensitive to air and moisture but thermally stable in solution at room temperature.

The X-ray single crystal structure analysis for the thallium(I) complex shows the thallium atom as deeply buried in a cavity created by the five phenyl groups. The metal atom is equally bonded to the five Cp carbons with an average bond length of 2.87 Å. The thallium complex adopts approximately C_5 symmetric conformation with the phenyl groups arranged in a chiral propeller array. The ^1H and ^{13}C NMR spectra of the complex indicate free rotation of the phenyl groups at room temperature in solution. However, the solid phase structure implies that the enantiomer separation is possible by a suitable modification of the aromatic substituents that can inhibit ring rotation.

The structural constraints of the fullerene core cause significant deformation of local structure around the Cp ring. Still the C_{60} core largely retains its original spherical form, with the average lengths of the C–C double bonds (1.38 Å) and the single bonds (1.44 Å) in the C_{50} moiety being similar to those of monofunctionalized C_{60} derivatives. The UV-vis spectra of both the cyclopentadiene derivative $C_{60}Ph_5H$ and the thallium complex show that the 50 π-electron C_{50} moiety is a chromophore of intensity comparable to that of the parent C_{60}. The absorption extends to fairly long wavelengths (670 nm for $C_{60}Ph_5H$, 720 nm for the complex) suggesting that these fullerene derivatives have electronic properties similar to those of the parent C_{60}.

The reaction is very general for various aryl and alkenyl groups as well as for methyl group [113] (Fig. 19). The synthesis of the alkenyl product is accomplished using a 1-alkenyl copper reagent prepared from the corresponding lithium reagent instead of the Grignard reagent employed for the synthesis of the arylated and the methylated analog (Fig. 20). The alkenyl substitutents can be E or

Figure 20. Regioselective penta-addition of 1-alkenyl copper reagent to C_{60}. Adapted from [113c].

Z depending upon the alkenyllithium reagent used. The reagents react with retention of stereochemistry. Thus, the product $C_{60}[(E)\text{-}1\text{-propenyl}]_5H$ (**47**) is found to be C_s symmetrical from NMR studies. Upon conversion to $C_{60}[(E)\text{-}1\text{-propenyl}]_5K$ (**48**), the symmetry changes to the expected C_{5v}. The alkenyl substituents extend upward from the fullerene core, which is the most stable structure obtained by Monte Carlo structural search with a molecular mechanics (MM2) force field.

The mechanism of addition of the five R groups is not clear, though a rationale for the mechanism is proposed [110] where the reaction goes in a stepwise manner, first putting two R groups in a 1,4-manner (**49**) [114], then the third and the fourth, and finally the fifth (**51**) (Fig. 21). There is a series of experimental evidence that supports this pathway. When 1,4-dibenzylated fullerene is treated with phenylcopper reagent, dibenzyltriphenyl compound is formed quantitatively, indicating that the 1,4-di-adduct lies on the pathway to the penta-adduct. Interestingly, the reaction stops at the tri-addition stage when a phenyl Grignard reagent is used instead of a phenyl copper reagent.

Figure 19. The versatility of penta-addition to C_{60}. Adapted from [113c].
Figure 21. Proposed mechanism of penta-addition. Adapted from [110].

The reaction of the 1,4-dibenzylated fullerene derivative with PhMgBr cleanly affords the triaddition product.

Similar reactions are also investigated with C_{70} [115]. The reaction of C_{70} with the organocopper reagent does not lead to the expected pentakis adduct but a tris adduct $C_{70}(4\text{-CF}_3\text{-}C_6H_4)_3H$ (**52**) with an indene-like substructure flanked by the three sp^3 carbons (Fig. 22). The tris adduct **52** is deprotonated with metal alkoxides (KO^tBu, TlOEt) to form the corresponding C_s-symmetric metal complexes $C_{70}(4\text{-CF}_3\text{-}C_6H_4)_3M$ [M = K, Tl] (**53**). The *ab initio* MO studies (HF/3-21G$^{(*)}$) suggest that the fullerene group $C_{70}(4\text{-CF}_3\text{-}C_6H_4)_3^-$ in $C_{70}(4\text{-CF}_3\text{-}C_6H_4)_3M$ coordinates to the metal as an η^5-indenylide rather than an η^3-ligand. The η^5-coordination is confirmed from the X-ray diffraction study of the thallium complex. In contrast to C_{60}, the higher fullerene C_{70} has two areas of different reactivity. One is the inert equator area, and the other is the more reactive C_{60}-like region near the poles. The latter possesses two different kinds of double bonds, 10 $C_a\!=\!C_b$ and 10 $C_c\!=\!C_c$. The first step of the tris addition is likely to be the regioselective carbocupration of the most reactive double bond $C_a\!=\!C_b$ with one molecule of $(4\text{-CF}_3\text{-}C_6H_4)_2Cu^-$ giving the metalated fullerene **55**, which may equilibrate with the 1,4-addition product **56**. This species decomposes to form the 1,4-bisarylation product **57**, Cu(0), and one electron, which is given to the Cu(I) species that exists in excess in the solution. The third aryl group adds to $C_c\!=\!C_c$ to form the stable copper(I) species with three aryl groups (**58**), which gives $C_{70}(4\text{-CF}_3\text{-}C_6H_4)_3H$ upon hydrolysis.

Contrary to the isolated six cyclopentadienyl anion in the pentakis-arylated fullerene ligand $C_{60}Ph_5^-$, the corresponding five-membered ring of the C_{70} analog is directly conjugated with the remaining polyene moiety of the C_{70} cage. Therefore, various structures are conceivable for the complexes $C_{70}(4\text{-CF}_3\text{-}C_6H_4)_3M$ as to the position of the metal binding site. Among those the most probable ones are η^3- and η^5-complexes, in which the metal atom is coordinated to the three or five sp^2 carbon atoms flanked by the three sp^3 carbon atoms. Such a consideration is a reasonable one since the pyramidization at the three sp^3 carbons makes the adjacent three sp^2 carbons [C(1), C(2), C(2′)] more planar, and this planarity should favor the interaction with the metal atom. The C_s symmetry observed in the NMR spectra of the complexes is consistent with both the η^3- and η^5-structures. The *ab initio* molecular orbital calculations (HF/3-21G$^{(*)}$) and X-ray crystallographic analysis show that the thallium atom is located equidistant from the three aryl groups and bonded to the pentagon flanked by the three sp^3 carbons.
7. FULLERENE–FERROCENE HYBRID

Ferrocene is composed of a pair of 6π-electron pentagonal carbon arrays and a $6d$-electron iron(II) atom. Fusion of ferrocene and C_{60} through face-to-face resulting in a "bucky ferrocene" is intriguing, since such a molecule would manifest the properties typical of both ferrocenes and fullerenes. The ferrocene/fullerene hybrids of C_{60} (**60**) and C_{70} (**62**) by the use of penta- (**59**) and tri-adducts (**61**) of fullerenes, respectively, are reported (Fig. 23) [116].

The hybrid molecule $Fe(C_{60}Me_5)Cp$ is obtained in low yield by reaction between $FeBrCp(CO)_2$ and a thallium complex of pentamethylated [60]fullerene $Tl(C_{60}Me_5)$. A more expeditious route is heating $C_{60}Me_5H$ (**59**) and $[FeCp(CO)_2]_2$ together in benzonitrile at 180 °C for 8 h that was produced in 52% yield. The X-ray crystal structure shows the five methyl groups to protrude outward at an

Figure 22. The indenelike fullerene ligand, its metal complexes via tris-arylation of C_{70}, proposed mechanism of trisarylation, and subsequent complexation. Adapted from [115].

Figure 23. Synthesis of ferrocene fullerene hybrids. Adapted from [116].

angle of 42° relative to the symmetry axis of the molecule. The methyl and Cp hydrogen atoms are in van der Waals contact with each other. The Cp group and cyclopentadienide in the fullerene moiety are arranged in a staggered manner. All C–C bond lengths in each pentagon are equal to each other and hence both rings are aromatic. The distances between the pentagon carbon atoms and the iron are comparable to those in known ferrocene derivatives. ^{1}H and ^{13}C NMR spectra indicate that **60** has C_{5v} symmetry and that the methyl groups rotate freely (a single signal at $\delta 2.51$ ppm). The ^{13}C NMR signal of the Cp carbon atoms indicates strong electron-withdrawing effects of the fullerene moiety. The UV/visible spectrum is similar to those of C_{60}. The hybrid compound can be oxidized reversibly like ferrocene and reduced reversibly like fullerene. Such physicochemical properties of **60** are consistent with the presence of homoconjugation between the bottom C_{50} moiety and the Cp anionic moiety.

Treatment of $C_{70}Me_3H$ with $[FeCp(CO)_2]_2$ in benzonitrile at 160 °C for 21 h leads to **62** in 31% yield. ^{1}H and ^{13}C NMR spectra at 25 °C indicate that **62** is C_s symmetric and that the methyl groups rotate freely [singlet signals at $\delta 2.81$ (3H) and 2.93 ppm (6H)]. The Cp protons resonate also as a singlet at $\delta 4.89$ ppm, indicating free rotation of the Cp group. The X-ray crystal structure of **62** shows the distances between the pentagon carbon atoms and the iron as well as the C–C bond lengths in the Cp ligand as comparable to those of ferrocene. A small but significant difference between **60** and **62** is that the cyclopentadienide C–C bond connected to a hexagon in the "belt region" of the C_{70} core is slightly longer than the remaining four C–C bonds in the pentagon, a feature known for indenyl iron complexes.

8. RING EXPANSION REACTIONS

Fullerene ring expansions by a number of [2 + n]-cycloaddition reactions, where $n = 1$–4, have been reported. The subject has been comprehensively reviewed [117], some with exhaustive details [118].

8.1. [2 + 1] Cycloadditions: Reactions Leading to Bridging

[2 + 1]-Cycloaddition reactions on fullerenes are convenient routes to exohedral functionalization via metal, oxygen, carbon, and nitrogen bridging. Addends suitably modified lead to introduction of a number of functional groups attached to the bridging position. Both single and multiple additions are possible. Multiple additions lead to regiosymmetric isomers.

8.1.1. Metal Bridging

Fullerenes are versatile multifunctional ligands. Through the π-bonds they can react with a variety of metal centers. Some of the metal complexes form cocrystals readily with the fullerenes. For example, mixing solutions of C_{60} or C_{70} and ferrocene results in crystallization of the solid adducts with compositions $C_{60} \cdot 2\{(\eta^5\text{-}C_5H_5)_2Fe\}$ [119] and $C_{70} \cdot 2\{(\eta^5\text{-}C_5H_5)_2Fe\}$ [120]. A benzene solution of C_{60} and $Fe_4(CO)_4(\eta^5\text{-}C_5H_5)_4$ produces crystals of $C_{60} \cdot \{Fe_4(CO)_4(\eta^5\text{-}C_5H_5)_4\} \cdot 3C_6H_6$ [121]. Extensive study

involving a number of metal centers, such as, Ru, Re, Ir, Os, Pt, etc., covalently bound to fullerenes is known and the subject is reviewed periodically [122].

In reaction with metal derivatives, C_{60} behaves as an alkene (giving η^2-coordination) rather than an aromatic (η^6-coordination). Treatment of C_{60} with $(\eta^5\text{-}C_5H_5)_2ZrHCl$ in benzene yields a deep red solution which is believed to contain a mixture of adducts: $\{(\eta^5\text{-}C_5H_5)_2ZrCl\}_nC_{60}H_n$ with $n = 1, 2,$ and 3. Hydrolysis of this mixture produces $C_{60}H_2$ along with $C_{60}H_4$ and $C_{60}H_6$ [123]. A number of stable $\eta^2\text{-}C_{60}$ complexes of tungsten and molybdenum are known. Photolysis of $W(CO)_4(Ph_2PCH_2CH_2PPh_2)$ and C_{60} in 1,2-dichlorobenzene produces both $(\eta^2\text{-}C_{60})W(CO)_3(Ph_2PCH_2CH_2PPh_2)$ and $(C_{60})\{W(CO)_3(Ph_2 \cdot PCH_2CH_2PPh_2)\}_2$ [124]. Similarly, photolysis of $Mo(CO)_4(Ph_2PCH_2CH_2PPh_2)$ and C_{60} produces $mer\text{-}(\eta^2\text{-}C_{60})Mo(CO)_3(Ph_2PCH_2CH_2PPh_2)$ along with a mixture of $C_{60}\{Mo(CO)_3(Ph_2PCH_2CH_2PPh_2)\}_2$ and $C_{60}\{Mo(CO)_3 \cdot (Ph_2PCH_2CH_2PPh_2)\}_3$ [125]. The radical $Re(CO)_5$ obtained from $Re_2(CO)_{10}$ through photolysis or from $(\eta^3\text{-}Ph_3C) \cdot Re(CO)_4$ through thermolysis in the presence of CO adds to C_{60} to produce $C_{60}\{Re(CO)_5\}_2$ [126].

Treatment of C_{60} with osmium tetroxide in the presence of pyridine yields either the single addition product, $C_{60}O_2OsO_2(py)_2$ (**63**), and/or a mixture of five double addition products, $C_{60}\{O_2OsO_2(py)_2\}_2$ (**64**) (Fig. 24) [127]. The single addition product can be separated from the double addition products, since the single addition product has a higher solubility in toluene. Osmylation of C_{70} in pyridine produces two single addition products, $C_{70}\{O_2OsO_2(py)_2\}$ [128]. The osmyl groups added to the C_a–C_b and to the C_c–C_c bonds of the fullerene, respectively.

The carbonyls of Os, Ru, and Fe also react with C_{60}. Heating toluene solution of C_{60} and $Os_3(CO)_{11}(NCMe)$ or other lower valent compounds such as $Os_3(CO)_{11}(PPh_3)$ and $Os_3(CO)_{10}(PPh_3)_2$ results in the triangular Os_3 compounds (Fig. 25) [129]. $Ru_3(CO)_{12}$ reacts with C_{60} to form soluble $Ru_3(CO)_9(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-}C_{60})$ (Fig. 26) [130] and insoluble Ru_3C_{60} [131]. $Ru_3(CO)_{12}$ also reacts with C_{70} to form two products, $Ru_3(CO)_9(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-}C_{70})$ and $\{Ru_3(CO)_9\}_2(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-}C_{70})$ [132]. The ruthenium carbide clusters, $Ru_5C(CO)_{15}$ and $Ru_6C(CO)_{17}$, react with C_{60} followed by treatment PPh_3 to form $Ru_5C(CO)_{11}(PPh_3)(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-}C_{60})$ and $Ru_6C(CO)_{12}(Ph_2PCH_2PPh_2)(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-}C_{60})$ [133]. In these complexes C_{60} reacts with a triangular face of the ruthenium cluster.

Iron carbonyl $Fe_3(CO)_{12}$ reacts with 1,2-(3,5-cyclohexadieno)C_{60} to form $Fe(CO)_3$ adduct (**68**) in which the metal is coordinated to the exterior cyclohexadiene portion rather than to the fullerene itself (Fig. 27) [134]. UV irradiation of toluene solutions of C_{60} and $Fe_2S_2(CO)_6$ results in the

63   **64**

**Figure 24.** Structures of $C_{60}O_2OsO_2(py)_2$ and $C_{60}\{O_2OsO_2(py)_2\}_2$ (one of the five isomers shown). Adapted from [127].

Figure 25. A triangular Os_3 complex of C_{60}. Adapted from [129].

formation of $C_{60}S_2Fe_2(CO)_6$, along with some multiple addition products [135].

Ir(CO)Cl(PPh$_3$)$_2$ and related complexes with different phosphine ligands react with C_{60} [136]. The reaction leads to formation of adduct of the type (η^2-C_{60})Ir(CO)Cl(ER$_3$)$_2$ (E = P or As, R = alkyl or aryl). Slow diffusion of a concentrated benzene solution of C_{60} into a benzene solution of Ir(CO)Cl(PPh$_3$)$_2$ produces the adduct (η^2-C_{60})Ir(CO)Cl(PPh$_3$)$_2 \cdot 5C_6H_6$ (Fig. 28) [136]. Like fullerenes, their epoxides also react very efficiently with iridium complexes. $C_{60}O$ reacts with Ir(CO)Cl(PPh$_3$)$_2$ to form crystals of (η^2-$C_{60}O$)Ir(CO)Cl(PPh$_3$)$_2 \cdot 5C_6H_6$ [137]. Reaction of a mixture of the two $C_{70}O$ isomers with Ir(CO)Cl(PPh$_3$)$_2$ yields (η^2-$C_{70}O$)Ir(CO)Cl(PPh$_3$)$_2 \cdot 5C_6H_6$ [138]. Heating a benzene solution of the indenyl iridium complex, (η^5-C_9H_7)Ir(CO)(η^2-C_8H_{14}), with C_{60} produces the complex (η^2-C_{60})Ir(CO)(η^5-C_9H_7) [139], which dissolves in aromatic and chlorinated solvents to give stable solutions.

RhH(CO)(PPh$_3$)$_3$ is a catalyst used for the homogeneous hydrogenation of olefins. Efforts to catalyze the hydrogenation of C_{60} using this have not been successful. However, it reacts with C_{60} forming the complex (η^2-C_{60})RhH(CO)(PPh$_3$)$_2$ [140]. The reaction of C_{60} with (η^5-bicyclo[3.2.0]hepta-1,3-dienyl)(η^4-tetraphenylcyclobutadiene)cobalt(I) proceeds via a ring slippage reaction through an η^3-intermediate that undergoes a [4 + 2] cycloaddition to the fullerene [141]. Mixing solutions of C_{60} and (Ph$_3$P)$_2$Pt(η^2-C_2H_4) produce (η^2-C_{60})Pt(PPh$_3$)$_2$ [142]. Related complexes with nickel, palladium, and platinum can also be obtained by treatment of C_{60} with M(PR$_3$)$_4$ [143]. Multiple addition to C_{60} has been examined through the reactions of M(PEt$_3$)$_4$ (M = Pt or Pd) with this fullerene. With an excess of M(PEt$_3$)$_4$, a stable hexaaddition
Figure 26. The structure of Ru$_3$(CO)$_9$(μ_3-η^2, η^2, η^2-C_{60}). Adapted from [130].

**Figure 27.** Fe(CO)$_3$ adducts of C_{60}. Adapted from [134].

product is obtained [144]. Addition of the labile complex, Pd$_2$(dba)$_3 \cdot$ CHCl$_3$ (dba, dibenzylideneacetone), to a benzene solution of C_{60} yields a black, amorphous, air-stable solid [145]. This material is insoluble in common organic solvents and, consequently, is believed to have a polymeric structure.

8.1.2. Oxygen Bridging

The mass spectra of C_{60} and C_{70} are accompanied by satellite ions in low abundance. Changes in the relative ion abundances of these peaks with the method of sample preparation and as a function of evaporation into the mass spectrometer suggest that there are several different fullerene adducts corresponding to the addition of 14, 15, 16, and 17 daltons. The mass increases are assigned to CH$_2$, CH$_3$, O, and OH, respectively. The M + 16 adduct is interpreted as sequential cyclopropanation and epoxidation product of monoxides [146]. Ultraviolet irradiation of C_{60} in the presence of oxygen in hexane gives rise to the corresponding epoxides [147]. When these epoxides are heated the corresponding ethers are formed. The addition of oxygen takes place across the 6,6-junction of pyracylene unit of C_{60}. The epoxides are degraded to the carbonyl containing compounds upon extensive irradiation. The eight symmetry nonequivalent bonds in C_{70} yield as many as eight isomeric epoxides and an equal number of oxidoannulenes. The isolation of $C_{70}O$, a minor component of the fullerene mixture obtained by resistive heating of graphite, is reported [148]. The compound is an annulene with the oxygen atom bridging an unspecified 6,6-ring fusion. Addition of O$_3$ onto C_{60} leads to molozonide. The spherical nature of C_{60} places stringent steric constraints on the conversion of the molozonide intermediate to the ozonide. In the presence of toluene molozonide rearranges to 1,2-diketone. The oxidation occurs at the various double bonds of C_{60} generating a mixture of oxidized product having ketonic, ester, and epoxide functionalities [149]. Small amounts of C_{60} epoxides are detected, but the bulk of the product consists of highly oxidized derivative of the fullerene.

Figure 28. Structure of (η^2-C_{60})Ir(CO)Cl(PPh$_3$)$_2$. Adapted from [136].

The photooxidation of C_{60} in benzene furnishes a mono oxide $C_{60}O$ as the sole isolable product in 7% yield [150]. Addition of benzil significantly enhances both the yield (16%) and the rate of oxidation. Electrochemical oxidation of C_{60} in benzene generates $C_{60}O_n$ ($n = 1$–4) [151]. A 1,2-diepoxy[60]fullerene is isolated in the analysis of the metabolic transformation of C_{60} [152]. From the spectroscopic data, out of the three possible symmetrical structures the diepoxide is identified as the 1,2;3,4-diepoxy[60]fullerene. It is seen that the oxygen atom transferred from the active species is introduced at a double bond adjacent to an existing epoxide. In addition to the diepoxide, two triepoxides are also isolated and identified as 1,2;3,4;9,10-triepoxy[60]fullerene and 1,2;3,4;11,12-triepoxy[60]fullerene.

8.1.3. Carbon Bridging

The cyclopropanation reaction is synthesis of a C_{61} or C_{71} species, the extra carbon atom forming a bridge. Cyclopropanation is accomplished through (i) the reaction with stabilized carbanion, (ii) addition of a carbene, and (iii) the thermal addition of diazo compounds followed by thermolysis or photolysis of the resulting intermediates. Addition may take place across either a 6,6- or a 5,6-ring junction, resulting in either closed-fullerene or open-fulleroid structures. A total of four configurations are possible, that is, 6,6-open, 6,6-closed, 6,5-open, and 6,5-closed (Fig. 29). If the derivative of fullerene contains cyclopropane rings (6,5-closed and 6,6-closed), the product is called methanofullerene; otherwise it is called fulleroid (6,5,6-open and 6,6-open).

A bridging carbon atom can be introduced by several routes, such as the Bingel reaction, which is the reaction of the fullerenes with a stabilized α-halocarbanion [153]. Treatment of C_{60} with (i) 2-bromomalonic ester in the presence of NaH, (ii) reaction of the bromo compound with C_{60} in the presence of DBU (1,8-diazabicyclo[5.4.0]undec-7-ene), (iii) a compound with a reactive methylene group with I_2 or CBr_4 in the presence DBU (*in-situ* formation of 2-iodo- or 2-bromomalonates) are the three most used routes for Bingel reaction (Fig. 30) [154]. NaH is nonnucleophilic; primary and secondary amines cannot be used as they add on to C_{60}. The mechanism of the reaction is the initial formation of a carbanion, which attacks C_{60}; the resulting C_{60} carbanion intermediate eliminates Br^- resulting in the methanofullerene. Reaction of phosphonium ylides or sulphur ylides also leads to methanofullerenes via an addition–elimination mechanism (Fig. 31) [155].

Cyclopropanation of fullerenes using haloalkanes can be carried out using reactions other than the Bingel route. A fast and simple route for the selective synthesis of methanofullerenes that use the reaction between iodo- and

Figure 30. Three most used routes for Bingel reaction. The reactions shown are illustrative examples. Adapted from [153, 154].

bromo-reagents and the C_{60} dianion generated by electrochemical reduction has been reported (Fig. 32) [156]. Addition takes place at the 6,6-ring junction.

Reaction of C_{60} with dibromocarbene generated from $PhHgCBr_3$ leads to efficient cyclopropanation, though fullerene dimers are formed as the product. Methanofullerene-containing stable phosphorous ylide is obtained by the reaction of C_{60} with a mixture of triphenylphosphine and dimethyl acetylene carboxylate. A carbanion generated as a reaction intermediate adds on to C_{60} [157].

In a number of reactions diazo compounds are used as precursors of carbenes. Thermal addition of the diazo compound to C_{60} leads to the formation of 6,6-closed and 6,5-open cycloadducts depending upon the condition of the reaction. There can be two possible routes to cyclopropanation: (1) thermal decomposition of the diazo compound to carbenes and addition of carbenes to the 6,6-bond in

C_{60} and (2) elimination of nitrogen from the pyrazoline intermediate. Formation of the pyrazoline intermediate **73** (Fig. 33) and elimination of nitrogen can lead to both 6,5-open (**74**) and 6,6-closed (**75**) isomers. The 6,5-open isomers containing stabilizing substituents in the methane bridge rearrange to the thermodynamically more stable 6,6-closed isomers. The pyrazolone is prepared by addition of diazomethane to a 6,6-bond of C_{60} [158]. Thermolysis of the pyrazolone furnishes the rearranged fulleroid (6,5-open isomer). The photolysis of the pyrazolone leads to, in addition to the fulleroid, the methanofullerene (6,6-closed isomer) [159].

Addition of diazomethane to C_{70} is more complex because there are eight different types of bonds in C_{70}. Several studies [160] have revealed that the bonds **I** and **II** in C_{70} (**76**) (Fig. 34) are the shortest bonds suggesting that they should be most reactive. Further it is observed that bond **I** is more reactive than **II**, which is attributed to greater local curvature [128]. In fact addition of diazomethane takes place at position **I** leading to a mixture of isomeric pyrazolines, which upon photolysis gives two isomeric $C_{71}H_2$ cyclopropanes. Thermolysis of the pyrazolines (**77**, **78**) produces two isomeric 6,5-open isomers [162].

A number of diazo compounds such as dimethyldiazomethane, diethyl diazoacetate, and diphenyl diazomethane undergo 1,3-dipolar addition reaction with C_{60} followed by elimination of N_2 to introduce $(CH_3)_2C$, $(C_2H_5)_2C$, Ar_2C groups, respectively, into the carbon framework (Fig. 35). The reaction of dimethyldiazomethane with C_{60} leads to the annulene the 6,5-open isomer, which upon

Figure 34. Addition of diazomethane to bond **I** of C_{70} leading to two isomeric pyrazolines, which furnish 6,6-closed or 6,5-open isomers on photochemical or thermal reaction conditions, respectively. Adapted from [162].

heating is converted to methanofullerene [163]. A similar conversion is observed for a fulleroid carrying phenyl and methyl butyrate substituents under photochemical conditions [164]. The mechanism of the conversion is stated to be di-π-methane rearrangement (Fig. 36). The diradical formed is stable due to the attachment of phenyl groups. For fulleroids with methyl substituent the thermal conversion to methanofullerene is a disrotatory migration of the bridging methylene group to a 6,5-ring junction followed by [1,5]-sigmatropic shift to the 6,6-ring junction. As stated previously there can be four possible configurations for a bridging group introduction to C_{60}. Among these the 6,5-open isomer is the lowest energy product. The energetic preference for this structure is due to maximizing the number of double bonded 6,6-ring junctions. The 6,5-open isomer is stable under kinetically controlled conditions while the 6,6-closed isomer is stable under thermodynamically controlled conditions.

Figure 38. Spiro-linked *C*-glycosides of C_{60}. Adapted from [168].

In some cases of addition reactions involving diazo compounds a specific product may be formed exclusively. Thus the thermal or photochemical reaction of fullerene with quinoid-type diazo compounds with C_{60} in *o*-dichlorobenzene under an atmosphere of nitrogen affords exclusively 6,6-closed spiromethanofullerenes [165]. In some cases a reactive substituent on the methylene bridge can take part in further reaction. In the thermal addition of diazoketone, the 6,6-closed isomer further rearranges to the dihydrofuranofullerene derivative [166]. The production distribution from the reaction of carbenes with C_{60} can be influenced by catalysts, for example, $Rh_2(OAc)_4$ complex catalysis of the reaction of ethyl diazoacetate and ethyl diazomalonate with C_{60} [167]. The catalyst increases the selectivity and yield. Reaction carried out without catalyst gives a 6,5-open isomer as the predominant product, whereas in presence of the catalyst the 6,6-closed isomer is almost exclusively formed (Fig. 37).

Alkyl and acyl-protected 1-azi derivatives can be used as precursors of nucleophilic carbenes of monosaccharides. These derivatives react with acceptor- and donor-substituted alkenes to yield spiro-linked glucosylidene cyclopropanes. The *O*-benzyl protected diazirine reacts with C_{60} to afford the monoglycosylated adduct, **90** (Fig. 38) [168].

Stable hydrazones and their derivatives are also used for cyclopropanation. The reaction proceeds through the initial 1,3-dipolar cycloaddition reaction of the hydrazone to C_{60} followed by nitrogen elimination from the resulting pyrazoline intermediate, **91** (Fig. 39). The reaction is carried out in the presence of MnO_2–KOH–EtOH. Mixtures of 6,6-closed and 6,5-open derivatives are obtained [169]. Thermolysis of lithium or sodium salts of tosylhydrazones leads to mixtures of 6,6-closed and 6,5-open isomers. Reaction conditions are optimized to yield the 6,5-open isomer. On prolonged reaction, the kinetic product rearranges into the more stable 6,6-closed thermodynamic product [170]. Reaction of hydrazones containing *p*-diarylaminoaryl electron-donating groups affords the thermodynamically more favored 6,6-closed isomer as the only product even at low temperature [171].
The silyl enol ether under the influence of KF/18-crown-6 or tetrabutylammonium fluoride can generate nucleophilic species *in-situ*. The reaction of C_{60} and silyl enol ether of 4-methoxyacetophenone in the presence of the complex of KF and 18-crown-6 leads to efficient cyclopropanation (Fig. 40) [172].

Interaction between Substituents and Fullerene Cage

Substituents attached to the bridging carbon atom can exercise considerable influence on the fullerene sphere though not directly attached to it. Cyclovoltametry is the most direct method for studying the influence of addends on the electronic properties of fullerenes. CV data of a number of spiroannelated fullerene analogs show remarkable substituent effects. For a number of fluorenofullerenes isolated exclusively as adducts on 6,6-ring junctions [173], the CV spectra clearly demonstrate the striking influence of electron-donating and electron-withdrawing groups of the fluorenyl group on the C_{60} moiety (Fig. 41). This indicates that the substituents, even though separated from the fullerene cage by a spiro atom, can still strongly interact with the fullerene. Interestingly, the CV data of diphenylmethanofullerene with electron-donating and electron-withdrawing groups in the *p,p*'-positions of the phenyl rings are independent of the functional groups, indicating that similar interactions as seen for the spiroannelated fullerenes is not operating in the diphenylmethanofullerene.

This is explained by periconjugation, which is the interaction between the p_z orbitals of the addends and the "p_z" orbitals of the adjacent fullerene carbon atoms (Fig. 42). The mode of interaction of the p_z orbitals is geometrically completely different from spiroconjugation as seen from the relative orientations of the orbitals involved. The crucial difference between 9,9-fluorenofullerenes and diphenylmethanofullerene is that in the latter the phenyl rings are free to rotate but prefer to lie "parallel" to the fullerene surface, whereas the aromatic rings in fluorenofullerenes are held rigidly perpendicular to the surface of the spheroid.

Periconjugation is also possible when the substituents attached to the bridging carbon atom carrying π-bonds are strongly electron withdrawing. Among a number

of methanofullerenes with cyano, nitro, and carboethyl substituents on the bridging carbon (Fig. 43) [174], the bis(cyano)methanofullerene showed an irreversible reduction peak, which is 160 mV more positive than the corresponding step in C_{60}. A comparative study of methanofullerenes carrying electron-donating and electron-withdrawing substituents, using Hammett σ_m, shows that the cyano substituent appears to be more electron withdrawing than predicted by the Hammett relation. This is ascribed to periconjugation, as seen for the spiroannelated fullerenes. A number of electroactive substitutents such as ferrocenyl, tetrathiafulvalene, etc. are appended to the bridging carbon in C_{60} (Fig. 44) [175].

Introduction of Coordinating Ligands The Bingel reaction is versatile since many derivatives with active methylene groups are known. Functional groups with specific properties can be appended choosing the right kind of reactants, such as introduction of groups with coordination sites (Fig. 45). Reaction of a stabilized carbanion from bis(4-pyridyl)chloromethane with C_{60} under Bingel conditions leads to introducing pyridyl rings to the fullerene [176], which can act as a ligand for generation of metallo-organic frameworks.

A C_{60} derivative containing a 2,2′-bipyridine (bpy) moiety (**108**) is used for electrochemical, quantum chemical, and spectroscopic techniques to study the dynamics of the reduction of bpy-C_{61} (Fig. 46) [177]. Quantum chemical calculations showed that triply and quadruply reduced bpy-C_{61} undergoes facile conversion among three of its structural isomers.

Fullerene-substituted 2,2′:6′,6″-terpyridine (tpy) ligands (**109**) are synthesized [178] (Fig. 47). Polyethyleneoxy spacers are introduced between the tpy ligand and the fullerene to allow the synthesis of a series of Ru^{II} diad and triad

systems with variable metal–fullerene distances. The electrochemical interaction between the pendant fullerenes and metal-based photocenters are studied. Electron-releasing dimethylamino substituent is seen to have a dramatic effect upon the Ru^{II}–Ru^{III} redox processes for these complexes.

Multiple Additions Multiple additions on C_{60} lead to a number of regioisomeric products. Regioselective and stereoselective syntheses starting from bis-adducts to hexakis adducts have been reviewed [179]. The problem is best illustrated by the sequential cyclopropanation of C_{60} with diethyl 2-bromomalonate in the presence of base. With reference

to a group already existing on a 6,6-ring junction, a second addend can occupy any one of the nine possible 6,6-bond positions. These are *cis*-1, -2, -3, *trans*-1, -2, -3, -4, e_{face}, and e_{edge} (**111**) (Fig. 48). Eight bisadducts are possible because the two positions e_{face} and e_{edge} are identical if the two addends of the bisadduct are identical. In case of addition of 2-bromomalonate to $C_{61}(COOEt)_2$, of the possible eight bisadducts, $C_{62}(COOEt)_4$, seven regioisomers have been isolated in various quantities [180], affording the e-$C_{62}(COOEt)_4$ in highest yield (~15%) followed by *trans*-3-$C_{62}(COOEt)_4$ (~12%).

The cyclopropane rings fused to the carbon spheres have generally been found to be highly stable, though the monoanion of 1,2-methano[60]fullerene-61,61-dinitrile reverts back to C_{60} [181]. Exhaustive controlled potential electrolysis (CPE) of diethyl-1,2-methano[60]fullerene-61,61-dicarboxylate leads to removal of the cyclopropane ring to yield predominantly C_{60} [182]. This is called the retro-Bingel reaction, which has been employed to remove up to four substituted cyclopropane rings from fullerenes. If CPE is not exhaustive, the fullerene adduct undergoes isomerization by the migration of the cyclopropane ring on the C_{60} surface. This electrochemical "walk on the sphere" rearrangement has been observed for the six regioisomeric bis-malonate adducts, **112** (Fig. 49) [183]. Coulometrically controlled two electron per molecule electrolysis of six regioisomers leads to a mixture of regioisomeric bis(methano)adducts, but none of the mixtures contained *cis*-2 and *cis*-3 adducts. These derivatives, with two cyclopropane rings located in close proximity in one hemisphere, are the most strained of the isolable regioisomeric bis(methano)adducts.

The malonate bridges appear to be migrating around the fullerene sphere, but not in a random manner. The major isomer formed is always the *trans*-2 derivative (40–50%). About 10% of the *trans*-1 adduct is produced in every case, and the *trans*-1 and *trans*-2 isomers, therefore, appear roughly in their expected 1:4 statistical ratio. The *trans*-1 and *trans*-2 derivatives predominate over the *trans*-3 and *trans*-4 ones, while e-isomer is also formed in high percentage (~25%). The preferred formation of both e- and *trans*-isomers could be a consequence of their inherently

Figure 48. Eight 6,6-ring junction positions to which a second cyclopropane ring can be attached in reference to the existing cyclopropane ring. Adapted from [180].
Figure 49. Migration of di(alkoxycarbonyl)methano bridges in C_{60} bisadducts. Adapted from [183].

higher stability. As a working hypothesis, it is proposed that, after introduction of two electrons into an isomer, a bond to one of the cyclopropane rings is broken, thus giving rise to a singly bound stabilized malonate anion, which might undergo "moon walking" around the carbon sphere. This would presumably delocalize the second electron. The migration could occur one foot at a time, involving sequential formation and breaking of methano bridges at 6,5- and 6,6-junctions, until the thermodynamic equilibrium of the dianionic species is reached.

It is shown that multiple additions to the fullerene core show a remarkable high regioselectivity [184], because addends already bound provide directing influence for further addition. Among the possible sites for a subsequent attack of a 6,6- double bond, *e* positions are significantly preferred followed by *trans*-3 positions [185]. The regioselectivity of attacks to the remaining *e* positions becomes even more pronounced as the number of addends already bound in *e* positions increases. Thus, upon moving from bis- to higher adducts, the regioselectivity of the additions becomes remarkably enhanced. The introduction of a third addend in the Bingel reaction occurs preferentially in the *e* position. Starting from the *e,e,e* trisadduct, stepwise *e* additions take place with amazing succession leading in high yield to hexakisadduct with a pseudooctahedral, all-*e* addition pattern [184a]. Starting from C_{60} and 8 equiv. of diethyl 2-bromomalonate/1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), hexakisadduct is directly obtained [186].

Addition of 9,10-dimethylanthracene (DMA) to the reaction mixture enhances the overall yield of the hexakis adduct. The Diels–Alder reaction of C_{60} with DMA is reversible at room temperature. The reversible templated activation of C_{60} using 10-fold excess of DMA leads to $C_{60}(DMA)_2$ and $C_{60}(DMA)_3$ as the predominant products. Among the various regioisomers of $C_{60}(DMA)_3$, the C_3-symmetrical *e,e,e*-isomer with an incomplete octahedral addition pattern is by far the most abundant. The remaining unsaturated octahedral bonds are significantly preferred for subsequent attacks. After addition to the fullerene, the template directs diethyl malonate addends in the Bingel reaction regioselectively into *e* positions, ultimately yielding hexakisadduct **112** (Fig. 50) [187]. Monoadducts of fullerenes also undergo efficient templated activation of *e* 6,6-bonds. Thus, the bis(alkynyl)methanofullerene **113** reacts with diethyl 2-bromomalonate/DBU (8 equiv.) and

Figure 50. Synthesis of hexakisadducts of C_{60} with a pseudo-octahedral addition pattern. Adapted from [187].

DMA (12 equiv.) to provide hexakisadduct **114** in 28% yield [188]. Without template, the yield is only 12% and the targeted product is contaminated with an inseparable impurity. Also, monoadduct **115** is transformed in 35% yield into hexakisadduct **116** [189].

Template activation has been observed in several other cases too, such as the fulleropiperazine **117** and the triazoline **119** (Fig. 51) [190]. Starting from **117** and **119**, the mixed

Figure 51. Synthesis of mixed hexadducts of fulleropiperazine and triazoline, and the thermal decomposition products of the triazoline. Adapted from [190].

hexaadducts **118** and **120** are formed, respectively. Extrusion of N_2 from the triazoline **119** by refluxing in toluene leads preferably to aziridine **121** than the fulleroid **122**. Further, **122** rearranges slowly at room temperature to **121**. Unfavorable steric interactions between the ester groups of the aza-bridge with those of a nearby methano bridge in **122** could be the possible reason for this rearrangement. In addition, in **121** a complete octahedral addition pattern is present, which is thermodynamically favorable.

Azides can be used as protecting groups for octahedral 6,6-bonds, since the triazoline group in **120** undergoes facile cycloreversion. For example, cycloreversion of the triazoline group in **120** leads to the synthesis of pentaadduct like **123** in comparatively high yields. Since a direct synthesis of pentaadducts of C_{60} with di(ethoxycarbonyl)methylene yields mixtures of regioisomers, this cycloreversion reaction is of synthetic importance. The pentakis adduct **123** can be considered as an excellent reagent in the sense that further reactions can be carried out almost exclusively at the remaining octahedral 6,6-bond. Oxidation of **123** by $KMnO_4$ in the presence of dicyclohexano-18-crown-6 followed by hydrolysis by acetic acid leads to the formation of the diol, which on further oxidation by $Pb(ac)_4$ gave a dioxetane. Addition to this vacant octahedral site is particularly favorable since it generates a residual fullerene π-chromophore consisting of an eight stable benzenoid ring substructure (see Fig. 6) [186].

Heating a sample of crystalline C_{60}-anthracene monoadduct **124** at 180 °C for 10 min affords 48% each of C_{60} and bisadduct **125**, resulting from an intermolecular anthracene-transfer reaction (Fig. 52) [191]. In this preparation of *trans*-1 bisanthracene adduct, the crystal packing provides the molding effect characteristic of a template. The bisadduct is used for the synthesis of the hexakis adduct **126** by Bingel reaction of the bromomalonate. The two anthracene units direct the four malonate addends regiospecifically into the *e* positions. Thermal removal of the anthracene templates provides tetrakisadduct **127** with all four addends aligned along the equatorial belt of C_{60} [192]. Like **123**, the tetrakis adduct **127** with two vacant reaction sites can add on with suitable reactant selectively in the octahedral positions.

Tether-Directed Functionalization Tether-directed remote functionalization of C_{60}, followed by addition to the
vacant sites and subsequent removal of the tether, is an elegant approach for the synthesis of C_{60} regioisomers of defined structure. Such addition patterns are difficult to obtain by thermodynamically or kinetically controlled reactions with free untethered reagents. From semiempirical PM3 calculations the anchor-tether-reactive group conjugates such as **128** are designed (Fig. 53) [193]. The conjugate **128**, after attachment through a Bingel reaction to C_{60}, undergoes Diels–Alder additions at the two *e* positions on opposite sides, yielding trisadduct **129** in 60% yield with complete regioselectivity [194]. Reaction of **129** with a large excess of diethyl 2-bromomalonate and DBU in toluene gives by sequential *e* additions in 73% yield the yellow hexakisadduct **130**.

Addition reactions on **129** are also carried out in controlled steps, which provide tetrakis- and pentakisadducts. The pentakis adduct is left with only one vacant reactive site in the *e* 6,6-bond. However, repeated treatment of this pentakisadduct with diazomethane provides the heptakisadduct and octakisadducts with high regioselectivity and excellent yields, via hexakisadducts. The intermediate pyrazolines could only be isolated during the formation to hexakisadducts. These are not stable during the subsequent conversions in which N_2 extrusion occurs quickly even at low temperatures. The products obtained by both thermolysis and photolysis of pyrazoline are similar to those isolated in the addition of diazomethane to C_{60} followed by N_2 extrusion: the thermal process exclusively provides the 6,5-open derivative, whereas photolysis gives a 1:1 mixture of 6,5-open and 6,6-closed methanofullerenes.

The final step in the process is to remove the tether. Since the reactive ends of the tether have undergone $[2+4]$ cycloaddition reaction, a cycloreversion reaction can lead to removal of the tether. However, this was found to be not successful for the hexakis- or the pentakisadducts. Eventually an elegant procedure is introduced, which could successfully remove the tether [195]. The $^1O_2$ ene reaction at the two cyclohexene rings of **130** yields a mixture of

Figure 52. Templated synthesis of tetrakisadduct using anthracene as the reversible template. Adapted from [191].

Figure 53. Tether-directed remote functionalization and subsequent *e*-attacks generating octahedral hexakisadduct. Adapted from [193].

isomeric allylic hydroperoxides **131** with endocyclic double bonds (Fig. 54). Reduction of **131** *in-situ* with PPh₃ gives a mixture of isomeric allylic alcohols. The allylic alcohol is heated in toluene together with toluene-4-sulfonic acid and dimethyl acetylene dicarboxylate (DMAD) [196]. This leads to the dehydration of the alcohol to the corresponding bis(cyclohexa-1,3-diene) derivative **132**. Further the diene **132** reacts with DMAD via a Diels–Alder reaction resulting in the tetrakisadduct **133**. Transesterification of **133** yields the octakis(ethyl ester) **134**, with all the addends in the equatorial belt. This tetrakis adduct has two reactive 6,6-bonds at the pole, activated by the four malonate addends in the *e* positions. Thus, addition of 2 equiv. of dialkynyl bromide affords hexakisadduct, which after deprotection, leads to the reactive compound tetrakisethynylated **135** with scope for further functionalization.

The fullerene properties change with increasing reduction of the conjugated chromophore resulting from increasing functionalization. Thus, the physical properties and chemical reactivity of the multiple adducts are comprehensively investigated as a function of degree and pattern of addition and the nature of the addends using UV-vis, IR, and NMR spectroscopy, voltammetry, calculations of LUMO energies and electron affinities, and chemical competition experiments. With increasing reduction in the conjugated
fullerene π-chromophore, (i) the optical (HOMO–LUMO) gap in the UV-vis spectrum shifts to higher energy, (ii) the number of reversible one-electron reductions decreases, and the first reduction potential becomes increasingly negative, (iii) the computed LUMO energy increases and the electron affinity decreases, (iv) the reactivity of the fullerene toward nucleophiles and carbenes or dienophiles in cycloadditions decreases, and (v) the capacity for photosensitization of ¹O₂ formation decreases [197]. The smallest perturbation of the fullerene π-chromophore by multiple additions occurs when all-methano addends are introduced along an equatorial belt [198]. Thus the properties of the parent fullerene in the highly functionalized fullerene derivatives are considerably retained if the addends are in an equatorial belt.

Macrocyclization A double Bingel reaction between C₆₀ and bismalonate derivatives leads to macrocyclization. This is the most versatile and simple method for the preparation of covalent bisadducts of C₆₀ with high regio- and diastereoselectivity. All possible bisaddition patterns (**136**), except *cis*-1, have been obtained by this tether-directed remote functionalization (Fig. 55).

Examples of regiosymmetric bisadducts are given in Figure 56 (**137–141**) [199]. Double Bingel reaction of bis(ethyl malonate), iodine, and DBU in toluene at 20 °C generates the macrocyclic bisadducts. Each macrocyclic regioisomer forms as a mixture of diastereoisomers, depending on how the EtOCO groups at the two methano bridge carbon atoms are oriented with respect to each other. Three diastereoisomers, in principle, are possible: *in–in*, *in–out*, and *out–out*. The *out–out* diastereoisomer is almost exclusively formed, except for **140**, which has the *in–out* geometry [200]. The tether in the bisadducts can be readily removed, making it a true template. Thus, transesterification of the fullerene crown ether conjugate **142** yields the symmetrical *trans*-1 bisadduct **143** (Fig. 57) [201].

Blocking the *trans*-1 positions by double Bingel macrocyclization leads to molecules that have three vacant octahedral sites for further reaction. Though the tether blocks the *trans*-1 positions (**144**), one of the *e*-positions is not accessible to cyclopropanation as the tether masks this position (Fig. 58) [202]. In targeting construction of highly organized three-dimensional scaffolds where all the addends in the octahedral sites are different (**145**), the *trans*-1 bisadduct **144** is used as the starting material.

The selective formation of *trans*-1 bisadduct has been challenging because this regio isomer is the least likely to form on statistical and electronic grounds. For successful formation of this bisadduct, the tether in the intermediates has to favor the second intramolecular [2 + 4] cycloaddition at the *trans*-1 position over attack at any nearby

for their metal complexing ability and electron-withdrawing homoconjugative effect on the fullerene π-system.

The high symmetry of C_{60} provides an opportunity to expand the diversity of molecular libraries. One can make a useful analogy between C_{60} and Werner's octahedral framework. Contrary to the freely rotating ligand-to-metal bonds in the octahedron, the 6,6-bonds in the octahedral sites to C_{60} are fixed in space, being included in the three planes of symmetry that are implicitly part of the T_h point group. In the octahedral model, there is only one possible diastereomer for each of the all-*trans* and all-*cis* configurations,

double bonds, including the four closely positioned *trans*-2 bonds (Fig. 59). A suitable tether is designed using AM1 semiempirical calculations. The tether length has the effect of significantly bending the alkyne and aromatic moieties for both the *trans*-1 and *trans*-2 approaches. The crude experimental mixture contained a 1:1.5–2 ratio of the *trans*-1 to *trans*-2 regioisomeric diastereomers. The *trans*-3, *trans*-4, and *e* regioisomers are not detected experimentally. The least polar *trans*-1 bisadduct (**148**) is isolated in 25% yield. The *trans*-1 bisadduct represents a strategically protected octahedral building block. The three available *e*-positions are strongly activated toward subsequent nucleophilic additions. Reaction of **148** with malonate under *in-situ* bromination conditions affords the mixed pentakis adducts **149**. Elimination of the tether by sequential Diels–Alder and retro-Diels–Alder steps leads to the trisadducts **150**. Further reaction leads to unprecedented heterohexaadducts by attaching different sets of addends to the vacant *e*-positions. The addends 4,5-diazafluorene and 2,7-dinitrofluorene added to these *e*-positions with exquisite selectivity under the *in-situ* bromination/nucleophilic addition conditions, and the mixed hexaadducts **151** are formed almost instantaneously at 25 °C. These hexaadducts are of interest, as the diazafluorene and dinitrofluorene addends are known

while in the pseudo-octahedral (T_h) model, each of the all-*trans* and all-*cis* relationships gives rise to a pair of compounds that are regioisomers or *permutational* isomers.

The number of isomers that arise from $A_2 + B_2 + C_2$ functionalization at these bonds increases to 7 and goes up to 30 if all six adding groups are different. Using the "*mer*-3 + 3" stepwise regiocontrol strategy where the *trans*-1 bisadduct is the starting material, all seven isomers have been synthesized (Fig. 60) [203]. Following a similar strategy, complete control over addend permutation at all six pseudooctahedral positions of C_{60} has been achieved [204]. The C_{60} regioisomer with all six addends different (ABCDEF) is synthesized, which will eventually lead to all 30 possible regioisomers.

Hexakis adduct that features the location of all addends along an equatorial belt rather than evenly distributed over the entire carbon sphere is reported [205]. In the chiral D_2-symmetric structure A (Fig. 61), the addition sites are aligned in a distinct helical array whereas B, with a D_{3d} symmetric addition pattern, features a circumferential ("Saturn"-like) functionalization about the equator

Figure 61. The D_2 (**A**) and D_{3d} (**B**) symmetric hexakis addition patterns that feature all addends in an equatorial belt. Adapted from [205].

which dissects the residual π-electron chromophore of the fullerene into two equal polar halves with no direct π-electron conjugation. The D_2-symmetric hexakisadduct reported features addition pattern A. The target compound is obtained in two sequential tether-directed remote fictionalization steps. The first consisted of the preparation of *trans*-1 bisadduct (±**152**) by Bingel macrocyclization of C_{60} with dibenzo[18]crown-6 appended with two bismalonate moieties. Cleavage of the crown ether template and *tert*-butyl ester groups affords tetraacid **153**, which is converted to **156** (Fig. 62).

Fourfold intramolecular Bingel addition of **156** gives the target compound (±**157**) as a single hexakisadduct in 10% yield. The molecular formula of the hexakisadduct is revealed by high-resolution matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS). 1,3-Benzenedimethanol-tethered bismalonates are well known to yield *cis*-2 addition patterns on the fullerenes [206]. Fourfold addition of **156** with *cis*-2 selectivity can only give (with equal probability) two hexakis adducts, with addition patterns **A** or **B** (see Fig. 61). Single crystal X-ray structure determination nicely reveals the helical nature of the addition pattern **A** and allows an unambiguous assignment of structure ±**157**. π-Electron conjugation between the unsubstituted poles in ±**157** is maintained through two *trans*-stilbene-like bridges (Fig. 63). As a result of this extended conjugation the compound is red in solution (end absorption 600 nm). This contrasts with the light yellow color (end absorption ~450 nm) with pseudooctahedral addition patterns, in which the residual π-electron is reduced to a benzenoid "cubic cyclophane"-type structure (see Fig. 6). The novel hexakisadduct undergoes further functionalization at the central 6,6-bond of each pole. A Bingel reaction with diethyl 2-bromomalonate affords the heptakisadduct. Addition of 20-fold excess of the same 2-bromomalonate to ±**157** produces the octakisadduct.

The covalent cyclotriveratrylene-C_{60} adducts are prepared by the tether-directed Bingel reaction [207], which gives the two C_3-symmetrical *trans*-3,*trans*-3,*trans*-3 and *e*,*e*,*e* trisadducts with a high degree of regiospecificity. Cyclo-[*n*]-alkylmalonate is used in a one-step Bingel reaction with C_{60} that leads to products with remarkable stereoselectivity [208]. When cyclo-[2]-dodecylmalonate (**158**) is treated with C_{60} under Bingel conditions, the *trans*-3 bisadduct (**159**) is obtained almost exclusively (Fig. 64). If cyclo-[2]-octylmalonate is used under the same conditions, a mixture of several adducts as well as polymeric material is formed. In order to get the *trans*-1 bisadduct, cyclo-[2]-hexadecylmalonate is used. A mixture of *trans*-3 and *trans*-1 (55:45) is obtained. When C_{60} is treated

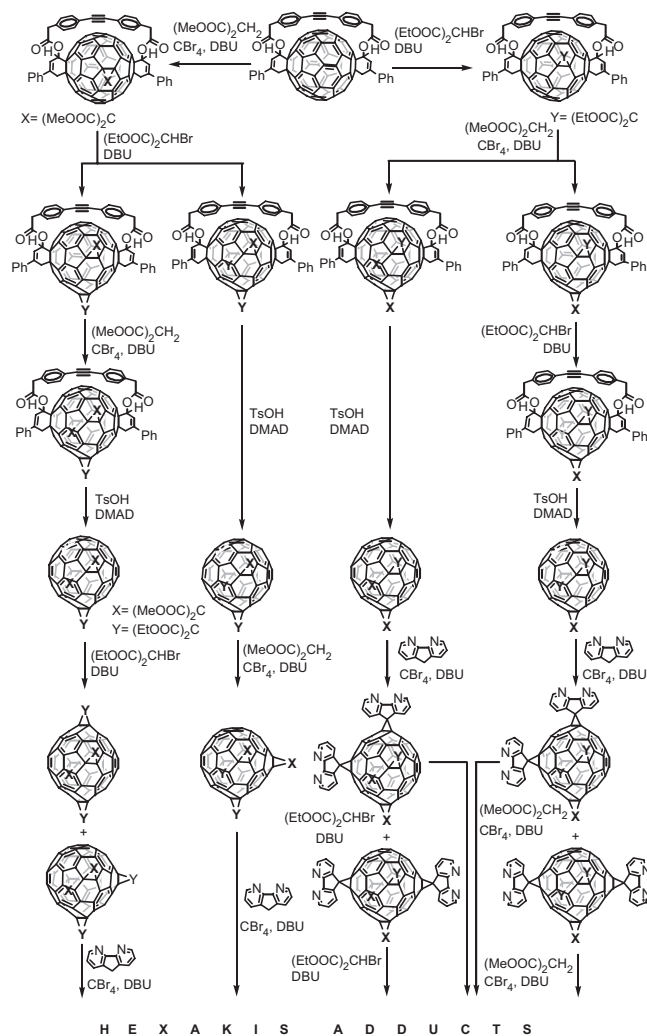

Figure 60. The *mer*-3 + 3 approach toward synthesis of pseudooctahedral regioisomers: synthesis of the hexakisadducts of the type $A_2 + B_2 + C_2$. Adapted from [203].

with cyclo-[2]-butyl-octylmalonate or cyclo-[2]-octyl-tetradecylmalonate, the exclusive formation of adducts that have a C_s-symmetric bisaddition pattern is observed. In the former case, the *cis*-2 bisadduct is isolated and in the latter the *e*-bisadduct. The reaction of cyclo-[3]-octylmalonate (**160**) with C_{60} leads to *e,e,e* isomer (**159**) in 94% relative and 42% isolated yield (Fig. 65). A less polar by-product *trans*-4,*trans*-4,*trans*-4 trisadduct is formed. Reaction of the trisadduct **161** with another equivalent of cyclo-[3]-octylmalonate leads to the hexaadduct **162**. The trisadduct is also treated with an excess of didodecylmalonate under template activation conditions with 9,10-dimethylanthracene to produce the hexaadduct **163**. When cyclo-[4]-octylmalonate is used as the tether component in the reaction with C_{60}, the main product formed is *trans*-1,*e′*,*e″*-tetraadduct.

8.1.4. Nitrogen Bridging

Aliphatic and aromatic azides readily add on to fullerenes under thermal and photochemical reaction conditions. Since a wide range of aliphatic and aromatic azides are available, they offer considerable synthetic possibilities for functionalization of the fullerene sphere. Depending upon the reaction condition and the nature of the azide, nitrogen bridging takes place at the 6,6- or the 6,5-ring junctions. In some cases addition takes place by the azide decomposing first with the loss of a nitrogen molecule to nitrene (analog of carbene) intermediate, which adds to C_{60}. The azide can also add directly to C_{60} by a [2 + 3] cycloaddition reaction leading to isolation of a stable triazoline derivative, which then undergoes nitrogen extrusion by thermolysis or photolysis. In a number of reactions, one of the two products (6,6-closed and 6,5-open) constitutes the major component, whereas the other component may be present in very small amounts. Multiple additions may also take place leading to isolation of regiosymmetric products. Excellent collections of literature reviews are available in the subject [209].

Alkyl azides, such as [(trimethylsilyl)-ethoxy] methyl, and benzyl azides (RCH_2N_3) add on to C_{60} to give the corresponding azafulleroids (Fig. 66) [210]. Heating a mixture of the azide and C_{60} in chlorobenzene overnight produces a more polar product (A) stable at room temperature, along with the less polar azafulleroid. The more polar product is

**Figure 63.** (A) Residual π-electron chormophore, (B) a view of the polar cap showing the reactive 6,6-bond. Adapted from [205].

Figure 67. Reaction of isocyanourato-substituted azides with C$_{60}$ gives both open and closed isomers. Adapted from [211].

evidently the triazoline derivative of C$_{60}$. When heated in refluxing chlorobenzene for a few hours or for a few minutes in solid state the triazoline is transformed to the less polar azafulleroid (**164**), the structure of which is confirmed by ^{13}C and ^{15}N NMR studies. The fast atom bombardment mass spectrometry (FAB-MS) of the final product shows the typical M$^+$ cluster with loss of the alkyl or benzyl moiety to give [C$_{60}$N]$^+$ and C$_{60}^+$. Addition across the 6,5-ring junction leads to polar triazoline, which under thermal conditions loses a molecule of nitrogen giving the less polar azafulleroid.

Reaction of isocyanurato-substituted azides with C$_{60}$ leads to *N*-isocyanurato-substituted 6,5-open and 6,6-closed and isomers. The yield of the product depends upon the azide used. In some cases the azahomofullerene (6,5-open) is the major product, whereas in other cases the main product is the aziridinofullerenes (6,6-closed) (Fig. 67) [211]. Presumably, under the thermal reaction conditions (180 °C, *o*-dichlorobenzene) the azafulleroid rearranges to the aziridine.

The reaction of C$_{60}$ with aryl azides (PhN$_3$, 4-NCC$_6$H$_4$N$_3$) at room temperature leads to isolable triazoline derivatives, **167** (Fig. 68). Photolysis of this derivative selectively furnishes fulleroaziridines (**169**) by the loss of a molecule of nitrogen. Thermolysis on the other hand gives azafulleroids (**168**) as the main product. The rearrangement of the azafulleroid can be induced photochemically to the fulleroaziridine [212]. Besides aziridines, the photochemical reactions of azides with C$_{60}$ predominantly yield C_s symmetrical bisadducts. The mechanism of 1,3-cycloaddition of methyl azide to C$_{60}$ forming the triazoline and subsequent extrusion of a molecule of nitrogen is theoretically studied by semiempirical (AM1) and density functional quantum chemical calculations (B3LYP/6-31G*) [213]. Additions take place at the 6,6-double bond forming the triazoline derivative, the structure of which has been confirmed by X-ray crystallography [214]. Subsequent thermal extrusion of nitrogen molecule proceeds by a stepwise mechanism in which

Figure 66. Azafulleroids from addition of alkyl azides to C$_{60}$. Adapted from [210].

**Figure 68.** Addition of 2,3-diphenyl-2*H*-aziridien to C$_{60}$, synthesis of triazolinofullerne, and its conversion to aziridinofullerenes. Adapted from [212].

the cleavage of the N–N bond precedes the cleavage of the C–N bond. Under thermal reaction conditions the formation of the 6,5-open azafulleroid is explained on the basis of the steric effect of the leaving nitrogen molecule that prevents the attack of the nitrene nitrogen atom on the 6,6-bond and facilitates attack on the 6,5-bond.

The reaction of C_{60} to acyl nitrenes, generated by photolysis of acyl azides (N_3COR), leads to fulleroaziridine derivatives as the predominant products. These are formed in excellent yields by trapping of the nitrene at a 6,6-ring junction. Thus, the first step in the case of acyl azide addition to C_{60} is the formation of a resonance-stabilized nitrene intermediate, which then adds on to the 6,6-ring junction. The reaction of C_{60} with an azido formate leads to the isolation of the fulleroaziridine with a closed 6,6-structure. The fulleroaziridine formed, on heating, rearranges to an oxazole (**170**) (Fig. 69) [215]. Upon further heating it rearranges to fullerooxazoles bound to the 6,6-ring fusion sites.

A similar reaction of aroyl azides generates the corresponding acyl nitrenes (**171**) by photolysis of the azides and the nitrenes added on to C_{60} giving the fullerene adducts with the closed 6,6-ring fused fulleroaziridine structures, **172** (Fig. 70) [216]. The results confirm the nitrene addition to be the key step for the formation of fulleroaziridine derivatives. The fulleroaziridine on boiling in tetrachloroethane rearranged to yield the fulleooxazole, **173**.

From the foregoing results a generalization emerges. The addition of the azide can take place leading to the 6,5-open azafulleroid or 6,6-closed fulleroaziridine as the principal products, depending upon whether the reaction is thermal or photochemical, respectively. In cases of the fulleroaziridine formation, further rearrangement to fullerooxazole takes place on heating the 6,6-azafulleroid if a C=O group neighbors the nitrene. The azide can decompose to give the nitrene intermediate if it can be resonance stabilized, and then the nitrene intermediate can react with C_{60}. If the nitrene cannot be resonance stabilized, addition of the azide takes place as the first step leading to the formation of the triazoline intermediate which loses nitrogen, furnishing the desired product. This generalization is supported by many other examples. An N-hydroxysuccinimide functionalized perfluorophenyl azide reacts photochemically with C_{60} with the addition of the nitrene occurring at the 6,6-ring junction (Fig. 71) [217]. Further, the ester group of the aziridine is converted to the reactive functional group, which allows for the attachment of other organic or bioactive molecules to C_{60}.
Figure 69. Acyl azide addition at the 6,6-ring junction of C_{60} and rearrangement of fulleroaziridine to fullerooxazole on heating. Adapted from [215].
Figure 70. Photochemically generated nitrenes react with C_{60} to give the fulleroaziridine, which rearranges to fullerooxazole on heating. Adapted from [216].

Thermal addition of 2-azidobenzothiazole and 1-azido-4-(3′,5′-dimethyl-1′-pyrazalyl)tetrafluoro benzene to C_{60} is studied to discover whether the formation of aziridine or the fulleroid can be explained by the duality of azide decomposition mechanism. The addition of 2-azidobenzothiazole leads to the 6,5-open azafulleroid whereas 1-azido-4-(3′,5′-dimethyl-1′-pyrazalyl)tetrafluoro benzene furnishes 6,6-closed fulleroaziridine (Fig. 72) [218].

In addition to the azides, another source of nitrene for capture by C_{60} is the base-induced α-elimination from substituted O-4-nitrophenyl sulphonyl hydroxamic acid. Rearrangement of the resulting fulleroaziridine bearing N-ethoxycarbonyl group under the influence of chloromethylsilane results in the quantitative formation of a fullerooxazolidin-2-one, which can be cleaved to yield 1-hydroxy-2-N-methylamino[60]fullerene. Isomerization of the 6,6-bridged adducts to the corresponding oxazolofullerene derivatives occurs upon heating, with the exception of the *tert*-butoxycarbonyl adducts, which eliminates isobutene and carbon dioxide to yield the parent aziridinofullerene $C_{60}NH$. In this work it is reported that isolation of closed 6,6-bridged fulleroaziridines is accompanied by
Figure 71. Reaction of azidofluorobenzoate C_{60}. Adapted from [217].
Figure 72. Formation of 6,6-closed and 6,5-open isomers depends upon the duality of azide decomposition mechanism. Adapted from [218].

a small amount of previously undetected closed 6,5-adducts [219]. The report of the closed 6,5-aziridine derivatives ($C_{60}NCOOR$, R = Et, *tert*-butyl, and 2,4,6-tri-*tert*-butylphenyl) [220] is reexamined [221] and it is concluded that the addition of these nitrenes to C_{60} furnishes the fullerene derivative, which are 6,5-open azaannulenes rather than the 6,5-closed aziridines.

An example of 6,6-open-bridged compounds by selective reduction of the C–C bond of 6,6-closed-bridged azirido-fullerene is reported. The fulleroaziridine is reduced in acid medium (Zn/glacial acetic acid) to give the dihydro derivative having a bridged 10-membered ring (Fig. 73) [222]. The removal of the *N*-protecting group leads to $C_{60}H_2NH$ (**181**) which is remarkably air stable, although under basic conditions it suffers an unusual oxidative ring contraction to the parent fulleroaziridine.

The regiochemistry of azide addition to C_{70} is more complicated since it has five sets of different carbon atoms. Treatment of C_{70} with (2-methoxyethoxy)methyl azide (MEM-N_3) or methyl azidoacetate at moderate temperatures gives three (two with C_s symmetry and one with C_1 symmetry) out of a possible six triazoline isomers [223]. The addition pattern shows chemoselectivity as well as regioselectivity. The major product arises from addition of azide to the double bond of C_{70} possessing the greatest local curvature (polar 6,6-bonds). Selective thermolysis of the least stable triazoline, the one resulting from addition to the least curved 6,6-double bond, allows solution of the structure of the three isomers. Thermolysis of the triazoline isomers produces mixtures of azafulleroids and fulleroaziridines (Fig. 74).
Figure 73. An example of 6,6-open nitrogen-bridged C_{60} derivative. Adapted from [222].
Figure 74. Thermolysis of three triazolines of C_{70} gives azafulleroids and fulleroaziridines. Adapted from [223].

The bridging nitrogen with useful functional groups can impart specific properties to the fullerene derivative. Aqueous C_{60} solution under photoirradiation expresses several biological activities due to singlet oxygen ($^1O_2$). A C_{60} derivative with an acridine group (**190**) (Fig. 75) is synthesized and used for the study of DNA-cleaving activity [224]. An acridine moiety is chosen because of its intercalating activity with DNA double strands. The DNA-cleaving activity of C_{60} and the acridine adduct, both solubilized in water with poly(vinylpyrrolidone), are tested under visible light irradiation using pBR322 supercoiled plasmid. Under dark
Figure 75. A C_{60} derivative with acridine group on the bridging nitrogen atom used for DNA cleaving studies. Adapted from [224].

conditions none of the chemicals show any DNA-cleaving activity. Under visible light irradiation, C_{60} itself shows weak but significant DNA-cleaving activity at 0–5 °C within 4 h of photoirradiation. C_{60} showed stronger DNA-cleaving activity at higher temperature. Within 1 h of visible light irradiation at 35–40 °C, about 25% of the supercoiled DNA is converted to the nicked DNA. In comparison, the fullerene–acridine adduct showed stronger activity even at 0–5 °C within 4 h of visible light irradiation. About 50% of the supercoiled DNA is cleaved in 2 h and more than 90% is converted to nicked DNA after 6 h of photoirradiation. The minimum dose of the acridine adduct is 17.5 μM at 0–5 °C for 4 h of visible light irradiation.

Synthetic lipid bilayer membranes possess fundamental physicochemical properties similar to those of biomembranes and can be immobilized as molecular lipid films. The synthesis and characterization of a C_{60}-bearing triple-chain lipid on the bridging nitrogen (**191**) is reported (Fig. 76) [225]. Spectral evidence suggests the lipid to exist as a closed aziridine structure at a 6,6-ring junction of C_{60}. The amphiphile is not soluble in water because of the lack of a suitable hydrophilic moiety in the molecule but it is soluble in organic solvents. The phase transition between the crystalline phase and liquid crystalline phase is one of the most fundamental characteristics of lipid bilayer membranes. The work demonstrates that the lipid forms multiplayer membrane films, which possess main and subphase transitions, and the subtransition regulates electronic properties of the fullerene.

8.1.5. Bisazafullerenes and Fullerides

As described in the previous section, addition of diazo-compounds or azides to C_{60} leads to fulleroids (C_{60}NR) by extrusion of N_2 of the initially formed 6,6-bridged pyrazolines or triazolines. In C_{60}NR the π-electron system of $C_{60}$ remains intact. The opening of a 6,5-single bond means a fullerene core that contains a bridged nine-membered ring. The 6,5-azafulleroids are isolated in good yields. However, the C=C adjacent to the nitrogen atom bonds are very susceptible to singlet oxygen. The N-ethoxymethoxy ethyl (MEM)-substituted 6,5-azafulleroid (**192**) reacts with singlet oxygen to afford the ring-opened N-MEM keto lactam, **193** (Fig. 77) [226]. The structure of the holed fullerene is proved by FAB-MS and ^{13}C NMR studies. The resonances at 198.5 and 163.6 ppm are assigned to ketone and lactam carbon atoms, respectively.

Following this observation, multiple additions of azides to C_{60} are carried out [227]. Addition of one equivalent more

Figure 77. Reaction showing the C=C adjacent to nitrogen as susceptible to singlet oxygen, leading to the first fullerene with a hole. Adapted from [226].

of the azide N_3R to C_{60}NR leads to the bisazafullerenes, **194** (Fig. 78). The second nitrogen atom also forms a bridge by breaking a neighboring 6,5-single bond. The resulting diazafulleroids, having three 7-membered and one 11-membered ring, are formed in an extraordinary regioselectivity pathway. Treatment of C_{60} with methyl azidoacetate furnishes triazoline, which is not isolated. In addition to a mixture of nitrogen-bridged monoadducts with 6,5-open and 6,6-closed structures, a bisadduct is formed in which two neighboring 6,5-open bonds are imino bridged. This addition pattern of methyl azidoacetate to C_{60} is proved to be a general case with a number of other azides, such as substituted benzyl azides RN_3 (R = benzyl, 4-methoxybenzyl, 4-bromobenzyl) reacting a similar way. The addition of trimethylsilylethoxymethyl azide (SEMN$_3$) to C_{60} is a special case, because of the formation of the bisadduct as the major product. When a dilute solution of C_{60} and excess SEMN$_3$ in chlorobenzene is heated to reflux for approximately 12 h, the diazafulleroid is formed as the main product (60%) along with the 6,5-open (30%) and 6,6-closed (10%) monoadducts. The bisadduct is not stable in

Figure 76. A C_{60} bearing lipid that forms self-organized multilayer films. Adapted from [225].

**Figure 78.** Regioselective formation of diazafulleroids. Adapted from [227].

refluxing chlorobenzene. On heating for about 12 h, the bisadduct is converted quantitatively to a 7:1 mixture of 6,5-open and 6,6-closed monoadducts. The bisazafulleroid has a unique structure in that it has a highly symmetrical ^{1}H and ^{13}C NMR signal pattern. The two R groups are magnetically equilvalent. The compound has C_s symmetry with the mirror plane crossing the four carbon atoms of two 6,6-junctions. The distinct ^{13}C NMR signal at $\delta 160$ is attributed to the central bridgehead C atom (carbon in the bisazafulleroid marked with an asterisk, **194**). A twofold addition of azidoformates under thermal conditions leads to reaction of azides with C_{60} as nitrenes (rather than azides). This reaction leads to all conceivable eight regioisomeric bisadducts [228]. In contrast to nucleophilic cycloadditions of C_{60}, the *cis*-1 isomers are among the preferably formed regioisomers. The *cis*-1 adducts represent the first examples of open *trans*-annular 6,6-bonds. As in case of C_{60}, bisazafulleroids are formed when the reaction of C_{70} with alkyl azides, $N_3CH_2CO_2R$ (R = Me, Et), is carried out at 120 °C [229]. Two C_s-symmetric isomers (**195**, **196**) are formed as the only regioisomers (Fig. 79).

Reacting C_{60} with diethyldiazidomalonate leads to a doubly bridged fulleroid [230], which exhibits a base peak at m/z 906 (M$^+$) in agreement with the expected molecular mass of the doubly bridged fulleroid (Fig. 80). Three structures are considered for the compound, corresponding to a double 6,5-insertion, a double 6,6-insertion, and a 6,5/6,6-insertion. From NMR results and considering the nonequivalence of the two carboethoxy groups, a double 6,5-insertion (**197**) is proposed as the most plausible structure of the double-bridged fulleroid.

Treatment of C_{60} with an excess of $N_3(CH_2)_nN_3$ ($n = 2$ or 3) in refluxing chlorobenzene furnishes the corresponding bisazafulleroids [231]. The addition at the two 6,5-ring junctions of the same five-membered ring or at the two five-membered ring junctions of different five-membered rings is possible (Fig. 81). From ^{1}H NMR studies and characteristic absorption profiles in the UV-visible spectra, the bisazafulleroid is assigned the structure in which the addition is shown at the two 6,5-ring junctions of the same five-membered ring (**200**). This work is extended to the synthesis of chiral bisazafulleroids, expecting that the chirospectroscopic properties of the chiral bisazafulleroids would demonstrate some unique properties (Fig. 82) [232]. Two C_2 chiral diols are converted to their diazides, which furnish the chiral bisfulleroids on treatment with C_{60}. The results establish that tunable chiral substituent significantly enhances the chirospectroscopic response in these fullerene derivatives.

Figure 80. Double-bridged fulleroid, the double 6,5-insertion being the most plausible structure. Adapted from [230].

A bisazide has the structural constraints to allow double 6,5-open insertion in two different five-membered rings, as well as a Diels–Alder addition (Fig. 83) [233]. This reaction is pursued to effectively create an opening within the C_{60} core. The opening has been achieved in which four bonds of the fullerene cage are cleaved. The reaction of the diazidobutadiene with C_{60} followed by N_2 extrusion affords iminofullerene derivative. Subsequent reaction with singlet oxygen yields endo peroxide intermediate, which rearranges by spontaneous [2 + 2 + 2] ring opening. This is further treated with 5,6-dicyano-1,4-benzoquinone or oxygen to afford the desired ring-opened fullerene (**205**), which is an unprecedented class of ligand for supramolecular chemistry. This unique one-pot reaction provides efficient formation of the largest orifice created so far on the C_{60} molecule, thus giving the opportunity to test if small atoms or molecules could be made to pass through it. Incorporation experiments with helium and hydrogen are followed by ^{1}H and ^{3}He NMR studies. The results provide a fully convincing demonstration of a H_2 molecule or a He atom inside the ring-opened fullerene [234].

Figure 81. A bisazafulleroid: addition occurs at the two 6,5-ring junctions of the same five-membered ring. Adapted from [231].
Figure 82. Chiral bisazafulleroid. Adapted from [232].

The open-cage fullerene derivative **205** can incorporate a He atom and a H_2 molecule in 1.5% and 5% yields, respectively. To achieve 100% encapsulation of these gas molecules, it is desirable to have a larger orifice on the fullerene surface. An open-cage fullerene derivative has been synthesized which has a 13-membered-ring orifice on a C_{60} cage [235]. The derivative has an orifice of 5.64 Å along the long axis and 3.75 Å along the short axis. Encapsulation of a H_2 molecule into it does take place to produce the endohedral complex in 100% yield [236], and that $H_2@C_{60}$ can be generated in the gas phase by restoration of the C_{60} cage from the endohedral complex upon laser irradiation.

8.2. [2 + 2] Cycloadditions

The curved geometry and lack of significant conjugation of the π-bonds in C_{60} endow the π-bonds with efficient ene character resulting in a number of [2 + 2] cycloaddition reactions. *o*-Benzyne typically reacts with polycyclic aromatic compounds by adding across the 1,4-positions within a ring, not between rings, thus participating in [2 + 4] cycloaddition reactions. However, with C_{60} and C_{70}, the addition of benzyne takes place by [2 + 2] cycloaddition leading to the attachment of a benzene ring via a cyclobutane ring [237]. Addition takes place at the 6,6-ring junction. The ^1H NMR spectra of the diadduct are complex resulting from the
Figure 83. Ring-opened fullerene: ligands for supramolecular chemistry. Adapted from [233].

many regiochemical possibilities for adding a second benzyne molecule.

Under photochemical reaction conditions C_{60} reacts with a number of dienes. Again, instead of the [2 + 4] cycloadduct, the products are formed through [2 + 2] cycloaddition. In most of the cases both the double bonds of the diene undergo addition to give two different products with defined regioselectivity if appropriate substitutents are present on the dienes (Fig. 84). However, the stereochemistry of the double bond of the initial diene involved in the reaction is lost in all cases. The predominant products are the *trans*-cyclobutanes. The stereochemistry of [2 + 2] photocycloaddition of *trans,trans*-, *cis,cis*-, and *cis,trans*-hexa-2,4-diene to C_{60} [238] involves the addition of diene to C_{60} in the excited triplet state through electron transfer from diene followed by rapid conversion of the resulting ion pairs to [2 + 2] cycloadducts. The collapse of the ion pairs determines the diastereoselectivity. In the process the thermodynamically more stable *trans*-cyclobutane adducts predominate. The lifetime of the biradical intermediate is sufficiently large for rotation about the C_2–C_3 bond. If the diene is an unsymmetrical one, cycloaddition can involve either of the two double bonds. Photochemical cycloaddition of *trans*-hepta-3,5-dien-2-one to C_{60} is an example that utilizes both of its nonequivalent C=C bonds in giving different regioisomeric products [239]. Another example where the two C=C bonds are nonequivalent is *trans*-2-methylhepta-2,5-dien-4-one. In this compound one of the two electronically and sterically nonequivalent double bonds adds on photochemically to C_{60} to give a single product [239]. In contrast to the formation of this cycloadduct in good yields, photoreaction of C_{60} with mesityl oxide requires a 1000-fold excess of the mesityl oxide and the reaction is reversible.

Acetylenes can also undergo photochemical [2 + 2] cycloaddition with C_{60}. Thus C_{60} on reaction with diethylaminopropyne leads to a cycloadduct, which on hydrolysis cleaves the cyclobutene ring resulting in an amide (Fig. 85) [240]. Photoaddition of a silyl ketene acetal to C_{60} takes place at room temperature in wet toluene to afford a fullerene substituted carboxylic ester instead of the expected [2 + 2] cycloadduct. The mechanism is suggested to involve a zwitterion formed through a radical ion-pair [241]. An addend with both a double and a triple bond adds on to C_{60} through the triple bond, if the triple bond is electron rich. Thus an addend with *N*-diethylamine moiety attached to a triple bond under photocycloaddition with C_{60} leads to a fused cyclobuteneamine, which suffers photooxidation leading to a fullerenocarbamide [242].

Photochemical [2 + 2] addition of C_{60} and C_{70} with yndiamine leads to cyclobutene adducts, which suffers from self-sensitized photooxidation to furnish fullerene anhydrides $C_{62}O_3$ (**223**) and $C_{72}O_3$ (**225**) (Fig. 86) [243]. Reaction of C_{60} with *N,N,N'N'*-tetraethylenediamine gives the corresponding cyclobutene intermediate, which upon self-sensitized photooxygenation in toluene gives a diamide. The cyclobutanamine (R = CH_3) is unique in that it has a photosensitizer (the dihydrofullerene) and a photooxidizable group (the enamine) in the same molecule. On brief exposure to air at room light the enamine double bond gets cleaved producing the ketoamide. On treatment with *p*-toluene sulphonic acid the diamide hydrolyzes to a
Figure 84. Photocycloaddition of dienes to C_{60} leading to cyclobutane adducts of defined regiochemistry. Adapted from [238].

fullerene dicarboxylic acid anhydride. Compared to C_{60}, C_{70} reacts ~4 times faster. Addition of a thioyndiamine takes place across the 1,9-bond of C_{70}.

A highly strained ketene acetal undergoes stepwise [2 + 2] cycloaddition to give a cycloadduct, the C–C bond of which is cleaved upon heating in aqueous H_2SO_4 to give an alcohol derivative, **227** (Fig. 87) [244]. A variety of functionally substituted derivatives of C_{60} can be prepared by [2 + 2] photocycloaddition to cyclic enones. The preparation and resolution of enantiomers of *cis*- and *trans*-fused [2 + 2] photoadduct of C_{60} and cyclic enones are reported

[245]. Photocycloaddition of 3-methylcyclohexenone to C_{60} forms both *cis*- and *trans*-adducts in a 40:60 ratio. The course of reaction upon UV irradiation of crown ether fulleroid and 3-methylcyclohexen-2-one in benzene solution is followed by electrospray ionization mass spectrometry (ESI-MS) (Fig. 88). Photocycloaddition of a number of cyclic enones is studied [246]. Bulky substitutents in the enones hinder addition of the enones to C_{60}.

Reaction of C_{60} with quadricylene gives a stable adduct, a derivative of C_{60} bearing a reactive double bond in the side chain, **233** [247] (Fig. 89). The norbornene double bond
Figure 85. Photocycloaddition of alkenes, alkynes to C_{60}. Adapted from [240].
Figure 86. Photochemical [2 + 2] addition of C_{60} and C_{70} with yndi-amine and thioyndiamine leading to synthesis of fullerene anahydrides. Adapted from [243].

is unhindered and reacts readily with electrophiles such as PhSCl to afford quantitatively the product of *anti* addition. [2+4] Cycloaddition of norbornene-containing C_{60} with 3,6-di(2-pyridyl)-*s*-tetrazine providing powerful chelating sites is reported [248] (Fig. 90). The diene 3,6-di(2-pyridyl)-*s*-tetrazine (**235**) reacts site specifically at the external site with norbornene-containing C_{60} molecules. The products are oxidized to the corresponding pyridazine adducts. Similarly, an acetylene derivative bearing ester group is added by an additional [2 + 2] cycloaddition to norbornene-containing C_{60} (**239**). These compounds represent the first example of a new class of polydentate nitrogen ligands incorporating an attached C_{60} moiety.

8.3. [2 + 3] Cycloaddition

8.3.1. TMM Adducts

A five-membered ring can be attached to C_{60} via [2 + 3] cycloaddition of trimethylenemethane (TMM). A nonpolar TMM is the one generated from a 7-alkylidene-2,3-diazabicycloheptene, whereas a polar TMM is generated by thermolysis of methylenecyclopropanes. These TMM precursors have provided simple access to five-membered ring compounds. The parent TMM-C_{60} adduct **240** is synthesized by palladium-catalyzed [2 + 3] cycloaddition by mixing C_{60} with a stoichiometric amount of [Pd(PPh₃)₄] and Ph₂PCH₂CH₂PPh₂ in benzene which results in the palladium–C_{60} complex and then adding a benzene solution

of the TMM precursor (Fig. 91) [249]. Use of TMM precursors leads to further functionalization of C_{60} via the five-membered ring. The TMM precursor, which gives the best results in terms of isolation and characterization, is the methylene cyclopropanone ketal (Fig. 92) [250], which on treating with C_{60} results in the isolation of two products, **241** and **242**, the ester **242** being a possible silica gel catalyzed hydrolysis product of the ketene acetal **243**. The ester **242** is further functionalized through the alcoholic OH group to benzoate **244**, methacrylic ester **245** (Fig. 93) [251], and a number of such compounds varying R and R′.

Figure 90. Attachment of chelating capacity to C_{60} through a $[2 + 2]$ cycloadduct. Adapted from [248].

The $[2 + 3]$ cycloadditions of buta-2,3-dienoates with C_{60} provide a very efficient route to the synthesis of cyclopentene attachment to fullerene (Fig. 94) [252]. In the presence of phosphine catalysts, ethyl buta-2,3-dienoate and ethyl but-2-ynoate undergo $[2 + 3]$ dipolar cycloaddition to C_{60}. A number of derivatives are synthesized by varying the alkyl group.

8.3.2. Further Functionalization via Five-Membered Ring

Reaction leading to fulleropyrrolidines by 1,3-dipolar cycloaddition of azomethine ylides is proven to be a very facile route to functionalization of C_{60} [253], due to the many ways available to generate the reactive intermediates from a wide variety of easily accessible starting materials. Azomethine ylides, such as $H_2C{=}N^+(CH_3)$–CH_2^-, are expediently generated following the Prato reaction, which is the decarboxylation of immonium salts obtained from a mixture of N-methylglycine (sarcosine) and paraformaldehyde. The reaction affords exclusively the product of cycloaddition across a 6,6-ring junction of C_{60}. The scope of the azomethine ylide addition is very broad. A number of α-aminoacids and aldehydes can be used. Aldehydes other than formaldehyde lead to 2-substituted N-methyl-3,4-fulleropyrrolidines, whereas condensation of N-functionalized glycines with aldehydes leads to N-substituted fulleropyrrolidines (Fig. 95) [254]. Glycine
Figure 91. Synthesis of trimethylmethane cycloadduct of C_{60}. Adapted from [249].
Figure 92. Trimethylmethane derivatives of C_{60}. Adapted from [250].

cannot be used, because the parent fulleropyrrolidine is unstable, probably because the generated secondary amine reacts with fullerene. Since the addend is symmetrical, there are eight possibilities for bis(N-methylpyrrolidine)-C_{60} formation, out of which six isomers have been isolated and characterized [255]. Unless there is a specific interest in multiple adducts, for the isolation of pure single addition products, the reaction is typically carried out until about 50–60% C_{60} is consumed, when the product mixture contains about 40–50% of the monoadduct.

Fulleroproline *tert*-butyl ester prepared by reacting glycine *tert*-butyl ester, paraformaldehyde, and C_{60} in refluxing toluene is unstable (Fig. 96) [256]. This is due to the reactivity of amines with fullerenes. Treating the reaction mixture directly with acetic anhydride results in stable acetamido derivative. When fulleroproline *tert*-butyl ester is hydrolyzed by trifluoromethanosulphonic acid, the protonated amino acid is obtained which reacts with acetic anhydride to give the N-acetyl derivative, **252**. The N-acetyl proline is a water-soluble compound and a potential candidate for synthesis of peptides containing C_{60}.

Synthesis of N-substituted fulleropyrrolidine without the carboxylic acid function on the fused five-membered ring is possible. The synthesis of C_{60}-fused N-benzylpyrrolidine
Figure 93. Further functionalization of trimethylmethane C_{60} cycloadduct. Adapted from [251].
Figure 94. [2 + 3] Cycloaddition of buta-2,3-dienoates with electron-deficient alkenes. Adapted from [252].

is accomplished by generating *in-situ* *N*-benzyl azomethine ylide by desilylation of *N*-(methoxymethyl)-*N*-[(trimethylsilyl) methyl]amine catalyzed by trifluoroacetic acid (Fig. 97) [257].

A direct reaction between amino acid esters and C_{60} has also been reported [258]. Thermal reaction between glycine ethyl ester and C_{60} results in an unexpected product, **254** (Fig. 98), formed by an initial reaction of acetone present in solvent reacts with glycine ester generating a 1,3-dipolar intermediate, which adds on to C_{60}. Under photochemical conditions, the isolated product is **255**. Photochemical addition of sarcosine provides **256**; the reaction is twice as fast as the glycine ester reaction. Thus the methyl group on the nitrogen has a positive effect on the reaction rate. The *t*-butyl ester **257** is hydrolyzed by trifluoromethane sulphonic acid to yield the dicarboxylic acid **258**, which is useful for biological studies because of the appended hydrophilic function.

In addition to amino acids, under photochemical conditions, certain tertiary amines are found to add onto C_{60} leading to pyrrolidine derivatives. It is shown that C_{60} and triethylamine (TEA) undergo a characteristic photoinduced electron transfer–proton transfer reaction in a room temperature toluene solution leading to the formation of *N*-ethyl, 2′,5′-dimethylpyrrolidine derivative [259]. The C_{60}–TEA ion–pair intermediate in a nonpolar solvent is formed, which gets transformed to the cycloadduct. Similarly, photoinduced reaction of C_{60} with $RNMe_2$ (R = Ph and Me) gives adducts formed by the addition of a α-C–H bond of the amine to a 6,6-ring junction of C_{60}. On further irradiation in the presence of C_{60}, the adduct (R = Me) is converted to the pyrrolidine derivative [260]. Aziridines under thermal conditions undergo ring opening to furnish azomethine ylides and hence can be used for the synthesis of fulleropyrrolidines. Thus heating the aziridine with C_{60} in toluene leads to the pyrrolidine, **259** (Fig. 99) [254].

Figure 96. Synthesis of water-soluble *N*-acetylfulleroproline. Adapted from [256].

Yet another method for the synthesis of azomethine ylides involves heating 3-triphenylmethyl-5-oxazolidinone with C_{60}, which provides **260** (Fig. 100) [254]. Reacting **260** with trifluoromethanesulfonic acid gives the parent fulleropyrrolidine. Though reasonably stable at ambient temperature in dilute solutions, when the solution is concentrated it decomposed. However, addition of dansyl chloride to **261** brings about the isolation of dansyl pyrrolidine derivative **262**. The possibility of further reacting **261** through the secondary nitrogen, such as reaction with acid halides in presence of pyridine, provides an extremely versatile approach to many functionalized fullerenes, **263**.

A number of fulleropyrrolidine–bridge–ferrocene diads (**264–267**) have been synthesized by condensing the suitably functionalized ester of sarcosine and paraformaldehyde (Fig. 101) [261]. A systematic steady-state fluorescence and time-resolved flash photolysis investigation on these diads is carried out. The nature of the spacer has important consequences on the lifetime of the charge-separated states.

Figure 95. Addition of azomethine ylides to C_{60}. Adapted from [254].
Figure 97. Cycloaddition of *N*-benzyl azomethine ylide to C_{60}. Adapted from [257].
Figure 98. Reaction between amino acid esters and C_{60}. Adapted from [258].

Electron transfer occurs from the ferrocene donor to the fullerene acceptor upon irradiation at 532 nm.

In addition to attaching ferrocene, a number of fulleropyrrolidines are synthesized in which a strong electron donor such as tetrathiafulvalene is attached to the electronegative fullerene moiety. The substituents on the pyrrolidene are either a rigid array or a flexible arm. Such compounds are appealing as on–off components in molecular switches. The electrochemical properties of a number of these compounds are systematically studied [262]. A covalently functionalized fullerene comprising an electron donating aniline group coupled to the fullerene unit via the pyrrolidine unit is reported and its photophysical properties studied (Fig. 102) [263]. Photoinduced electron transfer to C_{60} across an extended 11-bond rigid hydrocarbon bridge leads to creation of a long-lived charge-separated state [264].

$Ru(bpy)_3^{2+}$ complex, a photoactive compound known to give energy transfers in the excited states, is coupled with C_{60}. Azomethine ylide cycloaddition to C_{60} leads to fulleropyrrolidine, which has a bipyridyl group. Reaction of the bipyridyl-functionalized derivative with $Ru(bpy)_2Cl_2 \cdot 2H_2O$ leads to a C_{60} derivative covalently linked to Ru(II) tris(bipyridine) complex (Fig. 103) [265].

The synthesis of compounds possessing stronger electron-withdrawing properties as compared to fullerene by itself is reported. The tetracyanoquinodimethane (TCNQ) and

dicyanoquinonimine (DCNQ) fragments are attached to fullerene (Fig. 104) [266]. These fullerene derivatives are precursors suitable for the synthesis of intermolecular charge-transfer complexes.

Nicotine has a range of biological activities and is used as a pharmacological tool. To check the influence of C_{60} on the toxicity of nicotine a fullerene-fused natural nicotine is reported. However, the nicotine derivative is not water-soluble and hence a *N*-substituted glycine is used. It is reacted with several aldehydes leading to the formation of a number of nicotine analogs, **273** (Fig. 105) [267]. All the compounds exhibit moderate solubility in water–DMSO. One of the compounds tested is found to be active against a variety of microorganisms.

Cycloaddition of chiral azomethine ylides from chiral aldehydes or chiral amino acids is of interest by itself

Figure 100. Addition of azomethine ylides by heating 3-triphenyl-methyl-5-oxazolidinone: a versatile route to functionalized fullerenes. Adapted from [254].

Figure 99. Addition of azomethine ylides obtained by thermal ring opening of aziridines. Adapted from [254].

Figure 102. Photoinduced electron transfer to C_{60} across extended 11-bond hydrocarbon bridges. Adapted from [263].

because it allows one to prepare disymmetric compounds with unusual chirality of the fullerene derivatives. The reaction of O-substituted $(2S,4R)$-4-hydroxypyrrolidine-2-carboxylic acid, formaldehyde, and C_{60} in refluxing toluene affords two diastereomeric monoadducts (Fig. 106) [268]. *In-situ* condensation of the $(+)$-2,3-O-isopropylidene-D-glyceraldehyde with sarcosine in refluxing toluene affords chiral azomethine ylide. The addition of the latter to C_{60} also gives two diastereomeric fullerenopyrrolidines [269].

Through the functionality on the pyrrolidine ring, C_{60} is anchored to silica for the construction of a new support for HPLC. The thermal reaction of C_{60} with N-[3-(triethoxysilyl)propyl]-2-ethoxycarbonylaziridine affords the corresponding fullerenopyrrolidine derivative. It is then anchored to silica gel via the reaction of triethoxysilyl group to silica surface, **277** (Fig. 107) [270].

8.3.3. Miscellaneous Functionalizations via the Five-Membered Ring

A pyrrolidine ring with a C–N double bond can be attached to C_{60} leading to pyrroline-fused C_{60} by 1,3-dipolar cycloaddition of nitrile ylides. The addend ylide can be generated by the photochemical cleavage of azirine derivatives. The reaction of C_{60} with a 10-fold excess of 2,3-diphenylazirine affords the corresponding pyrrole [271]. The reaction is also useful for the synthesis of monoaryl-substituted products (Fig. 108) [272]. The 1,3-dipolar cycloaddition of 1,3-diphenyl nitrilimine generated *in-situ* gives a dinitro heterocycle-fused C_{60}. In the presence of triethylamine a solution of C_{60} and N-(α-chlorobenzylidine)-N'-phenyl hydrazine gives the desired adduct (Fig. 109) [273]. Intramolecular charge-transfer interaction between the benzene rings and the C_{60} sphere is studied.
Figure 103. Attaching ruthenium complex to C_{60}. Adapted from [265].
Figure 104. Attaching electron-withdrawing groups to C_{60} via the pyrrolidine ring. Adapted from [266].

Nitrile oxide generated *in-situ* adds on to C_{60} in a dipolar fashion leading to the formation of isoxazoline. To a solution of C_{60} in toluene addition of triethylamine leads to the formation of a number of isoxazolines (Fig. 110) [274]. Since a number of oximes are available with various substituents, the reaction offers considerable possibilities for functionalization of C_{60}. 1,3-Dipolar cycloaddition of pyrazolidinium ylides to C_{60} is reported [275]. The obtained bicyclic γ-lactam structures are not stable enough for further reaction on the side-chain. The synthesis of fullerene-fused 2-imino-1,3-thiazolidines is carried out. C_{60} reacts with the heterocyclic masked 1,3-dipoles, the 5-imino-1,2,4-thiadiazolidine-3-ones furnishing corresponding fullerene thiazolidines (Fig. 111).

8.4. [2 + 4] Cycloaddition Reactions

8.4.1. Addition of Simple Dienes

In the [2 + 4] cycloaddition reaction the fullerene nucleus acts as a reactive dienophile [276]. This is due to the fact that inter-five-membered ring bonds are electrophilic in nature and fulvenoid. Fullerene is substantially more reactive than typical dienophiles, the reactivity being comparable with those of maleimides [277]. Dienes with electron-donating substituents readily undergo Diels–Alder reaction with the fullerenes. Up to six molecules of diene can be added to both C_{60} and C_{70} across the six pyracylene units. A number of classical dienes such as anthracene, furan, cyclopentadiene, nitrile oxide, isobenzofuran, o-quinodimethanes, etc. undergo [2 + 4] cycloaddition reaction with C_{60} to give the corresponding cycloadducts. C_{60} addition takes place across the junction of two six-membered rings rather than
Figure 105. Synthesis of fullerene-fused nicotines. Adapted from [267].
Figure 106. Attaching chiral azomethine ylides to C_{60}. Adapted from [268].

at the junction of five- and six-membered rings. In reaction of C_{60} with excess cyclopentadiene, it is not possible to isolate the cycloadduct. However, in using freshly distilled cyclopentadiene, a monoadduct is isolated in 74% yield [278]. The cycloadduct undergoes ready retro-Diels–Alder reaction. However, reaction with a pentamethylcyclopentadiene leads to a stable cycloadduct [279]. Hydrogenating the generated double bond on the diene moiety can prevent the reversal of the reaction. The hydrogenated product becomes thermally stable [280]. Cyclohexadiene exhibits somewhat lower reactivity than cyclopentadiene. Again, hydrogenation of the lone double bond on adduct prevents retro-Diels–Alder reaction [281]. Like reaction with cyclopentadiene the reaction between anthracene and C_{60} is facile but the adducts are not be isolated and characterized [282]. The multiple addition product formation by the addition of excess cyclopentadiene or anthracene to C_{60} is reported and the polyadducts are isolated [283] (Fig. 112). Up to six molecules of cyclopentadiene or anthracene could be added to C_{60} moiety. Following this a number of works reported several cycloadducts of C_{60} with anthracene, cyclopentadiene, 1,3-diphenylisobenzofuran, and 1,3-dimethyl butadiene. With anthracene both mono- (**284**) and bis-adducts (**285**) are isolated and characterized by NMR, UV-vis, IR, mass spectroscopy, thermogravimetric analysis, and EPR studies [284]. In all the reactions studied, the cycloadduct
formed revert back to C_{60}. Cycloaddition experiments with anthracene are particularly attractive when it is found that at room temperature anthracene reacts with C_{60} under irradiation of the reaction mixture. Irradiation of a solution of equimolar amounts of C_{60} and anthracene in benzene affords mono- and bisadducts along with anthracene dimer. Presence of a methyl group on position 9 of anthracene prevented dimerization of anthracene [285], which suggested a stepwise mechanism for cycloaddition involving photoinduced electron transfer. However, when 9,10-DMA is used, cycloaddition takes place by a concerted mechanism [286]. High-speed vibration milling of the mixture of C_{60} and DMA leads to efficient formation of the mono-adduct. However, when dissolved in a suitable solvent, the cycloadduct undergoes ready dissociation with a half-life of about 2 hours [287].

Higher linear acenes like pentacene also add on to C_{60} at the central C(6), C(13) atoms when the mixture is refluxed in toluene [288]. Under solid phase milling conditions both mono- and bisadducts are formed along with a *trans*-bisfullerene adduct (Fig. 113) [287]. Use of two equivalents of C_{60} increases the yield of the bisfullerene adduct. When positions C(6) and C(13) are substituted with aryl groups, *cis*-bisfullerene adduct is the major product [289].

Cycloaddition of tetracycline involves the initial electrocyclic isomerization into bicyclooctatriene, the diene component on the six-membered ring reacting with C_{60} (Fig. 114) [290]. As in the case of cyclohexadiene, the reaction is reversible, the product reverting back to the starting materials on heating. The product, however, is stable at room

8.4.2. Functionalizations via Six-Membered Ring

A variety of Diels–Alder reactions performed on C_{60} lead to introduction of functional groups on an attached six-membered ring. The cycloaddition product **302** resulting from the Diels–Alder reaction of 1,3-butadiene and C_{60} is unstable toward air and light, affording hydroperoxide, **303** (Fig. 115) [291]. This instability arises out of efficient photoexcitation of C_{60} to a triplet excited state and subsequent energy transfer to oxygen from air to generate singlet oxygen ($^1O_2$). Reaction of **302** with $^1O_2$ affords the allylic alcohol **304** after reduction with PPh_3. A number of 1,2-dihydrofullerenes obtained by Diels–Alder reaction of the functionalized 1,3-dienes with C_{60} are known. This strategy leads to the synthesis of a rich variety of oxygenated systems after reduction of the corresponding hydroperoxide with PPh_3 [292].

Diels–Alder reaction of 2-trimethylsilyl-1,3-butadiene with C_{60} is an efficient reaction that leads to further functionalization of C_{60} via the six-membered ring. Cycloaddition of the butadiene with C_{60} leads to the ketone **305** which is reduced to the 1,9-(4-hydroxycyclohexano)fullerene **306**. The compounds **305** and **306** bear the versatile ketone and alcohol functionalities, respectively, which permits the preparation of a variety of other, water-soluble C_{60}-α-amino acid derivatives, **307** and **308** (Fig. 116) [293]. A bromoacetate derivative of **305** is used for a C_{60}-linked deoxy-oligonucleotide [294]. This C_{60}-oligonucleotide conjugate is hybridized to a complementary single-stranded DNA. This oligonucleotide conjugate reacts with light and oxygen to cleave only guanosines in the single stranded region, which are closest to C_{60}, by a single-electron transfer mechanism between guanosine and $^3C_{60}$.

Figure 112. Cycloaddition of cyclopentadiene and anthracene to C_{60}. Adapted from [283].

Several chiral nonracemic C_{60} derivatives are synthesized by cycloaddition of C_{60} with 1-methoxy-3-trimethylsilyloxy-1,3-butadiene and 3-trimethylsiloxy-1,3-pentadiene [295]. The cycloadducts lead to ketones **309** and **312**, respectively, after hydrolysis (Fig. 117). A related cyclohexanone-C_{60} adduct **311** has a temperature dependent NMR spectrum due to slow cyclohexanone ring inversion but such inversion is prevented for substituted ketones **309** and **312**.

A facile photochemically promoted rearrangement of the diene **313** leads to the synthesis of a stable bridged bis-fulleroid **315** (Fig. 118) [296]. This process occurs via the initial [4 + 4] photoadduct **314**, which undergoes a thermally
Figure 113. Cycloaddition of pentacene to C_{60}. Adapted from [287].
Figure 114. Addition of cyclotetracene to C_{60}. Adapted from [290].

allowed $[2 + 2 + 2]$ cycloreversion to afford a bridged bis-fulleroid **315**, which also forms a Co(III) complex readily. In an alternate route to synthesis of **315** in higher yields, a twofold excess of 1-(trimethylsilyl)-1,3-butadiene is added to C_{60} leading to the silly ether **316**, which on acidification furnishes the allylic alcohol **317**. Photolysis of the allylic alcohol affords good yields of the bridged bisfulleroid.

A diastereomeric alcohol **320** is synthesized which is a C_{60}-based inhibitor of HIV-1 protease. The reaction involves a "double-Michael" addition of a dienolate anion to C_{60}. Protonation of **318** results in the ketone **319**, which on reduction furnishes the desired diastereomeric alcohol **320** (Fig. 119) [297]. Synthesis of the cyclohexane ring to C_{60} with a sterically crowded 1,4-position is accomplished. This is a remarkably facile method for the synthesis of sterically crowded fullerene derivatives. Various enones are subjected to the dienolate addition to give bicyclic ketone of C_{60} (**321**–**325**) (Fig. 120) [297].

Crown ether can be appended to C_{60} via diene carrying the crown ether moiety. Thus a crown ether bearing the diene component adds on to C_{60} giving a stable cycloadduct. Again a monoadduct is obtained at room temperature and

Figure 116. Appending α-amino acids to C_{60} via the hydroxycyclo-hexano-buckminsterfullerene. Adapted from [293].

the reaction yields a 1:1 mixture of mono- and bisadduct at higher temperature (Fig. 121) [298].

Multiple cycloaddition to C_{60}, as seen in case of cyclopropanation reaction, leads a mixture of regiosymmetric products. Using saccharides as template molecules two boronic acid groups are introduced into C_{60}. A number of saccaride–boronic acid 1:2 complexes are reacted with C_{60}. It is found that the regioselectivity of bisaddition depends on the saccaride structure [299]. Regioselective sixfold $[2 + 4]$ cycloaddition of 1,3-diene to C_{60} is reported (Fig. 122) [300]. A sixfold Diels–Alder reaction of a 1,3-diene at the six symmetry equivalent 6,6-ring junctions results in a chromophore structure of eight completely symmetry-equivalent, strained benzene rings (**327**), which is apparently a multiply bridged cyclophane.

8.4.3. [2 + 4] Cycloaddition via *o*-Quinodimethane Intermediate

A number of [2 + 4] cycloadditions on C_{60} have been carried out using *o*-quinodimethane precursors. Since *o*-quinodimethane (**328**) is unstable and undergoes first aromatization, it is generated *in-situ* for which various methods are known (Fig. 123). The reaction of *o*-quinodimethane and its derivatives lead to stable products, because the cleavage of adducts is an uphill reaction due to the generation of unstable *o*-quinodimethane species.

Cycloadduct becomes thermally stable and the reaction irreversible when the generated double bond in adduct is a part of the aromatic ring, for example, the cycloaddition of isobenzofuran to C_{60}. When C_{60} reacts with isobenzofuran generated *in-situ* from 1,4-dihydro-1,4-epoxy-3-phenylisoquinoline, the corresponding cycloadduct does not undergo cycloreversion [301]. Synthesis of adduct by [2 + 4] cycloaddition of C_{60} with a norboranenone leads to a stable adduct **331** by elimination of CO (Fig. 124) generating an aromatic ring. Hence the adduct cannot revert back to the starting materials by retro-Diels–Alder reaction.

o-Quinodimethane is routinely generated by 1,4-elimination of Br_2 from 1,2-bis(bromomethyl)benzenes. From a bromomethyl bicyclooctadiene, the *o*-quinodimethane intermediate is obtained by dehydrohalogenation on treating with potassium *tert*-butoxide. The adduct is unstable and it eliminates a molecule of HBr to produce fullerocyclohexadiene derivative, which is too unstable
Figure 119. Synthesis of a diastereomeric alcohol by a "double-Michael" addition. Adapted from [297].
Figure 120. Dienolate addition to C_{60} giving bicyclic ketones. Adapted from [297].

and decomposes further [302]. However, a number of reactions with C_{60} lead to stable monoadducts [303]. *o*-Quinodimethane can be used as a vehicle for the introduction of a multitude of reactive functional groups. Reaction of 4-amino-*o*-quinodimethane with C_{60} affords a thermally stable and chemically reactive adduct [304]. The synthesis of carboxy-substituted adducts of C_{60} and *o*-quinodimethane is reported and the products are used for subsequent reactions [305]. Following this strategy a variety of C_{60} derivatives are synthesized to study their biological activities and material properties. For example, through the reactive acid moiety a molecule of cholesterol is attached (**334**) for the purpose (Fig. 125).

Heating 1,2-bis(bromomethyl)-4,5-dimethoxybenzene with C_{60} in toluene in the presence of tetrabutylammonium iodide leads to functionalized C_{60} readily (Fig. 126) [306]. As stated earlier, the [2 + 4] cycloaddition reactions involving *o*-quinodimethane intermediate generated *in-situ* are irreversible, because *o*-quinodimethane undergoes fast aromatization.

Benzocyclobutene as *o*-Quinodimethane Precursor
Benzocyclobutenes are interesting precursors for *o*-quinodimethane intermediates. The addition reaction of fullerene with *o*-quinodimethane-type species, using the thermally allowed conrotatory $[\sigma 2 + \pi 2]$ electrocyclic ring opening of benzocyclobutane homologs, is reported (Fig. 127) [307].

Thermolysis of the benzocyclobutenes also leads to generation of *o*-quinodimethanes *in-situ*. For example, heating a mixture of C_{60} and a benzocyclobutene derivative leads to facile synthesis of the adduct (Fig. 128) [308]. Both mono- and bisadducts are formed, the major product being the monoadduct.
Figure 121. Attaching a crown ether to C_{60}. Adapted from [298].
Figure 122. Regiosymmetric sixfold [2 + 4] cycloaddition of diene leaving behind an aromatic framework of eight benzene rings. Adapted from [300].

Reactive functional groups on benzocyclobutene moiety lead to *o*-quinodimethane carrying a center for further functionalization. Thus, refluxing a mixture of C_{60} and benzocyclobutenol in toluene affords a fullerene derivative with a hydroxy or ether function on the cyclohexane ring (**340**–**343**) (Fig. 129) [309].

Stable Diels–Alder adducts of C_{60} carrying reactive functions are also synthesized from benzocyclobutenols. For example, heating 3-methoxy-3-phenylbenzocyclobutene with C_{60} yields the cycloadduct stable upon prolonged reflux in toluene (Fig. 130).

The functional group on benzocyclobutene moiety can be further functionalized starting from an adduct, or the starting material itself can be functionalized before cycloaddition. For example, a benzocyclobutene carrying a carboxy group is allowed to react with azacrown ether by 1,3-dicyclohexylcarbodiimide (DCC) coupling and is then reacted with C_{60} (Fig. 131) [310]. Both mono- and bisadducts are formed, the monoadduct being formed as the major product.

8.4.4. Donor–Acceptor Systems from [2 + 4] Cycloadditions

A number of donor–acceptor systems from [2 + 4] cycloaddition reactions of fullerenes are known. Fullerene derivatives of quinones as a donor–acceptor system involving fullerene and quinone parts are known. Such a redox system containing fullerene and *p*-benzoquinone (**347**) is synthesized from 3,6-dimethoxybenzocyclobutane and C_{60} (Fig. 132) [311]. Removal of the methyl group leads to the *p*-benzoquinone adducts. The fulleroquinones are efficient redox-active materials. The synthesis of C_{60}-based electron acceptors with attached tetracyano-*p*-quinondimethane and dicyano-*p*-quinondiimine (DCNQI) moieties are reported. These derivatives can accept up to eight electrons in solution [312].

Use of sultines as the precursor for the generation of *o*-quinodimethane by extrusion of SO_2 is quite efficient.

Figure 129. Introduction of a reactive functional group on the cyclohexane ring by reaction of C$_{60}$ with benzocyclobutenol. Adapted from [309].

The facile formation of C$_{60}$ adducts from sultines via a Diels–Alder reaction for functionalization of C$_{60}$ is reported. The reaction of various substituted sultines with C$_{60}$ leads to the respective cycloadducts. The substituted 1,4-dialkoxybenzenes are converted into the corresponding *p*-benzoquinone moiety, which are interesting precursors for the preparation of stronger organofullerene acceptors derived from TCNQ and DCNQI (Fig. 133) [313].

Tetrathiafulvalene (TTF) is known as one of the strongest donors used in the design of donor–acceptor systems. Cycloaddition reaction of C$_{60}$ to 2-(thi)oxo-4,5-bis(methylene)-1,3-dithioles is a route to the bislinking of tetrathiafulvalene to C$_{60}$. The main step to the synthesis of the target molecules lies in the Diels–Alder reaction of C$_{60}$ with the *in-situ* generated *o*-quinodimethanes. To generate the 2-oxo intermediate, two alternative pathways—the thermal rearrangement of *S*-propargyl xanthate and the reductive 1,4-elimination of the corresponding 2-oxo-4,5-bis(bromomethyl)-1,3-dithiole—are adopted (Fig. 134) [314]. The first route furnishes the mono-, bis-, and trisadducts and the second route only a monoadduct.

Through a sultine TTF is attached to C$_{60}$. The Diels–Alder reaction between C$_{60}$ and tetrathiafulvalene sultine is facile which leads to the synthesis C$_{60}$-TTF diad, **355** (Fig. 135) [315]. Analogs of tetrathiafulvalene are also synthesized and attached via the *in-situ* generated *o*-quinodimethane moiety. The resulting donor–acceptor systems are photoactive compounds (Fig. 136) [316].

Like sultines, the sulfolene derivatives of oligothiophenes react with C$_{60}$ on heating. A sulfolene derivative of thiophene containing up to five thiophene rings per molecule on reaction with C$_{60}$ furnishes the corresponding fullerene–oligothiophene, **356** (Fig. 137) [317].

8.4.5. Attaching Heterocyclic Rings by [2 + 4] Cycloaddition

Heterocycle-fused C_{60} derivatives are conveniently synthesized by the Diels–Alder reaction of C_{60} with suitable dienes carrying the heteroatoms like *N*, *O*, and *S*. The reactions can be irreversible if the diene component is *o*-quinodimethane intermediate. Thus a nitrogen-containing heteroring is fused to C_{60} by the reaction of an *o*-quinodimethane generated by decarboxylation of a benzoxazinone (Fig. 138) [318].

The heterocyclic ring can have more than one heteroatom by a suitable choice of the diene moiety. With a carboethoxy-substituted azabutadiene and thio-substituted azabutadiene C_{60} undergoes hetero-Diels–Alder reaction to give derivatives fused with cyclic amino acid and thiourea, respectively (Fig. 139). When the diene itself is reacted a pyrrolidine derivative is formed [319].

Heterocyclic rings can be appended to fullerenes following reactions other than cycloaddition. For example, a 1-bromoisoquinoline derivative of C_{60} is synthesized by reaction of BrCN with $C_{60}Ph_5Cl$ (Fig. 140). The reaction results in chlorine loss and in the formation of a bromine-substituted CN bridge between the cage and the ortho position of the adjacent phenyl ring [320]. Nucleophilic substitution of the bromine by hydroxide leads to the isoquinolone derivative.

As in the case of introduction of a nitrogen atom, an oxygen atom can be introduced by reacting fullerene with a suitable *o*-quinodimethane derivative. Thermolysis of *o*-hydroxy
Figure 132. Synthesis of redox system containing fullerene and *p*-benzoquinone. Adapted from [311].
Figure 133. *o*-Quinodimethanes from sultines by extrusion of SO_2. Adapted from [313].

benzyl alcohol leads to *o*-quinomethide, which reacts with C_{60} giving a oxygen-containing heterocycle, **362** (Fig. 141) [321].

To introduce a sulfur atom, the thio analog of benzocyclobutene is used, which first generates the benzothietane. Later on reaction with C_{60} leads to the fullerothiochroman, **363** (Fig. 142) [322]. Sulfur containing heterorings can be fused to C_{60} by hetero-Diels–Alder reaction with an α,β-unsaturated thiocarbonyl compound, prepared *in-situ* from thioacrylamide and acyl chloride (Fig. 143) [323].

Attaching a Heterocyclic Ring to Fullerene via a Cyclohexane Linker Addition of a cyclobutene derivative carrying a useful functional group is a convenient approach to introduction of a functional group on the generated cyclohexane ring. Following this protocol compound **365** is synthesized, which has a great deal of potential as a starting point to various interesting functionalities. Its diketone is a direct precursor of different 1,4-diazine-fused fullerenes. The synthesis of **365** is easily carried out by

Figure 143. Dihydrothiopyran-fused C_{60}. Adapted from [323].

electrocyclic ring opening of 1,2-bis(trimethylsiloxy)-cyclobutene in dichlorobenzene at 180 °C, generating the corresponding butadiene followed by [2 + 4] cycloaddition to C_{60}. Oxidative cleavage of the bis(trimethylsilyl) ether **365** in nonprotic medium followed by low temperature bromination and direct derivatization of the diketone **366** with *O*-methoxyhydroxylamine under basic conditions leads to the isolation of the corresponding dimethoxime **367** in good yield. A number of 1,4-diazines (**368**) are obtained by using the *o*-diaminoarenes. The reactions are carried out in acidic conditions in order to avoid nucleophilic addition to the double bonds of C_{60} (Fig. 144) [324].

The pyrazine-containing cycloadducts **369** are also synthesized by Diels–Alder reaction of C_{60} with the corresponding 2,3-bis(bromomethyl)pyrazine derivatives. The 2,3-bis(bromomethyl)pyrazines are synthesized from condensation of diamines with diketones, from which corresponding *o*-quinodimethane is generated *in-situ*. These reactive intermediates are easily trapped as the respective Diels–Alder adducts by reaction with C_{60} (Fig. 145) [325].

Heterocyclic *o*-quinodimethanes are versatile intermediates for the synthesis of a number of heterocycle-linked C_{60} derivatives. The furan, thiophene, oxazole, thiazole, imidazole, and diazine linked C_{60} derivatives (**370–375**) are obtained by treating the corresponding *o*-quinodimethanes with C_{60} (Fig. 146) [326]. The furan and oxazole derivatives are photosensitive, and hence the products of photooxygenation of these derivatives are isolated.

The Diels–Alder cycloadducts obtained from reactions of C_{60} with electron rich, *cis*-fixed 2,3-dioxy-substituted butadienes are potential precursors of valuable functionalities like acyloin or diketone derivatives, which can be further functionalized (Fig. 147) [327]. The cycloaddition provides the 1:1 cycloadduct as the major product. However, ambient

light caused a rapid decomposition yielding the hydroperoxide derivative **377**. This high reactivity of the electron rich alkene in **376** provides a clue for further derivatization.

Cycloaddition reaction of thieno-*o*-quinodimethane derivatives to C_{60} furnishes the thiophene-linked C_{60} derivatives. Substituted thieno-*o*-quinodimethanes are generated *in-situ* from the respective 2,3-bis(chloromethyl)thiophene and 2,3-bis(bromomethyl[*b*]thiophene) (Fig. 148) [328].

8.4.6. Retro-Diels–Alder Reactions

The preparation of fullerene derivative is often hampered due to their poor solubility. This problem has been resolved through temporary addition of a solubilizing group to a fullerene framework [329]. A solubilizing "tag" is added to C_{60} and the resulting solubilized fullerene is functionalized with the desired group. The solubilizing tag is removed after chemical transformations by retro-Diels–Alder reaction leading to the fullerene derivative. Two illustrative examples of this principle are cited here. The Diels–Alder reaction of 1,3-butadiene and C_{60} leads to a product unstable in air and light affording hydroperoxide **380** (Fig. 149), which after reduction with PPh_3 afforded the allylic alcohol **381**. Soluble derivatives of alcohol **381** are converted to the cyclohexadiene derivative **382**. Diels–Alder reaction of the diene with maleic anhydride and *N*-phenylmaleimide affords bicyclic derivatives. A similar cycloaddition reaction with DMAD leads to the formation of the bicyclo[2.2.2]octadiene intermediate **384**, which readily suffers from retro-Diels–Alder reaction leading to the unreactive dimethyl phthalate and C_{60}. The derivatives of cyclohexadiene can directly be treated with DMAD, for the reversal to occur.

As shown the derivatives of the allylic alcohol can be cleanly removed. This property has been utilized in introducing a solubilizing tag to C_{60}, then carrying out further

Figure 149. Removing a solubilizing group from C_{60} derivative by retro-Diels–Alder reaction. Adapted from [329].

reaction on the carbon cage, and finally removing the solubilizing moiety. For example, the synthesis of highly insoluble adduct **387** is carried out by this method. For this the allylic alcohol **381** is converted to *t*-BOC-protected alcohol **385** (Fig. 150). Diels–Alder reaction of **385** with the diene gives a diastereomeric mixture of adducts **386**. The solubilizing component, which aided the synthesis of the diastereomers, is cleanly removed by heating **386** under reflux in toluene in the presence of *p*-toluenesulphonic acid and DMAD. The pure adduct **387** is obtained in excellent yield.

Following this strategy, the synthesis of a methanofullerene **390** has been achieved (Fig. 151). Reaction of 3-bromo-1,5-bis(trimethylsilyl)-1,4-pentadiyne with allylic alcohol derivative **385** leads to the solubilized diethynylmethanofullerene **388**, which is obtained after desilylation of the monoadduct. The solubilized diethynylmethanofullerene is obtained as a diastereomeric mixture. Coupling this with phenyl acetylene affords bis(phenylbutadiynyl) derivative **389**, which upon the removal of the solubilizing group leads to the ethanofullerene **390**.

In addition to synthesizing highly insoluble functional fullerenes by introducing easily removable solubilizing groups the reversibility of the Diels–Alder adducts to the parent compounds has been gainfully utilized in purifying C_{60} and separating a mixture of C_{60} and C_{70}. The reaction

Figure 148. Cycloaddition reaction of thieno-*o*-quinodimethane derivatives to C_{60} furnishing the thiophene-linked C_{60} derivatives. Adapted from [328].
Figure 150. Using retro-Diels–Alder reaction for the synthesis of an insoluble adduct. Adapted from [329].
Figure 151. Synthesis of a cyclopropane derivative by removing the solubilizing group. Adapted from [329].

of Merrifield peptide resin in toluene with excess sodium cyclopentadienylide at −20 °C forms a cyclopentadiene-functionalized polymer, which undergoes cycloaddition reaction with C_{60} at room temperature to give fullerene appended to a polymer support (**391**). The product is shown to readily undergo retro-Diels–Alder reaction upon heating, allowing recovery of pure C_{60} (Fig. 152) [330].

The property of reversible cycloaddition polymer supported dienes to C_{60} leads to devise a simple method for the purification of fullerenes [331]. A cyclopentadiene-functionalized silica gel is prepared by the reaction of chloropropyl-functionalized silica gel with lithium cyclopentadienylide (Fig. 153). Diels–Alder reaction of the cyclopentadiene on silica with C_{60} and C_{70} readily leads to silica loaded with C_{60}/C_{70}. This on heating released 93.7% of bound C_{60} and 41.1% of bound C_{70}. The difference in the extent of release of the fullerenes provided a route to purification of C_{60}. The initial C_{60}/C_{70} ratio is 90:10 and the final ratio is 96:4, thus leading to fullerenes significantly enriched in C_{60}.

Figure 153. Reversible cycloaddition to silica-supported dienes, a nonchromatographic means to fullerenes significantly enriched in C_{60}. Adapted from [331].

8.5. Higher Cycloaddition Reactions

While majority of the cycloaddition reaction carried out on C_{60} are [2 + 1], [2 + 2], [2 + 3], and [2 + 4] type, a few other higher cycloaddition reactions are known. For example, a [2 + 2 + 2] cycloaddition product **393** is obtained by slow addition of ethyl propiolate to a toluene solution of C_{60} in tricyclohexylphosphine $[P(Cy)_3]$ at ambient temperature (Fig. 154) [332]. $P(Cy)_3$ acts as a nucleophile as well as a leaving group. The spectral data strongly support a head-to-tail addition of two ethyl propiolate units to C_{60}.

Another uncommon reaction is the [2 + 5] cycloaddition. The reaction of C_{60} with 1,8-bis(bromomethyl)naphthalene in refluxing benzene in presence of NaI and 18-crown-6 results in a fullerocylcloheptane, **394** (Fig. 155) [333]. A lone example of [2 + 6] cycloaddition on C_{60} is known [334]. In the course of synthesis of fulleroaziridines by reaction between fullerene and ethyl azidoformate, two products are identified, the normal [2 + 4] cycloadduct (**395**) as well as a [2 + 6] cycloadduct (**396**) (Fig. 156). Benzene, used as the solvent, captures the photolytically generated nitrene from ethyl azidoformate to produce N-ethoxycarbonylazepine, which on further photoreaction with C_{60} furnishes the cycloadducts.

9. FULLERENE DIMERS

All-carbon fullerene dimers are intriguing molecules due to their unique properties and hence are of considerable interest [335]. The fullerene dimers provide intriguing possibilities as model compounds for nano- and polymer

Figure 152. Reversible covalent attachment of C_{60} to a polymeric support. Adapted from [330].

Figure 157. Synthesis of C_{120} through a [2 + 2] cycloaddition reaction. Adapted from [338].

science [336, 337]. There are two distinct approaches to synthesis of the fullerene dimers: (i) dimerization of either fullerene itself or a suitably functionalized fullerene and (ii) bifunctional cycloadditions to fullerenes. The simplest such fullerene dimer $(C_{60})_2$, or C_{120} (**397**), has been prepared by solid-state [338] and by chemical [339] methods. The generation of the $(C_{60})_2$ dimer was first accomplished via a mechanochemical reaction with KCN using a high-speed vibration milling (HSVM) technique (Fig. 157) [338a, b]. The structure of the dimer has been determined by X-ray crystallography for a single crystal grown in *o*-dichlorobenzene. The mechanism of dimerization is not clearly known. Dimerization can be via nucleophilic addition or there can be coupling through electron transfer.

A number of theoretical studies have been done to understand the mechanism of dimerization. Orbital-symmetry analysis of the dimerization of C_{60} via [2 + 2] cycloaddition indicates that reactant monomers should approach one another along a pathway in which C_{2h} symmetry is conserved [340]. A mechanism for helium incorporation into one of the C_{60} spheres in the dimer has been examined by modified neglect of differential overlap (MNDO), density functionalization theory, and *ab initio* calculations [341]. The mechanism involves dimerization of two molecules by [2 + 2] cycloaddition between double bonds at hexagon junctions, formation of a stable closed-shell window, and helium insertion through this window (Fig. 158).

A rigorous proof for photochemical interfullerene [2 + 2] cycloaddition has been provided by direct experimental evidence [342]. In this experiment a *m*-phenylene(methanofullerene) with general structure R–C_{61}–(1,3-Ph)–C_{61}–R is chosen as a synthetic target, since conformational freedom allows the two fullerene cages to be in close contact. For this purpose a bisfulleroid upon heating is first cleanly converted into the methanofullerene. Prolonged irradiation of a deoxygenated solution of the methanofullerene leads to the photodimer by [2 + 2] cycloaddition between the fullerene spheres in close contact, **401** (Fig. 159). Novel dimeric fullerenes incorporated
in a 2,3-diazabicyclo[2.2.2]oct-2-ene framework, with and without direct inter-fullerene-cage bonds, are synthesized and fully characterized spectroscopically; the electronic communication between the two fullerene cages is clarified by differential pulse voltammetry [343].

The C_{60} dimer has also been subjected to further reaction. A highly symmetrical decakis-cyclopropanated derivative of C_{120} is synthesized using template activation and the structure is determined by X-ray crystallography (Fig. 160) [344]. The reaction is carried out by addition of excess amounts of diethyl bromomalonate and DBU to a solution of C_{120} and DMA in *o*-dichlorobenzene. Further, the decakisadduct is converted into the icosa-carboxylic acid derivative that is water soluble.

The synthesis of dimeric $(C_{70})_2$ has also been reported. The synthesis is carried out by simply mixing C_{70} and K_2CO_3 in a small mortar and pestle and grinding the mixture by hand for 15 min [345]. Reaction leads to a mixture of five dimers. The isomers are separated and their structures elucidated. The fullerene C_{60}–C_{70} cross-dimer C_{130} is synthesized by the mechanochemical solid-state reaction using the HSVM technique [346]. The reaction is conducted by placing C_{60} and C_{70} in a mixing capsule made of stainless steel, together with 4-aminopyridine and a mixing ball, and treating them by HSVM for 30 min.

Thermolysis of $C_{60}O$ with a 6,6-epoxide structure in the presence of C_{60} affords the corresponding oxygen-bridged C_{60} dimer [347]. By similar experimental condition, the methylene bridged C_{60} dimer is synthesized from thermolysis of fullerene cyclopropane and C_{60} (Fig. 161). The thermolysis of $C_{120}O$ leads to the isolation of $C_{120}O_2$ [348]. The ^{13}C NMR spectra of $C_{120}O_2$ show two groups of four equivalent sp^3-hybridized carbon atoms which leads to the

conclusion that each fullerene cage is bislinked by adjacent furanoid rings. The two furanoid rings link the cages via 6,5-junctions. A 6,6-link results in unfavorable double bonds in pentagons. Semiempirical models confirm the stability of bridged dimer structures assigned in the literature to C_{120}, $C_{120}O$, and $C_{120}O_2$, interpreting all three as additions across formal double bonds of the C_{60} monomers. Analogous structures are proposed and compared for C_{60}/C_{70} dimers C_{130}, $C_{130}O$, $C_{130}O_2$, C_{140}, $C_{140}O$, and $C_{140}O_2$ [349].

There are several reports of C_{60} dimerizing into various singly bonded structures [350]. Some of the best-studied dimers are those of general structure $RC_{60}C_{60}R$ (R = H, halo, alkyl, fluoroalkyl) obtained by dimerization of $RC_{60}^\bullet$ radicals. The rotation about the intercage bond of $RC_{60}C_{60}R$ has been studied by molecular mechanics [351]. The radical adducts of C_{60} exist in equilibrium with their dimers and the dimer bond strength depends on the size of the group R (Fig. 162).

A monoprotected diethynylmethanofullerene is homocoupled under Hay coupling conditions to the corresponding butadiynyl-linked dimeric methanofullerene, **405** (Fig. 163) [352]. From cyclic voltametric experiments it is found that both through-bond and through-space electronic interactions are not very efficient. This is in agreement with the UV-vis data as well as X-ray structural data, which indicate that the sp^3 carbon atoms in the two butadiynyl-linked methano bridges act as insulators.

Dimeric fullerenes with acetylinic spacers attached directly to the fullerene core have been reported. Reaction of dilithioacetylene with C_{60} in toluene, followed by dodecyl iodide addition at reflux temperature, leads to a fullerene dimer with an acetylene spacer, **406** (Fig. 164) [353]. The synthesis of a bisfullerene, in which the fullerenes are linked directly by two acetylene units, has been accomplished by homocoupling of the ethynylfullerenes, bearing base stable
substituents at their 2-position [354]. In these dimers, even though there is a direct link between the fullerene units, electronic interaction between them is not observed.

Addition of methano-fullerenecarbene, $C_{60}C{:}$, to C_{60} leads two fullerene units to share the methylene bridge carbon forming a dimer **408** (C_{121}) (Fig. 165) [355]. The double-bonded dimer **409** (C_{122}) obtained by the dimerization of $C_{60}C{:}$ itself has been detected by mass spectroscopy. However, there is a possibility that both **408** and **409** are formed under mass spectrometric conditions. Further, the ^{1}H NMR spectra of the dimer show a very broad band indicating the presence of a number of isomers.

In all these studies, two fullerene units are reacted either directly or through a linking or spacer group. In an alternative but more versatile approach, fullerene dimers have been prepared by first preparing a suitable bifunctional linking group, which can undergo cycloaddition reactions with C_{60} leading to the desired dimer. A number of interesting products have been prepared following this strategy. However, the reaction invariably leads to formation of a mixture containing regioisomers, which are often difficult to separate. Following the first synthesis of a dimer by reaction of bisdiazo derivative [356], a number of dumbbell-like fullerene dimers have been synthesized by using Diels–Alder reaction of bisdienes with C_{60}. A solid-state [2 + 4] cycloaddition of pentacene to C_{60} using the HSVM technique has led to a C_{60} dimer, the structure of which is suggested to be the less sterically crowded *anti*-isomer (Fig. 166) [357].

Bis-*o*-quinodimethanes with spacer groups provide unique structures upon [2 + 4] cycloaddition reaction with C_{60}. Molecules providing controlled spacing with 1,4-cyclohexadienyl ladders and of different length are reacted with C_{60} by Diels–Alder cycloaddition [358]. Depending on the spacer length a number of dumbbell-like structures could be designed (Fig. 167).

The covalently linked, multichromophoric ball-and-chain molecules in which the bridge is a polynorbornane-bicyclo[2.2.0]hexane are synthesized [359]. Analogous reaction with a bisdiene affords the soluble dumbbell system, bearing two C_{60} chromophores (Fig. 168).

The first synthesis of a fullerene dimer by 1,3-dipolar cycloaddition of azomethine ylides to C_{60} is accomplished by treating sarcosine and a dialdehyde in refluxing toluene. The product, a black solid, is insoluble in most organic solvents. The CV experiment showed that there is no significant interaction between both fullerene cages of the dimer (Fig. 169) [360].

Functionalization of C_{60} using the Bingel reaction followed by a multistep reaction pathway leads to a fullerene dimer containing a bipyridine ligand between the fullerene units. Subsequent reaction of the ligand with $Ru(bpy)_2Cl_2$ leads to a Ru(II) complex, which is an electroactive moiety in the fullerene dimer (Fig. 170) [361]. The electronic absorption spectra suggest that there is no charge transfer between Ru(II) and fullerene units.

Fullerenes covalently attached to TTF lead to interesting species due to their potential applications in photovoltaic devices. The TTF units readily lose en electron, since in the process the radical cation and dication species are aromatic. Since fullerenes are strong electron acceptors, coupling these two species leads to easy electron transfer from TTF to C_{60}. A TTF unit is covalently linked to two or four C_{60} molecules through a flexible bridge (Fig. 171) [362]. These systems are promising candidates for photophysical studies. However, from UV-vis and CV measurements, no interaction between C_{60} and TTF unit has been observed.

The synthesis of a rotaxane, assembled via the copper (I) templated approach bearing two C_{60} units as chemical stoppers, has been reported [363]. The synthesis is based on the oxidative coupling reaction of terminal alkynes functionalized on C_{60} and copper (I) rotaxane in presence of Hay catalyst [CuCl-TMEDA-O_2 (TMEDA = N, N,N',N'-tetramethylethylenediamine)]. A homocoupling reaction leads to a dimeric fullerene derivative as a side product (Fig. 172).

10. HETEROFULLERENES

Apart from exohedral and endohedral fullerene derivatives, heterofullerenes represent the third fundamental group of modified fullerenes. In heterofullerenes, one or more carbon atoms are substituted by heteroatoms, such as trivalent nitrogen or boron atoms. In these cases, substitution of an

Figure 171. Tetrathiafulvalene linked covalently to two C_{60} molecules through a flexible bridge. Adapted from [362].

odd number of C atoms leads to radicals, whereas replacement of an even number of carbon atoms leads to closed-shell systems. In spite of such interesting chemistry, the area of heterofullerenes is still a very young discipline within the scope of synthetic organic chemistry. Nevertheless, there has been some pioneering work that clearly shows a great structural diversity of this compound class [364]. Nitrogen heterofullerene is first synthesized from cage-opened N-MEM ketolactam, which is obtained when N-MEM-substituted 6,5-azafulleroid reacts with singlet oxygen. Refluxing N-MEM ketolactam in o-dichlorobenzene in the presence
Figure 172. A copper(I)-complexed rotaxane with two fullerene stoppers. Adapted from [363].

of 12–20-fold excess of *p*-TsOH under an atmosphere of nitrogen leads to the formation of heterofullerene, $C_{59}N$ (Fig. 173) [365]. The suggested mechanism for the formation of the nitrogen heterofullerene dimer involves as a first step the acid-catalyzed cleavage of the MEM group, followed by an intramolecular ring formation.

The synthesis of $(C_{59}N)_2$ and $(C_{69}N)_2$ is also achieved using diazabis-(1,6);(1,9)-homofullerenes as starting materials via their butylamine monoadducts [366]. Heating butylamino adducts of diazabis-(1,6);(1,9)-homofullerenes bearing MEM-protected imino bridges with toluene-*p*-sulphonic acid provides the heterofullerenes and their adducts $RC_{59}N$ and $RC_{69}N$ (Fig. 174) [367]. Starting from a mixture of two different C_{70}-bisazafulleroids, it is possible to isolate three constitutional isomers of $(C_{70}N)_2$. Formation of heterofullerene can occur only if the substituents of the imino bridges are easily removed. 2-MEM is an easily removable protecting group. The C atom of the fullerene cage is eliminated as an isonitrile or carbodiimide species.

Mixed $C_{59}N/C_{69}N$ heterodimers have been also synthesized [368]. Starting with a 1:1 mixture of the ketolactams of C_{60} and C_{70} as well as thermal treatment of equimolar amounts of $(C_{59}N_2)$ and an isomer of $(C_{69}N_2)$, the mixed heterodimers are obtained along with some homodimers (Fig. 175).

A variety of derivatives of the heterofullerenes have been synthesized. Two possible processes of derivatization of $C_{59}N$ are (1) deprotonation of azafullerene $C_{59}HN$ followed by attack of an electrophile, and (2) homolytic dissociation of the interdimer bond of $(C_{59}N)_2$ followed by free radical reactions. Treatment of $(C_{59}N)_2$ with diphenyl methane in refluxing *o*-chlorobenzene provides the substituted azafullerene $C_{59}(CHPh_2)N$ (Fig. 176) [369]. The interdimer bond is relatively weak (18 kcal/mol) and, under photolysis and thermolysis conditions, undergoes facile homolysis. In the presence of a good hydrogen donor or radical source, the resulting azafullerenyl radical undergoes free radical reaction.

Another reaction sequence leads very efficiently to arylated heterofullerenes. The thermal treatment of the heterofullerene dimer with anisole, toluene, and 1-chloronaphthalene in the presence of toluene-*p*-sulphonic acid and air leads to the formation of monoarylated azafullerenes $ArC_{59}N$ in very good yields [370]. The mechanism of this reaction is assumed to be an electrophilic aromatic substitution (S_EAr) by $C_{59}N^+$, which is possibly formed via thermal homolysis of the dimer and subsequent oxidation with O_2. Since arylated aza[60]fullerenes are stable and are
Figure 174. Nitrogen heterofullerenes from diazabishomofullerenes. Adapted from [367].

obtainable in high yields, they represent ideal starting materials for investigation of the behavior of the nitrogen heterofullerene core toward addition reactions. The treatment of monoarylated azafullerenes in CS_2 leads to the exclusive formation of the tetrachlorinated heterofullerene $Cl_4ArC_{59}N$, which contains a pyrrole moiety in the fullerene cage, **430** (Fig. 177) [371]. The pyrrole moiety is decoupled from the conjugated π-system of the fullerene cage. An excess of PPh_3 can easily remove the chlorine addends, leading to reversal of the reaction.

11. OLIGOFULLERENES

Solubilized derivatives of C_{195} and C_{260}, a new class of carbon allotropes, are oligofullerenes having three or four fullerene units per molecule [372]. The smallest number of the methano-bridged all carbon family C_{195} consists of a cyclo-C_{15} core surrounded by three peripheral fullerenes, whereas C_{260} is a cyclo-C_{20} derivative with four fullerenes. The fullerenes are either attached to acetylenic core via methano bridges, or are incorporated into the macrocycle itself (**431**, **432**) (Fig. 178). Although these are expected to be stable compounds, their synthesis by oxidative coupling of 61,61-diethynylmethano[60]fullerene failed; the result is an intractable mixture of insoluble compounds [373]. The synthesis of these oligofullerenes as their derivatives is carried out using the tether directed remote functionalization technique. The starting material synthesized by the template activation method is subjected to nucleophilic

addition/elimination of 1,5-bis(trimethylsilyl)-3-bromopenta-1,4-diyne. This introduces diethynylmethano group leading to dialkynylmethanofullerene hexaadduct. Deprotection and subsequent oxidative cyclization leads to two major derivatives of the carbon allotropes C_{195} and C_{260} providing **434** and **435** (Fig. 179).

Cycloaddition reactions are a convenient route to synthesis of fullerene oligomers. For example, herecene, 2,3,5,6,7,8-hexamethylidenebicyclo[2.2.2]octane, reacts readily with C_{60} leading to a fullerene trimer. Herecene dissolved in hot toluene is treated with a toluene solution of C_{60} and the product is generated by threefold cycloaddition [374]. Clusters of bis- and trisfullerenes (**436**) have been prepared following the Prato reaction, in which a mixture of the trialdehyde, fullerene, and sarcosine is refluxed in toluene (Fig. 180) [375]. The fullerene trimers and larger assemblies form a new class of molecular system with potential applications in molecular electronic devices. The photophysical and photochemical behaviors of the cluster forms of bis- and trisderivatives are described. Reaction of C_{60} from addition of dienes generated *in-situ* upon elimination of SO_2 is an efficient approach to synthesis of cycloadducts. Refluxing of the tetrasufolene derivative of zinc meso-tetraarylporphyrinate with 10 equiv. of C_{60} in 1,2-dichlorobenzene produces porphyrins containing four fullerene substitutents (**437**) (see Fig. 180) [376]. Depending on the conditions and duration of the reaction, mono-, bis-, or tris(fullereno)porphyrinates can be obtained as the major product. The photophysical properties of the fullerene tetramer are studied.

12. FULLERENE DENDRIMERS

Starburst dendrimers [377] possess controllable size, shape, topology, surface chemistry, and flexibility. These three-dimensional, highly ordered oligomeric and polymeric compounds formed from smaller molecules by reiterative

reaction sequences can mimic certain properties of micelles, liposomes, even those of biomolecules, and still the more complicated, but highly organized, building blocks of biological systems. This branch of "supramolecular chemistry" has sparked new developments in both organic and macromolecular chemistry. Numerous applications of these compounds are conceivable, particularly in mimicking the functions of large biomolecules as drug carriers and immunogens. Combining various dendrimer morphologies would give rise to a wide variety of construction components and combinations.

The fascinating thing about the dendrimeric addition to fullerenes is the polymeric fragment, which, due to its globular three-dimensional structure, leads to greater encapsulation and the ability to prepare monofunctional, monodisperse materials of known molecular mass. The dendritic macromolecules dramatically improve the solubility of the fullerenes and would provide a more compact insulating layer around the clusters than would linear polymers, minimizing or preventing direct fullerene–fullerene interaction. If the dendritic moiety is hydrophilic, the dendritic fullerene (fullerodendrimer) may dissolve in water, which can be useful for biomedical applications. Dendrimers can be attached covalently to fullerenes, or there can be noncovalent com-

Figure 181. Synthesis of the first reported fullerodendrimer by cycloaddition of a dendritic azide to C_{60}. Adapted from [379].

plexation of fullerenes with a dendrimer. C_{60} is a convenient core for dendrimers, since its almost spherical shape leads to globular systems even with low generation dendrons. Furthermore, variable degrees of addition within the fullerene core, especially from mono- up to hexaadducts, are possible [378].

The first reported addition of dendrimeric molecules to fullerenes is the one-step cycloaddition reaction of a dendritic azide with C_{60} (Fig. 181) [379]. The dendrimer chosen is the terminally deuterated fourth generation azide, D_{112}-[G-4]-N_3 (**439**), which is prepared by reaction of the corresponding bromide with sodium azide in dimethylsulfoxide. Due to the increase of molecular mass by 3400 for each dendrimer addition, only mono- and diaddition products are observed and no higher addition products. When six equivalents of the dendrimer azide are used per C_{60} the mono- and diaddition compounds are again the major products (2:3 ratio) with little or no observable higher addition products. This inability to obtain significant tri- or higher substitution may be due to steric hindrance around the C_{60} nucleus and/or unfavorable electronic considerations after diaddition. Cyclovoltametry of the fullerodendrimer shows the expected multireduction waves. However, the first three reduction waves occur at lower values than those previously reported. This may be due to the insulating influence of the globular dendritic macromolecule.

The attachment of polyether dendrimers to phenol-functionalized fullerenes is reported [380], which is prepared by reaction of C_{60} with bis(p-methoxyphenyl)diazomethane followed by hydrolysis of methyl ethers with BBr_3 (Fig. 182). Polyether dendrimers prepared by the convergent synthesis route are ideally suited for attachment to phenol-functionalized C_{60} since they carry a single electrophilic site at their focal point, and their attachment to phenolic moieties has been studied extensively. The benzylic bromide group at the focal point of a fourth-generation dendrimer [G-4]-Br (**441**) reacts with the phenolic groups located at the surface of the functionalized fullerene in the presence of K_2CO_3. Two dendrimers couple with one fullerene to give the fullerene-bound dendrimer **442** together with a significant amount of higher molecular impurities.

If the dendrimer moiety is hydrophilic, the resulting amphiphilic fullerodendrimers can form monolayers at the air–water interface. However, the hydrophilic headgroups should be large and bulky enough to prevent strong fullerene–fullerene aggregation, while still keeping the fullerene spheres sufficiently close to each other so that
fullerene–fullerene interactions are not entirely disrupted. Such fullerodendrimers with peripheral acylated glucose units and a fullerene core are prepared and incorporated in Langmuir films (Fig. 183) [381]. Fullerene amphiphiles with their glycoldendron headgroups form stable ordered monolayers at the air–water interface and show reversible behavior in successive compression/expansion cycles. The dendron headgroup is effective in preventing the irreversible aggregation usually observed in amphiphilic fullerene derivatives [382].

The fullerene–dendrimer conjugates **445** and **447** are prepared by DCC(N,N-dicyclohexylcarbodiimide)-mediated amide bond formation between carboxylic acids **443** and **446** and the O-acetylated trisglucoside wedge. Successive compression and expansion cycles are performed on the monolayers of the fullerene-glycodendron conjugates in the air–water interface in order to explore the reversibility of their formation. The results indicate that the formed films are very stable. The hydrophilic carbohydrate dendrons are polar enough to establish a strong amphiphilic character of

fullerene derivatives, yet bulky enough to avoid the irreversible aggregation of the fullerene centers.

Dendrimers with a fullerene core are appealing candidates to demonstrate the shielding effects resulting from the presence of the surrounding dendritic shell. Lifetime measurements in different solvents can be used to evaluate the degree of isolation of the central C_{60} moiety from external contacts. With this idea in mind, two series of fullerodendrimers are prepared (Fig. 184) [383]. In the design of these dendrimers, poly(aryl ether) dendritic branches terminated with peripheral triethyleneglycol chains are chosen to enable the compounds to dissolve in a wide variety of solvents. The synthetic approach to prepare compounds **448–451** relies upon the 1,3-dipolar cycloaddition of the dendritic azomethine ylides generated *in-situ* from the corresponding aldehydes and N-methylglycine. Dendrimers **452–455** are obtained by regioselective reaction at the fullerene sphere with bismalonate derivatives in a double Bingel cyclopropanation.

The photophysical properties of fullerodendrimers **448–455** have been studied in different solvents like toluene, dichloromethane, and acetonitrile. Interesting trends are obtained in the lifetimes of the lowest triplet excited states

in air-equilibrated solutions. A steady increase in lifetime (τ) is found by increasing the dendrimer size in all the solvents (for example, τ in toluene increased from 279 to 374 ns for **448–451** and from 288 to 877 ns for **452–455**. This suggested that the dendritic wedges are able to shield, at least partially, the fullerene core from external contacts with solvent and from quenchers such as molecular oxygen. The triplet lifetimes for **451**, however, are different in the three different solvents, likely reflecting specific solvent fullerene interactions that affect excited state deactivation rates. This suggests that even the largest dendritic wedge is not able to provide a complete shielding of the central fulleropyrrolidine core. In contrast, the triplet lifetime of **455** in the three solvents lead to a similar value. This suggests that the fullerene core is in a similar environment irrespective of the nature of the solvent. In other words, the C_{60} unit is, to a large extent, not surrounded by solvent molecules but substantially buried in the middle of the dendritic structure. This creates a specific site-isolated microenvironment around the fullerene moiety. Molecular modeling calculations for both **451** and **455** reveal that in **451** the dendritic

Figure 184. Fullereodendrimers with versatile photoactive core. Adapted from [383].

of the dendrimers. Measurements on the resulting doped samples reveal efficient optical limiting properties [383].

Amphiphilic dendrimers with peripheral fullerene units **456–458** are synthesized and their Langmuir and Langmuir–Blodgett (LB) films are studied (Fig. 185) [386]. The compounds form stable Langmuir films at the air–water interface and exhibit reversible compression/decompression behavior. The films can withstand pressures up to $P \approx 20$ mN m^{-1}. In the compression–decompression cycles no hysterisis is observed as long as the collapse pressure is not exceeded. The films of **456** and **458** are transferred onto silicon or glass substrates covered with a monolayer of octadecyltricholorosilane.

A series of fullerodendrimers is investigated in which Fréchet-type dendrons have been connected to a fullerene moiety via an acetylene linker (Fig. 186) [387]. 2,6-Dihydroxyethynylbenzene bearing benzyl ether type dendrons on the oxygens is covalently linked to C_{60} via an intervening triple bond (**459**). The dendritic fullerenes $GnC_{60}H$ ($n = 1$–4) are highly soluble in common organic solvents. Their structures are characterized as 1,2-addition products with the ethynyl group and a proton added at a 6,6-bond on the fullerene cage. Molecular dynamics simulations with a MM2 forcefield show dense packing of dendron branches around the fullerene cages. The presence of favorable π–π stacking interactions is indicated by the face-to-face arrangement of the fullerene cage with several aromatic rings of the dendrons. Such interactions should have arisen out of intimate wrapping of dendron units with the fullerene core. The proton attached to the fullerene is highly acidic. The electronic properties of the fullerene core greatly change when it is transformed to the anion by the abstraction of this acidic proton. When the THF solution of the dendrimers is treated with one equivalent of Bu^{t}OK, the initial brown solution immediately turns dark green, indicating the formation of fulleryl anions. Oxidation of the anion GnC_{60}^- with iodine leads to the dimer GnC_{60}–GnC_{60}, the structure of which is confirmed by MALDI-TOF MS. ESR studies of the benzene solution of the dimer, however, indicated the presence of an equilibrium between monomeric and dimeric species. The photophysical and photochemical properties of these dendrimers are investigated by time-resolved fluorescence and time-resolved absorption methods, in addition to steady-state spectra [388]. The photophysical properties of the dendrimers such as lifetimes of the singlet and triplet excited states are essentially the same, regardless of the dendrimer generation. However, the rate constants of intermolecular processes such as triplet–triplet annihilation, triplet energy transfer, and electron transfer via the triplet states decrease with the increase in dendrimer generation.

Photophysical investigations of fulleropyrrolidine derivatives substituted with oligophenylenevinylene (OPV) moieties reveal a very efficient singlet–singlet OPV→C_{60} photoinduced energy transfer process. Based on this observation, dendrimers **460–463** with a fullerene core and peripheral OPV subunits are prepared (Fig. 187) [389].

The photophysical properties of fullerodendrimers are investigated in dichoromethane solutions. Upon excitation at the OPV band maximum OPV→C_{60} singlet–singlet

wedge indeed does not fully cover the fullerene moiety, whereas in **455** dendritic branches are able to fully cover the central fullerene core.

The efficient covering of the C_{60} core is useful to optimize the optical limiting property characteristics of fullerene derivatives. Fullerenes have a larger absorption cross-section in the excited states compared with that of the ground state. Therefore increased triplet lifetimes observed for the largest fullerodendrimers allow for an effective optical limitation. For practical applications, the use of solid devices is largely preferred to solutions and sol–gel glasses loaded with fullerene derivatives have demonstrated good application prospects [384]. Two factors, (i) faster deexcitation dynamics and (ii) reduced triplet yields, however, are limitations for fullerene-doped sol–gel glasses when compared to solutions [385]. The perturbation of the molecular energy levels due to the interactions with the sol–gel matrix and interactions between neighboring fullerene spheres due to aggregation are the possible reasons. The use of the fullerodendrimers prevents such undesirable effects. The incorporation of fullerodendrimers **448–455** in sol–gel glasses is achieved by soaking mesoporous silica glasses with a solution

Figure 185. Amphiphilic dendrimers bearing peripheral fullerene subunits. Adapted from [386].

quenching of OPV fluorescence is observed for all fullero-dendrimers. This indicates that the dendritic wedge is capable of channelling the absorbed energy to the fullerene core. In structurally related dendrimers it is established that the dendritic wedge plays at the same time the role of an antenna capable of channelling the absorbed energy to the fullerene core as well as of an electron-donating unit [390]. Phenylenevenylene dendritic wedge is attached to a pyrazoline[60]fullerene core, and efficient energy transfer from the excited antenna moiety to the C_{60} core is observed [391].

The dendritic wedges containing peripheral fullerene units are used to prepare new dendrimers with a bis(1,10-phenanthroline)copper(I) core [392]. This leads to dendrimers with a fullerene π-chromophore at the periphery (Fig. 188). The largest dendritic copper complex reported contains 16 peripheral C_{60} groups (**466**).

12.1. Dendritic Hexakisadducts of C_{60}

Fullerodendrimers in the foregoing examples have one dendritic wedge bound to the fullerene core. The single dendritic moiety imparts the property desired of a dendrimer. As the fullerene can undergo multiple additions, it can also

generate a dendritic species even when the addends themselves are not high generation number dendrimers. The globular dendrimers with a C_{60} core can be structurally varied because C_{60} allows synthesis with T_h (hexakisadduct), C_{2v} (pentakisadduct), C_s (tetrakis and e-bisadducts), and C_3 (e,e,e-trisadduct) symmetry. The addends can all be same or different, thus leading to a number of possible regioisomers. Starting from precursors of incomplete octahedral addition pattern, the regioselective formation of a further mixed hexaaddition pattern can be expected. Indeed, this aspect has drawn a lot of attention resulting in many interesting reports which are summarized in a review article [18]. Template-mediated cyclopropanation techniques or tether-directed functionalization allow for straightforward production of hexakisadducts. Two views of macromolecular architectures based on the T_h symmetric motif are shown in Figure 189.

By a suitable choice of the dendritic moiety and the linking chain it is possible to attach dendrimeric units at all the six octahedral sites. A number of hexakisadduct of the type T_h-$C_{66}(COOR)_{12}$, where R is benzyl ether based dendritic unit, are reported [394]. Even if low generation dendra are employed, the products are still spherical dendrimers, some
Figure 186. Benzyl-ether type dendrimers connected to C_{60} core by a single covalent bond. Adapted from [387].

of which can have more specific functions. For example, addition of six mesotropic cyanobiphenyl malonate addends produces the spherical thermotropic liquid crystal **467** and a highly water-soluble dendrimer **468** containing 12 carboxylic acid groups at the periphery (Fig. 190) [395].

A number of fullerene precursors with incomplete octahedral addition pattern and dendritic wedges of different generations in the form of their bromomalonates are used (Fig. 191) [396], which on nucleophilic cyclopropanation reaction affords the dendrimeric hexaadducts. For example, reaction of the C_{2v}-symmetrical penatkisadduct leads to the dendrimer **469** (Fig. 192). Similarly dendrimers from the tetrakis-, tris-, and bisadducts are obtained from multiple cyclopropanation of the bromomalonates containing the **G1**–**G3** dendrons. As seen before, the 6,6-ring junctions in the vacant octahedral sites are preferred for further reaction.

13. POLYFULLERENES AND FULLEROPOLYMERS

In view of the interesting properties of fullerenes, there have been a number of studies exploring the behavior of fullerenes under the routine polymerization conditions. Extensive literature is available on the subject, with a number of review articles [397]. Polyfullerene ideally should be a linear chain of the fullerene molecules joined by one or more covalent bonds. Fullerenes are known to undergo photopolymerization in the solid state [398]. In this reaction a [2 + 2] cycloaddition between two adjacent fullerene molecules involving double bonds at the hexagonal junctions has been suggested. C_{60} can also be polymerized under the combined action of high pressure and temperature [399]. Fullerene polymers revert to pristine monomer upon heating [400]. Photopolymerization of C_{60} in solution using CCl_4, CH_2Cl_2, cyclohexane, and decalin as solvents has been carried out [401]. Irradiation of C_{60} solutions under nitrogen flow produced C_{60} photopolymer, the structure of which is found to be comparable to that of C_{60} photopolymer prepared in solid state. A perfect linear C_{60} polymer has been difficult to comprehend and hence to realize in practice because of lack of specificity of reaction on the fullerene sphere. In order for such a linear polymer to be synthesized, it is necessary that the molecules of C_{60} be linearly arranged. Fullerenes are prone to co-crystallization with other molecules, and in such co-crystals it is possible that the C_{60} molecules could be organized in a linear fashion. One such example has been C_{60}-calixarene co-crystal, in which C_{60} molecules are arranged strictly in a linear manner. Further, such linear chains of C_{60} molecules are well separated. Action of heat and pressure on a co-crystallate of C_{60} and calixarene furnished a linear [2 + 2] addition polymer **470** without cross-linking (Fig. 193) [402].

Though this polyfullerene is interesting and attractive, most studies have been carried out with fullerenes incorporated into a conventional polymer. Fullerene molecules
Figure 187. Fullerene–oligophenylenevinylene conjugates. Adapted from [389].

can be incorporated in polymers by several means leading to distinctly different structures of the resulting fullerene polymer. The fullerene moiety can be (1) in the main chains of the polymer, (2) in the core of a starburst polymer, (3) a dendritic polymer, (4) cross-linkers in the polymer network, and (5) grafted onto a solid support. Further, these materials can be obtained by several means, such as free radical, cationic, and anionic polymerizations, condensation, and addition reactions, selected examples of which are discussed here. Since the field of fullerene-dendrimers has significantly grown in volume in recent years, this subject is described in a separate section.
Figure 188. A fullerodendrimer with a bis(phenanthroline)Cu(I) core and peripheral fullerene units. Adapted from [392].

13.1. Radical Polymerization

One of the earliest free radical reactions on C_{60} is the reaction of xylylene diradical leading to C_{60}-*p*-xylylene copolymer [403]. The diradical is obtained when paracyclophane is sublimed at 300 °C into a tube furnace set at 650 °C. It is then swept into a solution of C_{60} in toluene cooled to −78 °C. Such reaction conditions could allow multiple additions of the radicals, leading to a complex product.

Both C_{60} and C_{70} are copolymerized with a number of vinyl monomers, such as styrene, in a standard free radical polymerization either in bulk or co-dissolved in an aromatic solvent using azoisobutyronitrile (AIBN) as the initiator [404]. C_{60}-styrene random copolymers are prepared using bulk and solution polymerization techniques [405]. The resulting polymers are soluble and behave like ordinary polystyrene in solution except for the dark brown color. Multiple additions
Figure 189. 6,6-Bond positions for a T_h symmetrical octahedral addition pattern leading to a hexakisadduct: tow different views. Adapted from [393].

are commonly observed in radical polymerization of styrene and MMA in the presence of C_{60} leading to a branched structure [406]. Upon copolymerization, the characteristic UV-vis spectra of C_{60} disappears, which has been ascribed to incorporation of substitutenets onto C_{60} molecules as a result of polymerization. Other AIBN-initiated copolymerizations of C_{60} with 4-vinylbenzoic acid, 2-vinylpyridine, or 4-vinylpyridine have been carried out [407]. Laser light scatering studies of these polymers indicate that the change in the UV-vis pattern is a consequence of scattering rather than true absorbance. Solubility and micellization behavior of C_{60} fullerenes with two well-defined polymer arms leading to materials of the types C_{60}-(PS)$_2$, C_{60}-(PVP)$_2$, and C_{60}-(PS-PVP)$_2$, where PS is polystyrene, PVP is poly(p-vinylphenol), and PS-PVP is a diblock copolymer, are prepared by applying the nitroxide controlled free radical polymerization technique [408]. Direct fullerenation of commercially available optical polymer, polycarbonate (PC), is achieved by simply irradiating a solution of PC and C_{60} at room temperature using a conventional UV lamp or by warming a C_{60}/PC

solution to a moderate temperature in the presence of AIBN [409]. Radical polymerization of vinyl monomers can be inhibited by fullerenes. The effect of C_{60} on the radical polymerization of vinyl acetate with dimethyl 2,2′-azobisisobutyrate in benzene is investigated kinetically and by means of ESR. C_{60} is found to act as an effective inhibitor of polymerization [410].

13.2. Fullerene–Initiated Polymerization

The dications of C_{60} and C_{70} are found to initiate the polymerization of 1,3-butadiene in gas phase [411]. Reactions of $C_{60}^{\bullet+}$, $C_{70}^{\bullet+}$, C_{60}^{2+}, and C_{70}^{2+} with 1,3-butadiene are conducted. $C_{60}^{\bullet+}$ and $C_{70}^{\bullet+}$ are found to be unreactive toward 1,3-butadiene. However, both C_{60}^{2+} and C_{70}^{2+} are observed to react rapidly with 1,3-butadiene with the sequential addition of up to six molecules of 1,3-butadiene per C_{60}^{2+} and C_{70}^{2+} species. The sequential addition of allenes to C_{60}^{2+} leads to the formation of a chain of six-membered rings. Fullerene dications and trications have been used as initiators of polymerization of allene and propyne in the gas phase leading to observation of a remarkable periodicity in chain growth [412]. In the presence of $AlCl_3$, C_{60} is activated as a cationic species. This activated fullerene is reacted with poly(9-vinylcarbazole) (PVK) leading to grafting of C_{60} onto the polymer chain. The mechanism involves initial cationic activation of a C_{60} double bond by Lewis acid, followed by nucleophilic attack of the arene moiety of PVK [413].

13.3. Fullerenation of Polystyrene

C_{60} can be incorporated into non-cross-linked polystyrene by reaction with $AlCl_3$. The preparation of pendant C_{60}-polystyrene polymers is possible by use of Friedel–Crafts

467

type reactions (Fig. 194) [414]. The resulting polymers are soluble in organic solvents such as chloroform. The fullerenation of polystyrene provides a facile method of homogeneously dispersing fullerene molecules into polymer matrices in a structurally somewhat controllable fashion.

13.4. Fulleropolymers by Cycloaddition Reactions

Polymers containing suitable reactive functions can undergo cycloaddition reaction with C_{60} leading to covalent anchoring of the fullerene to the polymer. In the first such example,
Figure 192. The C_{2v}-symmetrical tetrakisadduct as a dendrimer core. Adapted from [396].
Figure 193. A linear polymer of C_{60} via supramolecular preorganization. Adapted from [402].

a simple linear polymer containing azide groups is reacted with C_{60} leading to a polymer with pendant C_{60} connected to the polymer backbone by nitrogen bridging. For this purpose, azidomethyl-substituted polystyrene is prepared. Percentage of azidomethyl units is controlled by the initial feed ratio of styrene and chloromethyl styrene. Reaction of the azimethyl-functionalized polymer with refluxing chlorobenzene furnishes the required polymer in which C_{60} molecules are pendant to the backbone polymer (Fig. 195) [415].

The end functionalization of hexaarm star-shaped polystyrene, prepared via living cationic polymerization by organosilicon compound, has resulted in a star polymer containing C_{60} as end caps [416]. After activation of the chain ends by $TiCl_4$, azido groups are introduced through the use of their trimethylsilyl derivatives, which on cycloaddition reaction with C_{60} furnishes the hexafullerene star polymer, **473** (Fig. 196).

Diels–Alder reaction of bis-o-quinodimethanes leads to a fullerene main-chain polymer. For this reason, bis-hexyloxy-substituted bis-sulphone is synthesized, which on heating generates the desired bis-o-quinodimethane *in-situ* [417]. Admixing of a mono-o-quinodimethane effectively suppressed cross-linking. The main-chain polymer **474** of high molecular weight consisting of 80 C_{60} units on the average is prepared (Fig. 197).

Benzocyclobutenone (BCBO) is known to generate reactive o-quinodimethane upon thermal activation. The diene α-oxo-o-quinodimethane is found to undergo [2 + 4] cycloaddition reaction with C_{60}. Benzocyclobutene is prepared in large quantities from anthranilic acid, homophthalic anhydride, or o-toluoyl chloride. Nitration followed by reduction gives a functionalized BCBO, which is used to prepare a BCBO containing vinyl monomer (Fig. 198) [418].

13.5. Anionic Living Polymerization

Reactions of preformed polymeric species in the form of anions have been studied following living anionic polymerization route. A starlike polymer with polystyrene units attached to a C_{60} center has been reported [419]. In this method polystyrene anions are allowed to react

with C_{60}, followed by an end-capping reaction with CH_3I. One to ten multiple polystyrene arms get attached to C_{60} leading to a star polymer which is insoluble. The key to the development of polymer-modified fullerenes is to form soluble fullerenated polymers in high yield under very mild conditions. Addition of C_{60} to carbanion intermediates of such polymers as polystyrene, poly(bromostyrene), and poly(vinylbenzylchloride) generated by an organometalic reaction leads to soluble polymers [420]. The preparation and structural characterization of novel starlike $C_{60}(CH_3)_3PAN$ and $C_{60}(CH_3)_3PMS$ copolymers by the reaction of living *n*-butyl-terminated polyacrylonitrile (PAN) and poly(methyl styrene) (PMS) with C_{60} in a heterogeneous medium, followed by a capping reaction with methyl iodide, have been reported (Fig. 199) [421]. Multiple

PAN and PMS arms are attached to the C_{60} core. The *n*-butyl-terminated polyacrylonitrile copolymer $C_{60}(CH_3)PAN$ has been pyrolyzed under vacuum [422]. As pyrolysis proceeds, evidence for aromatic ring formation is found. The *in-situ* infrared absorption measurements demonstrated that the nitrile groups of the polymers disappeared gradually as heating progressed and conjugated $C=N$ chains appeared.

Two methods to introduce a negative charge on a C_{60} and the further use of these carbanions as initiators for anionic polymerization of styrene and methyl methacrylate are investigated [423]. Fullerene anion is generated from the potassium salts of C_{60}, obtained by reduction with potassium naphthalenide. The resulting hexaanion only can polymerize MMA. The mechanism of polymerization is by electron transfer so that no fullerene is attached to the PMMA. Alternatively, polystyryllithium is added to C_{60} to form living star molecules with a C_{60} core bearing a well-controlled number of carbanion branches. While hexaanion of C_{60} can only initiate anionic polymerization of styrene by addition onto the monomer, five are enough to initiate the polymerization of MMA. Stars with seven PS branches and heterostars with six PS and two PMMA have been produced. By reacting six PSLi per C_{60} molecule, fairly pure star-shaped polymers with six branches and six carbanions located on the fullerene core are obtained. Only one of these six cabanions is able to initiate the anioninc polymerization of styrene or isoprene leading to well-defined palm-tree-like achitectures $(PS_a)_6C_{60}PS_b$ or $(PS)_6C_{60}PI$, **478** (Fig. 200) [424]. Also the out-growing chain bearing the carbanion has been allowed to react with the coupling agent dibromo-*p*-xylene and dibromohexane to produce the dumbbell-like structures.

Covalent incorporation of C_{60} onto the functionalized polyethylene film is reported by the anionic polymerization route (Fig. 201) [425]. Diphenylmethyl terminated ethylene oligomer is prepared from living oligomers by reaction with 1,1-diphenylethylene followed by deprotonation using *n*-BuLi. First films containing diphenylmethyl terminated ethylene oligomer are prepared by codissolving with HDPE, casting the solution mixture, and then treating with *n*-BuLi–TMEDA. The lithiated film is finally treated with C_{60}, which leads to the grafting of C_{60} onto polyethylene surface (**479**).

Figure 198. Incorporation of C_{60} into polymers by cycloaddition reaction with cyclobutenone. Adapted from [418].
Figure 200. Palm-tree-like polymer architecture based on C_{60}. Adapted from [424].

13.6. Condensation Polymerization

One of the early approaches to fullerene-based polymers is to first introduce reactive function to C_{60} and then co-condense it with another reactive monomer. Diphenyl fullerene derivatives bearing hydroxy- and amino-functions are used for C_{60} containing polyesters and polyamides. The diphenyl fullerene derivative containing phenolic OH groups is condensed with sebacryl chloride or hexamethylene diisocyanate to produce two polymers containing C_{60} molecules (**480**, **481**) dangling from the polymer chain (Fig. 202) [426].

Methano[60]fullerene dicarboxylic acid (MFDA) obtained from hydrogenolysis of diethyl methano[60]fullerene carboxylate is a suitable derivative for reaction with a preformed polymer, such as poly(propionylethylenimine-*co*-ethylene). Reaction of MFDA with poly(propionylethy-lenimine-*co*-ethylene) using 1-ethyl-3-(dimethylaminopr-opyl)carbodiimide as a coupling agent leads to a highly water-soluble pendant [60]fullerene-polymer, **482** (Fig. 203) [427].

Fullerenols contain multiple polar hydroxy functions and hence are versatile molecules in the prospective design of three-dimensionally stretched polymers. The synthesis of a urethane-connected polyether star utilizing fullerenol
as a molecular core is synthesized [428]. The polymer is found to contain six polymer arms per C_{60} on average. Fullerenol is first treated with a polymer of diisocyanated urethane polyether followed by termination reaction with dodecan-1-ol, which affords the corresponding C_{60}-based urethane-connected polyether polymers (Fig. 204). The synthesis of diisocyanate-terminated polyurethane is carried out by the reaction of poly(tetramethylene oxide) glycol and a diisocyanate. This polymer is then allowed to react with fullerenol [429]. The resultant flexible polymers **484** exhibit greatly enhanced thermal stability.

The addition of 2-methylaziridine to C_{60} and subsequent reaction of the adduct with a preformed polymer is investigated. The adduct, suggested to have 10 aziridine rings per molecule of C_{60}, reacts readily with Bisphenol A and Novolac via aziridine ring opening to produce polymers with good thermal stability [430]. The copolymers are three-dimensional polymers containing C_{60} with low coefficients of friction and good wear properties for use as potential solid lubricants. A new approach toward well-defined fullerene-containing poly(dimethylsiloxanes) using an *o*-xylylene derivative method has been described. The polymers **485** exhibited outstanding solubility in common solvents such as chloroform, THF, and benzene, a high thermal stability, and excellent film-forming properties (Fig. 205) [431]. Different strategies for the synthesis of polymers, either containing C_{60} in the polymer backbone or bearing C_{60} as part of the side chains, are described.

13.7. Nucleophilic Reactions

Polymers having amino groups either on the branch or at the termini react readily with C_{60}. Invariable such reactions lead to cross-linked products, which are insoluble. A bifunctional amino-terminated poly(oxyethylene) or poly(oxypropylene) is reacted with C_{60} or C_{70} in toluene [432]. Soluble products formed in the early stages of the reaction later cross-link by reaction between the polyfunctional fullerenes and the bifunctional polyethers. Fullerene functionalized amine
Figure 205. C_{60}-containing poly(dimethylsiloxanes): soluble polymers with high fullerene content. Adapted from [431].

containing polymers is capable of withstanding a temperature of at least about 300 °C and in some instances as high as 650 °C. In some cases cross-linking results in enhanced mechanical properties. Polymers with C_{60} pendants on the side chain of polymers soluble in toluene and carbon disulfide are synthesized by titrating toluene solutions of C_{60} with the aminopolymers: poly(ethylene imine), poly[4-[[(2-aminoethyl)imino]methyl]styrene] (**486**), and poly(propylene imine) (**487**) (Fig. 206) [433].

Fullerenes are found to add to amine containing flexible hydrocarbon polymers such as ethylene propylene terpolymer (EPDM-amine) to obtain C_{60}-functionalized polymers, **488** (Fig. 207) [434]. Thermogravimetric analyses show that the fullerene-attached EPDM-amine is thermoxidatively more stable than pure EPDM-amine.

A soluble well-defined fullerene-end-capped polystyrenes is prepared by reaction of amino-terminated polystyrene with C_{60} (**489**). The polymers formed clear homogeneous films; that is, no microphase or nanophase separation is observed (Fig. 208) [435].

A novel strategy to achieve water-soluble polyfullerenes is developed in which a bifunctional monomer is encapsulated in a cyclodextrin cavity and then the inclusion complex is reacted with C_{60}. The result is the first main-chain polyfullerene (**490**), where the cyclodextrin units are fixed at precise positions close to fullerenes without being in direct bond formations with the fullerenes (Fig. 209) [436].

14. FULLERENE MACROCYCLES

The attachment of macrocyclic compounds such as calixarenes, catenane, crown ethers, cyclophane, cyclotriveratrylene, phthalocyanines, etc. to fullerenes leads to a rich chemistry of supramolecular fullerenes [437], which is interesting because the materials lead to useful applications [438]. These applications stem from the remarkable ability of fullerenes to accept electrons resulting in the formation of donor–acceptor complexes. Fullerenes are known to interact electronically with molecules of organic and inorganic origin like P_4, S_8, I_2, benzene, saturated amines, metallocenes,
Figure 206. Binding of C_{60} to amino polymers. Adapted from [433].

Figure 209. The polyfullerocyclodextrins, water-soluble fullerene main-chain polymers. Adapted from [436].

tetrathiafulvalene, and so on [439]. For example, when C_{60} crystallizes from solutions of aromatic hydrocarbons as simple as benzene, the solvent molecules are incorporated into the crystal leading to species such as $C_{60}:4(C_6H_6)$. A solution of hydroquinone and C_{60} in hot benzene on evaporation leads to the black $[C_{60}][HQ]_3$ crystal. Solutions of C_{60} (or C_{70}) and ferrocene deposit black crystals of $[C_{60}][Fc]_2$. In these examples, the $\pi-\pi$ interaction between donor and acceptor is the driving force for the complex formation. These interactions are noticed in the solid state though in solution they disappear. The interactions between the fullerenes and the macrocycles, on the other hand, are strong and even exist in solution, often leading to stable complexes.

14.1. Fullerene Calixarenes

Fullerene complexes with calixarenes have been studied extensively [437a]. The reaction of toluene solutions of C_{60} with *p-tert*-butylcalix[8]arene leads to a sparingly soluble yellow–brown precipitate, which is identified as a 1:1 complex [440]. The selective inclusion of C_{60} into the *p-tert*-butylcalix[8]arene cavity leads to a viable method of purification of C_{60} [441]. When carbon soot is allowed to react with *p-tert*-butylcalix[8]arene, the crude product consists of 89% C_{60} and 11% C_{70} complex. This corresponds to a 90% extraction of the C_{60} content of the soot. Treatment of this *p-tert*-butylcalix[8]arene fullerene complex with chloroform dissolved the host that leads the fullerenes to precipitate. This paved the way for a substantial enrichment of the

C_{60} content over C_{70} in the fullerene mixture and a repetition of the process leads to the effective separation of C_{60} from C_{70}.

Most of the reported complexes are insoluble in water. A calix[8]arene with a hydrophilic SO_3Na function is reported to form a water-soluble complex [442]. The 1:1 complexes between *p-tert*-butylcalix[8]arene and C_{60} is micelle-like with trimeric aggregates of fullerenes as the core surrounded by three host molecules, each in double cone conformation and spanning two fullerenes along a triangular edge (Fig. 210) [443]. Introduction of electron-rich aniline and 1,3-diaminobenzene derivatives into calix[8]arene creates new C_{60} receptors [444], which gives no indication of complex formation. Deep inclusion of C_{60} into the calix[*n*]arene cavity, as expected for calix[8]arenes, is not a prerequisite for C_{60} inclusion. Calix[*n*]arenes that have a conformation and a proper inclination of the benzene rings such as a calix[5]arene, homocalix[3]arene, and to some extent calix[6]arene do interact with C_{60} in toluene.

Conformational freedom in calix[*n*]aryl esters can be frozen to cone conformation by complexation with appropriate metal cations. Such metal cations appropriately preorganize the calix[*n*]aryl ester derivatives into their cone conformers and can alter them into excellent C_{60} receptors

Figure 208. A fullerene-end-capped polystyrene. Adapted from [435].
Figure 210. Aggregate of fullerenes surrounded by calixarene host. Adapted from [443].

in solution. A conformationally mobile calix[6]aryl ester does not react with C_{60}. Introduction of bulky ester groups to OH groups leads the phenol units in the calix[6]aryl ester to stand up, which makes the cavity edge smaller and the benzene ring inclination improper. When the calixarene is reacted with a Cs^+ salt, the metal complex could easily include C_{60} into the cavity (**492**). The metal cation formed a complex with the phenolic oxygen converting the calixarene to a symmetrical cone conformation facilitating C_{60} binding to the upper rim (Fig. 211) [445].

Two calixarenes have been covalently connected in order to produce shape-selective receptors, with well-defined cavity sizes (Fig. 212) [446]. With these calixarenes a dramatic increase in association constants for 1:1 complexes with C_{60} in solution has been achieved. The bridged receptor binds to C_{70} even better than C_{60}. The binding constant for C_{60} in toluene at 298 K is 76,000 M^{-1} for C_{60}, whereas for C_{70} in similar conditions it is 163,000 M^{-1}. A bipyridyl ligand attached to a calixarene on reacting with metal ions can generate a suitable receptor for C_{60}. Thus, two calix[5]arene precursor units, each carrying a bipyridine ligand, upon complexation with a metal ion like Ag(I) create a cavity sufficiently large to bind C_{60} and C_{70} (Fig. 213) [447].

A number of covalently bound fullerene calixarenes such as a C_{60}-functionalized calix[8]arene connected by a polyether chain have been designed [448]. An azido-terminated polyether chain attached to the rim of the calix[8]arene is reacted with C_{60}. From UV-vis and fluorescence studies, it is proved that the covalently bound fullerene still interacts with the calixarene in solution. Two fullerene calixarenes are synthesized, one of which had two fullerenes bonded to the lower rim of the same calixarene [449]. From light scattering measurements, it is observed that in chloroform–acetonitrile and chloroform–methanol the compound with two fullerenes aggregates strongly. No aggregation is observed for compounds with a single fullerene. Two compounds, in which C_{60} is linked to a cone-calix[4]arene or to a 1,3-alternate-calix[4]arene, are synthesized (Fig. 214) [450]. The fullerene is used as a "lid" for the ionophoric cavity. Several metal cations such as Li^+, Na^+, Ag^+ influence the electronic spectra of C_{60} in cone-calix[4]arene, indicating the metal cation bound therein interacts with

Figure 212. A bridged calixarene dimer for encapsulation of C_{60} and C_{70}. Adapted from [446].

the C_{60} surface. No spectral change is noticed when 1,3-alternate-calix[4]arene is treated with the metal ions.

14.2. Fullerene Catenane

For the synthesis of the fullerene containing catenane the bis(*p*-phenylene)-[34]crown-10, which has two π-electron-rich hydroquinone rings, is fused to C_{60} in a regioselective manner (Fig. 215) [451]. The formation of cyclobis(paraquat-*p*-phenylene) around the C_{60}-appended macrocyclic polyether leads to the [2]catenane. ^{1}H NMR investigation indicates the molecule to be intramolecular stacks of donor–acceptor–donor–acceptor, exhibiting spatial interaction between fullerene and bipyridinium units.

14.3. Fullerene Crown Ethers

A fullerene monolayer is attractive because the interesting fullerene properties are transferred to the bulk materials by simple surface coating. However, strong hydrophobic interactions aggregate C_{60} resulting in multilayer films. The aggregation is prevented in the presence of crown ether. However, in spite of the several fullerene crown ether conjugates known, in reality, most lead to multilayer formation at the air–water interface [452]. Apparently, the hydrophobic head groups are not bulky enough to prevent aggregation of the carbon spheres. Amphiphilic azacrown derivatives and the fullerenes could form stable complexes because the substituents on the nitrogen atoms wrapped around the

fullerenes like lipophilic arms, thus creating a hydrophobic envelope around the fullerene sphere (Fig. 216) [453]. The binding between the fullerene molecule and the aza-crown is a noncovalent interaction. Mono- and multilayers of 1:1 mixtures of C_{60} and C_{70} and the macrocycles could be spread on the air–water interface. The monolayers could be transferred onto solid supports by the Langmuir–Blodgett technique.

Stable Langmuir monolayers and Langmuir–Blodgett films of C_{60} are also reported in a C_{60} benzo-18-crown-6 derivative [454]. This derivative forms a thin film at the air/water interface, especially when K^+ ions are present in the subphase. A pseudo 15-crown-5 macro ring directly attached to C_{60} via a bisaziridine linkage and the subphase containing K^+, Ba^{2+}, and NH_4^+ ions leads to monolayers [455]. The addition of the cations stabilized the monolayers and increased the limiting area. A gold surface is modified using a thiol-terminated ammonium salt (Fig. 217) [456]. When the modified gold layer is immersed in dichloromethane

solution of the fullerene derivative a compact monolayer of C_{60} is obtained (**498**).

The crown ether can also be precisely positioned in close proximity to the fullerene surface even when not bound directly (Fig. 218) [437b]. When it is made to complex with the alkali metal ions, a significant perturbation of the electronic structure of the fullerene is observed, indicating that fixing the macrocycle at a precise position on the fullerene surface leads to more effective interaction between the metal ion and the fullerene sphere.

14.4. Fullerene Cyclophanes

A cyclophane has been attached to C_{60} leading to a "charming ring" (Fig. 219) [457]. The [2.2]cyclophane had a diazoalkane moiety, through which reaction takes place at the [6,6]-ring junction, leading to a methanofullerene derivative. The ^{13}C NMR signals of aromatic carbons of the cyclophane ring are not markedly affected by substitution of C_{60}. However, changes in the UV-vis spectra indicated intramolecular charge transfer interaction between the cyclophane and fullerene.

14.5. Fullerene Cyclotriveratrylenes

The macrocycle cyclotriveratrylene (CTV) forms an inclusion complex with both C_{60} and C_{70}. It envelops the fullerenes in such a manner that the electron-rich aryl rings of CTV cover three adjacent five-membered rings of C_{60}. The stability of the complex, an outcome of the π–π interactions, leads to changes in the absorption spectra of CTV.
Figure 219. Attaching a cyclophane to C_{60} providing a "charming ring." Adapted from [457].
Figure 220. Noncovalently bound fullerene cyclotriveratrylene. Adapted from [458].

From a toluene solution of C_{60} and cyclotriveratrylene, solvated 1:1 complex $(C_{60})(CTV)$ is formed and from this solution crystals of $(C_{60})_{1.5}(CTV)(PhMe)_{0.5}$ have been isolated (Fig. 220) [458].

Polybenzyl ether dendritic branches with peripheral triethyleneglycol chains have been attached to a cyclotriveratrylene core and the supramolecular complexes obtained from the resulting macrocyclic derivatives and C_{60} are found to be water-soluble [459]. In the design of the CTV hosts (Fig. 221), the polybenzyl ether dendritic type structure is chosen to provide an internal cavity capable of encapsulating totally the hydrophobic C_{60} guest, thus preventing the fullerene–fullerene interactions and precipitation from the aqueous solutions.

The C_3-symmetrical cyclotriveratrylene-C_{60} trisadducts with a *trans*-3,*trans*-3,*trans*-3 addition pattern (Fig. 222) or with an *e,e,e*-addition pattern are prepared by regio- and diastereoselctive tether-directed Bingel reaction of C_{60} with the trismalonate appended cyclotriveratrylene derivative [460]. Interchromophoric interactions between the electron-rich cyclotriveratrylene cap and the electron-attracting fullerene moiety have a profound effect on the electrochemical behavior of the carbon sphere.

14.6. Fullerene Phthalocyanines

The absorption and electron-accepting properties of C_{60} and the properties of electro- and photoactive molecules are combined by covalently linking these two types of molecules [461]. This leads to donor–acceptor systems with long-lived charge-separated states for several applications with the ultimate goal of artificial photosynthesis or conversion of solar

light to electric current. The fullerene phthalocyanines are an interesting class of molecules, because the phthalocyanines themselves are known for their remarkable electronic and optical behavior. A nickel phthalocyanine is synthesized from which fullerene phthalocyanine is obtained by Diels–Alder reaction of the phthalocyanine derivative and C_{60} (Fig. 223) [462]. From cyclovoltametry studies it is found that the reduction of the fullerene moiety has a pronounced influence on the optical properties of the phthalocyanine.

14.7. Fullerene Porphyrins

The porphyrins are ideal donors and hence a number of molecules have been synthesized to covalently link the fullerene sphere with the macrocycle [463]. A large number of porphyrins have been synthesized and their interaction with C_{60} when bound noncovalently or covalently has been explored. For example two derivatives of a cyclic dimer of porphyrin without or with metal ions are shown to complex C_{60} and C_{70} (Fig. 224) [464]. The effect of the metal ions in the porphyrin ring on binding affinity toward the fullerenes has been explored. Extremely high association constants ($\sim 10^8$ M^{-1}) and low dissociation activities of the RhMe/fullerene system should allow construction of more complex supramolecular architectures based on fullerenes.

A fullerene porphyrin conjugate, covalently linked via a pyrrolidine linkage, is prepared [465]. The Ni(II) complex is similarly prepared from the Ni(II) complex of the porphyrin. A porphyrin-linked fullerene, where a C_{60} moiety is covalently linked to the meso position of 5,15-diarylporphyrin with a pyrrolidine spacer, is synthesized [466]. Three pyrrolidine-functionalized C_{60} has been reported [467], in
which a simple monomeric methyl pyrrolidine derivative, a pyrrolidine-linked tetraphenyl porphyrin-C_{60} dyad, and a pair of bifullerenes have been investigated. The Diels–Alder reaction has been used to prepare porphyrin-C_{60} dyads. The separation or spatial orientation of the donor and acceptor can influence the extent and rate of charge recombination. By changing the bond connectivity, the spacing and relative orientation of the porphyrin and fullerene moieties in the dyads are systematically changed (Fig. 225) [468]. Such dyads prefer to adopt a conformation in which the porphyrin and fullerene moieties are as close as possible in space as allowed by the structural constraints of the spacer [468, 469]. A few triads **509** have been synthesized and studied in terms of electron and energy transfer (Fig. 226) [470].

Several linear triads have been built around the zinc porphyrin/C_{60} (ZnP/C_{60}) couple. A set of molecular triads **510** in which a fullerene moiety is linked to a ferrocene-ZnP (Fc-ZnP) fragment (Fig. 227) [471]. In this molecule two consecutive electron transfers yield the Fc$^+$-ZnP–$C_{60}^{\bullet-}$. In oxygen-free benzonitrile, the final charge separated state decays to the singlet ground state. A fullerene moiety is also attached to an array of two prophyrins [472], in which the ZnP moiety performs as an antenna molecule, transferring its singlet excited state energy to the lower lying H$_2$P. By efficient funneling of light from the antenna chromophore, ZnP, to the H$_2$P chromophore and injecting charge into

Figure 228. A $(ZnP)_3$–ZnP–H_2P–C_{60} hexad. Adapted from [474].

the fullerene core effecting charge shift, this artificial reaction center reproduces the natural system very efficiently. Successful mimicry of the primary event of photosynthesis using these systems leads to combine two porphyrins, a ferrocene and C_{60}, into an integrated single system tetrad, Fc-ZnP–H_2P–C_{60}. The result turned out to be a highly efficient energy transfer system [473]. Indeed, the lifetime of the spatially separated radical pair, the product of a sequence of energy and multistep electron transfer reactions, reaches well beyond milliseconds into a time domain which has never been accomplished so far in an artificial photosynthetic reaction center.

A sophisticated $(ZnP)_3$–ZnP–H_2P–C_{60} hexad **511** comprised of a $(ZnP)_3$–ZnP model antenna system linked to a H_2P–C_{60} reaction center has shown to reveal indeed a cascade of efficient light-driven energy and electron transfer processes (Fig. 228) [474]. The antenna reveals rapid transduction of the singlet excited energy from the peripheral prophyrins to the central ZnP, which then transfers energy further to the ZnP chromophore, finally resulting in electron transfer to C_{60}. At the end of the process a 1.3 ns long-lived charge separated state $(ZnP)_3$–ZnP–H_2P$^{\bullet+}$–$C_{60}^{\bullet-}$ is formed in 70% yield.

A C_{60}–porphyrin interaction is reported in which the macrocycle is not covalently bound to C_{60} but fixed rigidly above the C_{60} leading to a true supramolecular dyad, **512** (Fig. 229) [475]. A pyridine-functionalized fulleropyrrolidone is linked to the Zn(II) ion of a tetraphenylphorphyrin by coordination with high affinity. Using the principle

of macrocyclization between C_{60} and bismalonate derivatives it is possible to synthesize a C_{60}–Zn(II) tetraphenyl porphyrin dyad in which the spatial position of the porphyrin ring is fixed above the fullerene [476]. The organic chromophore could be precisely positioned in close proximity to the fullerene surface.

The π–π stacked C_{60}-prophyrin dyad has been used to synthesize rigid electroactive arrays by reacting the dyad with diazabicyclooctane or a pyridine-fullerene ligand, respectively (Fig. 230) [477]. The triad **515** and the pentad **516** are obtained by a careful control of the reactant concentrations. Another triad is formed from a reaction of the C_{60}–Zn(II) porphyrin dyad with the corresponding fulleropyrrolidine.

Two zinc tetraphenylporphyrin (ZnP) chromophores are attached to C_{60} leading to compounds of the type ZnP–C_{60}–ZnP (**517**, **518**) (Fig. 231), a flexible molecule, which leads to rigid, confined model donor–acceptor ensembles by self-organization [478]. The monomeric species is confirmed by molecular modeling using semiempirical methods. Following tether directed bisfunctionalization, a molecule with four appended fullerenes **519** is synthesized, in which the porphyrin ring is rigidly fixed close to the fullerene spheres (Fig. 232).

14.8. Fullerene Cyclodextrins

14.8.1. Fullerene Cyclodextrin Inclusion Complexes

Cyclodextrins (CD) are oligoglycosides of six (α-CD), seven (β-CD), or eight (γ-CD) glucose units forming macrocyclic rings and they greatly vary in their aqueous solubility, β-CD being the least soluble. Noncovalent interaction between the cyclodextrin hosts and guest molecules has been effectively used to solubilize the otherwise insoluble hosts in water. The stability constants of the 1:1 inclusion complexes (k_{11}) depend upon the diameter of the guests and the cavity dimensions of the host. In the early stages of the fullerene cyclodextrin inclusion complexation studies, the dimensions of the three CDs, alongside those of C_{60} and C_{70}, are the major considerations that influenced the research of fullerene cyclodextrin inclusion complexation spanning over a decade. The matching cavity size of γ-CD and the diameter of C_{60} as well as its high aqueous solubility leads to synthesis of the host–guest complex and its detailed studies [479, 480]. In this complexation process, n–π donor–acceptor interactions between the n-orbitals of the sugar O atoms and the π-system of the fullerene contribute to the stability of the complex [481]. The cone-shaped cavity of γ-CD (950 pm) and the cavity depth of (780 pm) do not completely encapsulate the C_{60} sphere of van der Waals diameter of ~1000 pm. Hence a complex with a 2:1 (γ-CD:C_{60}) stoichiometry that very effectively covers C_{60} is proposed for the structure of the complex. From photophysical studies it is indicated that γ-CD covered a large portion of the carbon sphere [482]. This preferential complexation leads to extraction of C_{60} from a mixture of C_{60} and C_{70} in solid state on boiling the mixture with an aqueous solution of γ-CD.

Though the unmodified α- and β-CD are reported not to complex C_{60}, their derivatives such as dimethyl-β-cyclodextrin, hydroxypropyl-β-cyclodextrin, and α-, β-, and γ-cyclodextrin–epichlorohydrin prepolymers have been reported to form 1:1 and 2:1 complexes with C_{60} [483]. These complexes have been prepared by kneading. It was recently noticed that β-CD does indeed form a complex with C_{60}, contrary to what is believed to be not probable [484], though under similar reaction conditions α-CD is seen not to form a complex. However, the γ-CD/C_{60} complex is a lot more soluble in water than the β-CD counterpart. Encapsulation of the fullerenes by the cyclodextrins does not necessarily mean that the fullerene sphere is shielded completely from reacting further, although the reactivity of the fullerene in γ-CD/C_{60} complex is noticeably lower than in the unprotected form. The complex is still susceptible for easy reduction by radicals generated in the aqueous phase [485]. A number of electron donors can interact with γ-CD/C_{60} leading to donor–acceptor complexes though the fullerene moiety is embedded between two host molecules of γ-CD. The formation of donor–acceptor complexes with electron-rich molecules, such as triethylamine, pyridine, hexamethylene tetramine, acrylamide, thioglycolic acid, and 2,2'-thiodiethanol, have been reported [486].

14.8.2. Covalently Bound Fullerene Cyclodextrins

The synthesis of water-soluble, covalently bound fullerene cyclodextrin conjugates (**520**, **521**) reacting cyclodextrin monoamine derivatives and fullerenes has been reported (Fig. 233) [487]. Depending upon the macrocycle, the aqueous solubility of the corresponding conjugate varied. Even though α-CD has a very small cavity, which does not facilitate complex formation easily, covalent binding to the fullerenes leads to a material which is even more soluble than the ones from β-CD. Considering the fact that the cyclodextrins are bioamenable, the covalently bound monofunctionalized fullerene cyclodextrins can have a number of biomedical applications. Fullerenes have also been attached to cyclodextrins via a bridging nitrogen atom by treating α- or β-cyclodextrin azides with C_{60} [488]. The extent of their aqueous solubility is again dependent on the solubility of the macrocycle.

A 2:1 (permethylated-β-cyclodextrin)–fullerene conjugate **522** has been synthesized [489], in which two β-cyclodextrin units are attached covalently to C_{60} by Bingel cyclopropanation (Fig. 234). The linking units allow enough flexibility such that the CD rings effectively encapsulate C_{60} leading to high aqueous solubility. Such a complexation strategy is expected to prevent interaction of C_{60} molecules thus minimizing aggregation. However, in the UV-vis spectra of the compound in water, a relative maximum at 430 nm is not seen, which is a sign of aggregation. Nevertheless, the conjugate displays a negative solubility coefficient and has a partition coefficient between octanol and water in the suitable range for biological studies.

15. APPLICATIONS

The fullerenes have three distinct properties that are linked directly to their applications. These are (1) efficient electron transfer in the triplet state, (2) scavenging of free radicals, and (3) generation of singlet oxygen in presence of light. Electron transfer from an electron rich source such as a conducting polymer leads to applications of fullerene materials as photodiodes. Free radical scavenging and singlet oxygen generation are properties associated with the applications of fullerenes and their derivatives in the fields of biology and medicine. A number of fullerene derivatives are known to possess excellent liquid crystalline property. Some of these areas of applications will be discussed here briefly. Besides, there are a number of areas where fullerenes have promising applications. All-carbon ferromagnets of fullerenes are
Figure 233. Fullerene–cyclodextrin covalent conjugates. Adapted from [487].
Figure 234. Two β-cyclodextrin units are covalently attached to C_{60} by Bingel cyclopropanation. Adapted from [489].

exciting new materials [490]. The linear and nonlinear optical properties of a number of fullerene derivatives have been thoroughly studied [491].

15.1. Fullerenes and Conjugated Polymers

Fullerenes and conducting polymers with a nondegenerate ground state have been used to design photodiodes [492]. Several such polymers have been doped with C_{60} and C_{70} and their electrical conductivity and photoconductivity have been studied. The preparation of photoconducting films of polyvinylcarbazole (PVK) doped with fullerenes is reported [493], the performance of which is comparable to some of the best photoconductors available commercially. The synthesis of C_{60} and C_{70} chemically modified polymeric photoconductors such as C_{60}-modified PVK and its bromine and iodine modified derivatives is also reported [494]. In these polymers, the charge-transfer interaction between the positively charged carbazole, resulting from charge transfer toward the fullerenes, brought about the enhanced photoconductivity relative to PVK itself. Polymer-based photodetectors and photovoltaic cells have been made by using conjugated polymer soluble derivatives of poly(p-phenylene vinylene) (PPV) and poly(2-methoxy-5-(2′-ethylhexyloxy)-1,4-phenylene vinylene) (MEH-PPV) as donors and C_{60} as acceptor [495]. By optimizing the donor–acceptor ratio, a power conversion efficiency of 2.5% and a collection of efficiency of 26% have been achieved for photovoltaic cells. Doping effects of C_{70} on electrical and optical properties of conducting polymers such as poly(3-alkylthiphene), poly(2,5-dialkoxy-p-phenylene vinylene), and poly(9,9-dialkylfluorene) have been studied and compared with those by C_{60} doping. Fluorescence intensity is quenched and photoconductivity is enhanced upon doping [496]. In order to enhance the intramolecular energy and charge transfer of PPV derivatives and fabricate highly efficient photovoltaic cells, a novel C_{60}–PPV system has been synthesized. Flexible alkyl side groups have been introduced to further improve the processability of the copolymer. Carbazole and triphenylamine moieties are introduced into the

copolymer main chains to enhance electrical and photoactive properties [497]. From studies on X-band photoluminescence (PL)-detected magnetic resonance spectra of C_{60}- and C_{70}-doped PPV-based polymers it is concluded that fullerenes quench the PL, and both the polaron and triplet exciton resonances are dramatically enhanced [498]. Photoinduced electron transfer in films of poly(3-decyloxy-1,4-phenylene) (DO-PPP) blended with C_{60} is observed by infrared photoexcitation spectroscopy. The photoinduced IR-active vibrational structure and electronic subgap absorption features of the DO-PPP are greatly enhanced upon adding just 2% of C_{60} [499]. Photoinduced electron-transfer processes from oligothiophenes/polythiophenes to fullerenes have been studied by the nanosecond laser flash photolysis method, observing the transient absorption spectra in the visible and near-IR region. When fullerene is selectively photoexcited in polar solvents, electron transfer from oligothiophene to the excited triplet state of fullerene is confirmed [500].

15.2. Liquid Crystalline Fullerenes

Liquid crystals play a key role in everyday life as the essential component of several display devices. Fullerene-containing liquid crystals are interesting materials for fundamental studies as well as for practical applications. Binding the liquid crystalline moiety to C_{60} leads to better supramolecular organization of the liquid crystal. Further, C_{60} influences the formation and stability of the liquid–crystalline phase. The typical shape can facilitate the formation of molecular devices and switches showing outstanding performance and characteristics. For example, a hexapyrrolidine C_{60} adduct has been found to be suitable in designing a single layer organic light-emitting device [501]. Two concepts have been developed for the design of C_{60}-containing thermotropic liquid crystals: covalent [502] or noncovalent [503] binding of the liquid crystalline moiety with the fullerenes. The work on fullerene containing liquid–crystalline dendrimers with several examples where the dendritic liquid–crystalline moiety is covalently or noncovalently bonded to C_{60} has been reviewed [504]. Covalent linking of the liquid crystal to C_{60} is accomplished through a cyclopropane ring using Bingel reaction or via a pyrrolidine ring generated by reacting an aldehyde derivative and sacrosine with C_{60}. Mesomorphic cyclotriveratrylene (CTV) derivatives are used to noncovalently complex C_{60}.

15.2.1. Liquid Crystals Containing Covalently Bound Fullerenes

Cholesterol is a strong liquid–crystalline promoter. The precursor compound **523** containing cholesterol gives smetic A, chiral nematic phases, and a blue phase. The first fullerene-containing thermotropic liquid crystal **524** is prepared by reacting the malonate precursor **523** with C_{60} (Fig. 235) [502a]. Incorporation of C_{60} leads to a drastic change of the liquid–crystalline properties. For the fullerene-containing compound (**524**) a smetic A phase forms when the sample is cooled from isotropic melt, revealing a monotropic character of the mesophase. Introduction of C_{60} apparently disrupts the liquid–crystalline organization. This could be a consequence of the size and shape of C_{60} molecule.
Figure 235. Liquid–crystalline fullerene–cholesterol conjugate. Adapted from [502a].

Liquid–crystalline materials incorporating C_{60} along with electron-donor units such as ferrocene have been reported. Cholesterol-based liquid crystals containing ferrocene have been reported (Fig. 236) [505]. These are multifunctional liquid crystals and are promising candidates for the molecular switches since electron transfer is shown to occur in solution with fullerene–ferrocene dyads and chemical oxidation is applied to generate ferrocenium derivatives from ferrocenes. The photoinduced electron-transfer reaction in fullerene–ferrocene liquid crystals could be used as a switching mechanism because of the presence of either ferrocene (light off) or ferrocinium (light on). Starting from the ferrocene- and cholesterol-containing precursor **525** the fullerene bismalonate derivative **526** is synthesized. As expected, for the fullerene–ferrocene liquid–crystalline material **526**, photoinduced intramolecular electron transfer is observed in organic solvents. Each subunit (i.e., cholesterol, ferrocene and fullerene) plays a role in the supramolecular organization within the liquid–crystalline phases as well as contribute to the liquid–crystalline property and photoinduced electron transfer. In the smectic A phase, a relative order with microsegregation of the different units (ferrocene, fullerene, and cholesterol) is observed. This order might be important to control the electron-transfer processes upon light irradiation. Studies in solution reveal that the ferrocene–fullerene system does indeed give rise to intramolecular electron transfer with relatively long-lived charge-separated species.

Modification of C_{60} with dendritic addends is an elegant approach to prevent aggregation. A hydrophilic dendrimer allows the construction of stable and highly ordered Langmuir–Blodgett films. In such systems C_{60} is buried in the dendrimer. As a consequence, there is a decrease of the unfavorable C_{60}–C_{60} interaction and a beneficial increase of the interactions between the polar groups and the water surface. Functionalization of dendrimers with various mesomorphic groups leads to liquid–crystalline materials (Fig. 237) [506]. Such dendrimers can have tailor-made properties. The size of the dendrimers counterbalances that of C_{60} and minimizes the influence of C_{60} bulk. The second-generation dendrimer **527** represents dendritic structure incorporating the ferrocene. Both the dendrimer and its precursor showed a smetic A phase, indicating that in this case the presence of C_{60} does not have a disrupting influence on the liquid–crystal characteristics.
Figure 236. Multifunctional fullerene–ferrocene liquid crystals containing ferrocene and cholesterol. Adapted from [505].

Similar to cholesterol, cyanobiphenyl imparts liquid–crystalline properties to the molecule bearing this function. C_{60} derivatives bearing cyanobiphenyl functions **529** are synthesized starting from the precursor **528** (Fig. 238) [502e]. The d-layer spacing determined from X-ray diffraction in the smetic A phase is 76 Å. The layers are viewed as consisting several molecules of C_{60} containing mesogenic groups. The model proposed [504] is that the two arms of the molecule are folded in the same direction and structure consists of a head-to-tail arrangement of these groups (Fig. 239).

The effect of dendrimer size on evolution of mesomorphism is demonstrated by using a series of dendrimers varying in size. A comparison indicates that the stability of the liquid–crystalline phase increases with the increase in the dendrimer generation. The fullerene dendrimers **532–534** (Fig. 240) [502d] and their malonate precursors display the same mesophases, while the precursor of **531** gives rise to a nematic phase. In this case introduction of C_{60} changed the nature of the liquid–crystalline phase.

The layer spacing for **531** is 82 Å, which is a rather high value. Simulation experiments of **531** indicate that the molecule adopts a V shape, the arms of the V being of

mesogenic groups. This leaves enough space for mesogenic groups from adjacent layers to be included. Compounds **532–534** have a relatively lower layer spacing compared to **531**. In these dendrimers, the branching parts have large bulk and, to avoid steric crowding, the branches extend laterally rather than coming together to generate the V shape. The smetic A phase for these compounds is stabilized by an efficient lateral arrangement of the mesogenic groups. The dendritic branches with the mesogenic groups connected through intervening aliphatic spacers represent the major part. The fullerene moiety represents a minor part. Therefore the polar cyano groups essentially govern the characteristic properties of these molecules. Molecular modeling shows these groups as pointing to one main direction. This permits the interpenetration of the mesogenic groups from adjacent layers. Thus the central part of the layer is constituted by the fullerene moiety embedded in the dendritic branches. The long aliphatic chains and the ester groups provide the arms with a lot of flexibility that facilitates good space filling. The malonate precursors of **533** and **534** exhibit also smetic A phases similar to the fullerene derivatives. Hence the fullerene moiety does not play a significant role.

529
Figure 238. Liquid–crystalline fullerene derivative containing cyanobiphenyl function. Adapted from [502e].

The first fullerene dendrimer connected to C$_{60}$ via a pyrrolidone ring is **535** (Fig. 241) [502f]. Fulleropyrrolidones are stable to chemical or electrochemical reductions, in contrast to Bingel adducts which undergo retro-Bingel reactions. This property is interesting because the redox-active fulleropyrrolidone liquid crystals remain stable. A smetic phase is observed for its aldehyde precursor as well as for the fullerene derivative. Esterification of a bis(methanofullerene) carrying two carboxylic acid functions with an amine-based dendritic wedge leads to yet another cyanobiphenyl-terminated dendritic liquid–crystalline material **536**. The fullerene derivative displays a mesophase, whereas the precursor shows a nematic phase.

Hexaadducts of C$_{60}$ are attractive materials due to their three-dimensional architecture. Attaching six liquid–crystalline addends to C$_{60}$ leads to materials with remarkable liquid–crystalline properties (**538**) (Fig. 242) [502h]. The organization of 12 cyanobiphenyl units around a central fullerene core generated the required structural anisotropy and intermolecular interactions for mesomorphism to occur. Though the precursor **537** showed a nematic phase, an enantiomeric smectic A phase is observed for **538**. The formation of the smectic A phase indicates that the cyanobiphenyl

units are not oriented radially around C$_{60}$ but form a cylinder-like structure with the mesogenic fragments oriented upward and downward. This is a feature demonstrated by the liquid–crystalline materials from dendrimers with a central core functionalized by large number of mesogenic groups.

Attachment of five aromatic groups to one pentagon of a C$_{60}$ fullerene molecule yields deeply conical molecules that stack into polar columnar assemblies (Fig. 243) [507]. The stacking is driven by attractive interactions between the spherical fullerene moiety and the hollow cone formed by the five aromatic side groups of a neighboring molecule in the same column. This packing pattern is maintained when the aromatic groups are extended by attaching flexible aliphatic chains. The compounds possess excellent thermotropic and lyotropic liquid–crystalline properties.

15.2.2. Liquid Crystals of Noncovalently Bound Fullerenes

Cyclotriveratrylenes form supramolecular complexes with C$_{60}$. Such complexes are easily obtained by evaporation of a benzene solution containing the CTV and C$_{60}$ (Fig. 244) [503]. CTV containing liquid–crystalline units can form a complex with C$_{60}$ in a similar fashion. The noncovalent approach is interesting because it does not require the development of specific reactions to render C$_{60}$ mesomorphic. On the other hand, such a material cannot be used at high temperature when C$_{60}$ is expelled from the complex. Interestingly **540** shows mesomorphic properties at room temperature.

15.3. Fullerene Derivatives for Biological and Biomedical Applications

The biological and biomedical application potentials of fullerenes have received considerable attention [508]. These properties emerge from fullerenes efficiently scavenging free radicals. Additionally fullerenes generate singlet oxygen very efficiently in presence of UV and visible light [509]. In order for fullerenes to be used for these applications, they should be water-soluble. This is possible when hydrophilic groups are appended to the otherwise highly hydrophilic fullerenes.

A number of interesting syntheses have led to fullerene derivatives either soluble in water in an organic cosolvent or soluble in water without the need of a cosolvent.
Figure 239. Proposed supramolecular organization of the dendrimer in the liquid–crystalline phase. Adapted from [504].
Figure 240. Liquid–crystalline dendrimers of different generation. Adapted from [502d].

Attaching a hydrophilic function usually carrying OH and COOH groups has led to a number of such derivatives. Usually a minimum of 12 OH groups or 6 COOH groups is needed to effectively solubilize C_{60} in water. Thus, polyfunctional fullerene derivatives are more soluble in water than their monofunctional counterparts. Since the radical scavenging property is dependent upon the number of π-bonds left unbroken on fullerene, a compromise is often made between monofunctonalization and polyfunctionalization. Prevention of aggregation is also an equally important aspect. Close contact between fullerene spheres leads to a decrease in triplet lifetime, which then affects the generation of singlet oxygen. The singlet oxygen generated by fullerene in the presence of light is responsible

535

536
Figure 241. Cyanobiphenyl-terminated dendritic liquid–crystalline materials connected to fulleropyrrolidine or a bis(methanofullerene). Adapted from [502f].

for cytotoxic behavior of the fullerenes. Following is a brief outline of the major areas of biology and medicine in which such soluble fullerene derivatives find potential applications.

15.3.1. Antitumor Studies

One of the easily accessible water-soluble fullerenes studied for its anticancer activity is fullerol $C_{60}(OH)_{24}$. This compound affected the growth kinetics of human lymphocyte cultures, epidermal carcinoma cell cultures, efficiently preventing cell growth in a manner similar to known anticancer drugs such as taxol. When water-soluble C_{60}–PEG conjugate is intravenously injected to the tumor-bearing mice, their accumulation in tumor tissue is higher than that in normal tissue [510]. Treatment with C_{60}–PEG conjugate injection coupled with light irradiation is seen to strongly induce

tumor necrosis. The photodynamic effect on tumors greatly depends on the C_{60} dose and the power of light irradiation. All the tumor-bearing mice are cured. The synthesis of a highly water-soluble dendro[60]fullerene **541** is carried out (Fig. 245) [511]. Upon hydrolysis of the COOMe groups, the dendritic moiety generates 18 COOH groups, which impart the molecule a very high aqueous solubility. Further, the dendrimer effectively shields the fullerene moiety thus preventing aggregation.

The cytotoxic and photocytotoxic effects of the dendritic C_{60} monoadduct and the malonic acid C_{60} trisadduct are tested [512]. It is found that only the dendritic monoadduct inhibits cell growth, whereas the trismalonic acid adduct has little effect. These fullerene derivatives become toxic when irradiated with UV light. The cell death is mainly caused by membrane damage and it is UV dose-dependent. Trismalonic acid fullerene is found to be more phototoxic than the dendritic derivative.

Figure 246. Fullerene carboxylates used for antiviral activity experiments.

15.3.2. HIV Protease Inhibition and Antiviral Activity Studies

Fullerene dicarboxylates (Fig. 246) are amphiphilic. In one of the first reports, methano[60]fullerene dicarboxylate is suggested to show anti-HIV activities based on molecular modeling studies. This study showed that the fullerene derivative and hydrophobic surface of the enzyme cavity could have good van der Waals interaction. Under actual experimental conditions these compounds are found to possess good anti-HIV activity in the μM range [513]. The water soluble fullerene derivative N-tris(hydroxymethyl)propylamidomethano[60]fullerene is very active against HIV-1 and exhibited no cytotoxicity [514]. A number of C_{60} and C_{70} derivatives tested as dimethylsulphoxide–water emulsions against human cells infected with HIV showed antiviral activity in low micromolar range [515]. Two C_{70} derivatives are also evaluated for anti-HIV activity. Models analogous to those used for the C_{60} derivative indicate that C_{70} fits in the HIVP hydrophobic cavity like C_{60} or even better [508a]. A series of amphiphilic

fullerene derivatives also manifested enzyme inhibitory activity in the micromolar range [516]. Monosubstituted methanofullerene derivatives are found to be more potent compared to the disubstituted methanofullerene derivative. A kinetic study suggested that the monosubstituted derivative becomes hydrophobically bound to the active site of the enzyme.

15.3.3. DNA Cleaving Studies

A number of studies have been carried out with water-soluble derivatives of fullerenes for DNA cleaving experiments [517]. The photoinduced DNA cleaving activities of C_{60} itself and of a C_{60} derivative with an acridine group are reported. The acridine moiety is also incorporated into a poly(vinyl pyrrolidone) micellar system for the DNA cleaving study. Under visible light irradiation using a supercoiled plasmid (pBR322) the acridine adduct showed stronger DNA cleaving activity than C_{60} itself. Fullerene carboxylic acids also cleaved double stranded DNA with moderate efficiency at 100 μM concentration upon irradiation with visible light. Photolysis of the carboxylic acid in solution containing molecular oxygen generated singlet oxygen, which is responsible for cleaving. The cleaving takes place at the guanine base. A fullerene amine adduct, $C_{60}H_n(NHCH_2CH_2NMe_2)_n$, is highly efficient and it cleanly cut DNA (supercoiled pBR322) into nicked circular one under irradiation with visible light [516]. DNA–fullerene hybrids (**548**, **549**) are

Figure 245. A dendritic [60]fullerene used for cytotoxicity and photocytotoxicity studies. Adapted from [511].
Figure 247. DNA–fullerene hybrid for cleaving studies.
Figure 248. Cationic SAM containing C_{60} on gold for immobilization of DNA. Adapted from [518].

synthesized in which DNA is covalently bound to fullerene via a linking unit (Fig. 247). These hybrids could bind single and double stranded DNA, and upon exposure to light it cleaved DNA specifically at guanosine residues proximal to the fullerene moiety.

Immobilization of DNA on a two-dimensional solid surface is of interest both in studies of DNA itself and in various applications such as biosensors. On a gold surface, a well-ordered monolayer assembly containing quaternary ammonium salts that could interact with the phosphate groups of DNA has been devised. On such a self-assembled monolayer (SAM) C_{60} has been incorporated and then DNA has been immobilized for specific cleaving studies (Fig. 248) [518].

16. SUMMARY

The spherical π-electron surface of C_{60} has provided an unprecedented fundamental building block. The π-bonds in fullerenes are ethylinic and hence undergo a variety of addition reactions. These reactions lead to many derivatives of fullerenes synthesized for fundamental studies as well as for materials science applications. Since the fullerene surface contains a large number of double bonds, multiple additions can take place leading to a mixture of regioisomers. Quite often, addition takes place at the 6,6-ring junction π-bonds of the six pyracylene units. The driving force for such reactions is the creation of a stable framework of eight benzene rings. By tether directed functionalization, specific regioisomers can be synthesized. The electronic, magnetic, and optical properties of the fullerene derivatives have been investigated for materials science applications. Unmodified fullerenes as well as derivatives are excellent dopants for conducting polymers and very promising for photodiode applications. A number of dyad and triad molecules are synthesized for intramolecular photoinduced charge separation. C_{60} derivatives are studied for optical limiting applications. Water-soluble endohedral fullerenes find applications as magnetic resonance imaging contrast media agents. Fullerenes are powerful radical scavengers. In the presence of visible light they can cleave DNA. Fullerene derivatives soluble in water are efficient neuroprotective agents. A number of such derivatives have

been studied in HIV protease inhibition and tumor suppression experiments.

Since 1990, when milligram quantities of fullerenes could be accessible for preparative scale experiments, there has been an unprecedented growth of the chemistry and physics of the fullerenes. Science around these exotic molecules grew at such a rapid pace that, for a time, it was difficult to keep track of the new developments. At a time when it is felt that fullerene research has attained a level of saturation, new and exciting discoveries are being reported. Though functional fullerene chemistry has been thoroughly studied, these are mostly centered around C_{60} and to some extent C_{70}. Eventually such studies involving higher fullerenes will be enthusiastically pursued. Functionalization of endohedral fullerenes is almost at its infancy. Since magnetic, electrical, and optical properties of the endohedral fullerenes are very different from the parent molecules, their derivatives would be expected to possess quite interesting properties. The materials science applications of fullerenes in the broad disciplines of bio-, nano-, and information technology are yet to be thoroughly explored.

GLOSSARY

AM1 A method for semi-empirical molecular mechanics calculation.

Bingel reaction A general method for cyclopropanation of fullerenes by introducing a methylene or substituted methylene bridge onto the fullerene 6,6-ring junction.

B3LYP/6-31G* A hybrid method based on density functional theory (DFT) for predicting chemical reaction mechanism.

Buckminsterfullerene The hollow carbon cage made up of 60 carbon atoms named after R. Buckminster Fuller, American architect, engineer and constructor of geodesic domes.

Dendrimers Three-dimensional, highly ordered oligomeric and polymeric compounds formed from smaller molecules by reiterative reaction sequences.

DNA cleaving A process by which a DNA molecule can be cut into smaller ones.

Endohedral fullerenes Fullerenes with enclosed atom(s) in the cage.

Euler's theorem A applied to fullerenes, each molecule of the fullerene family (C_n) consists of 12 pentagons and m number of hexagons ($m \neq 1$), conforming to the relation $m = (n - 20)/2$.

Exohedral addition reactions of fullerenes Addition reactions on the exterior of fullerene molecule.

Fullerenes A family of large carbon cage molecules about 7–15 Å in diameter.

Fullerene dimers Fullerene derivatives containing two fullerene spheres per molecule.

Fullerene macrocycles Compounds obtained by the covalent or noncovalent attachment of macrocyclic compounds such as calixarenes, catenane, crown ethers, cyclophane, cyclotriveratrylene, phthalocyanines, etc. to fullerenes.

η^5-Fullerene metal complexes Exohedral fullerene-transition metal complexes, in which the fullerene act as an olefinic ligand and bind the metal center.

Heterofullerenes   Fullerenes in which one or more carbon atoms are substituted by heteroatoms, such as nitrogen or boron.

HF/3-21G$^{(*)}$ A method for *ab initio* molecular orbital studies.

HIV   A retrovirus that causes AIDS (aquired immune deficiency syndrome) by infecting helper T cells of the immune system.

Inclusion complexes   Complexes obtained by non-covalent interaction between a host and a suitable guest molecule.

Isolated pentagon rule   The rule that signifies that all pentagons in a fullerene be isolated by hexagons, C_{60} being the smallest possible fullerene to obey the isolated pentagon rule.

Macrocyclization   A double Bingel reaction between fullerenes and bismalonate derivatives leads to macrocyclization, a method for the preparation of covalent bisadducts of C_{60} with high regio- and diastereoselectivity.

MM2 force field   A method in molecular mechanics calculation.

MNDO   The semi-empirical molecular orbital (MO) calculations, using a modified neglect of diatomic (differential) overlap approximation.

Periconjugation   The interaction between the p_z orbitals of the addends and the "p_z" orbitals of the adjacent fullerene carbon atoms.

Oligofullerene   Low molecular weight derivative of fullerenes having three or more fullerenes per molecule.

PM3   A semiempirical molecular mechanics calculation.

Pyramidization angle   Defined as $\theta_{\sigma\pi} - 90°$, where $\theta_{\sigma\pi}$ is the angle between the σ and π bonds of a carbon atom.

***o*-Quinodimethane**   A intermediate generated by 1,4-elimination of Br_2 from 1,2-bis(bromomethyl)benzenes.

Radical sponge   A property of fullerenes to scavenge large concentrations of free radicals.

Ring expansion reactions   Reactions leading to the fullerene cage expansion by introducing brigdging atoms.

Schlegel diagrams   A convenient way to present the three-dimensional fullerene cage molecules in a two-dimensional plane.

Singlet oxygen   The lowest electronically excited singlet state of molecular oxygen, $^1O_2$.

Tether-directed functionalization   An approach to the synthesis of fullerene regioisomers defined structure.

Fullerenes for Photovoltaics

E. A. Katz

Ben-Gurion University of the Negev, Sede Boqer, Israel

CONTENTS

1. INTRODUCTION

The discovery [1] of C_{60}, a third variety of carbon in addition to the more familiar diamond and graphite forms, together with an easy method [2] to produce macroscopic quantities of the material, have generated enormous interest in many areas of physics, chemistry, and material science. Furthermore, it turns out that C_{60} is only the first of an entire class of fully conjugated, all-carbon molecules—the fullerenes (C_{60}, C_{70}, C_{82}, C_{120}, etc., carbon nanotubes). And yet, brief as the history of research into these materials may be [3], it is already clear from its vast and increasing literature that much complex and fascinating physics lies behind the geometrical simplicity of these structures. In addition to the interesting properties of pristine fullerenes, by doping these materials in an appropriate manner, not only can their electronic properties be "tuned" to coincide with those of semiconductors and conductors, but even superconductivity may result [4]. There are, accordingly, great expectations that fullerenes will find practical use in many advanced technologies. This chapter reviews the prospects of one such application—direct conversion of solar energy to electricity by photovoltaic solar cells.

2. PHOTOVOLTAIC SOLAR CELLS

Photovoltaic solar cells are devices that convert solar radiation directly into electrical energy due to the photovoltaic effect which was first observed by Becquerel in 1839 [5]. A photon can interact with matter by losing its energy, and using this energy to promote an electron to a higher energy level. If a semiconductor solar cell is illuminated with light of photon energy higher than its bandgap energy of E_g, free electron–hole pairs are generated. To separate these photoinduced charge carriers and generate photovoltage, a solar cell should have a junction between two materials across which there is an electrochemical potential difference in equilibrium.

There are at least three main types of such junctions, namely, homo- and hetero-p–n junctions, formed between p and n types of the same or different semiconductors, respectively, and the Schottky barrier, that is, a rectifying interface between a semiconductor and a metal. Other types of solar cells may include a p–i–n junction, formed from two doped and one intrinsic semiconductor layer, or a metal–insulator–semiconductor (MIS) configuration.

Most inorganic photovoltaic devices to date have been formed using a p–n junction [6]. The different Fermi levels E_F in p- and n-type regions result in a depletion region at their interface, where this difference is accommodated by a built-in electric field (Fig. 1). Photoinduced carriers, generated within approximately one diffusion length from the depletion region, may diffuse to this region, where they will be separated by the built-in electric field. Electrons and holes move to the n and p regions, respectively. A potential difference thus appears between the external metal electrodes attached to the p and n regions, and a current may flow through a connected load resistor.

Figure 2(a) shows the schematic diagram of a homo p–n junction solar cell. Ohmic contact is made to the back surface of the base region. The contact to the emitter top layer is made in the form of a grid pattern. An antireflection (AR) coating is then used to reduce the amount of light lost by reflection from the front surface.

A simple circuit for measurements of a solar cell's current–voltage (I–V) characteristics under illumination is shown in Figure 2(b). The dark I–V curve of an ideal p–n junction is given by the Shockley equation [6]

$$I_d(V) = I_0(e^{qV/KT} - 1) \qquad (1)$$

where I_0 is the reverse saturation current of the p–n junction, q is the electron charge, T is the absolute temperature,
Figure 1. Energy band diagram for a *p–n* junction under illumination.

K is the Boltzmann constant, and *V* is the voltage. The dark *I–V* curve is shown in Figure 3(a). The dark characteristic is measured with an external bias in the forward (first quadrant) and reverse (third quadrant) direction.

Under illumination, the equation for the *I–V* curve becomes

$$I = I_0(e^{qV/KT} - 1) - I_L \qquad (2)$$

where I_L is the photocurrent at zero bias, and results from the excitation of excess carriers by solar radiation. A plot of Eq. (2) is given in Figure 3(a) as well. Figure 3(b) represents the part of the irradiated solar cell *I–V* curve from the fourth quadrant just by its inversion around the voltage axis. The quantities $I_{\max}$ and $V_{\max}$, corresponding to the current and voltage respectively, for the maximum power output $P_{\max} = I_{\max} \times V_{\max}$ are also defined in Figure 3(b).

Now, we can define such important solar cell parameters as the short-circuit current I_{sc}, the open-circuit voltage V_{oc}, the fill factor *FF*, and the power conversion efficiency η.

For $V = 0$, $I = -I_L = I_{sc}$, and for $I = 0$, $V = V_{oc}$. The fill factor is defined by the relation

$$FF = \frac{I_{\max} \times V_{\max}}{V_{oc} \times I_{sc}} \qquad (3)$$
Figure 2. Cross-sectional view of a typical *p–n* junction solar cell (a) and a simplest circuit diagram for the measurements of solar cell *I–V* characteristics under irradiation (b).
Figure 3. Dark and light *I–V* curves (a) and the general representation of the light *I–V* curve in the first quadrant showing maximum power $P_{\max}$ (b).

Finally, the power conversion efficiency is given by

$$\eta = \frac{I_{\max} \times V_{\max}}{P_{\text{in}}} = FF \frac{V_{oc} \times I_{sc}}{P_{\text{in}}} \qquad (4)$$

3. FULLERENES AND PHOTOVOLTAICS

We consider a combination of the following five reasons that make fullerene-based materials unique among all known semiconductors, and promising for photovoltaic applications.

1. Relatively high values of photoconductivity (in comparison with the dark conductivity values) were observed in C_{60} thin films [7].
2. Early studies of solid C_{60} as a material for inorganic solar cells [8–9] were instigated by the theoretical prediction [10] that a C_{60} crystal has a direct bandgap of 1.5 eV. On one hand, this value is close to the experimental value of about 1.6 eV for the fundamental edge in the optical absorption spectra [11] and that of 1.7 eV for the photoconductivity spectra [12] of C_{60} thin films. On the other hand, this is the optimal value for high-efficiency photovoltaic devices of

the single-junction type [13]. Recent experimental studies [14–15] demonstrated that the electronic structure of a C_{60} crystal is more complicated. Specifically, the bandgap value is suggested to be about 2.3 eV (the mobility gap), but the optical absorption extends from the gap energy to the lower energy side (the optical gap is ~1.6 eV). These experimental works stimulated new theoretical calculations, using a "many-body" approach, which yielded a bandgap value of 2.15 eV [16]. However, even if this is true, the electronic structure and optical properties of C_{60} thin films are suitable for the use of this material in efficient heterojunction solar cells (such as C_{60}/Si devices).

3. Solid C_{60} is a molecular crystal in which C_{60} molecules occupy the lattice sites of a face-centered cubic (fcc) structure [17]. If one contrasts a C_{60} molecular crystal unit cell with the corresponding Si cell, the former has 240 atoms to the latter's 8. This allows the possibility of doping to a much greater percentage than would be possible with conventional semiconductors. Furthermore, unlike the case of conventional semiconductors for which doping is only possible via *substitution* of atoms (e.g., P or B for Si), fullerenes may be doped in three additional *distinct* ways: *intercalation* of dopants between the buckyballs, *endohedral doping* within the buckyballs themselves, and *adductive doping* to the outside of the buckyballs [4]. The spectrum of resultant doping energy levels will naturally differ from each manner of doping, thus greatly increasing the probability of finding successful dopants for high-efficiency photovoltaic devices [9].

4. For organic donor–acceptor solar cells, a C_{60} molecule is an ideal candidate due to the strong acceptor properties of the C_{60} molecule, which can accept as many as six electrons [4]. Such cells are now becoming a serious alternative to conventional inorganic photovoltaic devices due to a number of potential advantages, such as their light weight, flexibility, and low-cost fabrication of large areas. The efficient photoresponse of the donor–acceptor cells consisting of conjugated polymers and fullerenes [18–22] originates from an ultrafast (subpicosecond) photoinduced electron transfer from the conjugated polymer (as a donor) to a nearby C_{60} molecule (as an acceptor) [23, 24]. Since this process is faster than any other relaxation mechanism in the conjugated polymers, the quantum efficiency of this process is estimated to be close to unity. Accordingly, the best photovoltaic parameters ever reported for organic solar cells—and in particular, energy conversion efficiencies of 2.5 [25] and 3.6% [26]—were for fullerene-containing devices.

5. There is probably no more environmentally benign semiconductor than C_{60} in that it can be synthesized from graphite using nothing more than a beam of concentrated solar energy, and subsequently purified and crystallized using the same energy source (as described later). To demonstrate this statement, let us review very briefly the state of the art for fullerene production, and in particular, the production of fullerenes and carbon nanotubes by concentrated sunlight.

In 1990, Krätschmer et al. [2] discovered a simple technique to produce fullerenes. The method uses arc discharge between two graphite electrodes in a helium atmosphere to vaporize graphite and produce fullerene-containing soot, the subsequent extraction of soluble fullerenes from the insoluble species of the soot by an organic solvent (toluene, for example), and final chromatographic separation of isolated fullerenes (C_{60}, C_{70}, etc.). At present, the most efficient methods of fullerene production involve different modifications of thermal evaporation of graphite in an inert atmosphere (e.g., ac or dc arc discharge between graphite electrodes, laser ablation of graphite) [4].

The electric-arc process requires use of high-quality, electrically conductive graphite rods. On the other hand, the yield of fullerene production from the collected soot is low (5–10%) due to the photodestruction of fullerene molecules by UV radiation of the electric arc [27]. Furthermore, because the yield is low, excessive amounts of toluene are required to separate the fullerenes from the soot. These factors present serious limitations on the minimum cost that can be obtained by this process.

Even though the yield from the laser ablation process can be high, it is generally accepted that this process will not be cost effective for scaling up to large production levels [28]. The search for a more efficient and environmentally benign method led to the use of concentrated solar energy to evaporate the carbon and efficiently produce fullerenes [27–34] and carbon nanotubes [32, 34–40].

In all reported solar techniques, concentrated sunlight (≥ 1100 W/cm^2) is focused onto a graphite target, resulting in its heating up to temperatures in excess of 3500 K. Controlling vaporization and condensation conditions leads to the formation of fullerene-rich soot or/and carbon nanotubes (if the target consists of a mixture of graphite and metal catalysts).

The UV component in sunlight is very small (compared with irradiation of an electric arc). Therefore, the photodestruction process is very weak, and the yield of fullerenes is as high as 20% [32]. Increased yield leads to less solvent use, which reduces cost. Furthermore, the relaxation of the requirement to use conductive graphite rods opens the possibility to use less expensive forms of graphite, including mineral graphite powders. A preliminary cost analysis [29] suggested that solar production can be less expensive than the arc process by at least a factor of 4.

It is also noteworthy that fullerenes were demonstrated to be purified and crystallized via differential sublimation [4]. These technological steps are certainly possible to perform in a solar furnace.

4. INORGANIC C_{60}-BASED SOLAR CELLS

4.1. Solar Cells Based on Pristine C_{60}

4.1.1. Metal–Insulator–Semiconductor and Schottky Barrier Devices

In 1992, Hebard et al. patented an idea for the utilization of the photoconductivity and photovoltaic properties of fullerites, and in particular, fabrication of fullerene-based

solar cells and "the generation of a current by illumination of appropriate fullerene interfaces" [41]. Such photovoltaic response requires fabrication of a fullerene-based device structure with rectifying properties. However, in that patent publication, the authors described a symmetrical (nonrectifying) $Ag/C_{60}/Ag$ device structure which exhibited photoconductivity, but no photovoltaic effect.

A fullerene-based solid-state device, displaying a remarkable rectifying effect in the dark and photoresponse under illumination, was first demonstrated by Yohehara and Pac [42]. Polycrystalline C_{60} film with a thickness of 100 nm was deposited by the vacuum evaporation technique on a substrate of Al coated glass. This Al layer was used as the front electrode. Sandwich cells were completed by vacuum evaporation of an Al or Au back electrode (0.5 cm^2 in area). The devices without any exposure of the front electrode to oxygen exhibited no rectification and photoresponse. The devices with a front Al electrode exposed to oxygen (before C_{60} film deposition) exhibited a rectification ratio of 66 (at ± 2 V), and greatly enhanced the photocurrent (the quantum yield of the photocurrent for monochromatic irradiation of $\lambda = 400$ nm and 0.1 V forward bias was about 53%). The excitation profile of the photocurrent was observed to follow the optical absorption of a C_{60} film. The authors explained the results by the formation of an oxide layer at the front Al electrode interface and the MIS configuration rather than a Schottky barrier device. MIS devices with a fullerene layer as an active semiconductor contact were also studied by Pichler et al. [43]. Solar cells with a Schottky barrier at the C_{60}/Mg–In [44], C_{70}/Ca [44], and C_{60}/Ag [8, 45] interfaces were demonstrated later.

4.1.2. Fullerene/Inorganic Semiconductor Heterojunction Devices

A heterojunction between a C_{60} thin film and another semiconductor with a high rectifying ratio in the dark ($>10^4$ at ± 2 V) [46] and photovoltage generation [47] were demonstrated, first, for a C_{60}/p–Si interface. The properties of such a heterojunction were then extensively studied in the dark and under irradiation of various light sources [8, 45, 48–53]. Although different groups studied various device configurations ($Nb/C_{60}/Si$, $Ti/C_{60}/Si$ [46, 48], $Au/C_{60}/Si$, indium–tin–oxide (ITO)/C_{60}/Si [47, 51], $Al/C_{60}/Si$ [8, 45, 49–50]), all authors seem to agree that potential barrier formation at the C_{60}/p–Si rather than at the metal/C_{60} interface is responsible for the strong rectifying properties of the heterostructures. X-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS) [54–55], as well as low-energy electron diffraction (LEED) and Auger electron spectroscopy (AES) [55], have revealed an abrupt character of the $C_{60}/Si(111)$ interface, and no chemical reaction or diffusion between the C_{60} overlayer and Si(111) substrate.

Later, a rectifying heterojunction was reported for the C_{60}/n–Si [44], C_{60}/n–GaAs [56], and C_{60}/n–GaN [57] interfaces as well.

Figure 4 shows a typical dark current–voltage curve of a $Ti/C_{60}/p$–Si/Al device [48]. Polycrystalline fcc C_{60} film with a thickness of 200 nm was deposited by a vacuum deposition technique onto a chemically terminated (to remove
Figure 4. Dark current–voltage characteristics of a $Ti/C_{60}/p$–Si device. The inset shows data from thermal activation measurements at a fixed forward bias of -0.5 V. Reprinted with permission from [48], K. M. Chen et al., *J. Phys.: Condens. Matter* 7, L201 (1995). © 1995, IOP Publishing Ltd.

any surface oxide) substrate of (111) p-type Si (2–4 $\Omega \cdot$ cm) with a back ohmic contact of Al. Finally, Ti electrode dots of area 5.03×10^{-3} cm^2 were deposited on the C_{60} surface. The device was found to be forward conducting when the Si substrate was positively biased relative to the C_{60} film, the rectification ratio being greater than 10^4 at ± 2 V. Similar results were reported for $Nb/C_{60}/p$–Si/Al [46] and $Al/C_{60}/p$–Si/Al [49–51] device configurations. In [48], the forward I–V curve was analyzed using

$$J = J_0\{\exp[q(V - A_e J R_s)/nkT] - 1\} \quad (5)$$

where J is the current density, A_e is the area of the Ti contact, R_s is the series resistance of the sample, and n is the quality factor of a p–n junction.

The inset of Figure 4 displays results of thermal activation measurements over a temperature range of 280–300 K. For a given forward bias at 0.5 V ($A_e J R_s \ll 0.5$ V), the plot of $\ln J$ versus $1/T$ is a straight line, indicating that the current-transport mechanism involves a thermally activated process. After least squares fitting, it was found that J_0 in (1) is an exponential function of $1/T$, that is,

$$J_0 = J_{00} \exp(-q\varphi_{\text{eff}}/kT) \quad (6)$$

where $J_{00} = 1.4 \times 10^5$ $\mu A \cdot cm^{-2}$ and $q\varphi_{\text{eff}} = 0.48$ eV. $q\varphi_{\text{eff}}$ denotes the effective barrier height of the heterojunction under zero-bias conditions in the dark, which is generally related to the energy band structure of solid C_{60} and Si. For an ideal barrier, the $q\varphi_{\text{eff}}$ value is equal to the difference of the Fermi levels in C_{60} and Si. In a real heterojunction, this value also may be affected by the C_{60}/Si interface states [48, 58, 59].

It was demonstrated by measurements of capacitance–voltage (C–V) characteristics of heterojunctions between an Si substrate and C_{60} films of various thicknesses (from 200 to 900 nm) that the entire C_{60} films and the near-interface region of the Si wafer behave as a depletion region. This

means that an internal electric field necessary for a photovoltaic effect exists over the entire thickness of the C_{60} films [58].

Photovoltage generation of a C_{60}/p–Si heterojunction was demonstrated by Wen et al. [47]. C_{60} film with a thickness of 1500 nm was vapor deposited in vacuum on a chemically cleaned p–Si substrate (20 $\Omega \cdot$ cm) with a back ohmic contact of Au. Finally, a front ITO electrode was sputtered on the C_{60} surface. An Au front electrode (transparent to light) was also used for the measurements to confirm that there is no photoelectric effect of the C_{60}/p–Si interface. A difference between the results with ITO and Au electrodes was not observed. Although the rectification ratio in the dark of the ITO/C_{60}/p–Si/Au was not reported, the direction of the rectification was the same as that reported in [8, 46, 48–51]. The V_{oc} value was found to be about 0.2 V under irradiation by a 150 W Xe lamp (longer than 200 nm in wavelength). Unfortunately, other solar cell parameters, as well as the active area of the device, were not reported.

A more detailed study of the photovoltaic properties was performed in [8, 45, 49, 60] for highly crystalline C_{60} thin-film/p–Si heterojunction solar cells. Their dark I–V characteristics exhibited strongly rectifying properties: the rectification ratio being approximately 10^4 at ± 2 V. Under solar irradiation (AM 1.5), the short-circuit current density J_{sc} was found to be 42 $\mu A/cm^2$, the open-circuit voltage $V_{oc} = 322$ mV, and $FF = 0.3$. The low values of J_{sc} and FF were attributed to the high resistivity of pristine C_{60} films. SPV spectroscopy characterization of the devices (Fig. 5) suggested that the C_{60} film acts as an active layer in the device, in particular for the conversion of short-wavelength components of sunlight. Indeed, it is evident that the positive SPV signal at 1.1 eV originates from the valence band-to-conduction band transition in p–Si, while the signals at 1.6 and 2.25 eV are attributable to tail-to-tail (optical bandgap) and band-to-band (mobility gap) transitions in the n–C_{60} layer [15]. This conclusion is consistent with the experimental spectral response of similar Al/C_{60}/p–Si/Al solar cells (Fig. 6) [50] and that calculated in [48] using the solar cell property equations [59] and published values of optical absorption coefficient values for C_{60} [62–63] and Si

Figure 6. Schematic diagram of the Al/C_{60}/p–Si/Al cell structure. Reprinted with permission from [50], N. Kojima et al., *Jpn. J. Appl. Phys.* 39, 1176 (2000). © 2000, Institute of Pure and Applied Physics.

[Fig. 7(a) and (b)]. It should be noted that the experimental and calculated spectral response data qualitatively coincide, except for a surprising sharp peak at about 390 nm. The authors of [50] did not discuss the nature of this peak. A similar peak was observed in the spectral response of a C_{60}-based photoelectrochemical solar cell [64].

The maximum V_{oc} of a heterojunction corresponds to its $q\varphi_{eff}$ value that depends, as mentioned earlier, on the difference in the Fermi levels of both semiconductors forming the junction, in this case, of C_{60} thin film and Si. The Fermi level of Si can be controlled by changing the type and

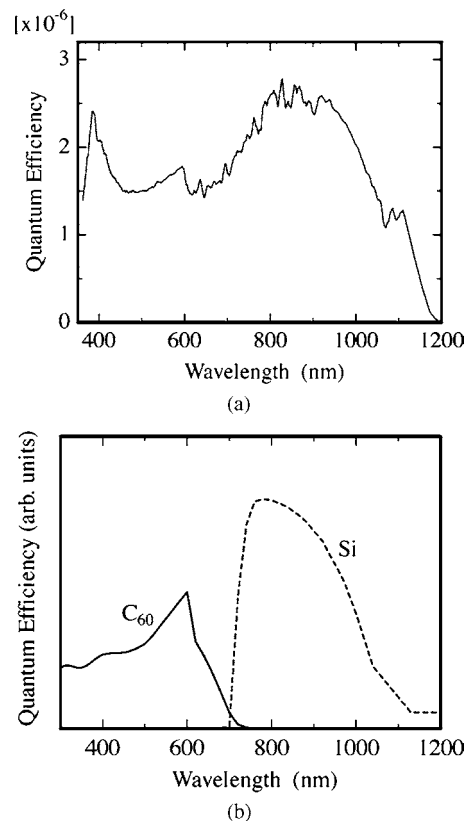
Figure 5. SPV spectrum of an Al/C_{60}/p–Si/Al heterojunction solar cell. Reprinted with permission from [45], E. A. Katz et al., "Thin Films Structures for Photovoltaics," Materials Research Society Series, Vol. 485, p. 113, 1997. © 1997, Materials Research Society.


Figure 7. Spectral response of an Al/C_{60}/p–Si/Al solar cell: experimental (a) and calculated (b). Reprinted with permission from [50], N. Kojima et al., *Jpn. J. Appl. Phys.*, 39, 1176 (2000). © 2000, Institute of Pure and Applied Physics.

concentration of dopant. In [50], photovoltage generation by a C_{60}/Si heterojunction was studied with four different types of Si substrates: heavily doped p–Si (8×10^{18} cm^{-3} of B), lightly doped p–Si (1.5×10^{15} cm^{-3} of B), lightly doped n–Si (5×10^{14} cm^{-3} of P), and heavily doped n–Si (5×10^{18} cm^{-3} of P). The lightly doped n–Si/C_{60} junction was measured to have the highest V_{oc}, 0.4 V, while the lightly doped p–Si/C_{60} junction was measured to have the lowest, 0.12 V. This result implies that the Fermi level of C_{60} should be more than 0.4 eV below the Fermi level of lightly doped n–Si and more than 0.12 eV above that of lightly doped p–Si. The Fermi level of C_{60} was estimated to be about 4.7 eV below the vacuum level. In our opinion, further research is needed to understand the true electronic structure of such heterojunctions.

An increase in the photoactive area of a C_{60}/Si heterojunction may be one of the possible techniques for improvement of the photovoltaic parameters of such solar cells. In order to use this idea, Feng and Miller deposited a C_{60} monolayer on a nanostructured substrate of p-type porous silicon [65]. The authors reported an increase in J_{sc} (by 100 times) and V_{oc} in comparison with the corresponding values for a planar configuration of the C_{60}/p–Si heterojunction. Unfortunately, the absolute values of these parameters were not reported.

The very low intrinsic conductivity of C_{60} crystals is considered by most authors to be one of the main limiting factors for solar cell efficiency. Therefore, doping of C_{60} is another research direction for the production of high-efficiency fullerene-based solar cells.

4.2. Devices Based on the Doped C$_{60}$ Layers

4.2.1. Ion Implantation into C$_{60}$ Thin Films

Rectifying device structures based on doped C_{60} films were reported, for the first time, in [52] and [66], where an ion implantation of phosphorus (P) into C_{60} films was demonstrated to result in an increase in their n-type conductivity. The same group observed p-type conductivity in C_{60} films doped with an Al by its simultaneous sputtering during the film deposition [52]. Photovoltaic parameters of C_{60}/Si solar cells were found to be improved by doping. In our opinion, the authors' conclusion about such p doping of C_{60} is quite speculative because of the known fact of the very high electron affinity of the C_{60} molecule.

The idea of ion implantation of P and B in C_{60} films was then developed and applied to solar cell production by Yamaguchi and coauthors [67–71]. Implantation of B$^+$ (with an energy of 50–80 keV and a dose of 10^{14} cm^{-2}) into C_{60} films, grown on an n–Si substrate, was shown to lead to structural changes from the crystalline C_{60} to amorphous carbon, and a dramatic increase in film conductivity. Hall effect measurements of the implanted films indicate p-type conduction. Boron implantation significantly improved the parameters of the resultant p–C/n–Si solar cells [67]. In particular, the cell series resistance R_s was improved by the implantation from 35 kΩ to 370 Ω. J_{sc} for the implanted cells was found to be 0.33 mA/cm^2, $V_{oc} = 0.17$ V, $FF = 0.415$, and efficiency $\eta = 0.023\%$. A typical I–V curve for such cells is shown in Figure 8.
Figure 8. Light-illuminated (AM 1.5) I–V curve of a boron ion-implanted $C_{60}(\alpha$–C)/n–Si heterojunction solar cell. Reprinted with permission from [67], K. L. Narayanan and M. Yamaguchi, *Appl. Phys. Lett.* 75, 2106 (1999). © 1999, American Institute of Physics.

The spectral response of these cells (Fig. 9) includes two broad features: 370–600 nm due to the α–C layer, and 700–1150 nm due to Si [67]. This result is in agreement with the experimental finding that the optical gap of the C_{60} films decreased after B$^+$ implantation [68]. Furthermore, it is possible to control this value by variation of the implantation dose. The optical gap was found to decrease gradually with the ion dose. For example, the gap was reported to be reduced continuously from 1.6 eV for nonimplanted C_{60} films to 0.8 eV after implantation with the dose of 8×10^{14} cm^{-2} [68]. The authors explained this effect by the structural transformation from C_{60} to α–C. We may attribute the intermediate optical gap values to a composite with various concentrations of C_{60} and α–C. In our opinion, this result is even more important than the improvement of the solar cell parameters (which are still not high). Indeed, using this effect, together with the control of the depth-implantation profile by the ion energy variation [69], it might be possible to produce a C_{60}/α–C composite with a nonhomogeneous depth profile optimized for maximum sunlight absorption and cell efficiency. We may predict that the next
Figure 9. Spectral response of a boron ion-implanted $C_{60}(\alpha$–C)/n–Si heterojunction solar cell. Reprinted with permission from [67], K. L. Narayanan and M. Yamaguchi, *Appl. Phys. Lett.* 75, 2106 (1999). © 1999, American Institute of Physics.

step in this direction will be the production of high efficient multijunction C_{60}/α–C/Si or α–C/C_{60}/Si (p–i–n) solar cells. The possibility of producing α–C/C_{60}/Si (p–i–n) solar cells already has been demonstrated [70, 71]. The efficiency of these devices was found to be 0.1% under AM 1.5 irradiation, which is five times higher than the best cells fabricated using the boron ion-implanted fullerenes without the insulating layer (for comparison, see Table 1). Furthermore, in another recent conference publication [72], the same group has suggested a novel approach for highly efficient quantum-well solar cells [73] with a C_{60}/α–C supperlattice structure produced by an intermittent supply of nitrogen ions during C_{60} deposition (Fig. 10).

4.2.2. Solar Cells with an Oxygenated Fullerene Thin Film

All of the research attempts described in the previous section were aimed at increasing the low intrinsic conductivity of C_{60} crystals by doping. If one uses a fullerene film as an insulator layer in the MIS solar cells, the opposite problem should be solved. Indeed, in this case, a decrease of the fullerene conductivity will increase the solar cell efficiency.

A variety of experiments [7, 74–77] has strongly suggested that the presence of oxygen reduces the dark conductivity and photoconductivity in C_{60} films and single crystals by several orders of magnitude. Yang and Mieno [78] have suggested using this effect in MIS solar cells with an Au/C_{60}/$C_{60}O_x$/Au structure in which C_{60} and $C_{60}O_x$ films act as a semiconductor and an insulator layer, respectively. Highly oxygenated fullerene films ($C_{60}O_x$, with $x =$ 8, 16, 24, 38, 50) were obtained using RF O_2 plasma with a cooling system. The experimental results revealed that the highest photocurrent was obtained when the total thickness of the oxygenated fullerene film and the pure fullerene film was about 200 nm. Under this condition, the photocurrent was observed to become 30 times higher than that without the $C_{60}O_x$ layer. Unfortunately, the absolute values of the photovoltaic parameters of these MIS solar cell have not been reported.

5. ORGANIC FULLERENE-BASED PHOTOVOLTAIC DEVICES

Over the last decade, tremendous progress has been achieved in fullerene/conjugated polymer solar cells. A number of detailed reviews are devoted to this topic [20–22, 79, 80]. The operating principles of such solar cells are similar to those for the initial steps of natural photosynthesis, and are based on a very fast (*subpicosecond*) photoinduced electron transfer from a conjugated, semiconducting polymer (as a donor) to a nearby C_{60} molecule (as an acceptor).

5.1. Photoinduced Electron Transfer from Conjugated Polymers onto Fullerenes

The discovery of semiconducting, conjugated polymers and the ability to dope these polymers over the full range from insulator to metal has resulted in the creation of a new class of materials that combines the electronic and optical properties of semiconductors and metals with the attractive mechanical properties and processing advantages of polymers [81–83]. The molecular structures of some semiconducting conjugated polymers are summarized in Figure 11.

Conjugated polymers in their undoped states are electron donors upon photoexcitation (electrons being promoted to the antibonding π^* band). If one uses this property in conjunction with a molecular electron acceptor, long-lived charge separation may be achieved. Once the photoexcited electron is transferred to an acceptor unit, the resulting cation radical (positive polaron) species are known to be highly delocalized and stable. Analogous to the chemical doping process, the photoinduced electron transfer from the conjugated polymer to an acceptor moiety may be considered as "photodoping" [20].

On the other hand, as already mentioned (see Section 3), the C_{60} molecule is an excellent electron acceptor capable of taking on as many as six electrons [4, 84]. In the beginning of the 1990s, independently, Heeger's group [23, 85–86] and Yoshino's group [24, 87–90] reported the discovery of a photoinduced electron transfer from semiconducting conjugated polymers onto C_{60} molecules in solid films. The observed phenomenon is schematically illustrated by Figure 12. The kinetics of this process has recently been time resolved to occur within 40 fs [91]. Since the time scale of this process is more than 10^3 times faster than the radiative or nonradiative decay of photoexcitations, the quantum efficiency for charge transfer and charge separation is estimated to be close to unity [79]. All of these findings provided a new "molecular approach" to low-cost and high-efficiency photovoltaics.

5.2. Bilayered Donor–Acceptor Solar Cells

Immediately after the discovery of photoinduced electron transfer from a conjugated polymer to a C_{60} molecule, this molecular effect was used for the preparation of a heterojunction between poly[2–methoxy, 5–(2′–ethyl–hexyloxy)–1,4–phenylene–vinylene] (MEH–PPV) [Fig. 11(c)] and a C_{60} thin film [18, 92]. Figure 13 displays the dark I–V characteristics of such a device, consisting of successive layers of ITO/MEH–PPV/C_{60}/Au. The rectification ratio at ±2 V was approximately 10^4. Analysis of this result suggests the formation of a heterojunction at the MEH–PPV/C_{60} interface, with rectifying properties analogous to those of a semiconductor p–n junction. The device demonstrated photovoltaic behavior. The values of J_{sc} were reasonably linear over five decades of light intensity up to approximately 1 W/cm^2, that is, one order of magnitude higher than the terrestrial solar intensity (AM 1.5). The following photovoltaic parameters (measured for a cell area of 0.1 cm^2 under illumination of an argon ion laser with a wavelength $\lambda = 514.5$ nm and a light power of 1 mW/cm^2) were reported: $J_{sc} = 2$ μA/cm^2, $V_{oc} = 0.5$ V, $FF = 0.48$, and $\eta = 0.04\%$.

Later, solar cells with a heterojunction between C_{60} thin films and other organic donor layers, both of various conjugated polymers (poly(paraphenylene) (PPP) [Fig. 11(a)] [93], poly(phenylenevinylene) (PPV) [Fig. 11(b)] [94–95], poly(2,5–dioctyloxy–p–phenylenevinylene) (OOPPV) [Fig. 11(d)] [96], poly(3–octylthiophene) (P3OT) [Fig. 11(e)] [97], poly(isothianaphthene) (PITN) [Fig. 11(f)] [98], poly(3–(4′–(1″,4″,7″–trioxaoctyl)penyl)thiophene) (PEOPT) [Fig. 11(g)] [99]) and small molecules (such as phthalocyanines

Table 1. Photovoltaic parameters of fullerene-based solar cells.

Solar cell design strategy	Cell structure	V_{oc} (mV)	J_{sc} (mA/cm^2)	FF	η (%)	Test conditions	Ref.
Pure C$_{60}$/inorganic semiconductor heterojunction	C$_{60}$/p–Si	306	1.1×10^{-4}	0.55	2.2×10^{-5}	AM 1.5, 100 mW/cm,^{2}	[50]
Ion-implanted C$_{60}$/inorganic semiconductor heterojunction	B ion-implanted C$_{60}$/n–Si	170	0.33	0.41	0.023	AM 1.5, 100 mW/cm^2	[67]
	α–C/C$_{60}$/Si p–i–n cell	90	4	0.29	0.1	AM 1.5, 100 mW/cm^2	[71]
Conjugated polymer/C$_{60}$ heterojunction	ITO/MEH– PPV/C$_{60}$/Au	500	2×10^{-3}	0.48	0.04	Monochromatic irradiation, 1 mW/cm^2, $\lambda = 514.5$ nm	[18]
	SnO$_2$/PPP/C$_{60}$/Al	300	4×10^{-3}	—-	—-	Xe arc lamp, 15 mW/cm^2	[93]
	ITO/PPV/C$_{60}$/Al	800	3.5×10^{-3}	0.48	0.39	Monochromatic irradiation, 0.25 mW/cm^2, $\lambda = 490$ nm	[94]
Phthalocyanine/C$_{60}$ heterojunction	ITO/OTiPc/C$_{60}$/Al	420	4.1×10^{-4}	0.2	0.35	Monochromatic irradiation, 10 μW/cm^2, $\lambda = 720$ nm	[100]
	ITO/ZnPc/C$_{60}$/Al	400	0.42	—-	—-	Xe arc lamp (with IR filter), 100 mW/cm^2	[101]
Donor–acceptor bulk heterojunction between a C$_{60}$ derivative and a conjugated polymer	ITO/MEH–PPV: PCBM/Ca	800	0.5	—-	—-	Monochromatic irradiation, 20 mW/cm^2 $\lambda = 430$ nm	[19]

(Fig. 14) [100–101]), were demonstrated as well. The photovoltaic parameters of some such devices are summarized in Table 1.

The main factor limiting photovoltaic parameters of these bilayered donor–acceptor solar cells lies in the basic proper-

ties of photogenerated excitations in molecular solids (such as fullerites and polymers), and in the very operation principle of such solar cells. Indeed, intermolecular van der Waals forces in molecular solids are weak compared to bonds in inorganic crystals, and much weaker than the intramolecular bonds. As a consequence, photogenerated excitations ("excitons") are strongly bound, and do not spontaneously dissociate into separate charges. (Dissociation requires an input of energy of ∼100 meV compared to a few millielectronvolts for an inorganic semiconductor [102].) This means that carrier generation does not necessarily result from the absorption of light. In other words, contrary to conventional solar cells with an inorganic semiconductor *p–n* junction, as described in Section 2, in a bilayered donor–acceptor molecular solar cell, neutral excitons are first created by light.

Figure 14. Molecular structures of phthalocyanines (MPc). Fullerene-based solar cells have been demonstrated with MPc, where $M = Cu$ [26], TiO [100], Zn [101, 178].

Finally, charges are separated in the narrow interface region due to donor–acceptor electron transfer interactions.

The above statement is well illustrated by the spectral response of an ITO/MEH–PPV/C_{60}/Au solar cell with illumination through the ITO/MEH–PPV side of the device [18] (Fig. 15). The onset of photocurrent at a photon energy of 1.7 eV follows the absorption of MEH–PPV, which initiates the photoinduced electron transfer. However, the minimum in the photocurrent at a photon energy of 2.5 eV corresponds to the region of maximum absorption in the polymer layer. The MEH–PPV layer, therefore, acts as a filter which reduces the number of photons reaching the MEH–PPV/C_{60} interface. The photoactive region is restricted to a very thin layer adjacent to the heterojunction interface. The thickness of this layer is limited by low values of the exciton diffusion length. In [20], this length in MEH–PPV was estimated to be only a few angstroms. Recent direct measurements of the exciton diffusion length in bilayered solar cells provided values of 4–6 nm for the PPV layer in C_{60}/PPV cells [94–95], as well as 4.7 and 7.7 nm for the PEOPT and C_{60} layers, respectively, in C_{60}/PEOPT cells [99]. These experimental values support the conclusion that, in bilayered molecular solar cells, the only photoexcitations generated in a very thin layer at the heterojunction interface may contribute to the cell photocurrent. This results in a relatively low collection efficiency of such cells.
Significant improvement of the collection efficiency has been achieved using composite material with a network of internal heterojunctions between a fullerene and conjugated polymer, forming so-called *bulk heterojunctions*.

5.3. Fullerene/Polymer Solar Cells with a Network of Internal Heterojunctions

A revolutionary development in organic photovoltaics came in the mid-1990s with the introduction of an *interpenetration network of internal heterojunctions* or the so-called *bulk heterojunction*, where an electron-accepting (fullerenes or fullerene derivatives) and an electron-donating material (conjugated polymers) are blended together, forming a composite. Through control of the morphology of the phase separation into an interpenetration network, one can achieve a high interfacial area within the bulk material. If any point in the bicontinuous network is within an exciton diffusion length from a donor–acceptor interface, then wherever an exciton is photogenerated in either material, it is likely to diffuse to the interface and break up. Then the separated charge carriers may travel to the contacts, and deliver current to an external circuit (Fig. 16).

Using this principle of the material construction, a solar cell based on an MEH–PPV/fullerene derivative composite (without any macrojunction!) was demonstrated [19]. The authors believed that a built-in electric field was created by asymmetric metallic contacts (with different work functions), one of which was transparent ITO. The idea of such internal electric field generation in organic devices was first described by Parker [103], and then developed for organic light-emission diodes (LEDs) [103], photodiodes, and solar cells [104–107].

In [19], uniform films of such soluble fullerene derivative as [6,6]–phenyl C_{61}–butyric acid methyl ester (PCBM) [108] and MEH–PPV were cast from 1,2–dichlorobenzene solutions containing 1:4 weight ratio MEH–PPV:PCBM. The enhanced solubility of PCBM compared to pure C_{60} allows such a high fullerene/conjugated polymer ratio, and strongly

supports the formation of bulk donor–acceptor heterojunctions. Using this film as a photoactive layer as well as Ca and transparent ITO films as asymmetric electrodes, bulk heterojunction solar cells, with $J_{sc} = 0.5$ mA/cm^2 under 20 mW/cm^2 monochromatic illumination, were demonstrated. This J_{sc} value corresponds to a collection efficiency of 7.4% electrons per incident photon, which is about 2 orders of magnitude higher than that of the bilayered MEH–PPV/C$_{60}$ solar cells described in the previous section.

Starting with [19], substantial progress has been made toward efficient solar cells based on fullerene/conjugated polymer blends [25, 109–120]. In particular, a significant breakthrough has been achieved by realizing that the morphology of the photoactive composite layer plays an important role in charge carrier mobility [25, 121] and solar cell performance [25, 112, 114, 118].

To the best of our knowledge, the highest efficiency of the fullerene/polymer bulk heterojunction solar cells under AM 1.5 irradiation has been reported for the following device configuration [25]: poly [2–methoxy, 5–(3′,7′– dimethyl–octyloxy)]–p–phenylene–vinelyne (MDMO–PPV) [125] was used as the electron donor in these cells, while the electron acceptor was (PCBM). The thickness of the spincast MDMO–PPV:PCBM active layer with the improved morphology was about 100 nm. As electrodes, a transparent ITO film on one side and an LiF/Al bilayer contact on the other side were used. An LiF/Al electrode was chosen instead of pristine Al in order to guarantee a good ohmic contact between the metal and the organic layer [123–124]. (Recently, it was shown that insertion of a thin LiF interlayer into such cells significantly enhances electron injection [118] due to the fact that such an interlayer between Al and PCBM prevents a chemical reaction of Al with the carboxylic oxygen of PCBM [125].) For improvement of the ITO contact, the ITO was coated with a thin layer of poly(ethylene dioxythiphene) (PEDOT) [113]. The device structure of ITO/PEDOT/MDMO–PPV:PCBM/LiF/Al layered solar cells, together with the molecular structure of the MDMO–PPV and PCBM compounds used for the active layer, are shown in Figure 17. Figure 18(a) displays the molecular structure of PEDOT. The reported photovoltaic parameters of such solar cells under AM 1.5 irradiation, at 50 °C, were $J_{sc} = 5.25$ mA/cm^2, $V_{oc} = 0.82$ V, $FF = 0.61$, and $\eta = 2.5\%$. These high parameters have been approved by accurate indoor [119] and outdoor [120] photovoltaic characterization of such solar cells, the results of which had been appropriately adjusted to standard test conditions (STCs). Such accurate characterization is necessary in order to quantify cell performance in a manner that may be compared from one laboratory to another. In the case of conventional inorganic solar cells, a set of STCs has been defined. These correspond to a radiant intensity of 1000 W/m^2, with a spectral distribution defined as "AM1.5G" (IEC 904-3) and a cell temperature of 25 °C. In spite of the existence of such a standard, all kinds of efficiencies have been reported for organic [126] and, in particular, fullerene-containing solar cells, based on measurements performed under a wide variety of test conditions (Table 1).

The I–V characteristics of an ITO/PEDOT/MDMO–PPV:PCBM/LiF/Al solar cell measured under appropriately corrected simulated STC conditions are shown in Figure 19

[119]. The correction [119–120] is based on the determination of the simulator spectral mismatch factor using spectral responses of the cell under test and of the reference cell (Fig. 20), as well as the simulator spectrum and the AM1.5G standard solar spectrum.

The authors of [127] suggested another approach for improvement of the morphology of the solar cell active layer, and the following enhancement of the charge transfer and improvement of the charge transport. In this study, a bilayer system, consisting of spin-cast MEH–PPV and sublimed C_{60} layers, was heated above the MEH–PPV glass transition temperature in order to enhance the diffusion of the fullerene into the polymer, resulting in a concentration gradient structure. With this process, a controlled, *bulk gradient heterojunction* was created. Because the fullerene acceptor was thus distributed throughout the film, exciton recombination was dramatically reduced. This was observed as a decrease in the photoluminescence by an order of magnitude and an increase in the photocurrent by an order of magnitude throughout much of the visible spectrum. Unfortunately, the photovoltaic parameters of such solar cells measured under the proper conditions were not reported.

5.4. Irradiance and Temperature Dependences of Photovoltaic Parameters of Fullerene/Polymer Solar Cells

To optimize cell efficiency, the electronic processes limiting device performance should be identified. Studies of *I–V* characteristics of fullerene/conjugated polymer solar cells as a function of temperature and illumination intensity may provide information on photovoltage generation and injection mechanisms, charge transport properties, and the presence of defects (both in the bulk and at the interface).

The irradiance dependence of the photovoltaic parameters of MDMO–PPV:PCBM bulk heterojunction solar cells was studied in the cell temperature and irradiance ranges $T = 283–306$ K and $P_{light} = 80–550$ W/m^2, respectively [120, 128]. The almost linear irradiance dependence of I_{sc} at all studied temperatures was demonstrated. Very recently [117], it was confirmed that the photocurrent behavior is close to linear at $T = 300$ K, that is, $I_{sc} \propto I_{sc}^{1.01}$, but deviates at lower temperatures ($T \sim 100$ K) and irradiance levels ($P_{light} \sim 10$ W/m^2). The observed near-linear dependence is a key condition for efficient photoconversion. In simple terms, it indicates that a recombination of the photogenerated charge carriers is sufficiently slow compared to charge transport for all of the photogenerated carriers to be collected at short circuit [129].

Figure 21 summarizes the temperature dependences of the principal photovoltaic parameters of an MDMO–PPV:PCBM bulk heterojunction solar cell, under real sun irradiation in the temperature range 30–60 °C [120].

V_{oc} was found to decrease linearly with increasing temperature [Fig. 21(b)]. For all studied samples, the observed linear decrease had a temperature coefficient in the range $dV_{oc}/dT = -1.40–1.65$ mV/K and extrapolated to $T = 0$ K values of 1.33–1.40 V. It should be noted, however, that recent low-temperature measurements on the current–voltage behavior of conjugated polymer/fullerene bulk heterojunction solar cells in the range 80–300 K showed that this linear temperature dependence of V_{oc} is lost at temperatures below 200 K, and that V_{oc} begins to saturate [117].

In order to try to understand the physical mechanisms which may be responsible for the observed temperature dependence of V_{oc} in the high- and low-temperature ranges, it is instructive to start with an analysis of the V_{oc} behavior of conventional inorganic semiconductor solar cells with a *p–n* junction (see Section 2). For that situation,

$$V_{oc} = \frac{A\kappa T}{q} \ln\left(\frac{I_{sc}}{I_0} + 1\right) \tag{7}$$

where A is a so-called diode quality factor of the *p–n* junction and I_0 is the reverse saturation current. According to a geometrically simple model of Shockley [6], I_0 is given by

$$I_0 = qN_vN_c[\exp(-E_g/\kappa T)] \cdot \left(\frac{L_n}{n_n\tau_n} + \frac{L_p}{p_p\tau_p}\right) \tag{8}$$

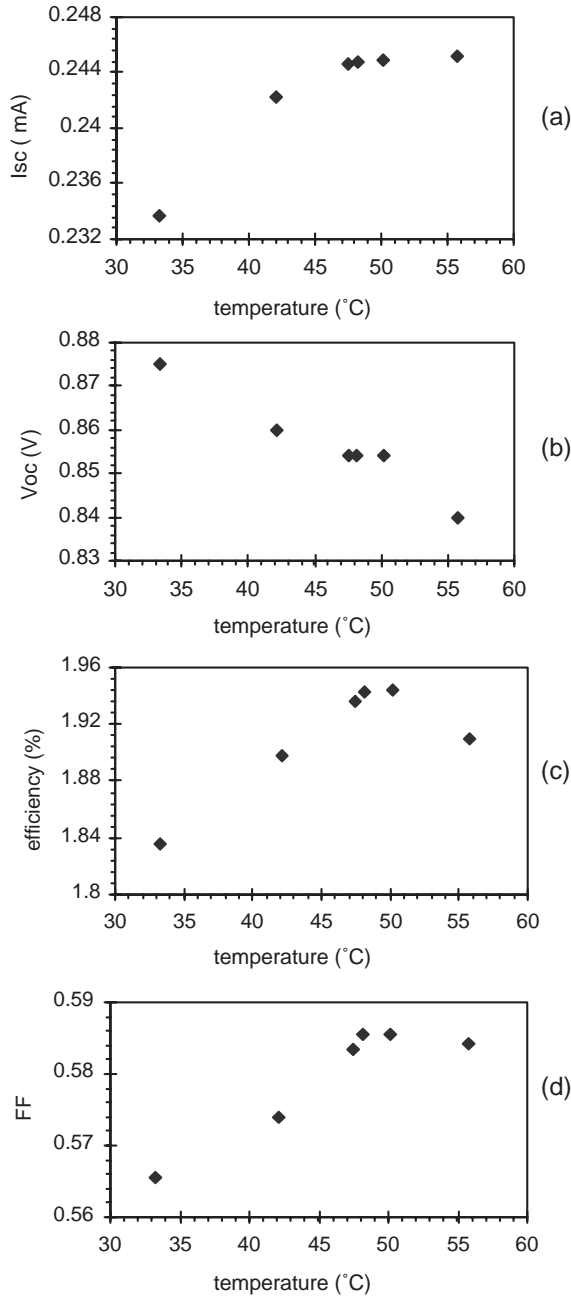
where N_v and N_c are the effective densities of states in the valence and conduction band, respectively, E_g is the


Figure 21. Temperature dependences of the principal photovoltaic parameters for a typical ITO/PEDOT/MDMO–PPV:PCBM/LiF/Al cell derived from outdoor measurements of its I–V curves. Plotted values of efficiency and I_{sc} have been adjusted to the STC irradiance level of 1000 W/m^2. Reprinted with permission from [120], E. A. Katz et al., *J. Appl. Phys.* 90, 5343 (2001). © 2001, American Institute of Physics.

semiconductor bandgap, and L_n, L_p, n_n, p_p, τ_n, τ_p are the diffusion lengths, the carrier densities, and the lifetimes of electrons and holes, respectively. Since $I_{sc} \gg I_0$, by inserting (5) into (4), one obtains

$$V_{oc} = \frac{AE_g}{q} - \frac{A\kappa T}{q} \cdot \ln\left[\frac{1}{I_{sc}} \cdot qN_vN_c\right]\left(\frac{L_n}{n_n\tau_n} + \frac{L_p}{p_p\tau_p}\right)$$
$$= a - bT \tag{9}$$

where

$$a = V_{oc}(0K) = \frac{AE_g}{q}$$

and

$$b = -dV_{oc}/dT = \frac{A\kappa}{q}\ln\left[\frac{1}{I_{sc}} \cdot qN_vN_c\right]\left(\frac{L_n}{n_n\tau_n} + \frac{L_p}{p_p\tau_p}\right).$$

To the extent to which such a simple model might also be relevant to the organic solar cell situation, that is, in that a linear decrease of V_{oc} with T was also observed for the fullerene/polymer solar cells [117, 120, 128], at least for the high-temperature range ($T > 200$ K), V_{oc} for these solar cells may be described by a diode equation similar to (4) with $I_0 \sim \exp(-E_{DA}/kT)$. Here, E_{DA} is a parameter analogous to E_g for a conventional semiconductor. If we adopt such a model for these fullerene–polymer bulk heterojunction solar cells, E_{DA} corresponds to the energy difference between the lowest unoccupied molecular orbital (LUMO) of the acceptor and the highest occupied molecular orbital (HOMO) of the donor components of the active layer, as will be argued later.

The observed room-temperature values of $V_{oc} \sim 0.8$ V [25, 111, 117, 119–120] are considerably higher than the V_{oc} value of 0.53 V previously reported for bilayer conjugated polymer/fullerene solar cells under intense illumination [18]. They are also two times higher than the work function difference of the two electrodes (Al:4.3 eV, ITO:4.7 eV), which would give a value of 0.4 V. This result strongly supports the conclusion of [109] that photovoltage generation in bulk donor–acceptor heterojunctions cannot be explained by a model of the work function difference of the two electrodes [103], which is generally accepted for single-layer conjugated polymers devices [104].

On the other hand, it has recently been shown that the open-circuit voltage in solar cells based on interpenetrating networks of conjugated polymers with fullerenes is directly related to the acceptor strength of the fullerenes [130–131]. This result fully supports the view that the open-circuit voltage of this type of donor–acceptor bulk-heterojunction cell is related directly to the energy difference between the HOMO level of the donor and the LUMO level of the acceptor components of the active layer. Furthermore, and also in full agreement with this view, it was found that a variation of the negative electrode work function influences the open-circuit voltage only in a minor way. This view on the V_{oc} generation is additionally supported by the fact that the values of the temperature coefficient $dV_{oc}/dT = -1.40$–1.65 mV/K for the cells with bilayered LiF/Al and ITO/PEDOT contacts [120] coincide with those reported for polymer/fullerene bulk heterojunction solar cells of the "previous generation" (i.e., with the same components in the active layer, but without LiF and PEDOT contact layers) [128].

In this picture, the temperature dependence of V_{oc} is directly correlated to the temperature dependence of the quasi-Fermi levels of the components of the active layer under illumination, that is, of the polymer and the fullerene.

Figure 21(a) and (d) shows a relatively large monotonic increase with temperature for I_{sc} and FF, followed by a saturation region. A slight increase in I_{sc} with temperature is

also a common feature for inorganic solar cells [132]. However, in the case of fullerene–polymer solar cells, the rate of increase was so dramatic that the increase of the I_{sc} and FF product, with temperature, overtook the decrease of V_{oc}. As a result, there was an absolute increase of the power efficiency η with temperature, reaching a maximum value at temperature T_{max} which, for different samples, lay in the range 47–60 °C [Fig. 21(c)]. It should be noted that similar positive temperature coefficients for I_{sc} also have since been observed for fullerene/polymer bulk heterojunction solar cells with other active layers, for example, in PCBM:poly(3–hexylthiophene) (P3HT) solar cells [133]. [The molecular structure of P3HT is shown in Fig. 11(h).] PCBM:polyfluorene solar cells showed even higher values of the I_{sc} temperature coefficient. For such devices, j_{sc} was revealed to increase linearly from 0.8 to 2.2 mA/cm^2 (i.e., by 175%!) as the temperature increased from 5 to 100 °C [134].

A positive temperature dependence of η is a remarkable peculiarity for fullerene–polymer solar cells, which is not observed in most conventional inorganic solar cells [132]. It is significant, therefore, that the heating of solar cells to the reported T_{max} temperatures may be expected to arise naturally by the absorption of solar radiation, that is, without any artificial heating. Therefore, unlike conventional solar cells, we would expect fullerene–polymer solar cells to perform more efficiently under natural (warm climate) operating conditions than under standard test conditions!

Possible reasons for the observed, unusually large, positive temperature coefficient for I_{sc} are still under discussion. It has been attributed to the thermally activated mobility of the charge carriers in the cell's active layer [120], the difference in the temperature dependences of the mobility of electrons and holes within the fullerene and polymer transport paths [117], as well as space-charge effects [129].

The observed temperature dependence of FF [Fig. 21(d)] was quite similar to that of I_{sc}. The former, however, can be qualitatively understood in terms of the temperature-dependent series resistance of the solar cell R_s. Fullerene/polymer solar cells have a relatively high resistivity of the organic active layer, but one which *decreases* with increasing temperature.

5.5. Efficiency Optimization of Fullerene/Polymer Solar Cells

5.5.1. Improvement in Short-Circuit Current and Fill Factor

While fullerene/polymer solar cells show quite respectable V_{oc}, the values of I_{sc} and FF are much lower than those available from inorganic solar cells. The lower photocurrent is caused by weak light absorption (the reported cells absorb only ∼60% of the incident photons [18]) and charge transport, while the low FF values are due to poor charge transport and the recombination in these solar cells. Therefore, research activity aimed at I_{sc} improvement should be focused mainly on the two following goals: improving light harvesting, and improving charge transport.

Improving Light Harvesting The optical bandgap of the poly(p–phenylenevinelene)s (PPVs) and polythiophenes that are currently used in the construction of bulk heterojunction solar cells lies in the range $E_g \sim$ 2.0–2.2 eV, and is not optimized with respect to the solar spectrum (see, for example, Fig. 20). One promising strategy is to replace donor moieties in devices with conducting polymers of lower bandgap ($E_g <$ 1.8 eV), which may increase the light absorption in the visible and near-infrared regions of the solar spectrum. In designing new lower bandgap polymers for bulk heterojunction solar cells, various aspects need to be considered. For a conventional homo-p–n junction solar cell, a reduction of E_g results in an increased light absorption and I_{sc} values, but at the same time lowers V_{oc}. As a consequence, the optimum bandgap of such devices is at ∼1.5–1.6 eV [13]. However, as mentioned in the previous section, V_{oc} of fullerene/polymer bulk heterojunction solar cells is likely related to the energy difference between the LUMO level of the acceptor and the HOMO level of the donor components of the active layer. A reduction of the bandgap of the polymer by increasing its HOMO level (i.e., decreasing the polymer oxidation potential) may therefore reduce V_{oc}. On the other hand, a lowering of the bandgap by bringing down the polymer LUMO level (i.e., reducing the reduction potential) will reduce the driving force for the polymer to transfer an electron in the excited state to the fullerene. To counteract such a decreased driving force, a lowering of the bandgap should be accompanied by a concomitant decrease in the oxidation potential of the polymer [135].

The synthetic principles for lowering the bandgap of linear π-conjugated polymers have been reviewed by Roncali [136]. Fullerene/polymer bulk heterojunction solar cells, using novel polypyrolle/thiadiazole (PTPTB) copolymers [Fig. 22(a)] with $E_g \sim$ 1.5–1.6 eV [135, 137] and thiophene/isothianaphthene (PDTI) copolymers [Fig. 22(b), (c)] with $E_g \sim$ 1.2–1.8 eV [138–139], as a low bandgap donor moiety, have been reported recently. The photovoltaic parameters of such devices are listed in Table 1.

Other strategies for a broad spectral sensitization of such solar cells include introducing a conjugated crystalline dye, such as a perylene derivative [Fig. 22(d)], to a fullerene/polymer blend in the cell active layer [140] or using a coevaporated layer of C$_{60}$ and a small organic molecule, such as zinc phthalocyanine (ZnPc) (Fig. 14), on top of the PCBM:MDMO–PPV blend [141].

In all of these studies [135, 137–141], serious improvements in photoconversion in the visible and near-infrared regions of the solar spectrum have been demonstrated. Although the energy conversion efficiency of these devices is still relatively small ($<$2.5%), further improvement can be expected. This obviously involves optimization of the synthesis, device architecture, and processing conditions. Multilayered structures of the solar cell active layer combining various bandgap materials, or solar cells with a smooth bandgap gradient in the active layer should be investigated as well. Some solar cells based on new ideas on device architecture will be reviewed in Section 5.5.3.

A different approach is to increase the number of absorbed photons by *light-trapping* structures. This number is limited by a strong requirement that the active layer in
Figure 22. Molecular structures of low-bandgap donor moieties used in fullerene-based solar cells. a: polypyrolle/thiadiazole (PTPTB) copolymer; b, c: thiophene/isothianaphthene (PDTI) copolymers; d: perylene tetracarboxylic derivative.

fullerene/polymer bulk heterojunction solar cells should be rather thin (≤ 100 nm). By making the active layer thicker, to collect more of the light by absorption, one also reduces the built-in electric field [142] and increases the solar cell series resistance [143], thus reducing the collection efficiency and forcing a compromise on the photocurrent. It is, therefore, desirable to make very thin devices, but to find ways of enhancing the photon path in their active layer. The possibilities for reconciling these requirements by light trapping in the active layer of fullerene/polymer solar cells were discussed by Inganäs et al. [144]. Some of them have been investigated by coupling the incoming light into waveguided modes within the embossed organic thin layers [145]. An elastomeric mold has been used to transfer a submicrometer grating pattern from a commercially available grating template to the active layer of fullerene/polymer bulk heterojunction solar cells. Using spectral response measurements of the grating and reference (flat) cells, with a 90 nm thick active layer, an enhancement in external quantum efficiency all over the spectrum has been demonstrated for the grating cell. At maximum peak position, an enhancement in external quantum efficiency of about 26% has been recorded.

An additional enhancement in light harvesting can be achieved by decreasing the fraction of the incident light reflected by the front surface of a solar cell. Usually, for this purpose, special antireflection coating layers are evaporated on the top of solar cells. It should be noted, however, that all of the solar cells described in the present review had no

such layer. The possibility of the discussed improvement has been demonstrated recently just by sandblasting the glass substrate of a fullerene/polymer bulk heterojunction solar cell [146]. Reduced reflection of the incoming light and a corresponding increase in I_{sc} were observed.

Improving Charge Transport Charge transport in fullerene/polymer solar cells is limited mainly by the low intrinsic mobility of charge carriers in molecular solids, and by the charge trapping effects of impurities and defects (in the bulk and at the interfaces).

Recently, several research groups have reported a very strong influence of fullerene concentration in the cell active layer on the carrier mobility, which can be tuned in order to obtain a bipolar transport mechanism [134, 147–149]. The most surprising result of these experiments is a still unexplained fact that an increase in fullerene concentration resulted not only in increased electron mobility, but also in an enhanced hole mobility [134, 149].

As already noted in Section 5.3, in fullerene/polymer bulk heterojunction solar cells, both photocurrent generation and charge transport (in particular, charge carrier mobility) depend upon the morphology of the blended active layer. In the case of the MDMO–PPV/PCBM active layer, an improved morphology and the highest photovoltaic parameters of the cells have been achieved by using chlorobenzene as a solvent [25]. However, a direct transfer of this finding to other systems is not straightforward; therefore, a morphology optimization, in which the choice of solvent is only one of the parameters, should be performed for any combination of materials.

A promising strategy for the vital improvement of morphology and charge transport is the preparation of so-called "double-cable" polymers, that is, supramolecules, in which the polymeric electron donors and the fullerene electron acceptors are covalently linked. The recent developments of the design, characterization, and photovoltaic application of this novel class of fullerene functional materials are reviewed by Cravino and Sariciftci [150]. In this supramolecular photovoltaic approach, the desired nanoscopic bicontinuous network has been achieved by synthesizing novel π-conjugated polymers with pendant fullerenes which prevents any problem arising from interface defects, as observed for fullerene/polymer blends. The molecular structures of some "double-cable" polymers [151–153] are shown in Figure 23. It is worth noting that the performance of the first solar cells based on "double-cable" polymers [153] [Fig. 23(c)], which were not optimized, is already competitive with that of devices prepared according to the p/n heterojunction and "bulk heterojunction" approaches [109, 154]. Photovoltaic measurements of the first "double-cable" solar cells under white-light illumination (100 mW/cm^2) revealed a J_{sc} value of 0.42 mA/cm^2, V_{oc} of 830 mV, and *FF* of 0.29 [153]. This new synthetic approach also offers great versatility for design tuning the photovoltaic system [153–162]. Figure 24 schematically illustrates one example of such a supramolecular solar cell based on a C$_{60}$–3PV hybrid compound, in which hole-conducting oligophenylenevinelene (OPV) moiety was chemically linked to an electron-conducting fullerene subunit [155–156]. In such a device, the compound is not only able to generate

electrons and holes, but it also provides pathways for their subsequent collection at opposite electrodes.

Another research approach for charge transport improvement suggests the use of the longest fullerene molecule, a carbon nanotube (CNT), instead of C_{60} or its derivatives in fullerene/polymer solar cells. Being blended with conjugated polymers, CNTs may not only act as electron acceptors, but also allow the transferred electrons to be efficiently transported along their length, thus providing percolation paths. CNT can be metallic or semiconducting, depending on their diameters and chirality [4]. The electrical and photoelectrical properties of CNT/conjugated polymer composites and interfaces have been investigated since 1996 [163–168]. Recently, bulk heterojunction solar cells based on conjugated polymers blended with multiwalled [169] and single-walled [170] CNTs (Fig. 25) have been reported. The photovoltaic parameters of these CNT-containing solar cells are listed in Table 1.

In addition to this application of CNT, Koprinarov et al. suggested using metallic CNT as a contact material for a wide range of inorganic solar cells [171].

5.5.2. Improvement in Open-Circuit Voltage

Since V_{oc} of fullerene/polymer bulk heterojunction solar cells is related to the energy difference between the LUMO level of the acceptor and the HOMO level of the donor components of the active layer (see Sections 5.4 and 5.5.1.1 and [130–131]), for further increase of the V_{oc}, one should be able to vary the LUMO level of the acceptor, that is, its electron affinity. Brabec et al. synthesized two new fullerene derivatives, ketolactam and azafulleroid, and compared them to C_{60} and PCBM, as acceptors of different strengths in bulk heterojunction solar cells (Fig. 26) [130–131]. It was found that PCBM, which has the lowest electron affinity, that is, acceptor strength, resulted in the highest V_{oc} values. For a further increase of the V_{oc}, new acceptors with lower electron affinity may help.

5.5.3. Novel Concepts of Organic Fullerene-Based Solar Cells

Yoshino et al. [21] have suggested the insertion of an additional *middle excitonic layer* between the polymeric donor and fullerene acceptor layers, in a three-layered molecular solar cell, which is reminiscent of a *p–i–n* structure in inorganic solar cells. To test this idea, the authors fabricated a three-layered cell utilizing OOPPV, octaethylporphine (OEP) (Fig. 27), and C_{60} films as the donor, middle excitonic, and acceptor layers, respectively. Photocurrent yield spectra, measured under irradiation from different sides of the cell, were interpreted by light absorption mainly in the OEP layer, exciton migration, and charge generation at both heterojunctions. Both interfacial regions of OOPPV/OEP and OEP/C_{60} were found to contribute to the charge generation by excitonic dissociation. Photocurrent enhancement and broadening of spectral sensitivity were observed for the OOPPV/OEP/C_{60} solar cells, as com-

pared with the OEP single-layer and OOPPV/C_{60} bilayered solar cells. The same research team suggested an idea of fullerene/conjugated polymer multilayered solar cells with a quantum well structure (Fig. 28) [172]. In our opinion, serious experimental research is still needed for further clarification of the advantages of either *the double-heterojunction* or *the multilayered* solar cells, in comparison with the most efficient bulk heterojunction devices.
Meanwhile, Peumans and Forrest [26] have experimentally demonstrated C_{60}/copper phthalocyanine (CuPc) bilayered solar cells, incorporating an *exciton-blocking layer*. The chemical structure of CuPc is shown in Figure 14, where $M =$ Cu. These devices showed an efficiency of ($3.6 \pm 2\%$) under AM1.5 spectral illumination of 150 mW/cm^2 (1.5 suns) [26]. The cells were fabricated on glass substrates predeposited with an ITO anode contact. The ITO film was then spin coated with an ∼320 Å thick film of PEDOT:PSS. The chemical structures of PEDOT and poly(styrenesulfonate) anion (PSS$^-$) are shown in Figure 18. Then the photoactive layers were grown at room temperature in high vacuum (∼10^{-6} torr) in the following sequence: a 50–400 Å thick film of the donor-like CuPc, followed by a 100–400 Å thick film of the acceptor-like C_{60}. Next, a 50–400 Å thick exciton-blocking layer of bathocuproine (BCP) was deposited. Figure 29 displays a molecular structure of BCP. Finally, an Al cathode was deposited by thermal evaporation. (Previously [173], a large-bandgap ($E_g > 3$ eV) and, therefore, a transparent BCP layer had been found to transport electrons to the cathode from the adjoining acceptor layer, while effectively blocking excitons in the lower energy-gap acceptor layer from recombining at the cathode.) The highest photovoltaic parameters were observed for the ITO/PEDOT:PSS/200 Å CuPc/400 Å C_{60}/120 Å BCP/Al solar cells. At an illumination intensity of 150 mW/cm^2, values of $\eta = (3.6 \pm 2\%)$, $V_{oc} = 0.58$ V, $I_{sc} = 18.8$ mA/cm^2, and

$FF = 0.52$ were demonstrated. It should be noted that some features of the reported results and their interpretation are still not clear. For example, the reported I_{sc} value is apparently inconsistent with the reported spectral quantum efficiency data (very recently [174], the authors have explained this inconsistency by the degradation of the devices during their exposure to air between the $I–V$ and the spectral response measurements). Nevertheless, this approach, of layered solar cells with fullerene and phthalocyanine molecular layers, is very promising, and is now being developed by different research groups [141, 175–176].

Other approaches utilizing the high absorption of phthalocyanines around 1.8 eV include doping of a phthalocyanine layer by C_{60} [175, 177, 178] and making covalently linked molecular systems, like phthalocyanine–fullerene dyads (Fig. 30) [179].

5.6. Stability of Organic Fullerene-Based Solar Cells

The relatively low stability of fullerene/polymer solar cells is a serious problem limiting their industrial application. Under the simultaneous influence of light and exposure to

oxygen, a rapid degradation of photogeneration and transport properties of conjugated polymer/fullerene composite material occurs [180]. A faster degradation rate was found for the polymer compared with the fullerene in this material [180–181]. Protection from air and humidity is absolutely necessary to achieve long lifetimes [182].

Stability studies on encapsulated bulk heterojunction fullerene/polymer solar cells were performed under outdoor [120, 183] and indoor [119] operational conditions. During 11 successive days of the outdoor experiment, V_{oc} was

found to remain almost constant, while degradation in the I_{sc} and *FF* values was evident [120, 183]. This V_{oc} stability and degradation of I_{sc} and *FF*, under operational conditions, was confirmed by the indoor *I–V* measurements. The latter were performed during 460 h of cell aging, both in the dark, at room and elevated temperatures, and under continuous illumination at 1 sun, equivalent at 50 °C (Fig. 31) [119]. The cells which were kept in the dark, at room temperature, remained stable in terms of V_{oc} and I_{sc}, while *FF* demonstrated a slight decrease [Fig. 31(a)]. At 40 °C in the dark, a substantial decrease of I_{sc} and *FF* was observed, while V_{oc} remained constant, resulting in an overall decrease of 30–50% in the efficiency. The combination of thermal stress at 50 °C and visible light soaking resulted in complete degradation of the cell, mostly by I_{sc} and *FF*, within 460 h of aging [Fig. 31(c)]. The corresponding degradation mechanisms have not yet been clearly identified. Morphological changes in the photoactive layer after thermal aging, as well as photochemical degradation of the polymers, seem to have detrimental effects on the cell performance [119].

6. CONCLUDING REMARKS

In this chapter, we have reviewed the prospects of fullerene-based materials for photovoltaics, and have presented a comprehensive picture of state-of-the-art and future directions of fullerene-based solar cell research. Device structures and photovoltaic parameters of inorganic and organic fullerene-based solar cells were presented.

The very low intrinsic conductivity of C_{60} crystals is one of the main factors limiting the efficiency of inorganic fullerene-based solar cells. As a consequence, development of the appropriate doping processes is ultimately needed. Photovoltaic parameters of C_{60}/Si solar cells were found to be improved by P and B ion implantation in C_{60} thin films. Such implantation resulted in a dramatic increase in film conductivity, partial structural transformation from C_{60} to α–C, and corresponding changes in the optical gap of the C_{60} films. Using this effect, together with the control of the depth-implantation profile by ion energy regulation, it might be possible to produce a C_{60}/α–C composite with a nonhomogeneous depth-profile optimized for maximum sunlight absorption and cell efficiency. We expect that the next step in this direction will be the production of highly efficient multijunction C_{60}/α–C/Si or α–C/C_{60}/Si (*p–i–n*) solar cells. The ability to produce α–C/C_{60}/Si (*p–i–n*) solar cells has already been demonstrated. Another approach may include a C_{60}/α–C supperlattice structure for quantum-well solar cells.

Over the last decade, significant progress has been achieved in fullerene-based organic solar cells. The operating principles of such solar cells are similar to those for the initial steps of natural photosynthesis, and are based on very fast (*subpicosecond*) photoinduced electron transfer from a donor molecule (a conjugated, semiconducting polymer, for example) to a nearby C_{60} or other fullerene (or their derivative) acceptor molecule. Such cells are predicted to become a serious alternative to conventional inorganic photovoltaic devices. Efficiencies of over

2% have now been reported for two different types of fullerene-containing organic photovoltaic devices, such as bulk heterojunction fullerene/conjugated polymer solar cells and C_{60}/copper phthalocyanine bilayered solar cells, incorporating an exciton-blocking layer. The performance of these devices is limited by weak light absorption, poor charge transport, and low stability, but improvements may be expected via further optimization of materials and device architecture. Based on current trends, an efficiency of 5% appears to be within reach in the near future [102].

It should be noted that, up to now, only one member of the fullerene family, C_{60}, has been used in inorganic solar cells. In organic photovoltaic devices, pure C_{60}, a variety of C_{60} derivatives, and carbon nanotubes have been already utilized. The photovoltaic parameters of fullerene-based solar cells are summarized in Table 1. For comparison, the parameters of the best monocrystalline and amorphous/nanocrystalline silicon solar cells are also listed. A complete table summarizing the photovoltaic parameters of the best inorganic semiconductor solar cells is documented in [184]. Table 1 shows that the highest efficiency values of 2–3% demonstrated by organic fullerene-based devices are comparable to, but still lower than, those of conventional inorganic semiconductor solar cells [184]. In spite of this, organic fullerene-based devices have a number of advantages, such as their light weight, flexibility, simple processing at relatively low temperatures, and therefore, low fabrication cost. Furthermore, fullerene/polymer solar cells can be scaled up for production of large areas without a significant loss of device efficiency. Recently, a photoactive layer of bulk heterojunction solar cells, consisting of an MDMO–PPV:PCBM blend, was successfully produced by screen printing [185]. The average thickness of the active layer and the root-mean-square surface roughness were 40 and 2.6 nm, respectively. The devices yielded a power conversion efficiency of 4.3% when illuminated by monochromatic light with a wavelength of 488 nm. These results illustrate that screen printing can be a powerful technique for the fast, inexpensive fabrication of roll-to-roll fullerene/polymer solar cells, while retaining nanometer-scale control of film thickness. Using this technique for solar cell fabrication further increases the strong potential that fullerene/polymer solar cells may have practical applications.

Finally, it is worth mentioning that a number of strategies have also been suggested for incorporating fullerene moieties in nanostructured *photoelectrochemical* solar cells [64, 186–201], photosensitive biomaterials, and *artificial photosynthetic centers* [193, 195, 202–218]. Although a detailed description of such devices was not within the scope of the present review, we should point out, for completeness, that various research directions aimed at the efficient harvesting of solar energy by photovoltaic and photoelectrochemical solar cells and artificial photosynthetic systems are closely interrelated. Progress in these directions, as well as a better understanding of natural photosynthesis [219], could well be achieved on the basis of a multidisciplinary effort in physics, chemistry, and biology.

GLOSSARY

C_{60} Fullerene molecule consisting of 60 carbon atoms located at the vertices of a truncated icosahedron.

Carbon nanotube   Tubular fullerene molecule, cylindrical in shape, with caps at each end such that two caps can be joined to form a fullerene. The cylindrical portion of a carbon nanotube consists of a single graphene sheet, rolled to form the cylinder.

Conjugated polymers   Polymeric molecules containing a regular array of alternating single and double carbon–carbon bonds.

Fullerenes   Closed cage molecules consisting of carbon atoms located at the vertices of a polyhedron which contains only hexagonal and pentagonal faces.

Homo- and hetero-*p*–*n* junctions   Rectifying interfaces formed between *p* and *n* types of the same or different semiconductors, respectively.

Photovoltaic solar cells   Devices that convert solar radiation directly into electrical energy due to the photovoltaic effect.

Schottky barrier   Rectifying interface between a semiconductor and a metal.

CONTENTS

1. INTRODUCTION

The structures and properties of novel dendritic polymers—dendrimers—have been studied extensively as nanomolecules with the attractive, potential applications in a variety of fields [1–8]. In particular, the investigations are focused on the phenomena based on the concept of "dendritic boxes" or "unimolecular micelles" for the capture of guest molecules and as the compartment of chemical reaction. Host-guest systems, consisting of dendrimers, have enormous demands in the fields of molecular recognition and transport, such as drug delivery, gene therapy, and chemical separation. The interest in dendritic polymers for such applications stems from their distinctive dual structural properties, an external periphery bearing multiple functional groups for solubilization in media and an internal region possessing cavities for the capsulation of small molecules.

Novel dendrimers are prepared by covalent bonding from a functional core through the successive repeating synthesis of a spacer and a branching part (divergent method) or from a conjugation at the conic center of dendrons, units of a dendrimer, (convergent method). When two steps are needed for the extension of repeating units, each step is called a half generation. While the structures of dendrimers at low generations are opened and asymmetric, the structures become crowded and spherical during the increase of the generation [9]. These structural changes influence the properties of dendrimers. Then, dendrimers have a unique surface of plural terminal groups, the number of which can be accurately controlled on a synthesis process. Furthermore, it is possible to bind covalently different functional units in the core, branches, and terminal groups on the divergent synthesis process and to conjugate the dendrons of different chemical constituents on the convergent synthesis process. Thus, dendrimers having various structures and properties can be synthesized.

In this article, the up-to-date investigations concerning the functionalities of dendrimers are reviewed. In particular, dendrimer properties of doping, molecular recognition, adsorption, and hybridization are the focus, and the phenomena of solubilization, complexiation, self-organization, and nanocomposite formation are discussed in relation to the structures and functionalities of dendrimers.

2. DOPING AND SOLUBILIZATION OF GUEST MOLECULES

It is well established that the solubility of hydrophobic molecules in water can be dramatically enhanced in the presence of water-soluble, surface-active agents. For instance, the number of pyrene molecules solubilized in nonionic surfactant micelles of heptaethyleneoxide monoalkyl ether (CnE_7) has been found to be linearly proportional to the aggregation number of the micelles [10]. The solubilization capacity for pyrene is low in spherical micelles of ionic dodecyl sulfate, limited at most to two pyrenes per micelle [11]. Since dendrimers have cavity for maintaining small molecules and may be regarded as unimolecular micelles, water-soluble dendrimers are expected to

increase the solubility of water-insoluble or weakly soluble organic compounds. The solubilization of guest molecules in such dendrimers has been investigated mostly by a fluorescence probing agent—pyrene [9, 12–15]. Caminanti et al. [9] have used pyrene as a photoluminescence probe to sense hydrophobic sites in poly(amido amine) (PAMAM) dendrimers possessing sodium carboxylated surfaces. The probe method provided experimental evidence for a surface structural transition between generations 3.5 to 4.5. Pistolis et al. [12, 13] have reported that the solubilizing capability of amine-terminated PAMAM and amine-terminated poly(propylene imine) (PPI) dendrimers in aqueous media increases with increasing their generations. Pyrene fluorescence undergoes significant quenching in the solubilized state, and excimer fluorescence is observed. It has been also concluded, by the findings concerning exciplex formation, that water is progressively excluded from the dendrimer interior, as the generation of PPI dendrimer increases. It has been reported by Schmitzer et al. [14] that glucose-persubstituted PAMAM dendrimers increase solubilizate quantities of pyrene and benzoylcyclohexane in water, depending on the number of microcavities in each dendrimer, although the solubility of pyrene is 3–4 times larger than that of benzoylcyclohexane. Quaternary ammonium chloride PPI dendrimers with both hydrophilic (triethylenoxy methyl ether) and hydrophobic (octyl) chain ends have been synthesized by Pan and Ford [15]. These amphiphilic dendrimers solubilize pyrene in aqueous solution, and the limiting solubility corresponds to one pyrene per dendrimer molecule.

In order to clarify the solubilization capacity of dendrimers, depending on structures and conditions, we have investigated ultraviolet-visible and steady-state fluorescence spectroscopy of aromatic guest molecules in aqueous solutions of fourth generation PAMAM dendrimer with hydroxyl and amine terminals (G4 PAMAM-OH dendrimer, G4 PAMAM-NH_2 dendrimer) and fourth and fifth generation PPI dendrimers with amine terminals (G4 and G5 PPI-NH_2 dendrimers) as host molecules. As seen in Figures 1 and 2, pyrene is soluble in aqueous solutions of dendrimers, although the solubility of pyrene in dendrimers depends on terminal groups, internal chemical structures, and generations of dendrimers as well as pH. On the other hand, a guest molecule larger than pyrene—benzopyrene—is not solubilized because of its larger size. However, the solubility of phenantherene and benzene are also not enhanced in the presence of dendrimers under the same conditions, except the solubility (0.2) of phenanthrene into an aqueous solution of G4 PAMAM-NH_2 dendrimer at pH 11.01. Phenanthrene and benzene are presumably too small, in comparison to the sizes of microcavities in dendrimers studied, and easily pass through the cavities. Therefore, the structural matching of guest molecules noninteracting with dendrimers plays an important role in their doping into the microcavities of dendrimers.

Since dendrimers with tertiary amine groups in interior and primary amine groups in exterior have pKa of 6.65 and 9.20, respectively, the electric charges of dendrimers change with the pH of the aqueous solutions of dendrimers [16]. The solubility of pyrene in aqueous solutions of dendrimers below pH 6.65 is larger than above
Figure 1. UV-visible spectra of pyrene solubilized in aqueous solutions with and without dendrimers at 25 °C. Powder of guest molecules was added into aqueous solutions of dendrimers at a concentration of 5.0×10^{-7} M, which were adjusted at pH ~6. After the mixtures were stirred overnight, excess guest molecules insoluble in the solutions of dendrimers were filtrated out. Then, UV-visible spectra of the filtrates were measured. From top to bottom: (1) fourth generation hydroxyl-terminated PAMAM dendrimer at pH 5.85; (2) fifth generation amine-terminated PPI dendrimer at pH 6.01; (3) fourth generation amine-terminated PAMAM dendrimer at pH 5.99; (4) fourth generation amine-terminated PPI dendrimer at pH 5.91; (5) without dendrimer.

pH 6.65 (see Fig. 2). This indicates that the protonation of amine groups in interior influences in the doping of pyrene, since the microcavities in the dendrimers are expanded into the preferable sizes by the protonation. Chen et al. [17] have caught the clear evidence for a pH-responsive conformational change of PAMAM dendrimer with amine terminals by means of polarity changes of a polarity-responsive probe, although they could not distinguish between the "denser shell" and "denser core" models. The solubility of pyrene in G4 PAMAM-OH dendrimer is higher than that in G4 PAMAM-NH_2 dendrimer (see Fig. 2). Dendrimers with protonated hydrophilic terminal groups may exclude hydrophobic organic molecules to approach, in contrast to dendrimers with nonionic terminal groups. Incidentally, a positively charged G4 PAMAM-NH_2 dendrimer has demonstrated having "closed" structure [18]. The dimensions of the charged dendrimers have been investigated for carboxylic acid-functionalized PPI dendrimers [19]. The dimension is larger for charged dendrimers and the uncharged dendrimers have the lowest radius. Therefore, the size change of dendrimers occurs with pH.

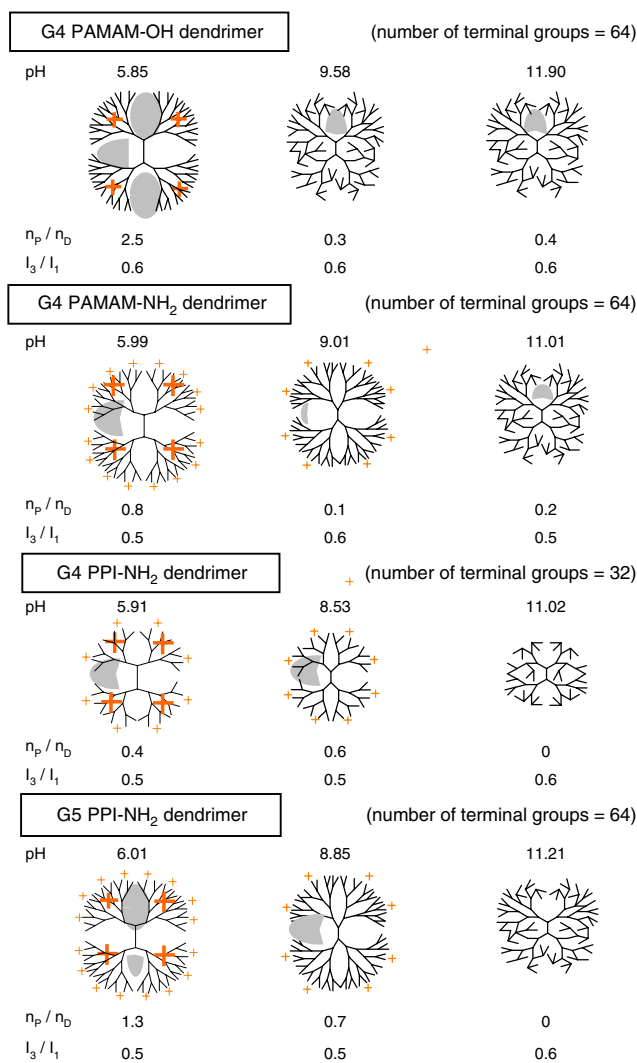
One must notice that the size change of dendrimers depends not only on the functionality of the branching


Figure 2. Solubility of pyrene in aqueous solutions of dendrimers at different pHs at 25 °C. The molar fractions of guest molecules per dendrimer were calculated by using molar extinction coefficients of guest molecules (1.7×10^7 cm²mole⁻¹ at 337 nm for pyrene, 1.4×10^7 cm²mole⁻¹ at 293 nm for phenanthrene). n_P/n_D = number of pyrene molecules solubilized in a dendrimer (solubility). I_3/I_1 = ratio of the third (I_3, 386 nm) to the first (I_1, 375 nm) monomer fluorescence emission intensities of pyrene (polarity index).

points and the functional terminal groups but also on the core, size of spacer, and generation. Although G5 PPI-NH$_2$ dendrimer and G4 PAMAM-NH$_2$ dendrimer have the same number and property of terminal groups, the solubility of pyrene in solutions of G5 PPI-NH$_2$ dendrimer is higher than that of G4 PAMAM-NH$_2$ dendrimer (see Fig. 2). Since the segment density of a PPI dendrimer is lower than that of a PAMAM dendrimer, due to a longer core alkyl chain [20], guest molecules are doped easier in a PPI dendrimer. The solubility is superior in solutions of G5 PPI-NH$_2$ dendrimer than in solutions of G4 homologue (see Fig. 2), because of larger volume or microcavity, as found in the solubilization of pyrene in CnE$_7$ micelles [10].

Pyrene is a useful fluorescence probe for getting micropolarity around it. Micropolarities around solubilization sites

of dendrimers can be evaluated as the ratio of the third to the first monomeric fluorescence emission intensities of pyrene, which is well known as a polarity index. As seen in Figure 2, the polarity index of pyrene in aqueous solutions of all dendrimers is close to that in water and independent of the pH. It can be predicted that pyrene exists in the hydrophilic environment in dendrimers, which is invented by the penetration of water [20]. This causes the less solubility of pyrene in dendrimers than in the hydrophobic interior in surfactant micelles, where a larger amount of pyrene is solubilized [10]. Caminati et al. [9] have revealed that pyrene is probably bound in the hydrophilic palisade layer of the PAMAM dendrimer at the small distance from the charged surface groups, supporting the conclusion previously described.

Besides determining the solubilization capacity of dendrimers, extensive works have been reported on the behaviors of solubilized pyrene in dendrimer assemblies and of covalent-bonded pyrene in dendrimers [21–23]. The solubilization of pyrene was used for the determination of micellar formation of amphiphilic linear-dendritic diblock copolymers consisting of hydrophilic linear polyethylene oxide and hydrophobic dendritic carbosilane [21]: The critical micelle concentrations were determined from pyrene fluorescence. It was also found that increasing the size of dendritic block increases the partition equilibrium constants of pyrene in micellar solution. The steady-state fluorescence anisotropy of 1,6-diphenyl-1,3,5-hexatriene in micelles of amphiphilic linear-dendritic diblock copolymers are lower than that of the linear polymeric amphiphiles, suggesting that the microviscosity of the dendritic micellar core is lower than those of linear polymeric micelles. Baker and Crooks [22] have synthesized four generations of PPI dendrimers, which are covalently modified with pyrene moieties, and compared the behavior of pyrene moieties with those of pyrene solubilized in dendrimers. More intensive excimer emission was observed for higher generation dendrimers, while little or no evidence for interdendrimer interactions was observed. Protonation of the tertiary amine units increased monomer fluorescence significantly, while there was only a slight increase in the observed excimer fluorescence. The excitation energy transfer has been investigated between a first generation dendrimer as a donor molecule and a pyrene-containing polymer as an acceptor molecule in Langmuir–Blodgett monolayers [23]. The adjacent donor and accepter layers dramatically increased the fluorescence activity of the pyrene group in a pyrene-containing polymer.

3. MOLECULAR RECOGNITION AND COMPLEXIATION WITH LINEAR POLYMERS

Dendrimers are regularly branched polymers possessing a large number of surface functional groups [24–30]. Their molecular recognition ability is strongly influenced by the nature of the terminal functionalities. The number of terminal groups of dendrimers is increased by the number of branching sites with increasing their generation. Since the terminals behave as functional groups, dendrimers are useful as probes of molecular recognition and carriers

of molecular transport. Dendrimers with ionic terminal groups electrostatically interact with counter-ionic groups. Such interaction is useful for catching linear polymers on interpolyelectrolyte complexiation. Many researches for such complexiation were carried out for native polymers [31–43] and synthetic polymers [44–49].

The investigations of the complexation with DNA were performed from the view of gene delivery in mammalian organisms. Since dendrimers are spherical molecules with a size comparable to histone, which is a gene-transporting globular protein, the biomimetic investigation for DNA transfer in the living cells was carried out by using PAMAM dendrimers [31–36]. Plank et al. [31] have examined the complement-activating properties of synthetic cationic molecules and their complexes with DNA. While strong complement activation was seen with a fifth generation PAMAM dendrimer, on the complexiation with DNA it depended on the ratio of polycation and DNA. The ability of PAMAM dendrimers to bind DNAs in a variety of mammalian cells and to enhance their transfer has been investigated by Kukowska-Latallo et al. [32, 33]. Since dendrimers bind various forms of nucleic acids on the basis of electrostatic interaction, the ability of DNA-dendrimer complexes for transfering oligonucleotides and plasmid DNA to mediate antisense inhibition was assessed in an *in-vitro* cell culture system. Although the capability of dendrimers to transfect cells appears to depend on the size and shape of dendrimers and the number of primary amine groups on the surface of the dendrimers, the results indicate that dendrimers function as an effective delivery system. Tang et al. [34] have reported that the transfection activity of the dendrimers is dramatically enhanced by heat treatment. The increased transfection after the heating process is principally due to the increase in flexibility which enables the dendrimer to be compact at the complexiation with DNA and swell at the release from DNA. Gebhart and Kabanov [35] have evaluated nonviral transfection *in vitro*, based on the complexes of DNA and polycations, with respect to their effectiveness, toxicity, and cell-type dependence. The effects of PAMAM and PPI dendrimers were compared to those of other polycations. Luo et al. [36] have chemically modified fifth generation PAMAM dendrimer with biocompatible poly(ethylene glycol) (PEG) chains. This novel conjugate produced a 20-fold increase in transfection efficiency in comparison with partly degraded dendrimer controls. Since the cytotoxicity of PEGylated dendrimer is very low, this kind of compound should be extremely efficient, highly biocompatible, and a low-cost DNA delivery system.

The physicochemical properties, interactions, and structures of DNA-dendrimer complexes have been investigated apart from the gene transport [37–42]. It has been proved by Ottaviani et al. [37] that the concentration dependence of the interaction between polynucleotide and dendrimers is different between small (second generation) and large (sixth generation) dendrimers. The interaction with small dendrimers decreased with an increase in concentration due to self-aggregation of dendrimer molecules. Conversely, the interaction with large dendrimers increased until saturation of the interacting sites occurred. It has also been demonstrated that the supramolecular structure of the complexes changes by varying the mixing ratio of DNA and dendrimers

[38]. According to Chen et al. [39], the electrostatic interaction between polynucleotide and PAMAM dendrimer is essential for the effective DNA transfer process. The DNA wraps around seventh generation dendrimers, as illustrated in Figure 3(a), while the wrapping does not occur for fourth and lower generation dendrimers. Kabanov et al. [40] have clarified that electroneutral water-insoluble interpolyelectrolyte complexes of PPI dendrimers interacting with DNA are formed at an equal concentration of amine groups of dendrimer and phosphate groups of DNA. However, the excess addition of fourth- and fifth-generation dendrimers to DNA solution forms positively charged, water-soluble interpolyelectrolyte complexes. Complexed DNA compacts, revealing a wound double-helical structure. These relations may be compared with the Monte Carlo simulations, which were used in the study of the complexation between a polyelectrolyte and an oppositely charged spherical particle in the Debye–Hückel approximation and chain rigidity effects [50, 51]. Bielinska et al. [41] have reported the formation of complicated DNA-dendrimer complexes. Electron microscopic examination of complexes indicated that the majority of plasmid DNA is contracted into isolated toroids, but larger irregular aggregates of polymer and DNA also coexist. This indicates that the binding of plasmid DNA to dendrimer appears to alter its secondary and tertiary structures. Mitra and Imae [42] have revealed the morphology of complicated DNA-dendrimer complexes from atomic force microscopic observation.

Imae et al. [43] have investigated the binding of fourth generation amine-terminated PAMAM dendrimer on native polysaccharide, sodium hyaluronate (NaHA), in an aqueous 0.25 M NaCl solution. The observed variation of molecular weight as a function of mixing ratios of dendrimer to NaHA obeyed the model, where an average number of dendrimers binds to each NaHA chain. However, at a high mixing ratio,
Figure 3. Binding models of cationic dendrimers on linear anionic polymers in solutions: (a) dendrimer-DNA complex; (b) dendrimer-sodium hyaluronate complex; (c) dendrimer-sodium poly(L-glutamate) complex.

the binding is saturated at two dendrimers per three repeating units on a NaHA chain, as illustrated in Figure 3(b). Whereas, at the initial stage of the addition of dendrimer, in a solution, NaHA maintains a worm-like character similar to NaHA without bound dendrimers, NaHA behave like a rigid rod at high dendrimer concentrations. In the NaHA-dendrimer complexation, the hydrogen-bonding interaction, besides the electrostatic interaction, should play an important role.

The investigation has also been performed for the binding of dendrimers to synthetic linear polyelectrolytes with pH-dependent charge density [44–48]. Dubin et al. [44–47] have reported the complexiation between polycations and carboxylated dendrimers. The complexiation with poly(diallyldimethylammonium chloride) and other polycations occurs most readily for the 7.5th generation with high-charge density and does abruptly at a critical pH. The proposed model is that the polyelectrolyte backbone in the complex is distorted for bending around the contour of the spherical macroions [46]. The interaction of PPI dendrimers to a linear polyanion was compared with that to DNA by Kabanov et al. [48]. That is, dendrimers are penetrable for flexible oppositely charged polyelectrolyte chains. However, rigid negatively charged DNA double helixes apparently bind only to the dendrimer shell. The mixtures of dendrimers with polyanions containing equal amounts of cationic and anionic groups consist of mostly water-insoluble, ion-pair (stoichiometric) complexes but include water-soluble nonstoichiometric interpolyelectrolyte complexes.

The binding of PAMAM dendrimers on sodium poly-L-glutamates (NaPGA) in an aqueous 0.25 M NaCl solution has been reported by Imae and Miura [49]. The apparent molecular weight and the radius of gyration increased rapidly above a certain mixing ratio of dendrimer to NaPGA. The numerical analysis supported the aggregation model that free dendrimers are in equilibrium with dendrimers bound to NaPGA. Dendrimer-NaPGA complexes make aggregates in solution through the junction of dendrimer, and the aggregates consist of i-mer of dendrimer-NaPGA complexes, as shown in Figure 3(c). The aggregates take globular structure with a larger size than that of a single NaPGA without bound dendrimers.

The interesting aspect is the different complexiations of dendrimers with different linear polyelectrolytes such as DNA, NaHA, and NaPGA chains. They depend on the chemical and morphological structures of linear polyelectrolytes. The persistence lengths of the polyelectrolyte chains decrease in the order of rather rigid DNA > semiflexible NaHA > randomly coiled NaPGA. The common is the electrostatic interaction of charged dendrimers with oppositely charged polyelectrolytes. Additionally, amide or hydroxyl groups in hyaluronate make hydrogen bonding with amide groups in PAMAM dendrimer, and, as a result, many dendrimers are attracted on a NaHA chain, where the steric and electrostatic repulsions between bound guest polyelectrolytes stretch the host polyelectrolyte chain. On the other hand, dendrimers act as a junction connecting between NaPGA chains, and the dendrimer-NaPGA complexes change from "intramolecular" (several guest polyelectrolytes attached to a single host polyelectrolyte) to "intermolecular" (containing more than one host polyelectrolyte), as found in mixtures of polyelectrolytes and surfactant micelles [52]. In the case of DNA, the morphology of complexes with dendrimers is complicated. It seems that the aggregation of complexes occurs simultaneously with the isolated DNA toroid formation including dendrimers and the aggregate sizes are not controlled.

Welch and Muthukumar [53] have examined by the computer simulation based on the theoretical background, the equilibrium and dynamic complexation behavior of monocentric dendrimer with charged terminal groups to a flexible, oppositely charged polyelectrolyte. They noted three different types of complexes depending upon the ionic strength of solution, the size of the dendrimer, and the length of polymer chain. In three complexes, a dendrimer encapsulates a flexible polyelectrolyte chain, mutually interpenetrates with it, or walks along it. Chodanowski and Stoll [50, 51] have also proposed, as computer-simulated results, the pictures of aggregates of charged dendrimers with oppositely charged polyelectrolytes and the conditions necessary for forming aggregates, such as chain rigidity. Three types of complexes depend upon the ionic strength of solution and the size of the dendrimer or polymer chain, being similar to the results by Welch and Muthukumar [53]. However, both groups did not attach importance to the aggregation of complexes.

We have focused on "intermolecular" dendrimer-NaPGA complexiation. The small-angle X-ray scattering (SAXS) intensity $I(Q)$ at a scattering vector Q for particle solutions is contributed by the number of density particles, the intraparticle form factor depending on the particle geometry, and the interparticle structure factor that is related to the interparticle interactions [20, 54–57]. Figure 4(a) shows SAXS profiles of aqueous 0.25 M NaCl solutions of fourth generation amine-terminated PAMAM dendrimer and its mixture with NaPGA. There is the difference between two $I(Q)$ curves, and both have a peak at $Q = 0.055$ or 0.07 A^{-1}. Moreover, SAXS intensities of PAMAM dendrimer decreased with the addition of NaPGA, indicating the interaction between dendrimers and NaPGAs. The complexiation and the aggregation between dendrimer and NaPGA were also supported from dynamic light scattering. Main hydrodynamic diameter (149.4 nm) for a solution of dendrimer-NaPGA mixture was larger than those of free dendrimer (6.2 nm) and free NaPGA.

Normalized intermediate correlation function $I(Q,t)/I(Q,0)$ at a time t from neutron spin echo (NSE) for particle dynamics, which is contributed by two diffusion modes, is described by a double-decaying exponential function [57–60]. As seen in Figure 4(b), the experimental data for a 0.25 M NaCl solution of fourth generation amine-terminated PAMAM dendrimer-NaPGA complex is described by a double-decaying exponential function, although the contribution of the fast mode is small (3–9%) the same as in a case of free dendrimer [60]. This mode may originate in the deformation motion of dendrimer [57]. The major effective diffusion coefficient, that is, the coefficient of the slow mode ($6{\sim}8 \times 10^{-11}$ m^2s^{-1}), is comparable to the hydrodynamic translational diffusion coefficient ($2{\sim}3 \times 10^{-11}$ m^2s^{-1}) of the complex obtained from dynamic light scattering. This indicates the translational motion of dendrimers is not disturbed by the complexation.
Figure 4. (a) Small-angle X-ray scattering intensities $I(Q)$ as a function of scattering vector Q for aqueous 0.25 M NaCl solutions of fourth generation amine-terminated PAMAM dendrimer (□) and fourth generation amine-terminated PAMAM dendrimer-sodium poly(L-glutamate) mixture (■). Dendrimer and poly(L-glutamate) concentrations are 5 and 0.1 wt%, respectively, and then a number ratio of amine terminal groups of dendrimer against side chains of sodium poly(L-glutamate) is 34.6. (b) Normalized intermediate scattering functions $I(Q, t)/I(Q, 0)$ as a function of time t for a 0.25 M NaCl solution of fourth generation amine-terminated PAMAM dendrimer-sodium poly(L-glutamate) mixture. Q (Å^{-1}); △, 0.06: ■, 0.08: ○, 0.1. Solid lines are theoretical ones with a decaying exponential function.

Interpolyelectrolyte complex formation between fourth generation amine-terminated PAMAM dendrimer and NaPGA in aqueous 0.25 M NaCl solution has been studied as a function of pH by Leisner and Imae [61]. Coacervation was observed at pH ~9 and it increased slightly with the dendrimer excess. Three relaxation modes were revealed from dynamic light scattering. The relaxation times of the faster modes are attributed to the hydrodynamic translational diffusions of dendrimer and of the interpolyelectrolyte complex. An additional slow mode dominates the multiexponential dynamic structure factor of the solution of interpolyelectrolyte complex network or the micro-gel inhomogeneity fluctuation. This mode is also associated with a sharp increase of the radius of gyration of mesoscopic particles from ~50 to ~250 nm.

4. ADSORPTION AND SELF-ORGANIZATION AT INTERFACES

4.1. Two-Dimensional Array in Bulk

One of novel utilizations of dendrimers is the construction of self-assemblies and supramolecular assemblies as building blocks, being valuable for the fabrication of higher ordered architectures. The structures of dendritic groups were discussed in relation to their self-assemblies and the liquid crystal formation was predicted [62]. Persec et al. [63, 64] have reported thermotropic nematic liquid crystal formation by dendritic polyethers. Poly(phenylenevinylene)s substituted with dendritic side chains also yielded thermotropic nematic liquid crystals [65]. Hudson et al. [66, 67] have found that flat, tapered, and conical monodendrons, respectively, self-assemble in hexagonal columnar and cubic thermotropic liquid crystal phases with high uniformity. The functionalization of poly(propylene imine) dendrimers with cholesteryl moieties through a carbamate linkage resulted in the formation of smectic A phases at a broad thermal range [68]. A series of polynorbornenes containing second-generation monodendrons as side chain have been synthesized [69]. Although the mesogens are rodlike, the polymers are conformationally flexible overall and displayed liquid-crystal behavior—during cooling, a nematic, smectic, and hexatic phase were observed.

In the cases described above, dendritic polymers with unique structures form the liquid crystals. Now it is assumed that the formation of anisotropically ordered architecture of dendrimers without unique structures is possible, once templates like liquid crystals are used. The lamellar liquid crystal of the cationic surfactant, didodecyldimethylammonium bromide (DDAB) in water, was selected as a template of two-dimensional architecture of anionic PAMAM dendrimers possessing carboxylate terminal groups [70]. The incorporation of dendrimers into the lamellar liquid crystal, at DDAB concentrations in the range of 4–30 wt %, resulted in the transition from a monophasic lamellar structure (L_α) to biphasic lamellar mixtures (L_α and L_α^D), at a similar molar mixing ratio for two dendrimers of 2.5 and 4.5 generations, as illustrated in Figure 5. The anionic dendrimer molecules doped into the water domains stick to the DDAB bilayers in the L_α structure, due to the stronger electrostatic interaction between the cationic surfactants and the oppositely charged dendrimers. In the narrow-spaced L_α^D structure, monolayers of flattened dendrimers are adsorbed between the DDAB bilayers, since the thicknesses of the dendrimer monolayers are smaller than the diameters of the corresponding dendrimers in aqueous solutions.

The investigations on the binding interactions and aggregation processes between dendrimers and surfactants have been carried out at low surfactant concentrations. Those are concerned with the supramolecular assemblies of surfactants with dendrimers [71–74], the dendrimer adsorption onto micelle surface [75, 76], and the structural modification of vesicles upon the interaction with dendrimers [77, 78]. The supramolecular assemblies are constructed by the primary noncooperative binding of monomeric surfactants and the secondary cooperative binding of micelle-like surfactants
Figure 5. Schematic models of the lamellar L_α structure (left) and the lamellar L_α^D structure (right) in mixtures of didodecyldimethylammonium bromide, anionic PAMAM dendrimer, and water. in/on dendrimer [71, 73]. Conversely, the reports at high surfactant concentrations are very few [79, 80]. Friberg et al. [79] have reported the formation of lamellar liquid crystal by octanoic acid and poly(ethylene imine) dendrimer. A third-generation dendrimer served as a solvent in the liquid crystal, and surfactants ionized and formed ionic pairs with amine terminals of dendrimer. Baars et al. [80] have investigated the scattering on the addition of dendrimers to continuous liquid crystals, but did not refer the morphology of hybrid liquid crystal structures.

4.2. Adlayers

Organization of dendrimers can be attained by the construction of one-, two-, and three-dimensional architectures. Especially, two-dimensional ordering is readily formed at air-liquid, air-solid, solid-liquid, and liquid-liquid interfaces. It is well known that traditional low-molecular-weight surfactants consist of hydrophilic head and lipophilic tail moieties and are characterized as typical amphiphilic molecules owing to their surface activity and association behavior. These kinds of molecules are suitable materials for the organization at the interface. On the process of the stepwise synthesis of dendrimers, central core, spacer, branch, and terminal group can be modified, and a variety of functional moieties or blocks are conjugated in dendrimers. Then, amphiphilic (hydrophilic and hydrophobic) characters can be introduced in dendrimers [81].

Linear polymer-dendrimer hybrids with unique head-tail structure have been synthesized [82–91]. Such copolymers with novel chemical structure possess specific characteristics such as amphiphilicity besides intrinsic dendritic and polymeric characters. They are surface active and arranged as a monolayer at the air-water interface. Amphiphilic dendrimers with a spherical shape have also been synthesized. Core-shell block dendrimers have different amphiphilicity at interior concentric generation layers and exterior generation layers [92–96]. Surface-block dendrimers have a character that the amphiphilicity of two hemispherical parts in dendrimers is different [82, 97–102]. That is, amphiphilic surface-block dendrimers consist of surface blocks with different affinities for solvents, where one is hydrophilic and the other is hydrophobic. Such structural character is dominant not only to associate into micelles, vesicles, microemulsions, liquid crystals, and other self-assemblies but also to adsorb at interfaces. Recently, Imae [81] has reviewed the association behavior of amphiphilic dendritic polymers.

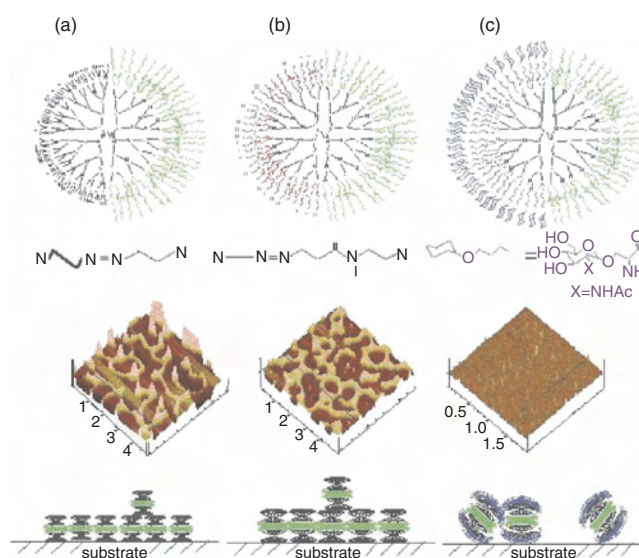
Two dimensionally organized systems of amphiphilic dendrimers are prepared as Langmuir or Gibbs monolayer at an air-water interface and adsorption layer or self-assembled monolayer on solid substrate. Gibbs monolayer formation of amphiphilic dendrimers has been investigated for third and fourth generation amphiphilic surface-block dendrimers with amine and n-hexyl terminals (amine/hexyl), hydroxyl and n-hexyl terminals (hydroxyl/hexyl) and N-acetyl-D-glucosamine and n-hexyl terminals (glucosamine/hexyl) at the air-water interface [81, 99]. The organized adlayer formation and adsorption kinetics have been reported for the same dendrimers on the liquid-solid interfaces [101, 102]. The amine/hexyl and hydroxyl/hexyl dendrimers formed bilayers and their accumulation, owing to their amphiphilic character, which were different from the disordered adsorption of symmetric PAMAM dendrimer, as seen in Figure 6. Dendrimers in the bilayer form the flattened "pancake" structure by pairing between hydrophobic surface blocks. The hydrophilic terminals face to the solution and the solid substrate, since the adsorption film surface is hydrophilic. On the other hand, the adlayer of the glucosamine/hexyl dendrimers was rather flat. The time dependence of the adlayer formation was monitored *in-situ*. It proceeded through fast and slow adsorption steps. The adsorbed amount at the equilibrium decreased in the order of hydroxyl/hexyl > amine/hexyl > glucosamine/hexyl dendrimers and increased linearly with dendrimer concentration. The adsorption was abundant for the third


Figure 6. Adlayer formation by amphiphilic surface-block dendrimers on solid substrates. Reprinted with permission from [102], M. Ito et al., *Langmuir* 18, 9757 (2002). © 2002, American Chemical Society. (Top) chemical structure; (middle) atomic force microscopic image; (bottom) Adlayer model. (a) Fourth generation amine/hexyl PAMAM dendrimer; (b) fourth generation hydroxyl/hexyl PAMAM dendrimer; (c) fourth generation glucosamine/hexyl PAMAM dendrimer.

generation dendrimer in comparison to the fourth generation dendrimer and proceeded more for surface-block dendrimers than for PAMAM dendrimer in relation to the hydrophilicity-hydrophobicity balance of dendrimers. The molecular orientation of the hexyl chains in the adlayers was in the order of amine/hexyl > hydroxyl/hexyl > glucosamine/hexyl dendrimers.

Functional dendrimers of symmetrically branched structure are also focused as building blocks of the architectures such as thin adlayer films on solid substrates. Watanabe and Regen [103] have reported multilayer construction by PAMAM dendrimers on solid substrate. Adsorption and aggregation of carbosilane dendrimers and their hydroxyl- or mesogen substitutes on mica and pyrolytic graphite have been investigated by Sheiko et al. [104, 105] and Coen et al. [106]. Bar et al. [107] have prepared dendrimer-modified silicon oxide surfaces and used them as a platform for the deposition of gold and silver colloid monolayers. The thermodynamics and kinetics of adsorption of redox-active dendrimers, containing ferrocenyl moieties on the periphery, have been studied on a Pt electrode surface [108]. Adsorption isotherm depended on the applied potential. At the potential where the ferrocenyl sites are in the reduced form, the adsorption thermodynamics were characterized by the Langmuir adsorption isotherm. When the ferrocenyl sites are oxidized, the electrodeposition of a multilayer of the dendrimer took place. Focally substituted organothiol dendrons were used to construct self-assembled adlayers on a gold surface [109]. As the number of hyperbranches in the dendron increases, the dendron adlayers become more permeable, indicating a tradeoff between size and the packing efficiency. This research suggests the formation of homogeneous but permeable dendron adlayers on the gold surface. Díaz et al. [110] have reported the interfacial reaction of the terpyridyl-pendant dendrimers with Fe^{2+} and Co^{2+} on highly oriented pyrolytic graphite surfaces. The films form highly ordered, two-dimensional hexagonal arrays, which appear to be composed of one-dimensional polymeric strands. The dimensions obtained are consistent with the size of the dendrimer. The ordering in the dendrimer film is dependent on the dendrimer generation. The films are electrochemically active. Sabapathy and Crooks [111] have prepared a hydroxyl-terminated monolayer from fourth generation PAMAM dendrimer and reacted it with heptanoyl chloride to yield ester-coupled bilayers. The interfacial reactivity was discussed in relation to the monolayer structure and the intrinsic properties of the particular coupling reaction studied. The lateral organization of alkyl-substituted polyphenylene dendrimers on the basal plane of graphite has been investigated by Loi et al. [112]. The dendrimers consist of a core of twisted, interlocked benzene rings and an external shell of dodecyl chains. While three kinds of dendrimers show a tetrahedral or a disk-like shape in solution, the dendrimers on graphite spontaneously form a stable, almost pinhole-free monolayer. Complex two-dimensional arrangements and supramolecular ordering were observed in the monolayers prepared by spin-coating. One prominent structure is regions of parallel rows of 6 nm spacing. In addition, pairs of dendrimers formed two-dimensional crystals on graphite. The crystal structure depends sensitively on the structure of the dendrimer, on the solvent, and on the

concentration. The interfacial behavior of third and fourth generations of hyperbranched polyesters with hydroxyl-terminal groups was studied by Sidorenko et al. [113]. The molecular adsorption on a bare silicon surface was described in terms of the Langmuir isotherm. A higher adsorption amount was found for a lower generation. The shape of a third generation dendrimer within an adsorbed layer evolved from a pancake within a thickness less than 1 nm for very low surface coverage to densely packed, worm-like bilayer structure with a thickness of about 3 nm for the highest surface coverage. The fourth generation molecules hold a stable close-to-spherical shape with a diameter of 2.5 nm throughout the entire range of surface coverage. The intermolecular flexibility or constrained mobility of dendrimers was considered to be responsible for different surface behavior.

Recently, the morphology of aggregates of dendrimers on the solid substrate was investigated. Sato et al. [114] have reported that dendrimers aggregate in a form of nanometer-sized round dots over an area measured in centimeters on rapid evaporation of a solvent from a thin cast film of an electrolyte solution of poly(amido amine) dendrimers on mica. Chemically specific adsorption, electrostatic interactions, phase transitions, and dewetting instabilities were shown not to be responsible for the dot formation. Changes in temperature and humidity have only little effect. There is a threshold evaporation rate for the formation of dots. Once formed, the dot size and spacing are independent of the evaporation rate. The self-assembly of monodendrons with peripherally attached alkyl substituents has been studied by scanning tunneling microscopy (STM) [115]. The disk-like assembly, a characteristic structure of low-generation dendrimers, was directly observed. The subunits of disk structure can be well resolved as well as the ordered alkyl parts. Xiao et al. [116] have reported organosilane thin films derived on mica surfaces from $SiCl_3$-terminated carbosilane dendrons by means of spin-coating. The morphology of the films was highly dependent upon the generation of the dendrons and the film thickness—mesoscopic ring, disk, or hole structures were observed. These structures were composed of nanoparticles with sizes corresponding to one dendron molecule or the cluster of a few laterally bound molecules. At submonolayer coverage, the molecules tended to flatten and spread out on mica surfaces. The mechanisms for the formation of the observed film morphology were discussed, based on the structure and properties of the dendrons and the effect of the evaporation process.

4.3. Self-Assembled Monolayers

The organized self-assembled monolayers (SAM) of dendrimers were prepared by using a template SAM on substrate. Amine-terminated PAMAM dendrimers were covalent-linked with organized, surface-confined, self-assembled monolayers of mercaptoundecanoic acid [117]. Yoon et al. [118] have also prepared same dendrimer monolayer on acid SAM on gold and then functionalized the dendritic surface amine groups with biotin analogues or desthiobiotin amidocaproate. For testing the association/dissociation reaction cycles at the affinity surface, avidine adlayer was formed onto the biotin analogue-functionalized surface and displaced with free biotin. With

the optimized affinity-surface construction steps and reaction conditions, continuous association/dissociation reaction cycles were achieved, resulting in a repeatedly regenerable affinity-sensing surface. Ionized, carboxylate-terminated polyphenylene dendrimer molecules were adsorbed on a carboxylic acid group-terminated, self-assembled monolayer on a gold substrate through the linkage with Cu^{2+} ions [119]. The strong interaction between dendrimer and Cu^{2+} ions, the latter of which is preadsorbed on the COOH SAM, led to a compression or deformation of the SAM and resulted in a decreased height of the dendrimer ions. Fail et al. [120] have immobilized amine-terminated PAMAM dendrimers onto anhydride-functionalized pulsed plasma polymer surfaces via amide linkage formation. The PAMAM dendrimer layers were useful for a variety of surface-related phenomena of fluorination, adhesion, and gas barrier enhancement.

Nagaoka and Imae [121] have reported adsorption structure of amine-terminated PAMAM dendrimer onto 3-mercaptopropionic acid (MPA) SAM on Au island film. The carboxylic acid species of SAM diminished, as the adsorption of PAMAM dendrimer from an aqueous solution proceeded. This indicates that the protonated, amine terminal groups of the dendrimer bind electrostatically to carboxylate groups of SAM. The flattened molecular structure or the imperfect covering of the adsorbed dendrimers was assumed. The dome-shaped, "spread out" configuration of PAMAM dendrimers on substrate has been visually observed by Li et al. [122].

Adsorption kinetics of fourth generation amine-terminated PAMAM and PPI dendrimers from aqueous solutions has been investigated on MPA SAM on Au film [123]. The adsorption kinetics at high dendrimer concentrations obeyed two-step adsorption process [124] but not Langmuir adsorption isotherm. Then, monolayer and additional adsorptions of dendrimers must occur on MPA SAM. There is a difference on the adsorption structure between two dendrimers, as seen in Figure 7. PAMAM dendrimer adsorbs with "the hemi-micellar structure," as illustrated in Figure 7(a), because amine and amido groups of PAMAM dendrimer interact electrostatically and through hydrogen bonding with carboxylate of MPA SAM. The adsorption

Figure 7. Adsorption models of PAMAM and PPI dendrimers on MPA SAM. Reprinted with permission from [123], H. Nagaoka and T. Imae, *Int. J. Nonlinear Sci. Numer. Simu.* 3, 233 (2002). © 2002, Freund Publishing House Ltd.

structure of PPI dendrimer is "the hour glass type" or "the conical type" (see Fig. 7(b) and (c)), since there is no hydrogen-bonding interaction between dendrimer interior and MPA SAM.

In the case of PAMAM dendrimers, surface-functionalized with ruthenium (II), the adsorption thermodynamics of this redox-active metallodendrimers onto Pt electrodes was well characterized by the Langmuir adsorption isotherm [125]. The adsorption kinetics was found to be activation-controlled with the rate-constant decreasing with decreasing dendrimer generation. The rate of adsorption of positively charged poly(propylene imine) dendrimers on glass, an oppositely charged surface, has been studied as a function of generation and charge [126, 127]. The adsorption kinetics was mostly diffusion/convection-controlled with a linear dependence on the bulk concentration. At high bulk concentration, there is a drop in concentration dependence, and this crossover concentration shifts to higher concentrations with decreasing pH. Bahman et al. [128] have studied *in-situ* adsorption of PAMAM dendrimers from dilute solutions onto cleaned gold. In ethanol, the equilibrium surface coverage corresponds to almost monolayer and increases slightly with generation. The adsorption is likely driven by the weak favorable interaction between the primary amine end groups on PAMAM dendrimer and gold. In aqueous media, under the conditions where the PAMAM amine end groups tend to protonate and bear positive charge, the equilibrium surface coverage grows exponentially with generation, indicating the multilayer formation. The formation of multilayers can be explained by a favorable electrostatic image-charge interaction between the positively charged dendrimers and the gold substrate. At the seventh generation, there was a manifestation of "dense-shell" packing, which lowers the effective charge on the higher generation dendrimers.

Stable ultra-thin self-assembled films were prepared by dendron thiol. Zhang and his collaborators [129, 130] have synthesized polyether dendron with a thiol group at the focal point and used it for the preparation of self-assembled monolayers on metal surface. The dendron SAM covered the gold surface homogeneously and consisted of the ordered stripes by the packing of two flat-cone shaped dendrons. The patterned stripes can be improved by thermal annealing. From the studies of the kinetic process of dendron thiol self-assembling on gold, it was shown that the dendron thiol assembling proceeds with different adsorption rates depending on the assembly time [130]. They have also fabricated ultra-thin organic films via dendritic growth on modified gold, silicon, and quartz substrates [131].

4.4. Composite Films

Investigation was extended to the preparation of composite self-assembled monolayers including dendrimer primarily by Crooks et al. [132–136]. PAMAM dendrimers were surface-immobilized in thiol, self-assembled monolayers by means of two different methods [132], which are the preparation of chemically sensitive dendrimer surfaces as a vapor-phase dosing probe. Zhao et al. [133] have embedded surface-confined dendrimers within self-assembled monolayers of alkane thiol. These films act as ion gates of molecular dimension. The two-dimensional
phase behavior of mixed monolayers composed of amine-terminated PAMAM dendrimers and n-alkylthiols has been studied by Lackowski et al. [134]. Mixed monolayers were prepared by sequential immersion of Au substrates in ethanolic solutions of dendrimers and then n-alkylthiols. Time-dependent morphological changes were observed in the mixed monolayers. Dendrimer monolayers immersed in a hexane solution of n-alkylthiols did not phase-separate to an appreciable extent. Moreover, thiol-terminated dendrimers did not phase-separate either, when exposed to ethanolic n-alkylthiol solutions. It was suggested that one of the driving forces for the phase segregation in the mixed monolayers is the difference in adsorption energies of the amine and thiol groups against the Au substrate. Tokuhisa et al. [135] have reported that exposure of high-generation dendrimer monolayers to ethanoic solutions of hexadecanethiol results in a dramatic compression of the dendrimers and causes them to reorient on the surface from an oblate to prolate configuration without desorb. It was shown that the primary driving force for the structural change is the solvation of the dendrimers. Oh et al. [136] have recently described a strategy for constructing a dendrimer-based electrochemical current rectifier permitting current flow in only one direction. The dendrimer-based rectifying layer was prepared by direct adsorption of ferrocene-functionalized poly(propylene imine) dendrimers onto Au surfaces, followed by adsorption of n-hexadecanethiol. The surface coverage of ferrocenyl dendrimers in the two-component monolayers is estimated to be about 50% of maximum coverage. It was revealed that the ferrocenyl dendrimer/n-alkanethiol-modified electrodes exhibit excellent barrier properties, which prevent direct oxidation/reduction of the solution-phase redox molecules. Electrochemical current rectification occurred via mediated electron transfer across the surface-confined ferrocenyl dendrimers. Friggeri et al. [137] have investigated the insertion process of individual, dendrimer sulfide molecules into self-assembled monolayers of 11-mercapto-1-undecanol. The immersion of thiol self-assembled monolayers in a dendrimer solution of increasing concentrations at longer immersion times leads an increase in the dendrimer number inserted into the thiol layer. A mechanism consists of rapid dissociation of surface thiols and follows slow dendrimer adsorption. The rate-determining step of the process is the insertion of the individual dendrimer molecules. On the dissociation step, first-order kinetics was found for the fraction of covered substrate versus time of exposure to solvent.

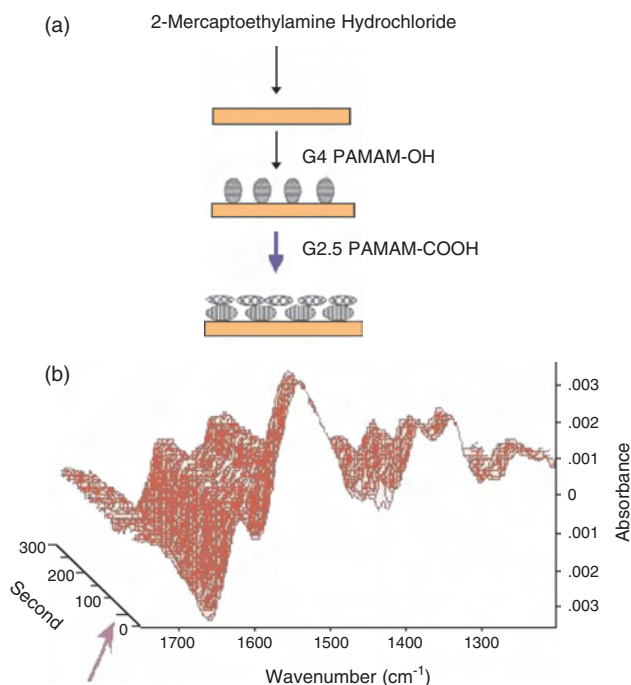
Layer-by-layer composite films were also prepared. Electrostatic layer-by-layer composite deposition films were fabricated by mutual self-assembly of dendritic macromolecules of two adjacent generations [138]. The formation of layer-by-layer composite films on cationic SAM has carried out by the stepwise adsorption of two PAMAM dendrimers among amine-, carboxylate-, and hydroxyl-terminated species, and is compared with the competitive adsorption of the same paired dendrimers in aqueous solutions [139]. There was apparent conformational change of hydroxyl-terminated dendrimers in the first layer by the accumulated adsorption of amine- or carboxyl-terminated dendrimers, as seen in Figure 8. Normal layer-by-layer accumulation was formed in other combinations of two dendrimers in three species.


Figure 8. Stepwise adsorption of carboxylate and hydroxyl-terminated dendrimers on 2-mercaptoethylamine hydrochloride SAM. After the adsorption equilibrium of 4th generation hydroxyl-terminated PAMAM dendrimer was attained, the desorption of adlayer in water was equilibrated. The adlayer after the desorption equilibrium was used for the adsorption of 2.5th generation carboxyl-terminated PAMAM dendrimer. (a) Scheme of the stepwise adsorption; (b) the *in-situ* observation of adsorption of 2.5th generation carboxyl terminated PAMAM dendrimer on the adlayer of 4th generation hydroxyl-terminated PAMAM dendrimer. The absorption bands of amide II and OH bending vibrations on attenuated total reflection surface-enhanced infrared absorption spectroscopy decreased in intensity, after the adsorption of carboxylate terminated dendrimer started.

Wang et al. [140] have constructed a photosensitive, layer-by-layered, self-assembled, ultra-thin film based on polyanionic PAMAM dendrimer (with carboxylate terminals) and polycationic nitrocontaining diazoresin via sequential deposition and subsequent UV irradiation, which causes the linkage between the layers to change from ionic to covalent. PAMAM dendrimer/poly(styrenesulfonate) (PSS) multiplayer films were prepared by an iterative electrostatic self-assembly process, namely, the layer-by-layer deposition of PAMAM dendrimer and PSS onto planar supports [141]. The evidence of multi-player film growth was provided. An adsorption-desorption phenomenon was sensitive to the pH and ionic strength of the PSS and dendrimer solutions, the dendrimer generation and concentration, and the PSS molecular weight and concentration.

5. HYBRIDIZATION AND NANOCOMPOSITE FORMATION WITH METAL NANOPARTICLES

Clusters of metals and semiconductors are focused due to their unique mechanical, electronic, optical, magnetic, and chemical properties. Metal nanoparticles are also investigated because of their novel optical, electrical, catalytic, and

other properties. Homogeneous, self-assembled monolayers or thin films of alkanethiol, N-hexadecylethylenediamine [142], polymer [143, 144], polymerized methyl methacrylate [145], hydrophobically modified dendrimers [146–150] have been used as stabilizers in the synthesis of stable hydrophobic nanoparticles. On the other hand, the synthesis of water-soluble hydrophilic particles is recently required in relation to the environmental pollution. Then, water-soluble dendrimers were focused as valuable materials for the protection of clusters and nanoparticles.

Zhao et al. [151] and Balogh and Tomalia [152] have introduced a template-synthesis strategy for preparing copper nanoclusters within dendrimer nanoreactors. Transition metal ions are condensed into the interior of a fourth generation PAMAM dendrimer and chemically reduced to zerovalent copper. Nanocomposite clusters prepared ranged in size from 4 to 64 atoms [151]. The surface properties of the host dendrimers seem to determine the solubility of the metal domains [152].

Esumi et al. [153] have prepared gold colloids by the reduction of metal salt by means of ultraviolet irradiation in the presence of zero to fifth generation PAMAM dendrimers with amine terminals. The average particle sizes decreased by increasing the concentration of dendrimers, and gold colloids with a diameter less than 1 nm were obtained in the presence of third to fifth generation dendrimers above the molar ratio of amine group of dendrimer: $HAuCl_4 = 4 : 1$. Sugar-persubstituted PAMAM dendrimers (sugar balls) were also used for the spontaneous formation of gold nanoparticles [154]. Au^{3+} ions were reduced by the hydroxyl groups of the sugar balls, resulting in the formation of very stable gold nanoparticles. Garcia et al. [155] have stated that large dendrimers encapsulate the colloids and lower-generation dendrimers give rise to larger colloids. Fourth-generation PAMAM dendrimers having terminals functionalized with thiol groups have been synthesized by Chechik and Crooks [156]. While these thiolated dendrimers formed stable monolayers on planar Au substrates, the reduction of $HAuCl_4$ in the presence of thiol-modified dendrimers resulted in the formation of water-soluble, dendrimer-stabilized nanoparticles with 1.5–2.1 nm in diameter. Stable nanoparticles were obtained at Au/dendrimer ratios as large as 120:1.

Esumi et al. [157] have compared the role of generations (third to fifth generation) and terminal groups (amine and carboxyl) of PAMAM dendrimers for preparing nanoparticles of gold, platinum, and silver. Whereas the size of gold and silver nanoparticles decreased with increasing the concentration and the generation of dendrimers, the size of platinum nanoparticles was insensitive against the concentration as well as the generation. Stable nanoparticles were obtained above unity of the ratio of surface group of dendrimer/metal salt for gold and silver nanoparticles and above 40 for platinum nanoparticles. It was suggested that the metal nanoparticles adsorb on the exteriors of the dendrimers.

Manna et al. [158] have synthesized silver and gold nanospherical particles stabilized by a fourth-generation, amine-terminated PAMAM dendrimer by the reduction of $AgNO_3$ and $NaAuCl_4$. The particle size could be controlled by the metal ion-to-dendrimer mixing ratio. Silver

nanoparticles are always larger than gold nanoparticles, when they are synthesized by the same condition. A short-ranged hexagonal arrangement of particles was observed in a monolayer onto a carbon-coated copper transmission electron microscopic grid. Then, the terminal amine groups of the dendrimers take part in the stabilization of the nanoparticles, and the dendrimers protecting nanoparticles behave as a spacer packed between the ordered arrangements of the nanoparticles.

PAMAM dendrimers with amine terminals possess both internal and external functional groups providing reaction sites for metal ions. Then, it is very important in the application that nanoparticles are either formed in the interior of dendrimers or at the external surface of dendrimers. The previous reports indicated that the hybrid structures of dendrimer-metal nanoparticles depend on the generation, concentration, and terminal group of dendrimers, the type of metals, and the ratio of dendrimers and metals. Gröhn et al. [149, 159, 160] have clarified the influence of reaction conditions and dendrimer generation on the resulting nanostructures of dendrimer-metal hybrid colloids. Second to fourth generation PAMAM dendrimers behave like colloid stabilizers; that is, several dendrimers surround the surface of the metal particle, as shown in Figure 9. On the other hand, sixth to tenth dendrimers act as effective nanotemplates. Then, metal particles are completely formed inside individual dendrimers. Gröhn et al. [160] have prepared hydrophilic polymer networks containing higher generation PAMAM dendrimers, where nanoparticles are located inside. Crooks et al. [161] have used hydroxyl-terminated PAMAM dendrimers for the preparation of metal nanoparticles in the interior of dendrimers, because the dendrimers do not have functional terminal groups as reaction sites for metal ions. They reviewed synthesis and characterization of dendrimer-encapsulated metal nanoparticles and their applications to catalysis. Recently, Ottaviani et al. [162] have achieved the transformation of silver from Ag^+ to Ag^0 in the interior of dendrimer by irradiating the solution of Ag^+-dendrimer complex by means of an excessive dose of X-rays to avoid alternation of the
Figure 9. Transmission electron microscopic (TEM) photographs and models of dendrimer-passivated and dendrimer-encapsulated nanoparticles. TEM: (a) deposition on a carbon-coated cupper grid of 4th generation amine-terminated PAMAM dendrimer-passivated gold nanoparticles prepared at the 1:10 ratio for the Au atom:terminal amine group of dendrimer; (b) dendrimer-encapsulated nanoparticles. structure of the complexes during transformation into nano-composites.

High stability of dendrimers surrounding the surface of the metal particles is indispensable not only in the protection of particles but also in the utilization of particles. We have investigated the exchange of dendrimers on gold nanoparticles by dodecanethiols at various mixing ratios of nanoparticle and dodecanethiol. The wine-red aqueous solution of dendrimer-passivated gold nanoparticles was vigorously shaken with an n-heptane or diethyl ether solution of dodecanethiols, until the exchange equilibrium was reached. When two phases were separated into the upper organic and lower aqueous phases, wine-red color shifted into organic phase. Figure 10(a) shows the absorption spectra of the water and n-heptane phases after the exchange reaction. The plasmon band (around 510 nm) intensity of nanoparticles in the aqueous phase decreased with the exchange and, at the same time, the band intensity in n-haptane phase increased. The intensity variation of the plasmon band as a function of the mixing ratio of dodecanethiol to gold ions is plotted in Figure 10(b). Although the average particle sizes are maintained even after the exchange reaction, the infrared absorption spectroscopic vibration bands of dendrimers exchanged by absorption bands of dodecanethiol.

Although the exchange of dendrimer by dodecanethiol in diethyl ether solution proceeded as well as in n-heptane solution, dendrimer on nanoparticles did not exchange with N-hexadecylethylenediamine in n-heptane solution. On the other hand, N-hexadecylethylenediamine, which was passivated on gold nanoparticles in n-heptane solution, also did not exchange with free dendrimer in water. (N-hexadecylethylenediamine-passivated gold nanoparticles were prepared according to the procedure previously reported for the preparation of silver nanoparticles [142].) The ligand replacement reaction is schematically illustrated in Figure 11. The replacement by the addition of a small amount of dodecanethiol indicates that the interaction of a gold particle surface with amine terminal groups of the dendrimer is weaker than that with thiol. However, the interaction of dendrimer and N-hexadecylethylenediamine on gold nanoparticle surface cannot be discriminated.

In the process of the replacement of dendrimer-passivated nanoparticles by dodecanethiols, gold nanoparticles, surface-confirmed by hybrid self-assembled monolayers, was synthesized in the mixing ratio shadowed in Figure 10(b), where both solutions of water and organic solvent were colored. The formation of the hybrid monolayer is very feasible by the partial replacement of surface-confined dendrimer onto the gold particle surface. The hybrid-layer-passivated nanoparticles separated into domains of small and large spheres [163]. That is, the change of the hydrophilic particle surface to the amphiphilic one induces the segregation into the close-packed monodispersed phases. This indicates that the replacement may be dependent on the particle size. The potentialities of nanoparticles stabilized by hybrid monolayers of fascinating molecules, such as dendritic polymers and surfactants, may be high as well as those of the homogeneous ones. Thus, the hydrophilic/hydrophobic hybrid-layer-protected nanoparticles may stimulate the new development of fundamental surface sciences and new applications of such nanoparticles on chemical sensing, catalysis,

Figure 10. (a) The ultraviolet-visible absorption spectra of hybrid-layer-passivated nanoparticles in water and in n-hexane phases after the ligand replacement reaction at the different ratios of dodecanethiol against Au atom, [dodecanthiol]/[Au^{3+}]. Dendrimer-passivated gold nanoparticles in water and dodecanethiol in n-heptane were shaken until the equilibrium was reached, and the water phase was separated from the n-heptane phase. (b) Plasmon band intensity, as a function of [dodecanthiol]/[Au^{3+}] in water phase (▲) and in n-heptane phase (△) after the ligand replacement reaction. In the shadowed region, solutions of both phases colored.

Figure 11. The schematic presentation of ligand replacement reaction. (a) Dendrimer-passivated gold nanoparticles in water + dodecanethiol in n-heptane or diethyl ether. (b) Dendrimer-passivated gold nanoparticles in water + N-hexadecylethylenediamine in n-heptane and N-hexadecylethylenediamine-passivated gold nanoparticles in n-heptane + dendrimer in water.

coating, etc., different from homogeneous hydrophobic or hydrophilic nanoparticles.

Esumi and Goino [164] have reported the adsorption of PAMAM dendrimer on alumina and silica particles at pH 5. The adsorption of dendrimers with surface ionic groups on oppositely charged particles increased with increasing dendrimer generation. While the earlier generation dendrimers behave as ordinary electrolytes, the later generation dendrimers behave as ionic surfactant or polyelectrolyte for the inorganic particle dispersion. The adsorption amounts of dendrimers with carboxylate terminals were greater than those with amine terminals. Esumi et al. [165, 166] have investigated the simultaneous adsorption of PAMAM dendrimers and anionic surfactants on positively charged alumina particles. There was competitive adsorption between the dendrimers with carboxylate terminal groups and sodium dodecyl sulfate at pH 5 [165]. A preferential adsorption of 5.5th generation over 1.5th generation was also observed in the competitive adsorption with anionic surfactant. The adsorption amount of sugar-persubstituted poly(amido amine) dendrimers, sugar balls, at pH 3.5 changes through a maximum, while the adsorption of anionic surfactant increases with increasing it [166]. The enhancement in the simultaneous adsorption is due to the adsorption of complexes consisting of sugar ball and anionic surfactant. In addition, the dispersion stability of alumina suspensions, which was caused by the adsorption of the sugar ball and anionic surfactant, depends on the zeta potential of alumina. The generation of sugar ball and the kind of anionic surfactant did not significantly influence the adsorption characteristics.

There are very few reports of nanocomposites of dendrimers with nanoparticles except metal nanoparticles. Naka et al. [167] have carried out the crystallization of $CaCO_3$ in the presence of PAMAM dendrimer containing carboxylate groups at the external surface. Spherical vaterite crystals were formed, different from the formation of rhombohedral calcite crystals in the absence of additives. CdS in PAMAM dendrimer solutions precipitated as aggregates composed of dendrimer-stabilized nanoclusters with long-term optical stability [168]. Kinetics for the growth of aggregates was discussed—temperature and reactant concentration are dominant variables controlling the aggregation kinetics.

6. CONCLUSIONS

Applications of dendrimers, in connection with the novel characters of dendrimers, are considered in the field of not only industry but also life science. Concerning the doping ability, one of the potentials for the use of PAMAM dendrimers, which are adaptable to native bodies, is biomedical application as magnetic resonance imaging (MRI) contrast agents and drug delivery for diagnoses [5, 7]. Recently, the potentials of water-soluble dendritic unimolecular micelles as drug delivery agents were explored using a model drug—indomethacin [169]. Entrapment of indomethacin in the dendritic micelles was achieved at 11 wt % loading content, and preliminary *in-vitro* release tests showed that sustained release characteristics were achieved. This study supports the possible application of dendritic unimolecular micelles with a hydrophobic core and a hydrophilic shell in drug

delivery and suggests the necessary construction of dendrimers with possible structures to optimize chemical, physical, and pharmacological properties.

For the complexation of PAMAM dendrimers with DNA, which is a mimicry of nucleohistone, the utilization as gene deliverer or vector is examined. Moreover, the complexiation ability of ionic dendrimers with polyelectrolytes may be relevant for applications in polymer separation and viscosity control. The extension of complexiation investigation of dendrimers with linear polyelectrolytes is the formation of gels and networks using dendrimers as building blocks. Amphiphilic hydrogels with highly shaped persistent cross-link junctions were synthesized using linear blocks and perfectly branched (dendritic) macromolecules [170]. The swelling of the gels formed is affected by the relative content of linear polymer, the polarity of the medium, and the temperature. In the preparation of the hydrogels, the influence of various factors on the degree of crystallinity and phase segregation must be considered. Covalently cross-linked, three-dimensional nano-domained networks were prepared from radially layered poly(amido amine-organosilicon) copolymers containing hydrophilic PAMAM dendrimer interiors and reactive organosilicon exteriors [171]. Sizes and shapes of the nanoscopic domains can be controlled by the selection of dendrimer network precursors and by conditions applied to the network conformation.

Architectures of dendrimers designed at the molecular level on interfaces are developed for the purpose of manifold applications such as molecular, chemical, biomimetic, electronic, photochromic, and pH-sensitive sensors or devices. Then, the dendrimer molecules that produce stable, functional, and select interfacial architectures as nanoreactors and nanoreservoirs are exploited as many nanoscopic smart materials or their building blocks, including molecular deliveries, segregations, reaction catalysts, transport agents, and molecular recognitions. The sensitive and selective sensor layers were prepared from polyphenylene dendrimers and used to monitor the concentration of various organic compounds in different environments [172]. The homogeneous, rigid layers of polyphenylene dendrimers allowed the selective detection with high sensitivity and accuracy of polar aromatic target molecules. This is comparable to the benzamido-terminated PAMAM dendrimer-type gas sensor [132]. This sensor probed volatile, organic molecules of heptane, carbon tetrachloride, trichloroethylene, benzene, and 1-butanol. These types of sensors should be of increasing significance in environmental science. The difference of microcavities between two dendrimers was elucidated using solvatochromic probe, phenol blue [173]. Fluorescence sensing a 2.5th generation PAMAM dendrimer with a naphthalene core unit was prepared, and its potential use as a pH sensor material was examined [174]. It displayed sensitive fluorescence signal amplification towards tetrafluoroacetic acid in comparison to acetic acid. It is then demonstrated that the effects of chemical structural differences of dendrimers are essential as selective sensing probe for different target molecules, and the design and synthesis of more elaborate dendrimers are a fascinating challenge for fabricating the best sensors.

Recently, the preparation of patterned thin films including dendrimers was reported [175–178]. The soft lithographic technique, microcontact-printing method, was used to transfer patterned thin films to surfaces with submicrometer resolution [175]. The fourth-generation amine-terminated PAMAM dendrimers were used as the "ink" molecules. Stable multilayer structures up to roughly 60 nm in height were prepared from dendrimer solutions of high concentrations. The deposition of gold-containing dendrimers on stripe-patterned self-assembled monolayer substrates was studied using the microcontact printing method [176]. The atomic force microscopic (AFM) image showed that the PAMAM dendrimers are selectively deposited on hydrophilic –COOH stripes of the patterned substrates but not on the hydrophobic –CH_3 stripes. Arbitrary submicrometer patterns of cobalt were fabricated on a nonconducting surface with wet chemical and microcontact printing methods [177]. A hydroxyl-terminated dendrimer was transferred from a stamp to the surface. The guests, palladium ions, adsorbed into the dendrimer layer as host and acted as nucleation centers for electroless cobalt plating. Patterned dendrimer/gold nanoparticles, immobilized on polymeric substrates, were prepared by masking a patterning method [178]. Polymer substrate, such as poly(dimethylsiloxane) or poly(ethyleneterephthalate) film, was plasma-treated with maleic anhydride. The resulting succinic anhydride groups on the surface were reacted with amine groups of PAMAM dendrimers containing gold salts. The film was irradiated with ultraviolet light through a photomask. The gold particles were well patterned on the surface of the polymer film.

New families of nanocomposite clusters and particles were synthesized. Nanoscale super clusters, assembled around a dendritic core, were synthesized and characterized as quantum dots [179]. Compounds were prepared by binding cluster units $[Ru_5C(CO)_{12}]$ or $[Au_2Ru_6C(CO)_{16}]$ to third-generation dendrimers. Those show a molecular multi-layer structure, which is viewed as a sphere consisting of a non-conducting dendritic core with a sheath of conducting metal clusters over the surface and, in turn, being covered by an additional outer layer of insulating carboxyl ligands. Their properties suggest that they may be of use in a gas delivery/storage system switched thermally or electrochemically, delivering metal particles of precise nuclearity for nanoelctronics and catalysis. Polymerization of styrene in aqueous dispersions of sodium dodecyl sulfate and PPI dendrimer with initiation by potassium persulfide at 80 °C produced latexes [180]. Microscopic observation showed independent particles with diameters of 26–64 nm and small clusters.

GLOSSARY

Dendrimer Spherical polymer prepared by covalent-bonding from a functional core through the successive repeating synthesis of a spacer and a branching part.

Deoxyribonucleic acid (DNA) A biopolymer consisting of two polynucleotide chains with the sugar-phosphate backbones. Two chains forming right-handed helices run in opposite direction.

Lamellar layer One type of lyotropic liquid crystals constructed by surfactant molecules. Molecules are associated into accumulates of bilayers with hydrophobic and hydrophilic spaces.

Linear polymer Molecule with high-molecular-weight which was prepared by the polymerization of bifunctional monomers.

Self-assembled monolayer Monolayer formed by the interaction (covalent bond) of adsorbed molecules with the substrate.

Sodium hyarulonate Native polysaccharide of the glucos-amminoglycan family, which is composed of alternating units of D-glucuronic acid and N-acetyl-D-glucosamine.

Sodium poly-L-glutamate Polypeptide composed of L-glutamic acid which is one of components of protein. It takes structures of α-helix, β-form and random coil, depending on the condition.

GaAs-Based Nanodevices

Eric Donkor

University of Connecticut, Storrs, Connecticut, USA

CONTENTS

1. INTRODUCTION

Gallium arsenide (GaAs) nanodevices are fabricated by growing ultra-thin heteroepitaxial layers of binary, tertiary, quanternary, or quinary III-V semiconductor alloys, having different energy bandgap, on a GaAs semi-insulating substrate such that one or more of the device feature sizes are comparable with the De Broglie wavelength of carriers in GaAs [1]. As a result, the carriers may be spatially confined into two-, one-, or zero-dimensions giving rise to quantum-well, quantum-wire, and quantum-dot nanodevices. In GaAs quantum-well nanodevices, the carriers are spatially confined into a two-dimensional (2D) space, GaAs quantum-wire nanodevices confine carriers into a one-dimensional (1D) space, and GaAs quantum-dot nanodevices confine carriers into a zero-dimensional (0D) space.

Quantum-well device technology is well established and practical devices have been reported in which the carriers were confined into single-quantum wells (SQWs), double-quantum wells (DQWs), multiple-quantum wells (MQWs), or superlattices (SLs). GaAs quantum-wire and quantum-dot nanodevices are new with fewer practical devices reported to date. Their fabrication is much more challenging since even small fluctuations in feature size or inhomogeneity of the constituents could suppress or destroy the low-dimensional confinement effects that are critical to the device operation.

Progress in GaAs nanodevice development has closely been linked to advances in thin film, or epitaxial growth of GaAs-based semiconductor materials. Epitaxial growth is a process of growing an epi-layer on a crystalline substrate layer. The epi- and substrate layers may be similar or dissimilar materials, resulting in homoepitaxy or heteroepitaxy growth, respectively. In epitaxial growth, it is crucial that the heterojunction be free of interface defects, since such defects render the structure unsuitable for device application. It is easier to achieve this condition with a heterosystem in which the lattice constants of the various epilayers are closely matched. The AlGaAs/GaAs system was the first lattice-matched heterostructure system to be widely grown and used for device applications ranging from tunnel diodes to laser diodes. Continued improvements in epitaxial growth techniques, such as molecular-beam epitaxy, metal-organic, chemical-vapor deposition, and chemical-beam epitaxy have enabled device quality growth of lattice-mismatched heterostructures as well.

Molecular beam epitaxy (MBE) is one of the most common processes for fabricating nanostructures. It can be employed to grow thin films with thicknesses from microns to atomic layer sizes. It has ultra-high vacuum (UHV) multiple chambers for growth, loading, preparation, and *in-situ* analysis. The growth chamber, usually of 450-mm inner diameter, holds a removable source flange, which provides support for effusion or *Knudsen* cells, their shutters, and liquid nitrogen (LN_2) shroud. Constituents of the growth material are evaporated, as atomic beams, from a solid source placed in the Knudsen cells. The cells are oriented such that their beams converge on the substrate in the growth position. The beam sources are thermally isolated from each other by an LN_2-cooled radial vane baffle, which prevents chemical cross-contamination. A second cryopanel surrounds the substrate whose purpose is to reduce contamination due to outgassing of the chamber walls. The sample preparation and loading chamber is connected to the growth chamber via large diameter channels and isolation valves. The analytical chamber allows for *in-situ* and after-growth

surface analysis without exposing the sample to outside environments. The substrate surface must be prepared prior to epitaxial growth. Preparation of the surface entails preloading chemical treatment, as well as *in-situ* cleaning processes. The goal of the preloading chemical treatment is to provide either a clean chemical oxide layer of a few Armstrong thick on the GaAs substrate surface or hydrogen passivation of the GaAs surface. Next, the substrate is loaded into the airlock high-vacuum growth chamber. The pressure of the growth chamber is typically 10^{-9} Torr.

Metal-organic chemical-vapor deposition (MOCVD) is another common process for the growth of GaAs nanostructures. The layers are grown by transporting different precursors or reactants in the vapor phase, under controlled pressure, into a reactor (vertical, horizontal, or barrel) chamber that holds the semi-insulating GaAs substrate. Alkyls of the group III metals and hydrides of the group V elements are typical precursors. The metal-organic sources are contained in stainless steel cylinders equipped with a temperature-controlled bath capable of temperature control over a wide range about $-20°$ to $100\,°C$ at $\pm 0.01\%$ accuracy. Controlling the temperature precisely regulates the partial pressure of the source. Electronic mass flow controllers control the exact amount of carrier gas flowing through the bubblers, and at the same time maintain a constant vapor pressure of the source. A heating system heats the substrate during growth. The heater can raise the temperature of the substrate to about $1000\,°C$. Heating can be achieved by radio frequency (RF) induction heating, radiative heating, and resistance heating. Radio frequency heating is common in large commercial systems. In this type of heating, the substrate susceptor is inductively coupled to the RF coil. In radiative heating, the heat energy from a resistance element is transformed into radiant energy. The susceptor absorbs the radiant energy and converts it back to heat energy. In the resistance heating method, current flows through an electrically conductive layer mounted to the susceptor to generate the required heat energy. Safety precautions include gas leak detectors for the carrier gas, the purifier, and toxic gases. Commercial MOCVD are computer controlled, and can be used for defining the growth process and for monitoring reactor conditions.

Nanodevices can be classified according to a) device structure, b) mode of operation, and c) circuit functionality. When described according to device, structure nanodevices are classified into quantum-wells, quantum-wires, and quantum-dots. Quantum-well nanodevices may be divided further into SQW, DQW, MQW, and SL. Quantum-wire and quantum-dot nanodevices may also be subdivided based upon the mode of carrier confinement, namely, mechanical confinement (strain, selective growth, and etching effects), electrostatic-field confinement, and self-organized (or self-assembly) devices.

A second method of classification is based on the quantum-mechanical transport phenomena underlying the mode operation of nanodevices. Accordingly, devices are classified into hot-electron and ballistic devices, resonant tunneling devices, quantum-interference, and spin precess devices. A third method classifies nanodevices, based upon their circuit application, into two-terminal diodes, three-terminal transistors, and multi-terminal integrated circuits.

Figure 1 depicts characteristic lengths of electronic material, namely, relaxation length, mean-free path, coherence length, and De Broglie wavelength. These characteristic lengths are used to illustrate and compare two nomenclatures of electronic device scaling. These nomenclatures are indicated at the top and bottom of the figure. In one such historical development shown at the top, scaling progressed from classical, hot-electron, ballistic, mesoscopic, and quantum-effect devices. Classical electronic devices have feature sizes between 0.5 μm to over 10 μm and are comparable with relaxation length of materials. The next scaled-down devices are the hot-electron devices and they have feature sizes of between 0.1 μm and 0.5 μm. Such feature sizes fall between the characteristic mean-free path and relaxation length. The carriers in hot-electron devices may have temperatures that exceed the thermodynamic equilibrium temperature. The next scaled-down devices are ballistic devices with feature sizes in the range 0.05 μm to 0.1 μm, corresponding to feature size between the coherence length and the free-mean path. Ballistic devices suffer little scattering, and therefore exhibit very high speed and high-frequency performance. The devices described thus far (classical, hot-electron, ballistic) can be characterized by classical or semi-classical physical laws. The electrical characteristics of classical devices are described adequately by the classical drift-diffusion theory. The electrical characteristics of hot-electron and ballistic devices are described by semi-classical laws. The semi-classical model is also based upon the classical drift-diffusion theory. However, transport parameters, such as relaxation time and conductivity, are determined based upon quantum-mechanical models incorporating additional effects arising from size quantization.

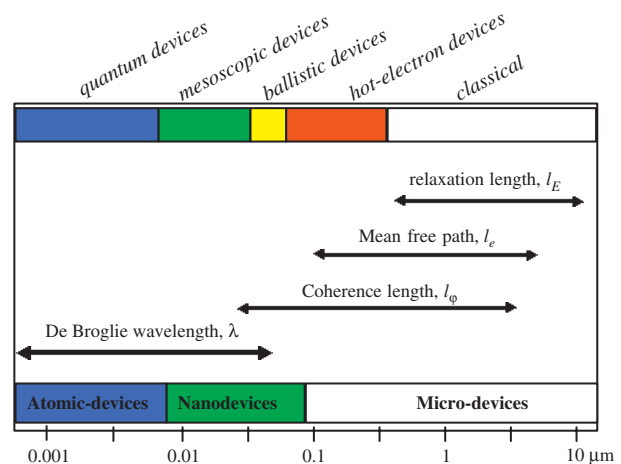
The two remaining scaled-down devices of the top nomenclature, namely, mesoscopic and quantum devices, require quantum-mechanical laws for their characterization. Mesoscopic devices have feature sizes that lie between 0.007 μm to about 0.015 μm (7 nm to 15 nm). Devices whose feature sizes are truly comparable with atomic feature size,


Figure 1. Comparison of two historical evolution of miniaturization of electronic devices in terms of material characteristics lengths (De Broglie wavelength, coherence length, mean-free path, relaxation length).

which for GaAs is of the order of 6 nm or less, are called quantum devices. They require full quantum-mechanical treatment to analyze or characterize their performance. Invariably, mesoscopic and quantum devices require low temperature operation.

The second type of nomenclature for device scaling is shown at the bottom of Figure 1, namely, microdevices, nanodevices, and atomic devices. Historically, this nomenclature for device scaling evolved correspondingly with advances in semiconductor material growth and device fabrication technology. Microelectronics material growth and device fabrication are based on the self-aligned technology. Self-aligned technology has the capabilities for scaling device feature size in the range of 0.1 μm to 10 μm. An effort to find a solution to the difficulty of applying self-aligned technology to fabricating scaled-down devices with feature sizes less than 0.1 μm gave rise to heteroepitaxial technology. Concomitant with heteroepitaxial growth came nanodevice technology, whereby one or more of the device feature size is a few nanometers.

This work treats GaAs nanodevices. The treatment includes emerging as well as existing quantum-well, quantum-wire, and quantum-dot devices. Electronic and transport properties in GaAs nanostructures are described in Section 2. In particular, we emphasize how size effects impact key electronic and transport parameters. Quantum-well and superlattice devices are treated in Section 3. In Section 4, GaAs resonant tunneling devices are discussed. In Section 5, quantum-wire and quantum-dot devices are discussed. GaAs spintronic devices are introduced in Section 6.

The rapid manner in which GaAs nanotechnology is evolving makes it impossible to include all devices reported to date. However, the devices covered here were carefully selected to adequately span the field of GaAs nano-device technology reported in the literature between 1980 and 2002. The references are only representative and by no means exhaustive.

2. ELECTRONIC AND TRANSPORT PROPERTIES OF GaAs NANOSTRUCTURES

The key features of the electronic properties of GaAs nanostructures for characterizing nanodevices are quantization of energy levels, density of states, excitonic formation, and spin precessing. These properties are observed as a consequence of quantum-mechanical carrier confinement induced by size effects, mechanical effect, electrostatic potential, or magnetic fields. A theoretical determination of these properties starts with a solution of the Schrödinger equation for the electronic wave function and the energy band. Many physical realities complicate solution of the Schrödinger equation. First, the electrostatic interaction that exists between the carriers in the confined system requires a many-bodied model to the problem. Second, band mixing requires a solution of couple nonlinear second-order differential equations. Third, compositional variations, material disorder, or statistical fluctuations influence the solutions. The effective mass, or k.p. method, offers a semi-classical approach to determining the electronic properties of nanostructures.

Scattering, high field, tunneling processes, hot electron, localization, and quantum interference effects dominate carrier transport in nanostructures. Scattering processes may be elastic or inelastic. The main sources of elastic scattering are ionized impurities, interface roughness, and electron screening. Inelastic scattering is primarily due to carrier-phonon interactions. Scattering in nanostructures causes transitions in momentum, energy, or quantum state. These transitions ultimately lead to momentum loss, energy loss, intersubband transitions, or change in spin number and are characterized in terms of transition probabilities from an initial state to a final state. Scattering limits the device operation speed and also introduces noise, and therefore its elimination or minimization is crucial. Elastic scattering can be minimized using selective doping in which some selected layers of a nanostructure are doped while others are undoped. The choice of materials and their arrangement is carefully designed to introduce real-space transfer of carriers from the doped layers to the undoped layers, so that the ionized impurities located in the doped layers are separated from the carriers transferred to the undoped layers. A spacer layer may be added to better separate the ionized impurities in the undoped layer. Also, minimization of elastic scattering can be achieved by eliminating interface nonuniformities during growth of the nanostructures.

High electric field inherent in nanostructures causes the mean energy and momentum of carriers to exceed their thermal equilibrium values. The most noted effects are velocity overshoot and saturation. The saturation velocity in GaAs nanolayers has a value between 1–2×10^7 cm/s and occurs at electric fields exceeding 10 kV/cm. Velocity overshoot is observable at low field of between 2–5 kV/cm, and depending on the composition of the nanolayer, the overshoot velocity could be as high as 5 times the saturation velocity. Velocity overshoot is also observed in the transient state on a time scale of 1–2 ps. The steady state velocity overshoot occurs at a critical electrical field, whereas the transient state velocity overshoot increases with increasing electric field strength.

3. GaAs QUANTUM-WELL AND SUPERLATTICE DEVICES

GaAs quantum-well and superlattice nanodevices may be classified based upon the physical phenomena employed to control current flow in the devices. Current flow may be controlled by an electric field, electric potential, or by quantum-mechanical tunneling. Accordingly, GaAs quantum-well and superlattice devices may be classified into a) heterostructure field-effect, b) heterostructure potential-effect, and c) resonant tunneling devices. These devices may be implemented as two-terminal diodes, three-terminal transistors, or multi-terminal integrated circuits.

3.1. GaAs Heterostructure Field Effect Transistors

GaAs heterostructure field effect transistor (HFET) is one of the earliest quantum-well field-effect devices. A family tree of GaAs HFETs is illustrated in Figure 2. The three

Figure 3. Cross-sectional view of a conventional HFET. An energy band diagram Is also shown. The two-dimensional electron gas (2DEG) is formed due to real-Space charge transfer. Due to size effects the energy of the 2DEG is quantized. Reprinted with permission from [3], E. Donkor, "Handbook of Advanced Electronic and Photonic Materials and Devices," 2001. © 2001, Academic Press.

main branches are conventional, insulated gate, and inverted HFET [2]. A quantum-well structure confines carriers into two-dimensional electron gas (2DEG). In a conventional HFET, the 2DEG resides in the smaller bandgap layer of the quantum-well and are separated from the gate by the wider bandgap material. The 2DEG is formed as a result of real-space charge transfer from the doped wide bandgap material to the undoped smaller bandgap material. MODulation-doped FETs (MODFETs) form a subclass of conventional HFET. In these HFETs, the wide bandgap material is uniformly doped. Another subclass of conventional HFET is the GL-MODFET in which the $Al_xGa_{1-x}As$ layer between the 2DEG and the gate is gradually graded in composition by varying the Al molar fraction from about $x = 0.3$ at the 2DEG interface to $x = 0$ at the gate interface. A third subclass of the conventional HFET is the SL-MODFET in which the quantum-wells are replaced by superlattices. The HFET may be doped in a narrow region called δ-doped to cause separation of the 2DEG from ionized impurities.

Insulated gated HFETs have an insulated layer separating the gate electrode from the quantum-wells that confine the 2DEG. Metal-Insulator-FET (MISFET) and semiconductor-insulator-semiconductor-FET (SISFET) form the two basic variations of the insulated gate HFETs. The motivation for developing these structures is to form complimentary HFET for low-power logic circuits analogous to silicon CMOS circuits. The challenge in growing insulated-gate FET is due to the fact that GaAs has no native oxide. In the inverted HFET, an undoped, small bandgap material is grown on a doped wide bandgap material. Also, the gate is grown on the small bandgap material. This structure is thus inverted with respect to the conventional FET. Inverted HFET may be further classified into single quantum-well, high-electron mobility transistor (SQW-HEMT), insulated-gate, high-electron mobility transistor (I-HEMT) and inverted-insulated gate, high-electron mobility transistor (I²-HEMT).

3.1.1. Conventional HFET

Modulation-Doped HFETs Figure 3 is a cross-sectional view of an GaAs/$Al_xGa_{1-x}As$ single quantum-well MODFET. It shows the various GaAs and AlGaAs layers. Due to the higher bandgap of AlGaAs compared to the adjacent GaAs region, free electrons diffuse from the AlGaAs into the GaAs and form a 2DEG at the heterojunction. A potential barrier, arising from the band discontinuities, confines the free electrons in the GaAs layer to a very thin sheet. Due to the absence of ionized donors in the channel of the MODFET, electrons forming the 2DEG suffer little Coulomb scattering and enjoy high mobility. A thin "spacer" layer of undoped AlGaAs placed between the doped AlGaAs and the undoped GaAs, further separates the 2DEG from the ionized donors at the interface, increasing electron mobility at the cost of a total charge transferred to the interface. The heavily doped GaAs "cap" layer facilitates formation of ohmic contacts to the device.
An energy band diagram of the MODFET is also shown in Figure 3. The difference in electron affinities translates into a discontinuity in the conduction band at the heterojunction. Electrons from the doped AlGaAs diffuse or tunnel to the GaAs, causing the formation of a dipole layer with ionized donors on one side and electrons on the other. Equilibrium is established when the potential difference equals the conduction band offset. Charge transfer across the heterointerface requires only that a discontinuity of greater than $2kT$ appear in the conduction band, not a difference in bandgap. Electrons in the 2DEG are confined to a potential well at the heterojunction, which is often approximated as a triangular well. Electron energies are quantized perpendicular to the heterointerface. Motion in the other two directions is unconstrained.

A simplified explanation for the formation of the energy band structure is to consider the impurities of the doped (AlGaAs) region as isolated with binding energy E_b. At very low temperatures $E_b \gg K_BT$, the carriers remain frozen onto the impurity sites. When $E_b \cong K_BT$, carrier detrapping takes place. To establish thermal equilibrium, the electrons escape, either by diffusion or quantum mechanical tunneling into the small bandgap (GaAs) material. The electrons quickly lose energy by emitting phonons. The reverse process, that is, recapturing of the electrons by the ionized impurities, is prevented by the built-in potential. The residual impurities however, affect the charge transfer. A band bending takes place due to the formation of a dipole between the ionized impurities and the electrons.

Graded-Layer and Delta-Doped HFET An improvement on the MODFET is obtained by grading the epilayers forming the heterointerface. The goal is to lower the effective interfacial resistance. In this case, the wide bandgap $Al_xGa_{1-x}As$ donor layer is graded in composition from $Al_xGa_{1-x}As$ (with the Al molar fraction $x = 0.3$ approximately) to GaAs at the cap interface to facilitate ohmic contact formation.

The delta-doped, or pulsed-doped HFET [4, 5] is so called because it has well-defined, high-peak, narrow doping carrier concentration. Delta-doped HFETs have many attractive characteristics relative to conventional HFETs, including high drain current, high intrinsic transconductance, high breakdown voltage, and better threshold controllability [6]. Delta-doped HFETs find applications in high-power microwave circuits and high-speed digital circuits.

Superlattice-Doped HFETs Another modification of the MODFET incorporates multiple quantum-well layers [7]. The goal here is to increase the 2DEG sheet density. This allows for increased device current and improved power performance. The disadvantage is lower frequency and speed performance [8] compared to single quantum-well MODFET. DX centers and doped impurities in heavily doped layers degrade device performance. One method of resolving this problem is to incorporate a superlattice donor layer in place of the doped layer [9, 10]. In the SL-doped HFET, only the thin GaAs layers are n-doped within the undoped AlGaAs. As a result, the donors are separated from the AlGaAs lattice and should not induce DX centers.

Pseudomorphic HFETs A pseudomorphic, or strained-layer HFET (PHEFT) can also improve upon the basic HFET performance by replacing the GaAs active region with a different material, such as InGaAs, which has relatively low DX centers and higher mobility [11, 12]. The most studied PHEFT is the n-AlGaAs/InGaAs/GaAs structure. By using a strained layer InGaAs instead of GaAs for the active region, higher band discontinuity, ΔE_c, is obtained so that an n-$Al_xGa_{1-x}As$ with $x < 0.2$ can be used as an electron supply layer and prevent DX centers. Pseudomorphic HFETs have been designed for low-noise amplification [13], high frequency, and high-power operations [14].

3.1.2. Insulated-Gate HFETs

Heterostructure insulated-gate field effect transistors (HIGFET) has two main subclasses: the SISFET [15, 16] and MISFET [17–19]. The SISFET has a semiconductor gate and a heterojunction barrier in contrast with a metal gate and Schottky barrier for the conventional HFET. The SISFET exhibits good thermal stability—its threshold voltage is near zero and less dependent on material characteristics [20]. The transconductance versus gate voltage shows a distinctive sharp turn at low temperatures near its knee region and has a higher slope in the linear region than conventional HFETs. Metal-insulator semiconductor HFETs offer the integration of n-channel and p-channel HFET to form complimentary circuits, which is the basic building block for integrated circuits.

Figure 4 illustrates a complimentary MIS-HFET. The substrate is a semi-insulating GaAs. An n^+-IMPLANT isolates
Figure 4. Cross-sections of a complimentary MIS-HFETs. The n-channel shown on the left incorporates a heavily doped Ge under the gate for low threshold voltage and for non-alloy contact with the gate metal.

the n-channel MISHFET, likewise a p^+-IMPLANT isolates the p-channel MISHFET. The n-channel incorporates an n^+-Ge under the gate electrode to maintain a low threshold voltage and for nonalloy contact to the gate metal.

3.1.3. Inverted HFETs

In inverted AlGaAs/GaAs HFETs, an undoped GaAs layer is grown between the gate metal and the AlGaAs layer. The advantages of the inverted HFET compared with the normal MODFET are lower contact resistance to the 2DEG, better carrier confinement, high transconductance, and higher carrier concentration. Inverted HFETs, however, suffer from large gate current, parasitic MESFET effects under the gate region, and performance degradation due to substrate effects.

3.1.4. HFET Electrical Characteristic

The most widely used analytical approaches for describing the charge distribution of the 2DEG are the self-consistent method [21] and the variational method [22]. An expression for the sheet carrier density of the 2DEG is given by

$$n_s = \left(\sqrt{\frac{2\varepsilon_2 N_d}{q}\left[V_{20} - \frac{\Delta E_{FO}(T)}{q} + \delta \right] + N_d^2(d_i + \Delta d)^2} \right) - N_d(d_i + \Delta d) \tag{1}$$

Here, ε_2 is the permittivity of the doped layer, N_d is the ionized donor density in the doped layer, d_i is the thickness of the undoped spacer layer, δ is a correction factor due to the use of the depletion approximation in the doped layer. For a donor binding energy of 15 meV, δ is 25 meV at 300 K and 50 meV at 77 K. The position of the Fermi level measured from the bottom of the potential well, represented by ΔE_{FO}, at the heterointerface is a function of the sheet carrier density [23].

Control of the sheet carriers in the HFETs is achieved through a Schottky gate. Accounting for the gate voltage, the sheet carrier density expression of Eq. (1) can be modified as

$$n_s = \frac{\varepsilon_2}{q}\frac{V_G - V_{TH}}{d + \Delta d} \tag{2}$$

$$V_{TH} = \phi_b - V_p - \frac{\Delta E_c + \Delta E_{Fo}}{q} \tag{3}$$

where $d = d_d + d_i$, d_d is the thickness of the doped AlGaAs beneath the Schottky gate, ϕ_b is the Schottky barrier height, and V_p is the pinch-off voltage.

Current voltage, transconductance voltage, and capacitance voltage are the main d.c. characteristics of interest. A simplified analytical model for these characteristics is derived from the charge control method [24]. The main difference between various analytical models is due to the choice of the functional relationship between the drift velocity and the applied electric field. The import of these relationships is to account for velocity overshoot, and other nonequilibrium effects, while still providing a tractable or closed-form functional relationship [25, 26].

A multiregion model, whereby the linear and saturation region are analyzed separately and then integrated into a unified model, is often employed to obtain analytical closed-form expressions for the I-V characteristics. The linear region corresponds to low-applied electric field, such that the velocity of carriers in the channel is directly proportional to the applied field. The saturation region is taken as corresponding to the saturation (or constant) velocity of the carriers with applied voltage. The I-V relation for the respective linear and saturation regions are of the form

$$I_d = \frac{w\mu\varepsilon_2}{2(d + \Delta d)} \frac{(V_G - V_{TH})^2 - (V_G - V_{TO} - V_d)^2}{L_g + V_d/F_c} \quad (4)$$

$$I_d = \frac{\beta V_{s1}^2\left(1 + 2\beta R_s V_g' + V_g'^2/V_{s1}^2\right)^{\frac{1}{2}}}{1 - \beta^2 R_s^2 V_{s1}^2} - \frac{\beta V_{s1}^2(1 + \beta R_s V_g')}{1 - \beta^2 R_s^2 V_{s1}^2} \quad (5)$$

Here $V_g' = V_G - V_{TH}$, $V_{s1} = F_c L_g$, $\beta = \varepsilon_2 \mu W/(d + \Delta d)$, L_g is the gate length, w is the gate width, and R_s is the source series resistance. A comparison between these models and experimental results show good agreement [27].

The ac model attempts to determine nonlinear elements such as gate capacitance and other parasitic capacitances, found in the equivalent circuit [28] of the HFET. The relationship between the maximum frequency, f_{max}, and the cutoff frequency, f_t, in terms of parasitics, have been widely reported and takes the form

$$f_{max} = \frac{f_t}{\sqrt{4\frac{g_o}{g_m}\left(g_m R_i + \frac{R_s + R_g}{1/g_m + R_s}\right) + \frac{4}{5}\frac{C_{gd}}{C_{gs}}\left(1 + \frac{2.5C_{gd}}{C_{gs}}\right)(1 + g_m R_s)^2}} \quad (6)$$

$$f_t = \frac{g_m}{2\pi C_{gs}} \quad (7)$$

Here g_m is the transconductance and the other parameters are as defined in the literature [29].

The dc characteristics turn to depend on device structure and material systems used to design the HFET. As the gate length shrinks, the dc characteristics generally improve [30]. Improvement in device characteristics is also observed at low temperatures [31]. The growth of pseudomorphic HFETs has new approaches to achieving enhancement in device characteristics opening up. Dickmann et al. [32] achieved transconductance of

368 mS/mm and a drain saturation current of 326 mA/mm in an $(Al_{0.7}Ga_{0.3})_{0.5}In_{0.5}P/In_{0.15}Ga_{0.85}As/GaAs$ pseudomorphic HFET. Likewise, Pereiaslavets et al. [33] reported drain saturation current of 800 mA/mm and transconductance of 600 mS/mm for a narrow channel (50–80 Å) GaInP/InGaAs/GaAs pseudomorphic HFET. The a.c. characteristics show similar trends of improvement in short channel devices, and in pseudomorphic structures that incorporate devices with high mobility and high velocity overshoot effects.

3.2. GaAs Potential-Effect Transistors (HPETs)

Heterostructure potential-effect transistors (HPETs) are current-controlled devices and are classified into heterostructure bipolar transistors (HBTs), ballistic-injection transistors and real-space transfer transistors as shown in Figure 5. The base or emitter structure of HBTs can be made to be single-well (SW-HBT), double-well (DW-HBT), or superlattice (SL-HBT). Ballistic injection transistors hot electrons are injected over or through an emitter barrier into the base region. The injected carriers travel through the barrier with little or no scattering. Current control is maintained by changing the collector barrier height. An induced-base, ballistic-injection transistor (or induced-base transistor) was proposed in 1985 [34] and experimentally implemented by Chang et al. [35]. Fabrication of this device is complicated albeit it has shown no remarkable improvement over the basic HBT. The resonant tunneling hot-electron transistor (RHET) and the tunneling hot-electron transfer amplifier (THETA) are two other ballistic injection transistors. The charge injection transistor [36] (CHINT) is an example of a real-space charge transfer transistor. The structure has a source, high-mobility channel, drain, and an additional collector terminal. Thus, it may be considered an integrated HFET/HBT.

3.2.1. Heterostructure Bipolar Transistor

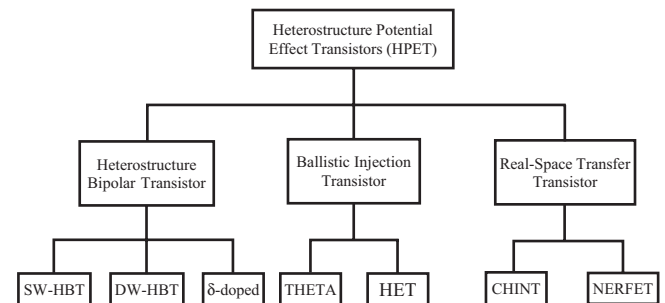
Figure 6 depicts a cross-sectional view of an npn AlGaAs/GaAs single heterojunction bipolar transistor (SHBT). The structure consists of a lightly (n^--) doped wide bandgap $Al_xGa_{1-x}As$ emitter, a heavily (p^+-) doped GaAs


Figure 5. Family tree of heterostructure potential-effect transistor. Reprinted with permission from [3], E. Donkor, "Handbook of Advanced Electronic and Photonic Materials and Devices," 2001. © 2001, Academic Press.
Figure 6. Cross-sectional view of an AlGaAs/GaAs SW-HBT. Reprinted with permission from [3], E. Donkor, "Handbook of Advanced Electronic and Photonic Materials and Devices," 2001. © 2001, Academic Press.

base, and a n^--doped GaAs collector. A double heterostructure bipolar transistor (DHBT) is formed by replacing the GaAs collector with another wide bandgap material such as AlGaAs. The performance enhancement that an HBT offers over a homojunction bipolar transistor can be deduced from the current gain figure of merits which is given by [37]:

$$\beta_{\max} = \frac{N_e}{P_b} \frac{v_{nb}}{v_{pe}} \exp(\Delta\varepsilon_g/kT) \qquad (8)$$

Here N_e and P_b are the emitter and the base doping levels. v_{nb} and v_{pe} are the mean speeds of electrons at the emitter end of the base and holes at the base end of the emitter, respectively. Also, the energy gap difference is $\Delta\varepsilon_g = q(V_p - V_n)$, where V_p and V_n are the potential barriers of holes and electrons. The energy gap difference of HBTs is several kTs; as a result, very high $\beta_{\max} > 1000$ can be achieved [38].

Improvement in high frequency performance can be realized in an HBT, since the base can be highly doped to reduce base resistance without deteriorating the current gain. However, the process of heavily doping the base can be impeded due to an increasing diffusion coefficient of the base acceptors at higher concentrations. Thus, the choice of dopant becomes very important. Carbon appears to be a promising acceptor in MBE, MOMBE, and MOCVD growth. Carbon diffuses less in comparison with Be or Zn, allowing for high temperature processing and high doping concentrations. The discontinuity in the energy bands may be abrupt or graded, and their advantages and disadvantages have been discussed [39].

The lattice-matched $Ga_{0.52}In_{0.48}P$/GaAs HBT [40–44] has evolved as an alternative to the more conventional AlGaAs/GaAs HBT. Some of its attractive features include near ideal current-voltage characteristics, high current gain [45, 46], and constant current gain for a wide range of temperatures [47]. An etching solution for GaInP does not attack GaAs [48], making selective etching possible for material processing. Also, GaInP is less susceptible to oxidation, whereas the AlGaAs is readily oxidized due to the acute reactivity of Al. Also DX centers are relatively less compared to AlGaAs.

3.2.2. Ballistic Injection Heterostructure Bipolar Transistor

Tunneling Hot-Electron Transfer Amplifier (THETA)
Figure 7 is an illustration of a tunneling hot-electron transistor. The structure consists of heteroepitaxially grown layers of heavily doped 200 nm-thick GaAs (emitter) layer, a 10 nm-thick intrinsic AlGaAs, a 30 nm-thick heavily doped GaAs (base) layer, a 6 nm-thick grade AlGaAs layer, a 100 nm-thick intrinsic AlGaAs, and a heavily doped thick GaAs (collector) layer. The tunneling hot-electron transistor is a unipolar potential effect device and forming an ohmic contact to the base is quite challenging. One approach is by reactive ion etching to expose the base. However, etching should not penetrate deep into the base; otherwise, the base-collector junction could be short-circuited.

The emitter-base junction forms an injector for hot-electron tunneling, from the emitter into the base, through the thin 10 nm i-AlGaAs layer. The kinetic energy of the injected carrier depends on the emitter-base voltage and the difference between the quasi-Fermi level and the bottom of the conduction band in the base region. The base is made thinner than the mean-free path of the carriers so that the emitted electrons travel ballistically through the base. The base collector forms a barrier and only hot electrons with energy in excess of the barrier height can reach the collector. The RHET can be biased to operate as an amplifier, if the emitter is negatively biased and the collector positively biased with respect to the base. A typical base-to-emitter voltage, $V_{be} > 0.6$ V. However, such high voltages can cause electrons in GaAs to scatter from the Γ-valley to the upper L and X valleys resulting in low-tunneling current arriving at the collector of the devices. For ballistic transport to occur $V_{be} < 0.3$ V. This can be achieved by higher doping of the base and emitter regions.

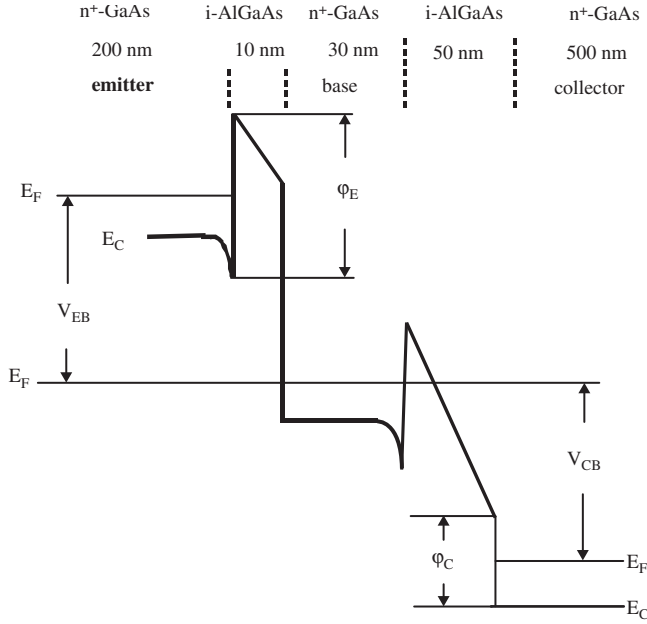
Hot Electron Transistor (HET) The HET is so called because at normal biased voltages, the electronic temperature, T_e, of the current carrying electrons is higher than their thermal equilibrium temperature T in the device. Such a situation occurs if the device feature size is smaller than the energy relaxation length of electrons for the material. The energy band diagram of the basic GaAs HET is shown in Figure 8. It depicts three heavily doped GaAs layers forming the emitter (200 nm), base (30 nm), and collector
Figure 7. Cross sectional view of a tunneling hot electron transistor.


Figure 8. Energy band diagram of GaAs hot-electron transistor.

(500 nm) regions, respectively, and separated by two intrinsic AlGaAs regions of thickness 10 nm and 50 nm. The first AlGaAs/GaAs heterojunction at the emitter-base junction is a ballistic injector of carriers, and the second AlGaAs/GaAs heterojunction at the base-collector junction forms a barrier with height φ_c allowing only hot electrons with kinetic energy higher than the barrier to surmount. By applying a base-emitter voltage, V_{be}, across the base-emitter junction, electrons are injected ballistically into the base region. A base-collector voltage, V_{bc}, of a few volts enables the carriers to be collected.

Two variations for the HET are the V-grooved barrier transistor (VBT) and the injected-induced barrier transistor (IBT). The VBT has an ultra-thin heavily doped base region. The base can be p^+-layer in which case a bipolar HET is formed or can be n^+-doped layer to form a monopolar HET. Unlike the VBT, the base of an IBT is undoped or rather the base carriers are induced and injected. As a result, it has both higher common base current gain and operating speed than the basic HET.

3.2.3. Real-Space, Charge-Transfer Transistors

Real-space, charge-transfer transistors are three-terminal devices in which hot electrons are transferred between two conducting layers separated by a potential barrier. There are two main types, namely, the CHINT and the negative differential resistance, field-effect transistor (NERFET). Hess first suggested the device applications of real-space hot-electron transfer [49]. In layered heterostructures, hot electrons can move between adjacent layers. If the layers have different mobilities, the charge transfer between these layers results in negative differential resistance (NDR) effects. A real-space, charge-transfer device has source, drain, and collector terminals. The source-drain configuration has the

basic HFET structure and is designed to inject hot electrons to be eventually collected at the collector terminal. The source-drain, hot-electron injector configuration is separated from the collector terminal by an insulator layer.

3.2.4. HBT Modeling and Characteristics

A procedure for modeling HBTs is based on a modification of the basic theory of homojunction BJTs to account for variation in semiconductor composition. In the simplest approximation, carrier fluxes are taken to be linear functions of the applied external biases, which lead to the drift-diffusion theory. In the drift-diffusion approximation, the electron current density, J_n, and the hole current density, J_p, are expressed as the sum of two terms—a drift one due to the electrical field and a diffusion term due to the inhomogeneous carrier densities. For the HBT, they are given by

$$J_n = nq\mu_n\left(\frac{-dV}{dx} + \frac{1}{q}\frac{dE_c}{dx}\right) + qD_n\left(\frac{dn}{dx} - \frac{n}{N_c}\frac{dN_c}{dx}\right) \quad (9)$$

$$J_p = pq\mu_p\left(\frac{dV}{dx} + \frac{1}{q}\frac{dE_v}{dx}\right) - qD_p\left(\frac{dp}{dx} - \frac{p}{N_v}\frac{dN_v}{dx}\right) \quad (10)$$

Here μ_n, μ_p, D_n, D_p are, respectively, the mobility and diffusion coefficients for electrons and holes and q is the electronic charge. In general, these parameters are dependent on the electric field. E_c, N_c, E_v, N_v are, respectively, the energy and effective density of states in the conduction and valence bands. The terms that involve the derivatives of the conduction and valence bands act as quasi-electric field that act on the electrons and holes, respectively. Similarly, the derivatives of the densities of states act as diffusion like terms for electrons and holes. The Poisson's equation has to be solved simultaneously with the drift-diffusion equation to obtain the behavior of carrier transport in the HBT. If we assume that the conduction and valence band bending are the same, then the Poisson's equation can be written simply as

$$div(\varepsilon_{eff}\, grad(V)) = q(n - p + N_a^- - N_d^+) \quad (11)$$

where ε_{eff} is the effective permittivity, N_a^- and N_d^+ are the ionized acceptors and donors, respectively. The solution to coupled Eqs. (9–11) is given by [50]:

$$J_n = qn\mu_n\frac{dF_n}{dx} \quad (12)$$

$$J_p = qp\mu_p\frac{dF_p}{dx} \quad (13)$$

where F_n and F_p are the quasi-Fermi levels for the conduction and valence bands, respectively. Numerical techniques, such as the Monte Carlo method, offers an alternative approach to solving the governing equations for the HBT. The Monte Carlo method is more appropriate if generation-recombination processes are to be accounted for [51]. Refinements of the basic drift-diffusion model are the thermionic-diffusion and the thermionic-field models [52].

The DC modeling of HBT entails the determination of the emitter current density (J_E), collector current density

(J_C), and base current density (J_B), the transconductance (g_m), and the current gain factor (β). These terminal currents can be obtained from the electron and hole current densities using the Ebers–Moll approach. The AC model determines device parasitics [53], the unity power-gain frequency, $f_{\max}$, the unity current gain frequency, f_t, and the high frequency and switching performance of the HBT.

4. GaAs RESONANT-TUNNELING DEVICES

The superlattice resonant-tunneling structure consists of a number of alternating layers of different energy bandgap materials with the layer thickness in the nanometer range, such that the electronic wave functions in adjacent layers overlap. Energy minibands and minigaps are formed which extend throughout the entire superlattice structure as a result of the overlap of the carrier wave functions. Doping and compositional superlattices form the two basic types. The *n-i-p-i* superlattice is an example of a doping superlattice. In a *n-i-p-i* superlattice, a periodic carrier concentration is introduced by selective doping a semiconductor material with acceptors and donors alternatively. The ionized impurities create repeated layers of negative (*n*) and positive (*p*) space charge separated by intrinsic (*i*) layers. As a result of such doping profile, a periodically repeating electric field is created in the semiconductor structure.

The first *n-i-p-i* structure was reported by Dohler in 1971 [55, 56]. Later in 1980, a GaAs *n-i-p-i* superlattice was grown by Ploog et al. [57]. These earlier structures were homoepitaxially grown. A schematic diagram of a homoepitaxial doping superlattice is shown in Figure 9. It consists of alternately *p*- and *n*-doped layers. Ohmic contact is established in all the *n*-layers by alloying Sn-metal, which is blocking to the *p*-layers, through all the layers. Likewise, ohmic contacts are established to the *p*-layer by alloying Sn-Zn metal through all the layers. Thus a bias voltage, V_{np}, can be

applied between all *n*-layers and *p*-layers of the superlattice. Space charge is formed at the *pn*-junctions as a result of real-space, charge transfer across the junctions. This produces a modulation potential that bends both the valence and conduction bands. In effect, the *p*- and *n*-layers of the doping superlattice have thickness corresponding to the width of the space charges created. Figure 10 shows the energy band diagram of a doping superlattice. Electrons and holes are confined in small layers by the confining potential, but are separated from each other by the depletion regions. The electronic wavefunction, ψ_n, and the energy level, E_n, of the *n*th subband are given by

$$\psi_{c,n} = (2^n a_c n! \sqrt{\pi})^{-\frac{1}{2}} \exp\left(\frac{-z^2}{2a_c^2}\right)$$

$$\times H_n\left(\frac{z}{a_c}\right) \quad n = 1, 2, 3, \ldots \quad (14)$$

$$a_c = \sqrt{\frac{\hbar}{m_c \omega_c}} \quad \omega_c = \sqrt{\frac{4q^2 \pi N_D}{\varepsilon_o \varepsilon_r m_c}}$$

$$E_{c,n} = \hbar \omega_c \left(n + \frac{1}{2}\right) \quad (15)$$

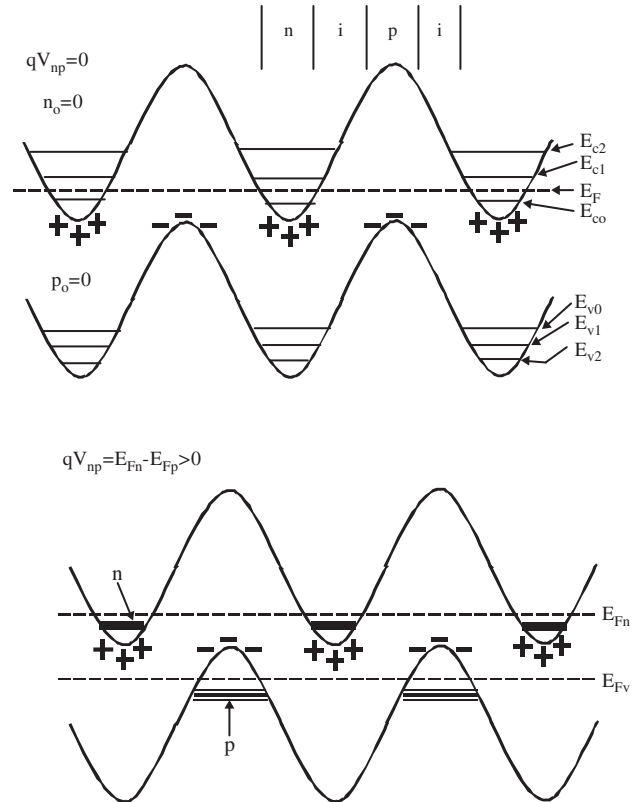
Here N_D is the doping concentration for electrons, m_c, the effective mass of electrons, ε_o is the permittivity of free


Figure 10. Energy band diagram of homoepitaxy *nipi* superlattice. Electrons and holes are confined in small layers by the confining potential, but are separated from each other by the depletion regions. Reprinted with permission from [54], G. H. Dohler, "Properties of III–V Quantum Wells and Superlattices," 1996. © 1996, IEEE.

Figure 9. Homoepitaxial *n-i-p-i* structure fabricated with alternating *p*- and *n*-layers. The Sn metal makes contact with all the *n*-layers but blocks contact to the *p*-layers. Similarly, the Sn-Zn alloy makes contact to all *p*-layers but blocks the *n*-layers. Reprinted with permission from [54], G. H. Dohler, "Properties of III–V Quantum Wells and Superlattices," 1996. © 1996, IEEE.

space, ε_r is the relative permittivity, $\hbar$ is the Planck's constant, and q is the electronic charge. Equation 15 indicates that the energies are quantized and characterized for the nth subband by an integer, n, analogous to any 2D system. The observation of such reduced dimensionality of doping superlattice has been demonstrated experimentally [58–60].

Compositional superlattices are grown as lattice-matched or strained-layer structures consisting of alternating layers of wide bandgap and small bandgap materials with a layer thickness of a few nanometers, which allow tunneling of the electronic wave function across the barriers. The wave function, energy states, and density of states in a compositional superlattice with quantum number j and subband index μ assuming infinite well approximation are as follows:

$$\phi_{j,\mu,k_x} = \sqrt{\frac{1}{N}} \sum_{l=1} \chi_j(z - ld)\exp i(k_x ld)\exp i(k_x x + k_y y)$$

(16)

$$E_{j,\mu,k_x,k_z} = \varepsilon_{j,\mu} + s_j + \frac{\hbar^2}{2m_c^*}(k_x^2 + k_y^2) + 2t_j \cos(k_z d) \quad (17)$$

$$\rho_{SL}(E) = \frac{L_x L_y m^*}{\pi \pi \hbar^2} \sum_{j,k_z} \Theta(E - E_j - s_j + 2t_j \cos(k_z d)) \quad (18)$$

The heteroepitaxy n-i-p-i superlattice structure, introduced in the 1980's [61], is designed as an integrated structure of doping and compositional superlattices. They are of two main types, namely, Type-I and Type-II. In the Type-I doping heteroepitaxial superlattice, the center of the n- and/or the p-layer consists of undoped quantum wells of a lower bandgap material, separated by an undoped spacer layer to reduce impurity scattering [62]. The Type-II doping heteroexpitaxial superlattice [63] also has intrinsic layers (i-layers) that consist of a quantum-well of a lower bandgap. In addition, the electrons and holes are spatially separated from their parent dopants. Figures 11 and 12 show their respective energy band diagrams.

Carriers may be transported in superlattices either parallel or perpendicular to the growth layer surfaces. Perpendicular transport is dominated by tunneling processes and is the predominant mechanism underlying superlattice devices such as SL-tunneling diodes, SL-bipolar transistor, and SL-hot-electron transistor. On the other hand, carrier transport in superlattice devices such as SL-FET, RT-FET, and
Figure 11. Energy band diagram of TYPE I heteroepitaxial *nipi* structure. Reprinted with permission from [54], G. H. Dohler, "Properties of III–V Quantum Wells and Superlattices," 1996. © 1996, IEEE.

gated quantum-well SL-transistor are parallel to the growth surface.

Superlattice and quantum-well resonant-tunneling devices exhibit current-voltage characteristics that uniquely exhibit negative differential resistance. Such negative differential resistance has been realized in double quantum-well, multiple quantum-well, *nipi*-superlattice and heteroepitaxial-superlattice diodes and transistors. In these devices, the peak-to-valley ratio of the negative differential resistance determines their performance. This ratio, especially for the superlattice-based resonant tunneling devices, is enhanced at low temperatures.

4.1. GaAs Quantum-Well and Superlattice Tunneling Diode

Quantum-well and superlattice tunneling diodes with a current-voltage relationship that exhibit multiple peaks have a wide range of applications, including implementing high-speed multiple-value logic circuits, high-frequency oscillators, and amplifier circuits. In order to achieve the desired multiple peak I-V characteristics, a number of superlattices are integrated in a series or in parallel. Figure 13 illustrates a GaAs/AlGaAs superlattice tunneling diode. The structure consists of two superlattice sections separated by a tunneling barrier. The period of the superlattice is 4 nm and the tunnel barrier is 20 nm and is therefore thicker than each superlattice section. The heavily doped GaAs layers under the Au contact ensure better ohmic contacts. The operation of the diode is described with respect to its energy band diagram. Consider the application of a bias voltage across the devices. At low voltage biasing, the device current is due to tunneling of electrons from filled states of a miniband in the top section (TOP-SL) to empty states in the corresponding bottom section (BOT-SL) miniband on the other side of the barrier.

Increasing the bias voltage causes the current to rise steadily until the Fermi level on the top superlattice section side of the barrier falls within the lower minigap. When the second miniband on the topside becomes accessible to the tunneling electrons, the current rises again. A typical current-voltage characteristics of a four-section series diode
Figure 13. Superlattice tunneling diode.

arrangement, is shown in Figure 14. The curve depicts four peaks symmetrical about the current axis.

Resonant-tunneling (RT) diodes may be integrated to form more complex circuits. They can be integrated either vertically or horizontally. The integrated diodes turn to have multiple peaks current-voltage characteristics. Such integrated RT diodes have been used as frequency multipliers, multiple logic circuits, and as memory elements.

4.2. GaAs Resonant Tunneling Transistors

4.2.1. Quantum-Well and Superlattice-Base HBT

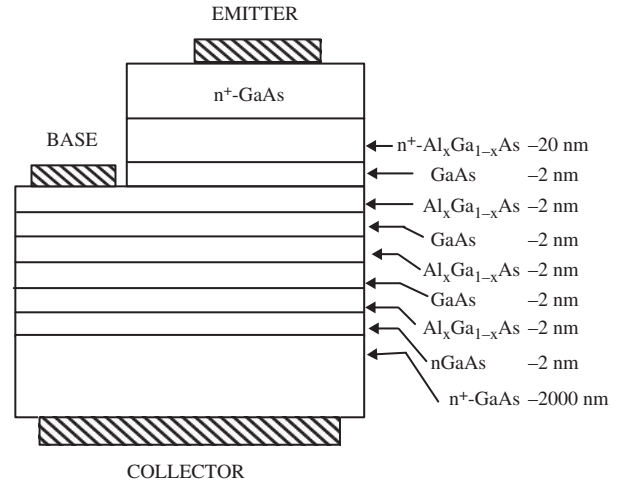
A superlattice structure can be incorporated in both a potential-effect and field-effect heterostructure transistor. Such hybrid structures have been used to design circuits with reduced transistor count. Both unipolar and bipolar potential-effect superlattice transistor operation is possible. A superlattice-base bipolar transistor is shown in Figure 15.
Figure 14. Current-voltage characteristics of a four-section superlattice diode. There are four distinct peaks that are symmetrical about the current axis.


Figure 15. AlGaAs/GaAs superlattice-based HBT.

The emitter forms an abrupt junction with the base and is heavily doped to allow for tunneling into the GaAs/AlGaAs superlattice base. The superlattice base is grown as 20-section alternating layers of GaAs and $Al_xGa_{1-x}As$ with $x = 0.3$. Each layer has a thickness of 2 nm. The base is p-doped and the emitter is a 3–5 μm thick n^+-GaAs and is separated from the base by an undoped GaAs layer, thereby forming an *npn* structure. A typical input transfer characteristics (I_C vs. V_{BE}) are shown together with the output characteristics (I_C vs. V_{CE}) for a common-emitter transistor configuration in Figure 16.

4.2.2. Quantum-Well and Superlattice-Emitter Resonant Tunneling HBT

A GaAs superlattice-emitter resonant tunneling heterostructure bipolar transistor has been reported in InGaP/GaAs structures [64]. The insertion of a superlattice in the emitter layer, and the large valence band discontinuity ΔE_V of the InGaP/GaAs material system serves to provide an enhancement in the negative differential resistance effect at room temperature in both the saturation and linear regimes of device characteristics. The device also gives higher current gain due to better confinement of minority carriers in the base region.
Figure 16. Input characteristics and output characteristics of AlGaAs/GaAs superlattice-based HBT.

5. GaAs QUANTUM-WIRE AND QUANTUM-DOT DEVICES

5.1. Single-Electron Transistor

A single-electron transistor (SET) is a device whose operation relies on single electron tunneling through a nanoscale junction. An SET can be considered as a field effect transistor whose channel consists of two tunneling junctions forming a quantum-dot (QD) island. The quantum-dot island is channeled to the source and drain so current can flow under the influence of the source and drain bias voltages V_s and V_d, respectively. The island is capacitive-coupled to a gate voltage V_g. An equivalent circuit representation of the SET is shown in Figure 17. The amount of charge that can occupy the quantum-dot island under the influence of the gate bias is discrete even though the bias voltage may change continuously. Thus, the charging energy of the system depends on the number of electron n on the quantum-dot island and the gate voltage. The charging energy, E_{ch}, is given by

$$E_{ch}(n, Q_G) = \frac{(ne - Q_G)^2}{2C} \qquad (19)$$

$$Q_G = C_s V_s + C_G V_G + C_D V_D \qquad (20)$$

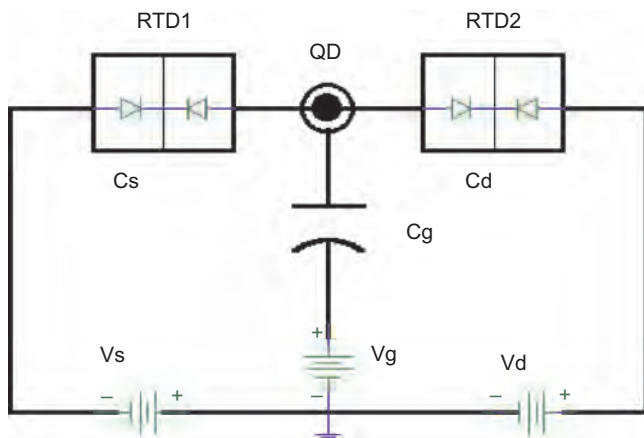
$$C = C_s + C_G + C_D \qquad (21)$$

The charging energy required to increase the charge on the quantum-dot island from n to $n + 1$ as a consequence of tunneling is given by

$$E_{ch}(n+1, Q_G) - E_{ch}(n, Q_G) = \left(n + \frac{1}{2} - \frac{Q_G}{e}\right)\frac{e^2}{C} \qquad (22)$$

The energy differences are equally spaced and can be tuned by the gate voltage. A single electron can tunnel from the source RTD1 to the drain RTD2 through the quantum-dot island (QD) if

$$eV_s > E_{ch}(n+1, Q_G) - E_{ch}(n, Q_G) > eV_d \qquad (23)$$

The current on a macroscopic conductor is often assumed to flow without any blockage in charging a capacitor. This is because the capacitance of such macroscopic wires is large, and therefore the energy $E_{ch} = e^2/2C$ required to charge an electron being transported on the wire is often negligible compared with the thermal energy of the electron. The situation is drastically different for nanoscale conductors or at extremely low electron temperatures. For instance, the capacitance of a quantum dot is of the order of 10^{-18} F or less. Thus, transporting a single electron through the quantum-dot requires energy of the order of 100 meV, which is comparable with the thermal energy of an electron at room temperature $kT = 25$ meV. As a result, the transport of the electron is blocked until the applied bias provides an energy in excess of the required charging energy. This phenomenon is an example of Coulomb blockade in quantum transport. The quantum-dot junction of the SET is in the nanometer scale and electron tunneling through the junction, and, consequently, the current-voltage relationship of the SET can be expected to be governed by Coulomb blockade processes. The I–V relationship of the SET can be expressed as [65]


$$I = \frac{1}{4R}\left[V - \frac{4e^2}{C^2V}\left(\frac{Q_c}{e} - n - \frac{1}{2}\right)^2\right]$$

$$\text{for} \quad -\frac{VC}{2e} \leq \frac{Q_c}{e} - n - \frac{1}{2} \leq \frac{VC}{2e} \qquad (24)$$

Here, R is the tunneling resistance and assumed equal at the source and drain ends.

5.2. Quantum Interference Transistor

The quantum interference transistor is an electron wave interferometer. One configuration is the Mach–Zehnder interferometer as shown in Figure 18. It has an input port or source, an output port or drain, and a control terminal or gate that is placed on one arm of the interferometer. Another nomenclature for this structure is the gated-ring, quantum interference transistor. The gate forms a Schottky barrier such that by applying voltage to the gate electrode the electron density under the gate region can be reduced. In a 1D electron gas, with carrier concentration n, the electron wavelength, λ_F, at the Fermi energy is related to the concentration n as $\lambda_F = 2/n$. Thus, an electron wavelength can be controlled to produce constructive or destructive interference at the output (or drain port).

Figure 17. Equivalent circuit of a single electron transistor.
Figure 18. Gated-ring quantum interference transistor.

An alternative structure of the quantum interference transistor is the electron wave stub tuner [66, 67] illustrated in Figure 19. The structure has source, drain, and gate terminals. Electron waves emanate from the source and travel towards the drain. A fraction travel directly to the drain, while a porting reaches the drain after reflection at the gate electrode. This causes a path length difference between the waves, which can be tuned by changing the length of the gate stub by using fringing fields under the gate. The strength of this field is controlled by the bias on the gate.

6. GaAs SPINTRONIC DEVICES

Spin transport electronics or spintronics [68] combine electronics and ferromagnetics technologies to store, amplify, and process information. In comparison to conventional electronic device, spintronic devices consume less power and are also nonvolatile. Spintronic devices that show promise for practical application are spin-diodes, spin-FETs, and spin valve transistor (SVT). Two basic requirement for the successful operation of spintronic devices are a) a method to inject spin-polarized current from a ferromagnetic material into a semiconductor material and vice versa, and b) detection of spin-polarized current. Many schemes may be employed to effect spin injection [69]. The simplest method is to inject spin-polarized current through an ohmic contact between the ferromagnet and the semiconductor materials. To form a good ohmic contact the semiconductor must be heavily doped. However, this leads to spin-flip scattering losses. An alternative approach is to inject spin-polarized current through a ferromagnetic-insulator-semiconductor, or ferromagnetic-insulator-ferromagnetic tunneling junction. Other techniques are ballistic-electron spin-polarized injection, and hot-electron, spin-polarized injection. Spin-polarized current can be detected using electroluminescence, ferromagnetic electrodes, or by potentiometric methods.

6.1. Spintronic Diode

A cross-sectional view of a spintronic diode is shown in Figure 20. It consists of a ferromagnetic p^+-(Ga,Mn)As and nonmagnetic n^+-GaAs epitaxially grown on top of a nonmagnetic n-GaAs/(In,Ga)As/p-GaAs quantum-well LED [70]. A spin-polarized current injection is achieved through

Figure 20. Schematic diagram of a spintronic diode/LED integrated structure. Spin polarized electrons from the GaMnAs ferromagnetic tunnel to the heavily doped GaAs and detected as electronuminescence of the LED.

interband tunneling between the valence band of the ferromagnetic layer and the conduction band of the nonmagnetic layer under reverse bias. The measurement scheme utilizes LED to detect spin by circular polarization of electroluminescense (EL). This detection state is based on the physical principle that all spin-polarized current in dilute magnetic semiconductors shows distinct circular polarization of the EL signal. The degree of polarization depends on the thickness of the spin aligner [71].

6.2. Spin Field Effect Transistor (SPINFET)

A cross-sectional view of spin-FET is shown in Figure 21. Its source and drain are dilute magnetic semiconductor materials. The density of states of electrons with one spin greatly exceeds that of the other spin at the Fermi level of the source and drain ferromagnetic material. Thus, the source and drain contacts preferentially inject and detect spin electrons. The channel of the spin FET consists of a narrow gap InGaAs quantum-well structure capable of splitting between up-spin and down-spin electrons even in the absence of a magnetic field. Suppose the magnetization of the injected electrons from the source is along the x-direction ($+x$ pol.); then the splitting between the spins will result in a positive z-polarized ($+z$ pol.) and negative z-polarized ($-z$ pol.) electrons, that is,

$$\underset{(+x \text{ pol.})}{\begin{pmatrix} 1 \\ 1 \end{pmatrix}} = \underset{(+z \text{ pol.})}{\begin{pmatrix} 1 \\ 0 \end{pmatrix}} + \underset{(-z \text{ pol.})}{\begin{pmatrix} 1 \\ 0 \end{pmatrix}} \qquad (25)$$

Figure 19. An electron wave stub tuner quantum interference transistor.
Figure 21. Cross-sectional view of a spinFET. The source and drain consists of highly doped dilute magnetic semiconductor in contact with ferromagnet source and drain metal. A spin precess 2DEG is formed at the interface of the InAlAs/InGaAs heterointerface.

The energies of the positive z-polarized and the negative z-polarized electrons are given by

$$E(+z \text{ pol.}) = \frac{\hbar^2 k_{x1}^2}{2m^*} - \eta k_{x1} \qquad (26)$$

$$E(-z \text{ pol.}) = \frac{\hbar^2 k_{x2}^2}{2m^*} + \eta k_{x2} \qquad (27)$$

Here, k_{x1}, k_{x2} are the electron wave vectors, η is the spin-orbit coupling constant, m^* is the effective mass of electrons, and $\hbar$ is Plank's constant. In the absence of inelastic scattering, the energy is invariant so that a differential phase shift is introduced between the up- and down-spin (or $+z$ pol. and $-z$ pol.), which is given for a spin FET with channel length L as

$$\Delta\theta = (k_{x1} - k_{x2})L = \frac{2m^*\eta L}{\hbar^2} \qquad (28)$$

The transistor action entails controlling or changing the spin-orbit coupling constant, which in turn changes the phase shift. This will effectively rotate or precess the spin of the electron and modulate the current. The spin-coupling constant is controlled by a gate voltage.

GLOSSARY

Ballistic device An electronic device with the feature size of its active medium being smaller than the mean-free path of electrons in the host material. Electrons transit the device with little or no scattering, thereby reaching ballistic speeds.

Gallium arsenide (GaAs) noanodevices Quantum-well, quantum-wire, and quantum-dot electronic and optoelectronic devices grown on semi-insulating GaAs substrate, with GaAs compounds serving as the active medium.

Hot-electron device A nanodevice in which the temperature of electrons, or carriers, exceed the temperate of the host material during its operation.

Nanodevice An electronic device with at least one of its feature size having dimensions of the order of a nanometer.

Quantum dot Heteroepitaxial thin-film structure with all three of its feature sizes of the order of a nanometer.

Quantum-dot device A nanodevice in which electrons are confined from moving freely along any of its dimensions. Electrons move by hopping from one *dot* to another.

Quantum-effect device Atomic scale device in which quantum mechanical phenomena such as diffraction, interference and electron hopping describe its behavior and performance.

Quantum interference device An electronic device whose operation is based on the constructive and destructive interference of electron waves.

Quantum well Epitaxially grown thin-film material system in which a narrow bandgap material, such as gallium arsenide (GaAs) is sandwiched between two wide-bandgap materials such as aluminum gallium arsenide (AlGaAs).

Quantum-well device A nanodevice in which electrons are confined from moving freely in one dimensions.

Quantum wire A heteroepitaxial thin-film structure with two of its feature sizes of the order of a nanometer.

Quantum-wire device A nanodevice in which electrons are confined from moving freely in two-dimensions.

Resonant tunneling The transport of electrons across a metallurgical interface of an electronic device or structure, when the electron energies are lower than the potential energy barrier arising at the interface.

Resonant tunneling device A device in which current is controlled by manipulating the tunneling of electrons across a potential energy barrier.

Single electron transistor A device whose operation relies on single-electron tunneling through a nanoscale junction.

Spintronic devices Quantum devices that combine electronics and ferromagnetic effects for their operation.

Superlattices Thin-film material system consisting of a large number of heterostructures.

CONTENTS

1. INTRODUCTION

When atoms are brought together to form a crystal, the energy levels of the electrons will merge to form bands of energy, in which electrons can only occupy the allowed bands separated by a forbidden bandgap. The band that is normally filled with electrons in the absence of thermal excitations (at $T = 0$ K) in semiconductors is called the valence band, while the upper unfilled band is called the conduction band [1]. The optical processes in semiconductors are mediated by transitions involving electrons in the conduction band and holes (the empty states) in the valence band. Electrons and holes can be injected into a semiconductor either by a voltage applied to electrical contacts at the surface of the crystal or by absorption of light.

The operating characteristics of semiconductor devices (e.g., diode lasers) depend critically on the physical properties of the constituent materials. At present, III–V compound semiconductors (which consist of elements from columns III and V of the periodic table), such as GaAs and InP, provide the material basis for a number of well-established technologies of electronic and optoelectronic devices and systems. Since the electronic and optical properties of semiconductors are completely determined by their band structures or crystal structures, in order to tailor the band structure one method is to alloy two or more binary compounds via an appropriate growth technique. Another method is to fabricate artificial heterostructures—quantum wells (QWs) and superlattices—at dimensions comparable to the electron or hole wavelength in the semiconductor

material (typically around 10 nm), in which a layer of one semiconductor is sandwiched between two layers of a larger bandgap material. As a result, the electrons and holes are unable to move freely in the crystal growth (confinement) direction. This confinement changes the density of the electron states and their specific energy levels, resulting in a totally new generation of quantum semiconductor devices (see Fig. 1).

Semiconductor diode lasers are small, efficient devices with typical dimensions of less than 1 mm. They are used in a wide variety of applications, ranging from the readout sources in compact disc players to transmitters in optical fiber communication systems. Similar to all lasers, a semiconductor diode laser is made of a gain medium providing the light amplification inserted between two reflective mirrors. It essentially exploits a forward-biased p–n junction to inject electrons and holes to generate light (photons). The device also consists of an optical cavity, which can guide the photons generated to achieve stimulated emission. The simplest way to make a mirror in a semiconductor is simply to cleave the crystal, and the facets will function as mirrors (often the facets are coated with antireflection and high-reflection layers to improve the laser performance and reliability).

The operation wavelength of semiconductor QW laser diodes is largely determined by the semiconductor bandgap. Figure 2 plots the bandgap vs. lattice constant for several families of III–V compound semiconductors. These direct bandgap semiconductors have emerged as the materials of choice for lasers that emit in the 0.7- to 1.6-μm wavelength range. For a long time, the alloy semiconductor $In_xGa_{1-x}As_yP_{1-y}$ grown on an InP substrate was the only material system for 1.3- to 1.55-μm-wavelength lasers used in optical fiber communications. Although InP-based lasers have proven successful for applications in optical communications, they have some drawbacks [2]: (1) The GaInAsP/InP laser has higher temperature sensitivity compared to shorter wavelength lasers that are grown on GaAs substrates, primarily due to the relatively small conduction band offset between InGaAsP and InP, $\Delta E_c / \Delta E_g = 0.4$ (about 0.6 for the GaAs/AlGaAs system), which allows electrons to escape from the QW when they have enough

thermal energy; (2) it is difficult to achieve single-step epitaxy in vertical-cavity surface-emitting lasers (VCSELs) in which high-quality distributed Bragg reflector (DBR) mirrors are required, since the refractive index difference of InP/InGaAsP is insufficient and the thermal conductivity is too poor to realize low-cost and high-performance long-wavelength VCSELs [3].

After the successful development of short-wavelength (850 nm) GaAs/AlGaAs VCSEL technology, the extension of light emission to the even more important 1.3-μm transmission window has been pursued to meet the demands of metro area network and optical switching and routers. One approach is using self-organized InAs-based quantum dots [4], in which the electrons are confined in three dimensions. Although 1.3-μm-wavelength quantum dot lasers have been demonstrated, they suffer from high temperature sensitivity and relatively low modulation speed. The second approach applies GaAsSb/GaAs type II QWs, however, with only modest success because of the gain blueshift with increasing current injection [5]. The last candidate for the 1.3-μm VCSELs is the GaInNAs/GaAs QW, which is discussed in this review.
Figure 2. Selection of ternary and quaternary III–V compounds (alloys) plotted as a function of energy gap and lattice constant.

Ga(In)N$_y$As$_{1-y}$ alloys have unique properties: Incorporation of nitrogen into Ga(In)As simultaneously decreases the lattice constant and the bandgap [6]. With 1% N incorporated, the bandgap of Ga(In)NAs is reduced by about 150 meV, exhibiting a giant bowing effect, which arises from the large difference in size and electronegativity of the As and N atoms. Therefore, with less than 2% of nitrogen incorporated into GaInAs, the emission wavelength of GaInNAs can be extended to 1.3 μm. Compared to the conventional GaInAsP/InP system, the GaInNAs/GaAs heterostructure offers several advantages. First, the GaInNAs/GaAs conduction band well is deeper and the electron effective mass is larger [7], thus providing better confinement for electrons and better match of the valence and conduction band densities of states. This should lead to a diode laser with higher operating temperature, higher efficiency, and higher output power [2]. Second, monolithic VCSELs can be straightforwardly fabricated using the well-developed GaAs/AlAs mirrors and selective wet oxidation of AlAs for current and optical confinement (the lattice mismatch between AlAs and GaAs is only 1592 ppm). Third, as compared to the control of group V composition in the InGaAs$_y$P$_{1-y}$ alloy, growth of the Ga(In)N$_y$As$_{1-y}$ alloy by molecular beam epitaxy (MBE) is relatively easy because atomic nitrogen is very active, resulting in the group V composition only determined by the N flux.

We review the present knowledge of dilute nitride Ga(In)NAs as well as the progress in the growth of high-quality GaInNAs materials and in realizing high-performance edge-emitting lasers and VCSELs. The review is divided into three main sections, which deal with the physical properties of Ga(In)NAs alloys, epitaxial growth, and state-of-the-art GaInNAs lasers.

2. GaInNAs MATERIALS

2.1. Ga(In)NAs Alloy

In the dilute regime of N $< 10^{18}$ cm^{-3}, the nitrogen atom acts as an isoelectronic electron trap in GaAs [8, 9]. The crystal potential is deformed at the N site such that a highly localized N-related state is formed due to the large difference in size and electronegativity of As and N. This isoelectronic N level is resonant with the conduction band about 180 meV above the conduction band edge [8]. The existence of this N-related state and the strong perturbation due to the introduction of N cause the dramatic band structure changes observed in Ga(In)N$_y$As$_{1-y}$ alloy [10]. The transition from nitrogen acting as an isoelectronic impurity to the formation of N-induced bands takes place in GaN$_x$As$_{1-x}$ grown on GaAs at $x \approx 0.21\%$. The corresponding mean distance between N atoms is about 30 Å.

2.1.1. Band Structure of GaNAs

The band structure of GaAsN is difficult to calculate, since alloys are not perfect crystals even if they have a perfect lattice. This is because the atoms are placed randomly and not

in any periodic manner. The bandgap of the alloy compound can usually be described by

$$E_g(A_{1-x}B_x) = (1-x)E_g(A) + xE_g(B) - x(1-x)C$$

where the so-called bowing parameter C accounts for the deviation from a linear interpolation between the two binaries A and B. The bowing parameter for conventional III–V alloys is typically a fraction of an electronvolt. However, it is surprisingly huge and composition dependent in GaN_xAs_{1-x} (∼26 eV for $x < 1\%$ and ∼16 eV for $x > 1\%$) [11]. Due to the giant bowing parameter, GaAsN alloys provide the opportunity to simultaneously decrease both the lattice constant and the bandgap with increasing N content. Unfortunately, it appears that when the N concentration increases, the alloy quality deteriorates dramatically as reflected by the very low photoluminescence efficiency and very short carrier diffusion length, impeding the potential application of Ga(In)Nas alloys in electronic and optoelectronic devices [2, 6, 12].

The carrier effective masses are fundamentally important in semiconductor lasers, as they determine the density of states (in a quantum well structure, the density of states in any subband is linearly proportional to the effective mass). The electron effective masses are greater in GaN_xAs_{1-x} alloy than in GaAs, whereas the hole effective masses are similar to those of GaAs. Values of $0.12m_0$ and $0.19m_0$ were reported for $x = 1.2\%$ and 2.0%, respectively (the electron effective mass of GaAs is $0.067m_0$) [13]. The observed trend of an increasing mass value with N content is in agreement with theoretical predictions [14, 15].

From absorption and photomodulated reflectance measurements [10, 16], the GaN_xAs_{1-x} alloy has been proven to have a direct bandgap and exhibits a decrease in the bandgap energy with increasing N composition. This can be explained by two main models: One is the two-level band-anticrossing model [15], and the other one is based on pseudopotential local density approximation (LDA) calculations [17, 18]. Recently, the empirical pseudopotential method has been adopted to yield detailed theories of many electronic anomalies and puzzling phenomena of GaAsN alloys [19].

2.2. Metastability of GaInNAs Alloys

Since Ga and N are smaller atoms than In and As, respectively, the bond configuration of Ga–As + In–N will be better lattice matched (thus, possess less strain) than that of Ga–N + In–As. On the other hand, the cohesive energies of the respective binary zincblende solids follow the sequence GaN > InN > GaAs > InAs (being, respectively, 2.24, 1.93, 1.63, and 1.55 eV per bond), so the (highly strained) Ga–N + In–As configuration is preferred in terms of bond energy [20]. Thus, in equilibrium, N prefers to be surrounded by In atoms ("local indium enrichment"), whereas As prefers to be surrounded by Ga. This type of short-range order is a novel feature of quaternary isovalent systems, leading to a significant blueshift of the bandgap (i.e., reduced bowing) with respect to random alloys. The interplay of growth conditions and metastability of GaInNAs alloys can explain many experimental findings [21].

2.3. Band Alignment in Ga(In)NAs/GaAs Heterostructures

One extremely important parameter in Ga(In)NAs/GaAs heterostructures is the band edge discontinuity produced when they are brought together, which has a large impact on the charge transport and recombination process in Ga(In)NAs/GaAs heterostructures and their potential device applications. Unfortunately, the experimental results are quite controversial, and both type I (the electrons and holes are located in the same layer) and type II (the electrons and holes are in different layers) band alignment were reported. Recent experimental results strongly favor a type I band alignment for this material system [22–24]. The studies of band alignment in Ga(In)NAs/GaAs have been based mainly on the effect of quantum confinement on the optical transition energies from strained Ga(In)NAs/GaAs QWs [25, 26].

The photoluminescence (PL) and PL excitation measurements of GaInNAs/GaAs QWs of different thickness have yielded important results: The conduction band discontinuity amounts to 80% of the bandgap difference and a strongly increased electron mass compared to InGaAs with the same In content is observed [27].

3. EPITAXIAL GROWTH

3.1. MBE/MOCVD

The key to growing semiconductor nanostructures is epitaxial growth techniques such as MBE and metal–organic chemical vapor deposition (MOCVD), which have had a tremendous impact on semiconductor physics and technology in the past decades. MBE and MOCVD are the techniques that allow monolayer (about 3 Å) control in the growth of the desired crystals. In MBE, atoms or molecules of the species (groups III and V) to be grown impinge upon the heated substrate in high vacuum (∼10^{-11} torr). The crystal growth is governed predominantly by a kinetic process. Achieving a stoichiometric III–V epitaxial growth lies in the surface chemical dependence of the sticking coefficient of the group V elements. Under proper growth conditions, the growth rate is only determined by the arrival rate of the group III elements. In MOCVD, the growth process is much more complex than that of MBE. The source materials in MOCVD are complex molecules (precursors) that are transported to the heated substrate in the reactor cell via a carrier gas stream. These reactants decompose in the heated zone above the substrate and growth takes place. Unlike MBE growth, the MOCVD process is mass transport limited, and the growth rate is dependent mainly on the partial pressure of the metal–organic reactants present in the reactor. A limiting factor of MOCVD, with respect to MBE, is carbon incorporation into the films, resulting from the organic nature of the precursors.

3.2. Characterization of Epitaxial Structures

X-ray diffraction is a powerful characterization technique (nondestructive) for providing very detailed information on epitaxial structures, which ranges from the determination of

the lattice constant of single epitaxial layers to studies of the structural parameters of superlattices and QW interfaces [28]. X-ray diffraction can probe large areas of the sample to a depth on the order of 10 μm, and X-ray rocking curves can be computer simulated to provide information on an atomic scale.

Another very useful characterization technique in studies of single QWs and superlattices is transmission electron microscopy (TEM). The TEM cross sections reveal the well and barrier thickness and provide some measure of sample uniformity. Cross sections imaged using (002) reflection yield detailed information on the strain distribution in the sample. The well–barrier contrast allows for evaluation of the interface abruptness [29].

The optical properties of epitaxial structures can be investigated by PL measurement, in which the carrier population is photoexcited with a pump laser and the recombination light is usually evaluated via a spectrum analyzer. It is fast and nondestructive and can provide valuable information of the bandgap of a material and QW spontaneous recombination as well as the crystalline quality of QWs via the shape of the PL spectrum (intensity and linewidth).

3.3. Growth of Ga(In)NAs/GaAs Heterostructure

The growth of high-quality Ga(In)NAs material on GaAs is not straightforward. It is essential that an alloy not be clustered or phase separated; otherwise, the material will not be very useful for optoelectronic devices and cannot be used in any reliable device process. Due to the large difference in size and bonding energy between N and As, it is difficult to achieve a good "mixing" in the Ga(In)NAs alloy formation process. Thus, nonequilibrium growth has to be applied to overcome the "natural dislike" of such materials. The most effective way is growth of GaInNAs at lower temperatures, which is one of the advantages of MBE over MOCVD (low-temperature growth would be a problem for MOCVD where decomposition reactions at the surface are difficult).

3.3.1. Growth of Ga(In)NAs/GaAs by MBE

Several nitrogen sources (e.g., NH$_3$, monomethylhydrazine, dimethylhydrazine, N plasma source, etc.) have been developed for MBE growth of dilute nitrides on a GaAs substrate. It has been shown that the best choice for growth of Ga(In)NAs by MBE is using a radio frequency (rf) plasma cell to generate an atomic nitrogen flux. In principle, the plasma (including ions and electrons) is produced by passing an rf electrical discharge through nitrogen gas at a low pressure. Due to the presence of very active atomic N, the group V composition of Ga(In)N$_y$As$_{1-y}$ is only determined by the arriving N flux at substrate temperatures below about 500 °C. In other words, the nitrogen content in the Ga(In)N$_y$As$_{1-y}$ epilayer is inversely proportional to the group III (Ga, In) growth rate, implying the sticking coefficient of atomic N is near unity [2]. These results are quite different from those of any other mixed column V, III–V alloy semiconductor (e.g., GaInAsP, GaInAsSb, GaInPSb), indicating that MBE-grown GaInNAs has certain advantages over InGaAsP in which the group V composition is

sensitive to changes in the growth conditions (temperature and group V fluxes) [30, 31], making control of the group V composition somewhat complicated.

3.3.2. Growth of Ga(In)NAs/GaAs by MOCVD

For growth of GaInNAs/GaAs by MOCVD, group III source materials of triethylgallium (TEGa) and trimethylindium (TMIn) have been used in combination with tertiarybuty-larsine (TBAs) and dimethylhydrazine (DMHy) [or 1,1-dimethylhydrazine (UDMHy)] as group V sources which decompose at a low temperature compared with that of often-used materials such as AsH$_3$ and NH$_3$ [32]. With DMHy as the N source, the MOCVD-grown samples showed a strong superlinearity in nitrogen composition against the nitrogen source flow, and the nitrogen composition increased with increasing growth rate, but decreased significantly by incorporating indium into GaNAs or by increasing the growth temperature [32].

The growth of GaInNAs using UDMHy as the N source is also quite complicated. Both the TBAs/UDMHy partial pressure ratio and the growth rate drastically influence N incorporation in the GaInNAs layers. It was shown that the key parameter for nitrogen incorporation in the GaInNAs/GaAs material system was the partial pressure of TBAs, and N incorporation was reduced with decreasing growth rate of GaInNAs. In addition, the N incorporation was also influenced by the In composition of the epitaxial layer [33].

3.4. Material Quality of Ga(In)NAs/GaAs Heterostructure

Since the growth window of GaAs is quite different from that of GaN, achieving Ga(In)NAs of high crystalline quality is very challenging. The growth of Ga(In)NAs at too high a temperature may result in surface segregation of nitrogen and clustering (or phase separation), which will deteriorate the crystalline quality [34, 35]. On the other hand, growth at too low a temperature leads to a high density of point defects (Ga vacancies, As$_{Ga}$, defect complexes) due to insufficient cation migration [36–38]. In addition, to reduce ion-induced damage of the growing layer, the plasma operating condition must be optimized to maximize the amount of atomic nitrogen in the beam flux.

Considering the large lattice mismatch between GaAs and GaN, even incorporating small amounts of N will give rise to a substantial tensile strain in pseudomorphic GaNAs on GaAs. The most promising range of N composition in Ga(In)NAs is around 2%, where the material quality is quite acceptable for device applications. Incorporation of more N atoms leads to a large amount of N interstitials and N clustering due to the large size mismatch between the solute and the solvent atoms [34, 37, 39]. Also, the photoluminescence (PL) efficiency degrades severely [2, 35, 40–42].

For the determination of the nitrogen content of Ga(In)NAs epilayers on GaAs, the X-ray diffraction (XRD) technique is often used. However, by XRD, the lattice spacings are determined and not directly the N content of the Ga(In)N$_y$As$_{1-y}$ alloys. Thus, the calculation of these values

requires assumptions on the variation of the lattice parameters and of the elastic constants with y. A linear interpolation (Vegard's law) between the values of GaAs and cubic-type GaN has been commonly assumed to be justified. On the other hand, although most N atoms are believed to occupy predominantly the As sublattice, the N atoms might energetically prefer moving out from their substitutional sites to neighboring interstitial sites [36, 39, 43]. It is shown that the formation of isolated interstitial nitrogen in GaNAs is unlikely because of its high formation energy in the lattice. Instead, N complexes such as As–N and N–N split interstitials are energetically favored to form, occupying a single lattice site [34, 37]. The formation of split interstitial N–As complexes induces a compressive strain in the epilayer, while N–N complexes cause less tensile strain as compared to the substitutional N_{As} atom [34].

Postgrowth annealing can significantly improve the PL efficiency of Ga(In)NAs alloys (the PL intensity typically increases by a factor of 10–100), which has been attributed to a significant reduction in the concentration of competing nonradiative defects [35, 36, 40, 44]. Both positron annihilation measurements and nuclear reaction analysis in conjunction with Rutherford backscattering spectrometry have been used to study the point defects present in MBE-grown Ga(In)NAs. The experimental data reveal a high density of nitrogen interstitials [$(2.3 \pm 0.2) \times 10^{19}$ cm^{-3}] and Ga vacancies [$(4.2 \pm 0.2) \times 10^{16}$ cm^{-3}]. The existence of a high density of N interstitials and Ga vacancies (part of the Ga vacancies may be converted into an arsenic antisite [38]) in the as-grown nitride–arsenide materials will significantly affect the device performance, since they introduce bandgap levels affecting the carrier capture and recombination as well as transport process. Therefore, Ga(In)NAs must be annealed to obtain device-quality material. It is also important to reduce the ion-induced damage and metastable neutral molecules N_2^* produced from the rf plasma source or to incorporate more indium into the epilayer, inhibiting the formation of the N interstitial. The role of indium is athreefold: (1) Adding indium reduces the bandgap; (2) highly compressive strain in the epilayer induced by In makes N atoms prefer the As sublattice rather than the interstitial sites [36]; and (3) incorporation of In can inhibit the formation of N-related clusters [45].

The annealing of GaInNAs/GaAs QWs also leads to a reduction in the PL linewidth, which is related to the more homogeneous In distribution [46, 47], as well as a blueshift of the PL spectra (typically in the range of 30–70 meV, depending on the growth and annealing conditions) as shown in Figure 3. The blueshift can be attributed in part to enhanced interdiffusion (As–N interdiffusion through a kick-out mechanism and/or vacancy assistant group III interdiffusion) [2, 36, 40, 47]. Another source of the blueshift is the rearrangement of the nitrogen nearest neighbor environments from Ga-rich to In-rich environments [20, 21], which reflects an interplay of growth conditions and metastability of the alloy. During the growth of GaInNAs, chemical bonding aspects dominate at the surface, which favor Ga–N bonds instead of In–N bonds. This surface state is frozen in during the nonequilibrium growth process. In contrast to the
Figure 3. Effect of rapid thermal annealing on the PL properties as a function of annealing time at 700 °C.

surface, In-rich nearest neighbor configurations of N ("local indium enrichment") are favored in bulk at equilibrium due to the dominance of local strain effects. Therefore, the frozen non-equilibrium bulk state can be transformed into the equilibrium bulk state by postgrowth annealing under appropriate conditions [20, 21]. Recently, we have used computer simulations of double crystal X-ray diffraction curves for as-grown and annealed 6-nm-thick Ga0.7In0.3N0.03As 0.97/GaAs multiple-quantum well (MQW) structures in conjunction with the photoluminescence experiments to clarify the origin of annealing-induced photoluminescence blueshift in GaInNAs/GaAs QWs. For samples annealed at 700 °C for 6 min, the atomic interdiffusion was negligible where the blueshift was significant. After annealing for 1 h, atomic interdiffusion was indeed observed, and the diffusion length of In and N were determined to be 0.6 nm and 1.0 nm, respectively. Our results indicate that short range atomic rearrangements in GaInNAs well layer dominate in the initial stage of annealing where the blueshift is significant; as annealing continues ($>= 700$ °C), the atomic interdiffusion across the QW interfaces takes place, which further blueshifts the emission.

In general, 7-nm-thick GaInNAs/GaAs QWs with In and N contents of about 35% and 1.7%, respectively allow us to achieve 300-K luminescence at 1.3 μm. To extend the emission of annealed GaInNAs/GaAs QWs to 1300 nm and beyond without deteriorating the material quality, GaNAs barriers have been grown instead of GaAs barriers. There are several advantages to GaNAs barriers: (i) The GaNAs barrier results in longer wavelength emission due to the reduced barrier potential; (ii) GaNAs acts as a source of nitrogen, which is believed to reduce out-diffusion of N from the QW; and (iii) the presence of tensile strain in the GaNAs barrier balances the highly compressive strain in the GaInNAs well layer, making the whole structure more stable [2, 48].

In attempts to further improve the structural and optical properties of the active region, a GaInNAs strain-mediating layer was inserted between the GaInNAs QW and the GaNAs barrier. It was found that the combination of strain-compensating GaNAs barriers and GaInNAs strain-mediating layers redshifted the PL emission due to

the broadening of the effective QW width and the reduction of In out-diffusion from the QW [48, 49].

3.5. Role of Sb in GaInNAs

The linewidth of the PL emission from a GaInNAs/GaAs heterostructure is extremely important from the physical and technological points of view. In general, there are two inhomogeneous broadening sources in these alloys: interface roughness and alloy potential fluctuations. It has been confirmed that the roughening of the growth front of GaInNAs, particularly at high In and N composition, can be reduced by incorporating Sb (<1%), which acts as a surface surfactant [50]. The incorporation of Sb in GaInNAs also improves the luminescence efficiency. Furthermore, it has been reported that the N incorporation rate is enhanced in GaAsSbN at a higher Sb content [51, 52]. Recently, a room-temperature lasing up to about 1.5 μm has been achieved by GaInNAsSb/GaNAsSb QW lasers (Sb incorporated 6–7%) [53].

3.6. Role of Hydrogen in GaInNAs

Since hydrogen is present during the growth (except for solid-source MBE) and the processing of semiconductor materials, considerable interest has been focused on the high chemical activity of hydrogen to passivate electrically active defects (including both n- and p-type dopants), which is likely due to the formation of a neutral complex with no dangling bond left [54]. Recently, the role of hydrogen in altering the electronic properties of InGaNAs/GaAs QWs has been investigated. The most remarkable effects observed are a decrease in PL efficiency and a blueshift in emission upon hydrogen irradiation. The optical properties are fully recovered by thermal annealing [55]. These phenomena can be accounted for by the formation of N–H bonds, which effectively passivate the N atoms in the lattice [55].

The incorporation of H also affects the electrical properties of GaInNAs materials [57]. It has been shown that H acts as an isolated donor in InGaNAs and makes the as-grown undoped samples slightly n type. Annealing above 700 °C reduces the hydrogen concentration and renders the samples p type [56].

4. QUANTUM WELL HETEROSTRUCTURE LASERS

The typical semiconductor laser diode consists of a thin slab of undoped active material sandwiched between p- and n-type cladding layers with larger bandgaps. The lower bandgap active region has a higher refractive index than the cladding, so that a transverse dielectric optical waveguide is formed. Modern semiconductor diode lasers utilize so-called separate-confinement QW heterostructures, which use a thinner QW carrier-confining active region ($\sim$10 nm) and a surrounding intermediate-bandgap separate-confinement region to confine the photons. Typically, QW lasers have threshold currents that are an order of magnitude below those of conventional double-heterojunction laser diodes fabricated from bulklike materials, because quantum confinement reduces the density of states in the active region and thereby lowers the number of injected carriers required

to invert the population. The other major attraction of QW lasers is their advantages in dynamic characteristics, which include a very high modulation speed, a low-frequency chirp, and a narrow linewidth.

Practical semiconductor diode lasers come in two basic configurations: those with in-plane cavities and those with vertical cavities (as illustrated schematically in Figs. 4 and 5, respectively). The planar geometry of the edge-emitting laser results in a beam emitted parallel to the surface of the substrate, while the vertical-cavity laser emits perpendicular to the substrate. Edge-emitting diode lasers have been in existence since the late 1960s. Vertical-cavity surface-emitting lasers (VCSELs) have been available from the beginning of the 1990s.

4.1. Broad-Area and Ridge Waveguide Edge-Emitting Lasers

For the assessment of material quality, broad-area lasers are often fabricated. Standard photolithographic processing is used to fabricate approximately 100-μm-wide oxide-defined stripes on the sample. Then the substrates are lapped and polished, n-type contacts are performed by alloyed Ni/Au/Ge/Au, and Ti/Pt/Au contacts are evaporated on the p side. Finally, various cavity lengths are formed by cleaving, and the resulting bars are cleaved into individual diodes for testing [58].

Another widely produced semiconductor laser is the index-guided single-mode laser. It is designed to propagate the lowest order ("fundamental") optical mode that has a *near*-Gaussian shape in both lateral and transverse dimensions [59]. A popular index-guided single-mode laser structure is the ridge waveguide laser, in which the waveguide in the plane of a p–n junction is provided by etching almost all of the p-side cladding region away from a narrow ridge (less than 5 μm in width). The two-dimensional optical mode is largely confined to the layer beneath the ridge. Contact metallization is fabricated on top of the ridge to channel light through the ridge waveguide and enable lasing.
Figure 4. Schematic of an in-plane (edge-emitting) diode laser.
Figure 5. Schematic of a vertical-cavity surface-emitting laser.

4.2. Implanted and Selectively Oxidized VCSELs

VCSEL fabrication generally involves establishing electrical contact to the anode and cathode of the diode and defining the transverse extent of the optical cavity. A method to achieve electrical confinement in a planar VCSEL topology is to utilize ion implantation [60]. Implantation of ions into the top DBR mirror can be used to render the material around the laser cavity nonconductive and thus to concentrate the injected current into the active medium. Fabrication of implanted VCSELs usually begins with the deposition of electrical contacts. Next, an implantation mask of photoresist or plated metal can be used to block the ions. Deep proton implants near the active region are used to define the transverse extent of the laser cavity.

Another method to achieve both electrical and optical confinement in VCSELs is to utilize selective oxidation of AlGaAs. Fabrication of selectively oxidized VCSELs begins with the deposition of electrical contacts. A silicon nitride mask is deposited and patterned on the wafer top to encapsulate the metal contact and to form an etch mask. Dry etching, such as reactive ion etching, is used to define mesas to expose the oxidation layers. The lateral oxidation extent of a layer within the etched mesa is controlled by the composition of the layer and the oxidation time. After oxidation, the nitride mask is removed to permit laser testing.

4.3. Characterization of Semiconductor Lasers

The semiconductor laser is unique in that the population inversion required to reach lasing threshold results from electrical charge injection into the active region. The accumulating electrical charge provides gain for the spontaneously emitted photons recirculating within the laser resonator. As the injection current is increased above its threshold value, the oscillation intensity builds up, and lasing results. Lasing is evidenced by both a sharp increase in output power and a narrowing of the broad spontaneous

emission spectrum into distinct lasing lines. From the light–current curve of a laser, its threshold current and slope efficiency can be obtained, while the current–voltage curve is principally characterized by its junction voltage and series resistance. The useful output of the laser is limited by multimode operation at the kink in its light–current curve, as witnessed by the broadening and steering of its lateral far-field pattern [59].

The temperature dependence of the laser characteristics is critical to device performance at high output powers, where the heat generation is highest. Some applications may require laser operation over a wide temperature range. The thermal characteristic is a result of the temperature dependence of the lasing threshold current [described by $J_{th}(T) = J_{th}^0 \exp(T/T_0)$], the thermal resistance of the laser and heat sink, and the conversion efficiency of the laser. In addition, the maximum temperature, T_{max}, at which continuous-wave (cw) operation can still be achieved, is determined by the heat resistance and the dissipation on the one hand and by the temperature dependence of the threshold current on the other.

Apart from the dc characteristics of QW lasers mentioned above, their dynamic characteristics also need to be evaluated to meet the requirements of optical communication. To examine the dynamic response of a semiconductor laser, small signal modulation is often adopted, in which the laser is biased at a point well above threshold and a small ac signal is applied to it. This approach provides important insight into the physics of the laser and how the laser design can be improved. In addition, the spectral properties of lasers are very important for high-speed transmission. In order to have no additional noise due to mode partition, single-mode lasers with side-mode suppression ratios, better than 30 dB, are preferred.

The reliability or lifetime of a semiconductor laser is an important factor to be considered, especially for its application in optical communication. The reliability of a laser is determined by dissipated heat, thermal stresses, current density, handling, and power density at the facet. All of these parameters are dependent on the waveguide structure, resonator configuration, thermal resistance, and packaging.

4.4. GaInNAs/GaAs Edge-Emitting Laser

Semiconductor lasers (see Fig. 4) emitting at 1.3 and 1.55 μm are key components for optical fiber communication systems. Currently, these lasers are predominantly based on GaInAsP alloys grown on InP substrates. They are quite sensitive to variations in temperature. This high temperature sensitivity is primarily due to Auger recombination and the weak electron confinement resulting from the small conduction band offset in GaInAsP/InP. The GaInNAs/GaAs heterostructures, on the other hand, with a deeper conduction band QW and a larger electron effective mass, will thus provide better confinement for electrons and better match of the valence and conduction band densities of state, which lead to a higher characteristic temperature (T_0) and higher operating temperature, higher efficiency, and higher output power [2, 61].

The first long-wavelength GaInNAs/GaAs laser operating at room temperature in the cw mode was reported in

1996 [62]. The laser emits at 1.18 μm with a threshold current density (J_{th}) of 1.83 kA/cm^2 and a T_0 of 126 K. Its structure consists of an active region of a single 6-nm-thick $Ga_{0.7}In_{0.3}N_{0.02}As_{0.98}$ well layer, a waveguide layer of 0.3-μm-thick GaAs, and 1.5-μm-thick n- and p-type $Al_{0.3}Ga_{0.7}As$ cladding layers doped to 5×10^{17} and 9×10^{17} cm^{-3}, respectively. Finally, a 0.2-μm-thick p$^+$-GaAs contact layer is heavily doped to 3×10^{19} cm^{-3} in order to minimize the contact resistance. After growth of the laser structure, it may not be necessary to carry out annealing if the cladding layers are grown at a temperature high enough to anneal out most of the nonradiative centers present in the GaInNAs QW.

The laser performance has also been found to depend strongly on the growth temperature of the active QW region [53]. A single-QW (SQW) laser grown under optimized conditions yields threshold current densities ($W = 20$ μm, $L = 800$ μm) as low as 450 A/cm^2 with wavelengths in the range of 1230–1250 nm. The laser thresholds decrease as the growth temperature of the active region increases up to 440 °C; beyond 440 °C, the threshold currents increase.

By introducing a strain-compensated barrier to GaInNAs/GaAs, it is possible to grow highly strained GaInNAs wells free of misfit dislocations and to increase the number of QWs in the laser structures. Growth of strain-compensated GaInNAs/GaAsP/GaAs/GaInP SQW laser structures has been proposed [40]. The active region of the laser consists of a single 6-nm-thick GaInNAs/GaAsP quantum well with two 100-nm-thick GaAs space layers sandwiched between $Ga_{0.49}In_{0.51}P$ cladding layers. Recently, high-performance strain-compensated $In_{0.4}Ga_{0.6}As_{0.995}N_{0.005}$ QW lasers, with a lasing emission wavelength of 1.295 μm, have been achieved by MOCVD utilizing AsH$_3$ and U-dimethylhydrazine (U-DMHy) as the group V sources. The threshold (J_{th}) current densities of the GaInNAs QW lasers have been measured to be 211 A/cm^2 ($L = 2000$ μm).

Truly high power GaInNAs/GaAs (emitting at 1.3 μm) SQW lasers have been achieved with a threshold current density down to 405 A/cm^2 for a 1000-μm-long cavity (at 10 °C) and 8-W cw output (10 °C) [63]. No catastrophic optical damage is observed at a facet power density of 30 mW/cm^2. Preliminary life tests carried out at $P_{out} = 1.5$ W and $T = 35$ °C for 1000 h indicate that the lasers are robust; no power degradation is found. For GaInNAs 3QW lasers, in which three $Ga_{0.65}In_{0.35}N_{0.017}As_{0.983}$ QWs with a thickness of 6–7 nm, separated by 20-nm barrier layers, are symmetrically inserted into the 300-nm-thick GaAs cavity, the laser ($L = 1120$ μm, $W = 100$ μm) exhibits very low threshold current density down to 680 A/cm^2 and a slope efficiency of 0.59 W/A (output per two facets) with wavelength around 1.29 μm. Using heat sinking at 10 °C, cw operation is demonstrated with output power of 2.4 W and 4 W under cw and pulsed operation, respectively [64]. The internal efficiency and losses are estimated to be 81% and 10 cm^{-1}, respectively.

To extend the lasing wavelength to 1.31 μm, increasing the nitrogen content in the GaInNAs quantum well has often been adopted, which results in much higher threshold current densities mainly due to the formation of the N-related nonradiative centers [36]. A GaInNAs SQW laser emitting at 1.3045 μm exhibits a threshold current density as high as 2.86 kA/cm^2 [65]. In our group, a GaIn-NAs/GaNAs/GaAs SQW laser structure has been designed and grown by solid-source molecular beam epitaxy using an rf plasma source. A threshold current density as low as 546 A/cm^2 was achieved for 1600-μm-long, as-cleaved shallow ridge stripe lasers emitting at 1.32 μm (20 °C). The characteristic temperature is 97–133 K in the temperature range from 20 to 80 °C. The internal quantum efficiency for these lasers is 80%, while the material losses are 7.0 cm^{-1}. Under cw operation, optical output up to 40 mW per facet was achieved at room temperature for these uncoated lasers [66, 67].

To achieve low threshold current and single-mode lasing, GaInNAs ridge waveguide lasers have been developed [68]. The emission wavelength is around 1290 nm at room temperature; the active region consists of two QWs. Lasers with as-cleaved facets show threshold currents as low as 21 mA with an efficiency of 0.25 W/A per facet. By high-reflection coating of one side (with a reflectivity of about 75%), the threshold is lowered to 16 mA and the efficiency increases to 0.35 W/A. The best laser achieved could be operated under cw conditions up to 100 °C and exhibits a T_0 of 110 K [44]. These values compare favorably to those of 1.3-μm InGaAsP/InP ridge waveguide lasers, where the typical T_0 is around 60 K.

To fully utilize GaInNAs edge-emitting lasers as Raman pumps or for nonlinear optical sources in channel switching, one must extend the wavelength over 1.4 μm and produce high power (>500 mW) in the single lateral mode. This is a key requirement for GaAs-based lasers to be competitive with their InP counterparts. With approximately 5% N incorporated in the QWs, a GaInNAs/GaAs laser with emission at 1.5 μm was achieved, while the threshold current density was extremely high (50 kA/cm^2) [69]. Recently, ridge waveguide lasers with cleaved facets and three GaInNAsSb QWs and GaNAsSb barriers have been fabricated. A maximum output power in excess of 70 mW and a slope efficiency of 0.21 W/A have been demonstrated. The emission wavelength is at 1.465 μm, and the minimum threshold current density is 2.8 kA/cm^2 [70].

4.5. Vertical-Cavity Surface-Emitting Lasers

Fiberoptic components commonly use two types of semiconductor lasers: edge-emitting lasers and VCSELs (see Fig. 5). The most prevalent gigabit-speed diode lasers at 1.55 μm in data communications and telecommunications are distributed feedback (DFB) edge-emitting lasers, which are based on the propagation of optical waves in a periodic grating to create strong mode selectivity. However, the edge emitters have numerous drawbacks in cost, manufacturability, and reliability. In contrast, VCSELs can be on-wafer tested. Large arrays of devices can also be fabricated to be used for the interconnection of data links in network computing and massive parallel computing. In the telecommunications industry, the VCSEL's uniform, single-mode beam profile (due to its short cavity length) is desirable for coupling into optical fibers. As a whole, VCSELs retain the following advantages over edge-emitting lasers: lower cost, lower power consumption, higher reliability, smaller size, easier testing, easier manufacturing and packaging, and more efficient coupling to fiber. The first VCSELs were

made by combining bulk active regions with metal mirrors. Subsequently, other approaches were tried, including dielectric mirrors, semiconductor distributed Bragg reflector (DBR) mirrors, and air–semiconductor DBR mirrors.

For a VCSEL, since the round-trip gain path length is very short, the reflectivities of the mirrors need to be very high. The only mirrors that can provide over 99% reflectivity are dielectric stacks created by growing quarter-wavelength-thick layers of semiconductors with alternating refractive indices, which are referred to as distributed Bragg reflectors (DBRs). For electrical-pump monolithic VCSELs, the DBR mirrors represent the most unique and challenging aspect of VCSELs. They serve a dual role, defining the laser cavity as highly reflective mirrors, as well as providing the pathway for current injected from the contact layers. Thus, the principal design issues associated with the DBRs are a trade-off between providing sufficiently high reflectivity for light generated in the cavity along with the lowest possible resistance for both electrons and holes transported to the active region [60].

In a typical VCSEL, as many as 60 individual semiconductor layers may be stacked within a structure that is only about 10 μm thick. After growth, conventional semiconductor processing techniques are used to define the laser and complete the device. VCSELs are most often fabricated with a circular aperture between 5 and 25 μm in diameter to enable single- or multiple-mode operation. Due to the high gain and small volume of the VCSEL structure, the lasers are very efficient and have low turn-on voltages, high modulation frequencies (can be directly modulated at speeds beyond 10 Gbps), and single longitudinal mode operation.

4.5.1. GaInNAs/GaAs Vertical-Cavity Surface-Emitting Lasers

As the Internet and data transmission continue to grow, a concurrent demand for higher bandwidth and decreasing costs makes the prospect of using VCSEL-based fiberoptic links very attractive. Presently, all commercial VCSELs are epitaxially grown on GaAs substrates, for which the standardized wavelength is 850 nm. At 1310 nm, however, due to the optical characteristics of a single-mode fiber (relatively low attenuation and minimal dispersion), the optical signal is capable of traveling much greater distances than can be achieved with 850-nm wavelengths. Therefore, 1310-nm VCSELs are the ideal solution for short to intermediate distances (less than 20 km) for telecommunications and data communications applications.

Despite the strong demand for 1310-nm VCSELs, the ability to grow an optimal combination of a high-quality active region and high-reflectivity mirrors with low electrical drop is technologically challenging. Furthermore, considering the higher free-carrier absorption of the p-type DBR mirrors at 1.3 μm than at 850 nm (the free-carrier absorption increases as λ^2), the mirror design for 1.3-μm VCSELs is far more challenging than for 850-nm VCSELs. The above-mentioned problems suggest that modifications to the conventional VCSEL structure are needed for achieving high-performance, long-wavelength devices.

The first VCSELs with an active region of GaInNAs/GaAs QWs, emitting around 1.2 μm, were realized in 1998 [71]. The etched-pillar VCSEL was designed for substrate emission to avoid optical losses. The epitaxial layers were grown by gas source MBE (As$_2$ was produced from cracked AsH$_3$). The bottom mirror was a 25.5-period Si-doped GaAs–AlAs n-type DBR. A single 7-nm-thick Ga$_{0.7}$In$_{0.3}$N$_{0.004}$As$_{0.996}$ QW was located at the center of the GaAs cavity. Above the cavity was a 21-period Be-doped GaAs–AlAs p-DBR with parabolically graded interfaces to reduce series resistance. A Ti–Au contact electrode, combined with a p-phase-matching layer and cap, enhanced the reflectance of the p-DBR. Electrical contact to the n substrate was made using indium solder. Room-temperature pulsed operation was achieved with a threshold current density of 3.1 kA/cm^2, a slope efficiency of 0.04 W/A, and an output power above 5 mW for 45-μm-diameter devices. Laser oscillation was observed for temperatures as high as 95 °C.

With a similar design, room-temperature cw operation of oxide-confined GaInNAs/GaAs VCSELs emitting at a wavelength of 1.2 μm was demonstrated later, in which the active region was embedded in a one-wavelength-long cavity and consisted of three 7-nm Ga$_{0.7}$In$_{0.3}$N$_{0.02}$As$_{0.98}$ QWs separated by 20-nm GaAs barriers [72]. The VCSELs were grown by solid-source MBE and the threshold current was as low as 1 mA and the slope efficiency above 0.045 W/A. Pulsed threshold current varied from 0.89 mA for 3.6-μm devices to approximately 21 mA for 29-μm sizes. The threshold current density was within the range of 2–2.5 kA/cm^2 at larger sizes, and a slope efficiency above 0.09 W/A was achieved. The slope efficiency dropped for aperture sizes below 7 μm, which was likely due to optical scattering, and the current density rose to nearly 7 kA/cm^2 for the smallest (3.6 μm) devices.

GaInNAs/GaAs VCSELs with a conventional p–n structure were also demonstrated. The growth was done in two separate MOCVD systems. The devices achieved cw room-temperature operation with a threshold current of approximately 7.6 kA/cm^2, a slope efficiency of 0.1 W/A, and an output power of 100 μW at 1.26 μm from a 10 × 10 μm^2 aperture with a threshold voltage of 2.8 V [73].

Truly 1300-nm GaInNAs VCSELs were demonstrated much later, in which a p^{++}/n^{++} tunnel junction was inserted at the first optical node above the microcavity to convert electrons into holes and then uses a second n-type DBR mirrors [74, 75]. The VCSELs were grown by MBE. The threshold current was 0.9 mA (5 kA/cm^2), and the threshold was 4.3 V. A maximum output power of 0.77 mW was obtained, and the peak differential efficiency was 0.24 W/A. The device with a large aperture (15 × 18 μm^2) exhibited a maximum cw output power of 2.1 mW. For a 5 × 5-μm^2 device, cw operation at temperatures as high as 105 °C was achieved. Devices with the more conventional p–n structure exhibited output characteristics similar to the tunnel junction devices. The threshold current density was 4.4 kA/cm^2, and the threshold voltage of 2.7 V was significantly smaller than that for the tunnel junction devices. Undoubtedly, the tunnel junction in that device contributes significantly to the voltage drop. Further improvements in the tunnel diode design may enable significantly lower device voltages without substantial increases in absorption losses.

Table 1. VCSELs on GaAs substrates.

Research group	λ (nm)	Active region	Growth method and design	Single-/ multimode	P_{out} (mW)	I_{th} (mA) V_{th} (V) @RT	J_{th} (kA/cm^2)	Remarks	Ref.
Infineon	1293	GaInNAs	MOCVD, intracavity	SM	1.40@25 °C 0.50@85 °C	1.25 1.06	3	cw, 10 Gb/s, SMSR > 40 dB	[80]

Cielo	1289	GaInNAs	MBE, p–n	SM	0.98@20 °C	2.9 2.2	—	cw, f-3 dB 7 GHz, SMSR > 50 dB	[85]
Ioffe Inst., Tech. Univ. Berlin	1300	InAs QDs	MBE, intracavity	MM	0.65@25 °C	1.2 1.5	1.5	cw, $P_{out} < 0.1$ mW@ 45 °C	[86]

To completely avoid the problems of optical losses and voltage drop in the mirrors, a double-intracavity contact design was proposed [76–78]. The MBE-grown VCSELs (oxide aperture 4×6 μm^2) exhibit an output power of more than 1 mW at room temperature with a wavelength of 1306 nm. Lasing in cw operation can be maintained up to 80 °C. The threshold current at room temperature is 2.2 mA, and the side-mode suppression ratio at a typical drive current of 5 mA (for 2.5 Gbit s^{-1}) is better than 30 dB, but near the thermal rollover it drops to about 10 dB. For MOCVD-grown GaInNAs VCSELs with the same structure, a record P_{out} of 1.4 mW (cw single mode with a side-mode suppression ratio greater than 40 dB) at room temperature and 0.5 mW at 85 °C have been obtained. The cw threshold current is 1.25 mA, and the wavelength is 1.293 μm. The threshold voltage is 1.06 V, which is remarkably lower than the voltage drop in tunnel junction VCSELs. This approach appears to be the most suitable for preparing low-threshold VCSELs of small sizes, while disadvantages are current crowding and nonuniform injection at power levels significantly higher than 1 mW. Modifications to the device structure could be a single-intracavity contact design, in which the top DBR mirrors are undoped and current driven through the bottom DBR mirrors [79].

The emission dynamics and the optical gain of 1.3-μm GaInNAs/GaAs VCSELs have been investigated both experimentally and theoretically [78]. An ultrabroad temperature operation range between 30 and 388 K with picosecond emission dynamics has been demonstrated. The shapes and widths of the gain spectra are similar to those of GaInAsP/InP at moderate carrier densities, while at higher densities the gain spectra broaden considerably. These results can be well described by the microscopic theory.

The data transmission properties of GaInNAs VCSELs are encouraging. It has been demonstrated that transmission rates up to 10 Gbit/s in a back-to-back configuration and 2.5 Gbit/s for transmission over 20.5 km using a standard single-mode silica fiber with a power penalty of only 0.5 dB over this distance [77, 80]. Clearly, the 1.3-μm VCSELs possess excellent capabilities for high-speed communications, incomparably better than those of their 850-nm counterparts.

Table 1 gives a selected list of performance characteristics of various 1.3-μm VCSELs, as reported in the literature. There are clearly many parameters not yet optimized for these devices, but the results to date demonstrate that the GaInNAs/GaAs material system is the most promising candidate for 1.3-μm VCSELs. Still, further improvement is desirable, since the performance of these devices lags that of the well-developed 850-nm VCSELs considerably.

5. SUMMARY

We have reviewed the physical properties of Ga(In)NAs alloys as well as their application in quantum well lasers for optical communications. Although substantial improvements have been made in the material quality and in the laser characteristics in recent years, there are concerns about the reliability of GaInNAs/GaAs lasers. Therefore, further improvements of both materials and device designs will be required to realize high-performance, reliable 1.3-μm GaInNAs lasers for optical communications.

GLOSSARY

Distributed Bragg reflector (DBR) Many-layered structure consisting of semiconductor material with contrasting refractive index and thickness such that the reflected components of the electromagnetic wave from the layers interfaces arrive in phase with each other and superpose to create a highly reflective mirror.

Electronegativity The tendency (or power) of an atom in a molecule to attract electrons.

Epitaxial structures Thin films, grown on single-crystal substrates, with the same crystal structure and orientation as the substrate.

Photolithography Pattern definition method that uses UV radiation to expose the resist.

p–n junction It consists of two semiconductor regions of opposite type and shows a pronounced rectifying behavior.

Rocking curve Intensity versus angle plot for X-ray scattering.

Stimulated emission The photons emitted are coherent with the photons already present and the rate is proportional to the existing photon density.

Superlattice Repeated sequence of layers forming a period structure.

1. INTRODUCTION

1.1. Importance of Nanomaterials

In 1959 Richard Feynman, the future Nobel Laureate, suggested in his famous lecture, entitled "There's Plenty of Room at the Bottom," a variety of tests that might be achieved at very small scales. Three decades later, Feynman's vision has become the greatest scientific frontier of the century. It opened a new field of "nanoscale materials" having microstructures with characteristic length scales of the order of a few (typically 1–100) nanometers. Nanoscale materials can often display chemical, optical, electric, magnetic, and thermal properties, which are both quantitatively and qualitatively different from their respective bulk materials and from the discrete atomic or molecular species from which they are derived. The intriguing alteration of these properties allows nanoscale materials to have numerous potential applications in various areas such as materials and biomedical sciences, optics, magnetism, electronics, catalysis, ceramics, energy storage, gas sensors, and electrochemistry. In almost all applications of nanoscale materials, fabrication represents the first and one of the most significant challenges to their realization. Many methods for the fabrication of nanoscale materials have been developed, ranging from lithographic techniques to sputtering, from the sol–gel method to chemical vapor deposition (CVD), from grinding to a template-based method, and from the microemulsion method to the γ-irradiation method, etc. Among these methods, the γ-irradiation technique has some special advantages such as processing at room temperature and ambient pressure, high yield, as well as easy control of particle size and size distribution. Therefore, the γ-irradiation technique has been more and more widely used to prepare nanocrystalline metals, alloys, metal oxides, metal sulfides, and nanocomposites since it can provide high energy and an evenly distributed irradiation field. The intent of this chapter is to provide an overview of the γ-irradiation technique as a promising method for fabricating nanoscale materials.

1.2. Phylogeny of γ-Irradiation Technique

Above all, it is necessary to illustrate the phylogeny of the γ-irradiation technique. In 1962, Fujita et al. began the synthesis of metal aggregates by the radiolytic reduction of metal cations in solution [1]. In 1982, Belloni et al. reported microaggregates of non-noble metals and bimetallic alloys obtained by radiation-induced reduction for the first time and used a magnet to separate the products, which were carefully examined by electron microscopy [2]. In recent decades, this method has been developed further [3–5]. The technique of pulse radiolysis has been used to study the yield of short-lived clusters and their optical spectra in dilute aqueous solutions of about 10^{-4} M metallic ions [6–8]. By this method, silver cluster and colloidal silver could form [9, 10]. The formation of other colloidal metals from corresponding ions such as Cu^{2+} [11–13], Ti^{4+} [14, 15], Pb^{2+} [16, 17], and Pd^{2+} [18] has also been studied. By high-energy electron irradiation of 1.7×10^{-4} M $NaAu(CN)_4$ solution, Mosseri et al. [19] prepared ultrafine Au particles. Marignier et al. [20] prepared ultrafine Ni and Cu–Pd alloy particles by separate γ-irradiation of $NiSO_4$ and $CuSO_4$–$PdCl_2$ solution. Several years later, the radiolytic generation and control of extremely small CdS particles [21] were first described by

Hayes and co-workers. However, the solutions used in the aforementioned studies are about 10^{-4} M metal ions, and the ultrafine particles produced are in the colloidal soluble state. Later, study of the γ-irradiation of more concentrated solutions containing 10^{-2}–10^{-3} M metal ions produces nanoscale metal, which thus makes the γ-irradiation technique become the new focus of nanoscience and extends to the fabrication of nonmetals, alloys, metal oxides, metal sulfides, and nanocomposites with all kinds of nanostructures.

2. γ-IRRADIATION TECHNIQUE TO INORGANIC NANOMATERIALS

2.1. Noble Metals and Their Alloys

2.1.1. γ-Irradiation–Hydrothermal Technique

Noble metals are the first objective class studied by the γ-irradiation technique to prepare nanomaterials. On the principle of γ-irradiation reactions, during γ-irradiation, the formation of hydrated electrons can be shown as follows [22, 23]:

$$H_2O \sim\sim\longrightarrow H^{\bullet}, {}^{\bullet}OH, e_{aq}^-, H_3O^+, H_2, H_2O_2, HO_2, H_2O^* \tag{1}$$
Then, the radiation reduction of metal ions by hydrated electrons leads to the formation of metal nanoparticles:

$$e_{aq}^- + M^{m+} \rightarrow M^{(m-1)+} \tag{2}$$

$$e_{aq}^- + M^+ \rightarrow M^0 \tag{3}$$

$$nM^0 \rightarrow M_2 \rightarrow M_n \rightarrow M_{agg} \tag{4}$$
where n is a number of aggregations of a few units, M_n is cluster colloid, and M_{agg} is the aggregate in the final stable state [12].

The typical experimental process can be described as follows: A solution containing metal salts of appropriate concentration (10^{-2}–10^{-3} M) was irradiated in a ^{60}Co γ-source at appropriate dose for a long time to precipitate powders, then filtered out and washed. It should be mentioned that appropriate $(CH_3)_2CHOH$ as scavenger to eliminate hydroxyl radicals needs to be added to the reaction system.

$${}^{\bullet}OH + (CH_3)_2CHOH \rightarrow H_2O + (CH_3)_2COH^{\bullet} \tag{5}$$

In the experimental process, salt concentration, irradiation time, and dose can be adjusted.

Based on the absorption spectrum studies on after-irradiated solution [24], it was found that not only were the above three parameters crucial to the formation of noble metal clusters and colloids, but also appropriate surfactant should be added to stabilize the formed small clusters and colloids. It seems reasonable [25] to attribute the stabilizing effect of the surfactant molecules to the adherence of their long hydrocarbon chains to the surface of colloidal silver particles, the anionic head groups sticking out into the aqueous surroundings and thus keeping the aggregates dispersed as colloidal silver in solution, as Scheme 1 shows.
Scheme 1. Schematic presentation of the cross section through a silver–surfactant aggregate.

With increasing surfactant concentration, the hydrocarbon-like layer at the surface of silver particle may be expected to become more complete and thicker; this favors the formation and stabilization of small clusters and colloidal silver.

In the experimental process, noble metal clusters were found to exist for more than one month in γ-irradiated concentrated saltsolution in air. This is much longer than that in dilute metal ion solutions previously reported [26–32]. Thus, the hydrothermal treatment was used to aggregate the colloid to metal powders. This process to prepare nanoscale noble metals was called the γ-irradiation technique. For example, in the case of preparing silver nanocrystals, the as-obtained silver solution was then hydrothermal-treated for several hours at about boiling point. As a result of transmission electron microscope (TEM) studies, it was found that the shape of the silver particles produced by γ-irradiation depended on the surfactant used. For example, when sodium dodecyl sulfate is used as a surfactant, the silver particles are uniform quasispherical (Fig. 1a). Under appropriate conditions, some silver dendrites can be obtained (Fig. 1b). However, when poly(vinyl alcohaol) is used, the silver particles have various shapes.

From these results, it can be concluded that the γ-irradiation technique is an excellent method to prepare nanoscale noble metals with as-desired nanostructures, combined with additional methods such as surfactant-assisted process. However, to get over the shortcoming that the produced metal colloids are difficult to aggregate and the as-obtained metals have poor crystallinity by γ-irradiation, the hydrothermal treatment should be used. This technique can be applied to synthesize nanoscale Ag [24], Cu [33, 34], Pd, Pt, and Au [35].

By adding a complex agent such as $NH_3 \cdot H_2O$ into the reagent mixture, this technique can be extended to prepare their alloys [36, 37]. The complex agent is used to adjust
Figure 1. TEM images of silver nanocrystals prepared by the γ-irradiation method. the condition of the solution, which may be caused by the change in the rate of reduction reactions of noble metal ions during γ-irradiation resulting from the complexation of metal ions with the complex agent. On the other hand, the ligand on metal ions may act as a bridge for electron transfer from the solution to the metal ions.

2.1.2. Fractal and Dendritic Growth of Metallic Silver Studies under γ-Irradiation

Many physical, chemical, technological, and biological processes exhibit noninteger (or fractal) dimensionality as was recognized by Mandelbrot in his studies on complex geometrical shapes [38]. Fractals are generally observed in far-from-equilibrium growth phenomena; hence they provide a natural framework for the study of disordered systems. There are many reports on the study of fractal structures and their formation in both theoretical and experimental aspects in the past decade. Electrochemical metallic deposition [39–41], fluid and air displacement in other media [42, 43], and dielectric breakdown [44] are a few experimental examples that are important for understanding general aggregation processes and establishing model simulation. The diffusion limited aggregation (DLA) model [45, 46] and cluster–cluster aggregation (CCA) model [47, 48] are widely used to explain and analyze these phenomena. The aggregating process of particles in a Laplacian field can be described by the DLA model, which involves cluster formation by the adhesion of a particle with random walk to a selected seed on contact. The resulting structure of the DLA model has a fractal dimension $D \sim 1.7$. Aggregation of small particles in a fluid medium, for example, metal colloids, can be depicted by the CCA model. Two limiting regimes of CCA aggregation have been accepted [49]: fast diffusion-limited cluster aggregation (DLCA) and slow reaction-limited cluster aggregation. In the DLCA regime, the fractal dimension D of the grown structures is about 1.45 in two dimensions

($d = 2$) and may increase to 1.75 ± 0.07 in a system of high initial particle density as the system approaches the sol–gel transition [50].

Since it was found that some silver dendrites could form via the γ-irradiation technique in the presence of surfactant more studies on their aggregating process should be put forward to reveal their mechanism [51]. With γ-irradiation on AgNO$_3$ dissolved in deionized water (a), ethanol (b), and C$_{12}$H$_{25}$NaSO$_4$ aqueous solution (c), the as-obtained products were determined by TEM images (Fig. 2). For measuring the dimensions of Ag fractals, TEM images were digitized by the use of an OPTON image analyzer at 512×512 pixels. A threshold criterion was then applied to separate pixels in the fractal regions from the background. The fractal dimension (D) was obtained by using the box-counting algorithm [52]. In this method, the digitized images were covered with a grid of squares.

The aggregating morphology of sample A is regular dendritic patterns along three different directions and with a fractal dimension of 1.81. Due to the restraining effect of ethanol and surfactant, the produced smaller silver particles of samples B and C aggregated to fractal patterns with center with a fractal dimension of 1.73 and without center with dimension of 1.70, respectively. The former two cases share common characteristics with the DLA model.

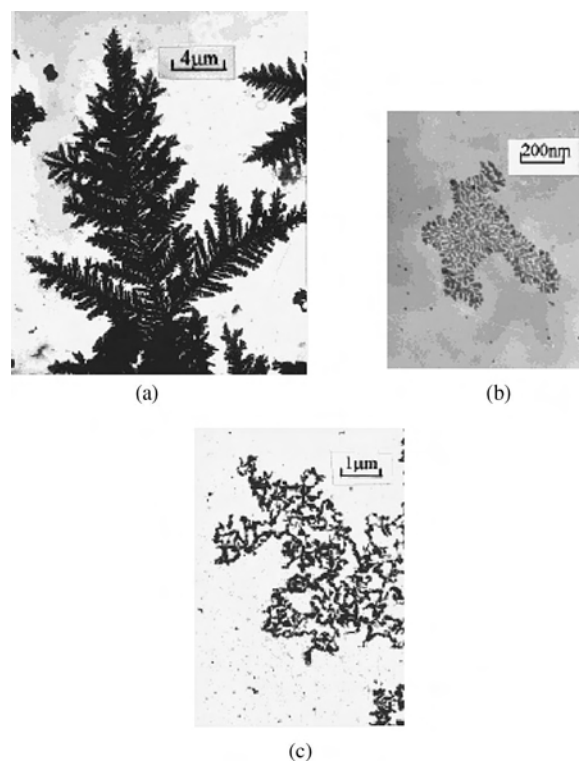
On the basis of these dimension calculations, the aggregating process of fractal and dendritic growth was given. First, silver particles formed in γ-irradiation, and ethanol and surfactant might prevent them from aggregating. Then,


Figure 2. TEM images of Ag colloids prepared (a) in aqueous solution; (b) in ethanol; (c) in C$_{12}$H$_{25}$NaSO$_4$ aqueous solution. Reprinted with permission from [51], S. Z. Wang and H. W. Xin, *J. Phys. Chem. B* 104, 5681 (2000). © 2000, American Chemical Society.

the aggregation of Ag particles on the C-coated Cu grid could cause van der Waals attraction between metallic Ag particles. By γ-irradiation on AgNO₃ aqueous solution (solution A), the Ag particles obtained were relatively large and these Ag particles were single crystals as determined from X-ray diffraction (XRD) patterns. When the turbid liquid was dripped onto the C-film of the Cu grid, the Ag particles crystallized on the edge of the tiny irregular edge of the Cu grid and involved low-angle grain boundaries. The other Ag particles, once absorbed on the surface of the aggregate from the turbid fluid, diffused with a random walk until they irreversibly stuck to the perimeter of the growing aggregate. According to the former reports, the dendritic patterns are formed only when the anisotropy dominates noise [53]. Anisotropy, which is essential for the formation of dendritic pattern, can come from the interaction between the background and aggregating particles [54] or the anisotropy of the growing crystalline itself [55]. In the present experimental system, the aggregation of Ag particles took place in a two-dimensional C-film-coated Cu grid. The substrate of C-film was amorphous and the medium was also isotropic; no noise was induced into the growth system. The anisotropy, which causes dendrite patterns of the aggregate, comes from the Ag particles themselves. Because the single crystals of Ag particles intrinsically contain a strong crystalline anisotropy, the aggregation of Ag particles was mainly along the preferred growth direction and, accordingly, brought about a dendrite pattern. On the other hand, the large Ag particles have lower mobility; they cannot change their position or growth direction freely under the agent of anisotropy and grow strictly along the preferred growth direction. Consequently, the final aggregation pattern was not very regular shaped branches, or oriented on definite directions.

The metallic Ag prepared in ethanol has a smaller particle size and formed fractal patterns as aggregation took place. This can be assumed for the following reasons: first, nanoscale Ag grains contain a significantly higher percentage of their atoms at the grain boundary and the distortion of lattice in the surface layer. These nanocrystalline characteristics decreased the crystalline anisotropy of Ag particles. Second, solvation occurred on the surface of Ag particles. The interaction of metallic surfaces with the solvent makes the surfaces become homogeneous; thus, Ag particles lost the anisotropy. When these Ag particles were absorbed on the C-film from the solution, they walked and stuck to the surface of aggregate randomly and formed typically fractal patterns.

The occurrence of Ag colloid by γ-irradiation on solution C was due to $C_{12}H_{25}NaSO_4$, which was absorbed on the surface of the Ag particles and prevented the Ag particles from aggregating. Following the standard theory of colloids, the stability of a colloid is governed by the balance between van der Waals attraction and Coulombic repulsion of charged particles [56]. Enhancing the van der Waals attraction force or weakening the Coulombic repulsion force induces rapid coagulation of colloids. When this Ag colloid was dripped onto the C-coated Cu grid, the evaporation of solvent resulted in the break of the balance and the aggregation took place. The final aggregates were random, tortuous structures and have no center (i.e., there were no seeds for

the aggregation of Ag particles). This process is analogous to the two-dimensional DLCA simulation.

The above analyses indicate that producing small silver particles in a surfactant-assisted system is crucial to form fractal patterns. The γ-irradiation technique has characteristics of dispersive energy and mild conditions, which are suitable for building a surfactant-assisted system. This further confirms that the γ-irradiation technique is an excellent pathway to form fractal patterns.

2.1.3. γ-Irradiation with Organic Capping Technique

Although the surfactant-assisted process is suitable for obtaining better-dispersed noble metal nanoparticles, it is difficult to control their sizes by adjusting some parameters. Thus, an organic capping technique was substituted for the surfactant-assisted process. For example, a γ-irradiation reducing route with citrate capping [57] was designed to prepare silver nanoparticles with different sizes: appropriate sodium citrate and N_2O were added to the irradiated reaction system. By adjusting the citrate concentration, the as-obtained products were well-dispersed colloidal nanoparticles with different sizes (Fig. 3). The reaction mechanism was identified as

$$\cdot OH(\cdot H) + (CH_3)_2CHOH \rightarrow H_2O(H_2) + (CH_3)_2C\cdot OH \tag{6}$$

$$e^-_{aq} + N_2O + H_2O \rightarrow N_2 + OH^- + OH \tag{7}$$

$$Ag^+ + (CH_3)_2C\cdot OH \rightarrow Ag^0 + (CH_3)_2CO + H^+ \tag{8}$$

$$Ag_x + citrate \leftrightarrow Ag_{x(citr)} \tag{9}$$

$$Ag_{x(citr)} + Ag_{x(citr)} \rightarrow Ag_{2x(citr)}, etc. \tag{10}$$
Figure 3. TEM images of silver colloidal nanoparticles obtained at various citrate concentrations. MT: multiple twinned particles. SP: particles with staple faults. Reprinted with permission from [57], A. Henglein and M. Giersig, *J. Phys. Chem. B* 103, 9533 (1999). © 1999, American Chemical Society.

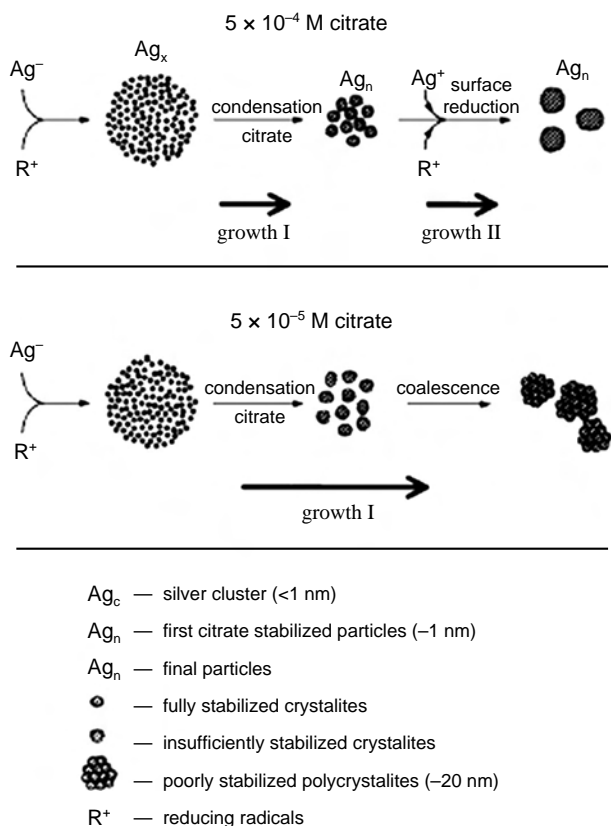
$$Ag_{m(citr)} + n(CH_3)_2C^{\cdot}(OH)$$
$$\rightarrow Ag_{m(citr)}^{n-} + n(CH_3)_2CO + nH^+ \qquad (11)$$

$$Ag_{m(citr)}^{n-} + Ag^+ \rightarrow Ag_{(m+1)(citr)}^{(n-1)-} \qquad (12)$$
By studying the size and size distribution of the silver particles formed at various citrate concentrations, the formation process of nanoparticles can be described as in Scheme 2.

This technique has also been applied to prepare copper nanocrystals [58] with different sizes.

2.2. Active Metals and Nonmetals

The preparation of monodispersed active metals and nonmetals is always a challenge due to their high reaction activity and low melting point, respectively. Since the γ-irradiation technique has been successfully developed to prepare nanoscale noble metals, it can be extended to the active metals and nonmetals field, which overcomes the above hindrances.

Active metals, for example, nickel ions, can be reduced under γ-irradiation and form small clusters. However, the


Scheme 2. Illustration of important routes of particle growth at two citrate concentrations. At the higher citrate concentration, the stages of nucleation and growth are well separated. At the lower citrate concentration, coalescence reactions of growing particles contribute to particle enlargement. Reprinted with permission from [57], A. Henglein and M. Giersig, *J. Phys. Chem. B* 103, 9533 (1999). © 1999, American Chemical Society.

zero valence state of nickel, which resulted from the two-electron transfer, could also undergo oxidation:

$$Ni_n + H_3O^+ \rightarrow Ni_{n-1} + Ni^+ + 1/2H_2 + H_2O \qquad (13)$$
Thus, selecting the appropriate pH condition is crucial to the preparation of active metals. For example, in the presence of $NH_3 \cdot H_2O$ [59], which acts as an alkalizing agent, the pH value of the solution is kept in the range of 10 to 11, so the reoxidation of atoms or aggregates of nickel in solution is greatly suppressed. It is obvious that the γ-irradiation technique can remain in a reductive environment and hold back the reoxidation of products under appropriate pH condition, which provides a pathway to prepare active metals (Ni [59] and Co [60]).

Some nanocrystalline metals (Cd [61], Sn [62], Sb [63], and In [64]) with low melting points can also be prepared by similar routes. Compared with other methods such as electrolysis and reduction with more active metals [65–67], the particle size of as-prepared nanoparticles by γ-irradiation was smaller.

In the case of nonmetals, selecting an appropriate precursor is the key problem. For example, to prepare nanoscale selenium, the most familiar selenium source is SeO_2 (IV). How can we transform it to a form that can contain hydrated electron best? It is well known that selenium (IV) exists as Se^{4+} ions and SeO_3^{2-} ions in hydrochloric acid and NaOH solutions, respectively. The reduction of SeO_3^{2-} ions was more difficult than that of Se^{4+} ions, which is due to the stability of SeO_3^{2-} ions caused by the strong covalent bonding between selenium and oxygen. So a hydrochloric acid system should be chosen to prepare selenium nanoparticles [68] (Fig. 4a) from SeO_2.

Nanoscale Te [69] and As [70] uniform particles (Fig. 4) have also been successfully prepared by γ-irradiation of an aqueous solution of TeO_2 and As_2O_3, respectively. From the above process, it is found that the γ-irradiation technique avoids thermal treatment and overcomes the difficulty of nonmetals' low melting point.

2.3. Metal Oxides

Many metal oxides have poor stability, resulting from the fact that they are easily oxidized in air. For example, cuprous oxide nanocrystals are difficult to prepare via regular methods. The γ-irradiation technique is advantageous for the maintainance of reductive environment and can prevent as-prepared products from oxidization. However, cupous ions will partially be reduced to elemental copper in the reagent solution with a pH value of about 3.0–3.5 and the final product is a mixture of copper and cuprous oxide. In this case, the adjustment of pH value is crucial to the value state of final products. When the solution contains a CH_3COOH/CH_3COONa buffer pair that keeps the pH value in the range of 4.0 to 4.5, the reduction and dismutation of cuprous ions are completely suppressed and the final product is pure cuprous oxide. Thus, γ-irradiation in solution of appropriate pH value has more application in the preparation of unstable metal oxides.

For instance, in the case of preparing nanosized Cr_2O_3 powders [72], there are two common chromium sources,
Figure 4. (a) TEM image of selenium. Reprinted with permission from [68], Y. J. Zhu et al., *Mater. Lett.* 28, 119 (1996). © 1996, Elsevier Science. (b) TEM image of arsenic uniform nanopaticles prepared by the γ-irradiation method. Reprinted with permission from [70], Y. J. Zhu and Y. T. Qian, *Mater. Sci. Eng. B* 47, 184 (1997). © 1997, Elsevier Science.

CrO_4^{2-} and $Cr_2O_7^{2-}$ ions. In the CrO_4^{2-} ion, there exists a tetrahedral arrangement in which a chromium atom is located at the center. In the dichromate ion, there are two tetrahedral units linked together by one oxygen atom. The Cr–O distance for the bridging oxygen is greater than that for the other oxygen atoms. The $\sigma-\pi$ donor properties of the bridging oxygen atom are much less compared with the terminal oxygen atoms. Thus, the Cr–O bond for the bridging oxygen in the $Cr_2O_7^{2-}$ ion could break down to form a CrO_3 radical in the process of γ-irradiation. The CrO_3 radical is unstable and is reduced rapidly by hydrated electrons to form Cr_2O_3. Thus, $Cr_2O_7^{2-}$ ions are more suitable for the precursor to nanoscale Cr_2O_3 under γ-irradiation.

Nanoscale γ-Fe_2O_3 [73], MoO_2 [74, 75], and Mn_2O_3 [76] have also been successfully prepared by γ-irradiation of an aqueous solution of $FeSO_4$, $[(NH_4)_6Mo_7O_{24}\cdot 4H_2O]$, and $KMnO_4$, respectively.

From the above example, it can be concluded that γ-irradiation can easily reduce metal ions of a high value state to as-desired metal oxides nanocrystals under the effect of hydrated electrons.

2.4. Metal Chalcogenides

In recent years, the synthesis and characterization of chalcogenides of different groups have attracted considerable attention due to their important nonlinear properties [77],

luminescent properties [78], quantum size effects [79], and other important physical and chemical properties [80].

2.4.1. γ-Irradiation Technique

Considerable progress has been made in the synthesis of metal chalcogenides powders. Conventionally, metal chalcogenides could be prepared by a variety of methods, including gas-phase, solid/vapor, and aqueous solution reactions [81, 82]. However, as-prepared metal chalcogenides have irregular crystallites with a wide size distribution ranging from 25 to 200 nm. Using organometallic precursors was another route for synthesizing metal chalcogenides, but most of the organometallic precursors were toxic, easy to hydrolyze and oxidize, and hard to deal with. To control better morphologies, soft-chemical techniques are necessary as assisted methods. Thus, seeking a mild method that can be well combined with other soft-chemical techniques is a challenge for the preparation of metal chalcogenides. The development of γ-irradiation on the preparation of metal and nonmetal nanomaterials provides a new pathway to synthesize metal chalcogenides.

It is clear that hydrated electrons produced in solution by γ-irradiation can reduce metal ions to lower valence [83]:

$$H_2O \rightarrow e_{aq}^-, H_3O^+, H^\bullet, H_2, {}^\bullet OH, H_2O_2 \qquad (14)$$

$$e_{aq}^- + M^{2+} \rightarrow M^+ \qquad (15)$$
As for the sulfur source, there are five common available compounds: carbon disulfide, thiourea, sodium thiosulfate, mercaptoethanol, and thiol. Research on γ-irradiation of carbon disulfide and thiourea indicates that the formation of nonionic intermediates, possibly as $S^\bullet$ radicals and free sulfur, might be liberated when such $S^\bullet$ radicals collide in solution [84, 85]:

$$CS_2 \rightarrow S^\bullet + CS^\bullet \qquad (16)$$

The precipitate of MS probably prevents the formation of sulfur from $S^\bullet$ radical in the irradiation. This was identified by the experimental fact that no sulfur was observed in the products.

$$S^\bullet + M^+ \rightarrow MS \qquad (17)$$

In the case of sodium thiosulfate as the sulfur source, S^{2-} was homogeneously released from its decomposition [86, 87]. Research of γ-irradiation on sodium thiosulfate indicates the following radiolytic reaction [88]:

$$2S_2O_3^{2-} + 4OH^- + 2H^+ \rightarrow HS^- + 3SO_3^{2-} + 3H^+ + H_2O \qquad (18)$$
Hayes et al. [21] report that aqueous thiol irradiated by gray releases sulfide ions into the solution. Another sulfur source, mercaptoethanol, which also has a -SH group, may also release HS^- ions under γ-irradiation. In both cases, HS^- can be formed in the γ-irradiation of the solution:

$$RSH + e_{aq}^- \rightarrow R^\bullet + HS^- \qquad (19)$$

$$HS^- \rightarrow S^{2-} + H^+ \qquad (20)$$

Thus, metal sulfides can be formed in the following way:

$$M^{2+} + S^{2-} \rightarrow MS \qquad (21)$$

From the above theoretic analyses, γ-irradiation may provide a mild pathway for the synthesis of metal sulfides.

Thus, the metal sulfides [89–91] can be prepared by following method: The solutions' dissolving metal sulfate (or acetate), various sulfur sources (i.e., sodium thiosulfate, carbon disulfide, thiourea, and mercaptoethanol), and a scavenger isopropanol in distilled water (or absolute ethanol) were irradiated for some time.

In the case of preparing ZnS, it is found from the XRD study that for sulfur sources with strong polarity such as sodium thiosulfate, the released energy of reactions (20) and (21) between ions is probably only sufficient to allow the formation of the sphalerite phase. When the sulfur source is mercaptoethanol, the polarity of which is in between that of sodium thiosulfate and carbon disulfide, the solvent plays an important role in the structure of the product: sphalerite in water and wurtzite in anhydrous ethanol. Thus, selecting an appropriate sulfur source is crucial to control the phase of products under γ-irradiation. Similar methods have been developed to synthesize CdS [92], ZnS [93], MoS_2 [94], NiS [95], CdSe, and $Cu_{2-x}Se$ [96].

Considering ethylenediamine's property of dissolving sulfur powder and forming a homogeneous solution, γ-irradiation can be extended in ethylenediamine systems. It was reported that sulfur–amine solutions contain S^{2-}, S_6^{2-}, S_4^-, S_4N^-, and other sulfur polyanions [97, 98]. Thus, sulfur dissolving in ethylenediamine may easily be reduced to S^{2-} by solvated electrons upon γ-irradiation.

On the other hand, ethylenediamine has a strong ability for N-chelation to many kinds of metal ions and can form a stable complex, which can well inhibit the reduction of many high-valence metal ions to lower valence metal ions or metal colloids by solvated electrons and can ensure the slower growth of sulfide nanoparticles.

Ag_2S, PbS [99], CdS [99, 100], CdSe [101], and PbSe [102] have been synthesized in nonaqueous phase by this route. Thus, γ-irradiation can prepare metal chalcogenide nanocrystals in either aqueous or nonaqueous phase. This development helps to build up soft-chemical systems among several solvents.

2.4.2. γ-Irradiation Soft-Template Technique

Recently, the preparation and properties of nanowires or nanorods of various materials have received considerable attention, and the potential wide-ranging applications of these kinds of nanomaterials have been predicted [103–108]. For the fabrication of nanowires or nanorods of desired materials, the template method has been demonstrated to be very effective; examples include the use of carbon nanotubes [103–105] and nanochannels in nuclear track polycarbonate membranes [106] or porous alumina [107, 108] which act as hard templates within which desired materials are synthesized. In addition, certain soft template methods [109] may be applied although soft templates cannot always regulate the size and shape of the products; for example, rodlike

cationic surfactant micelles have been used as templates for the preparation of rodlike gold particles [110]. It will be interesting to explore the possibility of the use of solution-based synthesis of one-dimensional nanomaterials without the presence of preformed templates.

However, soft-chemical environments are easy to destroy under thermal treatment. Thus, the γ-irradiation method can be combined with the soft template method to prepare one-dimensional metal chalcogenides. For example, there are strong hydrogen bonds among molecules of the alcohols. Therefore, long chains can be easily formed by molecules of hexadecanol through hydrogen bonds. These long chains can act as new soft templates. When metal ions meet with S^{2-} (S^{2-} ions can be from the decomposition of sodium thiosulfate ($Na_2S_2O_3$) upon γ-irradiation [111, 112]), metal sulfides may be grown along these long chains, leading to the formation of metal sulfides nanofibrils [113]. CdS and ZnS nanofibrils have been prepared via this route with hexadecanol as soft template.

2.4.3. γ-Irradiation Liquid Crystal-Template Technique

It is quite noteworthy that a "soft" liquid crystal phase could directly template a hard mineral phase. The liquid crystal-template-assisted route to group IIB–VI semiconductor nanowires has received more attention for its special properties, such as convenience in operation and ease in control of morphology. Li [114] also reported the synthesis of parallel nanowires of CdS via a hexagonal liquid crystal soft template. However, Braun and co-workers [115] prepared ZnS, CdS, and CdSe superlattices templated by a hexagonal liquid crystal using H_2S or H_2Se gas rather than semiconductor nanowires.

In the case of liquid crystal-template to sulfide nanowires, γ-irradiation is obviously appropriate as a reaction source: First, it does not disrupt the texture of the liquid crystal template. Second, the irradiation energy is so high that the reactants produce some radicals that play an important role in the expected reactions. Li [114] prepared CdS nanowires in a hexagonal liquid crystal template via a flow of H_2S gas at room temperature. Braun [115] prepared ZnS, CdS, and CdSe superlattices templated by hexagonal liquid crystal also under H_2S or H_2Se gas. The gaseous H_2S and H_2Se are toxic and should be used carefully. Except for them, thiourea and CS_2 were commonly used as sulfur sources. However, thiourea does not react with the metal salt at room temperature. When the temperature of this hexagonal mesophase is raised to 80 °C (at which point the texture of hexagonal liquid crystal was partly disrupted), metal sulfides nanowires cannot be obtained. Similarly, CS_2 was added to the hexagonal mesophase and no products were formed at room temperature without γ-irradiation. On the basis of the above research, γ-irradiation can activate the sulfur source well.

Thus, combining γ-irradiation with the liquid crystal-template method, a novel simultaneous in-situ formation (SISF) technique [116] for the synthesis of ZnS nanowires via γ-irradiation at room temperature has been developed. The so-called SISF technique is based on a mechanism of simultaneous occurrence of the decomposition of thiourea

(Tu) or carbon disulfide (CS_2) under γ-irradiation and the formation of ZnS nanowires in an inverted hexagonal liquid crystal phase. The hexagonal mesophase was formed by mixing 30 vol% $(EO)_{10}$-oleyl, 30 vol% n-hexane, 10 vol% n-hexanol/i-propanol (2:1), and 30 vol% water. It is found that the ZnS nanowires (Fig. 5) formed are well dispersed before and after removal of the liquid crystal template. The probable process of the formation of ZnS nanowires is shown in Scheme 3.

The SISF technique assisted by γ-irradiation can be applied to the synthesis of a wide variety of technologically important one-dimensional semiconductor nanomaterials.

2.4.4. γ-Irradiation with Ultrasonic Radiation Technique

Wang et al. [117] have reported the preparation of PbSe nanowires in ethylenediamine using KBH_4 as the reductant and proposed that the formation of PbSe nanowires may be attributed to the existence of active H_2 in KBH_4, and the special structure and N-chelation properties of ethylenediamine. γ-Irradiation can play the same role as KBH_4. It is thought that, upon γ-irradiation, solvated electrons (e_s^-) with strong reductive properties can be formed in ethylenediamine [118], hydrogen radicals ($H^{\bullet}$) and hydrated electrons can also be generated due to the presence of traces of water [23], and these reductive species can activate the reaction and favor the formation of nanorods in ethylenediamine.

However, the transformation from Se powder to Se^{2-} requires a lot of energy. It was reported that, under the sonolysis, Se powder tends to disproportionate in liquid ethylenediamine with basic, N-chelation properties and form divalent selenium. Hydroxyl (OH^-) ion may exist in ethylenediamine with traces of water.

$$3Se + 6OH^- \rightarrow 2Se^{2-} + SeO_3^{2-} + 3H_2O$$

In addition, the divalent selenium can further interact with N atoms in organic amines to form a pseudo-high-valent selenium [119], although there is no report about the direct
Scheme 3. Illustration of the formation process of ZnS nanowires in liquid crystal template. Reprinted with permission from [116], X. C. Jiang et al., *Chem. Mater.* 13, 1213 (2001). © 2001, American Chemical Society.

reaction between Se powder and amines. Therefore, sonication can favor the formation of Se^{2-} and the nonvalence interaction between Se^2 and ethylenediamine.

Prompted by these studies, an ultrasonic and γ-irradiation technique has been developed to prepare well crystallized PbSe nanorods in an ethylenediamine solution at room temperature [120]: An appropriate amount of selenium powder was added to 100 mL ethylenediamine in a vessel at room temperature. Then the tank was sealed and sonicated in a commercial ultrasonic cleaner under ambient conditions for more than an hour. Following this step, a stoichiometric amount of lead acetate was added to the sonicated slurry, which was then irradiated in γ-ray. Thus, the γ-irradiation and ultrasonic technique not only makes use of the reductive species in γ-irradiation but also obtains much reaction energy from the ultrasonic process.

3. γ-IRRADIATION TECHNIQUE TO POLYMER NANOMATERIALS

3.1. Polymerization under γ-Irradiation

During the past decade microemulsion polymerization, as a new branch of emulsion polymerization, has been extensively studied. However, most attention was paid to the polymerization rate. Only a few papers focus on the growth of polymer particles and the variation of the distribution of particles during polymerization. This may be due in part to the difficulties indirectly obtaining the particle size using the most conventional analytic techniques, because of the high emulsifier concentration and the various complications associated with microemulsions. It was reported that in W/O microemulsion, the nucleation is continuous throughout the polymerization [121]. The early work on styrene O/W microemulsion polymerization assumed that the nucleation occurs in the microdroplets and that nucleation was limited below 20% conversion. After reexamination of the same system, Guo et al. [122, 123] postulated that particle nucleation is continuous. Gan et al. [124] investigated the formation of polystyrene nanoparticles in ternary cationic microemulsion through photon correlation spectroscopy and TEM. It was reported that the initiation occurred mainly in the styrene swollen microemulsion droplets. The average hydrodynamic radius of swollen particles first increased rapidly to a maximum at 4–7% conversion. Due to the continuous nucleation, the number of polymer particles and the polydispersity of particle size increased continuously throughout the polymerization process.

Figure 5. TEM images of (a) ZnS nanowires before the liquid crystal template is removed; (b) ZnS nanowires after the liquid crystal template is removed; (c) one magnified part of a ZnS bundle composed of ZnS nanowires. Reprinted with permission from [116], X. C. Jiang et al., *Chem. Mater.* 13, 1213 (2001). © 2001, American Chemical Society.

The growth of poly(methyl methacrylate) (PMMA) particles in ternary cationic microemulsion had also been studied [125]. In contrast to that of the styrene system, the sizes of methyl methacrylate (MMA)-swollen polymer particles increased continuously during polymerization, and no maximum of hydrodynamic radius of swollen particles was observed. In a similar system [126], a two-stage process of polymerization is observed. The first stage, described by a very slow increase in conversion, is attributed mainly to homogenous nucleation. The second stage, characterized by a much higher rate of conversion, involves continuous nucleation and is governed mainly by a micelle-entry mechanism.

Research studies indicate that the polymerization under γ-irradiation in aqueous solution is considered a radical mechanism, meaning that the polymerization reaction is absolutely caused by the radicals produced by the decomposition of water under irradiation. During γ-irradiation, the formation of H· and OH· can be shown as follows:

$$H_2O \sim\sim\longrightarrow R^·(H^· \text{ or } OH^·) \tag{22}$$

$$\text{chain solicitation: } R^· + M \rightarrow RM\bullet \tag{23}$$

$$\text{chain increase: } RM^· + M \rightarrow RM_2^· \tag{24}$$

$$RM_{n-1}^· + M \rightarrow RM_n^· \tag{25}$$

$$\text{chain expiration: } RM_n^· + RM_m^· \rightarrow P_{(n+m)} \tag{26}$$

or

$$RM_n^· + RM_m^· \rightarrow P_n + P_m \tag{27}$$
The polymerization can be initiated with γ-radiation, while it is very easy to stop at the desired conversion by removing the γ-ray source.

In this way, variation of the size and its distribution of monomer-swollen polymer nanoparticles with conversion can be obtained in a microemulsion environment. On the basis of this strategy, the polymerization [127] of three different monomers, styrene, butyl acrylate, and methyl methacrylate, has been carried out in appropriate microemulsion [128]. In all these three microemulsion polymerizations, the evidence of continuous nucleation was observed. It was found that the size of polymer particles rapidly increases up to their maximum at the early stage. With the increase of conversion, the large particles supply their monomer to newly formed particles and become smaller.

From these studies, we can see that γ-irradiation is a convenient way to polymerize monomers without any solicitation reagent.

3.2. Multilayer Nanoparticles

One of the most prominent properties of amphiphilic block copolymers is their ability to form micelles [129–132]. The micelles consist of a dense core and a protective corona. The core formed by insoluble blocks can serve as a host for insoluble low-molecular-weight compounds, such as drugs. Numerous realized or potential applications are based on this property. The possibility of controlling the transport into

or from the micelle core and its solubilization capacity is of great importance for applications of micelles.

Three-layer (onion-type) micelles rank among promising candidates for the controlled uptake/release processes. It has been shown quantitatively [133] that the rate of the uptake of cyclohexane into the poly(2-ethylhexyl acrylate) cores of micelles with poly(acrylic acid) shells can be slowed by the presence of a PMMA middle layer in the micelles. The three-layer micelles have been prepared using a pair of diblock copolymers of types AB and BC [134–136], a heteroarm star copolymer (A_nB_n) with a BC copolymer [137], or an ABC block copolymer [133, 138]. The common drawback of these methods of preparing onion-type micelles is that the parameters of the resulting micelles are to a great extent predetermined by the properties of the copolymers used and cannot easily be varied.

Another possible technique of preparing multiplayer particles is polymerization of a suitable monomer dispersed in a micellar solution. Liu et al. [139] studied polymerization of MMA and butyl acrylate in aqueous micellar solutions of poly(methyl methacrylate)-block-poly(methacrylic acid). Hirzinger et al. [140] prepared PMMA particles using micelles of the copolymer polystyrene-block-poly(etheneco-propene) in n-decane. In these works, light-scattering techniques were used for the structure characterization. These methods could not provide direct information on the inner structure of the particles.

On the basis of the previous research on γ-radiation to polymerization, three-layer nanoparticles [141] were prepared by γ-radiation-induced polymerization of MMA in polystyrene-block-poly(methacrylic acid) aqueous micellar solution, and their structure was studied by small-angle neutron scattering (SANS). The scattering data were fitted using the bare-core approximation for a two-component core to elucidate the distribution of MMA before polymerization and the structure of nanoparticles with polymerized MMA. The newly formed polymer (PMMA) is deposited on the surface of polystyrene cores of the original micelles. The thickness of the PMMA layer depends on the monomer concentration. The SANS results indicate that the PMMA layer is penetrated by the poly(methacrylic acid) corona chains forming channels accessible to water.

From these results, it can be concluded that γ-irradiation combined with micelle science provides a new pathway to the preparation and assembly of polymer.

4. γ-IRRADIATION TECHNIQUE TO NANOCOMPOSITES

Quantum states in the nanocrystalline inorganic materials are size-dependent, leading to new electronic, optical, magnetic, mechanical, and catalytic properties [142–145]. The areas of application, which can be foreseen to benefit from the small size and organization of nanocrystallites, include nanoelectronics, nonlinear optics, catalysis, high-density information storage, and hybrid materials [146–149]. Studies relating to these well-defined inorganic particles have brought about not only a deep understanding of quantum confinement effects but also the development of new

and useful spectroscopic methods and detection technologies [150, 151]. Nanocomposite techniques provide convenient routes to improve the processability and stability of nanocrystals with intriguing novel electronic, optical, and magnetic capacities [152, 153]. Recently, special attention has concentrated on developing methods for assembling nanoscale building blocks [154, 155]. These methods usually rely on both building block components and assembly strategies. For example, a variety of methods have been developed for preparing monodispersed samples of CdS, CdSe, and Au particles with diameters ranging from 1 to 40 nm [147, 156–159]. The general principle in the construction of nanocomposites involves the intimate mixing of nanocrystallites with procurable matrices. The nanoscale matrices usually provide spatially localized sites for nucleation, which minimizes the degree of particle aggregation and imposes an upper limit on the size [160–162]. In the view of materials science, nanocomposites are usually valuable materials, for example potentially useful in improving the photocatalytic conversion efficiency of photoelectrochemical systems [163]. These properties are largely determined by matrix materials and the size of metallic or semiconducting nanocrystallites within the matrices. Therefore, it will be significant to select suitable reaction routes to obtain worthwhile matrix materials and control the size of nanocrystallites within the matrices.

4.1. Inorganic–Inorganic Nanocomposites

It is well known that nanoscaled metal oxides have potential or demonstrated applications in many technologies, such as solar energy conversion, batteries, catalysis, and ductile ceramics [164–170]. Thus, inorganic–inorganic nanocomposites, such as metal/oxide nanocomposites, have been of interest recently [171–179].

Various methods are used to prepare nanocomposite materials, the most common being gas evaporation [171, 172], radio frequency sputtering [173], ion exchange–reduction [174, 175], and the sol–gel process [176–179]. In these methods, heat treatment or hydrogen reduction at relative high temperature is necessary. However, high temperature readily leads to the growth or oxidation of nanocrystalline particles. Thus, a relatively low temperature is favorable for preparation of nanocomposite materials. Based on the successful preparation of inorganic nanocrystals by the γ-irradiation technique, a γ-irradiation sol–gel method has been developed to synthesize metal/oxide nanocomposites. In this method, hydrogels containing a homogeneous dispersion of metal ions were first prepared by the sol–gel process and then oxide–metal nanocomposites were prepared by γ-irradiating the hydrogels instead of the solutions of metal salts.

Ag/TiO$_2$ [180] and Ag/SiO$_2$ [181] nanocomposites have been prepared via this route.

4.2. Inorganic–Polymer Nanocomposites

Recently, a large amount of scientific and technological research has been devoted to hybrid inorganic/polymer composites [182–184], in which the particle sizes, morphology, and orientation can be confined by the reaction space [185].

Also such hybrid composites can frequently provide properties that are combinations of those of the original inorganic and polymer materials. The key step in the confinement of inorganic particle size employed in these works is the initial isolation of a space. Then, under controlled conditions, an inorganic component is induced to form within the limited space. This class of totally innovative materials is considered to be novel and functional, with a wide range of potential applications in nonlinear optical materials [186, 187], conductive composites [188], nanoscaled electronics [189], electromagnetic interference shielding materials, and the like. Since γ-irradiation is convenient for the polymerization of monomers and the preparation of inorganic particles, it can be extended to synthesize inorganic–polymer nanocomposites.

4.2.1. Embedded Metal–Polymer Nanocomposites

Nonlinear optical properties of metal colloids prepared by various methods were studied [190, 191]. In general, the polymer–metal nanocomposites were synthesized in two steps: the polymer was first synthesized, and then the metal ions introduced into the polymer matrix were reduced to zero valent state by a reducing agent or by postheating. This caused a wide distribution of metal particle size and poor dispersion of metal particles in the polymer. As the material to be used in nonlinear optical devices, the chemical stability and optical homogeneity of nanocomposites of inorganic particles dispersed in matrix are required, and for mass production a simple fabrication method for processing at relatively low temperatures is sought.

Thus, it was necessary that the γ-irradiation technique was introduced to the preparation of metal–polymer nanocomposites. For example, nanosilver particles embedded in polyacrylamide matrix [192] were synthesized *in-situ* by using radiation–reduction of silver ions and radiation–polymerization of acrylamide simultaneously with γ-rays.

This route has also been extended to the preparation of Ag/polyacrylamide [193], Ag/poly(butyl acrylate-co-styrene) [194], Ag/polyacrylonitrile [195], Cu/polyacrylamide [196], and Ni/polyacrylamide [197].

4.2.2. Embedded Metal Sulfide–Polymer Nanocomposites

Metal sulfide semiconductors/polymer nanocomposites are considered to be highly functional materials with many applications, such as in photoluminescent, photoelectric, and nonlinear optical materials. The flexibility and processability of polymer matrices can provide good mechanical properties. As optical materials applications are expanding, the need for novel optically functional and transparent materials increases. These needs range from high performance, all optical switches for future use in optical computing to hard transparent coatings as protective or barrier layers. In addition to optical needs such as switching and amplification, the materials must be integrated into existing structures such as waveguides and optical fibers. As such, films and fibers are of great interest as the final form of these novel materials. Nanocomposite materials show great promise as

they can provide the necessary stability and processability for these important applications.

In general, two basic routes have been used to synthesize the composites [198–201]. One is to carry the inorganic reaction between metal ion sources with H_2S or organometallic sulfur sources inside the polymer matrices. The other is to polymerize the monomer after doping the inorganic semiconductor components inside. In recent years, scientists have turned their attention to devising different strategies to control the morphology of inorganic components in the polymer matrices. However, in the above traditional methods, the dispersion of metal sulfide is difficult to control since the inorganic reaction and polymerization were performed separately, and semiconductors could not be well dispersed in the polymer matrix.

Thus, the progress on the extension of the γ-irradiation method to the preparation of semiconductor/polymer nanocomposites in a single step, in which the inorganic component displays nearly monodispersion and uniformity, was necessary. The synthetic factors optimized in order ensure the efficient dispersion of synthetic composites were (1) good "solvation" of the inorganic components in the polymer matrix and (2) an ordered, regular polymer environment in which to induce nucleation (matrix preorganization).

For example, CdSe/polyacrylamide nanocomposites [202] were prepared by this method. Being a material with good thermoplastic and water soluble monomers, polyacrylamide was selected to be the polymer matrix in this work. In addition, cross-linked polyacrylamide can provide a spongelike system in water, which requires that the nanoparticles are well distributed within the polyacrylamide network. CdSe, which shows quantum size effect by the shift of the optical absorption peak toward higher energies as the crystallite size approaches values comparable with or below its exciton size (9 nm for CdSe) and has unusual photoluminescence, etc., was selected to be the inorganic phase [203–205]. Using this approach, the metal ion source $CdSO_4$, selenium source Na_2SeSO_3, and organic monomer acrylamide were mixed homogeneously in the solution; the formation of nanocrystalline metal selenide particles and polymerization of monomer occurred almost simultaneously under γ-irradiation, leading to a good distribution of CdSe nanoparticles in the polymer matrix.

To ensure the formation of the polyacrylamide network, which precedes the further growth of inorganic particles, the concentration of the monomer was selected at the point with the highest rate of polymerization [206], judging from the concentration–polymerization velocity relationship (Fig. 6).

From the ultraviolet-visible spectrum analyses on products with different doses, it can be concluded that the as-prepared polyacrylamide surrounding, in which an amount of holes among the polymer chains fill the whole system and provide an ordered, regular network, is in fact used as a nanoreactor to carry out chemical reactions in restricted geometry.

The same route has been used to prepare CdS/polyacrylamide [207, 208], PbS/poly(vinyl acetate) [209], CdS/ polyacrylonitrile [210], and PbS/polyacrylonitrile [211].
Figure 6. The concentration–polymerization velocity relationship.

4.2.3. Metal Sulfide–Polymer Composite Nanofibers

Researchers are trying to explore novel templates for the synthesis of functional materials. For example, polycationic poly(N-vinylcarbazole) (PNVK) is applied as templates to fabricate regular composite nanowire arrays of thallic oxide (Tl_2O_3) and polycationic PNVK at the molecular level [212].

Thus, polymers with long chains can provide templates for the growth of nanowires. Particularly, maleic anhydride (MA) and styrene (St) are excellent candidates for templates. Under γ-irradiation, St monomers are activated by the radicals generated in solution upon irradiation and are converted into St radicals. These St radicals rapidly initiate copolymerization of St and MA, and copolymer chains are propagated and provide attachment sites for metal sulfide nanoparticles owing to the presence of highly polar groups along the chains. It has been reported that the copolymerization of St and MA gives a copolymer in which the monomers alternate with near perfect regularity along the chain [213]. This is due to the fact that MA with an electron-attracting substituent has electron-accepting character ($e = 2.25$) while St with an electron-releasing substituent has electron-donating character ($e = 20.80$), which leads to a very small value of the product of monomer reactivity ratios ($r_1 \times r_2 = 0.006$).

Part of the copolymer undergoes esterification in ethanol with the acid anhydride groups being esterified. In addition, the two carbonyl groups alternate with the aromatic ring, leading to a homogeneous dispersion of carbonyl groups. In most previous studies on inorganic/copolymer composites, the polymer matrices were block copolymers, and particle growth was expected to be restricted to ionic or highly polar microdomains so providing a mechanism for both size control and particle stabilization [214, 215]. However, such ionic or highly polar microdomains were not necessarily evenly distributed in the block copolymers in contrast to the highly polar carbonyl groups in this work that lead to better control over size and shape of the nanosize particles.

Thus, after introducing γ-irradiation to this field, CdS nanofibers [216] were prepared in an alternate copolymer of MA and St via a one-pot procedure using γ-irradiation. The ordered and regular polymer environment induces nucleation of CdS (matrix preorganization), and initially formed

highly polar groups evenly distributed along the chains can effectively control the size and shape of the CdS particles.

4.2.4. Assemblies of Metal Sulfide–Polymer Nanocomposites

In the traditional methods, the dispersion of metal sulfide is difficult to control since the inorganic reaction and polymerization were performed separately, and semiconductors could not disperse well in the polymer matrix. Thus, utilizing the hydrophilic and hydrophibic properties of monomers is an efficient way to solve this problem.

It is known that an organic monomer with polar groups can self-organize into micellelike aggregates with an inner hydrophilic region, utilizing the difference of the solubility of different fragments in the monomer molecule. Such micellelike aggregates can polymerize to polymer spheres with an inner hydrophilic region under γ-irradiation; the latter can act as both the template and nanoreactor for the following growth of inorganic semiconductor nanoparticles or nanofibers. In this approach, γ-irradiation offers an ideal means by which both polymerization of the monomer aggregates and the further growth of the inorganic nanofibers occur at room temperature and under ambient pressure. In a typical heterogeneous system of poly(vinyl acetate) (PVAc), $CdCl_2$, and CS_2, the mutual solubility between VAc and water is about 2% [217]. So before the polymerization, there is a small amount of water in the upper VAc layer. With the existence of water, the hydrophilic groups (C=O) in the VAc molecules tend to shrink together to form micellelike cores in order to minimize the free energy, and the other parts of vinyl acetate molecules then form the extended micellelike shell in its entity [218–220]. Such inner hydrophilic micellelike aggregates result in the inner hydrophilic cores in PVAc after γ-irradiation. In addition, under γ-irradiation, polymerization is faster than the formation of inorganic components, and the density of the PVAc spheres increases and the formed PVAc spheres drop into the under water layer. Water-soluble $CdCl_2$ will automatically distribute in the favorite inner hydrophilic region of the PVAc spheres and react further with CS_2 taken along with the PVAc spheres. The following nucleation and growth of acicular CdS are confined in the limited reactor region; thus the resulting CdS spreads homogeneously in the spherical polymer matrix. Based on the above strategy, spherical assemblies [221] of CdS nanofibers in PVA were successfully synthesized from a heterogeneous system of VAc monomer, cadmium chlorite, and carbon disulfide under γ-irradiation at room temperature and under ambient pressure.

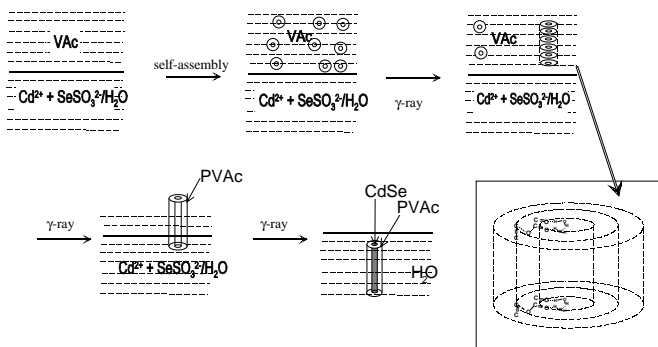
By appropriate control of the experimental parameters, this technique could be extended to the preparation of a variety of spherical assemblies of semiconductor in polymer in heterogeneous systems under γ-irradiation at room temperature and in ambient pressure.

4.2.5. Metal Sulfide–Polymer Nanocables

Special attention has been paid to nanotubes and nanowires due to their interesting properties and potential applications. Since the discovery of carbon nanotubes [222] various nanotubes such as WS_2, MoS_2, BN, and BC_2N and semiconductor nanowires such as CdTe and ZnCdSe have been synthesized [223–228]. The template technique is an important method of nanowire fabrication. Usually, there are two types of template: "track-etch" polymer membranes, such as the polycarbonate membrane with 60 nm diameter pores, and the porous aluminum oxide membrane, with a pore diameter of 70 nm [229, 230]. However, the challenges of fabricating semiconductor nanowires with a quantum confinement effect are great because technically useful quantum wires will require lateral dimensions less than 10 nm, and it is difficult to fabricate quantum wires on a scale lower than 10 nm [231].

Nanocables with a wire/sheath structure are another kind of potentially useful one-dimensional nanostructure. There have been a few reports on the preparation of semiconductor/insulator nanocables. For example, Si/SiO_2 nanocable has been prepared by combining laser-ablation cluster formation with vapor–liquid–solid growth [232], and β-SiC/SiO_2 nanocable has been obtained by the carbothermal reduction of sol–gel derived silica xerogels containing carbon nanoparticles at 1650 °C [233]. In both cases, the outer layers of SiO_2 in nanocables are induced by the reaction atmosphere.

As described in the former section, an organic monomer with polar groups can self-organize into amphiphilic supramolecules, utilizing the difference in solubility of different fragments in the monomer molecule. Such supramolecules can polymerize to a preorganized polymer tubule with a hydrophilic core and a hydrophobic sheath. Then the polymer tubule acts as both template and nanoreactor for the following growth of inorganic semiconductor nanowires in the hydrophilic cores from various water-soluble sources. Thus, a nanocable with semiconductor wire in a polymer sheath can be obtained in a heterogeneous solution system. In this approach, γ-irradiation offers an ideal means by which the supramolecules can be polymerized and the tubular structure can be solidified with the desired diameter at room temperature under ambient pressure.

For example, the PVAc tubule can be formed through a continuous process from monomer to supramolecule then to polymer in a heterogeneous system under γ-irradiation. As proposed in Scheme 4, the heterogeneous system includes the upper VAc region and the lower water region. The mutual solubility between VAc and water is about 2% [217]. In the presence of a small amount of water, the hydrophilic groups (C=O) in the VAc molecules tend to shrink together to form micellelike cores in order to minimize the free energy, and the other hydrophobic parts of vinyl acetate molecules then form the extended micellelike shell in its entity. Then the enthalpic contributions of hydrogen bonding interactions drive the self-assembly of the supramolecular structure [218, 234, 235] as shown in the inset of Scheme 4. Such a hydrogen bonding interaction model is widely used to explain the process of molecular self-assembly into a well-defined supramolecular structure [236, 237]. A similar process can also be found in the formation of macroporous polymer monoliths with large pores that are obtained in a poor solvent due to an earlier onset of phase separation [238]. Obviously, the self-assembly structure consisting


Scheme 4. Schematic illustration of the process of formation of CdSe/PVAc nanocables; inset: schematic illustration of the self-assembly of VAc. Reprinted with permission from [239], Y. Xie et al., *Adv. Mater.* 11, 1512 (1999). © 1999, Wiley-VCH.

of a hydrophilic core and extended shells in the massive monomer is related to the hydrogen-bonding bridge of the adjacent $C = O$ groups in VAc monomer in the presence of water.

In this approach, the entire preparation process is carried out by γ-irradiation at room temperature and under ambient pressure. A key of the method is irradiation of the heterogeneous system at a rather low dose rate for a relatively long time, to make sure there is enough time for the self-organization of the monomer into supramolecules. Then polymerization of the self-assembled supramolecules proceeds; the tubular structure forms and solidifies. Then the PVAc tubules drop into the lower water layer since the density of as-formed PVAc is greater than water. Water-soluble inorganic compounds will automatically distribute in the favorable hydrophilic cores of the PVAc tubules, and further irradiation will cause inorganic semiconductor to grow.

Based on the above strategy, a CdSe/PVAc nanocable with a 6 nm core and an 80 nm diameter sheath [239] (Fig. 7a) was successfully synthesized from a heterogeneous system of VAc monomer, cadmium sulfate, and sodium selenosulfate under γ-irradiation at room temperature and ambient pressure.

The successful approach is confirmed by the coexistence of some hollow tubules in the products, which can be clearly observed under the TEM, as shown in Figure 7b, and the ED
pattern (Fig. 7b, inset), without the CdSe diffraction dots or circles, confirmed that it is only amorphous polymer. This route can also be used to synthesize CdS/PVA nanocables with $Na_2S_2O_3$ as reagent. If substituting hydrophibic sulfur source CS_2 [240] with hydrophilic $Na_2S_2O_3$, the size of the cores (Fig. 7c) would be adjusted as desired.

It is reasonable that, under thermal initiation conditions, the violent thermal motion breaks the preorganized supramolecular structure while the hydrophilic groups (C=O) make the polymer shrink to a sphere in order to minimize the free energy. This point was identified by the experiment under solvothermal conditions [241]. Some composite nanorods (Fig. 8) rather than nanocables were found in the as-obtained product. It further confirms that γ-irradiation is a better way to soft-chemical synthesis.

Compared with the preparation of embodied nanocomposites, it is found that the key to the formation of CdSe/(polyvinyl acetate) nanocable is slow polymerization under mild conditions that ensures that there is sufficient time for self-organization of the monomer into the supramolecular, maintenance of the tubular structure throughout the polymerization process, and the growth of inorganic crystallites in good orientation. The irradiation process carried out at a rather low dose rate (20.3 Gy/min) for a relatively long time was designed in our approach. Another tick of slow polymerization is the adding of $(CH_3)_2CHOH$, which is present in a much higher concentration than metal salts. OH and H radicals, which are generated in the radiolysis of water and induce the polymerization of vinyl acetate, were scavenged by abstracting an H atom from $(CH_3)_2CHOH$, leading to the rate of chain inducement and thus the rate of whole polymerization is decreased.

This technique could be extended to the preparation of a variety of semiconductor/polymer or metal/polymer nanocables in a heterogeneous system, by an appropriate choice of the inorganic/organic system and the experimental conditions. The diameter of the inner hole in the polymer tubule, which will control the diameter of the semiconductor or metal core, can be adjusted by choosing a suitable organic monomer with different solubility of different groups in selective solvents. As well as the hydrophilic cores, hydrophobic cores can also be obtained in a selective solvent and growth of inorganic nanowires can be carried out in such hydrophobic holes by choosing suitable precursors. In addition, semiconductor or metal nanowires with a desired

diameter can be prepared by this method, since the polymer sheath can be easily removed by dissolving in suitable organic solvents.

5. CONCLUSION

In the preceding sections, a summary of recent reports on γ-irradiation preparation of nanomaterials has been presented. The γ-irradiated-synthesized nanomaterials encompass metals, alloys, nonmetals, metal oxides, metal chalcogenide nanocrystals, and inorganic–inorganic and inorganic–polymer nanocomposites, with as-desired morphologies, including nanoparticles, nanofibers, nanorods, nanocables, and some assemblies. The motivation for use of γ-irradiation obviously has been to produce hydrated electrons and reduce metal ions, avoiding using any additional reducing agents in reactions. It should be mentioned that appropriate $(CH_3)_2CHOH$ as scavenger to eliminate hydroxyl radicals needs to be added into reaction system. While the preparation of intended nanomaterials has been achieved, an understanding of the reaction mechanism in γ-irradiation has been investigated. Since it is a relatively new activity in the nanomaterial and nanochemistry field, there is a growing volume of empirical knowledge about γ-ray–material interaction.

On of the most important issues in γ-irradiation applications for syntheses of nanomaterials is that this technique with relatively high yield of product and low cost can process under normal pressure at room temperature. Thus, it can be conveniently combined with other methods, such as hydrothermal, hard/soft template, and sonochemical methods, or other chemistry branches, such as coordination chemistry, surface and colloidal chemistry, and polymer science. In particular, it is advantageous for the stability of some soft-chemical environments (for example, micelles and liquid crystals) and the polymerization of monomers, although inorganic compounds can act as photoinitiators to initiate the polymerization sometimes. Therefore, the γ-irradiation technique is especially suitable for the soft-chemical synthesis of one-dimensional nanomaterials and their assemblies of inorganic nanomaterials and inorganic–polymer nanocomposites.

However, the reported literature suggests that the shortcoming of the γ-irradiation technique is obvious in that its energy is too dispersive. Therefore, it is unsuitable for the preparation of materials (for example, III–V compounds) which need high temperature and energy. On the other hand, the products prepared by γ-irradiation are usually crystalline-poor. Thus, sometimes the combination of the γ-irradiation technique with the hydrothermal method is necessary.

By the combination with many other fields, the γ-irradiation technique is expected to focus on the synthesis of metals, metal oxides, metal chalcogenides, and their polymer composites with as-desired nanostructure.

GLOSSARY

Fractal A geometric pattern that is repeated at ever smaller scales to produce irregular shapes and surfaces that cannot be represented by classical geometry. Fractals are used especially in computer modeling of irregular patterns and structures in nature.

Gamma radiation Emission and propagation of energy in the form of a gamma-ray.

Hydrated electron Transferring electron in aqueous phase.

Liquid crystal Any of various liquids in which the atoms or molecules are regularly arrayed in either one dimension or two dimensions, the order giving rise to optical properties, such as anisotropic scattering, associated with the crystals.

Micelle A submicroscopic aggregation of molecules, as a droplet in a colloidal system.

Nanocable One-dimensional nanomaterial with wire/sheath structure.

Nanocomposite Metallic or semiconducting nanocrystallites within the matirces.

Nanomaterial Nanoscale material having a microstructure with a characteristic length scale on the order of a few (typically 1–100) nanometers and displaying a quantum-confined effect.

Nanorod One-dimensional rodlike nanomaterial.

Nanoscale Scale ranging from 1 to 100 nm (one billionth of a meter).

Nanowire One-dimensional wirelike nanomaterial.

Polymer Any of numerous natural and synthetic compounds of usually high molecular weight consisting of up to millions of repeated linked units, each a relatively light and simple molecule.

Ultrasonic Of or relating to acoustic frequencies above the range audible to the human ear, or above approximately 20,000 hertz.

Gas Adsorption on Carbon Nanotubes

A. D. Migone, S. Talapatra

Southern Illinois University at Carbondale, Carbondale, Illinois, USA

CONTENTS

1. INTRODUCTION

The study of gas adsorption on carbon nanotube substrates is an ever-expanding field of research. This chapter summarizes much of the experimental work done on this subject over the past five years. We review results obtained on a variety of systems, including the rare gases, and simple molecular systems such as nitrogen, oxygen, methane, and other hydrocarbons. The most important topic that, while mentioned throughout the chapter, will not be discussed in any great detail is the work on hydrogen adsorption on nanotubes. The choice to omit a detailed review of this subject was made because there are several comprehensive, and fairly recent, reviews of hydrogen adsorption available [1–3]. The present work is the first review devoted to summarizing the findings on all other adsorbates on carbon nanotube substrates.

We briefly describe the main experimental techniques that have been used to study gas adsorption in general, and adsorption on carbon nanotubes in particular. We then review separately work done on multiwall nanotube substrates and that conducted on single-wall carbon nanotubes. While the focus is on experimental work, occasional reference will also be made to especially relevant theoretical and simulational results; in each case, we try to provide the broader context in which the experimental research was conducted, pointing out the fundamental theoretical issues as well as the practical ones that the researchers were addressing with their experiments.

Adsorption is the process by which atoms or molecules of one chemical species (the adsorbate) are attracted, and stay on the surface of a solid of a different chemical species (the substrate). Depending on the strength of the interaction between the adsorbate and the substrate, we can have physisorption (weakly bound adsorbates, having binding energies typically below about 0.3 eV) or chemisorption (more strongly bound adsorbates) [4]. In physisorption, the adsorbate retains its chemical identity.

The study of gas adsorption on carbon nanotubes is of considerable interest, both from a fundamental point of view as well as from a practical perspective. Gases adsorbed on nanotubes can be used to provide us with one of the few readily available physical realizations of matter in one dimension [5–10]. As such, these systems are a testing ground for theoretical predictions specifically made for 1-D matter. In addition, because they permit the determination of the gas–substrate binding energy, gases adsorbed on nanotubes provide us with an experimental test for the level of accuracy achieved for the potentials used to describe the interaction between different adsorbate species and carbonaceous substrates [11].

From a practical perspective, carbon nanotubes, and other related carbon nanomaterials, hold significant promise for the development of an entirely new approach to gas storage technology [12]. The implications that these new approaches may have for the storage of hydrogen have been discussed extensively [1, 2, 12]. However, the development of new methods of gas storage would have an impact that would be felt well beyond hydrogen-related applications. In addition to gas storage applications, the significant levels of differential adsorption that can be achieved with these novel carbon materials can be effectively used to develop new methods for gas mixture separation and purification [13].

2. GAS ADSORPTION MEASUREMENTS

A number of the standard adsorption techniques have been utilized to study gases physisorbed on nanotubes. These include: adsorption isotherms [9, 14–35], thermal programmed desorption [6–8, 12, 36–40], neutron scattering [41, 42], X-ray diffraction [32], X-ray spectroscopy [43], Raman spectroscopy [44], thermogravimetric analysis [37], FTIR spectroscopy [37], and calorimetry [24, 45]. Several of these techniques have been summarized in a review article

[46] on adsorbed films by Vilches. In addition to techniques traditionally associated with the study of adsorbed systems, it has been found that some electrical transport properties [47–53] of carbon nanotubes are sensitive to the presence of adsorbed species on the tubes, and thus provide information on adsorption on these substrates.

2.1. Adsorption Isotherm Measurements

By far the most common approach used to investigate gas adsorption on any substrate is to perform adsorption isotherms. In this type of measurement, the amount of gas adsorbed onto a substrate is determined as a function of the chemical potential (or, equivalently, of the pressure) of the coexisting adsorbate that remains present in the vapor phase at a fixed temperature. The method by which the determination of the amount adsorbed is made varies.

In volumetric isotherms, the quantity of gas adsorbed on the substrate is obtained as the difference between the amount of gas initially dosed into the experimental cell which contains the substrate and the amount of gas that remains present in the vapor phase in the experimental cell after the new equilibrium conditions have been reached. Computer-controlled volumetric adsorption setups are able to produce isotherms of sufficiently high quality to allow for the meaningful determination of pointwise derivatives of the experimental data. The isothermal compressibilities of the adsorbed films can then be obtained directly from these derivatives.

In gravimetric adsorption isotherms, the amount of gas adsorbed on the substrate is determined by measuring the weight of gas adsorbed. The gravimetric approach is well suited for the performance of adsorption isotherms at and above room temperature, where in many cases the large fraction of the gas present in the vapor phase makes volumetric determinations impractical.

While other approaches for measuring adsorption isotherms (such as ellipsometric measurements or quartz crystal microbalance frequency determinations) have been applied to the study of gases adsorbed on planar substrates, their use has not yet been extended to the investigation of gases adsorbed on carbon nanotube substrates.

Collections of adsorption isotherms measured at a number of different temperatures (see Fig. 1, which displays such data, as presented in [23]) allow the determination of the isosteric heat of adsorption of an adsorbate on a substrate [54]. The isosteric heat of adsorption is the amount of heat released (adsorption is an exothermic process) when an atom or molecule adsorbs onto the substrate [4]. In terms of adsorption isotherms, the isosteric heat of adsorption q_{st}, is defined as [54]

$$q_{st} = kT^2 (d \ln P / dT)_n$$

Here, n is the fixed value of the coverage at which the isosteric heat is calculated, dT is the difference between the two temperatures used in the calculation of the isosteric heat, $d \ln P$ is the difference in the logarithms of the pressures at these two temperatures, k is Boltzmann's constant, and T is the average of the two temperatures. When the isosteric heat of adsorption is determined at sufficiently low
Figure 1. Set of very low coverage adsorption data, for various temperatures, for CH_4 adsorbed on bundles of SWNTs. The coverages (which are given in $cm^3 \cdot torr$ (labeled "cc-torr") in this figure; 1 cc · torr corresponds to 58.8 nmol) are plotted as a function of the logarithm of the pressure (in torr). The coverages displayed in this figure range between 1 and 10% of one full layer of methane on the nanotube bundles. The temperatures are, from left to right, 159.88, 164.82, 174.82, 179.84, 184.80, 189.85, and 194.68 K. The isosteric heat of adsorption can be determined from these data in the manner described in the text. Reprinted with permission from [23], S. E. Weber et al., *Phys. Rev. B* 61, 13150 (2000). © 2000, American Physical Society.

coverages [4], it can be used to provide an experimental value for the binding energy of the adsorbed species on the substrate.

2.2. Temperature-Programmed Desorption

In thermal-programmed desorption measurements (TPD), gas is adsorbed on a substrate at a low temperature. The adsorbate remaining in the vapor phase is then pumped out of the experimental cell, so that equilibrium is established at a low value of the pressure at the beginning of the measurements, and so that most of the gas present inside the experimental cell is adsorbed onto the substrate. The temperature of the cell is then allowed to increase at some preset rate. The amount of gas desorbing from the substrate is monitored (for example, with a mass spectrometer) as a function of the increasing temperature. Thermal-programmed desorption can be used for the determination of the binding energy of a gas on a substrate because the temperature at which the desorption rate reaches a maximum is related to the binding energy of the adsorbate. While this technique is most often used for studying chemisorbed systems (for example, it has been used to determine the thermal evolution of chemical functional groups chemisorbed on the nanotubes) [10, 38], thermal-programmed desorption also has been used for the determination of the binding energy of physisorbed adsorbates such as helium (Fig. 2) [6–8], and other simple adsorbates such as xenon, methane, and SF_6 (see Fig. 3) [36, 40].

2.3. Thermogravimetric Analysis

In thermogravimetric analysis, the change in the mass of the film adsorbed on a substrate, either as a result of adsorption or desorption, is studied under preselected conditions.
Figure 2. Temperature-programmed desorption data for helium on SWNT. The figure presents the helium desorption rates from the nano-tube substrate as a function of temperature. Reprinted with permission from [8], Y. H. Kahng et al., *J. Low Temp. Phys.* 126, 223 (2002). © 2002, Kluwer Academic/Plenum.

For example, the mass change can be determined when a gas mixture containing the adsorbate of interest, together with an inert (nonadsorbing) species, is made to flow at a constant rate over the substrate under isothermal conditions [37]. These determinations provide information as to the effectiveness of a substrate for differential adsorption processes for specific adsorbates. Experiments can also be conducted in a manner entirely analogous to TPD measurements, but instead of monitoring the amount of gas desorbed with a mass spectrometer, it is the mass change that is monitored as a function of the temperature of the system.

2.4. Scattering Techniques

Scattering techniques, in particular X-ray diffraction [32] and neutron scattering [42], have been applied to study the structure of the adsorbed films. Typically, the diffraction pattern corresponding to the bare substrate (i.e., the nanotube
Figure 3. Thermal-programmed desorption traces for CH_4, Xe, and SF_6 on HOPG (left panels) and on SWNTs (right panels). The higher values of the desorption temperature on the SWNTs indicate stronger binding than on HOPG. These data are somewhat different form previously published data from this same group (see [36]) in that lower temperature multilayer peaks are not present. This is probably due to the fact that the older samples were rougher, and diffusion in them was more inhibited than in the sample used here. The unpublished data presented in this figure were provided by T. Hertel.

bundles before the introduction of the adsorbate species) is measured. Gas is then introduced into the experimental cell, and the diffraction pattern is measured again. In its simplest approach, the difference between these two diffraction patterns is taken to correspond to the diffraction pattern from the adsorbed film. By monitoring the diffraction peaks of the substrate, these structural techniques can also be used to determine whether there are any changes in the structure of the substrate that occur as a result of the adsorption process [32, 42].

In addition to structural determinations, neutron scattering can be used to probe the dynamics of adsorbed films. Quasielastic neutron scattering measurements have been used to investigate the mobility of films adsorbed on carbon nanotubes (Fig. 4) [41].

2.5. Spectroscopic Techniques

Raman spectroscopy has been utilized to study the adsorption of hydrogen on single-wall nanotubes (Fig. 5) [44]. This approach uses shifts in the Raman frequencies of the adsorbate species relative to the values of the frequencies in the bulk phase (which occur as a consequence of adsorption) to obtain information on the adsorbed system. The shifts are compared with theoretical estimates of the shifts that would result under different adsorption scenarios. Inferences can
Figure 4. QENS spectra of 20 cm³ STP of methane adsorbed on 600 mg of SWNT (the contributions from the background have been subtracted) at: (a) 90 K and (b) 50 K for $Q = 0.91$ Å^{-1}. The 50 K data are characteristic of a solid phase, while the broad wings at the base of the 90 K data indicate the presence of a liquid phase. Reprinted with permission from [41], M. Bienfait et al., *Surf. Sci.* 460, 243 (2000). © 2000, Elsevier Science.
Figure 5. Raman spectroscopy data for hydrogen adsorbed on SWNT at 8 and 4 atm, together with data for C60 and HOPG at 4 atm. Reprinted with permission from [44], K. A. Williams et al., *Phys. Rev. Lett.* 88, 165502 (2002). © 2002, American Physical Society.

be drawn as to the locations of the adsorption sites, and their strength, as a result of comparing experiments and theoretical calculations.

FTIR spectroscopy has been used to look at the growth of films on carbon nanotube substrates [37]. The change in intensity of specific IR peaks of the adsorbate as a function of exposure time can be monitored to determine the increase in the amount of adsorbate present on the substrate.

2.6. Calorimetry

Calorimetry has been used to investigate gas adsorption on bundles of single-wall carbon nanotubes [24, 45]. Two different quantities have been determined calorimetrically: the heat of adsorption, and the specific heat of the adsorbed film. Measurement of the heat released when adsorption occurs under essentially isothermal conditions permits the obtainment of the isosteric heat of adsorption of a given adsorbate on the nanotube substrate [24]. The specific heat of an adsorbed film, on the other hand, is measured by substracting the heat capacity of the bare substrate from the heat capacity of the loaded substrate (i.e., the substrate that already has a fixed amount of gas adsorbed onto it) [45]. The film's contribution to the heat capacity is taken as the difference between these two values.

2.7. Adsorption Isotherm Simulations

In addition to these strictly speaking experimental tools, computer simulation "experiments" (in particular, simulated adsorption isotherms) [5] have been used to model the behavior of a variety of adsorbed species on carbon nanotubes. Combining the contributions from actual experiments with those from simulated experiments has proven to be a powerful approach to further our understanding of the behavior of films adsorbed on carbon nanotubes.

3. ADSORPTION ON CARBON NANOTUBES

3.1. Adsorption on Multiwalled Nanotubes

While some experimental techniques can be implemented with microscopic-sized samples, the nature of adsorption experiments is such that they almost universally require macroscopic amounts of substrate (on the order of milligrams or greater) on which to perform the measurements. Methods for the production of nanotubes in sufficiently large amounts to make adsorption studies possible were first developed for multiwalled tubes [55], and later for single-walled tubes [56, 57]. As a result, some of the first studies involving adsorption on nanotubes were conducted on multiwalled tubes [14].

Unlike the case with single-walled nanotubes (which, upon production, spontaneously arrange themselves into "bundles," that is, a triangular ordered phase) [57], multiwalled nanotubes do not self-organize into ordered arrays at production. There are just two groups of adsorption sites on samples of multiwalled nanotubes: the external surface of the tubes, and, if the tubes have at least one of their two end caps removed, the hollow space at the interior of the tube. This does not imply that multiwalled tubes cannot be grown on especially prepared substrates so that they form what, at the micron level, appears to be an ordered mat (see, for example, the electron micrographs shown in [19]). However, the arrangement in a mat is far from that which would give rise to new adsorption behavior, as occurs when SWNTs assemble into bundles, because the separation between the parallel multiwalled tubes in the mat is too large to give rise to a new set of adsorption sites.

Initial reports on the adsorption characteristics of multiwalled carbon nanotubes focused on the determination of the specific surface areas of these materials. In a study to establish a method for uncapping the ends of multiwalled nanotubes, Green's group reported on the effect of CO_2 treatment on the specific surface area of a sample of tubes as determined by applying the BET equation to nitrogen adsorption isotherms at liquid nitrogen temperatures [14]. They found that the specific area before the treatment was 21.0 m^2/g, while after the treatment it increased to 37.0 m^2/g. The increase in the value of the specific surface area was taken as evidence of the uncapping of the tubes after the CO_2 treatment [14].

The storage of Ar at high pressures, in the hollow interior of capped catalytically produced multiwalled nanotubes, has been investigated [43]. The study was performed by hot isostatically pressing catalytically produced multiwalled tubes with outer diameters between 20 and 150 nm and inner diameters between 10 and 60 nm under 170 MPa of argon gas at 650 °C for 48 h. The results, which identified Ar inside a sizable fraction of the close-ended multiwalled tubes, were obtained by performing energy dispersive X-ray maps of the tubes. They were explained in terms of the high pressure helping the gas penetrate into the hollow center of the tubes, and the amorphous outer layer of the tube that formed as a result of the high temperature helping seal the gas at the interior of the tube. However, Kuznetsova et al. [10] noted that the interpretation of the above experiments is complicated by the presence of large amounts of impurities that

can incorporate gas in regions other than the interior of the nanotubes. There has been one other study that explored the encapsulation of gas [58]. In this case, however, the encapsulation process was quite different. The more recent study investigated the simultaneous formation of CN_x nanotubes and the encapsulation of N_2 gas inside the tubes. The encapsulation process takes place in a single step, at the time in which the MWNTs are produced. The presence of the gas inside the tubes was determined from the existence of a peak corresponding to molecular nitrogen in the EELS spectrum of the sample.

Gaucher et al. [15] investigated the adsorption of nitrogen and argon on catalytically produced multiwalled carbon nanotubes at liquid nitrogen temperature. In this study, the ends of the nanotubes were always open. The diameters of the hollow interiors of the tubes investigated were about 4 nm, while the outer diameters of the tubes ranged typically between 20 and 40 nm. Adsorption–desorption cycles displayed hysteresis loops, indicating the presence of mesopores in the samples. The mesopore volume and pore radius were determined from the adsorption data by using the Barrett–Joyner–Halenda (BJH) approach [59]. The maximum pore radius, at about 2 nm, coincided with the diameter of the hollow core of the tubes seen in electron micrographic studies. Upon heating the samples in an argon atmosphere to 2800 °C, a majority of the tubes developed closed ends, and BJH analysis of the adsorption–desorption data on these samples yielded much smaller mesopore volumes.

Gravimetric adsorption isotherms at 77.3 K were used to investigate the adsorption of N_2 on multiwalled nanotubes, produced by Hyperion [16]. A majority of the nanotubes that were used in this study reportedly were open at one end. The tubes had diameters on the order of 4 nm and wall thicknesses on the order of 3 nm (yielding an average overall tube diameter of 10 nm). The study undertook to determine the values of the interior and exterior surfaces of the tubes, and the presence or absence of capillary condensation for this system. The determination of the adsorption areas on the interior and exterior surfaces was accomplished by using an alpha-plot comparison in which the nonporous reference isotherm was measured on nonporous carbon black. An alpha plot is the curve that results when one displays the amount adsorbed (in fractions of a layer) at a given value of the reduced pressure P/P_o on a test substrate (Y axis) as a function of the amount adsorbed, at the same value of P/P_o, on a nonporous reference substrate of similar adsorption characteristics (X axis). For a nonporous test sample, such a plot should yield a straight line. Deviations from a straight line are interpreted in terms of the presence of porosity on the test sample. The overall specific area determined for the tubes employed in this study was 268 m²/g, of which 90 m²/g were attributed to the inner surface. No hysteresis was seen in the adsorption–desorption cycle; this result was expected for tubes that are open only at one end. (It should be noted that very recently, however, on especially prepared porous Si substrates, it has been shown that even tubes with one end open show adsorption hysteresis [60].)

Mackie et al. [17], in a set of volumetric measurements performed at 77.3 K, studied methane adsorption/desorption cycles on catalytically produced multiwalled nanotubes.

Studies were performed on two groups of tubes: one of these groups of tubes had interior diameters ranging between 10 and 100 nm (with an estimated 70% falling between 40 and 70 nm), and the other group consisted of larger tubes, with interior diameters between 1 and 2 μm. The narrower tubes were split into three subgroups that received different treatments before being used as a substrate in the adsorption studies. One subset was treated with nitric acid, another was subjected to high temperatures (2400 °C) under vacuum, and the final subset was used in an as-produced fashion. This study focused on three things: determining the wetting characteristics of the methane films on the tubes, ascertaining the presence or absence of hysteresis loops indicative of capillary condensation on adsorption–desorption cycles for these substrates, and determining the specific areas of the different sets of tubes. The study found that solid methane forms very thin, incompletely wetting films on the nanotubes. By contrast, thick solid methane films, of at least 8–11 layers in thickness, can be formed on planar graphite before reaching saturation [61, 62]. This difference in behavior is due to the additional strain on the film growing on the tubes, which results in a reduction of the number of layer that are present at saturation. Hysteresis loops were present in the chemically treated tubes (which were supposed to have both of their ends uncapped), while they were not observed on the as-produced tubes. The specific surface areas for the untreated tubes were on the order of 17 m²/g, while they were 23 m²/g for the acid-treated tubes. On the vacuum-heated tubes (which have more highly graphitized outer surfaces), a number of steps were obtained in the adsorption data, indicative of layer-by-layer adsorption. The pressures at which these steps were observed, relative to the saturated vapor pressure, were similar to those observed for planar graphite (not a very surprising result, in view of the relatively large thickness of the walls of the tubes used in these measurements).

Bougrine et al. [18], who studied the adsorption of Kr films on catalytically produced multiwalled tubes, conducted a somewhat similar investigation. The majority of the tubes used in this investigation were closed. The diameters of the tubes fell into three groups within the same batch: around 10 nm, between 20 and 30 nm, and around 50 nm. The smaller diameter tubes had walls that were more uniform than those in the larger diameter tubes. The diameter of the hollow center of the tube was observed to be inversely correlated to the outer diameter of the tube. This study focused on determining the value of the relative pressure at which the first and second steps appeared on the tubes, and compared these features to the corresponding ones on planar graphite. The steps occurred at higher pressures on the nanotubes than the corresponding first- and second-layer steps for Kr on planar graphite. The authors explain this behavior as resulting from the curvature exhibited by the nanotubes. Only two separate steps were seen in the adsorption data before the saturated vapor pressure was reached. This indicates that the solid film incompletely wets the tubes, in contrast to the behavior on planar graphite, which is completely wetted by solid Kr [62]. No hysteresis was observed between the adsorption and desorption curves. The specific area estimated for the tubes used in this study was 105 m²/g.

Hilding et al. [19] investigated the adsorption of butane on multiwalled nanotubes by performing gravimetric isotherms at room temperature. The tubes used were grown through chemical vapor deposition, which resulted in the formation of an aligned mat with very few contact points between nanotubes. TEM studies were used to determine that, in many cases, one end of the tubes was open. Three batches of tubes were produced, all having diameters for the hollow interior of the nanotubes on the order of 2.6 nm, but having outer tube diameters of about 24, 49, and 53 nm. Adsorption took place primarily on the external surface of the tubes, with tubes with smaller outer diameters having greater specific adsorption capacities. The smaller tubes were determined to have a surface area of 38 m^2/g, the next smaller tubes 14.8 m^2/g, and the largest diameter tubes 11.2 m^2/g. A small amount of adsorption (corresponding to between 0.97 and 0.07 m^2/g) occurred in the hollow interior of the tubes. No hysteresis loops were observed in adsorption/desorption cycles for these samples.

Yang et al. [20] investigated adsorption of N_2 on pristine and purified, catalytically grown carbon nanotubes. As a result of the purification process, some of the tips of the nanotubes appear, upon TEM inspection, to have been opened. Adsorption isotherms were conducted volumetrically at 77.3 K. A hysteresis loop was observed in the adsorption–desorption cycles for the purified tubes, while measurements made on pristine samples show no sign of hysteresis. The largest fraction of the hysteresis loop observed on the purified tubes (close to 80%) was attributed to aggregated pores, that is, condensation in the space between tubes, while a much smaller fraction of the capillarity observed was attributed to adsorption in the space at the interior of the nanotubes, which were uncapped as a result of the purification process.

Very recently, Masenelli-Verlot et al. [21] reported on the layering behavior of ethylene films adsorbed on multiwalled carbon nanotubes. From measurements performed between 90 and 100.5 K, these authors infer the existence of a layering transition, for the second layer of ethylene, at a temperature in the vicinity of 82 K. The layering transition temperature for the nth layer of an adsorbed film is the temperature at which the number of layers present in the film in equilibrium at the saturated vapor pressure (i.e., in coexistence with the bulk adsorbate) increases from $n-1$ to n. The layering transition temperature for the second layer of ethylene on planar graphite is 78.9 K [63]. The authors also report that the value of the layering temperature increases for decreasing tube diameters. In other words, there is a temperature interval over which, at the same temperature, thinner solid ethylene films grow on nanotube substrates than on planar graphite. This effect is more pronounced, the narrower the tubes used.

A summary of adsorption results for various adsorbates on multiwalled carbon nanotubes is shown in Table 1.

3.2. Adsorption on Single-Wall Nanotubes

After methods were developed for the production of macroscopic amounts of single-walled carbon nanotubes [56, 57], adsorption studies on these systems became possible. While theoretical activity had provided some initial stimulus for these experimental investigations (specifically, calculations for the adsorption of helium and hydrogen on carbon nanotube bundles) [66], there is little doubt that a great deal of the impetus for performing adsorption studies came from the very remarkable results from Heben's group regarding hydrogen adsorption [12]. Using thermal-programmed desorption on a sample that contained approximately 0.2% of SWNTs, Heben's group reported that this new carbon material was able to adsorb relatively large amounts of hydrogen at room temperature [12]. This study estimated a value for the binding energy for hydrogen on the SWNTs of 19.6 kJ/mol, and it estimated the H_2 uptake by the SWNTs to be somewhere between 5 and 10% by weight. These

Table 1. Summary of adsorption results for various gases on multiwalled carbon nanotubes.

Adsorbate	Production/treatment	Tube diameter (nm)	Temp. (K)	Specific surface area (m^2/g)	Ref.
N_2	Arc discharge/as produced		77.3	21.0	[14]
	Arc discharge/CO_2 at 850 °C		77.3	37.0	[14]
	Manufactured by Hyperion/heated in vacuum at 373 K for 2 h	4 (interior) 3 (wall thickness)	77.3	268 (total) 90 (tube interior)	[16]
Kr	Catalytic/heated in vacuum to 773 for 6 h	10–50	77.3	105	[18]
CH_4	Catalytic/evacuated at room temp. for 12 h	10–100	77.3	17	[17]
	Catalytic/HNO_3 treated, then evacuated at room temp. for 12 h	10–100	77.3	23	[17]
Butane	CVD grown/heating 473.15 K at atmospheric pressure	2.6 (interior)/24 (exterior)	298.15	37.9	[19]
	CVD grown/heating 473.15 K at atmospheric pressure	2.6 (interior)/49 (exterior)	298.15	14.8	[19]
	CVD grown/heating 473.15 K at atmospheric pressure	2.6 (interior)/53 (exterior)	298.15	11.2	[19]

Note: The columns include a listing of the adsorbate used, a brief description of the method of production of the nanotubes and the treatment to which they were subjected, the diameters of the tubes, the range of temperatures at which the measurements were conducted, the specific surface areas, and the source.

results opened the possibility that this novel carbon material could be used for the room-temperature, low-pressure storage of H_2. A number of other studies of H_2 storage and H_2 adsorption followed this initial, exciting report [1–3]. Some of the more recent reports are not able to confirm the initial claims of very high H_2 storage capacity by the SWNTs (see, for example, [3]).

Single-walled nanotubes form bundles [56, 57]. The van der Waals interaction among the individual tubes causes them to order in a triangular array. For (10, 10) tubes, which have a diameter of 1.37 nm, the intertube separation is 1.7 nm. Typically, bundles are formed by between 40 and 200 tubes [56, 57]. The formation of bundles has important consequences for the adsorption characteristics of these materials.

Three different groups of sites for adsorption have been predicted to exist for bundles formed by close-ended, single-walled carbon nanotubes [11] (see Fig. 6). These are: the sites present on the surface of individual nanotubes which sit on the perimeter or periphery of the bundle, which we will call outer surface sites; the sites present in the convex valleys formed by the space in which two of these tubes on the periphery of the bundle come together, called groove sites or grooves; and, finally, the open spaces at the interior of the bundles which are left by three tubes coming as close together as they can, called the interstitial channels or ICs. In case the nanotubes are open or cut, in addition to these three groups of sites, the hollow interior of the open tubes will also be potentially available for adsorption.

On close-ended tubes, the outer surface sites and the grooves are always accessible for adsorption. Whether the interstitial channels are or are not available for adsorption

will depend on the relative sizes of the adsorbate species and of the channels [11]. A purely geometrical calculation for (10, 10) nanotubes which considers the tube diameters and the intertube separation gives a diameter of 5.2 Å for the interstitial channels. This simple calculation, however, grossly overestimates the actual space available for the ICs because it neglects the effect of considering the electronic clouds present on each of the tubes. When a reasonable guess is made regarding the size of this electronic cloud, the diameter of the interstitial channels becomes approximately 2.3 Å [26]. A more sophisticated analysis, one which takes into consideration both the attractive and repulsive portions of the adsorption potential [11], concludes that only the smallest adsorbates (helium, neon, and hydrogen) can adsorb in the interstitial channels. For the first two of these adsorbates, in fact, the adsorption potential on the interstitials is most favorable, while it is less so for hydrogen; all other adsorbates are too large to fit in. Experimentally, the question whether adsorption occurs in the interstitial channels for the smallest adsorbates is one that has not yet been completely settled [25, 31, 32].

Adsorption studies on SWNTs have dealt with a variety of questions. Some of these include: determining which of the various sets of sites present in the nanotube bundles are actually available for adsorption by a given adsorbate; establishing the values of the binding energies, or of the isosteric heats of adsorption, of different species adsorbed on the SWNT bundles; and identifying which new phases, if any, are present in the adsorbed films. Many studies have also determined the area available for adsorption on specific samples of SWNTs as part of their characterization of the substrates used.

3.2.1. Adsorption on As-Produced and Purified SWNT Bundles

Eswaramoorthy et al. [22] investigated the adsorption of N_2, benzene, and methanol on as-produced arc discharge SWNTs, as well as on SWNTs treated with hydrochloric and with nitric acids. No characterization for the samples was provided (e.g., no value for the estimated purity was given), and no details were provided on the adsorption measurement process. The report dealt with overall features of adsorption, such as the determination of the specific surface areas of the samples (which presumably was obtained by using the BET equation) and the determination of the pore surface area (the latter was determined by means of alpha plots with the comparison substrate being nonporous carbon black). Large microporosity was found in all cases. The Horvath–Kawazoe (HK) equation [65] was applied to the data in order to obtain an estimate of the pore size distribution, and a maximum was found at the expected tube diameter of about 1.0 nm in all cases, indicating that, according to this analysis, even a large number of the as-produced tubes are open. Adsorption/desorption cycles were investigated for the as-produced sample, and a hysteresis loop was found.

From a temperature-programmed desorption investigation of helium, Hallock and his collaborators determined the value of the binding energy of this rare gas on SWNT bundles at low temperatures to be 340 K [6]. This value

Figure 6. Schematic drawing depicting the three groups of sites that are potentially available for adsorption on bundles of closed-ended single-wall carbon nanotubes. The groove sites and the outer surface sites are available for adsorption by all gases, regardless of the size of the adsorbate. Whether adsorption occurs or not in the interstitial sites is currently a matter actively being investigated. Reprinted with permission from [26], A. J. Zambano et al., *Phys. Rev. B* 64, 075415 (2001). © 2001, American Physical Society.

was in very good agreement with calculations for helium adsorbed in the interstitial channels of SWNTs, which predicted a value for this adsorbate [11, 66]. The numerical agreement between the measured binding energy and the theoretically calculated binding energy for the interstitial channels, together with the large amount of gas desorbed, led the authors to conclude that the interstitial channels were the sites on which helium was adsorbing. Since the atoms adsorbed on the interstitial channels form a long column that is 1 atom thick, the phase was identified as one dimensional. In a subsequent paper, the authors revised downwards the value of the binding energy measured by TPD to 210 K, as a result of a correction of their temperature scale [7]. However, since the amount of gas desorbed was unaffected by the correction, they still interpreted their data in terms of adsorption in the ICs. A recent set of measurements, and a new analysis by the same group, found that the TPD data for helium indicate that the binding energy of this gas on SWNTs is coverage dependent [8]. The binding energy decreases for increasing coverage until a plateau region is reached, in which this quantity remains constant with coverage. This more recent report (Fig. 2) tentatively concluded that, for the higher coverage regime explored in the study, adsorption occurred in the grooves, and that the much higher binding energy sites observed for the lower coverages investigated may originate from surface inhomogeneity or corrugation.

Weber et al. [23] investigated the binding energy of methane on a sample of unpurified single-walled nanotubes produced in Prof. P. Bernier's laboratory by the arc-discharge method. The binding energy was determined from the isosteric heat of adsorption measurements. In turn, the isosteric heat values were obtained from a series of adsorption isotherms performed at different temperatures, following the procedure described in Section 2 (see Fig. 1). The adsorption isotherms were performed at relatively high temperatures and at very low coverages (only coverages of less than 8% of one full layer were used in the analysis). Thus, in this experiment, only the binding energy of the highest energy sites was determined. The measured value was 1.76 times larger than the corresponding binding energy for methane on planar graphite [67]. This study did not univocally identify the sites on which adsorption occurred. Rather, it provided two exclusive possible alternative interpretations for the data. The authors noted that methane was larger than neon, helium, or hydrogen, gases for which very favorable adsorption in the interstitial channels had been calculated [11, 66]. For He and Ne, the values of the binding energy were greater by about 150% than the corresponding values on planar graphite [11]. They suggested that one possibility was that the higher binding energy sites for methane could be a set of adsorption sites on the ICs, on which methane would fit less favorably than either helium or neon (and, hence, would have a lower relative value of the binding energy increase than these other gases). The alternative possibility suggested by these authors was that methane was too big to fit in the interstitial channels, and that the higher energy sites corresponded to adsorption on the grooves.

Muris et al. [24] reported on the adsorption of methane (and krypton) on single-walled carbon nanotubes. The sample used in their measurements was unpurified nanotubes produced by the arc-discharge method, also from Bernier's laboratory. They reported on volumetric adsorption isotherm measurements and microcalorimetric results. The adsorption isotherm data corresponding to the formation of the first layer on the carbon nanotube bundle surface displayed two well-defined, but broad, substeps. This indicated the presence of two groups of sites, each with a fairly uniform binding energy, in the first layer. From adsorption isotherm measurements performed at different temperatures, they extracted the two values of the first-layer binding energies. The higher binding energy value, determined from a coverage corresponding to the midpoint of the lower pressure substep, was approximately 1.2 times larger than the binding energy for methane adsorbed on planar graphite. On the other hand, the binding energy of the lower energy sites was lower than that for the first layer of methane on graphite, but larger than that for the second layer of methane on graphite [68]. The values derived from the adsorption isotherm measurements were confirmed by microcalorimetric determinations performed at the same coverage. The lower pressure step was identified as resulting from adsorption on the interstitial channels, while the higher pressure (lower binding energy) step was identified as adsorption occurring on the outer surface sites. The possibility of adsorption on the grooves was not considered in this study.

Bienfait's group reported on the mobility of the methane films adsorbed on single-wall nanotube bundles [42]. They used quasielastic neutron scattering to determine the diffusion coefficients of the adsorbed gas (Fig. 4). The results indicated that, on the more strongly binding sites, the adsorbed film was solid-like for temperatures below 120 K. For the less strongly binding sites, a very viscous liquid-like behavior was observed for temperatures between 70 and 120 K. At 50 K, the film in the lower energy binding sites was solid.

Talapatra et al. [25] reported on the binding energy determinations for the highest energy binding sites for neon, methane, and xenon on SWNT bundles. The measurements were performed on the same sample of SWNTs. The binding energy of the highest energy sites was determined from isosteric heat measurements performed at very low coverages. In all three cases, the values of the binding energies were higher than those found on planar graphite by a factor of about 1.75. Since the amount of the increase was the same in all three cases, the authors concluded that the different gases were all occupying the same type of sites. Theoretical calculations provide the values of the binding energies for these gases for the three different groups of sites: ICs, outer surface sites, and grooves [11]. For adsorption on the interstitial channels, the changes in the binding energies relative to the values on exfoliated graphite are very different for neon, methane, and xenon. On the other hand, the changes on the grooves, relative to planar graphite, are very similar for these three gases, and in all cases, they are greater than those for graphite. Additionally, the size of the Xe atom is too large to allow it to fit in the ICs. Taking these different factors into account, the study concluded that none of the gases studied was able to penetrate in the ICs, and that the high energy-binding sites present on the nanotube bundles

were on the grooves. The same conclusion was reached from specific surface area measurements, which found essentially the same values of the specific surface area for the same sample of SWNTs using Ne and Xe as the adsorbates. It should be noted, however, that in [25], incorrect values for the monolayer capacities were used in these determinations, leading to incorrect estimates for the surface area. When the correct values for monolayer completion are used, the specific surface areas are found to be 161.1 m^2/g using Xe and 173.1 m^2/g using Ne. Since these results are very similar, the validity of the argument made in [25], leading to the conclusion that the ICs are not accessible for adsorption by any one of the three gases studied, remains unaffected.

Very similar binding energy increases to those reported by Talapatra et al. [25] were found in a temperature-programmed desorption study performed by Hertel et al. [36], who investigated thermal desorption spectra from methane, Xe, and SF$_6$ (Fig. 5). The nanotube sample used in this study came from tubes@rice. A very interesting aspect of this study is that the treatment to which the nanotubes were subjected to was significantly different from that used by Talapatra et al. [25]. While in the Talapatra study [25] the as-produced sample was just subjected to extended pumping at room temperature, the sample investigated by Hertel's group was subjected to heating to 1200 K in a Ta foil in an UHV chamber, and cycled repeatedly to anneal it [36]. The study determined that, for methane, xenon, and SF$_6$, adsorption at lower coverages occurs principally in the groove sites. From the peak desorption temperatures, they concluded that the value of the binding energies for these gases on the groove sites were between 190 and 160% greater than on the surface of HOPG for methane, and between 170 and 130% greater than on the surface of HOPG for Xe. The ranges of values quoted for each species correspond to the range of coverages studied. The higher percentage increases correspond to the lower coverages studied, while the lower percentage increases correspond to the higher coverages studied for each gas.

Zambano et al. [26] reported on adsorption isotherm results for xenon on SWNT bundles. The measurements for this study were conducted on arc-discharge, as-produced tubes produced in Prof. P. Bernier's laboratory by Journet. The study involved the performance of complete sets of monolayer adsorption isotherms at a variety of temperatures. As had been the case for the report by Muris et al. [24] for methane adsorbed on SWNTs, two substeps were found in the adsorption data. The top of the second substep was identified as monolayer completion [26] (as had been done by Muris et al.) [24]. In order to identify the nature of the adsorption sites responsible for the lower pressure substep, the authors performed a geometrical calculation. They estimated the number of Xe atoms that would adsorb on the outer surface sites and on the grooves; they then considered two cases: that the ICs were available for adsorption, and that they were not available. Comparison of the experimental results with these calculations led to the conclusion that only adsorption on the grooves and the outer surface sites was needed to explain the results, and that, thus, no adsorption occurred in the ICs. A comparison was also made between the values of the isosteric heat of adsorption and binding energy for Xe determined experimentally

and theoretically calculated values for the binding energy on the grooves [11]. Very good agreement was found between the two values. As a result of comparing both the geometric calculations and the theoretically calculated value of the binding energy on the grooves with experiment, the authors concluded that the lower pressure substep corresponded to adsorption on the grooves.

Talapatra and Migone [27] investigated in some detail the adsorption of methane on closed-ended SWNTs. Their results largely confirmed those of Muris et al. [24]: two substeps were observed in first-layer adsorption isotherms, corresponding to the presence of two groups of adsorption sites with different binding energies, one greater and the other smaller than those for planar graphite. The interpretation of these results, however, differed from that of Muris et al. [24] as the more strongly binding sites were identified in this study as corresponding to the grooves. Both studies agreed in the identification of the weaker sites as corresponding to the outer surface sites. Talapatra and Migone [27], were able to explain why previous studies had reported different increases in the strength of the binding of methane on SWNTs bundles relative to that on graphite: (Talapatra et al. [25] had found that the binding energy of methane on the most strongly binding sites on the bundles was 1.75 times that found on graphite; while Muris et al. [24] had found an increase of only 1.2 times in the value of the isosteric heat of adsorption relative to that on graphite). They noted that the values reported by Muris et al. [24] were measured at higher fractional coverages on the nanotube surface than those used by Talapatra et al. [25] in their determinations, and that the isosteric heat was a strongly dependent function of the coverage at low coverages on the SWNT substrates [27].

Muris et al. [31] performed a comparative adsorption study of Xe, SF$_6$, and CF$_4$, adsorbed on nanotubes produced by arc discharge. They combined their results for these gases with those already available, from measurements performed by the same group [24], for CH$_4$ to determine the location of the sites on which these different gases adsorb on the bundles of single-walled nanotubes. Based on the size of the substeps present in the data for the first layer for the different gases (Fig. 7), the authors concluded that Xe, SF$_6$, and CF$_4$ adsorb only on the grooves and outer surface sites, and that they do not adsorb in the interstitial channels. In the case of methane, the adsorption data from these authors display a relatively larger lower pressure substep than that which is present for Xe (and for the other gases studied). The authors concluded that the larger low-pressure adsorption substep present for methane is due to adsorption occurring on some of the largest interstitial channel sites present in this substrate, in addition to the adsorption occurring on grooves for this adsorbate.

Fujiwara et al. [32] performed adsorption isotherm and X-ray diffraction measurements on as-grown nanotube samples, as well as on samples that had been heat treated in air at 350 °C (the latter were estimated to be open ended). They found that the specific surface area increased from about 245 m^2/g on the as-grown samples to about 515 m^2/g for the samples heat treated in air, indicating that there were additional sites available in the heat-treated sample. The authors looked at one single diffraction peak for the as-produced samples, and found that the peak shifted to a
Figure 7. Adsorption isotherms for (from left) methane at 78 K, xenon at 110.6 K, CF4 at 96 K, and SF6 at 142.6 K on single-walled carbon nanotubes. Reprinted with permission from [31], M. Muris et al., *Surf. Sci.* 492, 67 (2001). © 2001, Elsevier Science.

lower Q (Å^{-1}) value after adsorption. In contrast to all other experimental and theoretical results for adsorption on nanotubes, these authors interpreted their adsorption and X-ray results for nitrogen and oxygen on closed-ended nanotubes exclusively in terms of adsorption in the interstitial channels. Thus, these authors entirely neglected to consider adsorption on either the grooves or the outer surface sites that are present and available in the bundles [32]. In their results for the heat-treated samples, these authors interpret the data as indicating adsorption in the interstitial channels and on the interior of the tubes, once again neglecting the outer surface sites and the grooves. As the two groups of sites that these authors neglected to consider in their interpretation (i.e., the grooves and the outer sites) are always present and available for adsorption by adsorbates of the molecular sizes used here, and as the area measured in the closed tubes can be very effectively explained in terms of adsorption occurring only on grooves and outer sites (and, for the heat-treated tubes, in terms of adsorption occurring only on grooves, outer sites, and the inside of the open tubes), the interpretation put forth by Fujiwara et al. [32] has to be viewed with a great deal of skepticism.

Bienfait's group investigated the adsorption of methane and deuterium on bundles of as-grown SWNTs using neutron scattering [42]. They observed, for the case of CD_4, a 5% shift toward smaller scattering vectors for the 0.4 Å^{-1} peak, indicating an apparent expansion of the lattice. They offer two alternative explanations for this shift, both of which can account for this experimental feature. The first one is that some CD_4 is adsorbing in the interstitial channels, and that this adsorption results in a deformation (expansion) of the nanotube lattice. The second explanation is that the lattice expansion is only apparent; it is the result of CD_4 adsorbing on the grooves, at a position that is displaced by 1 Å outwardly above the lattice sites, that is, 1 Å above the surface of the bundle, thus appearing as an expansion of the lattice. Combining the results of their diffraction experiments with prior adsorption isotherm measurements,

they proposed a scenario in which the formation of the first layer of CD_4 on SWNT bundles starts with the adsorbate filling the groove sites and the widest available ICs (these two groups are the highest binding energy sites present) [42]. After these sites are filled, monolayer completion proceeds by filling the less attractive sites in the first layer, that is, the outer surface sites.

3.2.2. Adsorbate Size Effects on Phase Formation

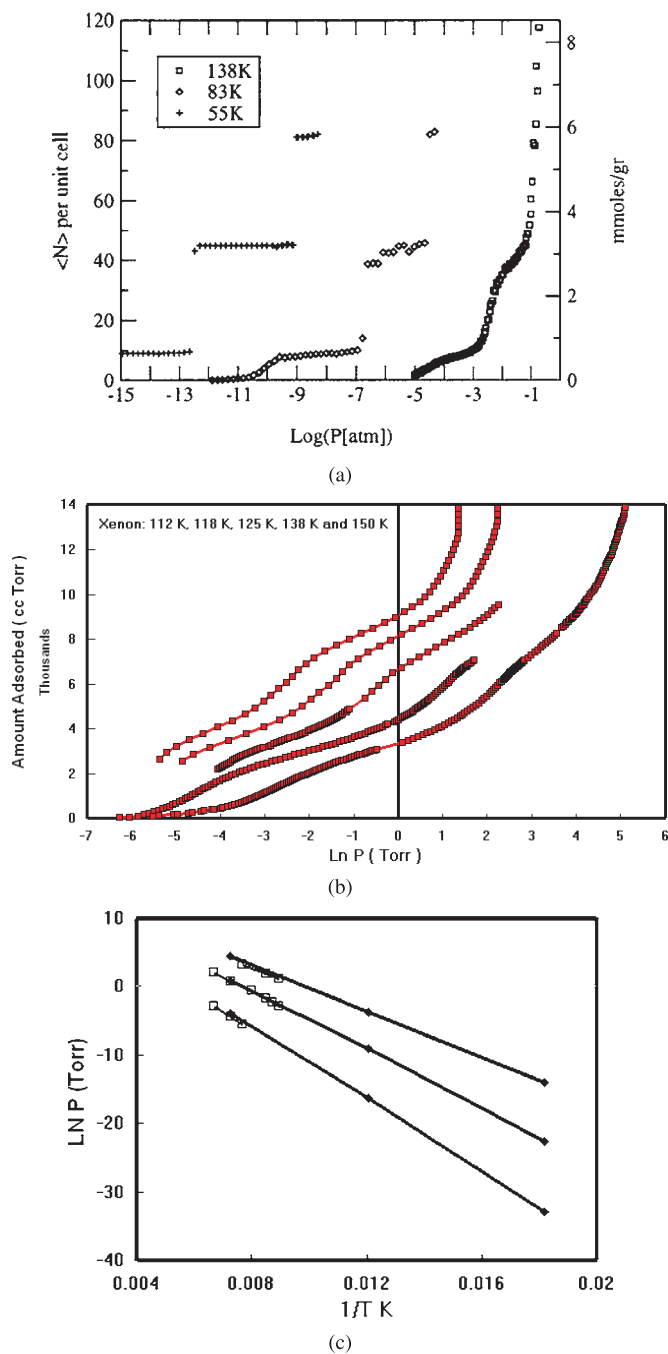
The existence of new phases in the systems formed by gases adsorbed on closed-ended SWNTs has been explored in an adsorption isotherm study by Talapatra and Migone [9]. This study focused on first-layer features of the adsorption of Xe and Ar films on the nanotubes. It provided a detailed comparison with results obtained in computer simulations of adsorption isotherms for these same systems [5]. The simulations predicted that monolayer completion for these gases proceeds in a series of stages [5]. The number and characteristics of the stages vary from one adsorbate to another, depending on the size of the adsorbate. For the case of Xe, simulations predict that adsorption takes place in two stages. In the first stage, formation of the first layer begins with the filling of the grooves, at the lowest pressures. The adsorbate forms 1 atom thick long lines of atoms on the grooves; in the simulation study, these lines were termed the "one-channel" phase [5]. After the grooves are filled, monolayer completion follows with the filling up of the outer surface sites, with what in the computer simulation study was called the "five-channel" phase. The adsorption isotherms obtained in the simulations [see Fig. 8(a)] closely match the features obtained by Talapatra and Migone in their experimental work [some of the experimental results are displayed in Fig. 8(b)] [9]. To provide a quantitative comparison, the pressures at which the two first-layer features occurred in the simulations were plotted in a $\log P$ versus $1/T$ curve, as were the pressures determined from the experiment for the two first-layer substeps [9]. The experimental points fell on the same line as those from the simulations, indicating that the agreement between them was excellent [see Fig. 8(c)]. This permitted the identification of the lower pressure substep in the experiments as a one-dimensional phase formed by adsorption on the grooves. For the case of Ar, the simulations predict that monolayer completion proceeds in three stages [5]. The first one is the formation of the one-channel phase on the grooves. This phase is followed, at higher pressures, by the formation of two additional lines of atoms, one on each side of the atoms present on the grooves, in what was called the "three channel" phase in the simulations. Finally, at pressures only slightly higher than those needed to form the three-channel phase, monolayer completion occurs in what was identified as a "six-channel" phase. Because the difference in chemical potential between the three-channel and six-channel phases is not too large, and because the surface offered by the SWNT substrates is not ideal and exhibits heterogeneities that broaden and blur adsorption features, it is difficult to extract evidence for the existence of the three-channel phase from the adsorption data. In order to search for evidence of the existence of the three-channel phase in the experimental data, the isothermal


Figure 8. (a) Grand canonical Monte Carlo simulations for adsorption isotherms for Xe on the outside surface of closed-ended single-wall carbon nanotubes. The amount adsorbed, in arbitrary units, is presented as a function of the logarithm of the pressure (in atmospheres). One full layer on the surface of the bundle corresponds to a coverage of approximately 50 in these units. The temperatures shown are, from left to right, 55, 83, and 138 K. The lower pressure substep (0–10 in coverage) corresponds to the filling of the grooves, and the second substep (10–50 in coverage) to the filling of the outer surface sites. Reprinted with permission from [5], M. M. Calbi et al., *J. Chem. Phys.* 115, 9975 (2001). © 2001, American Institute of Physics. (b) Adsorption isotherms measured for Xe on the outer surface of bundles of closed-ended carbon nanotubes. The temperatures displayed are, from left to right, 112.07, 118.06, 125.07, 138.05, and 150.06 K. The coverage (vertical axis) is in cm³ · torr; the logarithm of the pressure (in torr) is given in the horizontal axis. The lowest coverage substep corresponds to adsorption on the grooves, the middle coverage substep corresponds to adsorption on the outer surface, and the highest coverage substep is the formation of a second layer on the outside surface of the bundles. compressibility of the adsorbed films was obtained [9]. Computing the isothermal compressibility of a film essentially involves performing a derivative of the adsorption data. Features that are hard to resolve in the adsorption data appear with greater clarity in the compressibility (in particular, a step or a substep in the isotherm will appear as a peak in the isothermal compressibility). For Ar, the higher pressure substep in the isotherm that results from all of the adsorption that occurs in the monolayer after the filling of the grooves gives rise to two peaks in the isothermal compressibility [9]. The lower pressure peak in this structure was identified as corresponding to the three-channel phase. The pressures at which the one-channel, three-channel, and six-channel phases were observed in the simulations were plotted in a $\log P$ versus $1/T$ curve, as were the experimental results for the pressures of the lower coverage substep, and those for the two peaks in the isothermal compressibility present at higher coverages. Again, very good agreement was found between experiments and simulations [9]. Thus, by conducting a detailed comparison with computer simulation results, this adsorption isotherm study was able to identify one-dimensional phases for Ar and Xe (the one-channel phases) and a new phase (the three-channel phase) for Ar adsorbed on the outer surfaces of closed-ended SWNTs.

3.2.3. Coverage Dependence on Isosteric Heats of Adsorption

A number of quantum [28, 29] and classical [28] adsorbates have been explored by adsorption isotherm measurements (and, in the case of helium, also by heat capacity) [45] by Vilches' group. They studied adsorption isotherms on arc-discharge produced nanotubes for H_2, D_2, N_2, Ar [28] and, more recently, for ^{4}He [29]. The monolayer data investigated for H_2, D_2, N_2, and Ar display the characteristic two substeps that have been observed by other authors for several other adsorbates. The low-pressure substep (high energy-binding sites) was attributed to adsorption on the grooves and on the widest interstitial channels present in the bundles, and the higher pressure substep (lower binding-energy sites) to adsorption on the outer surface sites. The isosteric heat of adsorption was determined for a wide range of coverages in the first layer for H_2, D_2, N_2, and Ar [28]. This quantity is found to be higher for lower coverages, and to reach a plateau as coverage increases (Fig. 9); the plateau starts roughly at coverage of one third of a complete monolayer. The behavior of the isosteric heat is consistent with that seen in other experiments for this quantity. The helium adsorption isotherm measurements were conducted between 2.1 and 12 K. This study was able to resolve, for the first time for any adsorbed system on SWNT bundles, up to three distinct layers in the data measured at the lower temperatures [29]. The isosteric heat of adsorption was calculated from the lowest coverages in the first layer up to the third layer. The first-layer isosteric heat increases as the coverages decreases, and then it plateaus. The values of the isosteric heat are consistent with an interpretation in which the groove sites get filled first at the lower coverages, and then the external surface sites get filled as monolayer completion is approached [29]. There are two additional plateaus, at even lower values of the isosteric heat, as the coverage
Figure 9. Coverage dependence of the isosteric heat for N_2, Ar, D_2, and H_2 adsorbed on SWNT bundles. Reprinted with permission from [28], T. Wilson et al., *J. Low Temp. Phys.* 126, 403 (2002). © 2002, Kluwer Academic/Plenum.

goes through the second and third layers. The heat capacity measurements for helium films on the SWNTs are currently in progress [45].

The adsorption of N_2 on SWNTs has been explored by Kim's group with adsorption isotherms [30]. Their results indicate that the isosteric heat is higher for lower coverages, and that this quantity decreases with increasing coverage, in a manner that is entirely consistent with the observations of other experimental groups. These measurements were performed on pulsed-laser-produced nanotubes that were purchased from tubes@rice (this company's present name is Carbon Nanotechnologies Inc. or CNI). Interestingly, the two substeps that are present in the arc-discharge tubes investigated by other groups are not present in these data. This suggests that there is a possibility that nanotube bundles produced by different methods may result in significantly different adsorption characteristics. The question of the dependence of the adsorption characteristics on the production and treatment of the nanotube substrates used in adsorption measurements is one which has not yet been addressed in a systematic fashion.

3.2.4. Adsorption Results on Chemically and Mechanically Opened SWNTs

Stepanek et al. [33] investigated the effects on adsorption of opening the ends of the tubes, and making the interior space of the nanotubes available to the adsorbate species. These authors employed a mechanical process, involving the use of abrasive diamond powder, to cut open single-wall nanotubes. This mechanical approach obviated the need for the relatively harsh chemical treatments that are the norm in opening processes for tubes. The nanotubes preserved a well-organized structure after the mechanical cutting. Evidence that the tubes were open was obtained from high-resolution transmission electron micrographs, and evidence that the process did not disturb the order in the tubes was obtained from X-ray diffraction measurements. Adsorption measurements were performed before and after the cutting treatment. The adsorption results were analyzed in terms of the Horvath–Kawazoe equation [65]; this analysis revealed

significant differences in the data taken before and after the treatment. In particular, the HK analysis showed evidence of the presence of nanoporosity, in the appropriate range for open tubes (1–2 nm), only for the nanotubes that were cut open mechanically [33].

Two recent studies have investigated the effects of purification on the pore structure and adsorption characteristics of HiPCO single-walled carbon nanotube bundles [34, 35]. Samples from two different batches of as-produced HiPCO SWNTs, manufactured by Carbon Nanotechnologies Inc., were investigated by Simard's group [34]. Studies on the samples were conducted before and after subjecting them to acid purification treatment. The samples were investigated with X-ray diffraction (for the verification of the ordered nature of the bundles), Raman spectroscopy (for independent confirmation of the tube diameters), and with argon and nitrogen adsorption isotherm measurements (at 87 and 77 K, respectively). The pore structure was estimated using the HK equation [65]. The results, both for the specific surface areas as well as for the HK pore distribution, on the samples from the two batches of as-produced samples were significantly different from one another. This indicates that the adsorption characteristics of the same type of material can vary significantly from batch to batch. The pore structure analysis of the low-pressure portion of the data obtained from the HK analysis for the untreated tubes yielded two peaks in the pore size distribution. These peaks were interpreted in terms of adsorption occurring on the grooves and on open tubes. The fraction of open tubes in the as-produced samples, as estimated from the HK approach, was observed to vary from an upper limit of 38% in one batch, down to 15% in another. After the purification treatment, the HK analysis yielded a smaller proportion of open tubes. This result was interpreted in terms of blocking of the tube openings by the functional groups that result from the chemical purification process [34].

HiPCO nanotubes produced by Carbon Nanotechnologies Inc. were also investigated by Kaneko's group [35]. The nanotubes were subjected to two different purification treatments (one involving attack by concentrated HCl for 48 h, and the other involving heating in air at 623 K, followed by immersion in concentrated hydrochloric acid for 48 h). These cleaning procedures have been shown to be effective in removing the metallic catalyst impurities present on HiPCO nanotube samples. The adsorption characteristics of the nanotube samples before and after the purification processes were investigated by means of volumetric N_2 adsorption isotherms at liquid nitrogen temperature. The pore structure of the samples was inferred from the determination of alpha plots on the materials investigated. There is clear evidence of the presence of hysteresis loops after subjecting the tubes to either one of the purification treatments, indicating the formation of mesopores as the result of the purification processes. The adsorption at low values of P/P_o is considerably enhanced for the tubes subjected to both air oxidation and HCl treatment, indicating the production of micropores on these samples, in addition to the mesopores produced by either treatment. The alpha-plot analysis yields an external surface area for pristine HiPCO tubes on the order of 436 m^2/g, which was attributed to the presence of amorphous carbon on the untreated material; the total

external area of the tubes is estimated at 524 m^2/g. After treatment with just HCl, the total area increases to 587 m^2/g, while the external area is estimated at 364 m^2/g. After treatment with both oxidation in air and attack by HCl, the total area is considerably increased, to 861 m^2/g, while the external area in this case is estimated at 334 m^2/g [35].

The values of the pore-size distribution and the internal and external areas determined in the three previous sets of studies depend on the applicability of the Horvath–Kawazoe analysis [65] and on that of the alpha plots, respectively, as techniques for interpreting adsorption data for bundles of carbon nanotubes. The validity of these approaches is not automatically assured in these cases since there are uniform high binding energy surfaces on the nanotube bundles that are not the result of pores, and since there will be considerable adsorption occurring on them at low pressures. However, these three studies [33–35] make it very clear that the purification and tube-opening processes (either mechanical [33] or chemical [34, 35]) have a dramatic effect on the adsorption characteristics of the resulting material.

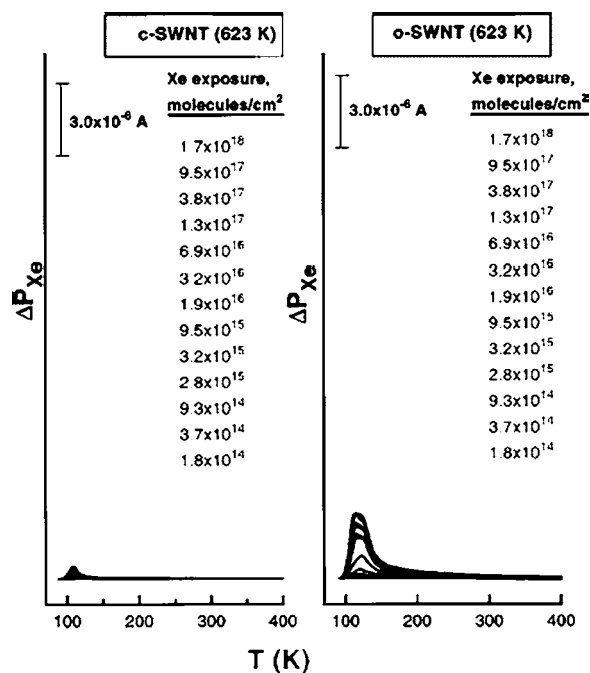
The effects of the functional groups that result from purification and opening treatments with nitric and sulfuric acids on the adsorption characteristics of the SWNT bundles has been investigated by Yates's group [10, 38]. Kuznetsova et al. studied the adsorption of Xe on both closed-ended and open-ended nanotubes by means of temperature-programmed desorption and other analytical techniques [10, 38]. The closed-ended nanotubes were purified by the nitric/sulphuric acid treatment. The open tubes were sonicated in a mixture of nitric and sulfuric acid, followed by treatment with oxygen peroxide/sulfuric acid. The resulting samples were placed inside an ultrahigh-vacuum apparatus, and heated *in-situ* to either 623 or 1073 K prior to exposure to Xe. A mass of 45 μg of tubes was used for both the open- and closed-ended tubes. After a heat treatment to 623 K for closed tubes, a small desorption peak was observed near 120 K in temperature-programmed desorption measurements for Xe. For the open tubes heated to 623 K, at least two temperature-programmed desorption peaks, and a much greater desorbed amount than for the closed tube case, were observed (Fig. 10). There was a factor of 12 larger amount of Xe adsorbed on the open tubes than on the closed ones. During the heating process, the evolution of CO, CO_2, H_2, and CH_4, was observed; this evolution started at about 500 K [10, 38]. These gases result from chemical decomposition processes occurring in the nanotubes. Similar gas evolution characteristics were observed for open and for closed nanotubes. Xe thermal desorption spectra were also measured after heat treatment to 1073 K. The intake of Xe on both closed and open tubes increased very considerably after the high-temperature heating relative to the intake of Xe exhibited for tubes heated to 623 K [10, 38]. The closed tubes show two weak desorption peaks at about 105 and 120 K. For the open tubes, the 120 K feature shifts to higher temperature as the initial Xe coverage of the sample is increased. These experiments showed that the chemical treatment with nitric and sulfuric acids leaves functional groups containing carbon, oxygen, and hydrogen on the nanotubes, and that these groups block the entry ports to the nanotube interior. The high-temperature heating treatment of the sample leads to the removal of the blocks on


Figure 10. Comparison of programmed desorption rates for xenon on bundles of closed (c-SWNT) and open (o-SWNT) after activation at 623 K at a variety of different Xe exposures. the entry ports of the tubes, and hence results in increased adsorptive capacity. From the analysis of the desorption kinetics observed for Xe from the high-temperature treated open tubes, this study concluded that the Xe inside the tubes is quasi one-dimensional. The value for the binding energy measured at the interior of the tubes agrees well with calculated values for this quantity obtained by Cole's group [11].

The same group also investigated the effects of successive etching of purified SWNT with ozone on the adsorption of Xe gas [39]. A sample of purified nanotubes was heated in vacuum to 1073 K, exposed to a monitored amount of ozone, had the ozone removed, was heated to 973 K, and had Xe temperature-programmed desorption measurements performed. The sample was then reexposed to ozone, and the same sequence was repeated. The effect of ozone exposure on the tubes was initially to increase the Xe uptake. After a certain point, repeated exposure to ozone resulted in a decrease in the Xe uptake. The decrease became progressively worse as exposure to ozone continued. The comparison of the experimental results with simulations for this system led to the conclusion that there was an optimal etching of the nanotubes that corresponded to openings at the ends and at the side walls of the tubes on the order of 0.5–0.7 nm, and that etching beyond this point results in a decrease in the level of Xe uptake because further removal of C atoms from the tubes reduces the surface area available for adsorption [39].

A summary of adsorption results for various adsorbates on single-walled carbon nanotubes is shown in Table 2.

3.3. Adsorption Effects on Electrical Transport Properties of SWNTs

The effect of gas adsorption on the electrical properties of carbon nanotubes has been the object of considerable attention [47–53].

The possibility of using semiconducting SWNTs for chemical sensor applications has been explored by Kong et al. [47]. These studies were based on changes on the electrical resistivity of the semiconducting SWNTs upon exposure to gaseous NO_2 and NH_3, which were present at dilute concentrations (2–200 ppm for NO_2 and 0.1–1.0% concentrations for ammonia, respectively) in a carrier gas (air or Ar). The conductance of the nanotubes was observed to change by about three orders of magnitude upon exposure to NO_2, and by about two orders of magnitude for ammonia. The effects of the change were slowly reversed (over a 12 h period) upon continued exposure to the flowing inert gas or more quickly by heating.

Zettl's group reported that exposure of carbon nanotubes to air or oxygen resulted in dramatic changes in the electrical resistance and thermopower [48, 49]. The electrical resistance at room temperature changed between 10 and 15% as a result of cycling between an air atmosphere and vacuum. At 350 K in an initial atmosphere of pure oxygen, the thermopower was +20 μV/K. As the oxygen was removed from the space surrounding the tubes, the thermopower switched gradually to lower values, passing through 0, and eventually settling on an equilibrium value while under vacuum of −10 μV/K. This group also investigated the temperature dependence of the reversibility of these changes when the gas pressure surrounding the samples was changed. Switching between vacuum values and air-exposed values occurred very fast at 380 K. At 350 K, reverting back to the equilibrium values under both sets of conditions took a period of several minutes. At 300 K, these changes were much slower, taking periods of hundreds of hours. The explanation proposed for these observations was that oxygen dopes the tubes so that they go from n type in vacuum to p type when in air or oxygen [48]. The study also concluded that previous measurements of electrical properties of nanotubes that had not taken into account the effects of air exposure (and consequently, exposure to oxygen) would yield "air-doped" and not intrinsic nanotube values for the quantities measured [48].

The values of the electrical resistance of mats of SWNTs in vacuum and upon exposure to different adsorbates (including N_2, H_2, O_2, Ar, CO_2, H_2O) were studied by Marliere and co-workers [50, 51]. For N_2, H_2, O_2, and Ar, an increase in the electrical resistivity was observed upon introduction of gas. For CO_2, after the initial increase in resistivity, there was a decrease in the resistivity measured. A decrease in the resistivity was also observed with the introduction of water. The interpretation was that water and carbon dioxide act as electron donors upon adsorption on the SWNT mat [50, 51].

The effect of gas adsorption on the thermoelectric power and on the electrical resistivity on SWNTs was investigated by Eklund's group [52]. The thermopower went from positive to negative as a sample prepared in air was degassed under vacuum at 500 K. The electrical resistivity decreased

Table 2. Summary of adsorption results for various gases on single-walled carbon nanotubes.

Adsorbate	Production/treatment	Temp. range	Isost. heat/ bind. energy	Specific surface area (m^2/g)	Ref.	Source
He	Laser ablation/purified by boiling in 70% HCl at 120 °C for 4 h and degassed at 500 °C and at ~5×10^{-6} torr for 4 h	7.94–33.6 K	274 K (G)		[8]	E

during the same process. The effect of introducing and pumping out N_2 and then He was, first, to produce small increases in the thermopower and resistance (introduction of the gas), and then, to decrease both quantities (pumping out) in a reversible manner. The observations for the air-saturated samples were explained in terms of weak electron transfer from the O_2. The smaller effects observed for nitrogen and helium were attributed to changes in the

Note: The columns include a listing of the adsorbate used, a brief description of the method of production of the nanotubes and the treatment to which they were subjected, the range of temperatures at which the measurements were conducted, the values for the isosteric heats (in italicized numerals) or of the binding energies (standard numerals) both in K, the specific surface areas (when they were available), the source, and a letter to indicate whether the result is experimental (E), theoretical calculation (T), or computer simulation (S). The entries for the isosteric heat of adsorption and binding energies are reported for the different binding energy sites, namely, the interstitial channels (IC), grooves (G), outer surface of the outer tubes in the nanotube bundles (OS), and the inside of the open nanotubes (I).

electron and hole lifetimes due to collisions with nonthermal phonons generated by collisions of the gas molecules with the tube walls [52].

The IBM group headed by Avouris very recently [53] explored whether the *p*-to-*n* conversion of vacuum-annealed nanotubes is the result of doping of the nanotubes by O_2, as has been suggested [48]. This group investigated the characteristics of two different approaches for converting the nanotubes from *p* type to *n* type in carbon nanotube field-effect transistors (CN–FETs) [53]. Results for conventional doping of the tubes with an electron donor (K) were compared to those obtained for tubes in which the conversion was achieved by annealing the nanotube–metal electrodes, and partially exposing them to different oxygen atmospheres. The evolution of the transfer characteristics of the FETs as a function of gradual introduction of oxygen in the case of the annealed tubes was quite different from the evolution observed for the conventionally doped tubes as a function of K doping. This indicates that there are fundamental dif-

ferences in the mechanisms of the transformation for each one of these cases. This group proposed a different explanation for the effect of oxygen adsorption on the nanotubes [53]. This study concluded that oxygen did not dope the bulk of the nanotubes, but that, rather, it modified the Schottky barriers at the metal electrode–semiconducting nanotube contacts. That the contacts were central to the observed behavior, as was proposed in this explanation, was verified by performing a test in which the characteristics of the nanotube FET were investigated for a case in which only one of the two contacts of a nanotube FET was annealed by local heating (by passing a large current in vacuum through only one of the two metal-semiconducting contacts). The drain current curve characteristics of the FET went from being symmetrical (before the heating) to completely asymmetrical (after heating just one of the contacts), verifying the conclusion that the observations were the result of changes at the metal–nanotube contact.

4. APPLICATIONS

Multiwalled carbon nanotubes have been investigated for potential use in differential adsorption. The adsorption of NO, CO_2, and SO_2 by multiwalled nanotubes from a gas stream which consisted of a mixture of He and O_2 has been investigated. Long and Yang [37] produced the multiwalled tubes used in these measurements by catalytic decomposition of acetylene on a metal catalysts; the tubes were purified prior to performing the measurements. The differential adsorption of the three different gases tested was investigated by means of thermogravimetric analysis, temperature-programmed desorption, and FTIR spectroscopy. It was found that the tubes were quite effective adsorbers for NO at room temperature, but were not equally effective for adsorbing CO_2 or SO_2.

Multiwalled carbon nanotubes have been used to produce capacitive and resistive prototypes of gas-sensing devices [64]. In the capacitive device, a silicon dioxide/multiwalled nanotube composite was used as the active sensing element of the capacitor, while in the resistive device, the active sensing elements were multiwalled nanotubes grown on a serpentine silicon dioxide pattern. The basis of the operation of such devices is that the impedance of the nanotubes changes as a result of the adsorption of different chemical species on them. The prototypes proved especially effective in sensing water and ammonia. The effects of water on the sensors were reversible, while those of ammonia were not.

Calculations for molecular sieving, using the SWNT bundles for separating hydrogen isotopes have found that the interstitial spaces between the nanotubes provide suitable pores for such process [13]. Specifically, the calculations found that the ICs of (10, 10) nanotube bundles can act as a quantum molecular sieve for separating hydrogen from tritium. If it turns out that such separation can be achieved with nanotubes, it would be of significant technological importance, since the present isotope separation techniques are expensive and complicated. However, one should note that this potential application depends on hydrogen and tritium being able to access the ICs. Whether hydrogen, or any other gas smaller than Xe, can access the ICs is a question that, at present, remains unresolved and the subject of some controversy [6–8, 24–29].

The high binding energy offered by the SWNT surface can be used to simplify, in some cases, the separation of gas mixtures, for example, xenon–krypton. Processes to achieve the separation of this mixture could have commercial implications because xenon is being increasingly used in the automobile industry, in headlights of automobiles; this provides a strong economic incentive for finding new and efficient ways of distilling this rare gas from air. Xenon's extraction from air is carried out in several consecutive steps [73]. In the last one of these steps, krypton (Kr) and Xe are separated by solidifying an Xe–Kr mixture at liquid nitrogen temperatures, and using the difference between the respective vapor pressures of these two rare gases to extract what is essentially pure Kr from the vapor, leaving an Xe-rich solid as residue. Since xenon has a sufficiently larger binding energy than Kr on SWNT bundles, a room-temperature xenon-capturing filter could be designed to replace this last purification step.

5. SUMMARY AND FUTURE DIRECTION

There is a considerable degree of consistency among the different sets of adsorption results obtained on the multiwalled nanotubes described above. There is a general trend in the data that shows an inverse correlation between the external tube diameters and the values of the specific surface area of the samples. The different sets of data also indicate that the greater the number of walls in the tubes, the closer the adsorption pressures for the formation of different layers on the tubes are to the values observed on planar graphite. All of the studied solid films adsorbed on multiwalled nanotubes are found to incompletely wet these substrates, even in those cases in which solid films of the same adsorbate completely wet planar graphite. Finally, the data on hysteresis in adsorption/desorption cycles indicate that such a feature is less likely to be present in pristine or as-produced tubes, while they are generally present for multiwalled tubes that have been subjected to some purification or activation treatment.

None of the trends in the data reported by the different authors cited above is unexpected. Thicker tubes, which involve a greater number of walls, have interaction potentials that resemble more closely those of planar graphite (which is the limiting case of an infinitely thick tube wall). On the other hand, the effects of curvature, in particular, the strain on a solid adsorbed film that results from it growing on a curved surface, will result in incomplete wetting. The presence of hysteresis loops in adsorption–desorption curves for nanotube substrates subjected to purification or activation treatments is probably the result of damage on the tube walls produced by the treatments.

Unlike the case with multiwalled carbon nanotubes, the degree of consensus that has been reached as a result of investigations on adsorption on single-walled nanotubes is more limited. Regarding the determination of the sites where adsorption takes place on bundles of closed-ended single-wall nanotubes, most authors now agree that the grooves and the outer surface sites play an important role, and that these sites account for either the majority or the totality of the adsorption that occurs on the bundles. All of the measurements performed at low coverages indicate that the isosteric heat of adsorption increases with decreasing coverage. The issue of whether or not various gases are able to adsorb on the ICs is one that is not completely settled yet, although it is generally accepted that gases as large or larger than Xe do not go into the ICs. Several new phases have been identified on the nanotube bundles, and it is clear that some of them are essentially one-dimensional entities. The potential for discovering a greater variety of phases when more systems are investigated in detail is considerable. The effect of contaminants on the tubes as a result of the purification processes to remove metal catalysts and amorphous carbon impurities is one that has been partly explored. It is clear that, on chemically cut tubes, the cutting agents have a pore-blocking effect that requires their removal at high temperatures to make the space at the interior of the tubes available for adsorption. The effect of adsorbates on the electrical properties of SWNTs has been explored; rather dramatic changes in the resistivity and other electrical properties have been found as a result of adsorption. The source

of this dramatic change is a subject of current investigation, but it now appears clear that adsorption at the nanotube–metal electrode contact plays a major role.

A number of issues remain to be investigated or more fully explored.

- No systematic study of the differences between the adsorbed systems formed by gases on carbon nanotubes produced by different methods has yet been undertaken. A significant fraction of the work discussed here has been conducted on samples of less than ideal purity. As purer samples become available as a result of gentler purification processes, it would be of great interest to compare the results of adsorption on these samples with the results summarized in this chapter.
- Although exploration of some of the effects of the chemical purification treatments on adsorption has began, a more complete investigation of this subject remains to be undertaken.
- The question of access to the interior of cut tubes is one that requires additional exploration. It is not clear, for example, whether the availability of this interior space is limited to treated tubes maintained in ultrahigh-vacuum conditions or whether the space would be available under less stringent environments.

All in all, the study of adsorption on carbon nanotubes has been an exciting area of research. With the open questions that need to be answered, it is likely to remain such for some time to come.

GLOSSARY

Adsorption   A process by which atoms or molecules of one chemical species (the adsorbate) are attracted, and stay on the surface of a solid of a different chemical species (the substrate).

BET method   A simple theoretical model proposed by Brunauer, Emmett, and Teller in 1938 (*J. Am. Chem. Soc.* 60, 309) that arrives at an equation for the determination of the monolayer capacity of a substrate from volumetric adsorption isotherm measurements.

Chemical potential   Total free energy per molecule.

Heat of adsorption   Amount of heat released when an atom or molecule adsorbs onto a substrate.

Isostere   Function that relates the equilibrium value of the pressure to the temperature at a constant value of the amount of a gas adsorbed by a given amount of substrate.

CONTENTS

1. INTRODUCTION

1.1. Nanomaterials and Applications

Most properties of solids depend on the microstructure, that is, the chemical composition, the arrangement of the atoms in the structural lattice and the size of the solid in one, two, or three dimensions. This basic result of material science implies that a change of one or several of these parameters causes a variation of the material properties [1]. In particular, when the size of the crystallites in a polycrystalline material is reduced from macroscopic dimensions down to the scale of a few nanometers, some special effects, such as interfacial effects, size effects, and macroquantum tunnel effects, occur so that a new class of nanostructured materials, with different (electronic, optical, electrical, magnetic, chemical, and mechanical) properties with respect to single crystalline materials (or coarse-grained polycrystals) and/or glasses with the same average chemical composition, can be distinguished [3, 24]. The term "nanoparticles" is generally used in the material science community to indicate particles with diameters smaller than 100 nm [2, 3, 7]. However, in many applications, the term nanoparticles is used when the particle sizes are less than 50 nm [4, 5] or even 10 nm [1, 6].

The explosion in both academic and industrial interest in nanostructured materials (a broad spectrum of which includes insulators, semiconductors, superconductors, metals and alloys, nanocomposites) in the last ten years arises just from the extremely fascinating and useful properties of such materials. Some examples of these properties are: an increased electrical conductivity of ceramics and magnetic nanocomposites, an increased electrical resistivity in metals, an increased magnetic coercivity down to a critical particle size in the nanoscale regime, and below this critical particle size, the occurrence of supermagnetic behavior, an increased hardness and strength of metals and alloys, and an enhanced ductility of structural and functional ceramics [9]. A blue shift in the optical spectra of quantum-confined particles [10, 11], an increase in the luminescent efficiency of some porous semiconductors [12–14], and a lower melting temperature [15] are also observed.

In general, the nanomaterial properties, incompletely understood today, are the results of the small size and/or dimensionality of the nanoparticles, as well as of the large fraction of interfaces between adjacent crystallites (grain boundaries), and hence of the increased percentage of surface atoms. In fact, one important feature for nanocrystalline materials is the large surface area. Since the average size of an atom is on the order of 1–2 Å in radius and a nanometer comprises 10 Å, in 1 nm, there will be 3–5 atoms, depending on the atomic radius, and a grain with a size ranging from 1 to 100 nm will have a number of atoms varying from several to a million. Thus, as a schematic example, we can notice that, for a 4096-atom cubic grain, the relative percentage of surface atoms N_t/N_s (N_t: bulk atoms, N_s: surface atoms) is 33%; it becomes 57% by splitting the cube into eight cubes, and increases up to about 87% after splitting each cube into eight cubes (Fig. 1) [8].

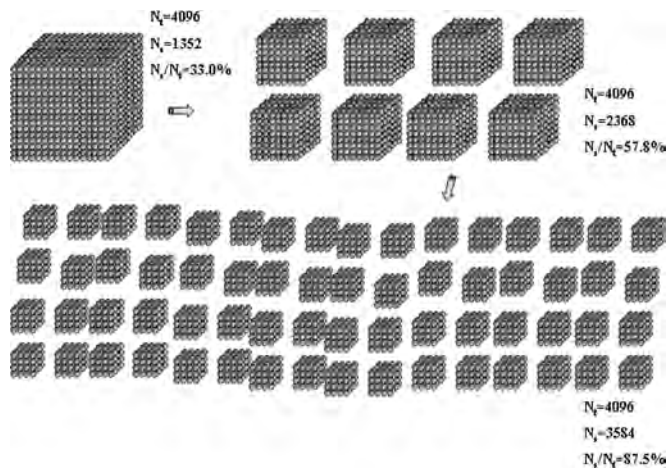
Crystallites and grain boundaries in a nanocrystalline material have comparable volume fractions, and are both of the dimension of a few nanometers. Hence, the overall properties of the solid will be strongly influenced by the contribution coming from grain boundaries. The grain boundaries are complex and highly disordered structures consisting of a few layers of atoms with different coordination numbers compared with the corresponding atoms in the grain; they generally contain high densities of interface states that may induce an intrinsic chemical reactivity property toward the environment chemical compounds. The


Figure 1. Schematic example that shows how the ratio N_t/N_s (N_t: bulk atoms, N_s: surface atoms) increases for a 4096-atom cubic grain by splitting the cube into eight cubes, and next each cube into eight cubes [8].

study of grain boundaries and their effect on the properties of nanocrystalline materials has been the subject of extensive discussion among researchers working in the field of nanostructured material science [20–23]. Moreover, the atomic structure in the interior of crystallites is modified through the introduction of defects, strain fields, or short-range correlated static or dynamic displacements of atoms from their ideal crystal lattice positions. Many physical properties of nanocrystalline materials will be modified as a consequence of the combined effects of these structural changes, that is, the reduction of the length scale on which there is coherency in the atomic arrangement (long-range order) and the introduction of interfaces with an atomic short-range order different from the one in the crystal lattice [19].

Because of their unique properties, nanostructured materials can be exploited for a wide variety of functional applications, most of which use nanocrystalline films supported by a suitable substrate [2–7, 27–36]. Nanoscale materials have a promising future in microelectronic and optoelectronic applications (quantum nanostructures: wells, wire, dots, tubes, belts) [25, 26]; electroluminescent silicon-based devices; and next-generation computer chips, single-electron devices, and so on. They also can be used in the development of new photocells, very small active elements in magnetic recording, electrochromic display devices, high-energy density batteries, scanning nanoprobes, physic filters to separate different specimens, and "aerogels" for insulation, heating, and cooling bills, in addition to longer lasting biocompatible medical implants, biomimetics, smart structures, microdevices for telemedicine, are further examples of the broad spectrum of nanomaterial applications. In applications to bulk devices, the small size and the homogeneity of nanomaterials give rise to particular solids with very special mechanical properties; they are exceptionally strong, hard, ductile at high temperature, wear resistant, erosion resistant, and corrosion resistant.

Moreover, a high catalytic and a strong reactivity with gaseous species are fundamental properties of nanocrystalline semiconducting metal oxides that make them particularly suitable for applications in catalyzers [16] and semiconductor gas sensors [17, 18, 37, 38].

The field of nanostructured materials is thus really very broad, and the scientific research (nanoscience) that studies material and system properties in the nanoscale range involves an interdisciplinary approach based on solid-state physics, chemistry, biology, and material science whose cross fertilization will lead in the future to new avenues in material science. Gleiter reported a simple and exhaustive classification schema for nanostructured materials (NsM) according to their chemical composition (families) and the dimensionality and shape of the crystallites forming the NsM (categories) [1, 11] (Fig. 2). The cluster of novel technologies, related to the synthesis of materials and/or the development of devices with new properties by means of the controlled manipulation of their microstructure on a nanometer scale, is well known as nanotechnology, and it no doubt constitutes the most innovative and emerging technology of the 21st century [5].

1.2. Nanocrystalline Oxides in Gas Sensors

In this chapter, the main research lines of nanoscience and nanotechnology applied to semiconductor gas sensors (SGS) will be reviewed. They cover new materials, new concept and device types, and a basic understanding of the gas-sensing function. The application of nanocrystalline metal oxides films in semiconductor gas sensors will be extensively discussed, with the aim of better understanding the new opportunities offered by such nanostructured materials for enhancing the performance of this kind of gas sensor.

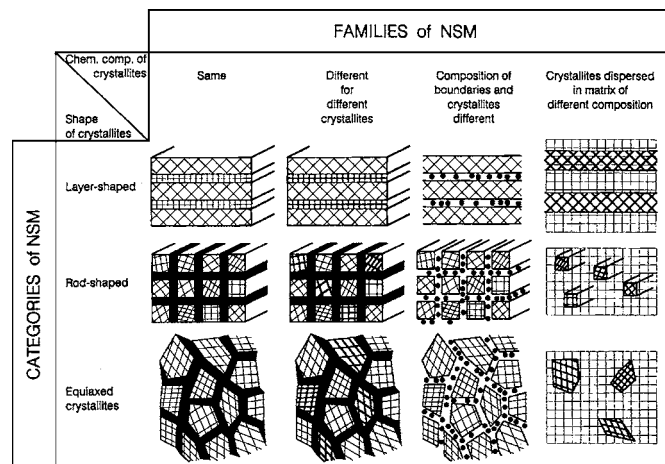
In the field of semiconductor gas sensors, recent applied studies and product releases have shown some significant trends in nanotechnologies and gas-sensing layers to be employed. One of these trends aims to implement low cost,


Figure 2. Classification schema for NsM according to their composition and the dimensionality (shape) of the crystallites (structural elements) forming the NsM. The boundary regions of the first and second families of NsM are indicated in black to emphasize the different atomic arrangements in the crystallites and in the boundaries. The chemical composition of the (black) boundary regions and the crystallites is identical in the first family. In the second family, the (black) boundaries are the region crystallites where two crystals of different chemical compositions are joined together, causing a steep concentration gradient. low-power consumption, reliable, smart, and miniaturized sensing devices, and it shows the decisive advantage of using a micromachined silicon platform as a substrate for the sensitive layers [39–42]. On the other hand, several theoretical and applied articles have shown the advantage of reducing the metal-oxide grain size down to nanometer scale in order to improve the sensing properties (mainly sensitivity and selectivity), as well as stability over time of the oxide layer [43–54]. Nanocrystalline semiconducting metal oxides with controlled composition are indeed of increasing interest in gas sensing, and also constitute a new and exciting subject of fundamental research. In fact, it is well known that the response of semiconductor gas sensors to gases, the gas sensitivity and selectivity, and the degradation of performance with time of the sensing layers depend on the grain size, the surface morphology, and the internal porosity. The microstructure of the sensing layers is determined by the preparation method and the deposition parameters, as well as by postannealing treatments at high temperature for material stabilization, and in general, both an empirical and systematic study of the influence of all of these parameters is needed to obtain improved sensor devices by better control of the microstructure of their active layers. Some examples of sensing films of different morphologics are given in Figures 3–5.

Thanks to their small grain size, high density of grain boundaries, and interfaces, nanostructured metal oxides show a strong reactivity with gaseous species. The high reaction rates of these fine-grained semiconducting oxides with chemical species in air are a direct consequence of their high specific area. This specific feature, together with

Figure 4. TEM micrographs of W/TiO$_2$ thin film (W : Ti ratio of 1 : 33) (bar 20 nm). Reprinted with permission from [195], C. Garzella et al., *Sensors Actuators B* 83, 230 (2002). © 2002, Elsevier Science.

the potential to control both the microstructure and the chemistry due to the high technological levels reached in the preparation of the sensing layers, make nanocrystalline semiconducting oxides very attractive materials for the development of high-sensitivity fast-response semiconducting gas sensors, in which surface interaction processes play the key role in the formation of the sensor signal [47, 55, 56]. The gas/semiconductor surface interactions on which is based the gas-sensing mechanism of SGS occur at the grain boundaries of the polycrystalline oxide film. They generally include reduction/oxidation processes of the semiconductor, adsorption of the chemical species directly on the semiconductor and/or adsorption by reaction with surface states associated with preadsorbed ambient oxygen, electronic

transfer of delocalized conduction-band electrons to localized surface states and vice versa, catalytic effects, and in general, complex surface chemical reactions between the different adsorbed chemical species [17, 18, 69]. The effect of these surface phenomena is a reversible and significant change in electrical resistance (i.e., a resistance increase or decrease under exposure to oxidizing, respectively reducing, gases referring as an example to an *n*-type semiconductor oxide). This resistance variation can be easily observed and used to detect chemical species in the ambient. The gas/solid interactions exploited in SGS can involve changes in the surface conductance or changes in the bulk conductance; correspondingly, two principal types of metal-oxide-based gas sensors can be distinguished [69, 78]. Since a semiconductor oxide is, in general, nonstoichiometric and the oxygen vacancies are the main bulk defects, changes in the bulk conductance are due to changes in the oxygen partial pressure at operating temperatures so high (600–1000 °C) that the oxygen vacancies can quickly diffuse from the interior of the grains to the surface and vice versa, and the bulk of the oxide has to reach an equilibrium state with ambient oxygen. The main application of this first kind of sensor is the measurement of oxygen partial pressure as required in combustion control systems, in particular, in the feedback control of the air/fuel ratio of automobile engine exhaust gases near the λ point in order to improve the fuel economy efficiency and reduce the harmful emission of gases as CO, NO_x, and hydrocarbons [79–81]. The second principal type of semiconductor gas sensors is based only on changes in surface conductivity at lower temperatures (<600 °C) and at quasiconstant oxygen partial pressure. In this condition, the sensor detects small concentrations of reactive gases in air by a displacement from the constant oxygen pressure equilibrium state, induced by gas-interfering effects at the surface of the sensor. Also in this operation mode, there is a sensitivity of the sensor to changes in the oxygen partial pressure, but in this case, the defect oxide chemistry has a minimum importance as far as the gas sensitivity is concerned. This chapter will be devoted especially to this latter class of resistive-type gas sensors.

The working temperature at which these devices work varies, depending on the specific target gas in the ambient, and on the selected sensor material in conjunction with its properties in every case. As this working temperature usually ranges from 200 to 400 °C, it is necessary to implement a heating element in a sensor device. A simple SGS is thus basically composed of a substrate in alumina or silicon (on which the sensing layer is deposited), the electrodes (to measure the resistance changes of the sensing film), and the heater (commonly a Pt resistive-type heater) to reach the optimum sensing temperature. A simple scheme of a sensor on alumina substrate is shown in Figure 6.

A gas sensor has three principal functions [40, 57]: (1) the *receptor function*, that is, the ability to detect a particular gas, which depends on the surface chemical processes; (2) the *transducer function*, which translates the gas-induced changes at the semiconductor surface into an electric output signal, and which depends on the microstructure of the sensing material and on the electrical conduction mechanism through the grain network; and (3) the *operation mode*, the
Figure 6. Simple scheme of a gas sensor on alumina substrate.

most used one based on the monitoring of the sensor resistance at constant temperature operation. Other operation modes are the modulated operation temperature [58–61], the single and/or simultaneous measurement of sensor resistance and thermovoltage [62, 63], and the single and/or simultaneous measurement of sensor resistance and temperature [64–68].

In this chapter, we will first consider the background and the gas-sensing principles of semiconductor gas sensors. Next, since the most important factors affecting the sensing properties of these devices via the transducer function are the microstructure and the morphology of the sensing element, the models for electric transport in polycrystalline semiconductors will be reported, discussing the modifications of these models for nanocrystalline semiconductors. The aim was to gain a deeper insight into the nature of the gas-sensing properties of semiconducting nanostructured metal oxides by correlating the macroscopic characteristics of semiconductor gas sensors to the microscopic characteristics of their sensing elements [70]. Great efforts are in fact devoted to the basic understanding of the real grain boundaries and size effect. A survey of the most used nanostructured metal-oxide films and deposition techniques for semiconductor gas sensors also will be reported. Next, particular interest will be devoted to the influence of dopants and the use of mixed oxides or heterolayers, the latter representing a new design concept of a semiconductor gas sensor. Application examples of SGS to the detection of toxic and/or pollutant gases will be looked into on the basis of experimental results reported in recent literature. Moreover, the concept of electronic nose will be introduced, and the most recent research developments in multisensor systems for specific functional applications in the food industry, environmental monitoring, analysis of different ambients, and so on, will be reviewed. Finally, the future of nanostructured oxides and the trends of scientific research in the gas-sensing field will be discussed in the last section.

2. GAS-DETECTION PRINCIPLES

2.1. General Features

The principle of operation of gas sensors based on semiconducting metal oxides relies on gas-induced variations of the surface chemistry that cause large and reversible changes in the electrical conductivity of the sensing layers

when exposed to oxidizing or reducing gases. The discovery of an electrical response of a semiconductor to variations in the chemical composition of the ambient is not recent. Gas-sensitive effects on semiconductors were first discovered by Brattain and Bardeen [71] (1953) on Ge. Soon after, Seiyama et al. (1962) [72] and Taguchi (1971) [73] applied this discovery to gas detection by producing the first chemoresistive gas sensors. Seiyama et al. demonstrated that the conductivity of thin films of ZnO, when heated up to 300 °C, was strongly modulated by the presence of traces of reactive gases in air. Taguchi also demonstrated similar properties for sintered compressed and polycrystalline SnO_2 powder, with the advantage of greater stability and high sensitivity at a lower operating temperature, and established Figaro Engineering Inc., which today remains one of the major manufacturers of gas-sensor devices.

Since then, a huge literature on the characterization and use of semiconducting oxides as gas sensors has been produced. Various books that report the principles and applications of such a kind of gas sensor also have been published [17, 18, 74–77]. Nowadays, an appreciable number of manufacturers of gas sensors and multisensor systems (often referred to as *electronic noses*) are on the market. Section 4 will be completely devoted to the development of these latter multisensor devices. The major international conferences on gas sensors and electronic nose of such devices are listed in Table 1.

The urgent demand for gas-sensor systems is clearly explained by the growing number of their potential applications. Two important groups of applications are the detection of single gases (such as NO_2, O_3, CO, CH_4, etc.) and the discrimination of odors or generally the monitoring of changes in the ambient. Single-gas sensors can, for example, be used as fire detectors, leakage detectors, controllers of ventilation in cars and planes, and alarm devices warning the overcoming of threshold concentration values of hazardous gases in workplaces. Next, we will report some of the most noteworthy examples of applications of gas sensors and electronic noses.

The great interest of the industrial and scientific world in SGS comes from their numerous advantages, like small size, high sensitivity in detecting very low concentrations (at levels of ppm or even ppb) of a wide range of gaseous chemical compounds, the possibility of on-line operation, and due to possible bench production, low cost. Besides, it should be considered that semiconductor gas sensors belong to the class of solid-state gas-sensor devices that furnish information about the ambient composition directly in the form of an electric signal. The possibility of easily combining in the same device the functions of a sensitive element and a signal converter and control electronics markedly simplifies the design of a sensor, and constitutes the main advantage of chemoresistive-type sensors over biochemical, optical, acoustic, and other gas-sensing devices. This real simplicity in function is also the main advantage over analytical techniques as gas chromatography (GC) and mass spectroscopy (MS), which are complex, expensive, difficult to operate, and off-line apparatus.

In spite of the numerous advantages of resistive-type gas sensors, they show different disadvantages, such as poor reproducibility and long-time instability due to aging. There are two undesired aging effects that may appear when the sensor works for a long period: a *drift* of the baseline signal (defined as the conductance in air or in a reference gas) or a *drift* in the sensor response. The sensor response is usually defined as

$$X = \begin{cases} x_s/x_0, & \text{if } x_s > x_0 \\ x_0/x_s, & \text{if } x_s < x_0 \end{cases} \quad (1)$$

or

$$X = \begin{cases} x_s - x_0/x_0, & \text{if } x_s > x_0 \\ x_0 - x_s/x_s, & \text{if } x_s < x_0 \end{cases} \quad (2)$$

(x_s and x_0 are the electrical signal values at equilibrium in the presence of a gas/odor and in a reference gas, respectively), depending on the reducing or oxidizing character of the chemical species interacting with the sensor surface. A general trend, which has been experimentally verified, is that the sensor response to a particular gas increases up to a maximum corresponding to an optimum working temperature, then falls off toward zero at higher temperatures. As the sensor response is used to characterize the change in the sensor signal due to a certain stimulus, on the other hand, the (partial) sensitivity S describes the change in the sensor response due to a specific change in the stimulus. In particular, if y_k is the concentration of the chemical species k, the (partial) sensitivity S_k of the sensor to detect the species

k is defined by the slope of the sensor calibration curve at concentration y_{k_0}:

$$S_k = \left(\frac{\partial X}{\partial y_k}\right)_{y_k = y_{k_0},\, y_{j \neq k}\, \text{const.}} \tag{3}$$

Metal oxides are nonlinear sensors; the change in sensor response due to a defined change in gas concentration depends generally on the concentration of the gas to be monitored y_k, and also on the concentration of other gases $y_{j \neq k}$ (cross-sensitivity effect). In this case, more than one sensor or more than one operation mode of the same sensor are required to determine the concentration level y_k. In the worst case, S_k varies with the aging of the sensor due to drifts or contamination effects.

Long-time instabilities are of considerable importance for the practical use of the sensor; preaging thermal treatments and cycle calibration checks have to be carried out in order to avoid incorrect use of the device. The causes of instabilities are mainly microstructural and morphological changes (change in size, number, and distribution of grains and intergranular boundaries) of the sensing elements, but also irreversible reactions with chemical species in the ambient, modifications of the sensor heating element, or of the electrodes have to be taken into account.

Other important disadvantages are the sensitivity to water vapor and the lack of selectivity. Metal-oxide-based gas sensors are normally sensitive to more than one chemical species in air, and usually show cross sensitivities. This nonspecificity of the response to a chemical species whose presence, identity, and concentration in air have to be determined is by now considered an intrinsic property of metal-oxide-based gas sensors. It is easy to understand how this disadvantage represents a real problem when different reactive gases are present simultaneously in the same atmosphere and interference effects between them can occur. Unselectivity cannot be eliminated completely, but it can be improved in different ways, such as: (1) the use of filters [82, 83] or chromatographic columns to discriminate between gases on the basis of their molecular size or other physical properties [84], (2) the use of catalysts and promoters or more specific surface additives [85–88], (3) the selection of the material for the sensing layer [89, 38] and its physical preparation, (4) the analysis of the transient sensor response [90], (5) the selection of a fixed temperature to maximize sensitivity to a particular analyte gas [91], or (6) the use of a temperature-modulated operation mode [58–61]. A different approach to the problem of unselectivity is based on the development of the above-mentioned *electronic nose*, which consists of an array of different sensing elements with partially overlapping sensitivity and a *pattern recognition* system [92]. Basically, the idea of an electronic nose is to exploit the unavoidable cross sensitivity of the sensors instead of trying to eliminate it, by linking the sensors in an array configuration, and by analyzing the responses of the sensors in a subsequent data-processing step in order to perform a qualitative and/or quantitative analysis of the ambient under examination.

The basic part of the efforts made nowadays by the scientific research community in the SGS field are devoted to solving the problems that sensing elements can have.

Sensitivity, selectivity, and stability are the three principal parameters that have to be improved in order to develop more accurate devices. These parameters are strongly dependent both on the surface chemical processes of the specific material used as a sensing element and on its structural and morphological properties. Both aspects have to be considered in order to gain a deeper insight into the receptor and transducer function of the gas sensor.

In general, the characterization and development of chemoresistive gas sensors has been based on an empirical approach. This approach consists principally of systematic experimental conductivity measurements in a controlled atmosphere by using the direct-current (dc) or alternating-current (ac) method. dc measurements are the most used ones in gas-sensing tests, and constitute the most common operation mode in commercial gas sensors. However, the ac method is a powerful tool to examine the nature of conduction processes. As processes of different time constants can be distinguished by varying the frequency, ac measurements compared with corresponding dc measurements allow us to separate contributions from contacts, bulk, surface, and grain boundaries, all of which may contribute to the overall sensor response; equivalent circuits with different resistance/capacitance (RC) units describe formally the frequency behavior [113–115, 118]. Gas-sensing tests are carried out by using suitable and flexible gas-mixing benches [94] that allow mixing many gases in a wide range of concentrations and combinations, and adjust all of the conditions that are essential for the sensor's behavior (temperature, gas flow, humidity, etc.). The aim of gas-sensing tests in a controlled atmosphere is to analyze the sensor response and characterize the sensor in terms of a few phenomenological parameters (sensitivity, selectivity, response and recovery time, optimum working temperature, and repeatability of the measure and stability) [95].

Moreover, as the reactivity of the sensor surface is critically dependent on the condition of the surface, that is, on its elemental composition including any alloying, doping, or impurity constituents, on its electronic and defect structure, and on its morphology, a good general characterization of a gas sensor should also include a spectroscopic and microscopic characterization of the sensor surface. A large number of techniques, suitable for application to the analysis of gas-sensing layers, have been developed to study various surface properties, including the structure, composition, oxidation states, morphology, and changes of chemical or electronic properties by utilizing scattering, absorption, or emission of photons, electrons, atoms, and ions [96, 97]. Advances in modern surface instrumentations allow the detection of finer detail: atomic spatial resolution, ever-smaller energy resolution, and shorter time scales. Moreover, the ability to monitor surface conditions during exposure of the sensor surface to reactants could be fundamental for the understanding of sensor mechanisms and behavior. Hence, a great interest has been devoted to surface analytical techniques that can be applied under an *in-situ* real operating state of the sensor [98, 107, 111, 112]. Table 2 reports some of the most commonly used surface-science techniques.

Thus, in the above-described experimental approach, mainly chosen by *users* of gas sensors, the commercially

Table 2. Most commonly used surface-science techniques for application to the study of gas-sensor surfaces.

Name	Acronym	Primary surface information
Transmission electron microscopy	TEM	Surface morphology
High-resolution transmission electron microscopy [97–101, 109, 116]	HRTEM	Surface morphology with atomic scale resolution
Scanning electron microscopy [97, 98, 100]	SEM	Surface morphology
Atomic force microscopy [97, 101]	AFM	Surface morphology
Scanning tunneling microscopy [105, 107, 108]	STM	Surface morphology with atomic scale resolution
Fourier transform infrared spectroscopy [109–112]	FTIR	Bonding geometry and strength, surface reactions, and surface species
Surface photovoltage spectroscopy	SPS	Energy position of surface state, surface charge distribution, bandgap, photosensitization in semiconductors
Electric-field-induced surface photovoltage spectroscopy [103]	EFISPS	
X-ray photoemission spectroscopy [96, 105, 115–117]	XPS	Composition, oxidation state

Energy dispersive X-ray spectroscopy	EDX	Composition, oxidation state

available sensors or sensors from research labs are tested and used without changing their conditions of preparation. The results of the experimental approach are necessary for optimizing the sensor parameters, and they constitute a useful practical guidance for the *developers*. In production, during the sensor-processing phase, the approach is different because the efforts are devoted to developing sensors that have been optimized by systematically changing all of the system parameters, that is, preparation of gas-sensitive films, doping and aging procedures, device structure (substrates, electrodes, heater, packaging), materials for filters, modulation conditions during sensor operation, and so on, for different applications. In spite of extensive activities in the scientific research and development of chemoresistive gas sensors based both on "trial and error" or on an empirical systematic research approach, our present comprehension of the elementary steps in gas-sensing phenomena is still poor. A basic science understanding of the processes underlying sensor operation is a fundamental prerequisite for further improvements of these types of gas sensors. The processing of the sensors in production, the experimental characterization procedures, and the theoretical studies on sensor behavior have to be closely linked, and the advances of one field have to be functional for the advances of the others. A better connection among theoretical, experimental, and technological aspects of semiconductor gas sensors is essential for a complete description of gas-sensing mechanisms [56, 93]. Basic research on gas sensors provides a framework for experimental results, and attempts to define atomistic models that relate the behavior of a sensor system as a whole to the elementary mechanisms of chemical sensing, and to the assumed electrical properties and grain structure of sensor (*modeling*) [121, 122]. In such a way, the macroscopic response of a sensor, consisting of a modulation of its surface resistance, is explained from a microscopic point of view based on gas/semiconductor interaction processes

and on the electrical transport properties of the sensing layers. To this purpose, the basic scientific approach, by interpreting experimental data provided by gas-sensing tests and surface microscopic and spectroscopic analysis techniques, performs quantum-mechanics-based calculations, considers thermodynamic and kinetics aspects of gas-sensing mechanisms, and applies semiconductor physics theory. By using quantum-mechanical calculations, the energy levels related to surface and adsorbed molecules can be determined, while by using thermodynamics and kinetics, these calculated electronic levels can be linked to the surface coverage of adsorbed species corresponding to the real experimental condition (dependent on sensor working temperature, gas concentration, etc.). Finally, changes in the concentration and mobility of free charge carriers and in the sensor resistance are correlated on the basis of specific models for electrical conduction mechanisms [56].

The receptor function by which a sensor recognizes a chemical species at the surface of semiconducting metal-oxide film includes adsorption processes (physisorption, chemisorption, and ionosorption), chemical and catalytic reactions at surface adsorption sites, and at grain boundaries and similar reactions at electrode/semiconductor interfaces or at surface metallic clusters. The influence of these surface chemistry phenomena on the sensor response may be understood on the basis of the charge-transfer model (CTM) and the modified band model of semiconducting metal-oxide sensor devices that also take into account the effects of additives, dopants, grain size, as well as contacts [18, 122, 123]. According to these models, the changes in the electrical resistance of the sensor are described by the formation of depletion space-charge layers at the surface and around the grains, with upwards bending of the energy bands. Surface-energy barriers for conduction electrons result, whose height and width are variable, depending on the occupancy of surface states related to adsorbed species. Other models, such

as the Volkenstein model (VM) [124], have been defined to describe the dependence of conductivity variations on gas interaction.

However, a complete comprehensive theory on the gas-sensing mechanism is still missing due to the real complexity of the specific reactions between gas species and a semiconducting polycrystalline metal-oxide film when the latter is exposed to a reactive ambient. Moreover, the microstructure of the sensing material transduces such gas reactions into a measurable sensor signal. For a basic understanding of the gas-sensing mechanisms in a resistive chemical gas sensor, it is useful to separate the receptor function from the transducer one. By a combination of various transducers and operation modes, a large variety of sensor signals results. Next, in this chapter we will present a review of the necessary theoretical background in gas-sensing mechanisms by considering both receptor and transducer functions. Finally, particular interest will be devoted to the grain-size effect on the gas-sensing properties.

2.2. Receptor Function

2.2.1. Intrinsic and Gas-Induced Surface States

The surface of a solid, even when ideally perfectly "clean," that is, without impurities, deposited metals, or adsorbed species, is itself an imperfection for the crystalline lattice because the periodicity of the crystal is roughly broken. The atoms or ions on the semiconductor surface are not surrounded by the exact number of their nearest neighbors like the corresponding atoms in the bulk; hence, they have to rearrange themselves, producing substantial deformation and a large local electrical field. This condition gives to the surface itself a reactivity toward the environmental components. Quantum-mechanics calculations, that take into account only the interruption of lattice periodicity, demonstrate that a solid surface leads to the formation of "intrinsic" localized energy levels that may lie in the forbidden energy region of a semiconductor material [18, 125]. In this case, these surface states can capture or inject charge carriers to crystal bulk—they can be acceptors or donors or both.

In highly ionic semiconductors, any surface ion has an incomplete coordination; hence, they can electrostatically interact with molecules in the environment. Most metal oxides are ionic semiconductors, with the metal atoms as cations and the oxygen atoms as anions; the surface metal cations tend to capture extra electrons (acting as acceptors), while the surface oxygen anions tend to give up electrons (acting as donors). In a semiclassical approach, Madelung calculated, in a surface site of interest, the potential due to all of the point charges in the crystal, and he showed how this electrostatic effect gives rise to intrinsic surface states.

In covalent semiconductors, on the other hand, there are covalent bonds resulting from the overlap of valence orbitals along preferential directions, with each atom contributing an electron; hence, for each covalent bond, there is an electron pair shared by the atoms. At the surface, a surface atom finds no neighbor to pair its electron with, that is, a valence orbital of a surface atom facing the ambient finds no neighboring orbital with which to be overlapped. The orbital with

an unpaired electron and extending out of the surface forms the so-called "dangling bond." Now, this dangling bond can either accept another electron from an external or it can be given to the bulk of the crystal, leaving the surface energy level (the "surface state") unoccupied. Again, both acceptor and donor electronic levels may be available at a clean surface. Shockley first calculated the intrinsic surface states for a covalent semiconductor.

Although it is really impossible to obtain a perfectly clean surface, that has no practical application, the study of the electrical effects of surface states at a clean surface constitutes the first fundamental step toward the comprehension of a more important and realistic case where gases and/or odorous molecules are adsorbed onto the semiconductor surface and complex adsorbates may be formed.

The effects of impurities and chemical compounds adsorbed from the environment are very similar to the effects of the "intrinsic" surface states at a clean surface, although they are complicated by adsorption/desorption processes, relocations in the neighboring active sites, and other chemical reactions. Both kinds of surface states are dealt with in the same way by using quantum-mechanical or semiclassical methods.

In quantum mechanics, two approaches are generally applied: the rigid band and the molecular approach. In the rigid-band model, the electrons are described by nonlocalized Bloch wave functions, and localized surface states arise when the electron affinity of the surface species (adsorbed atoms or ions) is very different from that of bulk atoms or ions. The surface electronic levels due to the adsorbates can act as acceptors or donors, but local bonding of the adsorbate to one or a few atoms of the solid can be neglected, the adsorbate being treated simply as a perturbation of the electronic band scheme of the semiconductor. This model is commonly used in the treatment of adsorption with charge transfer (ionosorption) on ionic solids, such as ambient oxygen on metal oxides. Contrary to the rigid-band model, the molecular-orbital model, used especially in the case of strong interaction between the adsorbate and the solid, considers the local bonding of the adsorbate and the solid, neglecting the energy band structure of the solid.

A semiclassical approach is a useful method based on the Madelung potential, and applied in particular to ionic surface states of metal-oxide semiconductors. It considers the energy affinity of any cation or anion in the lattice as the electron affinity at infinity, slightly modified by the electrostatic potential of the ionic lattice (Madelung potential). Details of the approaches used by the two methods are given in [69, 126].

2.2.2. Physisorption and Chemisorption

Due to the reactivity of surface atoms, which lack binding partners, molecules from the gas phase will be adsorbed at the surface, leading to the previously discussed surface states. Before discussing how intrinsic and gas-induced surface states cause the formation of surface-charge layers, and consequently the modulation of the surface conductivity of semiconducting gas-sensitive films, it is worthwhile emphasizing some aspects of the adsorption processes [18, 69, 124, 126, 127].

In general, one distinguishes two major types of adsorption with respect to the underlying adsorptive forces: physical and chemical adsorption. Physisorption is a weak adsorption caused by van der Waals' forces, whereas chemisorption is based on the stronger covalent forces (overlapping between the adsorbate and adsorbent wave functions), and hence is connected with a partial electron transfer between adsorbent and adsorbate.

Starting from the physical picture that physical adsorption arises at large distances R from the adsorbent ($R \gg$ lattice constant), a molecule approaching the surface becomes slightly polarized, and induces an equivalent dipole in the adsorbent, that typically leads to 0.10–0.12 eV (i.e., a physisorption heat of about 2–5 kcal $\cdot$ mol^{-1}) dipole–dipole binding interaction of the adsorbate to the surface. According to quantum mechanics (the Volkenstein model [127, 124]), the overlap between the Bloch function of the conduction-band electron and the wave function of the ad electron tends to zero, and therefore it is sufficient to restrict the perturbation theory to second-order approximation of the dipole–dipole interaction to explain the van der Waals interaction ($\Delta E \propto R^{-6}$). As the ad particle approaches closer to the surface (R tends to zero), repulsive forces arise, so that a weak minimum in the curve of the energy potential $E(R)$ arises, and the ad particle will be physisorbed at a certain distance R_{phys} from the support surface. According to the VM model, chemisorption will take place depending on the "quantum-mechanical nature" of the system; other wave functions which allow stronger attractive forces like antiparallel spin orientation result in covalent binding. Hence, physisorption should be treated separately from chemisorption. The latter can have different degrees of chemisorption: the neutral weak-chemisorbed form and the charged strong-chemisorbed form (if charge transfer occurs). Due to the different electronic systems (wave functions) being involved in physisorption and chemisorption, the Fermi–Dirac statistics cannot describe the distribution on both states. According to the VM, this is the point at which the charge-transfer model fails because the latter uses Fermi–Dirac statistics for both physisorbed and chemisorbed states, while it is valid only for the same electronic system.

In the CTM, physisorption is a first step of association of gas species with a solid surface; then the physisorbed species can be chemisorbed/ionosorbed if they exchange electrons with the semiconductor surface. As in CTM, in the Lennard–Jones representation of adsorption processes, physisorption and chemisorption are closely linked. Moreover, the model also takes into account that, for stronger bonding of chemisorption, normally a gas species must dissociate into atoms. Figure 7 shows the energy of the system for physisorption (E_{phys}) and chemisorption (E_{chem}) as a function of the distance R from the adsorbent surface. In the case of physisorption, the system is at zero energy (defined) with infinite R, while in the case of chemisorption, it has substantial energy, even at infinite distance R, to account for the dissociation energy (E_{dis}). Physisorption, with its small heat of adsorption (Q_{phys}), is characterized by a high fractional surface coverage θ at a low temperature and a low coverage at a high temperature. The fractional
Figure 7. Lennard–Jones representation of physisorption and chemisorption: energy of the adsorbent (semiconductor surface)/adsorbate system versus the distance R between the adsorbate and the surface for physisorption (a) and for chemisorption with dissociation (b).

surface coverage θ, as long as no more than a monolayer is adsorbed, is defined as

$$\theta = N/N_t \tag{4}$$

where N is the number of adsorbed molecules per unit area, and N_t is the total surface density of adsorption sites available.

The chemisorption energy curve shows a deep minimum corresponding to the higher heat of chemisorption (Q_{chem}) ($Q_{\text{chem}} > 15$ kcal $\cdot$ mol^{-1}). The intersection of curves a and b yields an activation energy (E_a) for chemisorption. This is the energy that has to be supplied to a molecule so that it can be dissociated, and hence chemisorbed, starting from its physisorbed state, while, starting from if the molecule is in the gas phase, the total dissociation energy (E_{dis}) needs for its chemisorption. A lesser energy is thus sufficient to promote chemisorption starting from already physisorbed molecules. However, direct chemisorption is also encountered, as asserted by the Volkenstein model.

Also, desorption, like chemisorption, requires an energy (E_d) to be promoted ($E_d = Q_{\text{chem}} + E_a$). So, in contrast to physisorption, which is a slightly exothermic, unactived process, chemisorption and desorption are activated processes. The activation energies can be supplied either thermally or by a nonequilibrium process such as illumination.

Assuming a uniform distribution of identical adsorption sites, the net rate of adsorption is given by the algebraic sum of an adsorption term and a desorption term:

$$\frac{d\theta}{dt} = k_{\text{ads}}(1 - \theta)P_g - k_{\text{des}}\theta \tag{5}$$

where $k_{\text{ads}} = A \exp(-E_a/kT)$ is the rate constant for adsorption and $k_{\text{des}} = B \exp(-E_d/kT)$ is the rate constant for desorption.

Setting $d\theta/dt = 0$ for the steady state leads to an equilibrium coverage θ:

$$\theta = \frac{P_g}{P_g + k_{\text{des}}/k_{\text{ads}}} \tag{6}$$

that represents the Langmuir isotherm. At very low pressures, the Langmuir isotherm reduces to the simple Henry's law:

$$\theta = \frac{k_{\text{des}}}{k_{\text{ads}}} P_g$$
$$= C \exp(Q_{\text{chem}}/kT) \cdot P_g \tag{7}$$

in which the fractional coverage is simply proportional to the gas pressure. The preexponential term C is given by $C = A\sigma\tau(2\pi RTM)^{-1/2}$, where A is Avogadro's number, σ is the cross-sectional area of the adsorbed molecule, τ is the molecular vibration time, R is the universal constant of gases, and M is the molecular weight. In most real cases, Henry's isotherm is a very useful, but oversimplified approximation, inadequate to describe the more complex dependence of coverage on the pressure of the species in the gas phase. Many expressions, both analytical and empirical, have been proposed [128]. We report, as an example, the isotherm of the Volkenstein model [124, 127]:

$$\theta = \frac{\beta P_g}{\beta P_g + 1} \tag{8}$$

with

$$\beta = b \left\{ f^0 \left[1 + \frac{\nu^-}{2\nu^0} \exp\left(\frac{E_f - E_c}{kT} \right) \right] \right\}^{-1},$$

$$f^0 = \frac{1}{\frac{1}{2} \exp[(E_f - E_s)/kT] + 1}$$

occupation probability of the neutral weak-chemisorbed state, $E_s = E_{\text{ads}}^- - E_{\text{ads}}^0$, ν^0 and ν^- typical phonon frequencies on the order of 10^{-13} s^{-1}, E_f the Fermi level, and E_c the energy of the bottom of conduction band. In contradiction to the Langmuir isotherm, where $b = k_{\text{des}}/k_{\text{ads}}$ is a function of only the temperature, here the coefficient β additionally depends on the difference of E_f and the surface energy E_s; hence, according to VM in chemical adsorption, the fractional coverage depends not only on the external parameters gas pressure P_g and temperature T, but also on the electronic state of the system as a whole.

In Figure 8, a typical adsorption isobar, reporting the temperature dependence of the volume adsorbed, is sketched.
Figure 8. Typical dependence of the volume adsorbed V_{ads} on the temperature (adsorption isobar).

Physisorption, which is an unactivated process, starts from the lowest temperatures, and decreases exponentially with increasing temperature. At very high temperatures, there is equilibrium chemisorption, again decreasing with increasing temperature following the dependence of $b = k_{\text{des}}/k_{\text{ads}}$ in Eq. (7). In the intermediate temperatures, the adsorption isobar indicates an irreversible chemisorption, so that a maximum adsorption is observed at some temperature T_{max}. This can be explained by taking into account the increase of the activation energy E_a and the decrease of the heat of chemisorption Q_{chem} when increasing the fractional coverage θ. Moreover, due to the opposite variation with θ of E_a and Q_{chem}, the activation energy of desorption $E_{\text{des}} = (E_a + Q_{\text{chem}})$ will not vary too much with the coverage, and thus also the desorption rate. So in the intermediate temperature range, the higher the temperature, the higher the value of E_a reached, and thus the higher the θ value reached; in opposition to this trend, as T increases, the progressive increase of E_a with θ limits the volume adsorbed, and on the other hand, the rate of desorption is negligible because of its high activation energy E_{des}. The adsorption rate in the range of irreversible chemisorption can be expressed by the empirical Elovich equation: $dN/dt = a \exp(-bN)$, with a and b experimental adjustable parameters.

Since metal-oxide-based sensors should be reversible devices, gas molecules have to be coupled retrievably on the surface of the sensing elements so that adsorbed species can leave the sensor surface. At the same time, for a change of the electrical properties of semiconducting metal oxides, it is essential that formation of the charged adsorbed species, that is, a charge transfer between the adsorbed species and the semiconductor, takes place (ionosorption). Thus, the careful adjustment of the operation temperature and ionosorption are the most basic parameters for gas-sensor functioning.

Next, we will analyze the formation of surface space-charge layers and of surface energy barriers by surface states associated with the chemisorption of active species, in particular oxygen, whose presence is fundamental for the basic processes of sensor behavior.

2.2.3. Surface Space-Charge Layers and Charge-Transfer Model

For simplicity, we will take as a reference the case when there is no net excess charge at the surface, and the energy bands of a semiconductor have the same levels from the bulk up to the surface (ideal flat-band state); this ideal situation neglects the presence of "intrinsic" surface electronic states in the bandgap. However, in the presence of surface states introduced by chemisorbed species, the electronic band scheme near the surface has to be modified by reaching a new equilibrium. Figure 9 shows the electronic band scheme of an n-type semiconductor near its surface in the ideal flat-band state (A) and after chemisorption and charge transfer from the semiconductor to the acceptor-type surface state E_{SS} (B).

According to the just-mentioned charge-transfer model, the connection between the partial pressure of the gas phase and the concentration of chemisorbed species is interposed by physical adsorption, by considering the "kinetic" interaction between the gas phase and the physisorbed state,
Figure 9. Schematic representation of chemisorption and charge transfer at an n-type semiconductor surface in the electronic band scheme of the surface. (A) situation before the chemisorption (ideal flat-band case), and (B) band bending after charge transfer from the semiconductor to the surface state. The gas-phase molecule X_{gas} is first physisorbed in a precursor state X_{phys}. Acceptor-type states due to molecules (e.g., $X = O_2$, NO_2) with an electron affinity higher than the work function of the semiconductor ($E_{SS} < E_F$) capture electrons from the conduction band, leading to a negatively charged surface with the countercharge the positively charged donors below the surface ("double layer") and to surface energy barriers for the conduction electrons. In the sketch, the work functions Φ before chemisorption and Φ' after chemisorption, corresponding to electron affinity χ and band bending $-e\Delta V_S$, are also indicated. Chemisorption can be measured by monitoring changes of the work function ($\Delta\Phi = \Phi' - \Phi$) and changes of the surface conductivity ($\Delta\sigma$) upon occupation of surface states E_{SS} by forming $(X_{ads})^{\delta-}$.

where the physisorbed state acts as the precursor state of the chemisorbed state. Hence, as a molecule X from the gas phase approaches the semiconductor surface, it is first physisorbed, then it can be chemisorbed, and it can exchange electrons with the semiconductor. If the molecule is an acceptor-type molecule (e.g., $X = O_2$, NO_2) with an electron affinity higher than the work function of the semiconductor ($E_{SS} < E_F$) (as in Fig. 9), it attracts electrons from the conduction band, whereas if it is a donor-type molecule (e.g., $X = H_2$) with an electron affinity lower than the work function of the semiconductor ($E_{SS} > E_F$), it injects electrons into the conduction band. When such a transition occurs (specifically, Fig. 9), after the electron has moved from the immobile ionized donors to the acceptor-type surface states, a "double layer" is formed: on one side, the positively charged donor ions below the semiconductor surface as a "space-charge layer" compensated, on the other side, by the negatively charged surface states as a surface sheet of charges. An electric field develops between the double layer, and raises the surface band energies with respect to those of the surface; in such a way, the surface energy bands result bent upwards, building up energy barriers for the conduction electrons. The depth of the "depletion layer" (x_0) and the surface potential, or Schottky barrier height (ΔV_S), both depend on the electronic properties of the semiconductor and on the density of surface states.

Depending on the type of surface states (acceptor or donor type) and on the conductivity type (n or p) of the semiconductor, three types of space-charge layers may

appear below the surface: (1) a depletion layer, (2) an accumulation layer, or (3) an inversion layer.

The depth of the "space-charge layer" (x_0) and the surface potential, or Schottky barrier height (ΔV_S), can be calculated by solving the one-dimensional Poisson's equation:

$$\frac{d^2V}{dx^2} = -\frac{\rho}{\varepsilon\varepsilon_0} \qquad (9)$$

where V is the electric potential, x is the distance from the surface, ε is the dielectric constant of the material, ε_0 is the permittivity of free space, and ρ is the charge density in the space-charge layer, consisting of electron (n), holes (p), ionized donors (N_D^+), and ionized acceptors (N_A^-):

$$\rho = (N_D^+ - N_A^- + p - n)e \qquad (10)$$

The boundary conditions are

$$V = V_S \quad \text{at } x = 0 \quad \text{and} \quad V = V_b \quad \text{at } x = x_0 \qquad (11)$$

and, since at $x \geq x_0$ the semiconductor is uncharged, we can used the further boundary condition $dV/dx = 0$ at $x = x_0$.

For the condition of charge neutrality, the surface sheet of charges stored in the surface states (Q_S) has to be compensated by the space charges contained in the space-charge layer of thickness x_0 (Q_{SC}): $Q_S = -Q_{SC} = \int_0^{x_0} \rho(x)\, dx$. Assuming that all donors are fully ionized, and neglecting the electron and hole concentrations in the space-charge layer (Shockley approximation of exhaustion layer), the Poisson's equation can be solved analytically. In this case, in fact, the charge density in the space-charge layer ρ is constant:

$$\rho = eN_D^+ = eN_D, \qquad \text{for } 0 \leq x \leq x_0 \qquad (12)$$

Therefore, the thickness of the depletion layer results to be

$$x_0 = -Q_S/eN_D. \qquad (13)$$

By twice integrating the Poisson's equation reduced to the simpler form

$$\frac{d^2V}{dx^2} = -\frac{eN_D}{\varepsilon\varepsilon_0} \qquad (14)$$

we obtain

$$V(x) = -\frac{eN_D}{2\varepsilon\varepsilon_0}(x - x_0)^2 + V_b \qquad (15)$$

So the height of the Schottky barrier $e\Delta V_S = e[V(0) - V_b]$ is given by

$$e\Delta V_S = -\frac{eN_D x_0^2}{2\varepsilon\varepsilon_0} = -\frac{Q_S^2}{2eN_D\varepsilon\varepsilon_0}$$

$$= \frac{e\left(\sum_j N_{S,j}\alpha_j\theta_j\right)}{2N_D\varepsilon\varepsilon_0} \qquad (16)$$

where N_{Sj} is the number of surface states of the adsorbed species j with charge α_j electronic units per unit area, and θ_j is the fractional coverage of surface states (occupancy) of the type j.

A rate equation simulation with mobile donors has been considered by Lantto and co-workers; the solution $e\Delta V_s = -kT \ln\lfloor 1 - (Q_s^2/2eN_{Ds}\varepsilon\varepsilon_0 kT)\rfloor$ gives much smaller, and also more realistic values for $e\Delta V_S$ compared to those calculated with a constant distribution of donors [129, 130]. It seems that the grain geometry has a marked relative effect on the $e\Delta V_S$ values only in grains with $L < 10$ nm, as results from the mathematical analysis reported in [133].

Of course, the presence of Schottky barriers at surface and at grain boundaries directly influences the electrical conductance of the gas-sensing layer. However, the real situation for a gas-sensing layer that consists of numerous interconnected metal-oxide nanocrystals with different intergranular contacts is very complex. The heights of these potential energy barriers may vary due to grain size, or the size and shape of the necks between grains [134]. The microstructure is a fundamental in the electrical conduction of the sensing materials, as will be discussed in Section 2.3.

2.2.4. Gas Interaction

The Role of Oxygen   In general, a semiconducting metal oxide is a nonstoichiometric oxide, and more commonly, an oxygen-deficient oxide containing oxygen vacancies. As surface defects, they may influence chemical reactions with adsorbates; on the other hand, they behave as donors in the bulk. Indeed, bulk oxygen vacancies are known to be the origin of the *n*-type behavior of tin oxide (SnO_2)—the most used material in semiconductor gas sensors—but also of other oxides [135]. SnO_2 is a wide-bandgap ($E_{gap} = 3.6$ eV) semiconductor with a thermodynamically stable rutile structure. Two donor levels E_{D_1} and E_{D_2} due to singly and doubly ionized oxygen vacancies are located at 0.03 and 0.15 eV below the Fermi level [131, 136]. However, according to theoretical calculations by Rantala et al., it seems that surface vacancies have no influence on the conductance, but they have to move toward the bulk in order to become electrically active [132]. In fact, at high temperature (700–1100 °C), oxygen vacancies diffuse quickly from the interior of grains to the surface or from the surface to the interior of the grains, and the basic reaction between oxygen molecules in the gas phase $O_{2(gas)}$, and the oxygen vacancy $V_{O(bulk)}^{2+}$ in the bulk can be expressed as

$$O_{lattice} \leftrightarrow V_{O(bulk)}^{2+} + 2e^- + \frac{1}{2} \cdot O_{2(gas)} \qquad (17)$$
In this high-temperature range, semiconducting metal oxides are used as oxygen sensors due to their strong dependencies of electrical conductivity σ on oxygen partial pressure P_{O_2}:

$$\sigma = A \exp(-E_A/kT) \cdot P_{O_2}^{1/m} \qquad (18)$$

where E_A is the activation energy which represents the sensitivity of the electrical conductivity to temperature changes, and the absolute value of $1/m$ depends on the dominating defects involved in the reaction between oxygen gas and the sensor [81].

At low and medium temperatures (about 200–500 °C), that is, in the working temperature range of resistive-type gas sensors, chemisorption of oxygen at the surface of oxide and at the grain boundaries leads to the formation of surface

oxygen ions and Schottky barriers between grains. According to the above-discussed model, the height of the Schottky barriers depends on the density of the ionosorbed gas molecules. Since semiconducting metal-oxide-based gas sensors usually work in air, and oxygen is known as a main active component of the air participating in charge-transfer processes at the oxide surfaces, the analysis of the interaction of oxygen species with the semiconductor surface and with other adsorbed species is crucial.

It has been shown, by using different experimental methods (infrared analysis IR [137], temperature-programmed desorption TPD [138–140], and electron paramagnetic resonance EPR [119, 141]) that oxygen is adsorbed onto the surface of semiconducting *n*-type metal oxides in the molecular neutral form (O_2 physisorbed) and in different charged forms: mainly $O_{2,ads}^-$ and O_{ads}^-, and seldom O_{ads}^{2-}. This last form, doubly charged adsorbed oxygen, is unstable, and its stabilization should signify lattice incorporation.

Oxygen chemisorption is an activated process; the activation energy is lower for $O_{2,ads}^-$ than for O_{ads}^-; therefore, $O_{2,ads}^-$ is found on the surface at temperatures below 200 °C at which no O_{ads}^- is found. The energy level for O_{ads}^- is deeper than the level for $O_{2,ads}^-$, which first desorbs when the temperature increases further. So below 200 °C, the molecular species ($O_{2,ads}^-$) dominate, and above this temperature, the atomic species (O_{ads}^-, O_{ads}^{2-}) dominate. The adsorption sites for oxygen are the surface oxygen vacancies. We can describe in a simple model the adsorption of oxygen using the quasichemical reaction steps:

$$O_{2,gas} \longleftrightarrow O_{2,phys} \qquad \text{physisorption} \qquad (19a)$$

$$\left.\begin{array}{l} O_{2,phys} + e^- + S \longleftrightarrow O_{2,ads}^- \qquad\qquad\qquad (19b) \\[4pt] O_{2,phys} + 2e^- + 2S \longleftrightarrow 2O_{ads}^- \qquad\qquad (19c) \\[4pt] \text{or} \\[4pt] O_{2,ads}^- + e^- + S \longleftrightarrow 2O_{ads}^- \qquad\qquad\quad (19d) \end{array}\right\} \text{chemisorption}$$

$$O_{ads}^- + e^- \longleftrightarrow O_{ads}^{2-} \longleftrightarrow O_{lat}^{2-} \quad \text{lattice incorporation} \quad (19e)$$
where S is an adsorption site for oxygen (i.e., an oxygen vacancy $V_{O(surf)}$).

As a result of this ionosorption of oxygen, conduction electrons are depleted from the surface regions, and potential energy barriers are developed, as discussed in the previous paragraph. So, in air, the most common operating ambient for gas sensors, adsorbed oxygen is the dominant contributor to the negatively charged surface states referred to in Eq. (16), providing the main surface coverage θ with ionosorbed oxygen. It has been experimentally observed that the coverage with ionosorbed oxygen can increase up to a saturation level. The concentration of negative charges on the metal oxide surface (in the present case, ionosorbed oxygen) is limited, as is directly seen from Eq. (16), when a reasonable limit (say 0.5–1 eV) is placed on ΔV_S. A maximum of 10^{12}–10^{13} cm^{-2} surface charges is expected (Weisz limitation), while a simple evaluation of depletion layer thickness x_0 [Eq. (13)] gives $x_0 = 1$–100 nm. It is equally important to note the corollary that about 10^{12}–10^{13} cm^{-2} surface states will normally completely control the surface barrier. With about this density of surface states, the Fermi level of

the semiconductor will equalize the electrochemical potential of electrons in the surface states; indeed, since the system semiconductor–adsorbent/adsorbate is at equilibrium, the Fermi level is constant through all phases. This limitation on the amount of ionosorbed species, and the resulting ability to control the depletion layer with this density of states, was first pointed out by Weisz [142]. The term for such surface control is *Fermi energy pinning*, that is, the Fermi energy in the semiconductor is pinned at the value determined by the surface states.

The effect of adsorbed oxygen on the electrical properties of the semiconductor is to cause a high resistance in *n*-type semiconductors (as they are mostly metal oxides) [144]. Kačiulis et al. studied the effect of surface oxygen species on the chemoresistance by XPS of the surface chemical composition before and after different sample treatments [143]. Reducing gaseous species (e.g., CO) react with oxygen at the surface of the semiconductor; they remove a fraction of the ionosorbed oxygen, restoring, in such a way, electrons to the conduction band, and decreasing the resistance of the semiconductor. This sensitivity of resistance to the coverage of adsorbed oxygen leads to a close connection between the resistance and the concentration of the reducing agent in the gas phase, and this is very schematically the way in which standard semiconductor gas sensors work to detect traces of reducing gases in air.

Next, some gas interactions will be reported in more detail.

Water Vapor In many applications, water vapor is present as an interfering compound, hence, the interaction of a metal-oxide semiconductor with water vapor is of great interest in gas sensing. It is well-known experimental evidence that water vapor increases the conductance of semiconductor gas sensors, in a similar way to reducing gases [153]. At low temperatures, water vapor is physisorbed as a molecule, but this specie, completely desorbed below 400 K, does not make any contribution to electrical conduction, while at higher temperatures, H_2O is chemisorbed after dissociation in an hydroxyl group OH^-, that shares its electronic pair with a lattice tin atom Sn_{lat}, and in a weakly bonded proton H^+, that reacts easily with lattice oxygen or with adsorbed oxygen [140, 144, 145].

Two surface interaction mechanisms between SnO_2 and water vapors have been suggested [146, 147] to explain the conductance increase. In the first mechanism, the hydrogen atom H, resulting from a homolytic dissociation of an H_2O molecule, binds itself to a lattice oxygen O_{lat} in a hydroxyl group $O_{lat}H^-$, creating a free electron:

$$H_2O + Sn_{lat} + O_{lat} \longrightarrow (HO - Sn_{lat}) + O_{lat}H^- + e^- \quad (20)$$
In the second mechanism, a "rooted" specie, consisting of two hydroxyl groups bound to two Sn atoms, is formed. One derives from the dissociation of a water molecule, and the other from the reaction between the hydrogen and the oxygen lattice. The result is the formation of surface oxygen vacancies:

$$H_2O_{gas} + 2Sn_{lat} + O_{lat} \longrightarrow 2(OH - Sn_{lat}) + V_{O(surf)}$$
$$V_{O(surf)} \longrightarrow V_{O(bulk)}^{2+} + 2e^- \quad (21)$$
These surface oxygen vacancies can diffuse to the bulk, where they can be ionized, hence acting as an electron donor.

It can be observed that, according to these two interaction mechanisms, the adsorption sites for H_2O are proportional to O_{lat} and Sn_{lat}, while the adsorption sites for gaseous oxygen are the oxygen vacancies V_O. However, water vapor adsorption creates oxygen vacancies that can be occupied by chemisorbed oxygen species (O_{2ads}^-, O_{ads}^-), compensating for the resistance decrease due to water adsorption. Since the number of adsorption sites O_{lat} and Sn_{lat} is normally quite a lot more than the adsorption sites $V_{O(surf)}$, this explains the predominant resistance-decrease effect in humid air compared with the resistance-increase effect due to the only oxygen adsorption in dry air.

Morrison [126], as well as Henrich and Cox [148], considered an indirect effect, that is, the interaction between either OH^- or H^+ with an acidic or basic group, which are also acceptor surface states. The coadsorption of water with another adsorbate, which could be an electron acceptor, may change the electron affinity of the latter. Henrich and Cox suggested that preadsorbed oxygen can be displaced by water adsorption. Also, Caldararu et al. [149] assumed a blocking of the adsorption sites for oxygen by water. In fact, if there are many surface oxygen vacancies, it is difficult for water to find enough lattice oxygen to be adsorbed. On the contrary, if the level of humidity is too high, so that there is a large coverage with hydroxyl groups OH^-, the adsorption of oxygen can be limited. In this condition, the presence of water vapor can interfere with oxygen adsorption, not allowing gaseous oxygen to be adsorbed onto the surface vacancies. The relative surface distribution and coverage of hydroxyl groups and oxygen species may be related to the history and thermal treatments of the samples. This is why the effect (enhancing or interfering) of humidity on the response to reducing gases is often ambiguous and controversial [150–152, 162].

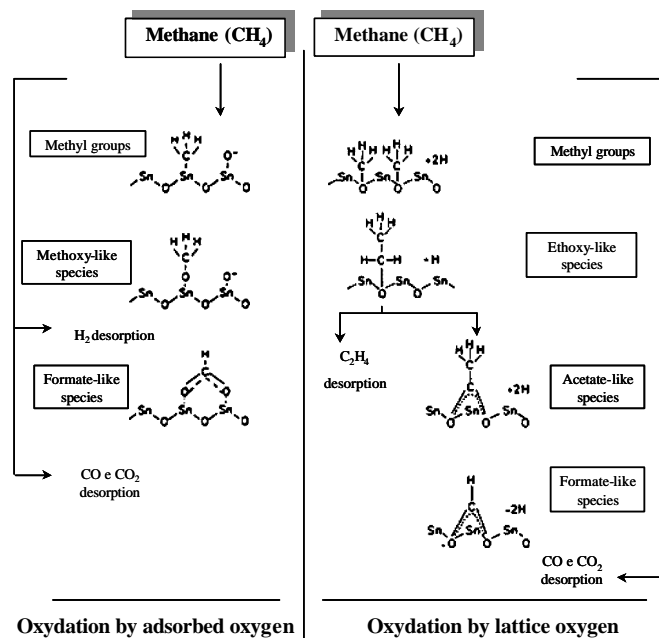
CO Carbon monoxide is generally accepted to act as a reducing gas for a metal-oxide semiconducting film [145, 154–158], even if some anomalous responses have been observed [159, 160]. All experimental studies in air in a temperature range of 150–450 °C reported a decrease of the surface resistance in the presence of CO. CO molecules react with ionosorbed oxygen species adsorbed or lattice oxygens [148]. IR studies identified CO-related species, that is, unidentate and bidentate carbonate between 150 and 400 °C and carboxylate between 250 and 400 °C [161]. Moreover, the formation of CO_2 as a reaction product between 200 and 400 °C was identified [137].

$$\text{a) } CO_{gas} + 2O_{ads}^- \longrightarrow CO_3^{2-} \begin{array}{l} \longrightarrow CO_{2gas} + O_{ads}^{2-} \\ \longrightarrow CO_{2gas} + O_{ads}^- + e^- \\ \longrightarrow CO_{2gas} + 1/2 \cdot O_{2gas} \\ \quad\quad + 2e^- + S \end{array} \quad (22)$$

$$\text{b) } CO_{gas} + O_{ads}^- \xrightarrow{\uparrow O_{ads}^-} CO_2^-$$
$$\downarrow$$
$$CO_{2gas} + e^- + S$$
CH$_4$ Experimental studies report a decrease in the sensor resistance in the presence of methane. Since methane is thermodynamically more stable than most other reducing gases, it is relatively difficult to detect it with high sensitivity at temperatures lower than 350–400 °C. Only a few works report the detection of CH$_4$ at low temperature [165]. The CH$_4$ detection mechanism involves the oxidation reactions of methane with the adsorbed oxygen species, but also with the lattice oxygen, especially at high temperatures, producing CO$_2$ and H$_2$O via CH$_n$ or CH$_n$O intermediates $(0 < n < 4)$ [163, 164].

Kohl assumed, based on TDS, two different pathways for methane [144, 147]. The first involves the reactions with ionosorbed oxygen, and the second involves the reaction with lattice oxygen (Fig. 10). The decrease of the resistance of a semiconducting gas sensor as a consequence of the interaction with methane is due to the formation of surface oxygen vacancies and/or electrons.

For the influence of water on methane, several models have been proposed [145, 151, 166]. Egashira et al. assumed that water blocks the adsorption sites for methane to explain the decreasing interaction of CH$_4$ with oxygen decrease in the presence of water [166]. Ionescu et al. proposed a model, which is based on the measurement of conductance transients during and after rapid transitions from dry into humid air containing CH$_4$ and CO, respectively [151]. They assumed that CH$_4$ reacts with lattice oxygen, thereby competing with water for the same oxygen site, whereas CO reacts mainly on other oxygen sites, which are not involved in the reactions with water vapor.

Moreover, in considering the gas/solid interaction phenomena at the surface of a gas-sensor device, we have to remember the role of the metal electrodes, which give two different contributions: an electrical and a chemical contribution. An electrical contribution of the semiconducting


sensing layer/electrode interface to the overall sensor resistance has, in fact, to be considered. Moreover, a chemical influence of, for example, the catalytic activity of the contact material in the region close to the contact may occur. The electrode geometry and position effects are also important for semiconductor gas sensors. Several works that took into consideration the role of electrical contacts have been produced [156, 162, 167–174].

Figure 11 shows schematically a typical situation for a conductometric gas sensor based on polycrystalline film, including the current path through, the role of adsorption, charge-transfer processes, surface chemical reactions, the effect of contacts, and also possible catalytic effects at the contact area.

2.3. Transducer Function

2.3.1. Electrical Conduction Mechanisms

The microstructure of the sensing layers together with the chosen operation mode determine how the above-discussed surface reactions, which allow us to detect a chemical species, are transduced in the output signal. The microstructure is strongly dependent above all on the deposition technique, but also on the addition of dopants, promoters, as well as the chosen burning-in cycles. Both thin-film and thick-film deposition techniques are available for the production of metal-oxide layers for semiconducting gas sensors [175]. Most of the chemical (CVD) and physical (PVD) vapor deposition techniques provide thin films with microstructures and transducer functions which are very different from the one obtained by thick-film deposition.
Figure 11. Scheme of a conductometric gas sensor with electrodes placed high up in the sensor face. The figure shows the energy profile of the semiconductor along the path between a pair of electrodes with the energy barriers at grain boundaries and at the metal/semiconductor interface, the species (O$_2$, H$_2$O, CO) adsorption, the charge transfer from the gas to sensor or to electrodes, the surface chemical reaction between CO and chemisorbed oxygen species, and possible catalytic effects at the contact area.

Figure 10. Diagram of the methane oxidation process by lattice oxygen (right side) and adsorbed oxygen (left side).

According to Bârsan et al., a simple distinction between two different types of layers can be made [56, 156].

- Compact oxide layers, in which the interaction with chemical species in the gas phase takes place only at the geometric surface. The electron flow is parallel to the surface, that is, to the depletion layer.
- Porous polycrystalline layer, in which the volume of the layer is also accessible to the gases, and in this case, the active surface is much higher than the geometric one.

The former is obtained by most CVD and PVD techniques, and the latter is characteristic of thick-film deposition techniques and thin-film deposition techniques such as RGTO[1] [175, 176] and sol–gel process [194–200], which result in porous layers with a large surface area. In Section 3.2, a brief survey of some the most used depositions will be given.

For a compact layer, two kinds of behavior can be distinguished, depending on the ratio between the layer thickness t and the width of the depletion layer x_0 (or, equivalently, the Debye length[2] L_D).

1. In the first case, the layer is completed depleted ($t \sim L_D$); the conductance is limited by surface traps, that is, the conductance is determined by the electrons excited from the surface states, and their activation energy equals the surface-state energy E_{SS} (*surface-trap-limited conduction*).

2. In the second case, the layer is partly depleted ($t > L_D$), and the surface reactions do not influence the conduction in the entire layer. The conduction takes place in a bulk layer of variable width ($t - x_0$) (much more conductive than the depleted layer) by means of electrons provided by donor states, with the energy of the bulk donor E_D as the activation energy. The effect of surface states and surface gas reactions on the conduction is to modulate the conduction channel width ($t - x_0$). This behavior is known as *bulk-trap-limited conduction* (see Fig. 12). Based on simple geometric considerations, the conductance G of a thin single crystal layer of thickness t, width W, and length L is given by

$$G = G_0 \left(\frac{Wt}{L}\right)\left(1 - \frac{x_0}{t}\right) \quad \text{with}$$

$$x_0 = \sqrt{\frac{2e\Delta V_S \varepsilon \varepsilon_0}{e^2 N_D}}$$

(23)

For the case of a completely depleted layer in the absence of reducing gases, it is possible that exposure to reducing gases acts as a switch to the partly depleted layer case (due to the injection of extra free electrons). It is also possible that exposure to oxidizing gases acts as a switch from the partly depleted layer to the completely depleted layer. However, it is important to emphasize that, in this situation, the sensitivity to gases is poor, and the sample has to be very thin in order to obtain appreciable sensitivity values.

For porous nanocrystalline layers, the conduction mechanism is more complex, depending on the presence of necks

---

[1] Rheotaxial growth and thermal oxidation of tin layers.

[2] $L_D = \sqrt{(\varepsilon\varepsilon_0 kT/n_0 e^2)}$.
Figure 12. Schematic representation of a compact sensing with geometry and energy band representation. x_0 is the thickness of the depleted surface layer, t is the layer thickness, and $e\Delta V_S$ is the height of the energy barrier.

between grains, on Schottky barriers, and on the grain size. The nanocrystalline structure implies lower resistance paths through the bulk of crystallites alternating with higher resistance constrictions at the points of contacts. Three general cases may be considered, according to the degree of sintering of the material. They are illustrated in Figure 13.

Figure 13a shows the case of a well-sintered material with a fully open "neck" between adjacent grains. Surface states cause depletion layers extending below the grains to a depth marked by the dashed lines on both sides of the neck. In this case, the conduction mechanism takes place in a bulk layer of variable width ($z_n - 2z_0$) (much more conductive than the depleted layer) by means of electrons provided by donor states, with the energy of the bulk donor E_D as the activation energy. The effect of surface states and surface-gas reactions
Figure 13. Three models for conductance limited by intergrain connections. a) Open neck (*bulk-trap-limited conduction*), b) closed neck (*surface-trap-limited conduction*), c) Schottky barrier. In all of the cases, we considered the diameter of the grain l higher than the Debye length L_D ($l > L_D$).

on the conduction is to modulate the conduction channel width $(z_n - 2z_0)$. This behavior is known as *bulk-trap-limited conduction*.

Figure 13b shows the case of a "closed" neck in which the depletion zones from the surfaces of the adjacent grains overlap, leaving a higher resistance path through the center. This geometry corresponds to a less complete sintering that left a narrower neck or to an "open" neck that has been constricted by surface reactions to a change in the depletion layer thickness. In this case, the conductance is directly influenced by the gaseous ambient through the occupancy of the surface states; the conductance is determined by the activation of the electrons from the surface states into the conduction band (*surface-trap-limited conduction*).

Figure 13c shows a third situation where a Schottky barrier is formed at the boundaries of two adjacent grains. In this case, the conduction mechanism between grains is a thermionic emission, the conductance G depending on the barrier height $e\Delta V_S$:

$$G = G_b \exp\left(-\frac{e\Delta V_S}{kT}\right) \qquad (24)$$

This conduction mechanism (*barrier-limited conduction*) is clearly different from the other two cases, $e\Phi_b$ being the activation energy for conductance directly related to the square of the surface charge. The changes of Schottky barriers as a function of the ambient gaseous composition lead to a high gas sensitivity.

According to the grain boundary carrier-trapping model, in this latter situation, the presence of intergrain boundaries results in band bending, which sets up potentials barriers to current flow (effectively reducing the carrier mobility μ) or in a severe carrier depletion which reduces the carrier density n considerably below the bulk doping level N (or, in some conditions, to a combination of these two effects). The density n_t (per unit area) of charges trapped in extrinsic interface states depends on the environmental composition via the adsorption of active gaseous species. The density N_t of surface states determines the maximum amount of charge which can be trapped (Weisz limitation), while the trap energy E_t may determine the activation energy for free-carrier freeze out.

The standard treatment of the electrical transport phenomenon in polycrystalline thin films is due to Petritz [207]. The model is based on a thermionic emission mechanism between adjacent grains. Assuming that the electrical resistivity in the grain is negligible with respect to the electrical resistivity in the boundary regions ($\rho_{\text{grain}} \ll \rho_{\text{boundary}}$), he showed that the total electrical resistivity is controlled by the energy barriers at the grain boundaries:

$$\sigma_g = eN\mu_0 \exp\left(\frac{-e\Phi_b}{kT}\right) \qquad (25)$$

where N is the bulk doping level, $\mu_0 = (M/n_c kT)$, n_c is the number of crystallites per unit length along the film, and M is a factor that is dependent on the barrier, but independent of Φ_b (i.e., $e\Delta V_S$). Since $\rho_{\text{grain}} \ll \rho_{\text{boundary}}$, Petritz also assumed that the carrier concentration was not reduced by the exponential term, but rather, that all carriers took part in the conduction process, but with reduced mobility. The effective carrier mobility is so thermally activated:

$$\mu_g = \mu_0 \exp\left(\frac{-e\Phi_b}{kT}\right) \qquad (26)$$

Seto [208] developed a more comprehensive analysis of the grain boundary-trapping model based on some assumptions. He modified the preexponential term in Eq. (26):

$$\mu_0 = el\left(\frac{1}{2\pi m^* kT}\right)^{1/2} \qquad (27)$$

where l is the average grain size and m^* is the electron effective mass.

Thermionic emission results from those carriers with high enough energy to overcome the Schottky barrier at the grain boundary, but a contribution to current across the grain boundary also comes from tunneling from those carriers with less energy than the barrier height that go through the barrier by quantum-mechanical tunneling.

The Hall effect measurements are fundamental tools in order to obtain information about the electrical transport properties of polycrystalline gas-sensing films [210]. Since both μ and n can control the conductivity σ, the Hall effect allows us to distinguish if σ is mainly controlled by intergrain depletion barriers (modulation of μ) or by the carrier depletion in the grains (modulation of n) or by a combination of the two effects. However, more care has to be taken in the interpretation of the results of Hall effect measurements, depending on the relative magnitude of n_t compared to Nl and on the Debye length L_D compared to the grain size l. According to the Orton and Powell treatment of the Hall effect in polycrystalline thin films, three situations can be distinguished [209]. Figure 14 summarizes the three different conduction band profiles that can occur for an n-type film, and Table 3 shows the corresponding expressions for n and μ for the three regimes.

a) $n_t < Nl$: The resulting depletion layer width W is less than $l/2$, and the grains are partially depleted. In this case, the carrier concentration is quite high compared with n_t, and the depletion layer is just located at the surface of the grains, so that the Hall effect measures the carrier concentration N in the bulk of the grains. The conductivity σ will be mainly controlled by intergrain depletion barriers with a thermally activated Hall mobility given by Eq. (26), where μ_0 is related to the grain diameter l according to Eq. (27). Hence, the activation energy for Hall mobility is $E_\mu = e\Phi_b$.

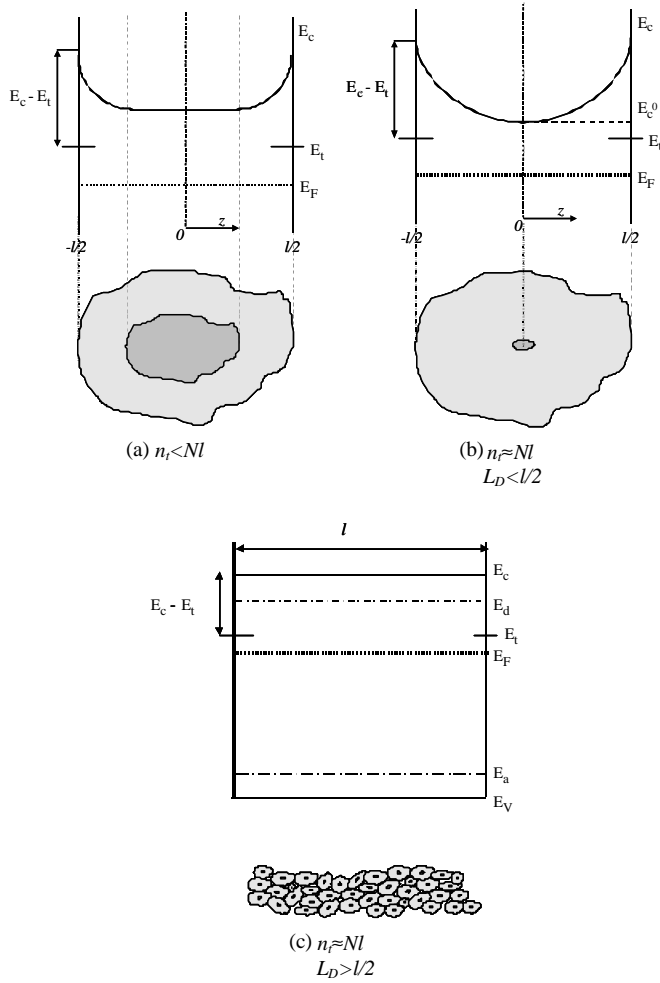
The height of Schottky barriers, calculated by solving the Poisson's equation and by equating the interface charge to the fixed charge in the depletion layer (i.e., $n_t = 2NW$), is given by

$$e\Phi_b = \frac{e^2 n_t^2}{8\varepsilon N} \qquad (28)$$

b) $n_t \approx Nl$, $L_D < l/2$: The depletion layer extends right through the grain. In this case, the carrier concentration n may be very much lower than the bulk doping level N; in particular, it is given by the following relationship:

$$n = \sqrt{2\pi}\frac{L_D}{l}\frac{NN_c}{(N_t/l) - N} \exp\left(-\frac{(E_c - E_t) - e\Phi_b}{kT}\right) \qquad (29)$$

(a) $n_t < Nl$

(b) $n_t \approx Nl$
$L_D < l/2$


(c) $n_t \approx Nl$
$L_D > l/2$

Figure 14. Conduction band profiles through single grains of an *n*-type film for the three cases discussed by Orton and Powell [209]: a) $n_t < Nl$, b) $n_t \approx Nl$, $L_D < l/2$, c) $n_t \approx Nl$, $L_D > l/2$.

and μ is still barrier limited (26). Thus, in this regime, both n and μ control the conductivity σ. Next, we will use the following general relation for *n*:

$$n = n_0 \exp\left(-\frac{E_n}{kT}\right) \quad (30)$$

One can notice that, since the activation energy for the mobility is $E_\mu = e\Phi_b$ and for the carrier density $E_n = (E_c - E_t) - e\Phi_b$, and since the conductivity $\sigma \propto n_{av}\mu \propto \exp[(E_c - E_t)/kT]$, the activation energy for the conductivity is $E_\sigma = E_n + E_\mu = (E_c - E_t)$.

Table 3. Expression of n and μ for the three regimes.

Regime	n	μ
a) $n_t < Nl$	N	$\mu_0 \exp\left(-\frac{e\Phi_b}{kT}\right)$
b) $n_t \approx Nl$ $L_D < l/2$	$\sqrt{2\pi}\frac{L_D}{l}\frac{NN_c}{(N_t/l)-N}\exp\left(-\frac{(E_c-E_t)-e\Phi_b}{kT}\right)$	$\mu_0 \exp\left(-\frac{e\Phi_b}{kT}\right)$
c) $n_t \approx Nl$ $L_D > l_1/2$	$\frac{NN_c}{(N_t/l)}\exp\left(-\frac{(E_c-E_t)}{kT}\right)$	μ_0 or μ_{bulk}

In this regime, the Schottky barrier is given by the following relationship:

$$e\Phi_b = \frac{e^2 Nl^2}{8\varepsilon} \quad (31)$$

Band bending is related to the doping level N and the interface trap density N_t. Comparing the case $Nl < N_t$ where $e\Phi_b$ varies linearly with N in this regime (31) with the case $Nl > N_t$ where $e\Phi_b$ varies with N^{-1} (28), it follows that there is a maximum barrier height that occurs when $Nl = N_t$ (Weisz limit), and correspondingly μ reaches a minimum.

c) $\boldsymbol{n_t \approx Nl,\ L_D > l/2}$: Since almost all of the conduction electrons are trapped in the available interface states on the grain boundaries, and since the Debye length L_D is larger than the grain size, the grains will be almost fully depleted of free carriers, and the energy bands will be essentially flat through each grain. This always occurs below a critical grain size so that it is now clear how the grain size is a fundamental parameter in determining the electrical properties of polycrystalline, and why it should be measured and controlled. In this regime, there are no barriers to current flow, and the mobility will not be activated, although the carrier concentration may be thermally activated because of the excitation of the carriers from the trap level E_t to the conduction band. In particular, n is given by the following relationship:

$$n = \frac{NN_c}{(N_t/l)}\exp\left(-\frac{(E_c - E_t)}{kT}\right) \quad (32)$$

Thus, in this regime, only n controls the conductivity σ with an activation energy $E_n = E_c - E_t$. Small variations in n may quickly change the grains from highly depleted to nearly fully undepleted; this conductivity modulation by carrier depletion in the grains is enhanced when $L_D > l/2$, and could explain the better sensitivity toward gas compounds of nanocrystalline films.

Finally, it has to be remembered that, for porous oxide layers, since the volume of the sensing layer is accessible to gas, a diffusion theory has to be considered as an electrical transport mechanism, together with thermoelectronic emission theory. We refer to [93, 156, 245] for details.

2.3.2. Conductance–Concentration Relationships

Many different formulas for describing the dependence of the sensor conductance on the concentration of the gaseous species which has to be detected can be found in the literature. These different equations, expressing the conductance G as a function of the gas partial pressure or concentration P_g, are mostly power laws ($G \propto P_g^{-m}$). Several both empirical and analytical approaches have been used for deriving them. The variety of conductance–concentration relationships proposed is due to the different conduction mechanism assumed, to the different surface catalytic reactions assumed for the same adsorbate–adsorbent system, to the different adsorption isobar curve assumed, as well as to the real complexity of the numerous parameters that have to be controlled in the sensor device. Table 4 shows typical equations for describing the calibration curves of SnO_2-based sensors for reducing gases.

Table 4. Equations describing the dependence of conductance on the concentration of reducing gases as derived empirically or from theoretical calculations.

No.	Formula	Procedure	Comments	Ref.
1	$G = A_1 c^\beta$	Empirical	Large database, deviation at high concentration	[211]
2	$G = G_0 + A_1 \cdot p_{CO}^{1/2}$	Rate equations and SC physics	Reaction of CO and chemi-sorbed oxygen	[212]
3	$G = G_0 + A_1 \cdot p^{1/2}$	Empirical	Thin film	[213]
4	$R = R_0 p_{O_2}^\beta (1 + K_{CO}[H_2O][CO])^{-\beta}$	Empirical	For CO, CH_4, H_2O, CH_4/H_2 constant and modulated T	[145]
7	$G/G_0 = x_i \sim (1 + K_{ik} p_k)^{\beta ik}$	Empirical	i denotes the sensor, k the gas	[214]
8	$G \sim p_{O_2}^{-m/2.18}(A_0 + A_1 p_R^m)^{0.92}$	Rate equations and SC physics	Oxygen species (O_m^-) specified by $m = 0.5, 1, 2$	[135]
9	$G = A_0 + A_1 c^\beta + 1/\{A_2 \cdot c^\beta + 1/(G_0 - A_0)\}$	Williams' band bending and SC physics	Account for hole contribution in surface conductance	[154]
10	$R = p_R^\beta, \beta = -0.5(1 + 1/(1 - 2 \cdot a \cdot R/b))$	Rate equations and SC physics	Oxygen species O^-, exponent depends on the actual resistance	[18]
11	$G^2 - G_0^2 \sim p_{CO}$	Rate equations and SC physics	Fully depleted layer at the surface	[158]
12	$G/G_0 = \Pi(p_i/p_{i,0})^{\beta i}$	Empirical, Clifford '83	In gas mixtures, normalized to a reference	[215, 216]
13	$(G^\beta - G_0^\beta) \sim p_{CO}, \beta \geq 2$	Rate equations and SC physics		[217]
14	$(G^2 - G_0^2)/G_0 \sim p_{CO}$	Empirical	Procedure for reduced humidity interference	[218]
15	$G/G_0 = (p_{CO}/p_{0,CO})^{\beta CO} \cdot (p_{H_2O}/p_{0,H_2O})^{\beta H_2O}$	Rate equations and SC physics	Interaction of water vapor V_{O^-} and dipoles associated with hydroxyl groups uses a normalization	[152]
16	$G = p_R^{2\beta/(\alpha+1)}(L_D > r), G = p_R^{\beta/(\alpha+1)} (L_D < r)$	Rate equations and SC physics	Interacting oxygen species ($O_\beta^{-\alpha}$), α and $\beta = 1, 2$, mobility effects	[155, 156]
17	$G = A_0(A_1 \cdot p_R)^\beta$	Empirical	Long-term properties by calibration with reference gas	[219]

2.4. Grain-Size Effect on Gas Response

In Section 2.3, we discussed some important aspects related to the electrical conduction properties of a metal-oxide semiconductor layer, which are also closely linked to its microstructure and to the gas-sensing mechanisms. The grain size, the type of intergrain connections, and the distribution of the grains in the grain network that builds the sensing layer are fundamental parameters of a semiconductor gas sensor. However, it should be considered that there is no easy description of the electrical transport properties of polycrystalline films, and a simple distinction between the different conduction models (surface trap-, bulk trap-, or Schottky barrier-limited conduction) is not realistic. Even in the case of Schottky barrier-limited conduction, different regimes can be distinguished according to the above discussion. A real three-dimensional, incompletely sintered material normally has an inhomogeneous structure, and it likely contains more than one single type of intergranular contact ("neck" or "barrier"). Moreover, as the sensor works for a long time at a relatively high temperature, the proportion between the different types of intergranular contacts may change with time. In fact, small adjacent grains can sinter to a larger grain, so that an "aging" effect of the sensor is usually observed. Hence, experimental results could be misinterpreted if only one of the two connection mechanisms between grains is considered.

Wang et al. [48] defined a model that combines both the grain-boundary and neck mechanisms, which are formulated on the basis of the thermoionic emission and junction modulation theory. The neck-conduction mechanism alone has a very low sensitivity, while the grain-boundary resistance is more affected by the gas concentration variation. According to Wang et al., at a large grain size, grain-boundary resistance dominates at low gas concentration, while at high gas concentration, the neck resistance is dominant. However, the neck resistance is much increased over the entire concentration range for a much smaller grain size. They discussed quantitatively the gas response as a function of grain size and chemisorbed gas concentration. When the grain size decreases uniformly, the sensor response increases more and more quickly. According to their model, only for very small grains ($l \leq 40$ nm) does the sensor response have a threshold, linear, and saturation region over a large range of adsorbed gas concentrations N_{ads}. This conclusion, on the other hand, is well supported by experimental evidence. In the threshold region, the gas response increases slowly because the neck resistance is still large, while as the adsorbed gas concentration N_{ads} further increases, the increase of the sensor response becomes quicker because the N_{ads} modulation of the neck cross section becomes

more significant (linear region). According to the model, gas response saturates because, at high gas concentrations, N_{ads} is proportionally high; hence, most of the adsorbed oxygen is consumed to react with the gases, and the depletion width becomes very small. Consequently, the diameter of the neck cross section approaches its maximum, and the height of grain-boundary Schottky barriers approaches its minimum.

As emerges from the discussion above, the dimension of the grains in metal-oxide layers hence has a strong influence on the electrical conduction mechanism, and it is fundamental in determining the gas-sensing properties. At present, great efforts are being devoted to developing gas sensors based on nanocrystalline metal oxides, with a precise control of the sensing film nanostructure. Scientific research is also addressed to study the effect of grain size on the sensor response to specific gases. It is well known, in fact, that the gas response of a polycrystalline metal oxide with a very small average grain size may be even orders of magnitude higher than that of a metal oxide with a large grain size. As an example, Figure 15 reports the sensor response at 250 °C to 1 ppm NO_2 versus grain size for an In_2O_3 thin film deposited by the sol–gel process.

The grain size effect can be reasonably considered a very promising approach to the development of high-sensitivity metal-oxide gas sensors. However, the real role of grain size in the gas detection mechanism is not well understood yet. Fundamental studies are needed in order to define a comprehensive model that better explains the gas-sensing properties of a metal-oxide semiconductor layer on the basis of its microstructure and the surface chemical reactions. A theoretical investigation of the dependence of gas sensitivity of nanostructured semiconductor gas sensors on cluster size was presented by Vlachos and Xenoulis [46]. They developed a model in which spherical grains and a uniform surface-state density are considered, and the current between grains is calculated, taking into account the thermal emission and the tunneling of carriers. The sensitivity is calculated taking the derivative of the logarithm of the conductivity over the surface-state density. The results of this model show that there is a critical grain size, which is
material dependent, at which the sensitivity is maximal. This grain size depends mainly on free-carrier concentration, and thus on temperature too. Figure 16 shows the theoretical calculated sensitivity versus grain size for some metal oxides. Moreover, for metal-oxide gas sensors, this optimum size depends on the degree of oxidation, the presence of surface additives, and the poisoning of surface parameters, which are known to control the carrier concentration.

As just discussed in the paragraph above relative to the regime c) ($n_t \approx Nl$, $L_D > l/2$), under standard operating conditions of the sensor in air, the grains will be almost fully depleted of free carriers. The significance of the Debye length L_D can no longer be ignored, and the energy bands will be essentially flat through each grain. A flat-band condition is, in fact, the most frequently assumed hypothesis for nanostructured semiconductor films [108, 155, 156, 215, 220], although there is not exact agreement about the critical grain size value below which this condition may be justified. According to Bârsan, the flat-band condition is fulfilled in the range of grain sizes below 50 nm [155]. The flat-band approximation allows us to neglect both the exact electron distribution in the oxide crystallites and the change of the electron mobility at grain boundaries [221].

Recently, Castro et al. provided some experimental proofs of the flat-band condition by scanning-tunneling microscopy and spectroscopy on SnO_2 thick films whose average grain size is about 100 nm [108]. They found a quite symmetric behavior of the tunneling current–voltage characteristics with current flow for positive and negative voltages. This indicates that the SnO_2 nanocrystallites present a nonrectifying behavior. They also explained the observed changes in resistance with temperature in oxygen atmosphere by including oxygen adsorption and diffusion into the grains.

It is easy to understand how, for small grains ($l < L_D$), the effects of, for example, reducing gases can no more be traditionally described as for large grains, that is, as a decrease of chemisorbed oxygen species which is accompanied by a reduction of the band bending and the depletion layers. This is why the depletion layers can increase up to the point for which the grain depletion layers cover the whole grains. This happens when the grains are small enough for intergrain barriers to overlap, and then the entire

Figure 16. Theoretical calculated sensitivity versus grain size for some metal oxides: ZnO (circles), SnO_2 (triangles), TiO_2 (crosses), In_2O_3 (squares) at 500 K.

grains become electron depleted. All conduction electrons are trapped in the surface states at intergrains. The electron concentration changes dramatically and homogeneously within the grains upon changes in the occupation of surface states. The expected exponential dependence of the conductance on the temperature is

$$G = P\sigma_0 \exp[-(E_C - E_F)/kT] \qquad (33)$$

where σ_0 denotes the temperature-dependent bulk conductivity, which is determined by the concentration and ionization energies of the bulk donor and acceptor states, as well as the mobilities of conduction electrons. The proportionality constant P characterizes the sample geometry and the optimum percolation paths expected theoretically for $T \to \infty$ for the conduction of electrons through the sample [215]. The value of G in Eq. (33) is modulated by changes in the difference between the Fermi level E_F and the conduction band edge E_C in the bulk upon exposure to gases. Indeed, the effect of gases can be approximated by a shift in energy bands relative to the Fermi level and the related shift in electron concentration (Fig. 17). Here, no difference exists between the bulk and surface position of E_C, that is, $\Delta(E_C - E_F)_{\text{surf}} = \Delta(E_C - E_F)_{\text{bulk}}$, due to the flat-band approximation [122, 215].

The relationship between the G and gas concentration is a delicate matter. Kissine et al. derived some expressions for the electron concentration n in the film by assuming a flat-band condition [220]. Using the condition of charge neutrality and the adsorption–desorption balance rule for acceptors and surface donors, they expressed n as a function of partial normalized gas pressures p_a, p_d:

$$n = N_D + \frac{n_i}{n} + \Delta n(N_a, N_D, n_s, p_a, p_d) \qquad (34a)$$

where

$$\Delta n = \frac{n_s n_d p_d}{n + (n + n_d)p_d} \quad \text{for donor-like gas} \qquad (34b)$$

$$\Delta n = -\frac{n_s n_a p_a}{n_a + (n + n_a)p_a} \quad \text{for acceptor-like gas} \qquad (34c)$$

$$\Delta n = n_s \frac{n_a n_d p_d - n^2 p_a}{n_a(n + n_d)p_d + n(n + n_a)p_a + n_a n} \qquad (34d)$$

when donor- and acceptor-like gas are simultaneously adsorbed at the film surface.

Bârsan proposed a model for conduction in gas-sensing SnO_2 layers with a grain size below 50 nm [155]. Bârsan et al. also presented a modeling approach for the receptor and transducer functions, with particular attention to the microstructure influence and the role of grain size. He emphasized that, for small grains, since the mean-free path of electrons becomes comparable to the dimension of the grains, the number of collisions experimented by a free electron in the grain bulk becomes comparable to the number of collisions at the grain surface; the latter also may be influenced by adsorbed species acting as additional scattering centers. Using the formula derived by Many et al. [222] for the influence of surface scattering, adapted to a simple spherical grain geometry, one gets

$$\mu = \frac{\mu_b}{1 + W \cdot \lambda/2r} \qquad (35)$$

where W, which represents the probability of a diffuse (inelastic) scattering process, is assumed equal to surface coverage θ. In the case of very small grains, the ratio $\lambda/2r$ is not negligibly small, and the influence of the surface on the electron mobility may become relevant; hence, it should be taken into account. The dependence of G on the gas concentration of a reducing gas takes the form

$$\begin{aligned} G &= p_R^{2\beta/(\alpha+1)}, & L_D > r \\ G &= p_R^{\beta/(\alpha+1)}, & L_D < r \end{aligned} \qquad (36)$$

with $\alpha = 1$ for O_2^- and O^-, $\alpha = 2$ for O^{2-}, $\beta = 1$ for O^- and O^{2-}, and $\beta = 2$ for O_2^-.

A particularly attractive feature, that is beginning to strongly interest the basic science on nanostructured materials used as gas sensors, is the possible effect of the surface and quantum confinement of electrons in nanograins. However, scarce scientific literature on the matter is currently present. Li et al. studied this effect on a nano-$LaFeO_3$ surface by the vacuum adsorptive surface photovoltage technique (SPV) [103]. They verified a quantum confinement effect which depends exponentially on the gas pressure. They also found that there are basically two different methods of charge-transfer transition for a nano-$LaFeO_3$ surface adsorbed by ethanol molecules.

Finally, it is worthless for some aspects of the electrical transport properties of a gas-sensitive layer which can be considered as a large cluster of interconnected nanocrystalline grains. In real nanocrystalline films, the electrical current is constrained to flow in nonuniform patterns for purely geometric reasons, following a preferred path of least resistance, and the effective mobility may be limited by such effects, even in the absence of band bending (*percolation effect*) [209]. As long as each grain contributes to the conductivity of the layer, the size and shape of the conducting network do not change, and the gas sensitivity depends only

on the change in the conductivity at single-grain transitions. In this case, the morphology leads to a constant prefactor in the expression of conductivity, and the whole sample can be described approximately by a single mean-grain transition. On the contrary, when some grains switch between a conducting and an insulating state, only the conductive part of the sample will contribute to the conductivity. The size and shape of the conducting part depend on the morphology of the sensing layer and, of course, on the gas concentration.

Ulrich et al. reported a percolation model for a nanocrystalline gas-sensitive layer that takes into account the possibility of having ultrasmall compensated grains that are insulating [45]. The probability that a nanograin is insulating depends on the diameter and number of next neighbors (the coordination number k). According to the percolation theory, the concentration of conducting grains must exceed a critical concentration p_c, the percolation threshold, in order to form a conducting path spanning the sample (Fig. 18). The conductivity is given by a power law just above threshold:

$$\sigma \propto (p - p_c)^{\mu}, \qquad p > p_c \qquad (37)$$

This leads to a large dependence of σ on the gas concentration which triggers p. The critical exponent μ depends only on the dimension of the network, and not on its internal structure. The percolation threshold also leads to a gas-detection limit [44]. In fact, experimental studies revealed that the gas response does not change until a critical gas concentration is reached; above the detection limit, the gas response rapidly increases. Ulrich et al. attributed the enhanced gas response, when the grain size is decreased, to the presence of percolation effects. They also observed that the percolation threshold for a sample should be adjustable
Figure 18. Small grain cluster below and above the percolation threshold p_c. For simplicity, a two-dimensional cluster on a rectangular lattice is drawn. Open, shaded circles represent conducting grains. Above p_c, the first conducting path is drawn as a solid line. The side spanning conducting cluster of the sublattice is shaded with a cross mesh. with the grain size distribution and the average coordination k_{mean}. The first, together with the mean diameter, can be controlled by the synthesis and deposition parameters of the sensing layer; the latter is nearly random, and results from the sintering process.

3. CURRENT STATUS OF RESEARCH

3.1. Materials

SnO_2-based gas sensors represent the first prototypes of chemoresistive gas sensors. Tin oxide is the most known and used material in this type of gas sensor. However, SnO_2 is not the only material with acceptable gas-detection properties, but in general, metal oxides are the most suitable semiconducting materials for gas-sensing applications [146]. In fact, it results that materials with predominantly ionic bonding (such as ZnO, SnO_2) are much more sensitive to changes in the surface coverage by adsorbed molecules and, consequently, to changes in the gas-phase composition with respect to materials with covalent bonding (Si, Ge, GaAs) [47]. Moreover, by using metal oxides as semiconducting sensing elements, it is possible to avoid the problem of instability of other semiconductors (such as germanium), mainly due to the formation of stable surface oxide layers under cycled thermal annealing in air. On the contrary, metal oxides bind atmospheric oxygen at their surface in a reversible way [18]. Of course, oxides characterized by exceedingly high resistivity, such as SiO_2 and Al_2O_3, are not used in resistive gas sensors because of the difficulties encountered in electrical conductivity measurements.

A screening of a large group of oxides was originally carried out. It showed that the sensitivity of conductivity to low concentrations of reactive gases in air was a phenomenon common to metal oxides, and not specific to SnO_2 or to a few special cases [38, 223]. Also, at present, an important part of the scientific research is continuously involved in the systematic study of new metal oxides for gas sensors. The reason for the research on novel gas-sensitive materials is that, although it is obvious that other gas-sensitive oxides should exist, there is no a priori basis for identifying them or for determining which, if any, materials may have more advantageous properties than SnO_2, and particularly a selectivity of response.

A huge amount of studies on SnO_2-based gas sensors have been published. Table 5 shows an incomplete list of literature about SnO_2 sensors for specific target gases; it informs us about the preparation process and the doping/catalytic element [122]. The aim of these extensive research activities was to gain a better understanding of gas-sensing mechanisms [74–77, 224–226], and naturally, to improve the properties of SnO_2 sensors [49, 91].

Simple binary metal oxides, such as Ga_2O_3, WO_3, In_2O_3, and TiO_2, are the most investigated semiconducting materials. Additionally, there are several ternary (e.g., ITO, $SrTiO_3$, and $BaSnO_3$), quaternary, and complex metal oxides, including heterometallates, that are promising candidates [49]. A list of new gas-sensitive metal oxides, alternative to tin oxide, is reported in Table 6. The concept of n-type and p-type materials has long been established in

(like O_2, NO_2, etc.) and a resistance decrease to reducing gases (like CO, CH_4, hydrocarbons, etc.), while *p*-type oxides have the opposite behavior.

3.1.1. Influence of Dopants and Surface Additives

Noble metals (e.g., Ag, Pd, Pt, etc.), uniformly distributed and finely dispersed as catalytic clusters on the surface of the oxide-sensing layer or added as dopants into the oxide bulk, are often used in semiconductor gas sensors. It is well known and experimentally proven that catalysts added to the sensor may influence its response to specific gases, may speed up the surface reaction, or may impart selectivity to the reaction so that some reaction processes are favored over others [18, 227, 86, 87].

Because semiconductor gas sensors depend on surface chemical reactions, they are strongly influenced by the activation energy needed to initiate the reaction. As discussed in Section 2.2.2, the activation of a species involved in a surface reaction may be the dissociation of a molecule, the ionization of the species, or some other intermediate reaction that presents the species in a form ready for an exothermic reaction on the sensor surface. The activation energy necessary to promote a reaction, usually provided as thermal energy, depends on the route of the reaction. If the activation energy using a particular route is high, the rate of the reaction will be low, and vice versa, if a route for the reaction can be found with a low activation energy, the reaction will be fast. Energetically, the effect of catalysis is to provide a more favorable reaction path. In such a way, a lower operating temperature for the sensor may be needed, and the rate of only some reactions also can be greatly enhanced in contrast to the rate of others, so that selectivity is provided to the system.

Thus, the use of catalysts/dopants is a feature of great importance in semiconductor sensor design. Although the promoting effect of modifiers in the semiconductor bulk is not well understood yet, the way in which surface-dispersed metal additives influence the gas response characteristics

oxide semiconductors. In the gas-sensing context, the sign of response (resistance increase or decrease) leads to a simple and useful classification. Based on the *p*- or *n*-type conduction of the oxide, gases can be classified as oxidizing or reducing according to the sign of the response: *n*-type oxides show a resistance increase in the presence of oxidizing gases

could be explained in terms of the *spillover* and/or the *Fermi-level* mechanism [18, 88].

Spillover is a chemical interaction in which the metal catalyst dissociates the molecule, the atoms of which can "spill over" onto the surface of the semiconductor support, and eventually react with ionosorbed oxygen species, thus controlling intergranular resistance. Hydrogen and oxygen spillover has been extensively studied. Hydrogen spillover is important for hydrogen-containing combustible gases. Oxygen spillover, favoring its adsorption and dissociation in the atomic species O_{ads}^-, which is more reactive than the molecular species $O_{2,ads}^-$, accelerates the oxidation of reducing gases, and consequently promotes their detection in air.

The *Fermi-level* mechanism is an electronic interaction in which gas adsorption on the catalyst removes electrons from the catalyst, and the catalyst, in turn, removes electrons from the supporting semiconductor. The supported catalyst pins the Fermi level of the semiconductor support at the Fermi level of the catalyst, thus controlling the band bending in the semiconductor, and consequently, the intergranular resistance, in the same way as adsorbed oxygen or another adsorbate would do in a normal situation without a catalyst. Of course, the Fermi level of the catalyst at the catalyst/semiconductor interface has to depend on oxygen adsorption, and the small catalyst particles have to be highly dispersed (distance between clusters less than about 500 Å) so that the space-charge regions of neighboring catalysts overlap.

Platinum and palladium are the most commonly used dopants to improve the performance of SnO_2 for CO detection; it seems that Pt promotes CO oxidation via the spillover mechanism, while it seems that Pd acts via electronic interaction (Fermi-level control) [49], even if an electronic interaction between Pt and tin oxide also has been proposed [86].

The most active metal catalysts are known to be the transition metals (Pt, Pd, Rh, Ir, Os) that, having partially filled *d* orbitals of valence-band electrons, allow a strong gas–solid interaction [18].

A huge amount of experimental work on metal oxides doped with metallic elements or modified with surface metallic additives has been published. We mention, just as an example, only some of the most significant experimental works on the effect of dopants and/or surface additives on the gas-sensing properties of metal oxides. Capone and co-workers studied the gas-sensing properties of Pd-, Pt-, Os-, and Ni-doped SnO_2 thin films deposited by the sol–gel method [165, 198, 199, 228–233]. The films are prepared by spin coating, starting from a hydrolyzed alcoholic solution of tin precursors. The addition of inorganic transition metal salts in the solution enables the activation of the resulting film. The presence of modifiers is evidenced both in the form of nanoparticles (Pd and Pt) and doping atoms (Os, Ni). The dopants increase the sensitivity to certain gases, hence improving the selectivity of the sensing material. In particular, it has been shown that Pd and Os act as activators, respectively, for CO and CH_4, enhancing the sensitivity and simultaneously decreasing the optimum operating temperature. The good sensitivity to methane at a low working temperature makes the Os–SnO_2 thin films very attractive materials to be used in domestic CH_4 leak detectors.

An SnO_2-based sensor array also has been developed for application in the electronic nose. Good results have been obtained for the discrimination of air pollutants and different food odors.

A detailed analysis of the role and activity of three of the most common catalytic additives (such as Pd, Pt, and Au introduced in an SnO_2 nanopowder) in the gas-sensing mechanism have been reported by Cabot et al. [116, 234, 235]. Ruiz et al. also found that the efficiency in catalytic activity improves by incorporating Pt nanoclusters in anatase TiO_2, whose surface reactivity is better [236].

Palladium is the most used dopant/additive to improve the detection of CO and CH_4 [185, 188, 237–241]. Platinum is also a widely used metallic catalyst for gas-sensor applications. Wöllenstein et al. found that Pt nanoclusters, covering the surface of highly dense sputtered polycrystalline SnO_2 layers, increases the sensitivity to CO with lower temperatures without a distinctive influence on the dynamic response constants; on the other hand, the Pt-surface doping eliminates the reaction to O_3 and NO_2 at working temperature around 340 °C [242]. A simple method to achieve a layer of noble metal, such as Pd, Ag, Pt, or Au, nanoparticles on oxide surfaces was proposed by Mizsei et al. [243]. It consists of a first sputtering deposition of an amorphous metal nanofilm of about 5 nm thickness; the film is agglomerated to nanoparticles either via direct crystallization by heating, in the case of nonreacting atmosphere, or by the growth of oxide crystallites and the subsequent reduction of these in a reducing atmosphere. Finally, we mention a work on ruthenium-doped tin-oxide thin films prepared by spray pyrolysis; the films showed an unsually high sensitivity to hydrocarbon (LPG) at a lower operating temperature of 250 °C [244].

3.1.2. Mixed Oxides and Heterojunctions

The search for novel materials suited to gas sensing has led the scientific community working in the field to consider a new concept design for gas sensors based on the use of nanostructured mixed oxides and heterojunctions. The idea originated from some observations related to the working principles of metal-oxide-based gas sensors. As is well known, the resistance variation of the sensing layer involves two important functions, that is, the recognition and the transducer functions. Gas/solid interaction phenomena are involved in the receptor function, while the microstructure of the oxide determines the trasduction of the chemical stimulus in air into an electrical signal. Generally speaking, if a single-oxide system is adopted, these two functions cannot be optimized independently. Instead, by introducing in the system a foreign material, which is very reactive to a target gas and acts as an "antenna" material, both functions may be optimized simultaneously, and the sensor may become more sensitive, even to low reactive gas concentrations. In these cases, the material acting as a unique receptor (antenna material) should be interfaced electronically to the transducer material, and its chemical change should sensitively modulate the semiconducting properties of the transducer oxide through the heterojunction [246]. Layered-type sensors and composite-type sensors containing heterocontacts

between the two phases fulfill this novel concept of gas sensors. They constitute a promising class of gas sensors with enhanced gas-sensing properties.

Heterojunction gas sensors attempt to overcome the problems of existing monolithic gas sensors through the introduction of tunable selectivity, self-cleaning properties, and a built-in failure detection mechanism. Geometrically, heterojunction gas sensors consist of two semiconducting oxides in contact, and the active region is in the interface between the two materials, which behave like a *p–n* junction. Gas adsorbed on either side of the heterocontact is oxidized at varying rates at the heterojunction interface, and influences its rectifying characteristics [247]. Since a loss of rectifying characteristics implies a breakdown of the *p–n* junction, there is a built-in failure detection mechanism [248, 249]. Many works on the gas-sensing properties of junctions based on an *n*-type and a *p*-type oxide have been published. The most common *n*-type material used in these sensors is zinc oxide (ZnO) or tin dioxide (SnO_2), and the *p*-type component is usually a doped copper oxide (CuO) or nickel oxide (NiO) or a perovskite phase such as La_2CuO_4 [250–257].

Since the layered-type sensors are difficult to fabricate, mixed oxides were suggested as suitable materials to accomplish this new concept design of gas sensors. A mixed-oxide sensing layer should consist of nanograins of the two oxides connected by many heterojunctions. The efforts to achieve a mixed metal-oxide film also arise from the need for a stable and nanostructured material. There are, in fact, many effects that can derive from these mixed systems, such as the stabilization of the sensing material, ensuring, for example, the maintenance of its nanosized character. Furthermore, the presence of a second phase can maintain the grain size within dimensions comparable to the Debye length. Moreover, one of the two phases could act as a filter, and the other one as a sensing material. It seems that the oxide at lower concentration restrains the growth of the other oxide and stabilizes it, avoiding the well-known grain growth that occurs when the sensor is heated [258].

A mixed oxide can be represented as M_1O–M_2O, where M_1O is the nanocrystalline matrix and M_2O is the doping oxide distributed between the surface and the bulk of the M_1O nanocrystalline grain. According to Gas'kov et al. [47], the advantage of mixed oxides over simple nanocrystalline oxides is associated with the redistribution of M_2 between the bulk and the surface of the M_1O grain, depending on

the redox properties of the gas phase. Low oxidation levels of the M_2 cation, corresponding to a larger ionic radius and predominant distribution of M_2 over the surface of M_1O grains, occur in the reducing atmosphere. On the contrary, cations in higher oxidation states are formed in an oxidizing atmosphere, with increasing probability that M_2 cations occupy regular cationic positions in M_1O. The lability of the chemical state of the M_2 cation in the nanocrystalline system may result in a dramatic change in the state of grain boundaries, and in a modification of the electronic properties of the material in the presence of even trace amounts (0.1–10 ppm) of reducing or oxidizing gas molecules in the gas phase. The oxides to be used in creating nanocomposites are chosen taking into account the ionic radii of the elements.

Numerous studies on the gas-sensing properties of mixed oxides have been published. The most common mixed oxides which have been considered for application in gas sensors are: MoO_3–TiO_2, MoO_3–WO_3 [195, 258–263], In_2O_3–SnO_2, In_2O_3–NiO [264], MoO_3–In_2O_3 [50], TiO_2–Fe_2O_3 [265], SnO_2–TiO_2 [266], LaOCl–SnO_2 [267], and *n–p* TiO_2 [268].

3.2. Synthesis and Deposition Techniques

A variety of different preparation techniques can be used for the deposition of the nanocrystalline metal-oxide layers. The sensor preparation methods can be divided into two classes: preparation by thick- or thin-film technology. A summary of typical deposition methods is reported in Table 7. As mentioned in Section 2.3.1, thick-film sensors can be characterized by being rather thick (a few to several hundred micrometers) and porous, so that a high active surface area is exposed to the gas interactions. Thin-film sensors, on the contrary, can be prepared by established preparation methods from thin-film technology (semiconductor technology). They are rather compact, with a typical thickness in the range of a few to several hundred nanometers, and therefore comparably thin. In this case, gas interactions are mainly restricted to the surface layer. Comparisons of thin- and thick-film metal-oxide-based sensors showed that the changes in the electrical resistance of the sensors are typically much more significant for thick-film sensors than for thin-film sensors.

Table 7. Typical deposition techniques used for the preparation of sensitive layers for metal-oxide gas sensors.

Chemical vapor deposition (CVD)	Physical vapor deposition (PVD)		Powder preparation	Other techniques
	Sputtering	Evaporation		
Thermal CVD	Sputtering	Molecular beam epitaxy	Sol–gel from precursors	Sol–gel thin film
Plasma-activated CVD	Reactive sputtering			
Laser-induced CVD	Cathode sputtering with bias voltage	Thermal evaporation	Precipitation of precursors	Rheotaxial grow and thermal oxidation (RGTO)
Electroless plating		Reactive evaporation	Laser pyrolysis	
Spray pyrolysis	Ion beam deposition	Ion plating		
Melt dipping	Ionized cluster beam (reactive)	Reactive ion plating		
Liquid quenching		Arc evaporation		
Deposition of organic polymers	Plasma decomposition	Laser evaporation		
Deposition of emulsions				

The first metal-oxide sensors were thick (or ceramic) sensors. A heater coil and an electrode wire were pressed in the powder material. Then the so-called Taguchi sensors were introduced, where the sensitive material was painted as a paste on an alumina tube in which the heater was separated from the layer. Currently, SnO_2 is the most used material in ceramic sensors. SnO_2 thick films are usually prepared starting from commercial tin oxide, tin, tin salt (mostly $SnCl_4$), or organo–tin compounds (mostly tin alkoxides). The starting materials are used to prepare powders, colloid solutions (gels), or sprayable solutions. The sensitive layer is then fabricated based on these. The solutions of the base material can be used to prepare thin-film sensors.

The often-used term sol–gel is referred to this special preparation route: here, an aqueous tin salt solution forms a sol with poly SnO_2 clusters. They can be precipitated by basic solutions, or they undergo a gelation step when clusters grow, but still dissolve as a colloid. A critical step in this process is the calcinations of the powders because this will define the grain size of the material.

Different methods are used to deposit the powders or solutions onto electrode-equipped substrates with a heater at the back side. The most common methods are dipping, painting, screen printing, and drop coating for the deposition of thick films, and spraying and spin coating for the deposition of thin films. These methods use a thermal treatment after deposition to create the sensitive layer.

The sensors can be optimized by chemically modifying the SnO_2 material by adding dopants. Various methods have been developed for doping. These methods can be divided into two groups; in the first, a compound containing the dopant is added to the precursor; in the second, the SnO_2 powders are treated with such a compound. Typical examples for the first method are the addition of organometallic compounds to alkoxides or of metal chlorides to $SnCl_4$. If, in the latter case, the $SnCl_4$–metal chloride mixture is afterwards precipitated by means of adding NH_3, this is called coprecipitation. Typical examples for the second group are: the colloid method, the impregnation of SnO_2 with metal chlorides, the fixation of metallic particles on SnO_2, and the treatment of SnO_2 with nitric/hydrochloric acid solutions of the dopant [98].

Thus, the sol–gel technique is a wet chemical deposition method, that is well suited for the preparation both of thick and thin films. It offers several advantages with respect to conventional processing technologies.

1. It is simple.
2. It is inexpensive.
3. It is easy to control the morphology and to modify the composition with uniformly dispersed dopants and modifiers.
4. It produces films with a high porosity and a large surface area that improves the efficiency of the sensors in the mechanism dominated by surface phenomena.

Nowadays, the sol–gel method is mostly applied for the preparation of thick films through a dip- or drop-coated deposition procedure of the base material paste onto the transducer structure.

However, great interest is devoted to the preparation of sol–gel metal-oxide thin films because thin-film

devices are perfectly compatible with silicon technology and Si-micromachined heater substrates. Most of the commercially available gas sensors based on thick-film metal oxides use ceramic heater substrates (mainly alumina substrates). A common shortcoming of such thick-film devices is their high level of heating power consumption (0.5–1 W). This level can be reduced by about one order of magnitude using Si-micromachined heater substrates. A complicating feature in employing such miniaturization techniques, however, is that these are not compatible with standard screen-printing technologies, and hence, it is difficult to form miniaturized low-power-consumption devices with commercially established thick-film sensing layers. In this context, novel approaches such as drop coating have been proven to be fruitful and advantageous thick-film deposition techniques for the coating of Si microhotplates [39, 184, 185, 198].

Apart from the sol–gel thin-film deposition which gives porous layers with a large surface area [194–200], another technique that provides a thin film with these characteristics is the RGTO [78, 176]. This technique, called by Sbereveglieri [175] rheotaxial growth and thermal oxidation, allows the preparation of a thin film with a high surface area and crystallites with a nanometric size. Referring, for example, to SnO_2, the technique consists of the deposition of tin on a substrate with the temperature just below the melting point of tin, and subsequent oxidation (reactive growth) of the grains with a well-defined temperature program in an oxidizing atmosphere. Due to the melting point of the tin, spheres are formed. First, the spheres are not totally oxidized, and the contact among them is small; the conductance of this film is low, although it is partly metallic. Only an annealing step of the layer in an oxygen-containing atmosphere leads to an increase of the conductance because of the growth of the spheres (approximately 35% in volume [175]). We find cauliflower-like grains from a high surface area and good contacts among each other.

We do not describe here the CVD and PVD techniques, well known in semiconductor technology, but we mention some of the most interesting novel approaches to the deposition of sensitive layers for semiconductor gas sensors, for which we refer to [98, 123, 175–206].

3.3. Micromachined Substrates for Gas Sensors

Microtechnologies have been developed for the production of silicon semiconductors. Thanks to the batch production, the growing size of silicon wafers, and the miniaturization of each microdevice, an ever-increasing number of elements can be processed in parallel, resulting in a considerable reduction of costs. The silicon revolution has enabled us to produce small, reliable processors in the form of integrated circuits (ICs) using microelectronic technology. Silicon processing technology is no doubt the most advanced technology in the world, and may not be easily surpassed by other technologies.

All of the facilities offered by silicon microtechnology make it an excellent tool for the production of microsensors [269, 270]. Additionally, since the electrical sensor signals have to be acquired, amplified, and evaluated, the sensor technology has to be compatible with modern electronics.

Thus, another cost reduction may be achieved by the integration of the sensing part and electronic circuitry on the same chip, and this provides a second argument for second fabrication by microelectronic technologies.

In this context, micromachined gas-sensing devices are acquiring an ever-growing importance in the field of gas sensors [39–42, 271–273]. The heart of this structure is the active area that is comprised of a heater, sensor electrodes, and the gas-sensitive layer situated at the center of a thin membrane which itself is supported by an outer frame of silicon. Basically, there are two different structures for micromachined gas sensors: the *closed-membrane type* and the *suspended-membrane type* of gas sensors. The latter are also called *spider-type* gas sensors. This resistively heated dielectric membrane (a–SiON or LPCVD Si$_3$N$_4$) provides the thermal insulation between the active area heated up to high temperatures and the silicon frame that remains at room temperature.

The attractive features and advantages offered by using such membranes in gas-sensing devices are numerous.

- They can be handled easily in the electronic industry, and enable integration with electronics; in particular, they need a voltage source both for resistance measurement and for the necessary heater compatible with standard digital electronics (e.g., CMOS).
- They allow a low power consumption not exceeding 100 mW for operation. This small amount of heating power is caused by the reduction in the heated surface area, as well as by the excellent thermal isolation provided by the thin dielectric membranes.
- They allow the production of tiny sensor devices of small size and lower weight (greater portability).
- They allow the reduction of manufacturing costs.
- They can be easily grouped into battery-operated arrays (i.e., sensor arrays integrated on a sensing chip).

Figure 19 schematically shows a top view (a) and a cross section of a single micromachined structure drop coated by the sensing layer (b). In particular, this model of microhotplates was fabricated at the Institute of Microtechnology (IMT) of Neuchâtel in Switzerland [39, 198].

3.4. Electronic Nose

The previous sections of this review have described the science and technology underlying the present resistive-type semiconductor gas sensors based on nanostructured metal-oxide films. One of the main problems related to this kind of gas sensor is a still unsatisfactory understanding of the details of device function; in particular, the effective role of grain size, when it decreases to a nanometer scale, needs more intensive studies. Moreover, there is a significant development effort to turn even a laboratory device into a commercial useful sensor. In spite of the advantages reviewed in the sections above, our ability to design marketable sensors to respond selectively and sensitively to specific gases at an appropriate temperature is still limited. In particular, problems of drift and reproducibility are difficult to overcome. On the contrary, the poor selectivity of chemoresistive gas sensors can be overcome by the design concept of an *electronic nose*.
Figure 19. Scheme of a closed-membrane-type gas sensor. In particular, the model of microhotplates was fabricated at the Institute of Microtechnology (IMT) of Neuchâtel, Switzerland.

The performance of nonideal gas sensors with partially overlapping sensitivities can be improved by linking a number of different nonselective chemoresistive sensors in an array configuration. The term "array" is not intended as a particular spatial arrangement of the sensors in the device; on the contrary, it is in the sense of a vectorial organization of the output of the single sensors under exposure to the same environment, so that the contribution of each array element is a component of a multidimensional general problem. The signals of such a sensor array can be evaluated by means of pattern recognition (PARC) and multicomponent analysis (MCA) methods which, exploiting the cross correlations between the sensor responses, extract information contained in the sensor-output ensemble [274–278].

In particular, a PARC procedure performs a qualitative analysis of the environment; it evaluates the multidimensional dataset from a gas-sensor array, seeking the underlying main relationships in the dataset itself in order to analyze the data structure and discriminate between different data classes (*clusters*) belonging to different "chemical patterns" (*classification*). Figure 20 illustrates the basic principles of a pattern recognition procedure in the chemical gas-sensing scenario. Moreover, a PARC procedure has to assign a sensor array output from an unknown gas/odor to a class, recognizing in such a way the occurrence of a particular chemical pattern (*identification*). An MCA procedure, based on multivariate techniques of regression, performs a quantitative analysis of the environment, determining the concentration of one or more compounds in a mixture. These analytical regression methods provide a general correlation between the analytical information (composition of the chemical pattern) and the output of the sensor array.

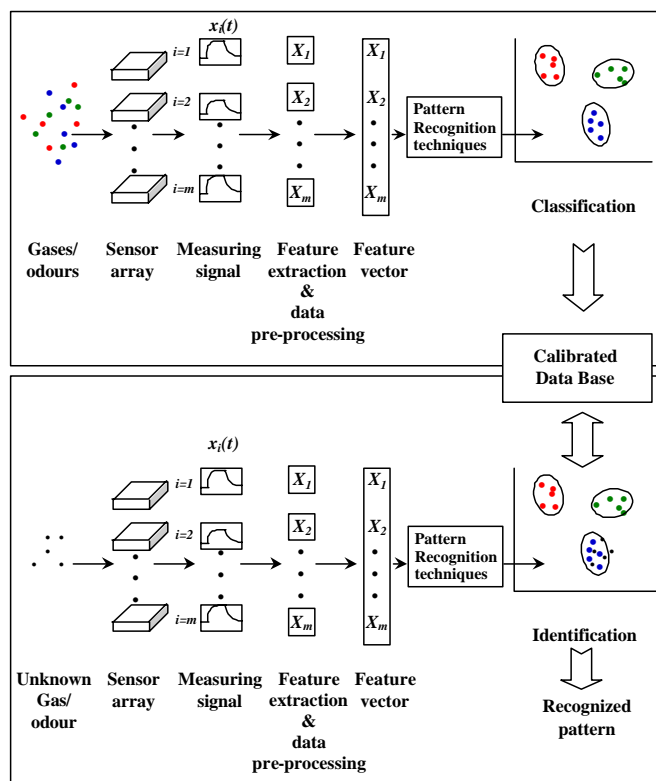
Of course, such multisensor systems need calibration; by presenting many different chemicals to the sensor array, a database of patterns is built up. This database of labeled


Figure 20. Basic principles for applying pattern recognition methods to gas/odor analysis. The sensor array is exposed to the ambient of interest, the measuring signals are preprocessed, and the resulting individual features X_i are extracted. The complete signal vector X containing all of the sensors' information is used as input of the pattern recognition algorithm. The method may be either unsupervised if it seeks to discriminate between different gases/odors, or supervised in the sense that an unknown gas/odor is analyzed using a dataset built up a priori from a set of known gases/odors in an initial calibration, learning, or training stage.

patterns is used to train the pattern recognition system. The goal of this training process is to configure the recognition system so as to classify and eventually quantify each chemical compound in a gas mixture.

Data processing techniques adapted to the data analysis from an electronic nose have a long history, and in parallel with the first well-established approach provided by *chemometrics*, a new approach based on *artificial neural networks* (ANNs) has been developed [276].

Chemometrics, which has been in existence since the 1960s, is the chemical discipline that uses mathematical and statistical methods to provide the maximum chemical information by analyzing chemical data. These chemometric techniques, applied to data from a sensor array, seek to determine the distribution of the data and the underlying relationships between one set of independent variables (i.e., the preprocessed sensor responses from a sensor array) and another set of dependent variables (i.e., the gases/odors classes or the component concentrations). This statistical approach is sometimes referred to as *parametric* in that it assumes that the data can be described by a probability density function, such as the multinormal distribution.

In chemometric techniques, the correlation between the measuring data and the composition or concentrations of the analytes in the chemical pattern during the calibration procedure may be described by a calibration function using an exactly defined set of parameters. These parameters normally are related to physical variables (such as partial sensitivity or slope of the calibration function). Most chemometric techniques use linear transformations so that, by explicitly determining the inverse calibration function, it is possible to calculate the concentrations of unknown samples from the measured sensor signals.

The second approach to data analysis in an electronic nose, based on artificial neural networks, is a relatively new one that arose in the 1980s. It seeks to solve multivariate problems in a manner similar to the human cognitive process by using a biologically inspired neural architecture and rules based upon human reasoning. This approach is also referred to as nonparametric because it uses an implicit representation of the correlation sensor signal/analyte concentrations without a definition of parameters which can be identified as physical variables.

For both the chemometrics- and ANN-based approaches, pattern recognition for qualitative analysis and the multicomponent analysis techniques for quantitative analysis are available.

An important distinction in data analysis techniques concerns their *unsupervised* or *supervised* character. Unsupervised methods makes no a priori assumption about the sample classes, but they try to discriminate between clusters of unknown gases/odors by enhancing the differences between their associated input vectors; on the contrary, the task of a supervised technique is to classify unknown gases/odors as known ones that have been learned during an earlier calibration procedure.

Numerous data analysis techniques are commonly employed to analyze data from electronic nose instrumentation. Multiple linear regression (MLR), principal component regression (PCR), and partial least squares (PLS) are quantitative data processing techniques which are well known in analytical chemistry and in the sensor array area, while the most used conventional statistical pattern analysis techniques are principal component analysis (PCA), cluster analysis (CA), and discriminant function analysis (DCA). Among the neural-network-based techniques, the most important ones are back propagation (BP), radial basis function (RBF), Kohonen self-organizing map (SOM), and learning vector quantization (LVQ). Moreover, there are other more recent dynamical methods, that seek to improve the performance of the pattern recognition method through the use of the dynamical (transitory) response $x_{ri}(t)$ of the sensors, or through the use of models that evolve with time. The latter type of technique is known as adaptive, and deals with nonstationary sources of data, for example, a sensor output that, say, systematically ages or becomes poisoned with time. Adaptive techniques are not well established, but currently are an important topic of research; we mention among them the methods based on genetic algorithms (GAs) or the adaptive resonance theory (ART). Finally, we mention the fuzzy neural networks (FNNs) that apply fuzzy logic to electronic nose data.

3.5. Applications

Since early work in the area of electronic noses arose in response to the problem of nonselectivity in toxic and contaminant gas mixtures, environmental monitoring remains one of the most interesting application fields for such sensing systems. It includes the analysis of fuel mixtures, the detection of oil leaks, the identification of household odors and toxic wastes, air-quality monitoring, and the monitoring of factory emissions.

But the analysis of gaseous environments is not the only task that an electronic nose is required to fulfill; an electronic nose can also be used to analyze and classify different kinds of odors. In this sense, the term "electronic nose" comes from the analogy of these electronic devices with the natural olfaction, generalizing odors as chemical patterns. Although the electronic nose is far from replacing the human olfactory system, the possible uses from this technology are endless. Currently, the largest market for electronic noses is the food industry. Applications of electronic noses in the food industry include (just to mention some of them): quality assessment in food production, inspection of food quality by odor, control of food-cooking processes, inspection of fish, monitoring the fermentation process, checking the rancidity of mayonnaise, verifying if orange juice is natural, monitoring food and beverage odors, grading whiskey, and inspection of beverage containers. In some instances, electronic noses can be used to augment or replace panels of humans experts. In other cases, electronic noses can be used to reduce the amount of analytical chemistry that is performed in food production, especially when only qualitative results are needed.

Moreover, because the sense of smell is an important sense to the doctor, an electronic nose also has applicability as a diagnostic tool. An electronic nose can examine odors from the body (e.g., breath, wounds) and identify possible problems. Odors in the breath can be indicative of gastrointestinal problems, sinus problems, infections, diabetes, liver, and even cancer problems.

In Table 8, examples of gas sensors and gas-sensor system applications are listed. Here, we report, as an example, some results related to metal-oxide gas sensors for applications in an electronic nose [198].

The application of a multisensor system to the analysis of binary gas mixtures of carbon monoxide and methane (CO/CH_4) in air at different relative humidity levels (0, 30, and 50% R.H.) have been considered by Capone et al. [198, 185]. The sensor array consisted of eight Pd-doped SnO_2-based sensors deposited by drop coating onto Si-micromachined hotplates used for this experimental work. They selected CO and CH_4 as target gases because both are toxic and hazardous gases which may be present in a domestic and/or industrial environment. Moreover, they chose Pd as the dopant in SnO_2 thick-film-based sensors to promote the gas detection mechanisms based on surface chemical reactions between the adsorbed oxygen species and the considered gases. In fact, it is known that Pd (as Pt) is a catalytically active metal that improves the sensitivity to reducing gases, such as carbon monoxide and methane, through chemical or electronic interaction. The sensing elements of the array were diversified by varying the Pd-doping

Table 8. Examples of gas sensors and gas-sensor system applications.

Automobiles
- Car ventilation control
- Filter control
- Gasoline vapor detection
- Alcohol breath tests

Safety
- Fire detection
- Leak detection
- Toxic/flammable/explosive gas detectors
- Boiler control
- Personal gas monitor

Indoor air quality
- Air purifiers
- Ventilation control
- Cooking control

Environmental control

- Pollution monitoring

Food
- Food quality control
- Process control
- Packaging quality control (off-odors)

Industrial production
- Fermentation control
- Process control

Medicine
- Breath analysis
- Disease detection

content (0.2, 2%wt. of Pd) and the geometry of the Pt contact electrodes in comb-like and gap configurations with differently spaced fingers. The idea was to modulate the selectivity of each sensor of the array, both by different Pd doping and by simply changing the geometric arrangement of the electrodes since it leads to a different Schottky barrier modulation at the SnO_2 semiconductor/metal contact interface, and so to a different overall resistance modulation [167].

Figure 21 shows, as an example, the dynamic response of the sensors to a sequence of different CO concentrations at 350 °C and 50% R.H. The sensors resulted as very sensitive both to CO and CH_4. Humidity enhances the response to CO and decreases the response to CH_4; however, in humid air, there is always an enhancement of the response of the SnO_2/Pd sensors when carbon monoxide and methane are present simultaneously.

Principal component analysis gave good discrimination results for the different binary CO/CH_4 mixtures. In particular, we found that data are distributed in PC space according to a well-defined geometric structure, with data clusters oriented along preferential directions (Fig. 22). This is a useful tool for a subsequent classification process between the different classes of CO/CH_4 mixtures, based on other pattern recognition methods like discriminant analysis (DA) or cluster analysis. Principal component regression (PCR) gave discrete results for the prediction of the real level of concentration of each component (CO and CH_4) in a mixture, especially for medium–high concentrations of the two gases.
Figure 21. Dynamic response of SnO₂–Pd thick-film-based sensor array to a sequence of different CO concentrations at 350 °C and 50% R.H. [198].

An array of differently doped SnO₂ sol–gel thin films (i.e., undoped SnO₂ and Pd-, Pt-, and Os-doped SnO₂) have been characterized in a controlled atmosphere toward NO₂, CO, CH₄, C₂H₅OH, and CH₃OH to test the ability of the sensor array to be applied in the discrimination of these air pollutants. The evaluation and analysis of the data coming from the array were performed by means of principal component analysis. As usually reported for visualizing clusters, Figure 23a shows the score plot as a function of the first
Figure 22. PCA results in the plane of the first two principal components for the dataset related to 30% R.H.
Figure 23. Results of the principal component analysis for some air contaminants. a) Score plot in the PC1–PC2 plane. b) Score plot in the PC1–PC3 plane.

two principal components. As one can see from the figure, the orthogonal projection of the scores onto the PC1–PC2 plane allow five gas clusters (CO, CH₄, NO₂, C₂H₅OH, and CH₃OH) to be well identified. A complete visualization of the discrimination process is also possible using the plot of the first and third principal components (Fig. 23b), where a better separation between the CO and the CH₄ groups is evident.

An important field of application of the electronic nose is also the food industry. Since the European community has defined strict standards for food quality, significant efforts have been devoted to the development of new techniques that could complement the traditional sensorial and analytical analysis of foodstuffs. The attention has been turned to electronic noses which, in mimicking the human nose, offer an objective way of detecting aromatic fingerprints. In particular, due to the fundamental importance of olive oil in the "Mediterranean diet" and in the marketplace, there is a great interest in all of the techniques able to provide an analysis of olive oil quality. Olive oil was the first foodstuff to be classified by both chemical and sensorial analysis according to the EU Normative. This means that an olive oil can be labeled as extra virgin only if both its chemical and sensorial characteristics are within certain standards established by law. Thus, the market requires urgently reproducible, reliable, inexpensive, easy to train and to use, objective "sniffing" electronic devices dedicated to olive oil for different applications, mainly for classification and degradation
Figure 24. PCA plot related to commercial and noncommercial olive oils from Salento, Italy. The commercial olive oils are labeled with the name of the trademark.

studies. Authenticity is an issue of major concern across the oil industry. Olive oil is marketed based on acidity grade in "olive-husk oil, olive oil, virgin olive oil, extra-virgin olive." Olive oil is also marketed based upon the country and region of production and upon olive type. There is a very large difference in price between, for example, an Italian and a Spanish or Greek olive oil.

The authors developed an electronic nose at the Institute IMM–CNR for testing a number of different commercial olive oils of various qualities produced in different areas in Italy [198, 232, 233]. Furthermore, the analyzed olive oils were compared with local oils of the Salento region in Apulia, Italy. Indeed, one of the most important goals in the field of olive-oil characterization is the classification of them on the basis of their region of origin. This is most important for the regions that have the so called DOP (protect origin denomination) label, which is an index of the quality of the product.

A significant result was obtained by analyzing the array response to the volatile compounds of some commercial and noncommercial local olive oils from Salento by PCA. In

Figure 25. PCA score plot in the space of the first three PCs for all six commercial olive oils.

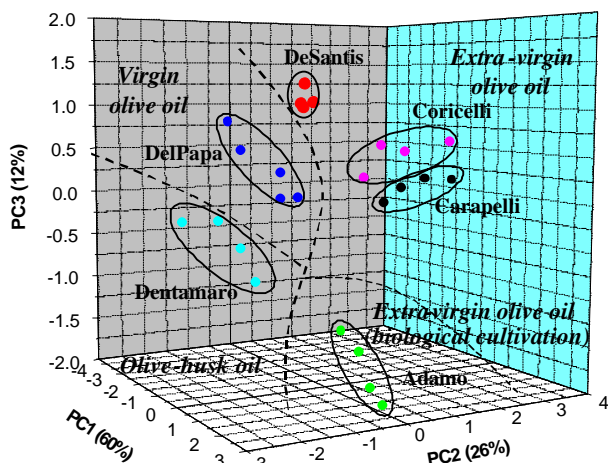
the score plot, we can clearly distinguish all of the different classes of olive oils, and a discrimination between the commercial and noncommercial local olive oils (Fig. 24). In Figure 25, the PCA score plot related to the same commercial olive oils included an extra-virgin olive oil derived from a Salento biological cultivation.

4. SUMMARY

In this chapter, the authors wanted to offer an overview of the basic science, the technology and the applications of one of the principal types of solid-state gas sensor, that is, resistive-type gas sensors based on nanocrystalline metal-oxide films. The nanostructured metal oxide has been considered as a particular group of the nanomaterials whose general properties and applications were mentioned in Section 1. The background and the gas-sensing principles of semiconductor gas sensors based on nanostructured metal oxides were given in Section 2. The understanding of the device working principles have focused on the description of the receptor and the transducer functions. Particular attention has been devoted to the importance of the microstructure of the sensitive layers, and to the role of grain size when the latter decreases down to the nanometer scale. In Section 3, we described the current status of semiconductor gas-sensor research and development. This section dealt with the most relevant metal oxides reported in the literature as gas-sensing materials, the synthesis and deposition techniques, the opportunity to improve the sensor properties related to the use of Si-micromachined substrates, the concept design of an electronic nose, and finally, some applications of gas-sensor and multisensor systems.

In the future, there is no doubt that nanocrystalline metal oxides will constitute the key for the development of semiconducting gas sensors with improved gas-sensing properties. Nanoscience and nanotechnology are also devoting great efforts to the development of novel materials for gas-sensor applications. We mention, just as an example, the interest in inorganic–organic hybrid nanocomposite-containing conducting polymers as the organic part and metal oxides as the inorganic part [279], and in ribbon-like *nanobelts* made of semiconducting metal oxides. The latter are chemically pure, structurally uniform, and largely defect free, with clean surfaces not requiring protection against oxidation; each nanobelt is made up of a single crystal with specific surface planes and shape. This new class of nanostructures offers a great potential for applications in ultra-small sensors because the conductivity of these materials changes dramatically when gas or liquid molecules attach their surfaces [280]. Driving elements in the gas-sensor field are also the miniaturization of the devices, the use of silicon microfabrication techniques in sensor production, the development of specific electronic noses trained for specific applications, and the optimization of smarter pattern recognition techniques.

GLOSSARY

Adsorption A process involving the separation of a substance from one phase accompanied by its accumulation or concentration at the surface of another. The adsorbing


phase is the adsorbent, and the material concentrated or adsorbed at the surface of that phase is the adsorbate. In semiconductor gas sensors the adsorbent is the semiconducting gas sensitive film and the adsorbate the gaseous molecules. Adsorption is thus different from absorption, a process in which material transferred from one phase to another (e.g. liquid) interpenetrates the second phase to form a "solution". The term sorption is a general expression encompassing both processes. According to the bond of the adsorbate to the adsorbent different types of adsorption processes can be distinguished: physisorption, chemisorption and ionosorption.

Electronic nose   A device which comprises an array of electronic chemical sensors with partially specificity and an appropriate pattern recognition system, capable of recognizing simple or complex odors and performing qualitative and quantitative analysis of gaseous mixtures.

Energy bands   They consist of a large number of closely spaced energy levels existing in crystalline materials. The bands can be thought of as the collection of the individual energy levels of electrons surrounding each atom. The wavefunctions of the individual electrons, however, overlap with those of electrons confined to neighboring atoms. The Pauli exclusion principle does not allow the electron energy levels to be the same so that one obtains a set of closely spaced energy levels, forming an energy band. The energy band model is crucial to any detailed treatment of semiconductor devices. It provides the framework needed to understand the concept of an energy bandgap and that of conduction in an almost filled band as described by the empty states.

Nanomaterials   Materials characterized by crystalline grains ranging in size from 0.1 to 100 nanometers (1 nanometer equal to 10^{-9} meters).

Semiconductor gas sensor   A gas detector whose gas sensing element is a thick or thin material with semiconducting electrical properties.

CONTENTS

1. INTRODUCTION

Since the discoveries of visible luminescence at room temperature from porous silicon (Si) [1] and the other forms of Si nanostructures [2, 3], there has been an increasing interest in the physical properties of semiconductor nanostructures distinct from those of bulk semiconductors. When the size of a material is scaled down to the order of nanometers, the number of atoms in the material becomes as low as 1000. Such a small material exhibits chemical and physical properties distinct from those of the bulk material. This is called the size effect. There are three major phenomena induced by the size effect: confinement of carriers and phonons, surface-related phenomena, and phase transformation. The visible luminescence from the Si nanostructures was often attributed to the confinement of carriers, and the luminescence mechanism was well reviewed by Kanemitsu [4].

The visible luminescence from the Si nanocrystals was rather surprising to us, because such a "simple" technique to form Si nanocrystals made Si more attractive as a light-emitting material. Here, a nanocrystal refers to a crystalline nanoparticle formed by various techniques and differs from the nanostructures formed by epitaxial growth or lithography. The most popular and "simple" techniques to form

Si nanocrystals are electrochemical etching, co-sputtering of SiO_2 and Si, and gas evaporation [4]. These techniques, except for electrochemical etching, have been employed to form germanium (Ge) nanocrystals, from which visible luminescence is also expected for the same reason as Si nanocrystals. Because of its lower melting point, the formation of Ge nanocrystals is easier than that of Si nanocrystals. In addition to the ease of fabrication, the quantum confinement is expected to appear more conspicuously for Ge than for Si, because the Bohr radius of the excitons in Ge of 24.3 nm [5] is much larger than that in Si of 4.9 nm [6]. The Ge nanocrystals formed by co-sputtering of SiO_2 and Ge, gas evaporation of Ge, and cluster-beam evaporation are included in this review. Although the last technique, cluster-beam evaporation, was developed by the authors and not commonly used to form Ge nanocrystals, it should be described in detail because of the manifestation of the third effect of the aforementioned size effects, that is, the phase transformation. While the first two size effects are well known, the phase transformation is less known to most readers and will be discussed in detail.

When the size of a material becomes smaller, its characterization becomes more difficult, simply because the intensity of the physical or chemical signal to assess the structural or physical properties becomes smaller with respect to the background noise. Although many methods used to characterize bulk materials have been applied to semiconductor nanocrystals, there is not well-established technique suitable for such extremely small materials. Even with a transmission electron microscope (TEM), great care must be taken so that the beam irradiation does not change the crystal structure of the nanocrystals, particularly the metastable structure. Various characterization techniques that have been applied to Ge nanocrystals are reviewed along with the characterization results.

One of the attractive features of Ge nanocrystals is visible-light emission. Like Si, bulk Ge with an indirect bandgap is less attractive for light-emitting device applications.

However, many photoluminescence colors have been observed from Ge nanocrystals. The mechanism of visible-light luminescence has been a subject of debate. Some support the radiative recombination in Ge nanocrystals, while others support the radiative defect center associated with the native Ge oxide. The arguments on both sides are presented and compared.

The application of Ge nanocrystals is still limited. Although an electroluminescence device was suggested, the light emission efficiency is far below those of the devices made of a direct-bandgap material. One promising application is a nanocrystal memory. To integrate them on a large scale, good control of the positioning and size of the Ge nanocrystals embedded in SiO_2 is mandatory. Recent progress in nanocrystal memory fabrication is reviewed.

This chapter is organized as follows. A discussion of the methods to form Ge nanocrystals, including the cluster-beam evaporation technique, is presented in Section 2, and various characterization techniques, which have been employed to study the properties of Ge nanocrystals, are described along with the characterization results in Section 3. Section 4 concerns the physical properties of the Ge nanocrystals. Among the physical properties, the phase transformation is an important size effect but unfamiliar to most readers. It is discussed in great detail. Section 4.3 is allocated for the phase transformation in Ge nanocrystals. This section is mainly based on our own work, because, except for our pioneering work, there are not many reports on the phase transformation in semiconductor nanocrystals. Section 5 describes the potential applications of Ge nanocrystals. In this review, we included a minimum number of figures and have selected several unpublished ones in order to supplement the discussion. Readers are encouraged to refer to the published figures in the articles listed in the References if they consider that the descriptions or discussions are not clear without the figures.

2. FABRICATION OF Ge NANOCRYSTALS

Several techniques used to form Ge nanocrystals are reviewed. The formed nanocrystals are either directly deposited on a substrate or embedded in the matrices, which are Si [7], porous Si [8], zeolites [9], and SiO_2. The Ge nanocrystals embedded in SiO_2 have been the most intensively studied because of good confinement of the electrons with a large potential barrier of the oxide. The as-deposited Ge nanoparticles formed by some methods are amorphous and become crystallized only after high-temperature annealing. The material properties of the Ge nanocrystals are also affected by the fabrication technique and are briefly presented for each technique in this section. More details of the properties are discussed in Section 4.

2.1. Chemical Synthesis

Chemical synthesis is the simplest technique to form Ge nanocrystals. The sol–gel method has been used to fabricate semiconductor and metal nanocrystals such as CdS CuCl, CdTe, PbS, Au, and Ag dispersed in SiO_2 glasses [10–14].

Nogami and Abe first fabricated Ge nanocrystals embedded in SiO_2 containing 7 wt% Ge by the sol–gel method using $Si(OC_2H_5)_4$(TEOS) and $GeCl_4$ as the starting materials [15]. However, it was very difficult to control the reaction and form nanocrystals with different sizes because the hydrolysis of $GeCl_4$ was extremely fast. Yang et al. synthesized the gels through the hydrolysis of $Si(OC_2H_5)_4$ and 3-trichloro-germaniumpropanoic acid (Cl_3–Ge–C_2H_4–COOH). The gels were then heated at 600 °C for 10 h in air to form the GeO_2–SiO_2 glasses [16]. The gels were further heated at 500–700 °C in a H_2 gas atmosphere in which the Ge^{4+} ions were reduced to precipitate cubic Ge nanocrystals. The sizes of the Ge nanocrystals ranged from 1 to 13 nm.

Highly crystalline Ge nanocrystals in the size range of 2–10 nm were grown in inverse micelles and purified and size-separated by high-pressure liquid chromatography [17]. Controlled nucleation and growth occurred in the interior of the nanosize surfactant aggregates called inverse micelles. An anhydrous ionic salt (e.g., GeX_4, where X = Cl, Br, or I) was dissolved in the hydrophilic interior of a solution of micelles. Since the ionic salts were completely insoluble in the continuous oil medium used (e.g., octane), the nucleation and growth of Ge was restricted to the micelle interior. The interior volume of the micelles could be varied over the range of 1–10 nm. Control over the final nanocrystal size was achieved by a variation in the micelle size, intermicellar interactions, and reaction chemistry.

Kauzlarich et al. synthesized Ge nanocrystals by reacting the Zintl phase precursors with Ge tetrachloride [18]. The surface of the Ge nanocrystals was passivated with alkyl groups through the reactions with RLi and MgBrR (R = alkyl). The surface was kept from oxidizing and was stable. These nanocrystals emitted light over a wide range in the visible range depending on the size.

2.2. Gas Evaporation of Ge

The gas evaporation technique has been conventionally employed to form ultrafine metal and semiconductor particles. Although this technique is similar to vacuum evaporation, the source material in a boat is evaporated in an inert-gas atmosphere. During the inert-gas evaporation of Ge, the Ge atoms that effused from the source will rapidly lose their energy by collision with gas atoms, that is, macroscopically, the Ge vapor is cooled in the gas. The collision mean free path is very short; for Ge atoms in 1 torr of argon (Ar), for example, it is approximately 10^{-7} m. This efficient cooling locally produces a high supersaturation of Ge vapor, which leads to a homogeneous nucleation. The size of the formed Ge nanocrystal increases with the increasing evaporation rate and shortening of the mean free path. In other words, for a higher evaporation temperature of the source material and higher gas pressure, a larger size is expected. Furthermore, some of the Ge nanocrystals collide with others and coalesce during travel to the substrate after the nucleation.

An earlier study of the Ge nanocrystals formed by the gas evaporation technique was reported by Saito [19]. He heated Ge powder in a tungsten boat at 1500–1900 °C in an argon atmosphere. The gas pressure was varied from 3 to

40 torr. In the transmission electron diffraction (TED) pattern, some Ge nanocrystals showed a diamond structure, while the others showed a tetragonal structure, which will be discussed in detail later.

Han et al. [20] observed a blueshift from the bulk's optical bandgap as large as 2 eV for 10-nm Ge nanocrystals in the optical absorption spectra and attributed the shift to quantum confinement. However, the luminescence from the Ge nanocrystals formed by the gas evaporation of Ge is generally weak due to nonradiative recombination via surface states. The surface dangling bonds of the Ge nanocrystal must be terminated by surface passivation. Si et al. made an attempt to passivate the surface of Ge nanocrystals with Si by evaporation of Si and Ge [21]. Two methods were employed in the gas evaporation technique to form Ge nanocrystals whose surface was passivated with Si. One used a boat with a SiGe alloy as the source, and the other used two boats each with Si and Ge. As a result of the characterization by X-ray diffraction (XRD), Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and TEM, it was found that the Ge nanocrystals with a Si-passivated surface were formed by the co-evaporation of Si and Ge from the two boats, while the SiGe alloy nanocrystals were formed by evaporation of the SiGe alloy source from one boat. However, even the Ge nanocrystals passivated with Si failed to exhibit visible luminescence at room temperature.

2.3. Co-sputtering of SiO$_2$ and Ge

An ideal Ge quantum dot, where carriers are confined by a high potential barrier, can be made by surrounding the Ge nanocrystal with SiO$_2$. The surface of the Ge nanocrystals is unstable and becomes oxidized or contaminated in air, while the surface of the Ge nanocrystals embedded in SiO$_2$ is passivated with SiO$_2$ and is expected to be more stable. Such a structure with Ge nanocrystals embedded in SiO$_2$ is also called Ge-doped glass. The thin film of Ge nanocrystals most often studied for size effects is the Ge-doped glass.

One of the most popular methods to make Ge-doped glass is the co-sputtering of SiO$_2$ and Ge. In this method, Ge chips are placed on a Si target and co-sputtered in argon gas [22–26]. The Ge nanocrystals are obtained by annealing the as-deposited Ge-doped glass film. In this technique, the size of the Ge nanocrystals can be controlled by changing the volume fraction of Ge in the as-deposited films or by varying the annealing profile [25–29]. Takeoka et al. obtained average diameters of 0.9–5.3 nm by changing the volume fraction of Ge from 0.2 to 7.2% [27] and modeled the relationship between the volume fraction, $f_{Ge}(\%)$, and the average diameter, d_{ave}, by

$$\frac{f_{Ge}}{100} = \frac{(4/3)\pi(d_{ave}/2)^3}{(s + d_{ave})^3} \tag{1}$$

where s is the distance between two adjacent Ge nanocrystals [27]. The size distribution of the Ge nanocrystals is often characterized by the log-normal function [30].

The growth process of Ge nanocrystals in a SiO$_x$ matrix was studied by an X-ray diffraction (XRD) technique using the grazing incidence of X-rays [24]. The conclusion drawn from the XRD analysis was consistent with those from

Raman spectroscopy and X-ray photoelectron spectroscopy. The as-deposited Ge-doped glass film consisted of Ge and GeO$_x$. Since the content of GeO$_x$ decreased with the increasing annealing temperature, the GeO$_x$ appeared to be thermally decomposed into Ge and O, which then oxidized the SiO$_x$ matrix, as proposed by Dutta [31]: SiO$_x$ + GeO$_x$ $\rightarrow$ SiO$_2$ + Ge. Two stages of crystallization were found in the temperature range studied for annealing; the first stage was the nucleation of Ge nanocrystals at 600 °C, and the second stage was the growth of the nanocrystals at 800 °C [24]. During the first stage, the Ge nanocrystals were formed by crystallization from the amorphous Ge, which was contained in the as-deposited samples. During the second stage, the decomposition of GeO$_x$ supplied additional Ge and enabled the nanocrystals to grow faster.

The sizes of the Ge nanocrystals in the Ge-doped glass film can be made smaller by oxidation. Rath et al. oxidized the Ge-doped glass film by wet oxidation [32]. After annealing the as-deposited film in an argon atmosphere, the nanocrystals were found to be oxidized. When the as-deposited film was annealed and oxidized at 800 °C, the sizes estimated from the phonon confinement model in the Raman spectra were 12 and 6 nm before and after oxidation, respectively. The size reduction was also confirmed by optical absorption measurements.

The film deposited by the co-sputtering of Ge and SiO$_2$ is amorphous Si$_x$Ge$_y$O$_z$. Amorphous Si$_x$Ge$_y$O$_z$ can also be deposited by co-sputtering Si and Ge in an oxygen-containing atmosphere. In the experiment reported by Zacharias et al. [33, 34], the water vapor added to Ar was the oxygen source. The oxygen content in the as-deposited Si$_x$Ge$_y$O$_z$ depended on both the deposition rate and the partial water pressure. With an increase in the sputtering power, the oxygen content decreased. The sputtering yield depended on the energy of the sputtering Ar ions and is 1.55 (Ge) compared with 1.0 (Si) for Ar ions of 1 keV. The formation of the Ge nanocrystals in the SiO$_2$ matrix was induced by annealing at high temperature. The average size of the Ge nanocrystals formed by annealing at 800 °C decreased with an increase in the oxygen content or sputtering power.

2.4. Ion Implantation of Ge in SiO$_2$

The implantation of Ge in SiO$_2$ is another way to form amorphous Si$_x$Ge$_y$O$_z$, which turns into Ge-doped glass by annealing of the Ge-implanted SiO$_2$ at high temperature. Kawamura et al. [35] and Hosono et al. [36], however, implanted protons in 9SiO$_2$–1GeO$_2$ glasses at 1.5 MeV without heating the substrate and formed Ge-doped glass, where Ge nanocrystals with diameters of 6–10 nm were embedded in SiO$_2$ without postthermal annealing. The fact that Ge nanocrystals were not formed by He$^+$ but by H$^+$ implantation was strong evidence that some chemical process was involved in the nanocrystal formation. The overall chemical reaction might be the reduction of GeO$_2$ by H$_2$, that is, GeO$_2$ + 2H$_2$ $\rightarrow$ Ge + 2H$_2$O.

There are numerous reports on the fabrication of Ge-doped glass by the ion implantation of Ge in SiO$_2$ [37–45]. In this method, Ge is implanted in SiO$_2$ thermally grown on Si substrates, and then the samples are mostly annealed in a

nitrogen atmosphere at high temperature. Zhu et al. found that the Ge dose was the controlling factor for the size distribution [37]. With a decrease in the Ge dose, the fraction of large particles in the size distribution decreased. In contrast to the finding by Zhu et al., Dowd et al. concluded that the size distribution was independent of the Ge dose [41]. Their size distribution was characterized by the log-normal function. In both studies, the range of the Ge dose was the same but the implant energy was different, that is, 500 keV and 1 MeV for Zhu et al. and Dowd et al., respectively.

The Ge redistribution and nanocrystal formation in Ge-implanted SiO_2 during annealing were systematically studied by Heinig et al [39]. The Ge redistribution and nanocrystal evolution could be strongly influenced by the annealing ambient [38]. The annealing behavior was explained by the in-diffusion of an oxidant from the annealing atmosphere, which significantly changed the Ge depth profile and nanocrystal distribution. Annealing in N_2 or Ar leads to a dramatic change in the as-implanted Gaussian-like Ge depth distribution to a bimodal profile and, additionally, an accumulation of Ge at the Si/SiO_2 interface. No Ge nanocrystals were found in the subsurface region, while nanocrystals were found in the center of the SiO_2 layer. Annealing in dry O_2 increases the surface concentration of the oxidant, and noncrystalline GeO_2 particles were formed.

The Ge nanocrystals formed in SiO_2 by ion implantation and postannealing are usually distributed in the depth direction and form the band in SiO_2 [39]. However, in some device applications such as nanocrystal memories, which will be discussed later, a monolayer of Ge nanocrystals should be formed in SiO_2. A thin layer of Ge nanocrystals with a thickness of 3–4 nm was successfully formed by lowering the implant energy to 3 keV [44].

For size uniformity, multienergy ion implantation [43] was proposed. In this method, the Ge ions were implanted with energies of 50, 80, 120, 200, and 360 keV, and with doses of 1×10, 1.2×10, 2×10, 4×10, and 1×10, respectively (a total dose of 1.82×10 cm^{-2}). The sizes of the Ge nanocrystals were more uniform than those obtained by single-energy ion implantation or co-sputtering of Ge and SiO_2 due to the improved uniformity of the Ge concentration across the depth of the as-implanted sample. The average size of the Ge nanocrystals after annealing at 800 °C was 3.7 nm. However, a further increase in the annealing temperature to 1000 °C resulted in an increased size and wider size distribution.

2.5. Cluster-Beam Evaporation

A unique method to deposit Ge nanocrystalline films, which is called the cluster-beam evaporation technique, was developed by the authors [46]. This technique resembles the well-known ionized cluster-beam (ICB) technique. The ICB technique was developed to deposit high-quality thin films by Takagi [47]. The major difference between the cluster-beam evaporation and ICB techniques is whether the formed cluster is ionized or not. In the ICB technique, the clusters are intentionally ionized and accelerated by an electric field. The clusters with sufficient kinetic energies become resolved into individual atoms when they land on the substrate. They migrate on the substrate surface and form an epitaxial film

even at low substrate temperature. In contrast to the ICB technique, the clusters make a "soft" landing on the substrate during cluster-beam evaporation. Because they are not ionized or accelerated, they are not resolved. The clusters may migrate on the surface after their "soft" landing.

In both techniques, the clusters are formed by supersonic expansion through the nozzle of a crucible. The classical nucleation theory predicts that the sizes of the Ge nanocrystals formed by these techniques will be much smaller than those formed by the gas evaporation technique, which is conventionally used to deposit metal or semiconductor micro- and nanoparticles. The cluster-beam evaporator apparatus is a vacuum evaporator with a capped carbon crucible. The cap is 1 mm thick and has a nozzle hole with a diameter of 1 mm. The crucible loaded with small pieces of undoped Ge is heated by electron bombardment.

During the deposition, the temperature of the crucible is kept at 2000 K, and the pressure in the chamber is 5×10^{-6} torr. The substrate temperature is either at room or liquid-nitrogen temperature. The typical film thickness is 100 nm after a 60-min deposition. The TEM micrographs of the nanocrystalline films showed a smooth morphology without any features and a rough morphology consisting of Ge nanocrystals with diameters ranging from 4 to 40 nm for substrate temperatures of 300 and 77 K, respectively [46]. However, even a larger nanocrystal in the latter film may be due to agglomeration of the smaller nanocrystals. The clusters in the former film seem to have migrated on the surface even at room temperature. They were also found to be hardly oxidized in air [46]. The depth profile of Ge3d indicated the presence of Ge oxide, GeO_x, and GeO_2 only on the surface of the Ge nanocrystalline film and did not change even after a long exposure to air. However, the nanocrystalline film deposited on the substrate whose temperature was 77 K was subject to oxidation and exhibited a unique oxidation process called photooxidation [46, 48], which will be discussed in detail in Section 4.1.2.

2.6. Oxidation of Ge

As mentioned earlier, forming a monolyear or a sheet of the Ge nanocrystals in SiO_2 is required for device applications such as nanocrystal memories. A clever and simple method to form a thin layer of the Ge nanocrystals embedded in SiO_2 is to oxidize a SiGe or SiGeC alloy layer [49–54]. King et al. formed a thin epitaxial layer of $Si_{1-x}Ge_x$ on the surface of a Si wafer by ion implantation of Ge and subsequent high-temperature wet oxidation, which caused the implanted Ge atoms to pile up at the Si/SiO_2 interface. The Ge segregated out of the growing oxide under these oxidation conditions. After the high-temperature oxide film was etched off, the oxide was grown in dry O_2. Next, a $Si_{1-x}Ge_xO_2$ layer was grown in wet O_2 in order to incorporate the Ge into the oxide. The top oxide was then grown in dry O_2. Finally, a high-temperature annealing step was employed to cause the Ge within the oxide to precipitate and form nanocrystals. The cross-sectional transmission electron micrograph clearly showed one monolayer-like Ge nanocrystals.

Instead of thermal oxidation of a SiGe layer, photooxidation can form Ge nanocrystals from the SiGe oxides. Craciun et al. exposed a 15-nm-thick SiGe strained layer

grown by molecular-beam epitaxy (MBE) to ultraviolet (UV) light from a low-pressure Hg lamp in the presence of oxygen [51]. The sample temperature was kept at 550 °C. After a 5-h photooxidation, the multilayer structure of the pure and Ge-doped SiO_2 layers was formed. The oxidation temperature was significantly lower than that usually used for the formation of Ge nanocrystals by the reduction of SiGe oxides.

The structures with Ge nanocrystals embedded in SiO_2 were also formed by oxidation of a Ge film on Si or the $SiO_2/Ge/SiO_2$ structure [55–57]. However, there was no conclusive evidence presented to show that the Ge nanocrystals were embedded in the SiO_2 without being pushed down to the SiO_2/Si interface.

Nevertheless, the oxidation of a Ge layer on Si to form Ge nanocrystals embedded in SiO_2 should be further explored, because it can form a two-dimensional (2D) array of Ge nanocrystals with controlled positioning. One possible way to obtain a well-ordered structure of Ge nanocrystals in SiO_2 is to oxidize the MBE-grown structure of Ge dots embedded in Si. The Ge dots can be ordered by making the best use of the self-assembly during the MBE growth. Oxidation of the MBE-grown structure was attempted in order to form the Ge-doped glass [58]. Although the oxide was formed on the layer of Ge dots, it was found that the Ge layer was pushed down to the Si substrate without oxidizing the Si layer underneath the Ge layer. This may have occurred because the MBE-grown Ge dots were not well separated from each other. There is plenty of room for improvement.

2.7. Miscellaneous

Other techniques to form Ge nanocrystals are pulsed-laser ablation (PLA) [7, 59] and the spark process [60, 61]. The apparatus for the PLA synthesis of Ge nanocrystals in the gas phase developed by Ngiam et al. [7] is similar to that for the cluster-beam evaporation technique. A target rod was ablated by a frequency-doubled pulsed Nd:YAG laser. The ablated Ge plasma was cooled by a pulse of He carrier gas released into the growth channel and started to condense in the growth channel before expanding into a vacuum. The Ge nanocrystals passed into the deposition chamber and were deposited on a substrate.

The spark process was performed in stagnant air by applying a pulsating unipolar high voltage (15 kV) and a low current between a tungsten-tip electrode (anode) and a p-type (100) Ge wafer (cathode) for 20 min [60, 61]. The surface of the Ge nanocrystals was found to be oxidized.

Since the nanocrystals were formed by gas condensation in both methods, they may be regarded as modified gas evaporation methods.

3. CHARACTERIZATION METHODS

The characterization method to directly observe Ge nanocrystals and determine their sizes is transmission electron microscopy (TEM). However, the specimen preparation requires time and great care in order not to damage the samples. Although various spectroscopies are also used, the signals are usually weak, and their analyses are more involved. In this section, the characterization methods often

used to obtain information on the structure and properties of the Ge nanocrystals are reviewed.

3.1. TEM

TEM is a direct method to observe Ge nanocrystals and requires a high resolution to obtain the lattice image of a Ge nanocrystal. A high-resolution TEM (HRTEM) image provides information on the crystal structure, crystal size, lattice constant, and defects of each nanocrystal.

The Ge nanocrystals or the Ge-doped glass thin film can be deposited either directly on a substrate or on the carbon-coated TEM grids as a plan-view TEM specimen. Plan-view and cross-sectional TEM specimens of the Ge nanocrystals deposited directly on a substrate should be prepared from the thin film containing Ge nanocrystals by the standard procedures for the preparation of TEM specimens described in a TEM textbook [62].

The HRTEM image of the as-deposited Ge nanocrystal fabricated by cluster-beam evaporation is shown as an example in Figure 1. The Ge nanocrystal is circled in the figure. The diameter of the nanocrystal is 3.6 nm.

The crystal structure of the Ge nanocrystal was studied in detail by using the ultrahigh vacuum (UHV)–MBE–HRTEM system [63]. Ge nanocrystals were deposited on thinned Si substrates in a UHV–MBE chamber and transferred into a UHV-field emission HRTEM through a UHV-transferring system without exposure to air. The developed UHV–MBE–HRTEM system keeps the samples from contamination or oxidation and allows observation of an individual nanocrystal without their overlapping. The real-time TEM images were collected using a video camera with a time resolution of 60 frames/s. Such real-time TEM was mandatory to observe the Ge nanocrystals, which are unstable under electron-beam irradiation.

The attachments of the TEM instrument such as transmission electron diffraction (TED) and energy-dispersive

10 nm
Figure 1. High-resolution transmission electron micrograph (HRTEM) of the Ge nanocrystalline film deposited by the cluster-beam evaporation technique. The Ge nanocrystal is circled.

X-ray spectroscopy (EDS) supplement the TEM analysis. The spacings between the lattice planes calculated from the TED pattern provide useful information on the crystal structure of a Ge nanocrystal, and Sato et al. identified the ST-12 structure in the Ge nanocrystalline film deposited by cluster-beam evaporation based on comparison of the obtained spacings with those of the ST-12 and diamond structures [64]. The TED also provides assessment of the crystallinity of the Ge nanocrystals, for example, single crystal, polycrystal, or amorphous. The EDS provides information on the chemical composition. The element maps of Si and Ge in the Ge nanocrystals embedded in SiO_2 or Si can determine whether Ge is localized in a nanocrystal or mixed with Si near the surface of a nanocrystal.

3.2. XRD

Conventional X-ray diffraction (XRD) may not be very useful for determining the crystallinity and dimension of small-sized Ge nanocrystals because of the lower intensity and broader width of the reflection peak [65, 66]. A meaningful analysis usually requires a thick sample including many nanocrystals. A glazing incidence XRD, which is sometimes called the thin-film diffraction (TFD) method, is, however, very effective for the measurement of thin films less than 100 nm thick because the X-ray penetration depth becomes shallow and the diffracted intensity is expected to be a few times greater than that of the conventional $\theta/2\theta$ method. It was found that the TFD was useful for characterization of the Ge nanocrystals in Ge-doped glass thin films [24].

The particle size of a Ge nanocrystal, D, is calculated from the full width at half-maximum (FWHM) of the XRD peaks at $2\theta_B$ using the Scherrer formula:

$$\frac{0.89\lambda}{\beta(2\theta_B)\cos\theta_B} \tag{2}$$

where λ is the X-ray wavelength (0.154 nm for Cu Kα radiation) and $\beta(2\theta_B)$ is the FWHM in radians. In the TFD, although the spatial width of the diffracted beams is fairly wide, the accuracy of $\beta(2\theta_B)$ is within 0.1° because the planar monochromator is set directly before the detector, providing a better angular accuracy. In the TFD on the films deposited on a Si(100) substrate, the samples are set at a glancing angle of 2° and to the (100) azimuth to avoid the 311 reflection peak of the substrate, since there is a strong reflection peak from the {311} planes of the substrate that appears for the glancing angle of 2.8°, which must be avoided. Even if this method is used, the XRD pattern still contains a small tail attributable to the 311 reflection peak of the Si substrate but the intensity of this tail is small compared to the reflection peak of the Si substrate using the ordinary method. For Ge nanocrystals with a good crystallinity, the Ge (111), (220), and (311) Bragg reflection peaks should be observed at $2\theta_B$ of 27.3°, 45.3°, and 53.7°, respectively.

3.3. XPS

The detection and energy analysis of photoelectrons produced by radiation whose energy exceeds their binding energies is the subject of an extensively used technique known as photoelectron (PE) spectroscopy. This technique can be conveniently divided into two broad areas, the first employing ultraviolet radiation and hence called ultraviolet photoelectron spectroscopy (UPS), and the second using X-rays, termed X-ray photoelectron spectroscopy (XPS). The details of XPS can be found in many textbooks on materials or surface science [67, 68]. XPS is also known as electron spectroscopy for chemical analysis (ESCA).

One of the most important applications of XPS is the accurate measurement of core-level binding energies. Figure 2 shows typical Ge3d XPS spectra of Ge nanocrystalline film deposited by cluster-beam evaporation. The peak for the as-deposited sample is fitted with three pure Gaussian curves (solid curves) [69, 70]. From the peak energies, these three peaks are associated with Ge ($\sim$29.3 eV), GeO_x ($\sim$31 eV), and GeO_2 ($\sim$32.6 eV). In the figure, the XPS spectrum of the film after annealing at 500 °C in N_2 flow is also shown. After annealing, the peak is fitted with two curves, which are for Ge and GeO_2. GeO_x is thermally decomposed into pure Ge and oxygen, which oxidizes Ge, for example, $2GeO_x \rightarrow xGeO_2 + (2-x)$Ge. Since x is less than 2, pure Ge atoms are supplied as a result of the thermal decomposition, and the Ge nanocrystal grows larger.

XPS is also able to probe the electronic structure of the valence band of metals, semiconductors, and insulators [71–73]. Joannopoulos and Cohen reported good agreement between the calculated density of states (DOS) and the XPS spectrum, which were related to the DOS for Si and Ge in amorphous structures [71]. We also studied the DOS of the ST-12 of the Ge nanocrystals by XPS [64] and these details will be discussed later. It was clear from a comparison with the calculated DOS curve that the XPS spectrum of the Ge nanocrystalline film was in good agreement with the theoretical DOS of the ST-12 structure; both showed two peaks at about 1 and 8 eV.

Another application of XPS for the Ge nanocrystalline film is to study the plasmon loss features [74]. After removing the oxide from the surface of the Ge nanocrystalline film, we collected the XPS signals in the range of the binding energy from 25 to 70 eV and transformed the data into the electron energy loss (EEL) spectra. Every zero-loss peak corresponds to the Ge3d XPS peak and the loss peak due to the bulk plasmon is seen at 16–18 eV. The plasmon energy of the Ge nanocrystalline film was observed at 17.1–17.4 eV, which was about 1 eV higher than the value of the bulk Ge
Figure 2. X-ray photoelectron spectroscopy (XPS) spectra of the Ge nanocrystalline films deposited by cluster-beam evaporation before and after annealing at 500 °C.

(16.3 eV). The plasmon energies of both the Ge nanocrystalline film and bulk Ge were well explained by the classical model, and we attributed the observed energy difference to a difference in the crystal structure.

3.4. Photoluminescence and Optical Absorption

Like Si nanocrystals, Ge nanocrystals have been mostly studied for light emission because of their potential application to light-emitting devices. Photoluminescence (PL) spectroscopy is widely used to assess the efficiency of light emission from Ge nanocrystals. It is important to physically understand the luminescence mechanism and the size dependence of the PL peak energy. Photoluminescence spectroscopy of crystalline semiconductors was reviewed in detail by Gilliland [75]. However, a simple PL spectroscopy alone is not sufficient to provide conclusive answers to questions on the luminescence mechanism and size dependence of the PL peak energy. The analysis of the PL spectrum should include effects of the surface oxide and nonhomogeneous sizes.

The measured peak is usually very broad and can be deconvoluted into a few peaks, which are still broad [61, 69, 76]. Because of the broadness of the peak, it does not seem meaningful to say that the PL peak energy increases with a decrease in the average size. The broadening of the PL peak is associated with the nonhomogeneous sizes of the Ge nanocrystals. The nanocrystals with different sizes contribute to the PL spectra with different peak energies. If each PL originates from the radiative recombination of carriers confined in a nanocrystal, the peak becomes much narrower in the plot of the PL intensity at a selected emission energy as a function of the PL excitation energy. Such a PL measurement is called photoluminescence excitation (PLE). In the PLE spectra, the nonhomogeneous broadening is suppressed. If the PLE peak energy is the same as the selected luminescence energy, the luminescence is most likely to originate from the band-to-band recombination or exciton recombination in the Ge nanocrystals. If there is a difference in the energies, which is associated with the Stokes shift between the absorption-edge energy and the PL energy, the luminescence is primarily due to Ge surface defects or defects present in the Ge nanocrystals or surface oxides. The PLE has been employed to study the luminescence mechanism of the Ge nanocrystals in great detail [77, 78].

Time-resolved PL, which measures the decay of the PL intensity for a selected wavelength, provides more profound information on the recombination of the carriers [61, 77, 79]. The internal luminescence efficiency is generally described by

$$\eta = \frac{1}{1 + \tau_r/\tau_n} \qquad (3)$$

where τ_r and τ_n are the lifetimes for radiative and nonradiative recombinations, respectively. The PL decay time constant is a combination of the radiative and nonradiative constants and is given by

$$\tau_{PL}^{-1} = \tau_r^{-1} + \tau_n^{-1} \qquad (4)$$

Therefore, if there is a large difference between the radiative and nonradiative recombination lifetimes, the PL decay becomes single exponential; otherwise, it becomes double exponential. It is clear from (4) that if the nonradiative lifetime is extremely small, the PL decay becomes fast. This suggests that a fast decay may not be necessarily due to radiative recombination but due to a fast nonradiative recombination [77].

Optical absorption measurements are often carried out to estimate the bandgaps of bulk semiconductors and to determine whether they are direct or indirect. They are also employed to characterize Ge nanocrystals [17, 20, 22, 77, 80–82]. The optical absorption coefficients of bulk semiconductors are mostly described by the following three expressions [83, 84]:

$$\alpha(h\nu) \propto (h\nu - E_g)^{1/2}$$

for direct-bandgap semiconductors (5)

$$\alpha(h\nu) \propto (h\nu - E_g - E_p)$$

for indirect-bandgap semiconductors (6)

and

$$h\nu\alpha(h\nu) \propto (h\nu - E_g)^2 \quad \text{for amorphous semiconductors}$$

(7)

where $h\nu$, E_g, and E_p are the photon energy, bandgap, and phonon energies, respectively.

Although some have claimed a good fit to (7) [20, 82], in most cases, the absorption spectra of the Ge nanocrystals do not follow any of the above equations. This is due to the following complications in the optical absorption of the Ge nanocrystals. First, both the optical absorption and the light scattering affect the transmission spectrum, which is directly measured to obtain the optical absorption spectra. To calculate the optical absorption from the transmission, one should not ignore the effect of light scattering. Second, the nonhomogeneous size distribution complicates the analysis of the optical absorption of the Ge nanocrystals. Third, one must consider the quantum confinement effect. If the size distribution is uniform, and the measurement temperature is low enough to suppress thermal fluctuation of the electron energy, the energy of three-dimensionally confined electrons should exhibit discrete levels and not follow the absorption expressions for bulk semiconductors. An analysis of the absorption spectra of Ge nanocrystals, taking into account all of the above complications, has not yet been undertaken.

3.5. Raman Scattering

Raman scattering is a very powerful characterization technique to detect a signal from as little as a few monolayers and has been employed to characterize Ge nanocrystals formed by various methods. Figure 3 shows the typical Raman spectra of two types of Ge nanocrystals: one with the ordinary diamond structure and the other with the ST-12 as a result of a phase transformation, which will be discussed in detail later. In the spectrum of Ge nanocrystals with the
Figure 3. Raman spectrum of the Ge nanocrystalline film deposited by the cluster-beam evaporation technique. The Raman spectrum of Ge particles with the diamond structure is also shown for comparison.

diamond structure, a broad peak is seen at the Raman shift of 300 cm^{-1}.

The Raman line shapes of the low-dimensional materials have been derived based on the phonon confinement model. A quantitative model was developed by Richter et al. [85] and was later improved by Campbell and Fauchet [86] to estimate the average size of the nanocrystals. Using this model, the first-order Raman spectrum of a spherical crystal can be written as

$$\int \frac{|C(0, q)|^2}{[\omega - \omega(q)]^2 + (\Gamma/2)^2} \, d^3q \qquad (8)$$

where q is expressed in units of $2\pi/a$; $C(0, q)$ is the Fourier coefficient, which describes the phonon confinement; $w(q)$ is the phonon dispersion curve; and Γ is the natural linewidth of the Raman spectrum of bulk Ge($\sim$3 cm^{-1}). The integral is taken over the entire Brillouin zone. Sato et al. used a Gaussian function for the Fourier coefficient, which is written as

$$|C(0, q)| = \exp(-q^2 L^2/4) \qquad (9)$$

where L is the diameter in units of the lattice constant, a, and an adjusting parameter to obtain the best fit to the measured line shape, and found a good match of the diameter with that measured by TEM [87].

The Raman scattering has been used to study the formation of Ge nanocrystals by high-temperature annealing [88–90]. Ninomiya et al. characterized the Ge-doped SiO$_2$ thin films annealed at various temperatures by Raman scattering and concluded that there were two stages of crystallization: crystallization of amorphous Ge contained in the as-deposited film at 600 °C and decomposition of GeO$_x$ at 800 °C [24]. The conclusion based on the Raman scattering was in good agreement with that from XRD and XPS.

For probing electronic transitions well above the fundamental bandgap, resonant Raman scattering (RRS) is superior to both optical absorption and emission, which are the standard techniques for studying the confinement of excitons [91, 92]. In addition to electronic transitions, RRS can provide information on phonons and their interactions with electrons. The latter ability is significant since it has been established that confinement effects can modify the vibrational modes and hence the electron–phonon interaction of semiconductor nanocrystals. Recently, RRS has been employed to study the E_1 transitions in nanometer-sized Ge nanocrystals embedded in SiO$_2$ [92]. The E_1 transitions in bulk Ge occur around 2.2 eV, well above the indirect and direct bandgaps with energies of 0.6 and 0.9 eV, respectively. Most semiconductors possess higher energy excitons with quite large oscillator strengths. Teo et al. studied Ge nanocrystals with diameters ranging from 4 to 10 nm by RRS [92]. The samples were formed by the ion implantation of Ge$^+$ ions into SiO$_2$ films followed by annealing. The observed size-dependent blueshifts of the E_1 exciton energy were found to agree with the theoretical calculations based on the effective mass approximation.

3.6. STM/AFM

Although scanning probe microscopy (SPM), such as scanning tunneling microscopy (STM) and atomic force microscopy (AFM), is known as a powerful tool to study nanostructures, its ability to image atoms has not been demonstrated for Ge nanocrystals. A difficulty in obtaining the atomic image of an individual nanocrystal comes from its spherical shape, which does not have an atomically flat area large enough to obtain an atomic image.

Sato et al. obtained the surface image of the Ge nanocrystalline film using an ultrahigh vacuum scanning tunneling microscope (UHV–STM) [64]. It clearly showed individual nanocrystals with diameters of 3–4 nm. The size distribution was narrow, and they were densely positioned so that the electron wave functions in two adjacent nanocrystals could overlap. Caragianis-Broadbridge et al. made a cross-sectional AFM study on Ge-doped SiO$_2$ thin films and obtained the sizes of the Ge nanocrystals and their distribution [53]. The cross-sectional AFM samples were prepared using a preparation technique based on the TEM tripod sample preparation method. This method allows imaging of nanocrystals without inducing electron-beam damage or beam-induced phase transformation. It is clear, however, that the resolution is quite limited by the radius of the AFM tip ($\sim$10–20 nm).

4. PHYSICAL PROPERTIES OF Ge NANOCRYSTALS

Like Si nanocrystals, Ge nanocrystals have been mostly studied for luminescence. The luminescence characteristic strongly depends on the methods used to form the Ge nanocrystals. For instance, the Ge nanocrystalline film deposited at 77 K by cluster-beam evaporation exhibited a unique property referred to as photooxidation and showed blue-light emission after photooxidation. Besides luminescence, the optical nonlinearity found in Ge-doped SiO$_2$ is another interesting optical property. In addition to the optical poperties, there is recent increasing interest in single-electron tunneling in Ge-doped glass films. In this section, the optical and electrical properties of Ge nanocrystals are reviewed.

4.1. Optical Properties

4.1.1. PL and EL

Various forms of Ge nanocrystals with a well-passivated surface exhibit strong visible-light photoluminescence (PL). The photoluminescence of Ge nanocrystals has been mostly studied in Ge-doped glass, where photogenerated electrons are expected to be confined in the Ge nanocrystals surrounded by a high potential barrier of SiO_2. A strong PL associated with Ge was observed only after annealing to form the Ge nanocrystals. Nevertheless, the mechanism of light emission is still a subject of debate.

Takeoka et al. observed strong size-dependent PL spectra from Ge-doped glass fabricated by the co-sputtering of Ge and SiO_2 and concluded that the PL originated from the recombination of the photogenerated electron–hole pairs confined in the Ge nanocrystals [27]. The PL peak energy was 0.88 eV for an average diameter of 5.3 nm and blueshifted to 1.54 eV with decreasing size to an average diameter of 0.9 nm. Broad PL spectra were observed in the visible wavelength range by Maeda [69]. The peak energy showed a blueshift from 2.1 to 2.5 eV with a decreasing average diameter from 5 to 2 nm, respectively. He, however, did not see any change in the PL peak energy for sizes greater than 5 nm. His experimental data for the sizes less than 5 nm were consistent with a quantum confinement model. Although both studies include the PL of Ge nanocrystals with the same sizes, and the fabrication methods are the same, the PL energies are significantly different.

Zacharias and co-workers observed PL with a peak around 3.1 eV regardless of the size of the Ge nanocrystals embedded in SiO_2, and they attributed the origin of the PL to a Ge/O-related defect [79, 93]. Okamoto and Kanemitsu also observed PL from the Ge-doped SiO_2 thin films fabricated by the co-sputtering of Ge and SiO_2 [77]. The surfaces of the Ge nanocrystals with an average diameter of 3.7 nm were covered with a native oxide. The nanocrystals had the characteristics of direct-bandgap semiconductors, but the PL spectra were similar to those of isolated small molecules. Excitons were localized near the surface of the nanocrystals, and the strong coupling of excitons and the stretch vibrations of the Ge oxides caused such PL spectra.

The surface oxides of the Ge nanocrystals also play an important role in PL from the Ge-doped glass thin films fabricated by the ion implantation of Ge into SiO_2. Several PL peaks have been reported. The PL peaks in the blue [65, 78] and infrared [94] wavelength regions are associated with the oxide covering the Ge nanocrystals, while that in the red [63] wavelength region was attributed to the radiative recombination of excitons confined in the Ge nanocrystals.

The electronic structure of the Ge nanocrystals was studied using the sp^3 tight binding description by Niquet et al. [95]. Their results with ab initio calculations in the local density approximation for smaller clusters indicated that the blue–green PL above 2 eV was associated with deep traps in the oxide, while the size-dependent PL in the near infrared of less than 1 eV involved deep traps in the gap of the nanocrystals.

Min et al. compared the PL from the SiO_2 films implanted with Ge and Xe [96, 97]. The peak was located around 1.8 eV for all the samples. Observation of luminescence in the Xe-implanted samples similar to that in the Ge-implanted samples suggested that the radiative defect centers in the SiO_2 matrix were responsible for the luminescence in the Ge-doped glass. The PL was quenched by implantation of deuterium into the Ge-doped glass thin film and recovered by removing deuterium by thermal annealing in a vacuum. These results also suggest that the observed PL is indeed defect related.

The Ge nanocrystals fabricated by the spark process [61], gas evaporation [98], and cluster-beam evaporation [48, 99] also exhibited visible PL, which was associated with the oxide defects. In particular, those by the cluster-beam evaporation at a substrate temperature of 77 K showed a strong blue PL at room temperature. The luminescence was seen only after photooxidation of the Ge nanocrystals, which will be discussed later. Since the PL intensity increases with the photooxidation time, and the peak energy of 2.8 eV was independent of the oxidation time, the PL was associated with the radiative centers in GeO_x on the surface of the Ge nanocrystals [48].

Tunable luminescence over a broad range in the visible region of the spectrum was demonstrated from the chemically synthesized Ge nanocrystals terminated with alkyl groups [18]. The PL peak wavelength was varied from 450 to 600 nm by controlling the size of the nanocrystals. The shift in the spectrum indicated size-dependent energy levels consistent with the quantum confinement model.

Electroluminescence (EL) was observed from a MOS-like capacitor with the Ge-doped glass thin film deposited on a Si substrate [100, 101]. Rectifying behavior was seen in the I–V characteristics. The EL was observed by Shcheglov et al. [100] at a reverse-bias voltage, resulting in an electrical field of 10^6 V/cm across the oxide, but by Zhang et al. under a forward-bias condition. Shcheglov et al. compared the PL and EL spectra and found similar results. The mechanism for the EL excitation was related to impact ionization by "hot" carriers in the oxide layer. However, the origin of the EL was not clarified. Zhang et al. observed a broad peak around 600 nm at low and moderate voltages and a sharp peak around 400 nm at high voltages. The broad peak around 600 nm was attributed to the recombination in the nanocrystals, while the sharp peak was attributed to the Ge oxygen-deficient center excited by impact ionization of the "hot" electrons.

4.1.2. Photooxidation

Photooxidation of the Ge microstructures was first reported by Harshavardhan and Hedge [102]. When the Ge nanocrystals are exposed to UV light, they are found to be rapidly oxidized even at room temperature. According to the model of photonically stimulated oxidation enhancement of Si proposed by Young [103], the rate determination step of the oxidation is the dissociation of molecular oxygen into its atoms. In his model, electrons in Si need to be excited to the conduction band of SiO_2 in order to dissociate molecular oxygen. The photooxidation of Ge nanocrystals was recently observed in those formed by the gas evaporation [98] and cluster-beam evaporation [48] techniques.

In the Ge nanocrystals made by cluster-beam evaporation, the photooxidation is evidenced by the optical absorption spectra in Figure 4. Although it is difficult to estimate the optical bandgaps from the spectra because of a gradual increase in the absorption near the band edge, it is clear from a comparison of both spectra that the photooxidation increases the optical bandgap. If we assume that the shift is due to the quantum confinement of carriers, the observed blueshift of the absorption spectrum can be explained by a decrease in the Ge core size after photooxidation.

Our systematic study [48] of the photooxidation of Ge nanocrystals deposited at a substrate temperature of 77 K by the cluster-beam evaporation technique supported Young's electron-active oxidation model. Since the dissociation energy of molecular oxygen is 5.1 eV and much higher than the photon energies of UV light, it is unlikely to be directly dissociated by the UV light. The schematic band diagram shown in Figure 5 depicts our model of the photooxidation of the Ge nanocrystals. As shown in Figure 2, a Ge core is surrounded by GeO_x. The surface of the GeO_x shell, where a supply of oxygen is sufficient, may be GeO_2. The bandgap of GeO_x increases with an increase in the value of x. When the Ge nanocrystal is exposed to UV light, the light is absorbed in the Ge core, where electron–hole pairs are generated. In the Ge nanocrystals, the electron injection into GeO_x was facilitated much more by the lower potential barrier due to an increase in the electron energy resulting from the quantum confinement. The electrons injected in GeO_x meet oxygen molecules during their diffusion in GeO_x and assist them in breaking up into smaller atomic components as discussed in the electron-active oxidation model [103]. On the other hand, the holes are not injected into the oxide but are confined in the Ge core because of its greater effective mass. The remaining holes make it easier for Ge atoms to bond to oxygen atoms.

If the preceding photooxidation model is correct, the size distribution of the Ge cores becomes smaller with the irradiation time, and the final size is determined by the photon energy of the incident light. The oxidation appears to stop when the size of the Ge core decreases and the apparent bandgap reaches the photon energy. A further increase in the apparent bandgap will result in the transmission of the incident light. Therefore, after prolonged photooxidation, the sizes of the Ge cores would become uniform. It is also
Figure 5. Schematic band diagram of the Ge nanocrystal to explain the photooxidation mechanism.

predicted that the higher the incident photon energy is, the smaller the final size of the Ge cores is.

In contrast to the Ge nanocrystals deposited at a substrate temperature of 77 K, those deposited at a substrate temperature of 300 K did not exhibit photooxidation. The difference was explained by the density of the nanocrystals, as discussed in Section 2. Since they were resistant to oxidation, no luminescence was observed from the samples.

4.1.3. Nonlinearity

Ge-doped silica is commonly employed for controlling the refractive index profile of optical fibers and exhibits other useful optical properties such as photorefraction [104] and second-harmonic generation [105]. In most of these applications, the Ge is present as a mixed oxide (SiO_2:GeO_2). However, recent experiments have shown that the Ge-doped glass exhibits a significant third-order optical nonlinearity [106–108].

The nonlinear response, intensity-dependent refractive index of the Ge-doped glass thin film with a Ge fluence of 3×10^{17} cm^{-2} implanted in SiO_2 was found to be large and more than three orders of magnitude greater than that of pure silica: 2.7×10^{-13} and 6.9×10^{-13} cm^{2}W^{-1} for the 100- and 650-fs pulses, respectively; that is, the nonlinear response increased with the increasing pulse duration [106]. It also linearly increased with the increasing Ge fluence implanted in SiO_2. The optical absorption in the films linearly increased with the Ge fluence, suggesting that the nonlinearity was absorptive rather than refractive.

Relaxation of the nonlinear response had two characteristic time constants, one less than 100 fs and the other about 1 ps. The carrier lifetimes are typically on the order of 10^{-3} s in pure Si and Ge, which is much longer than those observed in Ge-doped glass. However, the presence of impurities and defects can significantly reduce the carrier lifetimes. Therefore, the measured relaxation time of about 1 ps is characteristic of the defect-mediated recombination of excited carriers. The instantaneous response is believed to result from the field-induced polarization of the material.

4.2. Electrical Properties

Although the three-dimensional (3D) quantum confinement of an electron–hole pair is theoretically expected in the Ge nanocrystals, there has not been clear evidence

Figure 4. Optical absorption spectra of the Ge nanocrystalline films deposited by the cluster-beam evaporation technique before and after UV exposure.

reported until now. The difficulty in experimentally observing the physical phenomena indicating the 3D quantum confinement is mainly due to the nonhomogeneous size distributions of the Ge nanocrystals.

The effective Bohr radius, a_B, is given by

$$a_B = \frac{\varepsilon \hbar^2}{\mu q^2}, \tag{10}$$

where ε is the dielectric constant, $\hbar$ is the reduced Planck constant, μ is the reduced mass of an electron–hole pair, and q is the electronic charge. In the case of bulk Ge, ε is 15.8 [109], and μ is the reduced mass obtained from $1/\mu = 1/m_e + 1/m_h$. The lightest electron effective mass, m_e, and the lightest hole effective mass, m_h, at the L and Γ points are $0.082 m_0$ and $0.043 m_0$, respectively. We calculate $\mu = 0.028 m_0$ and obtain $a_B = 24.3$ nm. This effective Bohr radius is very large due to the small reduced mass of the electron–hole pair and the large dielectric constant.

If the nanocrystal size is much smaller than the effective Bohr radius, the electrons and holes can be independently confined into the infinite spherical potential. In this case, the lowest energy of the electron–hole pair E_1 is given by [110]

$$E_1 = E_g + \frac{\pi^2 \hbar^2}{2\mu R^2} \tag{11}$$

where E_g is the bandgap of bulk Ge. A more detailed calculation of the confinement energy was presented with the experimental data by Teo et al. [92].

Another interesting electrical feature associated with the Ge nanocrystals is Coulomb blockade and single-electron tunneling. Inoue et al. observed Coulomb gaps and step-like features in the low-temperature I–V characteristics of Ge-doped glass formed by co-sputtering and attributed them to the combined effects of resonant tunneling of electrons through the discrete electronic state of Ge nanocrystals and single-electron tunneling [111].

The Coulomb blockade and single-electron tunneling are also observed in Ge nanocrystalline films besides Ge-doped glass as long as there is a thin insulator between the Ge nanocrystals. The I–V characteristics of a 30-nm-thick Ge nanocrystalline film deposited at 77 K by the cluster-beam evaporation technique exhibited a distinct Coulomb gap and a steplike feature at 100 K [112–114]. They were also observed even at room temperature after photooxidation, which reduced the size of the nanocrystals and increased the inter-nanocrystal spacings. The observed Coulomb blockade effect results from a very highly selective electron transport process where the electron transport is dominated by one local well-defined current path with the largest conductance.

The carrier transport properties across Ge nanocrystalline films deposited by the cluster-beam evaporation technique have been thoroughly studied. There is a difference in the electron transport characteristics of the films deposited at substrate temperatures of 77 and 300 K. The difference is explained by a structural difference, which is mentioned in Section 2.5; that is, the Ge nanocrystals deposited at a substrate temperature of 300 K are hardly oxidized and are physically in contact with each other, whereas Ge nanocrystals deposited at a substrate temperature of 77 K often agglomerate and are oxidized. It was found

that, under relatively low electric fields, the Ge nanocrystalline film deposited at 77 K exhibited a $T^{-1/2}$ conductivity dependence, which could be explained by the variable range hopping model of Efros and Shklovskii [115] due to a weak overlap of electron wave functions, while in that deposited at 300 K, where the nanocrystals are in physical contact with each other, causing a significant overlap of electron wave functions, the conductivity–temperature dependence was explained by the variable range hopping model proposed by Mott and Davis [116] and Greaves [117].

4.3. Phase Transformation

4.3.1. ST-12 of Ge

One of the conventional methods to transform the crystal structure to a more closely packed one is the application of hydrostatic pressure. The high-pressure forms of a material are also experimentally obtained by reducing the size of a material [118–120]. The phase-transformation mechanism of a material due to size reduction is explained as follows. A strong surface tension due to many dangling bonds is expected to favor compact structures when the size decreases. A possible phase transformation of silicon nanocrystals from the diamond to the body-centered cubic (bcc) structure for sizes of 100–1000 atoms was theoretically predicted by Tomanek and Schluter [121].

For instance, Si and Ge, which are normally found in the diamond structure, are known to have several crystal structures, the so-called high-pressure forms: (1) hexagonal structure with four atoms per unit cell (2H-4), (2) body-centered cubic structure with eight atoms per unit cell (BC-8), and (3) simple tetragonal structure with 12 atoms per unit cell (ST-12). Figure 6 shows these four crystal structures with their densities, bandgaps, and types of bandgaps (direct or indirect) for Ge.

Among the high-pressure forms of Ge, the ST-12 structure is the most interesting from the viewpoint of device application. Joannopoulous and Cohen [71, 122] made a theoretical calculation and predicted that Ge with the ST-12 structure was a semiconductor with a direct bandgap of 1.47 eV. Bulk Ge with the diamond structure has been less attractive for device application because of its indirect and narrow bandgap. The earliest experimental observation of the ST-12 structure in Ge nanocrystals was reported by Saito [19], who found the ST-12 structure in Ge nanocrystals with diameters less than 20 nm formed by the conventional gas evaporation technique. Later Kanemitsu et al. found from high-resolution electron microscopy (HREM) that the crystal structure of Ge nanocrystals embedded in SiO_2 for diameters less than 4 nm was not like the ordinary diamond structure, although they could not identify the structure to be ST-12 [30]. They also briefly mentioned that the Ge nanocrystals with a new crystal structure had the characteristic of direct optical transition.

Recently, Wu et al. studied Ge nanocrystals smaller than 5 nm in diameter which were deposited in the MBE chamber with an ultrahigh vacuum field emission transmission electron microscope (UHV–FE–TEM) [63]. After deposition, the samples were transferred into the UHV–FE–TEM through a UHV-transferring system. They did not find the
Figure 6. Possible crystal structures of Ge.

ST-12 structure but rather β-tin structure. The β-tin structure was theoretically predicted as a high-pressure form of Ge [123] and experimentally observed by Oh-Ishi et al. [124]. Although the β-tin structure was obtained under high pressure, it was transformed to the ST-12 during pressure release [125].

We have successfully formed the thermally stable ST-12 structure of Ge by the cluster-beam evaporation technique and identified the structure of the formed Ge nanocrystals as the ST-12 structure by various characterization methods [64, 74]. Although the Ge nanocrystals for both substrate temperatures of 77 and 300 K had the crystal structure of ST-12, in this section, we limit our discussion to the ST-12 found in the Ge nanocrystalline film deposited at 300 K. A similar discussion can be applied to that at 77 K.

The Raman spectrum of Ge nanocrystalline film deposited by the cluster-beam evaporation technique at a substrate temperature of 300 K is shown in Figure 3. Two peaks were observed around 240 and 265 cm^{-1} in the Raman spectrum of the Ge nanocrystalline film. Kobliska et al. reported the peaks at 273 ± 3 and 246 ± 3 cm^{-1} for the ST-12 Ge obtained by applying a high pressure [126]. In Figure 3, the Raman spectrum of the Ge particles with the diamond structure is also shown for comparison. The peak wavenumber is 300 cm^{-1}, the same as that of bulk Ge. The Raman spectrum of the Ge nanocrystalline film resembles that of the ST-12 Ge obtained by applying high pressure and suggests that the crystal structure in the Ge nanocrystalline film is not the diamond but the ST-12. We also

identified the ST-12 by TED, XPS, and optical absorption measurements [64, 74].

4.3.2. Thermal Stability of ST-12 of Ge

The ST-12 of Ge is known to be metastable [127], and the ST-12 structure in the Ge nanocrystals disappeared after annealing at 300 °C [19]. We confirmed the metastability of the ST-12 of Ge by studying the ST-12 phase obtained by applying high pressure onto a small piece of bulk Ge placed in a diamond anvil cell [124]. The Raman spectrum suggested the presence of the diamond, wurzite, and ST-12 phases in the Ge piece after applying 6 GPa for a short time and then slowly removing the pressure. However, the peak for the ST-12 phase became weaker with time and finally disappeared after 4 h, while the other peaks remain unchanged.

In contrast to the ST-12 Ge formed by applying high pressure, the ST-12 Ge in the Ge nanocrystalline films deposited by the cluster-beam evaporation technique is surprisingly thermally stable. The DOS and optical absorption of the Ge nanocrystalline films annealed at 500, 700, and 800 °C were studied [64]. The sample annealed at 800 °C showed a DOS curve and absorption spectrum significantly different from those of the as-deposited and samples annealed at 500 and 700 °C. They resemble those of bulk Ge. From these studies, the critical temperature for the phase transformation from the ST-12 to the diamond structure was estimated to be between 700 and 800 °C. This result was consistent with those of the Raman [128] and plasmon-loss measurements [74]. It is concluded that the ST-12 structure of the Ge nanocrystals deposited by the cluster-beam evaporation technique is far more stable than that obtained by the other methods.

5. APPLICATIONS

Although light-emitting devices may be the first choice among the device applications of Ge nanocrystals similar to Si nanocrystals, the short-term development of such devices is hindered by a low luminescence efficiency and the broad peak of the luminescence spectra. These problems may be solved by improving the size uniformity of the Ge nanocrystals. Nevertheless, it is questionable that the light-emitting devices made of Ge nanocrystals can compete with conventional light-emitting devices made of compound semiconductor materials with direct bandgaps. Once the discovery of luminescence from Si and Ge nanocrystals attracted many researchers and engineers engaged in Si technology, it gave them hope that light-emitting devices such as light-emitting diodes (LEDs) and lasers could even be made of semiconductor materials with indirect bandgaps. Researchers and engineers in the Si technology area can easily accept the use of Si- or Ge-based materials rather than compound semiconductors. However, recent progress in blue-light-emitting devices made of GaN-based III–V compound semiconductors has lowered the value of Si or Ge nanocrystals as a light-emitting device material, because all colors are now commercially available with light-emitting devices made of compound semiconductors.

Like the other semiconductor nanocrystals, a new application that makes the best use of the properties of Ge

nanocrystals and that cannot be realized with any other material must be explored for Ge nanocrystals to become more industrially important.

One of the promising electron device applications of Ge nanocrystals is a nanocrystal memory. Currently, flash electrically erasable and programmable read only memory (EEPROM) is the most popular form of nonvolatile memory. Figure 7 compares the structures of the conventional EEPROM and the nanocrystal memory. During the operation of the conventional EEPROM, electrons are injected by tunneling into a continuous floating gate to cause a threshold voltage shift. To achieve nonvolatility in the flash EEPROM, the tunneling oxide thickness is maintained high enough (∼7 nm) in order to prevent floating gate charge loss under normal read and retention. The use of a large oxide thickness, however, necessitates the injection of a charge into the floating gate at large voltages, which result in hot-carrier degradation and large power consumption. To solve the problem of the flash EEPROM, a nanocrystal memory was proposed by Tiwari et al. [129]. In the nanocrystal memory, the charge loss through lateral paths is suppressed by use of a large inter-nanocrystal spacing. Thus, a smaller oxide thickness becomes possible without sacrificing the retention and makes the charge injection into the floating gate at small voltages possible. These nanocrystals can be made of either Si or Ge.

Nanocrystal memories have been demonstrated with Si [129, 130] and Ge [49, 131] nanocrystals. The electron storage characteristics of the nanocrystal memories with Si and Ge nanocrystals studied by computer simulation showed that the retention time for Ge nanocrystals was several orders longer than that for Si nanocrystals because of a higher potential barrier at the Ge/SiO$_2$ interface [132].

The capacitor with a Ge-doped glass film as a gate dielectric is a good test structure to quickly study programming and retention without forming a transistor structure [55, 56, 90, 133]. The capacitance–voltage (C–V) curve of the MOS capacitor should be shifted by injection of the charge into Ge nanocrystals, and the flatband voltage shift for a single electron per nanocrystal will be [129]:

$$\Delta V_{FB} = \frac{qn}{\varepsilon_{ox}}\left(t_{cntl} + \frac{\varepsilon_{ox}D}{2\varepsilon_{Si}}\right) \qquad (12)$$

where t_{cntl} is the thickness of the control oxide between the gate and the nanocrystal, D is the diameter of the nanocrystal, ε is the dielectric constant, q is the magnitude of the electronic charge, and n is the density of the nanocrystals. For the 5-nm-diameter Ge nanocrystals with a density of 1×10^{12} cm^{-2}, the flatband voltage shift is calculated as 1.0 V.
Figure 7. Comparison of the electrically erasable and programmable read only memory (EEPROM) and the nanocrystal memory.

The Coulomb blockade effect can also be significant for this nanocrystal size. The Coulomb charging energy ($q^2/2C$, where C is the nanocrystal capacitance) of a 5-nm-diameter nanocrystal is approximately 74 meV, larger than the thermal energy at room temperature, and limits the injection of additional electrons into the nanocrystal.

The process flow to fabricate Ge nanocrystal memories developed by King et al., which is described in Section 2.6, is easily incorporated in the present Si technology. In order to serve in a large-scale memory array, however, the distribution of the threshold voltage of the memory cells must be small. For high-density memory application, the memory devices have to be scaled to a deep submicrometer size. The variation in the number of electrons trapped, that is, the number of nanocrystals in the memory cell, has to be within a certain tolerance determined by the design of the sense amplifier. If there is nonuniformity in the size and density of the Ge nanocrystals, the variation in the threshold voltage in the programmed states increases as the size of the memory cell decreases. Therefore, the uniformity of the size and density of the Ge nanocrystals must be well controlled for application in high-density and large-scale memory arrays.

6. SUMMARY

We have reviewed the fabrication techniques, characterization methods, and properties of Ge nanocrystals. The most popular form of Ge nanocrystals is the Ge nanocrystals embedded in SiO$_2$, which is often called Ge-doped glass. The Ge nanocrystals in Ge-doped glass films are ideal quantum dots because of the high potential barrier formed by the surrounding oxide. Although the photoluminescence spectra reported for Ge-doped glass films are not conclusive evidence of quantum confinement, a recent RRS study supports quantum confinement in the Ge nanocrystals of the Ge-doped glass film.

Although light-emitting devices are the first choice among the device applications, it is not certain that the light-emitting devices made of Ge nanocrystals can compete with those made of compound semiconductors. In order for Ge nanocrystals to become an important electronic or photonic material, an application should make the best use of the properties of the Ge nanocrystals and should not be realized with any other material. One promising application of the Ge nanocrystals is a nanocrystal memory, which is to replace the conventional EEPROM flash memory. However, good control of the size and density of Ge nanocrystals is required for application in high-density and large-scale memory arrays.

Besides good control of the size and density, the challenge is to control the positioning of the Ge nanocrystals in SiO$_2$. The oxidation of the MBE-grown structure of the Ge dots embedded in Si is a good way to control the positioning of the Ge nanocrystals in the oxide. The Ge dots can be well ordered in an array by controlling the strain, resulting in a lattice mismatch between Si and Ge.

One of the unique deposition techniques of Ge nanocrystals is cluster-beam evaporation. The as-deposited Ge nanocrystalline thin films consist of the ST-12 Ge instead of the ordinary diamond crystal structure. The ST-12 structure is one of the high-pressure forms of Ge with optical

properties of a direct-bandgap semiconductor and is known to be metastable. In contrast to the ST-12 Ge formed by applying high pressure and the gas evaporation technique, the ST-12 Ge in the Ge nanocrystalline films is thermally stable. They also exhibited the unique property of photooxidation. The Ge nanocrystals were oxidized under UV irradiation and showed blue luminescence after photooxidation. The luminescence was attributed to defects in the oxide. The ST-12 Ge has a direct bandgap of 1.47 eV, which may lead to a wide variety of device applications in contrast to the diamond-structured Ge.

No matter what the device application might be, uniformity in the size and density and a good control of positioning may always be required. Future research on Ge nanocrystals must focus on control of the positioning, size, and density. Most techniques that have been used to fabricate Ge nanocrystals do not have a good control of positioning, and we are all longing for the emergence of a new technique.

GLOSSARY

Bohr radius   Radius within which the electron and hole are bound to each other, as in the case of the hydrogen atom. The electron and the hole are correlated in their motion in a way that can be described as the simple Coulomb attraction of the electron and the hole.

Coulomb blockade   Physical phenomenon that the electron tunneling is forbidden in one small capacitance tunneling junction under a certain bias condition, $-e/2C < V < e/2C$. This results from a significant change in the electrostatic energy of the junction by adding or removing a single electron for extremely small C.

Direct (indirect) bandgap   The bandgap is defined as the energy difference between the conduction-band minimum and the valence-band maximum. If the conduction-band minimum occurs at the same point in k space or momentum space as the valence-band maximum, then the bandgap is direct. If not, it is indirect.

Electrically erasable programmable read only memory (EEPROM)   NMOS memory utilizing Fowler–Nordheim tunneling to charge and discharge the floating gate through the thin oxide as the tunneling medium.

Flatband voltage   Gate voltage required to bring about the flatband condition (no charge induced in the semiconductor) in the MOS capacitor. Although the flatband voltage of the ideal MOS capacitor is 0, it can be shifted by a difference in the work functions of the gate (M) and semiconductor (S) and electronic charge in the oxide or at the semiconductor/oxide interface.

Ge-doped glass   Silicon dioxide layer with Ge nanoparticles or nanocrystals dispersed.

Nanocrystal   Crystalline particle with a size of several nanometers or less. It differs from the nanostructures formed by epitaxial growth or lithography in this chapter.

Photooxidation   Oxidation process enhanced under illumination. The light used for photooxidation is usually ultraviolet light with high-energy photons.

Tsukuba, Ibaraki, Japan*

CONTENTS

1. INTRODUCTION

Silicon (Si) technology clearly dominates the semiconductor industry. However, most optoelectronic devices still rely on the use of III-V semiconductors. The reason is that direct band structure in III-V semiconductors allows one to fabricate efficient light emitters while indirect band structure of Si and Ge puts a serious barrier in the way to achieve this goal.

It has been suggested that use of nanosize Ge and Si structures should result in the band structure modification, namely, making it direct. Several reports of intense photoluminescence (PL) from nanosize Si and Ge have generated increased interest in these materials.

There are two major ways to fabricate Ge nanostructures. One is epitaxial growth on Si when Ge nanostructures are formed as a result of self-assembly process and the other one is fabrication of nanocrystals confined in various matrixes. In this entry the latter process is discussed. We start with methods of Ge nanocrystal fabrication. This section is followed by description of their average and local structure. Optical and electrical properties of Ge nanocrystal structures are further discussed. The entry is concluded by a summary of possible advanced application of Ge nanocrystals.

2. FABRICATION TECHNIQUES

Attempts to incorporate the Ge nanocrystals into industrial Si technology are likely to be responsible for the fact that in most cases the Ge nanocrystals are formed embedded in a SiO_2 matrix, the substrate usually being silicon. Various methods of the nanocrystal fabrication have been successfully applied. These techniques include (co-)sputtering [1–7], sol–gel processing [8, 9], and ion implantation [10–13] followed by annealing at temperatures in the 300–1000 °C range (either conventional annealing or rapid thermal annealing (RTA) can be used). Each of the techniques has its own merits and disadvantages. Thus sputtering allows one to vary the Ge content in a very broad range, sol–gel seems to produce nanocrystals of a smaller size, and ion implantation allows to incorporate more Ge species into the SiO_2 host compared to the sol–gel technique and is compatible with the conventional Si technology.

Other methods include H_2-reduction of Ge-oxide [14], atmospheric pressure chemical vapor deposition (CVD) [15], epitaxial growth of Ge on oxidized Si substrates [16], low-temperature UV oxidation [17], and deposition of Ge on SiO_2 and subsequent high-temperature oxidation [18]. It should be noticed that the evidence for the formation of the Ge nanocrystals in the latter case is rather ambiguous.

Host materials different from SiO_2, such as silicon when Ge nanoparticles were produced by pulsed laser ablation and co-deposited in a Si film simultaneously grown by chemical beam epitaxy using silane [19], AlN (by pulsed laser deposition) [20], and SiC (by ion implantation and subsequent annealing) [21], have been used.

An interest has been observed in fabrication of Ge nanocrystals inside nanoporous materials, in particular in zeolite cages [22–26] and in opals [27, 28]. In the opal case, after filling the opal pores with Ge, the host matrix is etched away and the so-called "inverse opal" structure results. The interest in this case is mainly driven by photonic bandgap properties of three-dimensional periodic structures.

Arrays of Ge nanocrystals which are not embedded into any matrix have also been produced from colloids [29, 30] and using a Ge cluster source evaporation technique [31].

3. NANOCRYSTAL GEOMETRY

The nanocrystal geometry, that is, their size and shape as well as their spatial distribution within the host matrix, is determined by the preparation conditions. Most of

these data have been obtained by direct observation of the nanocrystals using high-resolution transmission electron microscopy (HR-TEM). While this technique is very convenient, it has some restrictions with respect to the sample preparation. Depending on the sample thickness, for example, certain nanocrystals may or may not be observed, occasionally resulting in poor reproducibility.

Some of the experimental problems related to TEM studies of the nanostructures are discussed in [32]. While there are some differences between the results reported by various groups, general trends can be summarized as follows.

- The minimum experimentally observed nanocrystal size reported in the literature is 1 nm [5].
- The size of the nanocrystals increases with the annealing time.
- The size of the nanocrystals increases with the annealing temperature.
- The maximum nanocrystal size reported is ∼30 nm [7].

It should also be noted that the nanocrystals generally possess a rather spherical shape and the typical size of the nanocrystals is smaller than the typical size of Ge/Si self-assembled quantum dots prepared by epitaxial growth through the Stranski–Krastanov mode. In the latter case the lateral size of the Ge nanostructures is usually on the order of 100 nm with the height on the order of 20 nm [33].

The geometrical parameters of the nanocrystals obtained by various groups are summarized in Table 1 together with the preparation conditions. The size of the nanocrystals also depends on the concentration of Ge in the sample, being larger for larger concentrations (Table 2).

It should also be noticed that the size of the nanocrystals strongly depends on the substrate material. Thus, in our experiments, when samples containing 60 mol.% Ge were simultaneously deposited onto Si(100) and quartz-glass substrates and then annealed in Ar atmosphere at 800 °C for 1 hour, the size of the nanocrystals formed on Si(100) was 20 nm while the size of the nanocrystals formed on a quartz-glass substrate was much smaller, namely, 5 nm [37].

The smallest observed size of the nanocrystals either may be determined by the TEM resolution or can be limited by the thermodynamical-energy balance. An estimate based on the latter assumption gives a value of 2–3 nm, which is in good agreement with the experimental observations.

The minimum nanocrystal size was also calculated in [38]. These authors have shown that Ge clusters with the diamond structure are stable for clusters containing more than 40 atoms, which also falls into the same size range.

In [4] it was suggested that double annealing at 300 °C and 600 °C for nucleation and growth results in a better size control and more uniform size distribution than annealing at a single temperature.

Annealing of a sample with a larger Ge content (60 mol.%) results in a bimodal Ge nanocrystal formation [37]. In a direct vicinity of the Si(100) substrate, spherical and rather densely placed nanocrystals were formed with a typical diameter of ∼20 nm. It is worth noticing that the film–Si(100) interface was no longer flat, with dips in the immediate vicinity of the nanocrystals. In the area away from the substrate, well-faceted nanocrystals of comparable

Table 1. Nanocrystal size dependence on the growth conditions.

Fabrication method	Annealing temperature, °C and time	Nanocrystal size, nm	Ref.
Sputtering	300, 30 min	2–3	[4]

Cluster source		3–4	[31]
Plasma-enhanced CVD		5	[36]

size were formed. It is worth noting that whilst the faceted nanocrystals in the bulk of the SiO₂ matrix were usually single-domain single crystals, those located in the vicinity of the interface possess multiple-twin structure [37].

Spherical Ge multiple-twin structured nanocrystals located at the Si–SiO₂ interface were also reported in [7] where rapid thermal annealing has been used. The size of the nanocrystals varied from 6 nm for 800 °C annealing to 20–30 nm for the 1000 °C annealing.

It has been suggested [39] that a higher concentration of the Ge nanocrystals close to the interface can be due to the fact that the solubility of Ge is different at the Si–SiO₂ interface and in the bulk of the oxide with the concentration gradient leading the diffusion flux and subsequent accumulation

Table 2. Nanocrystal size dependence on the Ge concentration.

Fabrication technique	Ge concentration	Annealing temperature	Size, nm	Ref.
Sputtering	25 mol.%	800	not detected	[37]
	60	800	20	[37]
Ion Implantation	1×10^{17} ions/cm²	800	4	[12]
	2×10^{17}	800	7	[12]
	3×10^{17}	800	10	[12]

of Ge at the interface. Alternatively [14], it has been argued that the outdiffusion of Si from the substrate at elevated temperatures should enhance the nucleation and growth of the nanocrystals at the interface.

While in [7, 37] the nanocrystals formed in the vicinity of the Si substrate are clearly separated from the substrate by an amorphous medium, in some cases Ge nanoislands can grow at the interface epitaxially [17].

In most cases annealing of a Ge-SiO_2 composite results in the formation of Ge nanocrystals. However, in the case of a higher Si concentration in the composite, GeSi nanocrystals can also be produced using this technique [6]. In this case it was found that the size of the nanocrystals, typically in the 10-nm range, was gradually decreasing with the increasing distance from the Si(100) interface.

4. NANOCRYSTAL STRUCTURE

The TEM results described above provide direct evidence on the formation of the nanocrystals. They can also in certain cases provide information on the structure of the nanocrystals. Alternative, or rather complementary, techniques for the investigation of the average and local structure of the nanocrystals are electron and X-ray diffraction, Raman scattering, and X-ray absorption fine structure and X-ray photoemission spectroscopy (XPS). The latter technique provides mainly the information on the oxidation state of Ge species [4, 7].

It should be noted that diffraction techniques rely on the long-range order in the nanocrystals and, as a result, measure the average structure of the nanocrystals; the same is true for the TEM measurements. Raman scattering and especially X-ray absorption fine structure are sensitive to local bonding and provide information on the local structure. The latter may be different from the average structure, as will be seen below. In this section we review the results obtained by different techniques and discuss the merits and disadvantages of each approach.

4.1. Average Structure

In most embedded Ge nanocrystal samples the interplane distances measured from HR-TEM images have led the authors to a conclusion that the nanostructures possess diamond structure [4, 17, 40]. In [2, 4] it was mentioned that the structure was size-dependent. While in the nanocrystals with a size >5 nm the (111) interplane spacing of 0.326 nm was observed which corresponds to the diamond structure, in the nanocrystals whose diameter was ≤4 nm the spacing was 0.298 nm which could not be derived from the diamond structure. It has been suggested [41] that small nanocrystals have tetragonal structure with the spacing of 0.292 nm. This value agrees with the interplane spacing observed in small embedded crystals and the authors of [2] suggest that smaller nanocrystals possess tetragonal structure.

For the nanocrystals embedded in AlN the observed lattice fringes correspond to (111) planes of the diamond structure (0.326 nm) [20]. A similar conclusion was drawn for the Ge nanocrystals in a Si host matrix [19] even though the size of the nanocrystals was rather small (≥2 nm).

X-ray diffraction studies on Ge nanocrystallites prepared by plasma-enhanced CVD revealed the presence of the crystalline plane spacing of 0.345 nm in the crystals with the diameter of 5 nm. This value is different from the diamond structure and the authors concluded that a new Ge crystalline phase was formed.

For the Ge nanocrystals grown from a cluster source [31], it has been argued, based on Raman scattering, XRD, TEM, and transmission electron diffraction (TED), that the nanocrystals possess the ST-12 structure [42, 43]. This high-pressure form possesses a direct gap of about 1.5 eV [44, 45]. The size of the nanocrystals in this case was 3–4 nm so that this result is in agreement with the previous suggestions.

On the other hand, the colloidal Ge nanocrystals retain the bulk-like crystalline structure down to the size of 2 nm [30].

What may be the reasons for the nanocrystal-size dependence of the crystal structure? A possible and likely explanation would be an increased surface tension for small-size crystals. It is known that a high-pressure form of a material can be produced by reducing the size [46]. The SP-12 structure is a high-pressure (tetragonal) form of Ge which is metastable and is transformed into the diamond structure upon annealing in the 200–300 °C range [41, 44]. Theoretical simulations also confirmed that a transition from tetragonal to diamond structure should occur on Ge clusters when the number of atoms in the cluster reaches 40 and more, that is, for the size exceeding 1–1.5 nm [38]. The host matrix and the preparation method may (and do) influence the interface energy and hence the crystal structure. For example, it has been shown [38] that chemical preparation methods should always yield diamond structures.

To summarize the known data, we can say that the nanocrystals with the size of 5 nm and larger possess the diamond structure while smaller nanocrystals may have the tetragonal structure. It was suggested that by tuning the surface properties, the pressure exerted on the dot core may be varied and used to tailor the atomic structure [38].

4.2. Local Structure

4.2.1. Raman Scattering: Merits and Pitfalls

Raman scattering is a technique used to characterize the Ge nanostructures most often. While it is a very powerful technique, in the particular case of Ge nanostructures and Si substrate it has severe restrictions, often not taken into account. Before discussing the positive knowledge provided by the Raman scattering studies, we shall discuss the pitfalls of this technique.

Ge possesses a Raman peak around 300 cm^{-1}. The exact peak position, its line shape, and intensity are often used to discuss the degree of phonon confinement, stress, composition, and size of the nanostructure as well as the amount of Ge-Ge bonds [47]. It should be kept in mind that comparison is usually made with the Raman peak position of bulk Ge. The latter has been measured in various samples under various conditions, for example, temperatures, and the reported values vary from 298.5 cm^{-1} (calculated from Eq. (3) of [47]) to 300.5 cm^{-1} [48] to 305 cm^{-1} [49]. If this

fact is neglected, one can draw quite different conclusions depending on the choice of reference.

The most serious problem arises from a fact which is often neglected, viz., a Raman spectrum of pure Si also exhibits a peak located at almost exactly the same position, the so-called two-phonon acoustic peak. The latter has been known since the 1970s and has been well documented [50, 51]. It has a characteristic shape with three features located at 225 cm^{-1}, 301 cm^{-1}, and 435 cm^{-1}. This peak intensity may be quite strong and is often mistaken for the Ge peak. A detailed summary of this has been given in [52–55].

Another problem is a similarity in positions of the 435 cm^{-1} peak of Si with the peak due to Ge-Si vibrations and the so-called local Si-Si vibrations. Their misinterpretation can result in significant mistakes in determining the composition of the nanostructures from the peak positions.

Finally, it should be kept in mind that in the case of nanostructures the peak intensity is not proportional to the number of the corresponding bonds. Thus annealing or capping of self-assembled Ge/Si(100) quantum dots results in simultaneous decrease of the Ge-Ge and Ge-Si peak intensities [56, 57]. This fact has been interpreted in [57] as intermixing of Ge with Si, but this should have caused an increase in the Ge-Si peak intensity, which is not what has been observed experimentally.

Possible ways to distinguish between the true Ge Raman peak and the two-phonon acoustic Si peak include use of resonant Raman scattering [12, 54], use of polarized Raman scattering [54], and measurements under pressure [58]. The former two techniques allow to suppress the relative contribution from the Si peak, while the latter one makes the two peaks shift in the opposite directions. Use of pure Ge isotopes is another possible technique [56], although the isotopes may not be easily available.

Now that the reader has been provided with crucial information on Raman scattering in the particular case of Ge nanostructure on Si substrates and can make his own judgment of the original papers, we shall proceed to discuss some of the positive results obtained through Raman scattering studies.

In cases of small-size nanocrystals, the observed Raman peaks are asymmetrically broadened [12] over the low-frequency range which is believed to be due to confinement of phonons [59] since the confinement results in the breakdown of the wave vector selection rules. Therefore, phonons at $q \neq 0$ also contribute to the Raman spectrum, resulting in the shift of the peak position from its bulk value and asymmetric broadening [60].

The size of the nanocrystals, determined from the line-shape fitting [60] using the approach developed in [61], agrees quite well with the size measured by TEM. The observed disagreement between theoretical and experimentally observed peak positions may be due to stress, intermixing, or inhomogeneous Ge distribution. Each of these reasons may be dominant in a particular case. Small nanocrystals whose presence can be detected by HR-TEM may exhibit completely amorphous-like Raman spectra [62].

In addition to the size-dependent line shape and peak position, the Raman scattering efficiency was also demonstrated to change (increase) considerably for the nanocrystals with smaller sizes [12, 63].

Use of polarized Raman scattering demonstrated that (in samples containing 60 mol.% Ge in SiO_2) any Ge-Si alloying is limited to the interface region and takes place on the Si substrate surface rather than in the nanocrystals. On the other hand, in samples containing excess Si (compared to SiO_2), the process is more complicated. The Ge phase has been found to be formed first, followed by the formation of GeSi outer shells [6]. This result may be explained by the fact that Ge oxide is thermodynamically less stable than SiO_2 [64].

While in most cases Raman scattering has been successfully used for characterization of the Ge nanocrystals embedded in SiO_2 [4, 5, 7, 12, 40], it has also been used to detect the Ge phase in zeolites [24, 26] and for the nanocrystals prepared by evaporation using a cluster source. In the latter case it was concluded [42] that the nanocrystals possessed ST-12 structure.

4.2.2. X-Ray Absorption Fine Structure

X-ray absorption coefficient of a solid above the absorption edge exhibits oscillations that are caused by back-scattering of the created photoelectron wave on the nearest neighbors. These oscillations are called extended X-ray absorption fine structure (EXAFS). Analysis of EXAFS spectra allows one to obtain information on the coordination numbers, distances to the nearest neighbors, and chemical nature of the neighbors, as well as a mean-square relative displacement, both in crystalline and amorphous phases.

The absorption edge itself is also strongly modified by the chemical surrounding and can be a source of additional information. Recent progress in theoretical simulation of XAFS makes it possible to simulate both the edge structure and EXAFS oscillations with high accuracy.

Use of XAFS has allowed one to measure the Ge-Ge bond length (usually with the accuracy of ± 0.005 Å). For example, in embedded 20-nm nanocrystals the bond length was found to be the same as in bulk Ge; that is, the nanocrystals are unstrained [37]. (In self-assembled Ge/Si(100) quantum dots the Ge nanostructures exhibit clear bond shortening [65].) The strain information obtained from EXAFS combined with the Raman peak position allows the best-to-date determination of the degree of the phonon confinement [6].

In zeolite-confined Ge clusters Ge-Ge bond length was found to vary from 2.41 to 2.55 Å depending on the CVD precursor and the host matrix [22].

Of interest is combined use of EXAFS and diffraction anomalous fine structure (DAFS). The latter technique, which exhibits similar oscillations in the Bragg peak intensity as a function of X-ray energy, is based on the long-range order, that is, only probes the nanocrystalline phase. EXAFS provides information on both phases. Combined use of both techniques allows one to investigate both phases of the same material independently; that is, the details of the crystallization process can be studied on an atomic scale [66].

5. PROPERTIES

5.1. Optical Properties

5.1.1. Electronic Band Structure

As already mentioned in the Introduction, one of the major reasons pushing the interest in Ge nanocrystals is a conjecture that they should possess direct bandgap structure and, as a result, can be a basis for fabrication of efficient light emitters perfectly compatible with Si, technology. This conjecture was first made in [67]. Since the effective Bohr radius for Wannier excitons in Ge (24 nm) is larger than in Si, it is likely to be easier to modify the electronic structure of Ge than that of Si [4].

Optical properties of Ge nanocrystals have been studied both experimentally and theoretically [29, 35, 68, 69]. Optical absorption of embedded and colloidal nanocrystals has been studied in detail in [13] and [30], respectively, and it was suggested [13] that scattering makes a significant contribution to the extinction spectra damping the spectral features.

In [35] optical nonlinearity of Ge nanocrystals embedded in silicon oxide thin films using Z scan and pump-and-probe technique with 532-nm ps laser pulses. The nonlinear refractive index and absorption coefficient are Ge-concentration-dependent and range between 0.0026 and 0.0082 cm^2/GW and 190 and 760 cm/GW, respectively, when the Ge atomic fraction increases from 8.5% to 27.6%. It was concluded that the nonlinearity mainly comes from excited carriers and two-photon absorption makes a small contribution. The excited carrier lifetime was determined to be ~70 ps and independent of the laser intensity up to 19.2 GW/cm^2.

Extinction spectroscopy of the colloidal Ge nanocrystals [29] over the 0.5- to 5-eV energy range revealed a number of features attributable to transitions both near and away from $k = 0$. Strong size effects were observed for the direct transitions near $k = 0$, while those away from $k = 0$ seem to be unaffected by confinement. The authors interpret these results within the context of bulk Ge electronic structure.

In [69] *ab initio* calculations were performed that provided evidence for a direct gap in the center of a two-dimensional Brillouin zone depending on the particular crystallographic orientation of the Ge structures. Strong optical absorption and emission of photons without phonon coupling is theoretically predicted for [100]-oriented Ge quantum films. This result is associated with the presence of a direct gap band structure, with a large mixing of the bulk Γ derived states into the conduction band minimum of the films, and with the particular localization of the band edges wave functions in the real space. The [110]- and [111]-oriented Ge films seem to not possess such a pronounced optical activity in spite of the fact that the bandgap in the [111]-oriented films is also direct. The authors concluded that the [100]-oriented Ge quantum films could be a good candidate for applications in silicon-compatible light-emitting devices.

Electronic structure of Ge nanocrystals has been studied in [68] using sp^3 tight-binding description. The authors claim that the blue-green photoluminescence of Ge nanocrystals comes from defects in the oxide and that the size-dependent photoluminescence in the near-infrared probably involves a deep trap in the gap of the nanocrystals. They also predicted

that radiative lifetimes remain long in spite of the small difference, ~0.14 eV, between direct and indirect gaps of bulk Ge.

The authors of [70] have used a tight-binding approximation to calculate the electronic states in silicon nanostructures. They have found that amorphous Si nanostructures (rather than those with special symmetries) are most promising for light-emitting devices. The same may or may not be true for Ge.

5.1.2. Photoluminescence

While intense photoluminescence (PL) in the visible range from Ge nanocrystals has been reported by numerous groups and is an established fact, its mechanism remains a subject of severe debates. Before addressing this controversial issue, we shall summarize the established experimental results.

- Ge nanocrystals exhibit strong PL in the visible range, the most often observed peak position being slightly above 2 eV [4, 5, 16, 30, 59, 71–77]. What "strong" PL means is a matter of the authors' perception. Regrettably, the PL intensities in the original papers are given in arbitrary units. For this reason it is difficult to compare these results with those for light-emitting III-V structures.
- The peak position does not exhibit strong size-dependence [2, 4, 8, 9, 14, 15, 59, 74, 75] (with the exception of [78] where it does).
- Strong size-dependence has been observed [78] for near-IR PL. These authors have also observed increased PL efficiency for smaller nanocrystals.
- In some cases (when the excitation energy is high enough), two peaks have been detected [9, 71, 76].

The dependence of the peak position on the nanocrystal size is summarized in Figure 1. One can see that there
Figure 1. Nanocrystal size dependence of the PL peak position for Ge nanocrystals embedded in SiO_2 (summary of the literature data; sources are indicated in the figure). For comparison, PL peak positions for Ge nanocrystals embedded in AlN and for self-assembled Ge/Si quantum dots are also shown. The lines indicate the direct optical gap in the bulk diamond Ge (dashed line) and in the high-pressure ST-12 structure.

the experimental data peak around three different energies, namely, $\sim$1 eV, $\sim$2 eV, and $\sim$3 eV. Most often the 2-eV peak is reported and we shall start the discussion with this.

Regarding the mechanism of the photoluminescence (in this paragraph we discuss the peak located above 2 eV), the opinions are strongly polarized. Thus in [4, 73, 76, 77] the authors argue, based on the observed weak size-dependence of the PL peak, that the PL is due to quantum confinement. PL intensity-dependence on the nanocrystal size is another argument [4, 73]. The observed size-dependence of the peak position is much weaker than predicted theoretically [67]. The supporters of the confinement approach explain this in terms of shortening of the Ge-Ge bond length in the nanocrystals which modifies the electronic structure of Ge [76] or by presence of fast nonradiative relaxation channels in nanocrystalline Ge taking part at the surface [4].

The opponents of the quantum confinement model argue that the size-dependence of the peak position is negligible [71, 72, 74, 79] and that the PL is due to emission from some centers in SiO_x layer surrounding the nanocrystals [5, 72], in the matrix itself [74], or is associated with Ge-related defects at the interfaces [71]. A similar conclusion has also been drawn from tight-binding calculations [69].

In the case of AlN host, the PL peak was observed at $\sim$1.0 eV [20]. We would like to mention here that PL from self-assembled Ge/Si quantum dots (which can be considered as Ge nanocrystals epitaxially embedded in Si) is also characterized by a peak located around 0.8 eV, the exact peak position being a function of Ge coverage (see, e.g., Fig. 19 of [33]). The dependence of the visible PL peak position on the host material is yet another indication that the interface states play a very important role in the process.

Of special interest is the PL reported in [78, 80]. These are the only reports where strong size-dependence of both the peak position and the intensity has been detected. The observed peak was located in the near-IR and did change its position from 0.88 eV to 1.55 eV as the nanocrystal size decreased from 5.3 to 0.9 nm. (It should be noticed that the authors were not able to directly detect the nanocrystals with the size less than 2.3 nm and the size of the smaller nanocrystals was estimated from the volume fraction of Ge. This is a disappointing fact because the strongest size-dependence was reported exactly for the range where the nanocrystals could not be observed by HR-TEM.)

It is worth noting that the observed peak position for the largest nanocrystals agrees very well with the value of direct gap in bulk Ge (0.88 eV) [81], which makes it reasonable that the observed PL is, indeed, due to the direct optical transition in small nanocrystals. It should be noted that despite the size-dependence being much stronger in this case than in the majority of other reports, it is still not as strong as theoretically predicted. Thus the prediction requires the peak position of 2.3 eV for the 4-nm Ge nanocrystals [67, 75], while the experimentally observed value is $\sim$0.9 eV.

Finally, there are reports of a peak located at $\sim$3 eV. Most authors seem to agree that its origin is related to defects, either Ge/O related defects [74] or implantation-induced defects [76].

As follows from the above discussion, the situation with the PL mechanism is very complex and it is impossible to draw a definite conclusion about the PL mechanism at this stage. In [38] it was argued that in understanding the properties of the small semiconductor dots, both quantum confinement and surface effects have to be taken into account.

It seems likely that PL around 1 eV is indeed mainly due to the quantum confinement because the peak value agrees with the direct gap of bulk Ge and the peak position does not depend on the host matrix. The peaks at $\sim$2 eV and $\sim$3 eV are likely to be due to the SiO_2 matrix. It may be possible, however, that the $\sim$2-eV peak is also a manifestation of the confinement in the case when the structure of the Ge of small nanocrystals embedded in SiO_2 changes from diamond structure to ST-12 structure.

The 3-eV feature is likely to be caused by defects. Further studies are needed in order to elucidate the true mechanism of photoluminescence in Ge nanocrystals.

5.2. Electrical Properties

Studies of electric properties of Ge nanocrystals are quite limited. Temperature-dependent current–voltage (I–V) characteristics have been studied across the thickness of Ge nanocrystalline films prepared by the cluster beam evaporation technique [82, 83]. It was found that in a film with a thickness of 30 nm, deposited on a substrate kept at 77 K, step-like features in the I–V characteristics were observed at low temperatures which are characteristic of single-electron transport.

6. ADVANCED APPLICATIONS

The present state of research of the Ge nanocrystals is still at a stage when basic properties of the nanocrystals are studied and the technological conditions optimized. One can only discuss potential advanced applications of the Ge nanocrystals which may be the following.

- Light emitters (based on numerous PL studies).
- Single-electron transistors. Since the pioneering paper [84], a great deal of interest has been generated around the detection of single-electron transport. Recent reports of step-like features in I–V curves of Ge nanocluster samples [82, 83] make the latter a possible candidate for the realization of the single-electron transistor ideas.
- Memories. A memory effect was observed in Ge nanocrystals embedded in an amorphous SiO_2 matrix of a metal-insulator-semiconductor structure [85].
- Photonic structures. Creation of high-quality three-dimensional periodic structures inside zeolites and opals [86] allows for fabrication of Ge-based photonic crystals.
- Nonlinear optical media [35], and photosensitive materials [87].
- Quantum computers [88].

GLOSSARY

Direct-gap structure Electronic structure of bands in a semiconductor when the minimum of the conduction band is located above the maximum of the valence band, i.e., at the

same wavevector. Optical absorption and emission due to direct transitions possess much higher efficiency than those due to indirect ones.

Inverse opal The structure resulting after incorporation of foreign species into the pores of an opal and subsequent etching of the host matrix.

Local structure Arrangement of atoms on a scale of a few Ångstroms; includes the coordination number, bond lengths and bond angles, and chemical nature of the first-nearest neighbor species.

Nanocrystals Crystals with a characteristic size in the 1- to 100-nm range.

Quantum confinement effect Manifestation of the small size of nanoparticles. When a charge carrier is confined in a small volume, its energy levels shift with respect to those in the bulk material, hence, size dependence of the photoluminescence peak.

ST-12 structure A high-pressure form of germanium. It is believed that Ge nanocrystals of very small size possess this form as opposed to the diamond structure of bulk germanium.

Germanium-on-Silicon Infrared Detectors

G. Masini, L. Colace, G. Assanto

University Roma Tre, Roma, Italy

CONTENTS

1. INTRODUCTION

Infrared (IR), that is, light of wavelengths from 700 nm to a few hundred micrometers, is of paramount relevance in several applications ranging from communications to defense, and airborne and environmental sensing. IR is commonly subdivided into three roughly defined regions: the near-infrared (NIR) or short-wavelength infrared (SWIR) from 0.7 to 2 μm, the mid-infrared (MIR) or mid-wavelength infrared (MWIR) from 2 to 10 μm, and the far-infrared or long-wavelength infrared (LWIR) beyond 10 μm. With regards to the NIR, despite the recent contraction of the related market, optical fiber communications remains the dominant application area, with spectral "windows" located around 900 nm (first), 1300 nm (second), and 1550 nm (third), where silica fibers exhibit minima in propagation losses and/or (chromatic) dispersion. For this reason long-haul systems operate in the second and/or third windows [1], while the first is employed in short-reach and low-cost systems employing plastic fibers, GaAs emitters, and silicon photodiodes [2]. The near- and mid-IR are the best option for remote sensing and imaging owing to a reduced Raleigh scattering (compared to the visible) and to atmospheric transparency around 1.6 μm, from 3 to 5 μm and from 8 to 14 μm, respectively. The latter is of great relevance for thermal imaging, since the blackbody radiation of an object at 300 K peaks at about 10 μm. Airborne or satellite-acquired SWIR maps are commonly used (often in conjunction with visible ones) to identify the water content in the flora and, thereby, assess the risk of fire occurrence in regions subject to dry and/or hot weather [3]. In the field of art restoration, near-infrared imaging can bring to evidence the preparatory drawing lying under a painting [4]. All of these applications, and many others in medicine, biology, spectroscopy, etc., rely on a sensitive, sometime fast, detection of IR light. The technology, the performance, and the use of infrared detectors based on a specific material system, namely germanium on silicon, are the subject of this overview.

This chapter is organized as follows: in Section 1, after the Introduction, we review the basic concepts of detection of near- and mid-infrared light and the relevant parameters characterizing sensors at these wavelengths. Section 2, examines the techniques used for the growth of SiGe and pure Ge on silicon. Finally, Sections 3 and 4 summarize the major achievements with NIR and MIR photodetectors and arrays based on Ge and SiGe-on-Si technologies.

1.1. Near-Infrared Detectors

Detectors for fiber optic communications must be very fast (speeds as high as 10 Gb/s are common today, and 40-Gb/s systems are entering the arena [5]), sensitive, and efficiently coupled to the fiber tip. Wavelength division multiplexing (WDM) efficiently exploits the enormous transmission bandwidth offered by silica fibers. In such systems, signals carried at different "colors" (i.e., wavelengths) travel in the same waveguide and are demultiplexed at the receiver before detection. Wavelength demultiplexers, usually arrayed waveguide gratings (AWG) [6], provide their output via a set of closely spaced waveguides to be matched to an array of detectors. The possibility to fabricate and integrate NIR detector arrays with AWG can therefore improve the compactness of WDM systems. As will be clear in the following, this is one of the key advantages of the Ge-on-Si technology for NIR photodetection. Furthermore, as mentioned above, near-infrared light around 1.55 μm is

also used in free-space communications owing to the transparency of the atmosphere and the eye-safety characteristic of this spectral region [7].

Near-infrared detection is commonly based on the promotion of an electron from the valence to the conduction band of a semiconductor, through the absorption of a photon [8]. The unbound electron and the corresponding hole created in the valence band, in the presence of an electric field, generate a current flow through the contacts realized on the sample. A very common device implementing this concept is the *p-i-n* photodiode, sketched in Figure 1 [9]. Its electric characteristic in dark is almost identical to that of a simple *p-n* junction diode; that is, the dependence of current *I* on applied voltage *V* obeys the Shockley equation

$$I = I_0\left(e^{V/V_T} - 1\right) \tag{1}$$

with V_T the threshold voltage and I_0 the saturation (reverse) current. When light of appropriate wavelength shines on the device, the photocarriers add up to the thermally generated ones to originate an extra current term flowing in the same direction as the reverse dark current, that is,

$$I = I_0\left(e^{V/V_T} - 1\right) - I_L \tag{2}$$

Typical current–voltage characteristics are plotted in Figure 2.

Due to the planar technology used to fabricate electronic devices in Si [10], the light to be detected enters the device through one of the doped layers. The intrinsic layer, sandwiched between the two oppositely doped ones providing the built-in electric field, is responsible for the light absorption and the transport of the photogenerated carriers. Therefore, in the spectral range of operation, the *i*-semiconductor must completely absorb the light in a limited thickness; at the same time it must exhibit high electronic quality to grant a sufficient drift-length for the generated carriers to reach the contacts before recombining. Absorption is nonvanishing if the material bandgap energy (cut-off energy) is lower than the energy of the photons to be absorbed; moreover, moving away from the cutoff, it increases more steeply in direct (e.g., GaAs) than in indirect (e.g., Si, Ge) bandgap semiconductors. From this point of view, the former ones are preferable. In choosing the best semiconductor for a given wavelength range, another important consideration is that, as explained above, photogenerated and dark currents add to one another and both originate shot noise [11] with power

Figure 2. Typical current–voltage characteristics of a *p-i-n* photodiode in the dark and under illumination.

spectral density proportional to the current intensity. Therefore, if sensitivity is a concern, care has to be taken to minimize the dark contribution. The latter, depending on the thermal carrier generation rate, decreases exponentially with the bandgap energy, suggesting the selection of bandgap values not much lower than the photon energies. This is further advantageous in order to prevent a too large absorption in the doped layer, where a lower electric field and poorer transport properties (than in the *i*-layer) would facilitate carrier loss by recombination. In Figure 3 we show the bandgap energy of various semiconductor crystals and alloys versus lattice parameter. Based on the preceding discussion, from Figure 3 it is apparent that suitable semiconductors for NIR detection are Ge, InGaAs, and InGaSb alloys, the latter two favored by a direct bandgap. Due to the commercial availability of InP substrates which are lattice-matched to InGaAs, InGaAs detectors are the most employed for the NIR.

To characterize NIR detectors, the most relevant and commonly used figures are their spectral range of operation, the responsivity, the dark current or the noise equivalent power, and the speed. The responsivity R_λ is measured in A/W and defined as the photocurrent generated per unity of impinging power at wavelength λ onto the device. It relates to the external quantum efficiency η_{ext}, that is, the number of electrons flowing in the circuit for each incident photon

Figure 1. The *p-i-n* photodiode: band structure and sketch.
Figure 3. The bandgap of various semiconductors as a function of the lattice parameter.

of wavelength λ:

$$R_\lambda = \eta_{\text{ext}} q \lambda / hc \tag{3}$$

with q the electron charge, h the Planck constant, and c the speed of light in vacuum. The external quantum efficiency is limited by the Fresnel reflection Θ_r at the photodiode surface, by the finite thickness d of the absorbing layer, and by the losses R due to recombination:

$$\eta_{\text{ext}} = (1 - R)(1 - \Theta_r)\left(1 - e^{-\alpha d}\right) \tag{4}$$

where α is the absorption coefficient. Owing to the dependence (3), the spectral responsivity typically increases with wavelength, up to the cutoff corresponding to the bandgap. At $\lambda = 1.24\ \mu\text{m}$, for a unity quantum efficiency, $R_\lambda = 1$ A/W.

The dark current, for the reasons outlined above, is orders of magnitude larger in InGaAs than in Si photodiodes. It is proportional to the device area for diameters larger than a few tens of microns, with densities J_d in the range 1–100 $\mu\text{A/cm}^2$. At smaller diameters, the leakage current (which scales with the perimeter rather than the area of the device) becomes dominant and the dark current density increases. Responsivity and dark current can be combined into the noise equivalent power (NEP) which, expressed in $\text{WHz}^{-1/2}$, is the optical power able to produce a current signal equal to the noise, for a unity bandwidth.

Finally, another important figure is the photodetector speed of response. The speed of a p-i-n photodiode is limited by two main mechanisms: the transit time and the RC time constant. The first is the time required by the photogenerated carriers to travel to the doped layers; it can be optimized by reducing the thickness of the intrinsic layer to the minimum required for complete absorption of the light, and by making the carriers move at the saturation velocity by increasing the electric field with an applied (reverse) bias. The second stems from the low pass characteristic of the load resistance (or feedback resistance when the detector is connected to a transimpedance preamplifier [12]) with the photodiode capacitance. Since the capacitance is proportional to the photodiode area, the speed can be increased by reducing the device size. InGaAs photodiodes for 40-Gb/s applications, for instance, have a diameter of about 10 μm [13].

1.2. Mid-Infrared Detectors

Going towards longer wavelengths (2–10 μm), semiconductors of progressively smaller bandgaps must be employed for infrared detection. Here, the most used material is the ternary II–VI alloy $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (or MCT). By increasing the Cd molar fraction (x), the bandgap energy of this compound can be varied from -0.14 ($x = 0$) to about 1.5 eV ($x = 1$) with only a 0.3% variation in lattice parameter [14]. This allows great flexibility in the fabrication of heterostructures where a wider bandgap material in one of the doped layers helps reduce absorption losses.

A more recent, and quite successful, approach to the realization of MIR detectors is based on *intra*band transitions (instead of *inter*band as in the previous paragraphs). In this case the absorption of a photon promotes a carrier (either an electron or a hole) from a bound state in a quantum well (QW) to the continuum, where it can drift away under an electric field (see Fig. 4) [15]. The barrier height from the bound state within the QW to the continuum, corresponding to the cutoff wavelength of the device, can be tailored by a careful design of the well width. Quantum-well infrared photodetectors (QWIPs) have been demonstrated using various semiconductor families: InGaAs/AlGaAs [16], InGaAs/InP [17], and GaAs/AlGaAs [18], the last being the most common thanks to technological maturity and despite short-wavelength limitations due to a relatively low band-offset. Advantages and disadvantages of QWIP versus MCT devices have been the subject of extensive investigations [19–24]. QWIPs with different cutoff wavelengths can be stacked on the same substrate to obtain multicolor detectors [25]; both MCT [26] and QWIP [27] focal plane arrays (FPAs) of detectors have been demonstrated and are used in commercial (rather expensive) cameras [28]. Due to the lack of an appropriate technology enabling the monolithical integration with electronics for pixel addressing and read-out, in these devices a Si read-out integrated circuit is often bump-bonded to the array [29]. Very recently, QWIPs have been suggested for THz detection at wavelengths longer than 30 μm [30].

Mid-infrared detector performance can be quantified again in terms of spectral responsivity, dark current (or NEP), and speed. However, in the MIR it is common practice to refer to the specific peak detectivity (D*), which is the NEP inverse normalized to the square root of the detector area. In this wavelength range an important contribution to shot noise comes from the photocurrent generated by background radiation (i.e., emitted by the "scene" at temperatures higher than 0 K). This contribution is unavoidable and limits the detector sensitivity. To reduce the shot noise stemming from the dark current and, eventually, reach the background-limited infrared performance (BLIP), MIR detectors are commonly operated at low temperatures. A widely used figure is the maximum temperature at which BLIP operation is attained.

1.3. SiGe: A Silicon-Compatible Alternative?

The monolithic integration of detectors (and FPAs) with Si electronics for amplification, I–V conversion, and processing of the photogenerated signal has been intensively pursued aiming at an increase in compactness, a reduction in costs, and an improvement in reliability [31, 32]. More
Figure 4. Schematic operation of a QWIP: photoexcitation of a carrier from a bound state (in a quantum well) to the continuum.

recently, the ultra-high speed required by optical communications and, at the same time, the lower cost sought for optical receivers in distributed FTTH (fiber-to-the-home) networks, have prompted extra efforts in this field [33]. Despite various interesting attempts (epitaxy [34,35], including the recent claim by Motorola [36], wafer fusion [37,38], wafer bonding [39–41]), however, the growth of III–V semiconductors on silicon has never reached the quality (in terms of defect density and reliability) required by optoelectronic devices. Moreover, even when detectors of reasonable performance have been integrated with silicon complementary metal-oxide-semiconductor (CMOS) electronics, the latter had to be fabricated using a modified process, thus giving up the advantages of a standardized technology [42].

Silicon-based MIR detection can be achieved with metal/semiconductor barrier detectors employing PtSi/Si or IrSi/Si Schottky junctions [43]. In such devices, free carriers in the silicide absorb infrared photons, thereby gaining the energy necessary to overcome the Schottky barrier, be injected in silicon, and drift under the electric field. In CMOS technology, silicides are often used to lower the resistance of the polycrystalline Si gates in MOS transistors; therefore, their compatibility with standard IC fabrication process is well established. Arrays of Schottky-barrier MIR detectors have been demonstrated and commercialized, despite the fact that their low quantum efficiency and limited spectral response (up to a few micrometers) cannot compare to MCTs in top-notch applications.

SiGe offers a valuable alternative to III–V, MCTs, and silicides for fabricating near- and mid-infrared detectors [44, 45]. The SiGe technology has gained a large popularity in recent years thanks to its success in heterojunction bipolar transistors (HBTs) [46, 47]. Si HBTs with a SiGe base outperform conventional homojunction bipolar transistors in terms of speed, reaching—or even exceeding—that of III–V devices; in addition, they can be seamlessly integrated with standard CMOS electronics to yield highly performing and dense integrated circuits. SiGe electronics is largely used in wideband circuitry with applications to wireless and optical communication systems [48].

SiGe, being a lower bandgap material than silicon, can extend the spectral responsivity of Si detectors to the NIR, while Si/SiGe heterostructures and QW can be used to detect the MIR. By choosing the appropriate molar fraction of Ge in a Si_xGe_{1-x} alloy, the bandgap can vary from that of silicon (1.16 eV; $x = 1$) to that of pure Ge (0.66 eV; $x = 0$). Unfortunately, contrary to MCTs, the full excursion from $x = 1$ to $x = 0$ implies a 4.2% change in the lattice parameter [49]. In the following section we review both the problems caused by such lattice mismatch in growing SiGe on Si and the methods to minimize or eliminate them.

2. THE GROWTH OF SiGe ON SILICON

Epitaxy, or the extension (i.e., thickening) of a crystal by growing on its surface layers replicating the substrate structure, has been a key in the development of microelectronics [50]. When the grown material differs from the substrate, the process is named "heteroepitaxy." Heteroepitaxy allows combination of materials with different electrical and optical properties in the same structure, thereby introducing a

great design flexibility. At the beginning of the microelectronics age, Shockley [51] and Kroemer [52] foresaw the enormous potential of heterojunction transistors. Later, the amazing physical properties of quantum wells and superlattices [53, 54] were exploited and mastered to improve existing devices (e.g., semiconductor lasers) or create completely new ones (quantum cascade devices [55], QWIPs [56]).

2.1. Films of SiGe

A successful heteroepitaxy relies on a substrate and a growing layer which share similar properties; in particular, they should exhibit the same crystalline structure and lattice parameter, as in the cases of AlGaAs deposited on GaAs or MCT on CdTe. Conversely, in the growth of pure Ge on Si (same crystalline structure but 4.2% difference in lattice parameter), the Ge layer tends to initially assume the Si lattice parameter, undergoing compression (tensile strain) in the growth plane (along the normal). This nonequilibrium persists until the elastic energy in the film builds up beyond threshold; the film eventually relaxes and its own lattice parameter is restored via the creation of dislocations [57]. These are line defects (see Fig. 5) which lay in the growth plane (misfit dislocations) as well as perpendicularly to it (threading dislocations); they act as scattering centers for the free carriers and introduce electronic states in the otherwise forbidden semiconductor bandgap [58], thus impairing its electronic quality. The maximum thickness which can be pseudomorphically (i.e., with the same lattice parameter of the substrate) grown is called critical thickness (h_c). For a SiGe alloy grown on silicon, the critical thickness is plotted in Figure 6 as a function of Ge content. It is apparent from Figure 6 that only a few monolayers of pure Ge can be pseudomorphically deposited on Si, larger thicknesses being allowed for lower Ge molar fractions. This limitation imposed by lattice mismatch has severe consequences in a number of applications. For NIR detectors, a high absorption is required in the range 1.3–1.55 μm; as shown in Figure 7, this can only be obtained at Ge fractions close or equal to 1. Even in this case, however, a reasonable efficiency with an absorption coefficient of about 10^4 cm^{-1} would require a thickness of a few micrometers (see Eq. (4)), well beyond the critical value [59–61].

A fundamental parameter for QW design is the conduction and valence band line-up at the Si/SiGe heterointerface. For strained SiGe films grown on unstrained Si, the alignment is of type I (Fig. 8a), with a larger barrier at
Figure 5. Schematic representation of a dislocation in a 2D lattice.
Figure 6. Critical layer thickness of SiGe grown on a silicon substrate as a function of Ge molar fraction.

the valence band discontinuity (Fig. 8b) up to a Ge concentration of about 60% [62–64]. The alignment changes to type II (Fig. 8a) for higher Ge molar fractions or when SiGe is grown on a strained Si layer (e.g., Si deposited on an entirely relaxed SiGe film).

Besides determining a critical thickness, the lattice mismatch affects the morphology of the grown layer. Epitaxy, in fact, can occur in three basic "growth modes": a two-dimensional or layer-by-layer mode ("Frank Van der Merwe"), a three-dimensional or island mode ("Volmer–Weber"), and a hybrid mode where islands grow on a few-monolayer-thick wetting layer ("Stransky–Krastanov") [65]. The latter is usually observed in the deposition of pure Ge (or high-Ge-fraction SiGe) on Si. A three-dimensional growth can give rise to strained/wavy layers [66] or islands [67].

SiGe layers are obtained by either molecular beam epitaxy (MBE) or ultra-high vacuum chemical vapor deposition (UHV-CVD). In MBE the substrate is heated in a vacuum chamber with pressure below 10^{-9} Torr. The materials to be deposited (grains or rods of Si and Ge in our case) are evaporated by electron beams and/or electric heaters, a shutter in front of the sources allows control of the molecular flux, and a piezoelectric balance monitors the film thick-
Figure 7. Absorption coefficients of bulk SiGe alloys versus wavelength. Data from [60] for pure Si and Ge, [61] for 20, 50, and 75% Ge, and [62] for 87, 91.5, and 97.5% Ge.
Figure 8. (a) Band alignment for type I and II heterostructures. (b) Conduction- and valence-band offsets at the SiGe/Si heterointerface versus Ge molar fraction in the alloy. We refer to strained SiGe on Si.

ness. Additionally, reflection high-energy electron diffraction (RHEED) is often available to monitor the crystallinity of the growing layer. MBE allows a very tight control of film growth, down to the atomic layer scale; for this reason, it is preferred whenever sharp and abrupt interfaces are needed, as in QW fabrication. On the other hand, UHV-CVD, being capable of processing a large batch of wafers in parallel, is best suited for large-scale production. In the case of CVD, the film precursors are in a gaseous state (typically SiH_4-silane and GeH_4-germane for SiGe) and are thermally decomposed. Two regimes are possible: a low-temperature regime in which the growth is limited by the reaction rate, and a high-temperature one dominated by the transport of chemical species (either precursors or reaction by-products) in the gas.

2.2. Relaxed Films of Pure Ge

As discussed above, the growth of thick pure-Ge films for the active layer in NIR detectors is hindered by the large lattice mismatch with Si. The direct growth of Ge-rich alloys with molar fraction exceeding 30% (corresponding to a lattice mismatch larger than 1%) yields films with threading dislocation densities exceeding 10^{11} cm^{-2} [68]. This figure must be compared with a maximum tolerable density of about 10^3 cm^{-2} for minority carrier devices (such as bipolar transistors, where a long diffusion length is a major requirement), or about 10^6 cm^{-2} for majority carrier devices (such as MOSFETs, which mainly suffer from mobility depression induced by defects). Various approaches have been developed to minimize the defect density in Ge films: the use of

gradual buffers, the incorporation of carbon, and the deposition of a low-temperature buffer.

2.2.1. Gradual Buffers

A slow, gradual transition in lattice constant from Si substrate to Ge reduces the strain accumulated in the film by a continuous nucleation of dislocations. The density of threading dislocations can be estimated to be much lower in presence of this gradual buffer than in the case of an abrupt change of the lattice parameter [69]. The process begins with the deposition of a low-Ge-content SiGe layer up to the thickness needed to achieve complete relaxation. Then the Ge percentage is raised to retrieve the same lattice mismatch. The cycle is repeated until the Ge content is 100%. Based on this idea, digital (i.e., stepwise) and linearly graded buffers have been attempted. Despite some initial failure [70], the advantages of such an approach were clearly demonstrated by Fitzgerald et al. using MBE [71, 72]. Their work outlined the importance of a complete relaxation at each stage in the realization of the gradual buffer, such that the strain is always low due to the small lattice mismatch between two successive steps. Record-low dislocation densities of $4.4 \cdot 10^5$, $1.7 \cdot 10^6$, and $3 \cdot 10^6$ cm^{-2} were obtained for Ge percentages of 23, 32, and 50% in the resulting film, respectively. This technique was applied to the CVD growth of pure-Ge films with the addition of chemimechanical polishing (CMP) at a 50% Ge concentration [73]. CMP is standard in planarizing wafer surfaces during IC fabrication; the wafer is pressed and spun over a velvet pad with an abrasive slurry in solution with chemical etchants [74]. The grading rates were 10 and 5% Ge/μm and the resulting buffers were 10 and 20 μm thick, respectively [73]. The threading dislocations in the Ge layer (of thickness 1.5 to 3 μm) had a density of about $2 \cdot 10^6$ cm^{-2}, an order of magnitude smaller than in samples without CMP. Two other groups have tried to grow Ge-rich alloys with the graded buffer approach; LeGoues et al. obtained similar results with step graded buffers, sometimes combined with linear grading [68]. Presting et al. grew Si$_m$Ge$_m$ short-period superlattices on a buffer graded up to 50% [75, 76]. Another technique often used in conjunction with graded buffers consists in the use of surface-active species (surfactants) [77]. The role of surfactants, deposited on the substrate before film growth, is that of reducing the surface free energy. This entails the successive atoms to accommodate on a bidimensional film instead of piling up into islands. Remarkable results have been obtained by Liu et al., who fabricated a 0.3-μm-thick, Si$_{0.5}$Ge$_{0.5}$ layer with $1.5 \cdot 10^4$ cm^{-2} threading dislocation density on a 25% Ge/μm graded buffer and a single layer of Sb [78]. Antimony, as well as other group-V elements used as surfactants, tends to be partially incorporated in the growing film, thus resulting in an undesired n-type doping [79]. A valid alternative, both in MBE and CVD, is the use of hydrogen [80–82]. Despite the encouraging results, however, the use of graded layers is not completely adequate for industrial processing, due to the long times required and the resulting thick (tens of micrometers) structure, the latter hindering a seamless integration of the detector (to be fabricated on the buffer) with standard MOS devices.

2.2.2. SiGeC Alloys

Carbon can be incorporated into SiGe to change its lattice parameter and obtain a better match to the substrate [83, 84]. The ternary compound Si$_{1-x-y}$Ge$_x$C$_y$ has a lattice constant given by the Vegard law:

$$a_{\mathrm{Si}_{1-x-y}\mathrm{Ge}_x\mathrm{C}_y} = a_{\mathrm{Si}} + (a_{\mathrm{Ge}} - a_{\mathrm{Si}})x + (a_{\mathrm{C}} - a_{\mathrm{Si}})y \qquad (5)$$

with $a_{\mathrm{Si}} = 5.43$, $a_{\mathrm{Ge}} = 5.64$, and $a_{\mathrm{C}} = 3.56$ Å. For a given Ge percentage, from (5) one can calculate the amount of carbon needed for an alloy constant as in Si. Unfortunately, carbon does not only reduce the lattice parameter, but widens the bandgap, thus counteracting the Ge-induced reduction. Nevertheless, this by-phenomenon is not as effective as the lowering of lattice constant, and carbon incorporation can be used either to reduce the stress in the film maintaining the same bandgap, or to lower the bandgap at a constant stress [85]. Threading dislocation densities of 10^5 cm^{-2} have been measured in films with up to 30% Ge [86]. When its concentration in SiGeC films exceeds 4%, however, carbon tends to precipitate by forming SiC [87]. This hampers its use in the growth of high Ge-content alloys: from (5), in fact, a $>5\%$ carbon concentration is required to compensate the lattice mismatch with Si when the Ge molar faction reaches 50%.

2.2.3. Low-Temperature Buffers

The direct deposition of pure Ge on silicon results in islands: after a few atomic layers, Ge atoms find it energywise more convenient to pile up and build three-dimensional structures on the surface (Stransky–Krastanov growth). However, if the substrate temperature is low enough (typically below 400 °C) to slow down the diffusion of precursors on the surface, a layer-by-layer growth can be achieved [88]. The latter is favored in CVD due to the presence of hydrogen as a surfactant [89]. Under such conditions, the deposition of a few tens of nanometers of pure Ge on Si results in a flat, completely relaxed film where stress has been released by dislocations. The realization of a thin buffer, however, is time consuming due to the low deposition rates at moderate temperatures. Nevertheless, once the buffer reaches the thickness required for complete relaxation, the temperature can be raised to the usual values (∼600 °C) and the growth can proceed at higher rates (above 10 nm/min) as in homoepitaxy. Such an approach was proposed by Colace et al., who demonstrated a material quality well suited for sensitive and fast metal-semiconductor-metal Ge-on-Si NIR photodiodes [90]. Later, the same technique was adopted by Luan et al., with the addition of a postgrowth cyclic thermal annealing [91]. The latter was very effective in further reducing the dislocation density from $9.5 \pm 0.4 \cdot 10^8$ cm^{-2} (in as-grown films) to $7.9 \pm 0.6 \cdot 10^7$ and $5.2 \pm 0.6 \cdot 10^7$ cm^{-2} after one and 10 thermal cycles between 900 and 100 °C, respectively. Thermal cycling, causing stress through the mismatch between Si and Ge expansion coefficients, enhances the drift of dislocations and thereby their probability to collide and annihilate [92, 93]. If Ge is deposited on a patterned substrate (e.g., oxidized silicon with small windows opened in the SiO$_2$), the dislocation density can be further reduced

to the extent that several small (10×10 μm^2) dislocation-free mesas exist. In this case, the mesa sidewalls act as sinkholes and allow dislocation to disappear upon reaching them [84]. As a final remark, it should be noted that the determination of dislocation densities can be affected by large errors due to the limited field of view in cross-section images by transmission electron microscopy (TEM). To alleviate this problem, Luan et al. combined two different techniques: TEM analysis and etch-pit density count (EPD) [94]. The latter consists in counting the threads in a plane-view SEM or TEM picture, after etching with a selective solution (CH$_3$COOH: 67 ml, HNO$_3$: 20 ml, HF: 10 ml, and I$_2$: 30 mg) acting faster near the defects [94].

2.3. Films of Polycrystalline Ge

The problems with the substrate/film mismatch can be avoided if the film is nonepitaxial: a polycrystalline film, while consisting of a material with inferior electronic quality, can be obtained at low temperatures, increasing the compatibility of the process with standard silicon technology. Polycrystalline SiGe, with Ge molar fraction lower than 60%, was proposed as an appealing alternative to polycrystalline Si in various integrated electronics components, among them the gate electrodes in CMOS transistors [95], and the active layer of thin-film transistors for liquid-crystal displays [96]. Poly-SiGe requires temperatures lower than poly-Si and exhibits higher conductivity and grain size. Poly-Ge was suggested as a buffer for the growth of GaAs (with nearly the same lattice parameter of Ge) on inexpensive substrates (glass) for solar cell applications [97]. Ge can be deposited in polycrystallites by evaporation at temperatures as low as 300 °C in a vacuum with base pressure of about 10^{-7} Torr [98]. Raman spectroscopy proves that amorphous and polycrystalline (poly-Ge) phases are obtained below and above about 250 °C, respectively [99].

3. NEAR-INFRARED DETECTORS AND ARRAYS

3.1. SiGe-Based Detectors

3.1.1. Waveguide Detectors

Due to the low absorption afforded by SiGe alloys at the wavelengths of interest (1.3 and 1.55 μm), a guided-wave configuration is to be preferred for detectors based on this material. For an adequate sensitivity under normal incidence, in fact, the thickness d of the active layer must exceed the absorption length (the inverse of the absorption coefficient α) to ensure efficient collection of incident photons, and be shorter than the drift length (the product of saturation velocity and free carrier lifetime) to avoid recombination losses. Conversely, in waveguide detectors, the light propagates and gets absorbed along a direction perpendicular to the path of photogenerated carriers (see Fig. 9), the latter being entirely collected in a properly designed active thickness. On the other hand, the device must be longer than the absorption length, and this can result in speed limitations owing to the detector capacitance. Waveguides can be integrated on silicon with various approaches: NIR
Figure 9. Sketch of normal incidence (left) and guided-wave photodetectors (right). Absorption and collection lengths are defined along parallel or orthogonal directions in the two cases, respectively. Black (white) circles represent electrons (holes), and incident photons are pictured as wormlike arrows.

light can be confined in the overlayer of silicon-on-insulator (SOI) wafers [100], or by way of a doping-induced refractive index increase in Si [101], or alloying Si with Ge [102]; moreover, silica or Si-nitride [103, 104] waveguides can be fabricated on silicon substrates using standard IC technologies. Among the above, SOI and nitride approaches are the most promising. SiGe waveguide detectors were first demonstrated in 1986 by Temkin et al [105]. A coherently strained Ge$_x$Si$_{1-x}$/Si superlattice (SLS), as in [106], was embedded in a *p-n* junction and became the active medium of the detectors, fabricated with various Ge fractions in it. Larger Ge contents resulted in a photoresponse extended towards longer wavelengths, the sample with 60% Ge showing a maximum external quantum efficiency of 10.2% at 1.3 μm, a dark current of 7.1 mA/cm^2, and a fast response of 312 ps for a reverse bias of 10 V. As expected from the drop in SiGe absorption, however, the photoresponse at 1.55 μm was much lower. This first achievement spurred a substantial interest, and was followed by several results in Europe and the United States. In [107] the device consisted of a *p*-type 2.5-μm-thick Si$_{0.98}$Ge$_{0.02}$ waveguide with a 5-μm-wide rib for lateral confinement, and the NIR sensitive region was made of 20 periods of 5-nm-thick Si$_{0.55}$Ge$_{0.45}$ quantum wells separated by 30-nm Si spacers. The detector was grown on top of the waveguide, with light reaching it through the higher refractive index of the active region. A maximum external quantum efficiency of 11% was measured at 1.282 μm and a reverse bias of 7 V, while the best dark current (at the same bias but for a shorter device with about 70% lower efficiency) was 1 mA/cm^2. The speed was investigated in both time and frequency domains measuring the response to a light step with a fast oscilloscope and a microwave network analyzer. The latter provided the "small signal" transfer function with a bandwidth well in the GHz range, while the former allowed to measure a 50-ns long-lasting photocurrent tail. The latter is usually associated to traps and results in a time-drift of the diode operating point and in a shrinkage of the eye-diagram at the receiver. Similar performances (1.32 μm external quantum efficiency of 7% and dark current of 2.7 mA/cm^2 at 14 V reverse bias) were demonstrated in [108] with a multiple quantum well with a 71% Ge content (in the alloy used for the wells). Wide open eye-diagrams were reported detecting 0.5- and 1.5-Gb/s pseudorandom

nonreturn to zero (NRZ) signals. The best performances of a SiGe-strained layer waveguide photodetector were theoretically explored in [109]. A number of constraints were accounted for in the simulation, among them, a maximum 60% molar Ge (to avoid ultrathin films), a 1-mm waveguide length, and a 10-μm width. The external efficiency included the Fresnel reflection at the fiber–waveguide interface, the modal mismatch, and the overlap between the guided mode and the absorbing region. By referring to two different models for the critical thickness, namely Dodson–Tsao [110] and People–Bean [111], efficiencies as high as 13 and 16%, respectively, were calculated for a (realistic) 1-μm thickness limit. It should be stressed that, when adopting the People–Bean model, the most important loss contribution is the fiber-to-waveguide coupling: neglecting it, a 60% quantum efficiency can be expected. This clearly suggests the need to use optimized waveguide couplers, rather than the commonly employed end-fire.

3.1.2. Normal Incidence Detectors

A few attempts have been made to fabricate normal-incidence photodiodes based on strained SiGe. Reference [112] describes a device employing a 500-nm SLS with 10-nm-thick wells of $Si_{0.5}Ge_{0.5}$ in a *p-i-n* structure. The detector was antireflection coated to optimize light in-coupling at 1.3 μm, and the external quantum efficiency was 1% for a reverse bias of 4 V, although a further increase was reported at voltages close to 20 V (breakdown). The dark current density was 3 mA/cm^2 (at 4 V), comparable to similar devices based on SiGe. More recently, undulating, Ge-rich SiGe multilayers have extended the spectral response towards 1.55 μm [113, 114]. A vertical MSM structure with a buried $CoSi_2$ bottom contact exhibited quantum efficiencies of 5.2% at 1.3 μm and 1% at 1.55 μm, respectively.

3.1.3. Avalanche Detectors

Aiming at an enhancement of the sensitivity of SiGe detectors, avalanche photodiodes (APDs) have been designed and demonstrated, as well. APDs are appealing for optical communications, since their large gain (easily in excess of 10^3) can eliminate the need for front-end amplifiers and the related noise. Moreover, owing to the large field applied to induce avalanche multiplication, they are also fast. In terms of excess noise produced by carrier multiplication, APDs perform better if the avalanche is promoted by only one type of photocarriers; for example, if electrons' and holes' ionization coefficients are very different from one another [115, 116]. Silicon is well suited for APDs, with a ratio between electrons' (α_n) and holes' (α_p) ionization coefficients varying from 5 to 500 (depending on the electric field). Such ratio is lower than 2 in bulk germanium. The dependence of the ionization coefficients on the percentage of Ge in a SiGe alloy on Si has been investigated in [117]. In this work, strongly absorbed light was shined on either the *p*- or the *n*-side of a SiGe *p-i-n* diode, thus originating a single-carrier current in the intrinsic layer: electrons for absorption near the *p*-layer and holes near the *n*-layer. A ratio α_n/α_p ranging from 10 to 0.75 was estimated for Ge percentages from 0 to 100% with an electric field of 330 KV/cm.

The good noise characteristic of Si can be combined with the nonvanishing NIR absorption of SiGe in "separate absorption and multiplication" APDs (SAM-APD): a relatively low-field region (lower than needed to start avalanche) where absorption occurs is adjacent to a Si high-field region devoted to photocarriers multiplication. SAM-APDs were first fabricated with III–V semiconductors [118] and later designed [119] and demonstrated [120] using SiGe-on-Si. As in the previous case, the SiGe SAM-APD was realized in a waveguide configuration and exhibited a maximum responsivity of 1.1 A/W at 1.3 μm when biased at about 30 V. Soon after, the same team reported an optimized SAM-APD [121] with a responsivity of 4 A/W at 1.3 μm and 30 V, and a 100-ps response. In terms of receiver sensitivity, that is, the minimum optical power required at the output of the fiber to grant a bit error rate (BER) better than 10^{-9} [122], the SAM-APD above yielded −29.4 dBm at a data rate of 800 Mb/s, comparable to commercial InGaAs *p-i-n* detectors [123].

3.1.4. Photoconductive Detectors

A different approach to obtain photocurrent gain in a semiconductor device is the use of photoconductivity [124]. Photoconductivity can be observed both in a semiconductor with ohmic contacts and in forward biased *p-n* junctions: conductivity is enhanced due to photon absorption and the related increase of free carrier density in conduction and valence bands. Since electrons and holes are swept at different speeds by the electric field in the semiconductor, however, a net charge builds up. Assuming that electrons move much faster than holes (i.e., the drift time τ_e for electrons is much lower than τ_h for holes), the semiconductor will remain positively charged. To reestablish charge neutrality, extra electrons are injected by the contact and so provide a "secondary" current. Therefore, from a single photon, several photocarriers contribute to the current and a net gain is obtained. The photoconductive gain is given by the ratio between the drift times

$$G_{ph} = \frac{\tau_h}{\tau_e} \tag{6}$$

It can be much larger than unity due to the presence of traps, which can slow down the motion of the holes. Despite the high achievable gain, however, photoconductors exhibit a lower sensitivity than photodiodes. Dark current densities in these devices and the associated shot noise are, indeed, typically much larger owing to the lack of injection barriers at the contacts. The speed is limited by the turn-off time, that is, the time required to sweep all the slower carriers (holes in our example) out of the active region. To increase the speed, it is therefore preferable to reduce τ_h, although this reduces the gain. A SiGe SLS waveguide detector operating in the photoconductive mode is described in [125], where the large difference in drift times was attributed to hole trapping in the wells. The sensitivity at 1.3 μm was about −16 dBm at 180 Mb/s.

3.1.5. SiGeC Detectors

Carbon was incorporated in a NIR detector to compensate for the lattice mismatch due to Ge in a SiGe alloy, in 1996 [126]. The active region of this normal-incidence *p-i-n*

diode was an 80-nm-thick $Si_{0.25}Ge_{0.6}C_{0.15}$ alloy. But, despite the use of carbon, this first device exhibited a quantum efficiency of only 1% at 1.3 μm, with a large dark current of 7 mA/cm^2 at 0.5 V reverse bias. Slightly better results were obtained by the same team using a waveguide [127], yielding 8 and 0.2% external quantum efficiencies at 1.3 and 1.55 μm, respectively, for a reverse bias of just 0.3 V. The dark current density was 4 mA/cm^2. Two years later, in order to raise the absorption in the active area, a normal-incidence detector was fabricated based on pure-GeC alloy [128]. Various C compositions from 0 up to 2% (due to the poor solid solubility of C in Ge: 10^8 atoms/cm^3) were attempted, well below the near 10% molar fraction required to compensate the lattice mismatch between pure Ge and Si. The films ended up being undercompensated and with a high (10^{10} cm^{-2}) dislocation density. The device exhibited a dark current in the mA/cm^2 range with responsivity extending up to 1.55 μm and a maximum of 35 mA/W at 1.3 μm.

3.2. Pure-Ge-on-Si Detectors

Ge detectors on Si were first grown in the 1960s by Milnes and co-workers [129, 130]. They exhibited an extended photoresponse in the near-infrared, with characteristics strongly affected by the large amount of defects at the Si/Ge heterointerface. It was only after two decades, in 1984, that Luryi et al. reported on graded buffers for the growth of Ge on Si [131]. Their *p-i-n* diode exhibited a 40% quantum efficiency at 1.3 μm; regretfully, the significant dislocation density resulted in a dark current larger than 50 mA/cm^2. To this extent, using a superlattice embedded in the buffer layer, the same group managed to reduce the defect density and the dark current [132], but at the expense of a smaller 3% quantum efficiency (at 1.3 μm). Research in pure-Ge detectors was therefore at stake compared to strained SiGe alloys and superlattices until 1994 when, in an effort to produce sensitive devices with a spectral coverage including the third window of optical communications (1.55 μm), Sutter et al. realized an MBE-grown Ge-on-Si *p-i-n* photodiode [133]. To minimize the dislocation count in the unavoidably relaxed thick Ge, a 50-nm-thick Ge buffer was deposited at a relatively low temperature (420 °C) and rate (0.1 nm/s) to prevent the formation of islands, while maintaining good crystalline quality. The devices underwent annealing steps at 700 °C before the lithographic processes for the definition of the mesas and the metallization. The dark current was still large (51 mA/cm^2), but the response extended to 1.6 μm with a peak 43% external quantum efficiency at 1.55 μm. Four years later, Samavedam et al. realized a *p-n* Ge photodiode on a graded buffer with a CMP step at an intermediate $Si_{0.5}Ge_{0.5}$ composition [134]. This device, despite the limited responsivity of 133 mA/W at 1.3 μm due to the thinness (240 nm) of the absorbing layer, exhibited a record low dark current of 0.2 mA/cm^2 thanks to the high quality of the epitaxial layer. Contemporarily and independently, Colace et al. introduced the concept of a low-temperature buffer in the CVD growth of Ge on Si [135, 136]. Metal-semiconductor-metal detectors fabricated using the latter approach provided high quantum efficiencies at both 1.3 and 1.55 μm and response times of 2.2 ns, but the incomplete rectification at the Ag/Ge contacts of the interdigitated structure resulted in large dark currents. Substantial improvements were brought about by complementing the low-temperature buffer with the introduction of postgrowth annealing steps in a *p-i-n* structure [137–140]. This allowed to reach high responsivities of 0.89 and 0.75 A/W at 1.3 and 1.55 μm, respectively, pulse responses shorter than 200 ps at 1.3 μm [141], and dark currents as low as 15 mA/cm^2 at 1 V (reverse bias).

3.3. Polycrystalline Ge Detectors and Arrays

The main advantage offered by SiGe with respect to III–V semiconductors is the integrability of detectors with standard silicon CMOS electronics. The relatively high temperatures used for the epitaxy of Ge-rich SiGe on Si, and the cleaning procedures required by high-quality "epi-ready" surfaces, however, impose to insert the Ge growth after the realization of the MOS oxide and before the deposition of the first metal contact. This would alter the standard CMOS process, thus resulting in impracticalities in silicon IC foundries. To alleviate this problem, the detectors have to be realized with a process conducted at a low temperature and less dependent on surface preparation, such that it can be performed at the very end of the IC fabrication, just before chip dicing and packaging. Polycrystalline Ge appears as one such viable solution and has been actively pursued by us [142]. Mesa poly-Ge on Si heterojunction photodiodes have been demonstrated [142] with a responsivity of 16 mA/W at 1.3 μm, fast (650 ps) pulse response, and low dark current (1 mA/cm^2 at 1 V reverse bias). A few functional devices have also been obtained in poly-Ge on Si: a linear detector array (16 pixels) [143], a wavemeter encompassing a set of photodiodes with different spectral responses [144, 145], a detector integrated onto a SOI waveguide [146]. More recently, the effective compatibility of poly-Ge deposition with standard IC technology has been demonstrated by integrating an 8-pixel array with the addressing/amplifying electronics in standard—2 μm—CMOS technology [147]. While the low responsivity remains the main problem of this approach, its simplicity and prospective low cost qualify it as one of the most promising candidates for future exploitation in consumer-oriented commercial devices.

In Table 1, a synoptic view of the most relevant SiGe-on-Si-based detectors for the NIR is reported.

4. MID-INFRARED DETECTORS AND ARRAYS

4.1. SiGe QWIPs

SiGe quantum wells for MIR photodetectors were first proposed in 1998 by Yang et al. [148, 149]. They investigated the advantages of an indirect-gap semiconductor QW for normal-incidence absorption of infrared light through inter-subband transitions. In direct-gap semiconductor QWIPs with an isotropic band structure at the Γ point, in fact, inter-subband transitions are forbidden at normal incidence, that is, when the electric field of the incident light is parallel to the walls of the quantum well. To be efficiently detected, then, the light must couple at a nonzero angle with the normal, as actually done by means of diffraction gratings [150].

Table 1. Synoptic view of SiGe on Si detectors for the near-infrared.

Material/deposition technique	Device structure	Responsivity, quantum efficiency	Speed	Dark current density	Ref.
SiGe/MBE	waveguide, p-n	10.2% @ 1.3 μm	312 ps	7.1 mA/cm^2	[105]
SiGe/MBE	waveguide, p-i-n	11% @ 1.28 μm	400 ps	1 mA/cm^2	[107]
SiGe/CVD	waveguide, p-i-n	7% @ 1.3 μm	1.5 Gb/s	2.7 mA/cm^2	[108]
SiGe/MBE	p-i-n	1% @ 1.3 μm		3 mA/cm^2	[112]
SiGe/MBE	m-s-m	5.2% @ 1.3 μm, 1% @ 1.55 μm			[114]
SiGe/MBE	waveguide SAM-APD	4 A/W @ 1.3 μm	100 ps		[121]
SiGeC/MBE	waveguide, p-i-n	8% @ 1.3 μm, 0.2% @ 1.55 μm		4 mA/cm^2	[127]
SiGeC/MBE	p-i-n	35 mA/W @ 1.3 μm			[128]
Ge/MBE	p-i-n	40% @ 1.3 μm		50 mA/cm^2	[131]
Ge/MBE	p-i-n	43% @ 1.3 μm		51 mA/cm^2	[133]
Ge/CVD	p-n	133 mA/W @ 1.3 μm		0.2 mA/cm^2	[134]
Ge/CVD	m-s-m	240 mA/W @ 1.3 μm	2 ns		[135]
Ge/CVD	p-i-n	0.89 A/W @ 1.3 μm, 0.75 A/W @ 1.55 μm	200 ps	15 mA/cm^2	[140]
poly-Ge/PVD	p-n (heterojunction)	16 mA/W @ 1.3 μm	600 ps	1 mA/cm^2	[142]
poly-Ge/PVD	waveguide, p-n (heterojunction)	8 mA/W @ 1.3 μm		0.8 mA/cm^2	[146]
poly-Ge/PVD	8 pixel array integrated on a standard IC	43 V/W @ 1.3 μm		1 mA/cm^2	[147]

Conversely, using Si or Ge, owing to the anisotropy of their effective mass tensor and, therefore, to the possibility of carrier acceleration perpendicular to the electric field, the absorption of normally incident photons is nonvanishing. This consideration, and the forthcoming integration of detectors with readout electronics on a single chip, has stimulated the investigation of SiGe QWIPs. While the first theoretical studies, in route with the understanding developed for III–Vs, focused on the use of conduction-band QWs [151–153], the control of the valence-band line-up between strained SiGe and Si has steered the research towards the use of holes rather than electrons. The use of strained Si (111) grown on relaxed SiGe layers was suggested in [154]. Despite the calculations, however, no related experimental results are available yet. In 1990 Lin et al. successfully fabricated the first SiGe-based MIR detectors [155, 156]. They departed from standard intraband transitions in QWIPs, exploiting photon-induced emission of holes from a heavily doped SiGe epilayer into the Si substrate at the heterointerface. For this reason these so-called heterojunction internal photoemission (HIP) detectors exhibited quantum efficiencies around 1% for wavelengths from 2 to 10 μm, with 30% Ge in the 40-nm-thick SiGe layer. Tailoring of the spectral response was also demonstrated by lifting the valence-band barrier through an increase of the Ge molar fraction from 20 to 40%. Following these results, a 400 × 400 focal plane array of HIP detectors was demonstrated, each pixel (28 × 28 μm^2) consisting of a Ge$_{0.44}$Si$_{0.56}$/Si heterojunction with an MOS transistor used as a transfer gate [157, 158]. In this array the photogenerated charges moved to the chip periphery through a charge coupled device (CCD), and a good image quality was obtained at 53 K (nominal temperature) in both LWIR and MWIR bands.

The devices described above were fabricated by MBE, and the degenerate p-doping of the SiGe layer, required to get a large hole density and a large free carrier absorption, was obtained by co-evaporating HBO$_2$. While the latter helped the deposition (HBO$_2$ has a relatively high vapor pressure), the high substrate temperature needed to initiate the reaction with silicon facilitated SiGe relaxation and, additionally, let oxygen from HBO$_2$ incorporate in the film. Both such effects lower the electronic quality of the SiGe layer. An alternative approach based on elemental boron is discussed in [159]: the authors largely improved the material quality at comparable doping levels (2 × 10^{20} cm^{-3}), which resulted in smaller dark currents of 50 μA/cm^2 at 38 K. A model explaining the photocurrent spectra exhibited by such a device can be found in [160]. Elemental boron for doping the SiGe layer in HIP detectors was also reported in [161], where the authors introduced an undoped SiGe spacer to improve the SiGe/Si heterointerface. The first truly SiGe-based QWIP was demonstrated by Karunasiri et al. in 1991 [162, 163]. The absorbing layer consisted of 50 periods of 3 nm-thick Si$_{0.85}$Ge$_{0.15}$ wells p-doped at 10^{19} cm^{-3} and separated by 50-nm-thick Si barriers. The SiGe composition and well thickness were adjusted to obtain a single energy level separated by about 120 meV from the extended states, thus providing an absorption peak close to 10 μm. The device exhibited high responsivities both for light coupling through a facet at a 45° angle with the surface (D* = 10^9 cmHz$^{1/2}$/W at 77 K) and at normal incidence [164]. By increasing the Ge in the QW, these authors also demonstrated a shift of the photoresponse peak to shorter wavelengths (2 and 3 μm for 60 and 30% Ge, respectively) [165]. Longer-wavelength QWIP operation with broadband response from 8 to 14 μm was demonstrated by People et al. with a

10-period, 4-nm-thick $Ge_{0.25}Si_{0.75}$ MQW [166]. The spectral response measured at 77 K showed three broad peaks centered at 8.2, 10.8, and 13 μm, respectively. In 1986 a detector with spectral response peaked at 5 μm and a background limited performance maintained up to 85 K was demonstrated [167]. In recent years, a systematic attempt to optimize SiGe MIR photodetectors has been carried out, testing a number of single and multiple QW structures [168, 169], and introducing some novel concepts [170]. In particular, the important role of the doping setback layer (i.e., the undoped SiGe layer at the Si/SiGe interface) in reducing the dark current, and, therefore, improving the detectivity has been outlined. Moreover, a gradient in the doping and in the Ge content of the SiGe layer was implemented to ease the photocarrier drift towards the heterointerface.

While free carrier absorption is commonly considered the excitation mechanism in p-type SiGe HIPs, the origin of the strong normal-incidence photoresponse of p-type SiGe QWIPs is quite debated. In [167], based on the theoretical work by Chang and James [171], researchers attributed the observed 8.2-μm response peak to inter-subband transitions from heavy hole 1 (HH1) to heavy hole 2 (HH2) levels, normally forbidden for normal-incidence light [172]. The second peak at 10.8 μm, instead, was associated to intervalence transitions between HH1 and the split-off band (SO) [173]. On the other hand, free carrier absorption was recognized as the fundamental excitation mechanism in p-type SiGe QWIPs by Robbins et al. [174], Strong et al. [175–177], and Corbin et al. [178]. In [179], a detailed comparison was carried out between absorption and photocurrent spectra of similar structures for different polarizations of the incoming light. A close-to-ideal agreement was found between the measured absorption spectra and the predictions of a model accounting for intervalence and inter-subband transitions with appropriate selection rules. The photocurrent spectra, conversely, gave a larger-than-expected contribution for light polarized in the quantum well plane. This was ascribed to a transport efficiency (and, therefore, photoconductive gain) higher in the light hole (LH) and SO (states excited by normal-incidence light) than in the HH2 band.

4.2. Quantum Dot Detectors

Zero-dimensional structures or *quantum dots* have been proposed to overcome the main limitation of conduction-band III–V QWIPs, namely the lack of photoresponse at normal incidence. In a classical view, in fact, light with electric field polarized in the growth plane can accelerate a carrier in a quantum dot, thus allowing its injection in the surrounding semiconductor. The same is not possible in conduction-band QWs, since an acceleration perpendicular to the barriers (i.e., a field polarization perpendicular to the growth plane) is required. In addition, reduced phonon scattering is expected in quantum dots compared to quantum wells, with an increased probability of photocarrier emission before relaxation to the ground state [180]. Several quantum dot IR photodetectors (QDIP) have been already demonstrated based on III–V semiconductors [181–184], and Ge-on-Si QDIPs have been introduced [185]. These encompass an active region realized as a multiple stack of layers of Ge islands interleaved with silicon spacers. The Ge is p-type

doped through co-evaporation of boron, and the average island-size ranges from 7.5 (height) $\times$ 75 nm (width) with a surface density of 4.4×10^9 cm^{-2} [186] to 1.5×15 nm with density 3×10^{11} cm^{-2} [187]. Photoresponse at normal incidence has been demonstrated in the mid-infrared [188], with detectivity peaking near 20 μm (1.7×10^8 cm Hz$^{1/2}$/W) and 9 μm (7×10^7 cm Hz$^{1/2}$/W) at room temperature.

5. CONCLUSIONS

Near- and mid-infrared light detectors with Ge and SiGe compounds on silicon are challenging III–V and II–VI based devices in a number of applications, from optical communications to remote sensing. High responsivity, detectivity, and speed have been demonstrated in different wavelength ranges and temperatures. Different approaches have been proposed and investigated to get rid of the lattice mismatch existing between SiGe and Si. Thanks to a mature and well-mastered fabrication technology, new devices based on nanoscale Ge islands grown on silicon are entering the arena. The integrability of these devices and standard silicon electronics into functional microsystems appears to be the fundamental advantage of SiGe, SiGeC, Ge, and poly-Ge, and is expected to drive research and development of such technology towards affordable and reliable components for the consumer market.

GLOSSARY

Bandgap The range of energy levels forbidden to electrons in the band structure of a semiconductor.

Mid-infrared (MIR) Light of wavelength in the spectral range from 2 to 10 μm.

Near-infrared (NIR) Light of wavelength in the spectral range from 700 mm to 2 μm.

Photodetector Electronic device used to transform a light-wave signal into an electrical one usually proportional to the power of the former.

Quantum well (QW) A potential well in a semiconductor heterostructure whose small thickness induces quantization of the allowed levels for electrons.

Giant Magnetoresistance in Cobalt-Based Multilayers

D. H. Mosca, D. K. Lottis

Departamento de Física–UFPR, 81531-990 Curitiba PR, Brazil

CONTENTS

1. INTRODUCTION

Co-based multilayers with nanometer spacings exhibit a wide range of fascinating phenomena, such as quantum well states, oscillatory magnetic coupling, and giant magnetoresistance (GMR). The presence of these phenomena in Co-based multilayered structures has led to extensive studies and wide use in various applications due to their high magnetoresistance effect at room temperature and moderate saturation fields. The most important of these is their use in magnetoresistive readout heads in the latest generation of high-density recording heads for the computer industry. Technological applications of GMR devices also include switching and logic elements as well as memory devices. The ensemble of revolutionary ideas and technology was initially termed magnetoelectronics [1], but currently the term *spintronics* has become widely used for all GMR materials as well as all systems where spin-polarized electron transport arising from band structure and spin scattering occurs: tunneling magnetoresistance (TMR) materials, dilute magnetic semiconductors (DMSs), and hybrid ferromagnetic metal–semiconductor structures.

From the perspective of fundamental physics, GMR systems are equally interesting. Phenomena such as the oscillatory interlayer exchange coupling and the GMR effect (with its dependence on sample structure, composition, and geometry) have provided challenges on both the experimental and the theoretical fronts, with new techniques and approaches being developed to solve new families of problems. In addition to extending and testing our knowledge by applying well-established physical models to new systems, advances such as these have frequently resulted in new insights into that knowledge.

The variety of devices and transducers available on the market might raise questions about continued progress: have researchers exhausted the possibilities for advances in this field? To the contrary, scientific conferences on magnetism devoted specifically to magnetic sensors and actuators still bring revolutionary news such as conceptually novel nonvolatile magnetoresistive random access memories.

The aim of this review is to survey the state of the art in physics and technology concerning the GMR effect in Co-based nanostructures. This implies good coverage of GMR in general, since the vast majority of systems displaying the effect are based on either iron or cobalt. Theoretical calculations and models reflecting current understanding of GMR in transition metal multilayers have been reported in many reviews [1–7]. The emphasis of this review will be on experimental physics. The physics of Co-based multilayers is presented comprehensively, and sophisticated GMR technology is described and discussed. The review is organized into six sections: (1) Introduction, (2) Fabrication of Cobalt-Based Structures, (3) Magnetic Coupling, (4) Charge and Spin Transport, (5) Technological Applications, and (6) Final Remarks.

1.1. Giant Magnetoresistance Phenomena

Many readers are already familiar with the most outstanding aspects of the phenomenon that has come to be known as giant magnetoresistance (GMR). They will be content to skip over this section, which introduces some of the underlying physical concepts and facts prior to the detailed discussions offered in Sections 2–5.

A well-known feature of electrical conduction in nonmagnetic metals is the increase in resistivity that is observed when a magnetic field is applied. Roughly speaking, the effect is due to the Lorentz force acting on the conduction

electrons, and it is not surprising that resistance tends to increase most dramatically when the field is applied in a direction perpendicular to the current flow. This "ordinary" magnetoresistance (MR) is quite small (under 1%) for most metals at room temperature and in moderate fields—a tesla or less [8].

Ferromagnetic materials, on the other hand, display qualitatively different properties. When a current flows in a bulk ferromagnetic alloy, resistance variations in the presence of applied magnetic fields are strongly dominated by the field's influence on the magnetization. For samples in a saturated, single-domain state, there is a dependence of the resistivity on the angle between the current and the magnetization that can be quite significant in some alloys: changes of 2 or 3% in small fields (under 10 mT) are achieved in many systems at room temperature. This effect, known as anisotropic magnetoresistance (AMR) or spontaneous anisotropy of the resistivity (SAR), has physical origins that are quite different from the ordinary MR.

One strong hint at the difference in mechanisms is the fact that bulk polycrystalline ferromagnets show a resistance *maximum* when the magnetization is parallel to the current, and a *minimum* when the current and the magnetization are perpendicular. Furthermore, at room temperature a ferromagnet's resistance continues to change even after the magnetization is saturated—forced into a single-domain state: the resistance is observed to *decrease* with increasing field. As we will see in Section 4, these effects are understood largely in terms of the interaction between the s electrons and the spin-polarized d electrons responsible for the ferromagnetism in transition metals and their alloys.

In 1986, Grunberg and co-workers [9] discovered antiferromagnetic interlayer exchange coupling in Fe/Cr(0.9 nm)/Fe sandwiches produced by molecular beam epitaxy. In the absence of applied fields, the magnetization in neighboring Fe layers points in opposite directions. This finding happened at the same time as Majkrzak and co-workers [10] were conducting research that resulted in the discovery of antiferromagnetic coupling in the Gd–Y superlattices. Two years later, while working as a postdoctoral research associate with the research group led by A. Fert in Orsay, Baibich [11] performed MR measurements on antiferromagnetically coupled Fe(3 nm)/Cr(X nm) superlattices with $X = 1.8, 1.2$, and 0.9 nm. The results were astonishing: the sample's resistance showed a decrease of about 50% in the resistance when the magnetic field applied was strong enough to magnetically saturate the system, bringing the magnetization of all layers into alignment. The magnitude of the effect motivated the coining of a term that has been almost universally adopted: giant magnetoresistance.

The discovery reported by Baibich and collaborators [11], along with a qualitatively similar report by Binasch and co-workers [12], quickly prompted the establishment of research projects in numerous well-known laboratories. In addition to replicating the initially reported effects, efforts were aimed at identifying new systems, particularly ones displaying large effects at room temperature. The best results for exchange-coupled multilayered structures were simultaneously obtained by Mosca et al. [13] and Parkin et al. [14] with an MR effect as high as 50% at room temperature (an

unpublished work announced results better than 110% at room temperature [15]). Parkin [16] also demonstrated that GMR can be produced in multilayered systems with various transition metal spacers and that the epitaxial stacking was not an essential characteristic.

Within a time span of only three or four years, research in GMR had taken on a position of substantial significance, with hundreds of accumulated publications and over a dozen well-established programs at world-class research laboratories. A number of fascinating and controversial physical phenomena were being studied, with the potential for applications rising at the same dizzying rate as the number of interesting fundamental physical issues.

1.2. Cobalt-Based Nanostructures: Multilayers, Pillars, Nanowires, Cluster Arrays, Dots

The preparation and characterization of materials at the beginning of this century makes it possible to fabricate materials with control on the atomic scale. The interest in low-dimensional materials is fundamentally driven by access to properties (electric, magnetic, optical, mechanical, and chemical) which are a function of the dimensions of the materials. Magnetic nanostructured systems are a particularly interesting subclass of atomically engineered structures, since the cooperative phenomenon itself (magnetic order) and the connections between magnetic properties and the underlying electronic states lead to a wealth of opportunities for developing magnetic devices.

Confinement and quantization phenomena, already visible in semiconductors at room temperature at dimensions greater than 100 nm [17], are typically seen in metals at dimensions of a few nanometers owing to their high electron density [4]. A particularly interesting example is the observation of confined standing waves in a "quantum corral" consisting of Fe atoms on top of a (001) surface of Cu single crystals [18].

Among the nanostructured materials described in the current literature, we can mention examples ranging from three-dimensional to zero-dimensional geometries: multilayers, stripes, pillars, nanowires, cluster arrays, and dots [4, 19]. Figure 1 shows different types of GMR nanostructured materials.

From the point of view of preparation methods, the most versatile class of GMR material is cluster arrays or granular systems consisting of nanosized granules of magnetic materials dispersed in a nonmagnetic host material which can be fabricated by co-deposition of immiscible ferromagnetic and noble transition metals from sputtering [20, 21], ultrahigh vacuum (UHV) evaporation [22], electrodeposition [23], melt spinning [24, 25], chemical synthesizing [26, 27], and ball milling [28] or by co-deposition of discontinuous multilayered structures [29, 30].

It is also worth noting that very interesting features have been recently observed in zero- and one-dimensional Co structures. Let us give two examples. First, a study of a monolayer-thick array of Co nanodots on Cu(001) and Au(111) indicated that Co dots have a spontaneous magnetization at a finite Curie temperature and the transition temperature to a long-range two-dimensional (2D)
Figure 1. Various types of GMR structures: (a) multilayer, (b) granular film, (c) spin valve, and (d) multilayered nanowires.

ferromagnetic state is higher than that for a Co film directly deposited on a Cu(001) surface [31]. Second, large magnetoresistance (described as *ballistic magnetoresistance*) has recently been observed in nanocontacts [32] and in an array of Co dots [33, 34].

The fabrication of early generations of magnetic nanostructured materials required very sophisticated and refined techniques such as molecular beam epitaxy (MBE) and ultrahigh vacuum sputtering. These materials can now be obtained using simpler and less expensive techniques such as electrodeposition [35, 36]. Typical methods include a variety of processes based on vacuum evaporation, electrodeposition, sputtering, ion plating, chemical deposition, thermochemical reactions, and mechanical alloying. Some of these methods will be described in Section 3.

2. FABRICATION OF COBALT-BASED STRUCTURES

Many compilations have been devoted to the physical and chemical properties of metallic cobalt. The most recent and complete of these dates back to 1979 [37]. First-principles theories of magnetic phenomena in Co nanostructures have been recently reviewed by Wu and Freeman [38]. Some important structural and magnetic properties of cobalt are reviewed later. Next, we briefly present the most important Co-based nanostructures and introduce the techniques employed in their preparation.

2.1. Metallic Cobalt: Stable and Metastable Phases

Bulk Co appears in two crystalline structures, that is, a hexagonally close packed (hcp) form which is stable below about 673 K and a face-centered cubic (fcc) form stable at higher temperatures up to the melting point. The lattice parameters of cobalt at ambient temperature are

$a = 2.5074$ Å and $c = 4.0699$ Å for hexagonal Co and $a = 3.5442$ Å for cubic Co, respectively. The major part of the binding energy in the cobalt is associated with the directional homopolar interaction of d electrons, which implies that the stacking-fault energy must be small [39]. A low allotropic transformation energy favors a martensitic phase transformation from hcp to fcc (470 to 510 J/mol) and phase coexistence of the cobalt near the ambient temperature in aggregates and thin films [37]. The relative stability of the two phases has long been known to depend on the grain size [40] and film thickness [41]. For very small grain size or small film thickness, the fcc structure becomes stable down to room temperature. Co exhibits a relatively high surface energy ($\gamma = 2.7$ J m^{-2}), owing to the partially filled d shell. Thus, smooth Co layers are, in general, difficult to obtain on top of noble metals [42] or insulating [43] substrates that have smaller surface energies.

To overcome the surface energy mismatch problems, nonequilibrium growth conditions are necessary, having sometimes been established by using a surfactant to promote a layer-by-layer growth mode [44, 45]. The self-diffusion of Co at constant temperature is markedly dependent on sample metallurgy due to the high diffusion rates along the grain boundaries [46] and are anomalously affected by the magnetic transformation [47].

Metastable phases were obtained for thin films epitaxially grown onto suitable single-crystal substrates. In general, the thickness to which a metastable cubic Co film will grow before transforming into hcp Co depends on the growth kinetics (substrate temperature and incoming Co flux rate) and also on the condition of the initial substrate surface.

Early in the history of epitaxially grown ferromagnetic films, cubic Co films were grown on the cleaved faces of NaCl and KCl [48] and the {111} faces of Cu single crystals [37]. Epitaxial cubic Co films have also been grown by electrodeposition on Cu and Ni substrates [49]. The structure of these films and the phase transformations depend on the film thickness.

More recently, metastable cubic Co was epitaxially grown on several substrates by the sputtering [50] and MBE [51, 52] techniques.

The match between the lattice spacing of body-centered cubic (bcc) Co and the (110) GaAs substrate is sufficiently close to enable Co epitaxy up to 37 nm [53, 54]. Ultrathin fcc Co on Cu(001) [55] and fcc Co(001)/Cu(001) [56] and Co(111)/Cu(111) [57] multilayers were also epitaxially grown by UHV evaporation. The influence of preparation techniques (UHV evaporation, direct-current (dc) magnetron sputtering, radio frequency (rf) diode sputtering) on different buffer layers and the coexistence of fcc/hcp Co phases were also investigated [58–60].

According to first-principles theoretical calculations by Moruzzi et al. [61], bcc Co is ferromagnetic for any reasonable value of unit cell volume, while fcc Co can exist in either a nonmagnetic or a ferromagnetic phase, and there is a range of volumes where the two phases can coexist. Experimental results confirm the ferromagnetic behavior of cubic Co, corroborating the theoretical predictions.

2.2. Magnetism and Magnetotransport of Cobalt

The spontaneous magnetization of cobalt at absolute zero is equal to 1.72 Bohr magnetons (μ_B), which corresponds to an absolute saturation magnetization of 162.5 G/g (16.25 T/kg) [62]. No significant change in the saturation magnetization is apparent at the allotropic transformation. As in the case of other ferromagnetic materials, the temperature dependence of the spontaneous magnetization of Co is weak at low temperatures. The magnetization decreases very slowly, with the slope increasing with temperature until it vanishes abruptly at the ferromagnetic Curie temperature T_c near 1121 °C (1394 K). Single crystals of Co are magnetically anisotropic.

For cobalt, the hexagonal axis $\langle 0001 \rangle$ is the direction of easiest magnetization at room temperature. On heating hexagonal Co, the magnetic anisotropy reduces; it becomes nearly isotropic around 250 °C (523 K). For cubic Co (above about 673 K), the crystal directions in order of increasing difficulty of magnetization are $\langle 111 \rangle$, $\langle 110 \rangle$, and $\langle 100 \rangle$, respectively. With increasing temperature, cobalt again becomes magnetically isotropic (~1000 °C). Single crystals of hexagonal Co exhibit a rather large volume magnetostriction with the ratio $\Delta V/V$ varying from contractions as large as 100×10^{-6} to expansions of up to 150×10^{-6}, depending on the crystallographic direction [63].

From the point of view of electronic transport, it is important to remember that the resistivity ρ at room temperature of single crystals of hexagonal Co is anisotropic. In the $\langle 0001 \rangle$ direction, the resistivity is almost twice the value observed along the $\langle 10\bar{1}0 \rangle$ direction. The magnetoresistance effect of single crystals of 99.8% cobalt along the $\langle 0001 \rangle$ direction has a saturation value $\Delta\rho/\rho$ of about 0.4% for a field strength of only about 200 Oe [64]. The anisotropic magnetoresistance (AMR) of single-crystal cobalt whiskers has been examined with current flow in different crystalline directions from temperatures below 4.2 K to far above room temperature [65]. It should be emphasized that for single crystals the dependence of the AMR on the current and field directions is much more complex than is the case for polycrystalline samples. More relevant to our discussion of GMR in Co-based nanostructures is the presence of a peak in the resistance versus applied field curves, near zero field, for the high-quality single-crystal samples of Coleman and Morris. This "GMR-like" feature is associated with the transition between multidomain and single-domain states and is observed at low temperatures. In the large field limit, the general behavior of the field dependence of magnetoresistance in hcp single-crystal Co is described by the functional form $\Delta\rho/\rho_0 = aB^n$, where the exponent n is less than 1 and Shubnikov–de Haas oscillations are observed [65].

2.3. Molecular Beam Epitaxy

MBE was originally developed for preparing compound semiconductors with improved structural and electrical qualities to allow the fabrication of devices such as lasers and modulated doped-channel FETs and HEMTs. In the 1990s, MBE was extensively applied to epitaxial insulators, magnetic metal multilayers, buried epitaxial metals in semiconductors, and dilute magnetic semiconductors. Co/Au, Co/Pd, Co/Pt, and Co/Cu were the first examples of MBE-grown magnetic superlattices with non-bulk-like properties [66].

An interesting property observed in MBE Co-based multilayers is the perpendicular magnetic anisotropy. We recall that an isotropic ferromagnetic material formed into a thin-film geometry shows "shape anisotropy": the magnetization tends to remain aligned in the plane of the film. This is due to the powerful demagnetizing field generated by the magnetization when it is perpendicular to the surface of the film. For Co/Au, Co/Pd, and Co/Pt structures with sufficiently thin cobalt layers, perpendicular magnetic anisotropy was observed persisting well above room temperature [67]. Co/Cr and Co/Pt multilayers as well as Co–Cr and Co–Pt alloys have been investigated for technological applications in perpendicular magnetic recording, which has enormous potential for ultrahigh density recording, but several breakthroughs will be required before their practical use [68]. Also, for Co/Pt multilayers a significant Kerr rotation of the plane of polarization of the light by the magnetization of the sample was also observed when interfacial Pt itself becomes magnetic due to its proximity to the Co [69].

Arrays of magnetic Co dots and wires are other interesting examples of MBE Co-based nanostructures. By demanding a higher degree of sophistication in the growth and characterization, Co nanometer-scaled dots self-arranged on a Cu(001) surface [31] and Co one- and two-dimensional nanostructures on a Au(111) surface [70] have been investigated. Both monolayer-thick arrays of Co dots on Cu(001) and Au(111) indicate that there exists a spontaneous magnetization and a superparamagnetic behavior below the finite Curie temperature (<50 K). An interesting feature observed was an oscillatory variation of the average surface in-plane lattice spacing with increasing Co monolayer coverage on Cu(001) which has been associated with relaxation of edge atoms [71].

2.4. Sputtering

Sputtering deposition methods (including diode sputtering, ion beam sputtering, and magnetron sputtering) emerged in the 1940s as a commercial coating process. It was only in the 1970s that the magnetically enhanced variant of diode sputtering (magnetron sputtering) emerged as a competitive alternative to other vacuum coating techniques such as thermal evaporation and electron beam evaporation. In the last two decades, along with applications such as metallizing for microelectronic circuits and chip carriers and depositing electrical resistance films, the industry has turned to sputter deposition techniques as a method for producing materials, samples, and devices. Particularly relevant here is the manufacture of magnetic thin films of Co and Co alloys for general magnetic storage devices, floppy disks, and thin-film magnetic heads. A wide variety of magnetic multilayered structures have been produced by sputtering. An extensive list of such structures was recently reviewed by Schuller et al. [72]. The low cost of the sputtering process and its compatibility with large-scale production with entirely automatic machines encouraged research activity.

Perpendicular recording materials such as Co–Cr with columnar microstructure and strong perpendicular anisotropy are good examples of Co-based films produced by

sputtering. It is also worth noting that Co alloys and refractory metals cause problems because of differences in alloy constituent vapor pressures and their high melting points when conventional thermal evaporation techniques are used.

Magnetic multilayered films produced by sputtering with a ferromagnetic layer consisting of body-centered cubic Co–Fe alloys have been extensively studied. We recall that among all possible pairwise combinations of the three ferromagnetic 3d transition metals (Co, Fe, and Ni), Co–Fe displays the largest values of the Curie temperature and saturation induction (a room temperature value of 24.5 kG is obtained at 35 at% Co). The large magnetization of Co–Fe alloys correlates with the transition between bcc and hcp structures as the concentration varies.

In addition to single films and multilayers, researchers have used sputter deposition to produce increasingly sophisticated structures with new geometries. Lithographically patterned pillars for the study of magnetization reversal by spin-polarized current have been obtained from sputtered Co/Cu nanostructures [73]. Finally, it is remarkable that the fabrication of planar tunnel junctions is commonly carried out in multitarget sputtering systems by means of a lithographic process [74].

2.5. Electrodeposition

Electrodeposition is one of the simpler and cheaper processes available for the fabrication of metallic films and nanostructures [36]. The electrodeposition of metal, often referred to as electroplating, is a highly versatile technique that has recently been used to fabricate metallic alloys, compositionally modulated alloys, heterogeneous alloys, nanowires, multilayered nanowires, pillars, point contacts, and nanodots.

Compositionally modulated alloys with an (FM/I/...) nanostructure composed of Co-based alloys have been made using a single-bath method using potentiostatic control and a pulsed deposition technique [75] exhibiting oscillatory exchange coupling and a GMR effect at room temperature [30, 76–79].

Heterogeneous alloy films consisting of ferromagnetic particles or clusters in a nonmagnetic matrix exhibiting the GMR effect were also prepared using an electrochemical method [80, 81].

Nanowires and multilayered nanowires can be fabricated by electrodeposition into templates [82–84]. In particular, isolated magnetic nanowires and arrays of magnetic nanowires have recently attracted considerable interest motivated by ultrahigh-density magnetic recording applications, understanding of the CPP-GMR, and the determination of spin diffusion lengths [84–87]. As an example, pure Co nanowires grown by electrodeposition appear essentially single crystalline and possess their normal equilibrium phase (hcp) with a preferred orientation along the $\langle 1010 \rangle$ direction, that is, with close-packed planes almost parallel to the wires [88].

Other types of nanostructures have been grown by electrodeposition such as Ni/NiO/Co pillars [89], dot arrays [34], point contacts [90–93], and nanodots [19].

3. MAGNETIC COUPLING

As mentioned in Section 1.1, the GMR effect was originally found in transition metal–based exchange-coupled multilayers. Subsequently, the effect was found to oscillate with increasing thickness of the spacer layer and was quickly correlated to the change of interlayer exchange coupling between the ferromagnetic and antiferromagnetic cases. The connection between GMR and interlayer exchange coupling (IEC) was soon understood as follows: antiparallel orientations of consecutive magnetic layers resulted in higher resistance than the magnetically saturated configuration with all magnetic layers having parallel moments. The IEC "causes" the GMR by ensuring field-driven transitions between the high-resistance and low-resistance states.

More recently, evidence has accumulated suggesting a connection at a more fundamental level. Both phenomena can be understood as arising at least in part because of quantum mechanical effects altering the wave functions of conduction electrons in the multilayer. The connections between oscillatory interlayer coupling and GMR, along with the intrinsically interesting nature of the coupling, motivated the inclusion of this section on magnetic coupling in the present review.

3.1. Background: Magnetostatic Coupling

The existence of magnetic coupling in a simple "sandwich" structure, consisting of two magnetic slabs separated by a nonmagnetic spacer layer, is rather intuitive. The magnetization in the two slabs will tend to assume a configuration such that the moments in each layer are aligned with the field lines produced by the neighboring layer. Since the moments in each layer also tend to align with the field lines produced by the remainder of the same layer, the moments have a tendency to lie in the plane of the layers (shape anisotropy). Consequently, an antiparallel configuration for the magnetizations in a sandwich structure is expected on the basis of simple magnetostatic (dipolar) interactions.

In the thin-film limit of a sandwich structure, however, the magnitude of the magnetostatic coupling (for ideal, smooth layers) is vanishingly small. In other words, as the transverse dimensions of the sandwich structure become large, the energy associated with the interlayer coupling becomes vanishingly small. Actual sandwich structures produced with typical deposition processes also tend to exhibit in-plane anisotropy: the magnetization has one or more preferred orientations. This anisotropy is frequently much stronger than the magnetostatic coupling expected for smooth, thin sandwich structures.

Even in the thin-film limit, magnetostatic coupling can become significant if surface roughness is present: steps, ripples, and other features in the surfaces of the magnetic layers result in "stray" magnetic field lines that couple with nearby magnetic moments in the neighboring layer. This type of mechanism for producing interlayer coupling in the thin-film limit has been evaluated with quantitative models and is expected to produce small but measurable effects [3].

Rather complicated models have been developed to take into account the various structural influences (such as interfacial roughness, pinholes, strain, misfit dislocations) [2–4, 94–97].

3.2. Interlayer Exchange Coupling

The magnitude of the antiferromagnetic coupling observed in Fe/Cr/Fe nanostructures by Grunberg et al. [9] was much larger than what could be expected on the basis of magnetostatic coupling. Instead, the interactions between moments in the neighboring magnetic layers seemed to arise from quantum mechanical mechanisms analogous to the exchange coupling responsible for ferromagnetism in metals. The presence and thickness of the intervening layers ruled out direct coupling of the moments: indirect exchange coupling involving the electrons in the spacer layer must be present.

The antiferromagnetic coupling was directly confirmed using neutron scattering [98]. Magnetometric methods and the magnetooptical Kerr effect (MOKE) were used to directly measure the coupling in magnetic multilayers [3, 6, 7]. It was clear that dipolar interactions could not be responsible for the strength of the antiferromagnetic interlayer coupling ($J \sim 1$ mJ/m^2) observed in the Fe/Cr multilayers.

In 1990, Parkin et al. [99] reported that GMR in sputtered Fe/Cr multilayers oscillates when the thickness of the Cr increases beyond 1.8 nm, indicating that the coupling changes with the thickness of the Cr layers. These oscillations correspond to a sequence of zero-field magnetizations along the multilayered film aligned either parallel or antiparallel as a result of an effective ferromagnetic and antiferromagnetic exchange coupling. In contrast with Gd–Y multilayers, the oscillation in Fe/Cr superlattices has a period of 1.8 nm, which is far higher than the value given by a direct and simplistic application of the Rudderman–Kittel, Kasuya–Yoshida (RKKY) theory [3]. The unique magnetic properties of Cr were also ruled out as providing a mechanism for the interlayer coupling for various reasons, including the lack of correlation between the oscillation period and the characteristic structural and magnetic lengths for bulk Cr, along with the persistence of significant coupling strength well above the bulk Néel temperature. Furthermore, Parkin et al. [99] soon determined that the Co/Ru multilayer shows an oscillatory IEC somewhat similar to what is observed in Fe/Cr, suggesting that other mechanisms could be present. The coupling strength (and GMR) of the Co/Cu multilayer described by Mosca et al. [13] and Parkin et al. [14] also oscillated with spacer thickness, and later work by Parkin [16] showed that the oscillatory IEC is indeed present in multilayers with a wide variety of compositions.

3.3. Long- and Short-Period Oscillations

In general, the period of oscillation depends on the material of the spacer, the crystal structure, and the growth direction of both ferromagnetic and nonferromagnetic layers [100, 101].

More precise investigations of exchange interlayer coupling have revealed that, besides the oscillations mentioned previously (long-period oscillations), faster oscillations (short-period oscillations) also existed. In fact, two different periods of oscillation were revealed [101–103]. Short-period oscillations are quite hard to detect since they are strongly dependent on the roughness of the interfaces. Oscillations of the GMR ratio reveal the oscillatory exchange coupling as shown in Figure 2.
Figure 2. Schematic drawing of oscillations in the magnetoresistance ratio. The character of coupling between consecutive FM layers changes from AFM to FM with some period when the spacer thickness is varied. Short-period oscillations in the zoom.

Grunberg and co-workers [104] and Purcell et al. [105, 106] used a wedge-shaped spacer to investigate the local value of the interlayer coupling for precisely determined thicknesses of the spacer. Similarly, a deeper insight into the complex behavior of the coupling oscillations with short-range and long-range periods resulted from studies conducted with epitaxial sandwiches of Fe/Cr/Fe [102] and Co/Cu/Co [107] with a wedge-shaped spacer layer. The same results were essentially obtained for sputtered Co/Cu multilayers with wedge-shaped Cu layers [108]. Various other methods have been used and new ones developed, such as Brillouin light scattering (BLS) [109], ferromagnetic resonance (FMR) [109], spin-polarized low-energy electron diffraction (SPLEED) [110], and scanning electron microscopy with polarization analysis (SEMPA) [102].

The magnetic interlayer coupling in various Co-based structures textured (111) and (110) for fcc and bcc, respectively, such as Co/Cu [13, 14, 56, 111], Co/Au [112], Co/Ru, Co/Mo, Co/V, Co/Ir [16], Co/Ag [113], CoFe/Cu [114], and Co/Cr [115], exhibits a period of oscillation Λ varying between 0.9 and 1.1 nm, except for the Cr spacer with 1.8 nm. It is also worth noting that for fcc Co/Cu(111) multilayers $\Lambda = 1.0$–1.1 nm [13, 14], whereas for fcc Co/Cu(100) multilayers $\Lambda = 2.1$–2.8 nm [107, 116]. A short-period oscillation is present in the case of fcc Co/Cu(100) multilayers where $\Lambda = 0.9$ nm [116].

These results corroborate the generalized RKKY theory [3]. This theoretical approach employs concepts and calculations employed in the original RKKY theory for magnetic impurities interacting by means of a free-electron gas. In the generalized form, the model must reflect the participation of the large numbers of magnetic moments in the interacting ferromagnetic layers, as well as incorporating the nonspherical shape of the Fermi surface of the spacer layer. The latter consideration is essential for accounting for experimental observations; the results obtained using the generalized RKKY model allow prediction in an essentially correct manner of the periods of oscillatory coupling. In particular, in the case of multilayers with noble metals as the spacer layer, two different oscillation periods are expected from Fermi surface nesting along the (100) and (110) orientations. In fact, two different periods of oscillation were revealed in other (100) textured multilayers such as Fe/Cr/Fe [105], Fe/Au/Fe [117], and Fe/Ag/Fe [118].

Although the theoretical results obtained from the generalized RKKY model for the periods of oscillation correspond fairly well with the experimental ones, results

of modeling the magnitude of the oscillations and phase are not as satisfactory. Furthermore, the magnitude of the oscillations is found to depend on certain properties of the ferromagnetic layer, once again departing from predictions obtained from the generalized RKKY model. Other theoretical models have been proposed to explain the interlayer exchange coupling. Jones and others [2–4, 94–97] have published comparative reviews of these models.

3.4. Other Coupling Effects

Besides the coupling effects mentioned previously, several others have been observed. We have selected a few of these for discussion in this section.

The magnetic coupling in spin valve structures is very complex relative to a multilayered structure since the exchange bias, RKKY-like, and orange peel or Néel couplings intervene with similar magnitudes.

Another type of coupling that may also occur is the so-called biquadratic coupling. This kind of magnetic coupling is represented by a term proportional to the square of the internal product of the unit vectors (i.e., cosine of angle) in the direction of magnetization of interacting adjacent layers. Biquadratic coupling tends to align the adjacent layers perpendicular to each other, and its origin is not fully clear. Ordinary, antiferromagnetic IEC is proportional to the same cosine, and it has been found that the biquadratic coupling term must be included in phenomenological expressions describing the behavior of certain systems. A comprehensive analysis of biquadratic coupling in magnetic trilayers was reported by Rezende and co-workers [119–123] using various techniques: MOKE, BLS, and FMR. In brief, they concluded that biquadratic coupling could not be attributed exclusively to intrinsic mechanisms.

A new direction in the research of the interlayer exchange coupling was opened, addressing the effect of the magnetic layer on the strength and phase of the oscillatory coupling. Bruno [124, 125] and Barnas [126] have predicted that the strength of the coupling should oscillate with the ferromagnetic layer thickness. Bloemen et al. [81] have confirmed that the oscillatory interlayer exchange coupling across Cu(100) depends on the Co thickness, strongly supporting the model of Bruno. To understand this effect, it has been necessary to consider the effect of the nanostructure on the electronic structure of the metals in each layer, reflecting the alteration (compared to the bulk) in the quantum mechanical states available to the conduction electrons.

3.5. Quantum Well States

The discovery that a quantum well state (QWS) exists in a metal overlayer grown on a ferromagnetic substrate promoted intense research on the intrinsic relation between the QWS and the oscillatory coupling and GMR magnetic multilayers [4]. The QWS nature of the interlayer coupling was identified by magnetic measurements [127, 128] and photoemission experiments [129].

The QWS can be regarded as a consequence of the nanometer-scale interlayer spacing, which tends to confine certain electron wave functions to dimensions comparable

with their wavelengths. A more fundamental way of describing QWS is to recognize that conduction electrons in the layers of a GMR structure can "experience" potential wells in the vertical direction associated with the material's layered structure. The energy contribution associated with their motion in this direction is quantized into bands with structure on the same energy scale as the band structure for the bulk metals. This results in changes to the shape of the density of states (DOS) function and to the value of the density of states at the Fermi level.

An essential physical aspect of (FM/N/...) layered magnetic nanostructures is the formation of the spin-polarized QWS due to spin-dependent electron confinement due to the reflection of electrons at the interfaces. These reflections are spin dependent. Figure 3 shows QWS formation by reflections of electrons at the interfaces of ferromagnetic layers.

Himpsel et al. [4] have recently achieved significant progress by modeling exchange coupling with the assumption that quantum well states tailor the electronic properties of a nanoscaled material.

The quantum interference model proposed by Bruno [96, 130] describes the exchange coupling as spin-dependent reflections of Bloch waves at the multilayer interfaces. It has been found that the antiferromagnet (AFM) coupling strength oscillates as a function of the ferromagnet (FM) layer thickness because of a density of polarized states modulation which, in turn, is due to multiple electron reflections within the FM layer.

The experimental observation of oscillations in the exchange coupling as a function of the thickness of the ferromagnetic layer corroborates the quantum interference model [127, 128]. Also, the strong temperature dependence of IEC strength in Co(hcp)/Cu sandwiches, implying temperature dependence which is not only governed by the spacer Fermi surface, supports the QSW models [131].

4. CHARGE AND SPIN TRANSPORT

The theoretical explanation for the GMR effect is relatively well established and covered in a large number of papers and books [3, 6, 7]. On the other hand, TMR systems continue to attract considerable research [132]. In this section, we will describe the most important milestones and ideas in the development of the GMR and TMR theories.
quantum well

4.1. GMR Systems

A brief introduction to GMR was offered in Section 1. In this section, we offer a more detailed discussion of the wealth of phenomena associated with GMR in a variety of systems. Initially, we shall broaden our scope of GMR systems by describing some of the nanostructures developed during the first few years of research on the magnetoresistance of layered systems. Next, we shall offer an overview of key advances in theoretical descriptions of this class of phenomena. The section concludes by describing some of the more interesting Co-based GMR nanostructures developed in recent years and by highlighting unresolved issues in theoretical models.

The spectacular magnitude of the negative MR reported for carefully prepared multilayers of Fe/Cr—and, within less than two years, Co/Cu—attracted a great deal of attention (see Fig. 4 for an example of typical GMR data for Co/Cu multilayers). Another less spectacular result reported at about the same time led to similarly important physical conclusions. The research group led by Renard reported "enhanced magnetoresistance" in $(Co/Au)_N$ multilayers with perpendicular anisotropy [133]. The resistance was found to pass through a maximum value during the reversal of the structure's magnetization, with an effect substantially larger than what would be expected based on AMR within the Co layers.

The same group subsequently reported similar effects in conceptually simpler sandwich-type structures, where the top and bottom Co layers had different thicknesses, which was known to result in different coercive fields. Since the Co layers experience magnetization reversal at different values of a reverse field, the structure has an antiparallel magnetic configuration for certain values of the applied field during a hysteresis cycle. The enhanced MR was observed for these ranges of applied field. Although the effect was only a few percent, it suggested that a mechanism similar to the one present in the AF-coupled Fe/Cr system could cause increased MR even in the absence of interlayer exchange coupling. The correlation between the magnetic configuration (parallel and antiparallel orientations of consecutive ferromagnetic layers) and the electrical resistance (low-resistance and high-resistance states) was further documented with the discovery, described in the previous section, of oscillations in the IEC between ferromagnetic and antiferromagnetic alignment. As described in the previous section, the GMR was found to oscillate in phase with the coupling strength, with maxima for the AFM-coupled and minima for the FM-coupled structures.

The presence of a "GMR-like" effect in uncoupled multilayers with ferromagnetic layers having equal thicknesses was hypothesized to arise due to a "partially antiparallel" configuration during the magnetization reversal process, since the resistance maxima were at or near the coercive fields.

Many other researchers later described the GMR effect in various uncoupled multilayered systems with asymmetric magnetic layers FM1 and FM2 in (FM1/N/FM2/...) structures [134–137], where FM1 and FM2 are similar ferromagnetic metals with distinct thicknesses, qualitatively similar to the Co/Au structure reported by Renard's group. The other way of ensuring that alternating ferromagnetic layers would have different coercivities was to employ dissimilar ferromagnetic metals (such as cobalt and Permalloy, a magnetically soft nickel–iron alloy) for FM1 and FM2 as defined previously. Figure 5 shows the principle of GMR in uncoupled FM1/NM/FM2 sandwiches.

Subsequent work showed that dissimilar metals (Permalloy and cobalt) can display *oscillatory interlayer exchange coupling* through copper spacer layers, resulting in two physically distinct mechanisms for driving transitions between the high-resistance (antiparallel) and the low-resistance (parallel) configurations of the layer-by-layer magnetizations.

Figure 4. Magnetoresistance curve of a $(Co\ 15\ Å/Cu\ 9\ Å)_{30}$ multilayer measured at 4.2 K for a magnetic field applied (a) parallel to the current in the film plane and (b) perpendicular to the film plane. The magnitude of the MR ratio, given in terms of the resistances as $1 - R(H_s)/R(0)$, is independent of the field direction; only the saturation field H_s is changed due to the large demagnetizing effect when the external field is applied perpendicular to the film plane [13].

Figure 5. Principle of the asymmetric spin valve mechanism for an uncoupled structure having magnetic layers with different coercive fields. For large magnetic field strength H, both layers are parallel magnetized. When H decreases, the layer of the smaller coercive field switches its state of magnetization M. The second layer remains magnetized antiparallel with respect to the first layer until H is sufficient to reverse its magnetization. The resistance R correspondingly follows these changes in magnetization alignment.

The interplay between the two mechanisms results in an intricate variation of the measured GMR with the various layer thicknesses [138, 139].

Dieny et al. [140–142] proposed a new exchange-biased coupled sandwich structure they called a *spin valve*, where an antiferromagnetic AFM layer (CoO, NiO, FeMn) is used for pinning the magnetization of one of the ferromagnetic FM layers in (FM/N/FM/AFM) structures. The pinned layer maintains a fixed magnetization in the presence of weak to moderate applied fields, whereas the free layer, particularly when magnetically soft, is easily reversed with small applied fields. These structures are therefore characterized by transitions between the high-resistance and the low-resistance states that are extremely abrupt compared to AF-coupled Fe/Cr and Co/Cu structures. This, in turn, can imply, in some cases, a very high *sensitivity,* or percentage change in resistance per unit applied field, at the expense of a narrow range of field values over which the resistance changes are produced.

The first generation of spin valves was constructed using the magnetically soft Ni–Fe alloy known as Permalloy [6, 140–142], thus optimizing the abruptness of the low-field transition. Later work investigated the increase in the GMR and better temperature stability produced by inserting a thin layer of cobalt at the interfaces between the Permalloy and the Cu layers [143].

An impressive compilation of data on various polycrystalline Co-based multilayers with magnetic layer composed of Co and spacer layers of the transition metals (T, V, Cr, Mn, Zr, Nb, Mo, Tc, Ru, Rh, Pd, Hf, Ta, W, Re, Os, Ir, Pt) and noble metals (Cu, Ag, Au) was reported by Parkin and co-workers at IBM [3, 16].

The starting point for theoretical research into the mechanisms responsible for the resistance variations between parallel and antiparallel configurations of ferromagnetic layer magnetizations in GMR systems was, of course, existing knowledge about conduction in ferromagnetic metals. In the case of the main ferromagnetic transition metals, the electrons responsible for the magnetic moments are in d bands that are near the Fermi energy and that are intermediate between the very broad s bands and the very narrow bands associated with localized core electrons. In other words, these metals are itinerant ferromagnets: the magnetic moments arise from electrons that participate in conduction, although in a much less significant manner than their s-band counterparts. The presence of d states at the Fermi energy implies that s–d scattering processes can be quite significant in these metals. Indeed, there is substantial experimental evidence supporting the importance of s–d scattering in Fe, Co, Ni and their alloys.

For these conductors, the majority band is almost entirely below the Fermi energy, while the minority band is displaced in such a manner that a larger portion of the band is empty. Given the shape of the bands (density of states versus energy), this tends to result in the s electrons having spin-dependent scattering probabilities for s–d processes. For example, the s electrons in the minority band usually "see" a larger number of available d states at the Fermi energy, increasing the probability of a collision (transition between k states) taking place.

In many cases, particularly at low temperatures, collisions involving a reversal of the electron's spin direction are extremely rare compared to spin-preserving collisions. The spin-up and spin-down conduction electrons behave essentially as separate currents, visualized as separate "wires" or resistors.

To account for properties of magnetic alloy resistivities, the preceding concepts were developed into a phenomenological model based on the classical two-current model introduced by Mott [144, 145], originally used to describe the contributions to the measured current from nearly free s electrons and the less mobile narrow-band d electrons in nonmagnetic transition metals. In adapting that model to ferromagnets, the two currents corresponded to majority- and minority-spin conduction electrons. The model focused on the s-electron contribution to the conductivity, with d electrons appearing only through their contribution to spin-dependent scattering rates and mean-free paths. This "spin-polarized" version of the two-current model was probed and substantiated by Campbell and Fert for bulk alloys with research conducted largely in the 1960s and 1970s [8]. These systematic studies allowed the determination of the resistivities associated with the spin-up and spin-down channels, as well as the corresponding asymmetries, for the ferromagnetic transition metals and a wide range of ferromagnetic alloys based on Fe, Co and/or Ni. Figure 6 shows the schematic diagram of the two-current mechanism using a density of states picture.

With the two-current picture of conduction in ferromagnets, a simple conceptual interpretation was formulated by Fert's group and included in the first report on GMR in Fe/Cr. For the ferromagnetic configuration, one spin direction is systematically less scattered than the other one. These electrons dominate the contribution to the total current, in a sort of "short-circuit" effect (see Fig. 7). For the antiparallel configuration, the short-circuit effect vanishes, since all of the electrons will experience substantial scattering for either one or the other magnetic alignments.
Figure 6. Schematic diagram of the density of states in nonmagnetic spacer and ferromagnetic metals. Energy bands for nonmagnetic metals are the same for electrons with different spins, whereas, for ferromagnetic metals, they split into two subbands, one in which electrons have their spin parallel to the magnetization (spin-up electrons) and the other in which the spin is antiparallel to the magnetization (spin-down electrons). The difference in the density of states at the Fermi level for spin-up and spin-down d electrons leads to different scattering rates with different mean-free paths and resistivities. The two-current mechanism corresponding to spin-up and spin-down electrons is represented in the AFM- and FM-coupled configuration of magnetizations.
Figure 7. MR ratio as a function of the Cu spacer layer thickness in (Co 15 Å/Cu t_{Cu} Å)$_{30}$ multilayer series. The dashed lines are the best fit of quantum calculations for fully antiferromagnetic and uncoupled magnetization configurations. The solid lines are the best fit of semiclassical calculations for fully antiferromagnetic and fully ferromagnetic magnetization configurations. Experimental data are joined by a short-dashed line only to guide the eyes [13].

Therefore, the physics of GMR is quite similar to the spin-dependent conduction in ferromagnetic metals where the two-current model is applied with current carried by spin-up and spin-down electrons flowing in two independent "channels." Due to the spin splitting of the electronic structure in ferromagnets, the number of spin states and spin diffusion length (length characterizing the spatial extent of the spin polarization) are different. There exists a spin asymmetry coefficient $\alpha = \rho_\uparrow/\rho_\downarrow$ defined in terms of the spin-up and spin-down resistivities, $\rho_\uparrow$ and $\rho_\downarrow$, respectively. The ordinary magnetoresistance of ferromagnetic metals and their alloys is proportional to this spin asymmetry coefficient. In GMR materials, spin asymmetry coefficients can also be defined, but the spin-up and spin-down resistivities differ due to the intrinsic and extrinsic spin-dependent scattering in the "bulk" and interfaces of the GMR structure. In Section 5.3, the bulk and interface contributions to GMR will be discussed in more detail.

In GMR materials, the magnetoresistance effect, which is traditionally defined by the variation in the electrical resistivity ρ as a function of the applied field as $(\rho(H) - \rho(0))/\rho(0)$, can be defined as

$$GMR = (\rho_{AP} - \rho_P)/\rho_{AP}$$

where ρ_{AP} and ρ_P are, respectively, the resistivities in the ideal antiparallel and parallel magnetization configurations in an antiferromagnetically coupled multilayer. A similar relation is also used in (FM1/NM/FM2/...)-coupled or -uncoupled sandwich structures when the ferromagnetic layers FM1 and FM2 show fully parallel and antiparallel magnetization configurations in a certain applied field interval. It is worth noting that the definition of GMR using ρ_P in the denominator allows a magnetoresistance effect larger than 100%; for example, the GMR record using the definition $(\rho_{AP} - \rho_P)/\rho_P$ is 220% in antiferromagnetically coupled Fe/Cr multilayers at low temperature [146].

Departing from the low-temperature limit, the transfer of momentum between the two channels occurs by spin-flip electron–magnon scattering. Therefore, the so-called spin-mixing effect tends to equalize the two currents due to spin-up (spin-down) scattering to spin-down (spin-up) states by the annihilation or creation of magnons. Since the shunting by the less resistive channel is reduced, the overall resistivity increases and the magnetoresistance decreases.

A simplified but quantitative approach to describing the GMR was reported early on, based on the semiclassical model for conduction in metals. To apply the model to GMR systems, the two-current model was associated with the semiclassical formalism originally developed by Fuchs [147] and Sondheimer [148] for describing conduction in nonmagnetic thin films. The Fuchs–Sondheimer theory had already been applied to nonmagnetic, metallic superlattice systems by Carcia and Suna [149].

For the GMR systems, separate spin-up and spin-down contributions to the current profile were computed by applying the Boltzmann equation and inserting spin-dependent mean-free paths in the ferromagnetic layers, as well as (in some cases) spin-dependent scattering at the interfaces and outer surfaces of the multilayers. The first results obtained using this approach were the Camley–Barnas [150] and Barthélémy–Fert [151] calculations. A simple albeit somewhat restricted version of the calculation was developed by Mosca and Lottis that employed the analytical expression for the conductivity of a metallic superlattice obtained by Carcia and Suna and allowed an analytical expression to be obtained for the GMR in hypothetical superlattices where the conduction electrons in the nonmagnetic spacer layer have the same mean-free path as one of the spin channels in the magnetic layers. This approach was used for the comparison between semiclassical and quantum calculations for the Co/Cu multilayers displayed in Figure 8 [152].

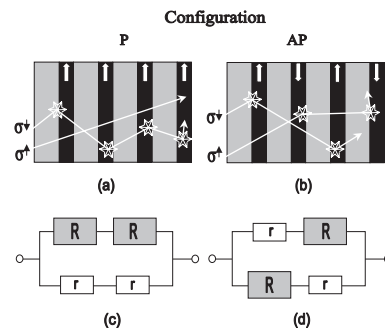
Early models using a Boltzmann equation incorporated, among others, the assumption that the two current channels do not mix and that scattering within the layers is isotropic with respect to conduction electron wave vectors. The first assumption corresponds to low temperatures, since collisions involving the reversal of a conduction electron's spin commonly involve thermally excited spin waves within the ferromagnet. The inclusion of spin-flip collisions couples the otherwise independent differential equations for the spin-up and spin-down electron distribution functions. Solutions of the coupled equations, thus incorporating spin


Figure 8. Spin-dependent scattering of the conduction electrons in a multilayered structure with magnetization aligned (a) parallel and (b) antiparallel. Network model of spin-dependent scattering for (c) parallel and (d) antiparallel magnetization configurations.

mixing, were obtained numerically by Fert's group in the early 1990s [153], with an analytical solution being reported more recently [154]. Calculations including anisotropic scattering within the ferromagnetic layers [155] and angle-dependent interfacial scattering and reflection coefficients [150] were also introduced fairly early on. The early models using a Boltzmann equation approach were followed by the resistor network of Edwards [156] and scattering in superlattices by White [157].

A quantum mechanical approach, based on the Kubo formula and surface scattering introduced by Tesanovic and co-workers [158, 159], was developed in a long series of papers by Levy [2, 160]. Results of the semiclassical calculations deviate from those of the quantum models when the film thickness is much smaller than the electron mean-free path. But the major open problem is the microscopic origin of the spin-dependent scattering by interfaces. Inoe and Maekawa [161] have introduced a theory of the spin-dependent scattering by interfaces in superlattices with nonmagnetic spacer layers by reducing the problem to the classical case of scattering by magnetic impurities. They have considered the scattering of the s electrons by the interface magnetic atoms and the formation of virtual bound states to describe the hybridization of the s- and d-band states at the interfaces. However, this type of calculation should be extended in order to describe rough interfaces and their scattering effects.

4.2. CIP and CPP Experiments

The usual measurements of GMR are made in a straightforward manner with the current flowing in the layer planes (CIP measurements). However, in this geometry, it is difficult to separate and quantify bulk and interface scattering. An interesting development was the breakthrough that allowed measuring GMR in magnetic multilayers with current flowing perpendicular to the multilayer planes (CPP measurements) [162, 163]. Current flowing in the plane of a multilayered structure is expected to be less sensitive to the magnetic configuration of the layers than current flowing *perpendicular* to the layers. Aware of this fact, researchers at Michigan State University (MSU) succeeded in implementing a technique that allowed them to perform an astonishing measurement of the resistance of a multilayer with current flowing from patterned electrodes deposited on the bare substrate (beneath the multilayer) to electrodes deposited on the top surface of the multilayers [164, 165].

The CPP (current perpendicular to the plane) geometry produced the expected enhancement of the GMR relative to the in-plane (CIP) geometry. To overcome the daunting obstacle of measuring the extremely small resistance of macroscopic regions of thin multilayered samples (typically 10–1000 nΩ for 1 mm^2 at 4.2 K), the MSU group employed a fascinating technique involving superconducting metals for the current/voltage leads and a SQUID-based detection system for registering the small voltages and corresponding variations.

The experimental requirements for detecting the GMR in the CPP geometry, at least using the approach developed at MSU, did not offer short-term potential for applications. Near the end of this section, we shall discuss novel systems

where the enhancement of the GMR in the CPP geometry has been brought much closer to future incorporation in devices of various kinds.

Much of the excitement over the development of a technique capable of performing CPP experiments was related to the theoretical models that were being employed to describe transport in GMR systems. Many of the models depend strongly on phenomenological parameters, and some of these are nearly impossible to determine without CPP measurements, which allow direct determination of the crucial bulk and interface spin-dependent parameters [166]. Besides, CPP measurements eliminate the shunting effects caused by buffers, capping or biasing layers present with CIP measurements.

Grooved substrates arise as structures intermediate between CIP and CPP structures to probe the GMR effect [167]. Figure 9 shows the basic geometries of current flowing in GMR systems.

In the current notation of CPP-GMR multilayered films, the resistivities of the magnetic layers for the spin-up and spin-down electrons are written as

$$\rho_{\downarrow(\uparrow)} = 2\rho_{\mathrm{F}}(1 \pm \beta)$$

Similarly, the interface resistance for the unit area is written as

$$r_{\downarrow(\uparrow)} = 2r_{\mathrm{b}}(1 \pm \gamma)$$

where β and γ are the spin asymmetry coefficients of bulk and interface scattering, respectively, and the "average" or zero-asymmetry-limit quantities ρ_{F} and r_{b} are given detailed definitions in the Valet–Fert model [166]. The determination of the spin asymmetry coefficients, β and γ, allows the separate identification of bulk and interface scattering contributions to the GMR.
Figure 9. Three basic geometries of current flowing in GMR systems: (a) current in the plane of the film (CIP), (b) current perpendicular to the plane of the film (CPP), and (c) mixed CIP and CPP geometry using the deposition of the CPP structures on the grooved substrate.

4.3. Spin-Dependent Scattering: Bulk and Interface Contributions

The spin asymmetry coefficients β and γ for bulk and interface scattering of Co and several Co-based alloys were measured in CPP multilayered structures by the group at Michigan State University [168–170] and multilayered nanowires by the Louvain group [171, 172].

Table 1 presents the spin asymmetry coefficients β and γ for bulk and interface scattering results obtained for Co and some Co-based alloys. Both spin asymmetry coefficients are positive and the interface contribution is higher than the bulk contribution for Co, in agreement with previous measurements performed on dilute alloys [8] and theoretical calculations in the dilute limit [179].

It is worth noting that Co/Cu and Co/Ag multilayers have positive values for β and γ, and γ is larger than β independently of the temperature and CPP-GMR measurements employed to derive these parameters.

Therefore, it is interesting to note that in Co/Cu, Co/Ag, and CoFe/Cu multilayers the bulk scattering prevails at larger thicknesses, and there is no compensation thickness where GMR passes through 0 as observed for Fe-based structures where bulk and interface scattering may compete, pulling in opposite ways and in some cases canceling out ($\beta > 0$ and $\gamma > 0$) [180].

That Co–Cr and Co–Mn alloys give rise to negative β is in accordance with measurements and theoretical arguments based on the electronic structure of the bulk materials.

Also, whereas the introduction of Cu in the spacer layer gives rise to positive γ, the introduction of Cr in the spacer layer gives rise to negative γ. The interfacial contribution is a more delicate subject since it is connected to extrinsic potentials (associated with diffusion centers at the interfaces) as well as intrinsic potentials (associated with periodicity of the multilayer). In a general way, the sign of the spin asymmetry coefficients of alloys and interfaces reflects the matching of the d states in the spin direction of majority electrons. Interfacial doping and dusting investigations may shed more light on the extrinsic and intrinsic contributions, but roughness effects make it difficult to clarify this problem.

Mertig et al. [179] have demonstrated that in multilayers, such as Co/Cu, the types of electrons in CIP electronic transport differ from those in CPP. Most of the electronic states involved in the CIP conduction are confined to the nonmagnetic layer probing the scattering potentials within the layer and at their interfaces, whereas the electronic states in CPP conduction are nonlocalized.

There is still another factor that contributes to the "channeling" of the current in CIP as compared to that in CPP: in CIP, the characteristic length scale of the scattering process is the mean-free path, which is, in general, of the same order or smaller than the layer thicknesses. Thus, the influence of the spin-dependent scattering inside the layers is limited to a length scale on the order of the mean-free path around the interfaces. As a consequence, the scattering processes in CIP and CPP systems are distinct with bulk scattering contributing more weakly in CIP than in CPP. Figure 10 shows the influence of QWS in CIP and CPP conduction.

Nowadays, there are at least two important open questions concerning the origin of the GMR: (i) is the GMR mainly an extrinsic effect resulting from the spin-dependent scattering by imperfections and impurities or is it due to the intrinsic nanoscaled potential of a multilayered structure without any need for spin-dependent scattering? (ii) can the spin asymmetry coefficients from bulk and interface scattering, adopted in the GMR models, be derived from electronic structure calculations? An important contribution to the discussion of these questions is given by Vouille et al. [169].

These questions remain open. There is evidence that extrinsic potentials effectively contribute to the GMR. For instance, the doping of the ferromagnetic layers with a few percent of impurities can strongly influence the GMR and even change its sign from negative (normal GMR) to positive (inverse GMR), in keeping with electronic structure calculations. Inverse GMR, where smaller resistance is attained in the antiparallel configuration of the magnetization of consecutive ferromagnetic layers, has been observed in both CIP [181, 182] and CPP [180, 183] geometries when magnetic layers FM1 and FM2 with opposite spin asymmetries alternate in (FM1/N/FM2/N/...) structures. Inverse GMR is

Table 1. Spin asymmetry coefficients for bulk and interface scattering obtained from CPP measurements at low temperatures (4.2–77 K) on selected (FM/Cu/Co/Cu) multilayers, where FM=Co or Co-based alloys [169], Co/Cu grooved substrates [173], Co/Cu multilayered nanowires prepared by electrodeposition [171], Co/Ag multilayers [174], Co/Cr multilayers [169], and CoFe/Cr [175].

System	Bulk scattering spin asymmetry coefficient, β	Interface scattering spin asymmetry coefficient, γ	Ref.
Co/Cu at 4.2 K	+0.46	+0.75	[176, 177]
Co/Cu at 77 K	+0.36	+0.86	[171]
Co/Cu (multilayers)	+0.51	+0.76	[169]
Co/Cu (grooved)	+0.27	+0.76	[178]
Co/Cu (nanowires)	+0.36	+0.85	[171]
Co/Ag	+0.48	+0.83	[174]
Co/Cr	+0.46	−0.24	[175]
$Co_{91}Fe_9$/Cr	+0.65	−0.14	[175]
$Co_{91}Fe_9$/Cu	+0.65	+0.76	[169]
$Co_{90}Cr_{10}$/Cu	−0.12	+0.35	[169]
$Co_{95}Mn_5$/Cu	−0.03	+0.96	[169]
Figure 10. Scheme of the CIP and CPP conduction in FM/NM multilayers. The conduction in CIP weakly probes the scattering process in the ferromagnetic layers since the electronic states responsible are partially confined in the nonmagnetic layer (quantum well states), whereas the conduction in CPP is mainly nonlocalized, probing the bulk as well as the interfaces of the multilayered structure.

strong evidence that extrinsic effects are important in many systems and that the two-current model with its spin asymmetry coefficients is useful for describing GMR phenomena.

Before closing this section, we will address some experimental findings on the influence of growth condition parameters on the GMR effect in Co-based nanostructures which demonstrate the complexity of the problem.

Resistivity is not a truly intrinsic property of metals determined exclusively by band structure. It depends on extrinsic properties such as concentrations of defects, impurities, and other scattering centers (zero resistivity is expected in an ideally perfect crystal or superlattice). Therefore, minor details introduced at the beginning or during the growth stage of Co-based GMR materials may have a significant impact on the strength of the GMR effect due to the interplay between bulk and interface spin-dependent scattering. Indeed, the field dependence of the resistance as a whole could significantly change.

In particular, several experiments indicate that the GMR is strongly dependent on the interface structure (interfacial effects are tremendously enhanced in a multilayer), which, in turn, can be influenced by the deposition parameters such as residual pressure in the growth chamber, the presence of surfactant agents, or intentional mixing of materials at the interface involving thermal treatment during growth.

As an example, let us consider how a specific surfactant modifies the magnetic properties of nanostructures. Thin Co films and Co/Cu superlattices grown with Pb exhibit an induced layer-by-layer growth of Co which delays the fcc to hcp structural transition and strongly reduces the twinning formation in the superlattices. As a consequence, the easy axis of magnetization remains perpendicular to the film plane, allowing the observation of complete antiferromagnetic coupling for both in-plane and out-of-plane magnetization [44].

Let us give two other examples, now involving the deposition conditions. First, the strong influence of the purity of the base pressure on the GMR ratio of Co/Cu multilayers was described by Egelhoff and co-workers [184]. By reducing the partial pressure of water below 10^{-7} Pa, an increase in the GMR ratio has been observed, but a further reduction to 10^{-8} Pa leads to a decrease of about 20% in the GMR ratio. According to Egelhoff et al., the oxygen in the gas acts as a surfactant on the growth, suppressing the intermixing

between Co and Cu and influencing the surface roughness. Second, the strong dependence of the GMR ratio of Co/Cu multilayers on the argon acceleration voltage U_B has been reported by Saito and co-workers [185]. By increasing the U_B from 400 to 600 V, the GMR ratio increases from approximately 5% to 50%. However, a further increase in U_B to 1000 V reduces the GMR effect to 30%. As demonstrated by nuclear magnetic resonance (NMR) measurements, the largest GMR ratio corresponds to the sharpest interface concomitant with predominance of the fcc Co component relative to hcp Co.

Parkin et al. [186], Greig et al. [187], and Tomlinson et al. [188] have discussed the integrity of the layers (pinholes and other accidental bridging) and emphasized the importance of the buffer layer in Co-based multilayers. George et al. [189], Parkin and co-workers [3], and Kataoka et al. [114] have discussed the results of planar doping or dusting in Co-based multilayers where a few atomic layers of any ferromagnetic or nonmagnetic metal is inserted at the interfaces which gives rise to an increase or decrease in spin-dependent scattering or, equivalently, resistivity.

4.4. Current-Driven Magnetization Reversal by Spin Injection

Berger [190] and Slonczewski [191] have argued that a sufficiently large current flowing perpendicular to a magnetic multilayer composed of alternating ferromagnetic FM and nonmagnetic N metals can accumulate and transfer spin between FM layers, stimulate spin wave excitations, and even excite precession of the FM layer magnetizations. Such current-driven magnetization reversal and spin wave excitation phenomena were first confirmed in Co/Cu multilayers at current densities of about 10^8 A/cm^2 [90–93]. To achieve the required high current densities, point contacts (with an area of about 10^2 nm^2) and electron beam lithographically patterned pillars (with an area of approximately 2500 nm^2) were used with contact resistance combining ballistic (Shaving) and diffuse (Maxwell) scattering. Magnetization precession on the femtosecond time scale and even precessional magnetization reversal in nanosized ferromagnetic bits can also be obtained by hot spin injection [192].

Recent experiments performed by Katine et al. [193] and Fert et al. [194] demonstrate clearly the feasibility of control of the magnetization configuration of Co/Cu/Co trilayers by the current intensity. Such experiments have potential applications in high-speed, high-density storage and memory.

4.5. Spin Polarization, Accumulation, and Relaxation

The current understanding of GMR illustrates an important basic point: spin electronic nanostructures work by transferring spin information from one part of the structure to another. This information is mediated by the charge carriers at the Fermi level or above (hot spin electrons), and it decays on a characteristic length scale (the spin diffusion length), which is the average distance diffused by a carrier spin before flipping.

A spin-polarized electron injected into a diamagnetic or paramagnetic medium undergoes many collisions that modify its momentum before it eventually spin flips. The spin diffusion length depends both on the mean-free path and on the spin-flip time and is very sensitive to the presence of impurities. Therefore, material composition and purity are crucial engineering parameters in GMR materials.

Spin accumulation is simply an excess number of up-spins over down-spins (or vice versa), which can be seen as a splitting of the electrochemical potential of the two spin channels. Spin dynamics essentially controls the accumulation and both longitudinal and transverse spin relaxation.

Typical values of the spin diffusion length l_s in Co-based multilayers, where both interfacial and bulk contributions must be taken into account, are 500 nm for Cu and 60 nm for spin-up electrons and 1 nm for spin-down electrons for Co.

Figure 11 shows the spin accumulation around an FM/NM/FM structure.

A crucial difference between the CPP and CIP geometries is the existence of spin accumulation in CPP-GMR systems with the appearance of the spin diffusion length as the unique damping length for the currents. The spin diffusion length is fixed by spin orbit scattering in the low-temperature limit and is expected to be relatively long in GMR systems composed of 3d and noble metals.

The spin accumulation effects at interfaces between ferromagnetic FM and nonferromagnetic NM metals have been described by Johnson and Silsbee [195], van Son et al. [196], and Valet and Fert [166] for isolated interfaces separating two semiinfinite media. Due to the spin accumulation around the interfaces with the NM metal, a spin-coupled interface resistance r_I appears at each FM/NM interface. The physical origin of the r_I is that, to balance spin accumulation by spin relaxation, the chemical potentials of the spin-up and spin-down directions are shifted in opposite directions, which gives rise to spin-dependent pseudo electric fields. As a consequence, there is an additional potential drop proportional to the product between r_I and the current density J. The case of multilayered structures consists of a sort of addition of interface resistance calculated for isolated interfaces.
Figure 11. Schematic drawing of spin accumulation in the case of two semiinfinite layers of ferromagnets FM with opposite magnetization spaced by a nonmagnetic NM metal: (a) the spin accumulation zone extends over a distance on the order of the spin diffusion length l_s at each side of the interface between NM and FM, and (b) variation of the spin-up and spin-down current densities and spin splitting of the Fermi level.

The same assumptions of the Valet–Fert model applied to the FM/semiconductor interface indicate that the main obstacle to spin transfer directly from an FM electrode into a semiconductor, which is associated with the large conductivity mismatch of these materials [197, 198], may be overcome by insertion of a tunnel contact [199]. A concomitant FM resistance comparable to the magnitude of the tunnel contact resistance is needed to induce a *spin splitting* of electrochemical potential in the FM for spin-polarized emission to occur. Recent experimental results corroborate these theoretical predictions [200–202].

Hybrid structures involving the integration of ferromagnetic metals onto semiconductors have been probed and studied in order to utilize the spin degree of freedom in semiconductors. Kikkawa and Awschalom [203] have recently demonstrated that the spin polarization and coherence in semiconductors can be sustained at a time close to a microsecond and transported over a 100-μm scale. A special issue of *Semiconductor Science and Technology* [204] covers the state of the art of semiconductor spintronics to date.

4.6. TMR Systems

In 1995, two research groups [74, 205] independently developed another kind of GMR multilayered material which had been proposed six years later by Slonczewski [206] from the seminal work of Jullière [207]. In these magnetic tunnel junctions, the magnetic layers FM are separated by a thin insulator I barrier in (FM/I/FM) structures. The GMR phenomenon in these tunnel structures is called TMR— tunneling magnetoresistance.

Although some applications of TMR are already in development, the fundamental physics of spin polarization of tunneling electrons is still not completely understood. For example, whereas the polarization of the probability of tunneling from a ferromagnetic metal is expected to be the polarization of the density of states at the Fermi level, the positive polarization found for electrons tunneling from most ferromagnetic transition metals, such as Co, across alumina disagrees with the negative polarization of their density of states [208]. The positive polarizations measured were exclusively attributed to the s character of the tunneling electrons. The state of the art of magnetotransport in tunnel junctions has been recently reviewed by Moodera and Mathon [74] and Tsymbal et al. [132].

Table 2 presents spin polarization measurements for selected ferromagnetic FM transition metals and their alloys, which were measured in superconductor/Al$_2$O$_3$/FM planar junctions by three different research groups.

Table 2. Experimental values of spin polarization of selected ferromagnetic transition metals and their alloys.

Ferromagnetic electrode	Research group		
	Meservey and Tedrow [208]	Moodera and Mathon [74]	Monsma and Parkin [209]
Fe	+40%	+44%	+45%
Co	+35%	+45%	+42%
Ni	+23%	+33%	+31%
Ni$_{80}$Fe$_{20}$	+32%	+48%	+45%
Co$_{50}$Fe$_{50}$	+47%	+51%	+50%

In spite of being distinct phenomena, GMR and TMR are essentially connected by the spin polarization states in ferromagnetic materials. In lithographically patterned magnetic tunnel junctions with planar geometry involving two ferromagnetic metals FM separated by an insulating barrier layer I (FM/I/FM), the tunneling conductivity varies as a function of the angle between the magnetization of the FM electrodes. Similar to those observed in GMR systems, normal TMR (negative) and inverse TMR (positive) have been observed.

Essentially, the physics of TMR is based on Jullière's work [207] using the spin polarization defined as

$$P = \frac{[D_\uparrow(E_F) - D_\downarrow(E_F)]}{[D_\uparrow(E_F) - D_\downarrow(E_F)]}$$

where $D_\uparrow(E_F)$ and $D_\downarrow(E_F)$ are the density of states at the Fermi level E_F for spin-up and spin-down electrons in the ferromagnetic FM electrodes of an FM1/I/FM2 planar junction with an insulating barrier layer I. In a planar junction, the tunneling magnetoresistance (TMR) effect is usually defined as

$$\text{TMR} = (\rho_{AP} - \rho_P)/\rho_P = 2P_1P_2/(1 - P_1P_2)$$

where ρ_{AP} and ρ_P are, respectively, the resistivities in the antiparallel and parallel magnetization configurations of the ferromagnetic electrodes, FM1 and FM2, in a certain applied field interval and P_1 and P_2 are the spin polarizations of the ferromagnetic electrodes at each side of the barrier layer.

In a review of recent results obtained by the Orsay group on the spin-polarized tunneling in magnetic tunnel junctions combining electrodes of ferromagnetic transition metal and half-metallic oxide ($La_{0.7}Sr_{0.3}MnO_3$—LSMO), it is demonstrated that the spin polarization of tunneling electrons is governed by the specific type of electronic bonding at the electrode/barrier interface [194].

In magnetic tunnel junctions Co/I/LSMO with I = $SrTiO_3$ (STO), $Ce_{1-x}La_xO_y$ (CLO), Al_2O_3 (ALO), and ALO/STO, a normal TMR confirms the positive polarization of the tunneling probability from Co when the barrier is ALO. In contrast, when the ALO barrier is replaced by STO or CLO the TMR is inverse. This means that when tunneling is through STO or CLO the polarization of Co is negative, therefore, with the same sign for the polarization of the density of states of the d band of Co at the Fermi level. The role of the nature of the barrier in determining the sign of the spin polarization is consistent with several recent *ab initio* calculations [210–212].

The covalent bonding between Co and O at the interface of Co with O-terminated ALO or hybridization between Co and Al at the interface of Co with Al-terminated ALO is identified as the mechanism responsible for electronic bonding at the interface. Studies of Co/ALO/STO/LSMO junctions with thicker STO exhibit normal TMR. Therefore, the influence of the barrier on the sign of the polarization is mainly due to interface effects.

There is a TMR of about 5% at 300 K in Co/STO/LSMO tunnel junctions. This means that junctions with half-metallic manganites are promising candidates for technological applications in the future.

5. TECHNOLOGICAL APPLICATIONS

MR sensors are based on materials for which the resistance depends on the magnetization state. MR sensors can be divided into two classes of sensors: anisotropic magnetoresistance (AMR) sensors and giant magnetoresistance (GMR) sensors. GMR sensors can be further classified according to the corresponding mechanisms and features: GMR, TMR, and spin valve structured materials. The AMR sensors are currently regarded as being essentially obsolete, whereas members of the GMR class of sensors are largely in development.

Thin-film MR sensors can be used in several kinds of applications, such as magnetic measurements (including magnetometers and gradiometers), electrical measurements (as current transducers as well as switching and logic elements), magnetic data storage (as magnetoresistive heads, magnetic random access memory devices, and magnetic card readers), mechanical transducers (for linear displacements or measurements of rotational speed), and magnetic field imaging.

In this section, we will only address the major improvements and new concepts resulting from the utilization of Co-based GMR sensors. A detailed and complete description of applications of MR sensors can be found in articles dedicated specifically to the subject such as the recent reviews published by Tumanski [6] or Prinz [213].

All devices using GMR, spin valve, and TMR structures are rather complex systems with properties and performance determined by various parameters. Technological factors related to sensors or reading heads and affecting their performance include the following: large MR ratio, large sensitivity, small change of parameters with temperature, and good repeatability and reliability. These features depend on the interface quality (roughness, interfacial mixing), crystal quality (texture, grain size), and material quality (purity of composition and structure definition). The technological parameters also depend on the deposition conditions intrinsic to each deposition method employed such as sputtering, electron beam evaporation, molecular beam epitaxy, and electrodeposition. Important deposition conditions include substrate temperature, quality of the substrate, base pressure, and bias voltage. Also, the performance of patterned sensors may be different from the as-deposited structure.

The most important technological applications of the GMR, spin valve, and TMR structures that we described here are magnetic sensors, read heads, spin valve transistors, and magnetic random access memories (MRAMs). Each of these will be discussed. Finally, we briefly discuss the implications of spin-dependent transport for quantum computing.

5.1. Magnetic Field Sensors

The first large-scale commercial application of GMR has been as magnetic field sensors in the read heads of magnetic recording media for digital information storage.

In comparison with other magnetic sensors, the MR sensors offer some very competitive behavior [214] such as the largest sensitivity per unit area; that is, extremely small sensors still retain good sensitivity. This advantage is appreciated in data storage reading applications [215]. The following attributes of MR sensors can be emphasized: small

dimensions, high reliability, low cost, and wide-frequency bandwidth (from 100 to 10,000 Hz), including dc fields [216].

The magnetic field range recommended for Co-based MR sensors is presented in Figure 12. According to comparative analyses of Co-based GMR systems performed by Tumanski [6], the higher GMR ratio and the higher magnetic field sensitivity for magnetic field sensor applications is found in Co/Cu and CoFe/Cu antiferromagnetic-coupled multilayers.

Despite the large MR effect, the room temperature sensitivity ($\Delta R/R/H_s$) is rather small in AFM-coupled multilayers. Best results are obtained with uncoupled structures and spin valve structures. The parameters responsible for these characteristics for selected systems are presented in Table 3.

A disadvantage of GMR sensors is that the fabrication technology is much more sophisticated, and, therefore, they are more expensive than AMR sensors. Furthermore, GMR sensors are not suitable at high temperatures, while AMR sensors can work without problems at temperatures well above room temperature (up to 190 °C). Therefore, it is not expected that GMR and TMR read heads will completely replace AMR heads.

5.2. Magnetoresistance Readouts

It may be stated that magnetoresistive heads are the main and most important application area of MR sensors due to their market price. The introduction of AMR-based MR heads by Hunt [225] caused a revolution in high-density recording in the beginning of the 1970s. The areal recording density is conventionally expressed in terms of the number of bits stored per unit area (1 Gb/in^2 = 1.55 Mb/mm^2). In the last 10 years, the areal bit density has increased from 0.1 Gb/in^2 to about 10 Gb/in^2 with a bit length of 0.1 μm [226, 227]. As a comparison, we note that a compact disc (CD) exhibits a recording density of about 0.7 Gb/in^2, and a digital video disc (DVD) exhibits a recording density of about 3.3 Gb/in^2.

The operating principle of the unshielded MR head is very simple. An MR head (vertical or horizontal type) in the form of a stripe detects the magnetic field above moving media such as disks and tapes.

Unshielded MR heads have poor performance for high-density recording. The requirements of higher resolution, areal density, and data transfer speed mean that unshielded MR heads are commonly used for long-wavelength signals such as magnetic card readers and detection of ample magnetic field sources.
Figure 12. Typical magnitude and field range of anisotropic magneto-resistance (AMR), spin valve (SV), and giant magnetoresistance (GMR) systems.

Table 3. Selected parameters of Co-based AFM-coupled multilayers, uncoupled structures, and spin valve structures at room temperature, according to Tumanski [6]. (1 kA/m = 12.57 Oe.)

Structure	$\Delta R/R$ (%)	H_s (kA/m)	$\Delta R/R/H_s$ (%:kA/m)	Ref.

[d] Exchange-biased spin valve.
[e] Double-exchange-biased spin valve.
[f] Typical anisotropic magnetoresistive sensor.

Usually, MR heads integrated with inductive writing heads require a shield. Thus, dual-shielded heads are widely used for very high density recording applications [228]. The shield on each side of an MR element can significantly improve its spatial resolution since the shields change the distribution of the magnetic field above the medium concentrating the flux in the gap over the MR element. The spatial resolution depends mainly on the gap length, sensor height (one-track or multitrack heads), and sensor permeability.

A typical commercial MR head consists of two magnetic layers ($Ni_{81}Fe_{19}$ and Co) with a few angstroms of thickness separated by a Cu spacer layer. The moments of one of the magnetic layers are pinned by an FeMn antiferromagnetic layer. The other layer is free to rotate under the influence of the fringing fields from the magnetized media.

Fontana [229] and Tsang [230] have reported the parameters of extremely small heads for gigabit density recording (over 40 Gb/in^2). Submicrometer-wide spin valve and GMR read heads have also been reported [231].

Practical limitations on electronics at very high densities arise from heat dissipation in the head and thermal instability of the medium, and comparisons between read heads containing both a TMR element and a GMR element with sense current in the plane (CIP-GMR) or perpendicular to the plane (CPP-GMR) of the sensor films, as well as the expected parameters of future 100 Gb/in^2 until 300 Gb/in^2 recording, are discussed by Ruigrok et al. [232].

5.3. Spin Valve Transistor

An important concept associated with spin-dependent transport is called spin accumulation, which is simply an excess number of up-spins over down-spins at the electrochemical potential level.

Datta and Das have proposed a spin-based device they called "spin-polarized field effect high transistor" or spin-FET [233].

Johnson [234] has proposed a three-terminal spin transistor, which includes a nonmagnetic base layer sandwiched between a ferromagnetic emitter layer and a ferromagnetic

collector layer. The spin accumulation effect makes the base layer have a different chemical potential than the collector layer and will pump the current either into or out of the collector, depending on the magnetization direction of the collector layer.

The first attempt to realize a GMR metal-based transistor was reported in 1995 [235] and is illustrated in Figure 13. This more sophisticated spin valve transistor uses two Si layers as emitter and collector and a GMR Co-based multilayer as the base [235]. The inelastic mean-free path of hot electrons is spin dependent in ferromagnets, but in spin valve transistors the hot electrons at a mean excess energy of about 0.9 eV became relevant for magnetic sensors and spintronics [237].

The source and drain are different and form Schottky barriers at the metal/semiconductor interface with the GMR metal multilayer base. When one switches the Co/Cu sandwich from the aligned to the antialigned state, a lower drain current will result due to the shorter electron path length (and higher base resistance). More work is needed on this interesting new device for future applications.

5.4. Magnetoresistive Memories

The MR readout scheme consists of the storage of data in a magnetic medium, which, in turn, produces a stray magnetic field that can be detected by a separate MR sensing element. Initially, this concept did not lead to high-density data storage because it was difficult to get a sufficiently large external stray field from a small magnetic storage cell. In the mid 1980s, a new concept of magnetoresistive memory (MRAM) was developed at Honeywell by Daughton and co-workers which included a writing operation using magnetic hysteresis and reading using magnetoresistance of the same components where data are stored. The new class of MRAM
Figure 13. (a) Schematic cross section of a spin valve transistor with Co/Cu nanostructure sandwiched between Si and GaAs substrates. (b) Schematic energy band diagram of the spin valve transistor. The emitter Schottky barrier is slightly higher than the collector Schottky barrier, reducing the quantum mechanical reflections of hot electrons. A 215% change in the collector current was observed at liquid nitrogen temperature between the parallel and antiparallel configurations of magnetization, but only 10^{-4}% of the emitter current was seen at the collector, which seriously limits the applicability of the device. The leakage current from base to collector also precludes operation at room temperature at reverse bias [236].

devices offered revolutionary advances for high-density, random access, nonvolatile memory that was later adapted for use with GMR and TMR structures as magnetoresistive elements. Indeed, the discovery of GMR materials in 1989 [11, 12] immediately prompted higher output signals (factor of about 3) and faster read access time (about 9 times) improvements.

The MRAM concept is illustrated in Figure 14. The magnetic field produced by a current through the stripe magnetized the data cell clockwise or counterclockwise when aided by a current (field) from an orthogonal strip line. Current in either strip by itself would not change the storage state. The original AMR version featured a readout process where the clockwise and counterclockwise configurations were distinguished by their differential resistance (dR/dH) in the presence of a modulated bias current in the orthogonal strip line. For GMR- and TMR-based memory cells, the logical states consist of parallel and antiparallel orientations. The resistance of the cell is higher when the magnetization of the soft layer is antiparallel to the magnetization of the hard layer, and lower for the parallel orientation. It is worth noting that a single MRAM cell within a two-dimensional array could be selectively written. The maximum difference in resistance of the cell between a "1" and a "0" when it is read is about 0.5% with differential sense signals of 0.5–1.0 mV. These MRAMs operate with a read access time of about 250 ns [238] while the write time was 100 ns [239].

It was initially believed that, as the memory cells approached the dimensions of a domain wall width, there would be no more problems with multidomain magnetization in the cells. Recently, a vortices magnetization storage mode in round MRAM cells has been observed [240, 241]. The practical lower limit to MRAM storage area would be about 0.1 μm on a side. The utilization of circumferential remnant magnetization structures may circumvent this problem. This storage method does not create vortices for cell sizes down to less than 100 nm diameter (approximately 30 nm inside diameter).

Another challenge for high-density MRAM is cell stability at nanometer dimensions. As the cell size shrinks and the volume of magnetic material becomes smaller, thermal agitation can cause a cell to lose data, that is, the so-called superparamagnetic limit. If a spin valve cell is used as the storage cell, the heating effects of the word and digit currents can heat the cell above the Néel temperature of the antiferromagnetic pinning layer, erasing the storage information.

The stability of the MRAM cell is an energy problem, involving thermal activation energy estimated as k_BT, where k_B is the Boltzmann constant and T is the temperature, and the magnetic energy associated with storage estimated as
Figure 14. Design of an MRAM cell which has radiation hardened and which has faster switching than the conventional SRAM. Comparison of performance and parameters for various types of volatile and nonvolatile memory chip alternatives can be found in [236].

MH_cV, where H_c is a critical field that prevents magnetization reversal, M is the saturation magnetization, and V is the volume of the magnetic material in the cell. If the volume is reduced, the magnetic energy approaches a value of k_BT and the error rate in the memory becomes unacceptable. It is interesting to note that making H_c ever higher does not work because of the current required to write and the resultant heating of the cell (raising kT).

Besides, GMR materials had serious limitations in comparison with semiconductor memories (SRAM and DRAM), which are still faster because of the low MRAM sense signal. Recently, MRAM as a nonvolatile, solid-state memory has been tested to replace flash memory and EPROM.

TMR devices provide a higher percentage of magnetoresistance than GMR sandwiches or spin valve structures and thus have the potential for higher signals and higher speed. Recent results indicate TMR cells giving magnetoresistance about 4 times higher than good GMR cells [242].

Promising results in the construction of an MRAM with tunnel junction cells arranged in the cross-point architecture were reported by Parkin et al. [243]. The design of the cell is quite similar to that shown in Figure 14. The tunnel junction consists of a bottom electrode and a top FM electrode of Permalloy separated by a tunnel junction of oxidized Al. The bottom electrode is composed of a Co/Ru/Co/FeMn exchange-biased sandwich. The Co-based exchange-biased magnetic tunnel junction devices might be used as magnetic nonvolatile storage elements. The advantages of TMR-based devices compared to GMR-based devices are the following: higher nominal resistances (typically 10 Ω in GMR becomes 1000 Ω in TMR), which reduce the required operation power; higher resistance change (typically 1 Ω in GMR becomes 100 Ω in TMR), which gives a better sensitivity, and an output signal about 100 times larger than those obtained in GMR-based devices and about 1000 times those obtained in conventional AMR-based devices.

5.5. Quantum Computation

The current standard of electronic devices and data storage media has reached a level of miniaturization and storage density such that magnetic materials have to be fabricated on a nanometer scale. The emerging concept of spintronics, which is based on the fact that current carriers have not only charge but also spin, requires the assembling of nanometer-sized magnetic structures with the desired magnetic properties. This is an important part of the background that motivates scientists and engineers to attempt to grow and characterize magnetic objects at smaller and smaller length scales, ranging from 2D films and multilayers to 1D wires and eventually to 0D dots.

In particular, Shen and Kirschner [244] recently addressed the impact of tailoring magnetic phenomena in artificially structured Co-based material in the spintronics field. They review, for example, the most significant progress in recent years in the effort of growing artificially structured magnetic materials and the new structural and magnetic properties of these materials are discussed.

An important point is that the quantum transport properties of charge carriers, such as an electron or hole, are not only determined by the quantum motion of the particle as a whole, but can involve internal degrees of freedom such as spin. Spintronics is the fastest growing area of quantum electronics due largely to the possible applications to conventional information processing and storage [245]. The possible application to quantum computing has been noted by many research groups [246].

6. FINAL REMARKS

The existence of ferromagnetic order and large magnetoresistance in nanoscaled structures obviously is encouraging and important news for scientists who are interested in low-dimensional magnetism. Since the magnetization direction can be oriented along any desired direction with high accuracy, magnetic structures can be efficiently used in data storage and magnetic switching and sensoring devices.

The field of spintronics has been growing dramatically in recent years. The central idea of spintronics is the fact that conduction electrons (or holes) carry not only charge, but spin. The recognition of this additional degree of freedom is the key that promises a new generation of spin-based devices whose operation relies on differentiated manipulation of independent families of spin-polarized current carriers.

The emerging field of spin-based electronics promises to have a substantial impact on the future technology. Major challenges in this field include (i) the efficient injection of spin polarization as well as spin-polarized currents, (ii) the transport of spin-polarized carriers across relevant length scales and heterointerfaces, and (iii) the control and manipulation of electron spins on sufficiently fast time scales. As demonstrated in this review, Co-based nanostructures are archetypes and intrinsically favorable as materials for spintronics applications because Co provides an effective source of electron spin polarization at room temperature for ohmic injection, tunnel injection, hot electron injection, and ballistic electron injection. Co-based GMR magnetic field sensors for general purposes and GMR spin valve read heads for hard disk drives are currently commercially available. Co-based MRAM prototypes are not available, but production is anticipated in the next few years. Co-based multilayers are also potential candidates for GMR isolator elements, which combine a planar coil and a GMR sensor on an integrated circuit chip to perform a function similar to that of opto-isolators, which provide electrical isolation of grounds between electric circuits.

Considerable advances in our basic understanding of spin interactions in the solid state as well as in new materials engineering, lithography, and device fabrication are still necessary, but certainly Co-based nanostructures will continue to be an important part of this future.

GLOSSARY

Exchange bias Exchange interaction across the interface between antiferromagnets and ferromagnets with pinning of the ferromagnet magnetization.

Giant magnetoresistance   Appreciable change in the resistance of nanostructured systems when an applied magnetic field, strong enough to magnetically saturate the system, brings the magnetization of all magnetic entities into alignment.

Interlayer exchange coupling   Magnetic interaction via quantum mechanical mechanisms that aligns parallel or antiparallel the magnetic moments of ferromagnetic layers spaced by an intervening layer.

Magnetoresistance effect   Phenomenon in which the resistance of a material depends on its state of magnetization.

Quantum well state   Quantum mechanical state of nanostructured systems that comes from the confinement of the electron wave functions to dimensions comparable with their wavelengths.

Spin accumulation   Excess number of up-spins over down-spins (or vice versa) and hence also of magnetization in a certain spatial zone.

Spin injection   Spin information transfer from one part to another mediated by the electrical carriers near the Fermi energy.

Spin polarization   Excess number of spin-up over spin-down electrons (or vice versa) at the Fermi level of ferromagnetic materials or in an electric current flow.

Growth Simulations of Nanoclusters

F. Baletto, R. Ferrando, A. C. Levi

Università di Genova, Genova, Italy

CONTENTS

1. INTRODUCTION

As this whole encyclopedia shows, the fabrication and study of nanostructures are presently central subjects of both science and technology. These structures typically form by growth (or by erosion), either on a substrate or in free space. The growth process occurs in the laboratory, but also may be simulated in a computer; in the latter case (provided that the simulation is realistic enough) the properties of the growing structure can be followed from the beginning and more deeply understood at the atomistic or molecular level.

In the 20th century, the study of how matter behaves has followed two streams: one focused on the properties and interactions of individual atoms, and later of subatomic components (which is the field of nuclear and particle physics); the other emphasized the properties of very many atoms or molecules together, so many that the aggregates they make can be treated as infinite. The realm between these two limits concerned only a few independent souls until about the late 1970s.

Although the birth date of nanotechnology can be fixed on December 29, 1959, when Richard Feynman in a famous speech said: "What I want to talk about is the problem of manipulating and controlling things on a small scale.... In the distant future we will be able to arrange the atoms the way we want.... There is plenty of room at the bottom." Very little happened until some time later. We recall that the term *nanotechnology* was introduced for the first time in 1974 by N. Taniguchi (of Tokyo University) to define the engineering of submicroscopic systems on the atomic scale (that of nanometres), and to separate it from the more conventional *microtechnology*. Since then, interest has increased explosively in the study of nano-objects, both deposited or grown on a substrate, and free in space (nanoscience), as well as in their fabrication for useful purposes (nanotechnology). For the latter, it is necessary to work with systems of sizes between 1 and 100 nm, and these systems have to be produced via well defined methods in order to get a good definition of the final structure and a good control on it.

In the 1980s two fundamental discoveries in the field of nanoscience were made, allowing a wider study of the nanoworld and opening new horizons. At the IBM of Zurich, G. Binnig and H. Rohrer (Nobel prize 1986) built the scanning tunneling microscope (STM), which is of basic importance in order to visualize and study a surface from an atomic point of view. At the Rice University of Houston, Texas, R. Smalley (Nobel prize 1996, with H. Kroto and R. Curl) found a new molecule, C_{60}, which became the progenitor of a new class of materials (called *fullerenes* in the honor of a famous American architect), including the so-called nanotubes.

What can we expect from this nanoworld? Introducing the nanotechnology into our macroworld, it is possible to improve the present technology, in order to fabricate more and more efficient microchips, able to elaborate data faster and faster; to accumulate terabytes in few square centimeters of magnetic substrates; to create new materials with new structural properties; to produce new sensors for medical purposes.... up to nanorobots and nanomachines: the new science fiction.

Of central importance in this context are what have come to be called *clusters*, which can be considered as the building blocks of nanoscience and nanotechnology. Clusters are aggregates of atoms (or molecules), generally intermediate in size between individual atoms and objects large enough to be considered as *bulk matter*. When we speak of *small* clusters we mean something of size $d \approx 1$–3 nm, containing no more than a few hundreds or possibly a thousand particles (atoms or molecules); *large* clusters, on the other hand, consist of many thousands of particles ($d \approx$ tens of nm). We can grow clusters either on a substrate or in free space. In both cases, clusters can be 2-D or 3-D.

The nanoworld is at the boundary between the world of atoms and molecules, which is ruled by quantum mechanics, and the macroworld ruled by classical mechanics. A basic aim of nanoscience is to understand the properties of nano-objects, grown either on a substrate or in free space: Since their behavior is intermediate between quantum and classical, it is not trivial to find a universal modeling to describe their properties.

In this sense, a good way to study both free and supported clusters (the latter corresponding to nanostructured surfaces) is to simulate their growth processes from the beginning, and to compare the results obtained with the experimental data, in order to understand more deeply the properties we wish to investigate. In this chapter, we will discuss such simulations in two geometries:

- Surface growth on a substrate, which may also be of the same nature as the growing structure.
- Cluster growth in free space (and then deposited on a substrate).

First of all, we want to describe the computational methods that can be used to analyze nanostructure growth processes, focusing our attention on a ticklish question in this field: the time scale. In fact, an important point that must be discussed before dealing with the simulation of materials growth is the problem of reaching the correct length and time scales. These scales depend on the specific features of the growth experiments, but there are typical ranges which can be easily singled out.

In the case of the epitaxial growth on a substrate [1], the typical length scale is determined by the size of the crystal terraces, which can be of 10^3 Å or more. This means that each atomic layer in the growing crystal contains at least several thousands of atoms. On the other hand, the experimental fluxes range from a few monolayers per second to fractions of a monolayer per minute.

On the contrary, the growth of free clusters of a few hundreds of atoms in gas phase takes place on the time scale of fractions of a millisecond. In this case, the length scale, which corresponds to the diameter of the cluster, is a few tens of Å [2–4].

Because of the above differences in the typical length and time scales, and depending on the quantities that have to be calculated, different methods are appropriate in the simulation of these systems. The typical tools range from *ab initio* calculations of the electronic structure to molecular dynamics (MD) with interatomic potentials to kinetic Monte Carlo (KMC) simulations. Let us analyze these methods in relation to their possible applications to the simulation of actual crystal or cluster growth.

The *ab initio* calculations [5] are the most reliable and least approximate, but are computationally very expensive. At the moment, they are limited to sizes around a hundred atoms, and they can extend to times of a few tens of picoseconds. Therefore, they cannot be used at all for simulating any real growth process, neither for crystals nor for clusters. However by *ab initio* methods, the energy barriers for many diffusion mechanisms can be computed, and these barriers may serve as an input for KMC simulations. Unfortunately, it is quite expensive to implement methods for the automatic search of saddle points into an *ab initio*

scheme. In the case of semiconductors, longer time scales (some nanoseconds, but again on small sizes) can be reached by tight-binding simulations [6]. These methods are thus better suited to investigate the elementary diffusion processes than for simulating crystal growth.

The MD [7] technique relies on the description of the element under study by means of semiempirical interatomic potentials. Reliable interatomic potentials have been developed for simple metals and transition metals, and for some semiconductors [8]. In the MD simulations, a detailed microscopic description of the system is achieved. In a standard MD simulation, the classical equations of motion are solved by the discretization of time in steps δt. In order to have a precise solution of the equations of motion, δt must be much shorter than the fastest phononic periods (which are in the order of 10^{-12} s). Therefore, typical δt are in the range of 10^{-14}–10^{-15} s. The number of steps that can be accumulated during a simulation depends on the system size; at present, systems with $N \sim 10^4$ atoms can be simulated on about 10^7 steps. This means that a simulation of epitaxial crystal growth on experimental sizes by standard MD can reach a time scale of 10^{-7} s, which is at least seven orders of magnitude faster than the real experiments. The situation is different in the case of free nanocluster growth. The experimental time scales are much shorter (10^{-3}–10^{-4} s), and many fewer atoms must be simulated. This allows one to extend the number of time steps up to 10^{10}, thus reaching a simulation time that is only one or two orders of magnitude faster than the experimental time, and this allows a direct comparison between the simulations and the experimental data.

A recent method for extending the time scale of simulations maintaining the detailed microscopic description of the MD technique is accelerated molecular dynamics (AMD) [9], for which different methods have been developed, mostly based on the assumption that the transition state theory (TST) holds [10]. The AMD simulations can reach the actual experimental time scales of epitaxial growth but still on small sizes (say a few hundred atoms) and only at low temperatures, where the acceleration boost is much more effective.

However, the most effective tool for simulating the epitaxial growth is still the KMC method [11, 12]. In these simulations, space is discretized on a lattice. A set of possible moves (a move corresponding to the displacement of an atom from an equilibrium site to another) is chosen, and time is coarse grained, so that the elementary time scale is the rate of the fastest movement. Rates are assumed usually to have an activated form, so that the rate of a given process a is $\Gamma_a = \Gamma_a^0 \exp[-E_a/(k_B T)]$, where E_a is the activation barrier and Γ_a^0 is a temperature-independent prefactor. The probability of choosing a move is proportional to its rate. In this way, both experimental length and time scales can be reached, at the expense of a much less detailed description of the system under study. In fact, it is practically impossible to take into account all possible atomistic processes in a KMC simulation. Therefore, one usually chooses a subset of processes, with the hope that it will be sufficient to grasp the essential physics of the growth process. On the other hand the KMC method is not well-suited to study free nanocluster growth, because nanoclusters can assume both crystalline

and noncrystalline structures, and this forbids the use of a fixed lattice of coordinates. Moreover, the rearrangement processes are so complicated that they cannot be fitted into a simple table of elementary moves.

This chapter is subdivided into two parts. In the first part, of general character, which corresponds to Section 2, we shall deal with a description of the three above mentioned computational/simulational techniques, describing the most important algorithms of specific interest for nanogrowth simulations. In the second part, we shall treat examples that constitute successful applications of the methods described in Section 2. Specifically, in Section 3 we shall describe applications to thin films and cluster growth on surfaces, whereas in Section 4 we shall deal with the growth, solidification, and coalescence of free nanoclusters. Finally in Section 5 we present the conclusions.

2. SIMULATION METHODS

2.1. *Ab Initio*

There are different kinds of *ab initio* simulations, depending on the degree of how *ab initio* they really are. In all cases, nowadays, density functional theory (DFT) is used. We briefly recall the main principles of the theory, as described (in the context of surface physics) for example in Refs. [5, 13].

According to the Hohenberg–Kohn theorems [14, 15], the specification of an electronic ground state density $n(\mathbf{r})$ determines the corresponding external potential $v_{ext}(\mathbf{r})$ uniquely: In other words, the density $n(\mathbf{r})$ contains all the relevant information for the calculation of the electronic energy and of all the other relevant properties of the system (and the explicit calculation of the many-body ground-state wave function is not necessary). The external potential v_{ext} in principle is nothing but the Coulomb potential due to the nuclei, assumed fixed according to the Born–Oppenheimer (BO) approximation (see below, however). The electronic energy is thus a density functional $E_v[n]$, that has to be minimized.

The functional is

$$E_v[n] = T[n] + \int v_{ext}(\mathbf{r})n(\mathbf{r})\, d^3r + 1/2 \int u(\mathbf{r})n(\mathbf{r})\, d^3r + E_{xc}[n] \tag{1}$$

where: $T[n]$ is the kinetic energy functional; the second term describes the interaction with the external potential; the third term describes the Coulombic repulsion

$$u(\mathbf{r}) = e^2 \int \frac{n(\mathbf{r}')}{|\mathbf{r}' - \mathbf{r}|}\, d^3r' \tag{2}$$

of the electrons among themselves; and the fourth, *difficult* term $E_{xc}[n]$ contains all the effects of exchange and correlation.

Because of the last term, evaluating the energy functional may seem hopeless. However, it must be recalled that for a *uniform* electron gas (where there is no external potential and the density is the only variable) the functional reduces to a *function*, which is known with considerable precision, such as from the work of Ceperley and Alder [16].

Minimizing the functional implies solving a system of effective single-particle Schrödinger equations (the Kohn–Sham equations [17]), the potential occurring in the equation being an appropriate functional derivative with respect to the density. In the local density approximation (LDA) the functional used is computed at constant density, using the above well-known results for the uniform electron gas, while more advanced approximations take into account approximately the effect of the density gradients for a nonuniform electron gas.

It must be observed that in real calculations the electrons studied are nearly always the valence electrons only. The core electrons are taken into account replacing the nuclear potential by an appropriate pseudopotential, which plays then the role of the "external potential" of the theory.

True *ab initio* simulations would imply treating the electrons and the nuclei together. For decades this was believed to be an impossible feat, not only because of mathematical complications, but also because of the very different time scales involved. From the BO (or, more generally, adiabatic) point of view, the rapidly moving electrons adapt at each instant of time to the nuclear positions, and their energy constitutes, in turn, the potential in which the nuclei move. To each electronic state corresponds a potential energy surface (PES), or rather hypersurface, in the space of nuclear positions and energy.

This point of view is still valid, of course (apart from special points on hypercurves where two hypersurfaces cross and the adiabatic approximation does not apply). But some modern calculations based on density-functional theory, while retaining the BO approximation, manage to follow both the nuclear and the electronic motions.

The most extreme case is the Car–Parrinello approach [18], where the electronic behavior (quantum-mechanical, of course) is simulated by replacing the electron variables by a (large) set of fictitious classical variables. If the latter are chosen properly, they mimic the electron behavior very closely while at the same time allowing the use of a classical simulation based on Newton equations.

A simple use of the Car–Parrinello method is to let the surface atoms move and relax until they find different (partial) equilibrium positions, whose energies are then compared to find the most favorable one, as in the true equilibrium situation. A very recent, instructive example is the work by Sonnet et al., where the different arrangements for coadsorption of C and H on a Si(100) are discussed [19]. (The most favorable arrangement, in particular, is found to be that where H is bound to C and C is imbedded in the Si surface: not surprisingly, since, as the authors point out, the C-H bond is considerably stronger than the Si-H bond.)

The Car–Parrinello method, however, may be used, more daringly, to follow the real motions of atoms in time: i.e., kinetically. This approach is completely correct, because by the Hellmann–Feynman theorem the forces follow exactly (within the BO approximation) from the simulation. The theorem [20] asserts, indeed, that (except for the small forces that arise from deviations from the BO approximation, and apart from magnetic or relativistic effects) the quantum-mechanical forces on the nuclei are just exactly the classical Coulombic forces arising from the charges on

the nuclei interacting with the charge density of the electron cloud.

In this case a new parameter, the total duration t_{total} of the simulation (in microscopic time), becomes relevant

Here an appropriate example is the simulated diffusion of a proton within a silicon matrix by Buda et al. (even though this outstanding work does not refer specifically to surfaces or clusters, we cite it here for its paradigmatic nature) [21]. Trajectories for the H$^+$ motion through both crystalline and amorphous Si are obtained. An inherent limitation, however, is that the proton dynamics is treated classically, while in principle H$^+$ should be treated quantum-mechanically along with the electrons. In the crystalline case, diffusion proceeds via jumps between states of high symmetry, while very different paths are followed in the amorphous case. This study is also remarkable for its rather long t_{total}, but in less fortunate cases the latter can be quite short.

To briefly explain the Car–Parrinello method, we recall that in DFT [15] the electron density (which can be written in terms of occupied single-particle orbitals) minimizes the energy functional for given nuclear positions and external constraints. Instead of writing down the equations corresponding to such minimization (i.e., the Kohn–Sham equations [17], which, for relatively large systems, become rapidly difficult to solve), Car and Parrinello introduced a Lagrangian equation including in the kinetic part, beyond the nuclear velocities with their real masses, the time derivatives of electronic orbitals with fictitious masses, and solve the problem by "classical" molecular dynamics, using *simulated annealing* to avoid being trapped in local minima. An illuminating discussion of the numerical implementation of the Car–Parrinello method was given by Remler and Madden [22].

The Car–Parrinello method is by no means the only relevant *ab initio* method for simulating surfaces, clusters, etc. The quantum Monte Carlo methods, in their various versions, are equally important. In particular, the *path-integral Monte Carlo* method (essentially due to Pollock and Ceperley [23]) allows the study of specifically quantum-mechanical properties. One such application is the remarkable study by Sindzingre et al. of the superfluidity of hydrogen clusters, which we shall quote again in the chapter dealing with nanoclusters [24].

The *ab initio* method proposed and used by Gross and Scheffler is quite different [25]. Since (if the electronic structure, total energy, and forces acting on the nuclei are to be evaluated during the journey of the particles) computing each trajectory is a heavy computational task to be performed over and over again, Gross and Scheffler prefer to avoid all this by first evaluating the PES once for all, then studying (usually classically, but in the case of hydrogen, quantum-mechanically [26]) the nuclear motion on such PES. This method reverts in a sense to a more traditional, adiabatic treatment, which is, however, quite sufficient in many cases where nonadiabatic effects are inessential. Surface chemistry usually involves nonadiabatic effects in a mild fashion; for example, the dissociative adsorption of a diatomic molecule, although a chemical reaction, can be satisfactorily described, as is well known, by a single PES where the relevant coordinates are the distance of the molecular center of mass from the surface and the distance between

the nuclei of the two atoms. This is precisely the case studied by Gross and Scheffler in their seminal article [25]; moreover, they consider the dissociative adsorption of *hydrogen* on Pd(100) in order to show that the quantum-mechanical properties of the nuclei do not hinder a satisfactory treatment according to their method.

A less delicate case (and also more relevant for the present review) is that of diffusion. For many diffusion problems, there is little doubt that Scheffler's methods apply: calculating correctly the PES may be a difficult problem, and studying the diffusion process on such PES may be another, but nonadiabatic effects (with the possible exception of diffusion on the surfaces of semiconductors and valence crystals, where bonds are continuously broken and reformed) can hardly be a difficulty.

In a previous article [27] Stumpf and Scheffler treated in great detail the self-diffusion of Al atoms on several aluminum surfaces, showing how density-functional theory affords considerable precision in the computation of the barriers for diffusion.

Using DFT, Stumpf and Scheffler investigated properties of Al(111), Al(100), Al(110), and stepped Al(111) surfaces. In particular, in the case of Al(111), for adsorption and diffusion of Al on flat regions, the hcp site was found to be slightly preferred energetically over the fcc site. The energy barrier for diffusion is very low (0.04 eV). Close to either of the two sorts of close-packed monatomic steps on Al(111), Al adatoms feel an electronic attraction toward the step edge, which has a range of several lattice spacings. Stumpf and Scheffler also discussed island shapes: in equilibrium the islands are hexagonal; during growth the shapes may be fractal, triangular, or hexagonal depending on the kinetics [27].

Similar to the methods of Scheffler's group are those of Feibelman [28, 29]. A general discussion of the theoretical methods used is given in the first paper cited, while for example in the second paper cited Feibelman computes from first principles the energetics of steps on Pt(111). Platinum is complicated because of the *d*-electrons (previous calculations, including those of Stumpf and Scheffler, had been mostly done on *sp*-bonded materials), and Feibelman stresses the new problems that arise for Pt. The pseudopotential is essential (Feibelman uses that of Hamann [30]), but equally essential is a correct use of the LDA where the energies of a uniform electron gas are those calculated with great accuracy by Ceperley and Alder [16] and parametrized by Perdew and Zunger [31]. The step energies computed by Feibelman, however, are not in complete agreement with experiments, probably showing that the LDA is not accurate enough.

Indeed, more recent work (too vast to be reviewed here) tries to achieve a better agreement by going beyond the LDA. For example, the generalized gradient approximation (GGA) goes beyond the LDA by including, besides the properties of the uniform electron gas, terms related in a rather sophisticated way to the density gradients. The GGA is believed to be a definite improvement over the LDA (contrary to older attempts to include the gradients, which failed, the reason being that those *naive* gradient corrections violated some fundamental physical rules of the electron gas,

such as that the exchange hole density must be strictly negative and its integral must be exactly −1 [5]).

But even with the GGA the results are sometimes disappointing. An interesting paper by Lorensen et al. on the mechanisms of self-diffusion on Pt(110) compares, both in the LDA and in two versions of the GGA (PW91, RPBE), two different diffusion paths along the grooves of the missing-row reconstructed (110) surface [32]: the *direct* path and a more winding *facet* path exploring the flanks of the groove. While the LDA favors the direct path, the GGA is ambiguous; the RPBE version favors the facet path, but for the PW91 version both paths are equally probable.

Recent papers by Feibelman consider various interesting problems relevant for surface diffusion [33–35]. *Concerted substitution*, i.e., the process where growth occurs by implanting adsorbed atoms into the outermost layer of a metal, was studied by Feibelman and Stumpf [33], who proved that such a process occurs more easily on those transition metal surfaces where the relaxation around an adatom is greater, as had previously been conjectured by Kellogg et al. [36]. Feibelman then considers diffusion along the bottom side of a step, where another kind of *concerted substitution* is possible, but proves that (at least on Pt(111)) this process has to overcome a higher energy barrier than hopping diffusion [34]. In the last paper cited above, two different diffusion modes of dimers on Pt(110) (dimer dissociation and recombination, and the leapfrog mechanism suggested by Montalenti and Ferrando [37] where the back atom overcomes the front atom) are compared [35]. Feibelman concludes that leapfrog should be by far the most probable mechanism. Since this is not what is observed experimentally, Feibelman suggests that the discrepancy may be due to CO contamination, frequent on Pt surfaces.

Finally we remark that calculations from first principles are desirable, but rather heavy computationally. As a consequence, the size of the systems that can be simulated is usually rather small: A typical piece of surface may contain, for example, $10 \times 10 \times 2$ atoms (the third number referring of course to the direction into the bulk). The situation is not catastrophic, however, since the cell is repeated on the surface and no spurious boundary effects appear. Concerning free clusters, the *ab initio* calculations are limited to sizes of about one hundred atoms.

2.2. Molecular Dynamics Simulations

Numerical simulations are good tools to study the properties of the many-body systems. They allow one to compute both instantaneous quantities and averages on time or the number of particles. The latter are of fundamental importance since they are comparable with experimental data. To estimate correctly these quantities it is necessary to introduce statistical mechanics into a computational simulation.

Molecular dynamics is the method used to study equilibrium and transport properties of classical many-body systems. *Classical* means that the motion of particles can be well described by Newtonian laws. This approximation is valid for a great variety of materials and in a wide range of temperatures. In fact, let λ_T be the thermal De Broglie wavelength given by $\lambda_T = \frac{h}{\sqrt{2\pi m k_B T}}$. For typical values of the

lattice constant $a \sim 2\text{–}3\,\text{Å}$, we have that $\lambda_T < a$ for $k_B T > \frac{h^2}{2\pi m a^2}$, which corresponds to consider $T > 20$ K for heavy metals. The aim of an MD simulation is not to predict precisely what will happen to a system that has been prepared in a precisely initial condition: we are always interested in statistical predictions. We wish to predict the average behavior of a system that was prepared in an initial state about which we know something (e.g., the total energy).

We deal with the techniques used to solve the classical equations of motion for a system of N particles (atoms or molecules) interacting via a potential $\mathscr{V}$, which can be written in terms depending on coordinates of individual particles, pairs, triplets, and so on:

$$\mathscr{V} = \sum_i v_1(\mathbf{r}_i) + \sum_i \sum_{j>i} v_2(\mathbf{r}_i, \mathbf{r}_j)$$
$$+ \sum_i \sum_{j>i} \sum_{k>j>i} v_3(\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k) + \cdots \tag{3}$$

We can simulate microcanonical systems to analyze the diffusive motion of adparticles on a substrate and canonical systems to study growth processes.

We consider a classical system Γ consisting of N particles in a volume V in the phase space $\Omega(\mathbf{p}, \mathbf{q})$: its microscopic state is described in term of positions p_i and momentum q_i of each element of our system. Working in the Born–Oppenheimer approximation, it is possible to write the Hamiltonian $\mathscr{H}$ of the system as $\mathscr{H} = \mathscr{T} + \mathscr{V}$, where $\mathscr{V}$ is the potential term and $\mathscr{T}$ is the kinetic energy, and it is usually given by

$$\mathscr{T} = \sum_{i=1}^{N} \sum_{\alpha=1}^{3} \frac{p_{i\alpha}^2}{2m_i} \tag{4}$$

where m_i is the mass of the particles and the index α runs on the components of the momentum.

If the potential is conservative, we can write the motion equations in the Hamilton–Jacobi formalism. In the configurational space $\mathscr{Q}(\mathbf{q}, \dot{\mathbf{q}})$, the time evolution of a holonomic system is given by

$$-\dot{p}_k = \frac{\partial \mathscr{H}}{\partial q_k}$$
$$\dot{q}_k = \frac{\partial \mathscr{H}}{\partial p_k} \tag{5}$$

If we consider a system of atoms, with Cartesian coordinates $\mathbf{r}_i$ and the previous definitions of $\mathscr{V}$ and $\mathscr{T}$, the motion equation can be written as

$$m_i \ddot{\mathbf{r}}_i = \mathbf{f}_i \tag{6}$$

where m_i is the mass of particles i and $\mathbf{f}_i = -\nabla_{\mathbf{r}_i}\mathscr{H} = -\nabla_{\mathbf{r}_i}\mathscr{V}$ is the force on particles i. For systems described by a potential that is independent of time and velocities, we have that $\mathscr{H}$ is automatically equal to the total energy; and thus we have

$$\dot{\mathbf{r}}_i = \frac{\mathbf{p}_i}{m_i}$$
$$\dot{\mathbf{p}}_i = \mathbf{f}_i \tag{7}$$

Computing center-of-mass trajectories, then, involves solving either a system of $3N$ second-order differential equations or an equivalent set of $6N$ first-order equations. Before considering how to do this, we can make just one general remark concerning the equations of motion: Newton's equations are time reversible, and so should be our algorithms. By changing the signs of all velocities or momenta, we will cause the particles to retrace their trajectories. The computer-generated trajectories will also have this property.

If we simulate a microcanonical system of N particles in a given volume V, its Hamiltonian $\mathcal{H}$ satisfies the condition $E < \mathcal{H} < E + \Delta E$ with $(\Delta E/E) \ll 1$; in other words in a microcanonical system N, V is constant and E is well conserved. The locus of points in Ω describing $\mathcal{H}(\mathbf{p}, \mathbf{q}) \equiv E$ defines a hypersurface of energy E. If the system evolves in time following the Hamilton equations, the representative point runs on this hypersurface. We require the system to preserve its energy in the range between E and $E + \Delta E$. We may also speak about a Gibbs ensemble, which is represented by a point distribution in the phase space characterized by a density function $\rho = \rho(t, \mathbf{p}, \mathbf{q})$. In the Gibbs scheme, the Hamiltonian satisfies the Liouville theorem $(\partial \rho / \partial t) + \{\mathcal{H}, \rho\} = 0$. If we want to study equilibrium properties we can focus our attention on those systems whose equilibrium density ρ_{eq} depends only on $\mathcal{H}$, i.e. on the energy. If ergodicity is assumed, time averages are equal to ensemble averages, the latter being defined by

$$\bar{f} = \frac{1}{N! h^{3N}} \frac{\int f(\mathbf{q}, \mathbf{p}) \rho_{eq}(\mathbf{q}, \mathbf{p}) \, d^{3N}p \, d^{3N}q}{\int \rho_{eq}(\mathbf{p}, \mathbf{q}) \, d^{3N}p \, d^{3N}q} \quad (8)$$

where f is a macroscopic function in phase space. In particular, letting γ_i be a generic coordinate $(\mathbf{p}_i, \mathbf{q}_i)$, its mean value in the microcanonical ensemble is given by

$$\overline{\gamma_i \frac{\partial \mathcal{H}}{\partial \gamma_j}} = \frac{\int_{E < \mathcal{H} < E + \Delta E} \left(\gamma_i \frac{\partial \mathcal{H}}{\partial \gamma_i}\right) d^{3N}p \, d^{3N}q}{\int_{E < \mathcal{H} < E + \Delta E} d^{3N}p \, d^{3N}q}$$
$$= \cdots \text{to first order} \cdots \delta_{ij} k_B T \quad (9)$$

which is the analytic form of the generalized energy equipartition theorem.

The limit of considering only the microcanonical ensemble is that we have to study only a given region of phase space and so it is impossible to describe directly the thermal equilibrium. We will show in the following that it is possible to simulate a canonical ensemble by a change in the Hamiltonian, i.e. adding a thermal contact with a thermostat. The most remarkable difference between the two approaches is that in a canonical simulation the energy fluctuates around its average and its variance is given by $\sigma_{\mathcal{H}}^2 = \overline{\mathcal{H}^2} - (\overline{\mathcal{H}})^2 = k_B T^2 c_V$, where c_V is the heat capacity at costant volume, which is proportional to the number N of particles, thus for $N \to \infty$ the limit $\sigma_{\mathcal{H}}/\overline{\mathcal{H}} \to 0$ will hold.

2.2.1. Force Calculation

A brief comment about the calculation of the forces among the N particles in the system: This is the most time-consuming part of almost all MD simulations. Here we deal with the computational time necessary to calculate the forces

at fixed system size to study diffusion properties, and varying the size of the system to study growth processes.

In the case of a pairwise additive potential, we have to consider only the interaction between a particle and its neighbors, which implies that, for N particles, we must evaluate $N \frac{N-1}{2}$ pair distances. Thus, in MD simulations, the computational time t_{mac} scales as $t_{mac} \propto cN + dN^2$ where c and d are constants. We can introduce some tricks to reduce this time a bit. The most common technique is to introduce a cut-off radius r_{cut} to make an evaluation of all pair distances every m time steps. It means that in this way, the t_{mac} scale as $cN + d'N^2$ where $d' = d/m$. For a very large system, the computational times scale are always as N^2. The introduction of a cut-off is possible only if the potential is short ranged, which means that it decays asymptotically faster than r^{-d}, where d is the dimensionality of the system. In a three-dimensional space, it means that a short-ranged $\mathcal{V}$ decreases faster than r^{-3}.

In the case of a growth simulation, the number of particles is not a constant. Let us evolve a system of $N = N_{in} + N_{dep}$ particles, where N_{dep} is the number of deposited particles and N_{in} is the initial size of the system, for a time t_{mac} depending on N_{dep} by

$$t_{mac}(N_{dep}) = cN + dN^2$$
$$= c(N_{in} + N_{dep}) + d(N_{in} + N_{dep})^2 \quad (10)$$

then each $\Delta t = n\delta t$ we increase N_{dep}, so the total computational time is given by $t_{mac}^{TOT} = \sum_{N_{dep}} t_{mac}(N_{dep}) \propto N^3$.

Of course, the calculation of the force is different depending on the choice of the interparticle potential, whose specific form (which is not necessarily analytic) depends on the particular system that is under study. Typical examples are the Lennard–Jones potential for rare gases, the embedded atom potential for metals, and the Girifalco potential for fullerites [38, 39].

2.2.2. Integration Method: Verlet Algorithms

A standard method for the solution of ordinary differential equations is the finite difference approach. The general idea is as follows: Given the molecular positions, velocities, and other dynamic information at time t, we attempt to obtain the positions, velocities ... at time $t + \delta t$ to a sufficient degree of accuracy. The equations are solved on a step-by-step basis; the choice of the time interval δt (time step) will depend somewhat on the method of solution, but δt will be significantly smaller than the typical time taken for a molecule to travel its own length. If the classical trajectory is continuous, then an estimate of the positions at time $t + \delta t$ may be obtained by Taylor expansion about time t

$$\mathbf{r}(t + \delta t) = \mathbf{r}(t) + \mathbf{v}(t)\delta t + \frac{\mathbf{f}(t)}{2m}\delta t^2 + \frac{\delta t^3}{3!}\mathbf{b}(t) + \cdots \quad (11)$$

similarly,

$$\mathbf{r}(t - \delta t) = \mathbf{r}(t) - \mathbf{v}(t)\delta t + \frac{\mathbf{f}(t)}{2m}\delta t^2 - \frac{\delta t^3}{3!}\mathbf{b}(t) + \cdots \quad (12)$$

Summing these two equations, we have the standard Verlet algorithm

$$\mathbf{r}(t + \delta t) \sim 2\mathbf{r}(t) - \mathbf{r}(t - \delta t) + \frac{\mathbf{f}(t)}{m}\delta t^2 \qquad (13)$$

The estimate of the new position contains an error of the order of δt^4. We can derive the velocity from a knowledge of the trajectory, but in this way the expression for the velocity is only accurate to order δt^2, which is not sufficient to calculate accurately the kinetic energy and thus the temperature T.

It is more useful to introduce the velocity-Verlet algorithm, which is equivalent to the standard Verlet [7] but involves explicitly the velocity variables in the propagation of the trajectories; at time $t + \delta t$ we have

$$\begin{aligned} \mathbf{r}(t + \delta t) &= \mathbf{r}(t) + \mathbf{v}(t)\delta t + \frac{\mathbf{f}(t)}{2m}\delta t^2 + \cdots \\ \mathbf{v}(t + \delta t) &= \mathbf{v}(t) + \frac{\mathbf{f}(t) + \mathbf{f}(t + \delta t)}{2m}\delta t^2 + \cdots \end{aligned} \qquad (14)$$

The velocity-Verlet algorithm is fast, even if this is relatively unimportant; it is not particularly accurate for long time steps. Hence, we should expect to compute the forces on all particles rather frequently. Also, it requires about as little memory as is at all possible. Plus, its short-time energy conservation is fair, but it exhibits little long-term energy drift. This is related to the fact that Verlet algorithms are area-preserving and time-reversible [7]. In fact, although Verlet algorithms do not conserve the total energy of the whole system exactly, strong evidence indicates that they conserve a pseudo-Hamiltonian approaching the true Hamiltonian in the limit of infinitely short time steps. The accuracy of the trajectories generated by the Verlet algorithms is not impressive. But then, it would hardly help to use a better algorithm. Such an algorithm may only postpone the unavoidable exponential growth of the error in the trajectories close to the true trajectories for a time comparable to the duration of a typical MD run.

Just a few comments about the choice of the time step. Obviously, if it is longer, fewer evaluations of the forces are needed per unit of simulation time. This would suggest that it is advantageous to use a sophisticated algorithm that allows the use of a long time step. Algorithms that allow the use of a large time step achieve this by requiring more memory storage. Moreover, it is necessary to integrate the motion equations on realistic time scales: The time step must be much less than the typical amount of time that a particle spends in a single oscillation in its well. The typical phonon frequency is of the order of 10^{12} s^{-1}; thus time steps in the range of some femtoseconds are small enough to ensure solving the Newton equations correctly.

2.2.3. MD at Constant Temperature

Before describing briefly how it is possible to perform canonical MD simulations, we want to underline that they are necessary for studying growth processes. In fact, when a particle is deposited on a surface, the release of its adsorption energy causes an increase of the temperature of the system, which is huge for the rather small systems used in MD

simulations (for example, several tens of degrees for a system of several hundreds of particles). Therefore subsequent depositions would cause the melting of the system, and this is not in agreement with the experimental observations of growth processes.

Even if at first sight it would seem impossible to perform canonical MD simulations, fortunately it turns out that there are two different solutions to this problem. One is based on the idea that dynamical simulation of other ensembles (e.g., $[N, V, T]$, $[N, P, T]$) is possible by mixing Newtonian MD with certain MC moves. The second approach is completely dynamical in origin. It is based on a reformulation of the Lagrangian equations of motion of the system. The latter, introduced by Andersen [40] in the context of constant-pressure MD simulations, has become one of the most important tricks to extend the applicability of MD simulations. Before describing briefly the Andersen approach, we want to discuss a bit the meaning of "constant temperature". From a statistical point of view, there is no ambiguity; we can impose a temperature on a system by bringing it into a thermal contact with a large heat bath. Under these conditions, the probability to find the system in a given energy state is given by the Boltzmann distribution. In the constant temperature method proposed by Andersen [40], the system is indeed coupled to a heat bath that imposes the desired T. The coupling to the heat bath is represented by stochastic impulsive forces that act occasionally on randomly selected particles. These stochastic collisions with the bath can be considered as MC moves that transport the system from one constant-energy shell to another. Between stochastic collisions, the system evolves at constant energy according to the standard Newtonian equations of motion. The collisions ensure that all accessible constant-energy shells are visited according to their Boltzmann weights. Before starting such a constant-temperature simulation, we should first select the strength of the coupling to the bath. This coupling strength is determined by the frequency of stochastic collisions. Let ν be this frequency. If subsequent collisions are uncorrelated, then the distribution of time intervals between two subsequent stochastic collisions, $P(t; \nu)$, is of the Poisson form

$$P(t; \nu) = \nu e^{-\nu t} \qquad (15)$$

Thus in a constant-temperature simulation, we follow the scheme: initialization of the system with given positions and momenta, integration of the Newton equations, and stochastic collisions with the heat bath with a probability of $\nu\delta t$ in a time step δt. For the particles that undergo a collision, the new velocity is drawn from a Maxwell-Boltzmann distribution corresponding to T.

The mixing of Newtonian dynamics a with stochastic collision model turns the MD simulation into a Markov process. As shown by Andersen [40], a canonical distribution in phase space is invariant under repeated application of the Andersen algorithm. Combined with the fact that the Markov chain is also irreducible and aperiodic, this implies that the Andersen algorithm does, indeed, generate a canonical distribution.

2.3. Kinetic Monte Carlo

Standard thermodynamical Monte Carlo is a method for the calculation of average values in a given *equilibrium* thermodynamical ensemble. States in a space of configurations are generated and used for the calculation of quantities of interest [41–43]. The focus is on the convergence of series for the calculated quantities, and one is not interested in the generation of a sequence of states that properly corresponds to the dynamics of a system (in many cases the opposite is true [44]).

About 20 years ago, MC started to be used also for the study of kinetic processes [45, 46]. The aim of KMC is to reproduce faithfully *nonequilibrium*, or *relaxation* processes. This time the emphasis is on the correctness of time evolution in the simulation.

In order to fix ideas, let us denote the space of all possible configurations, $\mathscr{C}$, in a statistical-mechanical model by $\mathscr{S} = \{\mathscr{C}\}$, and by $P(\mathscr{C}, t)$, a time-dependent distribution of configurations at time t.

The MC technique can be also viewed as a method of solving the master equation

$$
\frac{\partial P(\mathscr{C}, t)}{\partial t} = -\sum_{\mathscr{C}'} W(\mathscr{C} \to \mathscr{C}') P(\mathscr{C}, t)
$$
$$
+ \sum_{\mathscr{C}'} W(\mathscr{C}' \to \mathscr{C}) P(\mathscr{C}', t) \qquad (16)
$$

associated with a matrix of *transition probabilities*, $W(\mathscr{C} \to \mathscr{C}')$, between two states $\mathscr{C}$ and $\mathscr{C}'$. Equation (16) describes a stochastic process in the Markovian approximation [47].

The transition probabilities in standard thermodynamical MC do not need to have any relation to the dynamics of the system. They are not considered as given a priori, but they are constructed in a way that guarantees that the distribution of generated states converges as quickly as possible to the desired static distribution $P(\mathscr{C})$. At each MC step a trial configuration is generated, which is then either accepted or rejected. A sequence of configurations, $\mathscr{C}_k$, $k = 1, \ldots, M$, form a Markovian chain, which is used for the construction of series for the quantities to be calculated.

Let us now describe the principle of kinetic Monte Carlo. KMC is a method for solving the master equation (16), which describes the stochastic evolution of the system. The way of solving is essentially as in thermodynamical MC: making random choices so that a Markov chain is generated. Now, however, in contrast to standard thermodynamical MC, this chain has to represent a possible evolution of the simulated system. Configuration changes have to correspond to real events in the stochastic system. Each of the events in the real system can happen with some probability per unit time (rate). To be specific, let $N(\mathscr{C})$ be the number of possible events in a given configuration $\mathscr{C}$; in the case of crystal growth they are, for example, the hopping of an adatom, the adsorption of an atom, and so on. Let the rates of these events be Γ_a, $a = 1, \ldots, N(\mathscr{C})$. Both $N(\mathscr{C})$ and the set $\{\Gamma_a\}$ depend on the configuration $\mathscr{C}$. Let us define the total rate

$$
Q = Q(\mathscr{C}) = \sum_{a=1}^{N(\mathscr{C})} \Gamma_a \qquad (17)
$$

The transition probabilities can now be formally written as

$$
W(\mathscr{C} \to \mathscr{C}') = \sum_{a=1}^{N(\mathscr{C})} \Gamma_a V^a(\mathscr{C} \to \mathscr{C}') \qquad (18)
$$

where $V^a(\mathscr{C} \to \mathscr{C}')$ is again an "underlying" stochastic matrix for an event a, specifying whether the transition $\mathscr{C} \to \mathscr{C}'$ is possible by this event. In the simulation event a should occur with probability $(\Gamma_a/Q(\mathscr{C}))$. It is realized by selecting possible events with probabilities proportional to their physical rates. Therefore, the key point to obtain a good model is a proper choice of the transition rates. These rates belong either to deposition or diffusion processes. The rate of deposition processes is determined by the deposition flux F, usually given in units of adatoms per unit time per adsorption site. In simulations of growth by molecular beam epitaxy (MBE), adatoms land on any site with equal rate; if the site where the adatom lands is a stable adsorption site, the adatom stops there; on the contrary, a cascade process may begin to look for a stable site in the neighborhood [48, 49].

The rates of diffusion processes must have an activated form [10, 50]; for a process a, with energy barrier E_a (the latter is the energy difference between the saddle point and the initial minimum related to process a), the rate Γ_a is given by

$$
\Gamma_a = \Gamma_a^0 \exp\left(-\frac{E_a}{k_B T}\right) \qquad (19)
$$

where the prefactor Γ_a^0 can be evaluated for example in the framework of the TST [10], which gives

$$
\Gamma_a^0 = \frac{\prod_{i=1}^{3N} \nu_i^M}{\prod_{i=1}^{3N-1} \nu_i^S} \qquad (20)
$$

where the ν_i^M is the normal-mode frequency at the minimum, and the ν_i^S is the stable normal mode frequency at the saddle point.

A fast way to implement a KMC simulation without unsuccessful attempts (also called N-fold way algorithm) was formulated by Bortz, Kalos, and Lebowitz (BKL) [51] for the Ising model, and is often used in KMC simulations of crystal growth [52]. The basic idea is that at each MC step, one process is selected with its corresponding probability and then also realized, instead of attempting a generic process (whose probability may be much lower). We shall describe first the simplest variant of this algorithm. Let us consider the kth time step:

1. Choose a random number z_1 with uniform distribution in the range $[0, Q(\mathscr{C}_k)]$.
2. Find the corresponding event. This is done by the choice of the first index s for which $\sum_{a=1}^{s} \Gamma_a(\mathscr{C}) \geq z_1$.
3. Carry out the event s leading to a new configuration, $\mathscr{C}_{k+1}$.
4. Update those Γ_a that have changed as a result of event s; update Q and any data structure being used.

This algorithm is usually not applied in this form but in a modified, more effective form (see below). Let us consider the dependence of the computer time needed on N, which is

related to the system size. Steps 1 and 3 require a time independent of N, but Step 2 is time-consuming. If linear search is used, the search time is $\mathscr{O}(N)$. Since the growth rules are usually local the updating in Step 4 does not have to cost too much computer time, although careful programming is needed. One has to identify events that are not possible any more in a new configuration, they have to be removed from the list, and new events that become possible have to be added to the list. Depending on the data structure used, time needed in Step 4 is $\mathscr{O}(N)$ at the most.

A faster algorithm can be obtained if one considers, instead of individual events, groups of events. Let us group events into n groups, labeled by $\alpha = 1, \ldots, n$. This can be done either formally by forming groups with the same number of events, which allows maximal effectivity of the algorithm, or in a way that keeps physics clear, forming groups of the same kind of events that correspond to a certain kind of process (diffusion of an adatom over the specific energy barrier, desorption of an atom with the specific binding energy, and so on). Let us consider explicitly the second case; each group will represent a certain kind of process, all processes in a group have the same rate Γ_α.

In a given configuration, $\mathscr{C}$, there are some possible processes, and each kind of possible process can be realized in one or more ways, by one or more event. Assume that a process α can be realized in $n_\alpha(\mathscr{C})$ ways, in the configuration $\mathscr{C}$. We shall call *multiplicities* the quantities $n_\alpha(\mathscr{C})$. For example, there may be $n_{adat}(\mathscr{C})$ adatoms with the same surroundings that can diffuse, or there are $n_{dep}(\mathscr{C})$ sites where a new particle can be deposited. Some particles can take part in more processes, and some processes may not be possible in the given configuration. To each kind of process we assign a partial rate, $q_\alpha(\mathscr{C}) = n_\alpha(\mathscr{C})\Gamma_\alpha$, and a relative probability, $p_\alpha(\mathscr{C}) = (q_\alpha(\mathscr{C})/Q(\mathscr{C}))$, which are conditional to the given configuration. The total transition rate in a configuration $\mathscr{C}$ is now $Q(\mathscr{C}) = \sum_{\alpha=1}^{n} n_\alpha(\mathscr{C})\Gamma_\alpha$. In each step of the simulation (in the given configuration) the multiplicities of processes are known. The algorithm in the kth step of the simulation proceeds as follows:

1. Choose a random number z_1 in the range $[0, Q(\mathscr{C}_k)]$.
2. Decide which kind of process will take place choosing the first index σ for which $\sum_{\alpha=1}^{\sigma} q_\alpha(\mathscr{C}) \geq z_1$.
3. Select a realization of the process σ. Technically this can be done with the help of a list of coordinates for each kind of movement, and an integer random number z_2 in the range $[1, n_\sigma(\mathscr{C}_k)]$; z_2 is generated and the corresponding member from the list is selected.
4. Perform the selected movement.
5. Update multiplicities n_α, relative rates q_α, total rate Q, and any data structure being used.

To estimate computer time demands, let us suppose that the multiplicities are approximately the same, $n_\alpha \approx (N/n)$. The search has two parts: searching for group, which takes time $\mathscr{O}(N/n)$, and searching within the group, which takes time $\mathscr{O}(n)$. Minimizing the total time leads to an optimal number of groups $n \propto N^{1/2}$, and the computer time then scales as $\mathscr{O}(N^{1/2})$. The time for Step 5 may still be $\mathscr{O}(N)$ at the most, but it is quite short in many cases.

An even faster algorithm for large N can be obtained if we, instead of the two-level search scheme, use a $K > 2$

level search scheme [53], i.e., if we divide the groups into subgroups, and these subgroups again into smaller subgroups, and so on down to the level K. Then the total search time scales are as $\mathscr{O}(KN^{1/K})$. The best asymptotic behavior $\mathscr{O}(\ln_2 N)$ is obtained by using the largest possible K, for which there are only two events in the lowest level subgroups. In practice, for typical simulation sizes, $K = 4$ or $K = 5$, can give a faster scheme than the $\mathscr{O}(\ln_2 N)$ method [53].

We shall conclude this subsection on the problem of introducing the physical time into the KMC simulation. This can be done [54], provided that all physical processes can be separated so that in any time instance only one event takes place, and the events are Poisson processes. The time interval between two successive events (waiting time), τ, is a random variable with the distribution $P(\tau) = Qe^{-Q\tau}$, and the average value is $\langle \tau \rangle = \frac{1}{Q}$ [47], Q being the total rate as defined before. In the algorithms described above, another random number, z_3, uniformly distributed between 0 and 1, will be generated, thus obtaining the time interval, $\Delta t_k = -\frac{1}{Q(\mathscr{C}_k)} \ln z_3$, spent before the passage to a new configuration $\mathscr{C}_{k+1}$. Note that $Q(\mathscr{C}_k)$ depends on the configuration $\mathscr{C}_k$. In an approximation, one can only suppose that the system stays in the state $\mathscr{C}_k$ for a time inversely proportional to the total transition rate $Q(\mathscr{C}_k)$ [54]. Mean quantities during the growth are then calculated as time averages over M time points

$$\langle A \rangle = t^{-1} \sum_{k=1}^{M} \Delta t_k A(\mathscr{C}_k) \qquad (21)$$

where the total time is $t = \sum_{k=1}^{M} \Delta t_k$. It was tested that this procedure agrees with the results of the exact solution of the master equation [54].

3. MODELING AND SIMULATION OF CLUSTER GROWTH ON SURFACES

In typical growth experiments, atoms of molecules are deposited on a crystal surface by an atomic or molecular beam, which impinges normally on to the surface (shadowing effects due to non-normal incidence have been studied in [55]). Three parameters are usually controlled in the experiment:

- **Deposition flux** F, measured in number of atoms per second per adsorption site, which can be as slow as a small fraction of a monolayer per minute.
- **Substrate temperature** T, which is usually kept constant.
- **Coverage** θ (or equivalently, growth time t_g, since $\theta = Ft_g$).

The temperature of the beam source generally plays a minor role since the kinetic energy of the beam is usually a small fraction of the adsorption energy of the atoms or molecules on the crystal surface.

From the point of view of the simulations, the KMC method is almost universally adopted, and crystal growth

involves the modeling of the following physical processes (see Fig. 1):

- **Deposition:** Adparticles can land at any site of the surface. As they approach the surface, they acquire a considerable amount of kinetic energy, which comes out from the adsorption energy. This kinetic energy is directed toward the local normal to the crystal surface, and it is mostly dissipated in phonons upon impact [56]. However, a part of this kinetic energy can be transformed into translational energy on the surface plane, giving thus rise to what is called *transient mobility*, because it takes place before the adparticle is thermalized on the surface. For an excellent review on this topic see Ref. [57]. Transient mobility amounts usually to a few (one or two) lattice spacings in most systems (for example, in metal-on-metal epitaxy) and is usually not taken into account in simulations, even if in some low-T cases it can be the main source of atomic mobility, playing thus an important role. Another effect that can be important at deposition is *funneling* [48, 49]. This amounts to a way of effectively taking into account the different time scales of the mobility on different crystal facets. For example, consider the growth of an fcc(100) surface. There, adatom mobility is slow. During the growth of a thin film of this orientation, also (111) facets are formed. There, the mobility is much faster, so that a new adatom impinging on a (111) facet will hop there many times in a short period. This is very time-consuming to simulate. How to avoid this problem? Usually, when one adatom is deposited on (111) facet, it is treated as if it was in a metastable configuration, and a search of the nearest adsorption sites on other kinds of facets is automatically performed, so that the adatom is placed on one of them at the end of the deposition process. A possible choice is to treat all sites where the adparticle has a coordination lower than four as metastable, and all the other sites as stable.
- **Diffusion:** The adparticle makes a random walk on the surface, the movements of which have a frequency that depends on the local environment. Diffusion can

be on a flat terrace (*intralayer diffusion*) or between two different terraces (*interlayer diffusion*). It can lead the adparticle to attach to existing steps (*aggregation process*) or to detach from them (*detachment process*). Once the particle is attached at a step it can move along it (*periphery diffusion*), and cross corners toward a nearby step (*corner crossing*). All these processes are usually modeled in KMC simulations with TST rates (see Eq. (20)) depending on the local environment (number of neighbors in initial and final positions) of the diffusing particle. A special effort must be devoted to the calculation of the energy barriers pertaining to these processes, and (with less emphasis) of the prefactors. Energy barriers calculations can be performed either by *ab initio* or by semiempirical methods.

- **Desorption:** Adparticles may, in principle, leave the surface. However, the desorption energy is usually much larger than the energy barriers for diffusion, so that experiments usually can be performed in temperature ranges where desorption takes place on such a long time scale as to be practically negligible. This is certainly the case of metal-on-metal systems. In modeling these systems, adparticle desorption is simply not considered as a possible move in the KMC simulations.

In this section we want to illustrate, by three different examples, how the computational techniques described in the previous section can be used in the modeling of experiments involving the growth of aggregates or thin films on surfaces. Specifically, we shall treat the epitaxial growth of Pt on Pt(111), comparing the experimental results with those following from the density functional calculations; the epitaxial growth of Ag on Ag(110), comparing the experimental results with those of KMC simulations; and the growth of lipid aggregates at the air–water interface, simulated again by Monte Carlo techniques.

3.1. Three-Dimensional Cluster Growth in Pt/Pt(111)

This system gives a very nice example of the interplay among experiments and first-principle DFT calculations, showing that the experiments can simulate the calculations of the barriers of specific elementary processes, which in turn suggest further experiments.

The (111) surface has a hexagonal symmetry and high-symmetry steps on this surface can have two different symmetries (see Fig. 2); steps of type A, which present square nanofacets on the step riser, and steps of type B, presenting triangular nanofacets on the step riser. At sufficiently high temperatures, Pt islands epitaxially grown on Pt(111) are compact and limited by these kinds of steps [58]. Triangular islands are limited either by A steps or by B steps, while hexagonal islands are limited by steps of both kinds. When depositing further adatoms on these compact islands, growth proceeds in a 3-D mode [59], and mounds are formed.

The cause of the onset of 3-D growth is the inability of the adatoms deposited above the islands to descend down to the lower level, due to the existence of an additional energy barrier, the Ehrlich–Schwoebel (ES) barrier [60, 61], for downward crossing of the step (see Fig. 3). This extra barrier is

Figure 1. Representation of the elementary diffusion processes taking place during growth on a crystal surface: deposition, diffusion, and aggregation. These processes are common to free and to supported cluster growth. In usual epitaxial growth conditions for supported cluster growth desorption (not represented in the figures) is negligible; it must be taken into account in the case of the high-temperature growth of noble-gas or C_{60} nanoclusters.

Figure 2. Schematic representation of a (111) surface with a hexagonal island above it. The island is limited by three A steps (square faces on the step riser, atom A is place along one of them) and by three B steps (triangular facets on the step riser, atom B is placed along one of them). These steps are alternating along the island perimeter. On this surface, hexagonal islands must be limited by both kinds of steps, while triangular islands can be limited by steps of a single kind. This is equally true for islands placed either on fcc or on hcp stacking.

Table 1. Energy barriers (in eV) calculated by *ab initio* methods (in LDA and GGA for diffusion of Pt adatoms on Pt(111)).

Diffusion process	LDA	GGA
Hop on (111) terrace	0.29	—
Exchange down A step	0.31	—
Exchange down B step	0.64	—
Hop down A step	0.53	—
Hop down B step	0.80	—
Hop along A step	0.84	0.71
Hop along B step	0.90	0.77

Note: All data are taken from Refs. [34, 63].

due to the reduced coordination of the adatom at the saddle point position of the downward crossing process, and can be very low when exchange processes are possible (see for example [50]). The ES barrier is in general dependent on the step orientation, and therefore one could expect that A and B steps present different ES barriers. This has important consequences on the growth shape of the mounds. For example, if the ES barrier is small at A steps and large at B steps, deposited adatoms will descend down preferentially at A steps, and will accumulate there. As a result, A facets will tend to disappear during growth, and the mounds will present mostly facets with B steps.

The first experimental observation (by the group of S. Esch) of Pt mounds grown Pt(111) have the shape of triangular pyramids up to a temperature of 450 K, and these pyramids are mostly bounded by A steps [62]. This observation is consistent with a small ES barrier at B steps, and with a large ES barrier at A steps. This experimental result stimulated DFT calculations by P. J. Feibelman [34, 63], which were however in complete disagreement with the previous experimental finding. According to different DFT schemes,

the ES barrier is large at B steps and small at A steps (see Table 1).

The solution of this discrepancy came out of new experiments [64], which showed that the older experiments were affected by CO contamination. Removing the CO contamination, mounds on Pt(111) grow bounded by B steps, as predicted by the DFT calculations. This result shows the predictive power of state-of-the-art DFT calculations.

3.2. Homoepitaxial Growth of Ag(110)

The (110) surface of Ag is of rectangular symmetry (see Fig. 4), with channels along the $[1\bar{1}0]$ direction, which are separated by atomic rows. In-channel diffusion of adatoms occurs mostly by jumps, while cross-channel diffusion occurs by exchange and is more difficult [65].

Due to the anisotropy of the surface, one may expect that a rather peculiar surface nanostructuring can be achieved by growth on this surface. This is indeed the case, as shown by the experiments performed in the group of Valbusa, both in the submonolayer and in the multilayer regimes. At submonolayer coverages, different kinds of islands are grown depending on T [66]. At low temperatures, the islands are small and present preferentially a cross-channel orientation. At intermediate temperatures, islands change their orientation by 90 degrees, being well-defined one-dimensional strips in the in-channel direction. Finally, at high temperatures, the in-channel orientation is still preserved, but islands

Figure 3. Potential energy profile (*upper panel*) for an adatom diffusing on an array of equally spaced terraces (*lower panel*). The Ehrlich–Schwoebel additional barrier E_s hinders the descent of adatoms at the lower level, so that the descent rate Γ_d is smaller than the diffusion rate on the flat terrace Γ_0, since $\Gamma_0 \propto \exp[-E_0/(k_B T)]$, while $\Gamma_d \propto \exp[-(E_0 + E_s)/(k_B T)]$. At the lower side of the step, coordination is increased so that adatoms are trapped there for long times.

Figure 4. Left panel: fcc(110) surface with adatoms, and dimers adsorbed on it (adsorbed atoms are represented in white). The possible intralayer diffusion moves [75] are indicated by arrows. Right panel: fcc(110) surface with a 3×3 island adsorbed on it. Above the island there is a further atom, whose possible diffusion moves (intralayer and interlayer moves) are indicated by arrows. In both panels, the easy-diffusion in-channel $[1\bar{1}0]$ is horizontal.

are two-dimensional. In the case of multilayer growth, ripples are formed, and in analogy with the submonolayer islands, these ripples rotate from the cross-channel direction at low temperatures to the in-channel direction at intermediate and high temperatures [67]. The time scale of the experiments is several minutes (adatom fluxes are of 1 ML/min), and the size of the terraces is several hundreds of nanometers, while temperatures range from 100 K to room temperature.

To study these time scales and terrace sizes, it is necessary to perform KMC simulations, that aim to single out a small number of energetic parameters, which are able to describe accurately the growth process [68].

The first step in the KMC modeling is thus the choice of the important processes and the calculations of their activation barriers. To this end, Ag is described by means of semiempirical interaction potentials [69], and we calculate the barriers of several diffusion processes by means of quenche MD simulations [70]. The full barrier set can be rationalized by the following simple formula depending on a rather small set of energetic parameters [71]

$$E_{p,n} = E_{p,n}^0 + n_p E_p^b + n_n E_n^b + n^S E_{p,n}^S \qquad (22)$$

where $E_{p,n}^0$ are the barriers for diffusion on the bare surface in the parallel (in-channel) or normal (cross-channel) directions. $E_{p,n}^b$ and $n_{p,n}$ are the strengths and numbers of in-channel and cross-channel bonds, respectively. $E_{p,n}^S$ are anisotropic Ehrlich–Schwoebel barriers, and n^S is 1 for interlayer processes and 0 for intralayer processes. The resulting model is referred to as the anisotropic bond-breaking model (ABBM).

The values of these energetic parameters are given in Table 2, and the different diffusion moves are schematically represented in Figure 4. For simplicity, we set all prefactors to the common value of 10^{12} s^{-1}.

In a model with full fcc geometry, special care must be given to the way by which adatoms are deposited on the surface, and to the way by which the final position is chosen after an interlayer process.

For example, a deposited atom can land on any site of the surface. However, in a given surface configuration, not all sites fulfill the restricted solid-on-solid (RSOS) conditions: depositing on such *unstable* sites (which indeed can be either really unstable positions, like the on-top positions, or metastable sites; see Fig. 5) would create overhangs. In
Figure 5. fcc(110) surface with an island of 8 atoms above it. Compare this island with the one of the bottom panel of Figure 4. Above the island there is a further adatom, which is placed in a short-lived metastable site. In KMC simulations, this atom searches for the nearest sites of higher coordination and chooses one of them as a stable site [75]. The path to the closest stable site is indicated by the arrow.

our model, adatoms can be deposited on any site. If the latter is *unstable*, a cascade follows to look for *stable* sites (i.e., the sites that fulfill the RSOS condition) in its neighborhood. This procedure is justified for example when the *unstable* site is located on a (111) facet, where mobility is much faster compared to other facets [50, 72], and temperature is high enough. If T is so low that mobility on the (111) facets is frozen, overhangs are easily created [73]. In the case of silver, the diffusion barrier is of 0.10 eV or even less [50, 72], so that diffusion is activated well below 100 K on the experimental time scales. Our deposition procedure does not take into account the fact that adatoms are attracted by the mounds on a rough surface, as has been recently demonstrated by MD simulations [74]. However, this effect should be important only at very low temperatures, where the growing surface is found to be rough ($T <$ 100 K). A growth model that includes such an effect may be only tractable by MD simulations. This investigation is left for future work. Concerning the search for the arrival site after an interlayer move, we proceed as follows. If the nearest arrival site is *stable* (compare Figs. 4 and 5), the diffusing adatom stops there. If not, a cascade follows to look for a *stable* site in the neighborhood. Again, this procedure is fully justified on (111) facets. On the other facets, this procedure can *overestimate* interlayer mobility. In order to check this point, we made simulations also by a second procedure, letting the interlayer move to be executed only if the nearest arrival site is *stable*; on the contrary, we suppress the move. This procedure *underestimates* interlayer mobility. We have verified that this second procedure leads to very minor changes in our results, showing that growth morphologies are not influenced by the way the arrival site is searched for in interlayer moves. This could indicate that also the choice of the cascade procedure at deposition is not a crucial point for the results contained in the following.

Let us now briefly describe how the KMC algorithm decides to make a movement (either deposition or diffusion) process in a given configuration C of the system. The total probability of having a deposition event, $\Gamma_{dep}(C)$, is given by the total number of sites N in the surface multiplied by the deposition flux F (in ML/s). On the other hand, the total probability of having a diffusion process is calculated within a binary tree. The lowest level of the binary tree numbers

Table 2. Energetic parameters (in eV) of the ABBM model for the growth of Ag/Ag(110) [75].

Parameter	Value	Variability range
E_p^0	0.27	0.24–0.30
E_n^0	0.34	0.31–0.37
E_p^b	0.18	—
E_n^b	0.04	0.02–0.06
E_p^S	0.07	0.05–0.09
E_n^S	0.18	—

Note: In the last column we give the interval of variability of the parameters. Within these limits a good agreement with experiments is obtained.

N elements. (For simplicity, we choose the size of the simulation box in such a way that $N = 2^p$ for some integer p.) Each element is a diffusion rate associated with a given site i, and its value $\Gamma_0(i)$ is the sum of the four frequencies of the diffusion processes in the four diffusion directions. The rates of the level $m + 1$ of the binary tree are obtained by combining the rates at level m as follows: $\Gamma_{m+1}(i) = \Gamma_m(2i - 1) + \Gamma_m(2i)$, so that level $m + 1$ has half of the elements of level m. At level p, we have a single element, which is the total diffusion rate $\Gamma_{diff}(C)$. The total rate associated with C is $\Gamma_{dep}(C) + \Gamma_{diff}(C)$. For choosing the process to be performed, a random number z, in the range $[0, \Gamma_{dep}(C) + \Gamma_{diff}(C)]$, is extracted. If $z \leq \Gamma_{dep}(C)$, a deposition process starts; otherwise the algorithm chooses a diffusion process. If deposition is to be performed, a site is randomly extracted; if diffusion is to be performed, we go downward in the binary tree by extracting random numbers at each level to choose which branch to follow. In this way, at level 0 in the tree, a site is singled out. Now a further random number is extracted in order to choose one of the possible directions for diffusion, and the move is performed.

As shown in Figures 6 and 7, this model reproduces qualitatively both the island and the ripple rotation depending on temperature. Moreover, the agreement is quantitative since the rotation takes place in the same T range as in the experiments, and the experimental ripple wavelengths are well reproduced as shown in Figure 8 [75].
Figure 6. Snapshots from simulations of the growth of Ag/Ag(110) [75]; the in-channel direction is horizontal. The snapshots are taken after the deposition of 0.15 monolayers (submonolayer growth) at a flux of 1 ML/min at different temperatures: 100 (top left), 130 (top right), 170 (bottom left), and 210 K (bottom right). At 100 K the islands are small and irregular; at 130 K, the islands are elongated in the cross-channel direction; at 170 K, the islands are mostly monatomic strips oriented in the in-channel direction; at 210 K, the islands are elongated in the in-channel direction but present a more compact shape.
Figure 7. Snapshots from simulations of the growth of Ag/Ag(110) [75]; the in-channel direction is horizontal. The snapshots are taken after the deposition of 30 monolayers (multilayer growth) at a flux of 1 ML/min at different temperatures: 100 (top left), 130 (top right), 170 (bottom left), and 210 K (bottom right). The top-layer atoms are represented in white; lower layers in darker colors. At 100 K the surface is rough with no regular features; at 130 K, ripples are formed, with a cross-channel orientation (the same orientation as the islands grown at this temperature, see Fig. 6, left panel); at 170 K, mounds are grown with no special orientation; at 210 K, ripples are grown with an in-channel orientation, which is the same orientation of the islands grown at 210 K (see Fig. 6, right panel). These results about the ripple rotation with temperature are in excellent agreement with the experiments [67].

The behavior of the cross-channel ripple wavelength at low temperatures can be rationalized into a simple analytical expression by the following argument. Indeed, at sufficiently low temperatures (to be conservative, $T \leq 150$ K at the experimental fluxes), cross-channel mobility is practically inhibited; interlayer in-channel mobility is practically absent, so that the only possible process is intralayer in-channel diffusion. If one could neglect the existence of the cross-channel bonds, and the fact that the full fcc geometry induces some cross-channel correlations in the deposition process, one could consider adatoms in different channels as completely independent, and reduce the problem to a simple one-dimensional model (with no interlayer mobility) along the in-channel direction. In this one-dimensional model, the only characteristic length is the in-channel diffusion length ℓ of the adatoms on terraces [1]. It is known that [1, 76]

$$\ell \propto \left(\frac{D_p}{F}\right)^\chi \tag{23}$$

where D_p is the in-channel jump frequency, and $\chi = 1/4$ for one-dimensional systems. In this framework, we expect that
Figure 8. Ripple wavelength λ as a function of T. The triangles and the circles are the experimental [67] and the simulation [75] results for the low-T cross-channel ripples respectively. The stars and the squares are the experimental [67] and the simulation [75] results for the high-T in-channel ripples respectively. The agreement between experiments and simulations is remarkable. The full line is the best fit to the cross-channel ripple wavelength using Eq. (24). This equation assumes that the cross-channel ripple wavelength is proportional to the in-channel diffusion length of adatoms, because in-channel diffusion is the only process possible at low temperatures. The agreement Eq. (24) with both experiments and simulations is very good. Reprinted with permission from [75], A. Videcoq et al., *Surf. Sci.* 515, 575 (2002). © 2002, Elsevier Science.

λ is proportional to ℓ, and therefore

$$\lambda = a_0 \exp\left(-\frac{E_p^0}{4 k_B T}\right) \qquad (24)$$

where a_0 is treated as a fitting parameter, and the best fit is obtained for the value $a_0 = 1.7 \times 10^4$ Å. In Figure 8 we compare the results from Eq. (24) with the simulation data. As can be seen from Figure 8, the agreement is in general good, showing that the wavelength of cross channel ripples follows to a reasonable approximation an activated behavior with a barrier that is a quarter of the in-channel intralayer diffusion barrier, but with some discrepancies at low and high temperatures. The high T discrepancy is readily explained by noticing that the assumptions of the absence of cross-channel intralayer diffusion and of in-channel interlayer diffusion break up at increasing temperature. The low-T discrepancy might be due to the fact that cross-channel bonds are not negligible there. We have thus made a series of simulations with $E_n^b = 0$, comparing the results with Eq. (24). Even if there is some improvement in the linearity of the Arrhenius plot, the low-T deviation still remains, showing that it is not due to cross-channel bonds.

The analysis of the simulations allows us to single out the key microscopic mechanisms causing island and ripple rotation. At low temperatures, interlayer diffusion is completely inhibited, and intralayer diffusion takes place only in the in-channel direction. Both in-channel and cross-channel bonds are stable. In this way, islands are formed preferentially with cross-channel orientation, and the ripple instability develops in the cross-channel direction because there is

only an in-channel uphill surface current [67, 68]. At higher temperatures, cross-channel bonds are no more stable, while in-channel bonds are still stable, so that islands assume the shape of in-channel strips. On the other hand, cross-channel intralayer diffusion and in-channel interlayer diffusion become active, and begin to cause the rotation of 90 degrees in relation to the uphill surface current, and therefore to the ripples. Varying the energetic parameters of the model, and comparing the results with the experiments, one can set limits of variability of the parameter themselves. These limits are given in Table 2.

3.3. Lipid Cluster Growth at the Air–Water Interface

Phospholipids and fatty acids on the water surface can form Langmuir monolayers, which exist in a number of different phases. In Langmuir monolayers, one of the most important transitions is that between the liquid-expanded and the liquid-condensed phases, very often called the "main transition" [77]. When the equilibrium phase is liquid-condensed, but the system finds itself in the liquid-expanded phase, clusters of the liquid-condensed phase are seen to grow within the liquid-expanded phase with peculiar shapes, ranging from compact to fractal, according to the overall physical parameters. The simulations described in the present section generate clusters that bear a striking similarity with the experimental ones.

Since Witten and Sander introduced their fortunate diffusion-limited aggregation (DLA) model [78], the literature on the subject has developed enormously. The main reason is that DLA is the simplest tool to generate random fractals. Important connections were also discovered with clusters occurring in critical phenomena or percolation problems (although the properties were different in each case). The more important contribution of DLA was probably to furnish a *paradigm*, within which the fractal properties of natural or computer-generated objects could be studied, from the relatively simple overall fractal dimension to quantities obtainable only via much subtler analysis.

It is out of the question to discuss these problems here (see, for example, [79] or [80] for a thorough treatment). We wish, however, to consider cluster growth from the same point of view as we have considered crystal growth in the remainder of this paper: in terms of physical (thermodynamical) parameters, temperature T and disequilibrium $\Delta\mu$ in the first place. The clusters that we are going to consider, therefore, must in some limiting case ($\Delta\mu = 0$) be in equilibrium with the environment; hence they must be able to compensate growth by evaporation or dissolution, so a double DLA-like process must be involved. Such a double DLA process was first introduced (as many other things in statistical mechanics) by Kadanoff [81] (see below).

Let us first recall ordinary DLA, as was first proposed in [78]. DLA is a growth process, taking place in a computer. The growth starts from a preexisting *germ*, placed at the origin. In the simplest case the simulation is two-dimensional. *Atoms* are sent in sequentially from the circumference of a large circle, having the germ at its center. Each atom performs a *random walk* in the plane; finally either it reaches a site neighboring the growing cluster, in which case it sticks

irreversibly to the cluster, or it reaches the outer circumference again, in which case it is lost. In this way clusters are generated, possessing a characteristically ramified appearance. The fractal dimension of DLA clusters, as obtained numerically, is 1.71 ± 0.01 [82]. Precise and convincing theoretical results, in agreement with the above, were obtained in [83].

DLA growth is irreversible and, from our point of view, corresponds to $\Delta\mu \to \infty$. In order to allow for finite disequilibria, Kadanoff [81] introduced a very simple modification of DLA, which he calls a *pedestrian model*. Two competing processes are taking place. One process is ordinary DLA; in the other process atoms detach from the cluster, perform again a random walk, and either stick to the cluster at another point or are lost. A modified version of this model was studied in detail in [84]. The work of Gliozzi et al. was addressed to study the temperature and disequilibrium dependence of the *growth morphology* of two-dimensional clusters. The morphology changes in terms of physically significant parameters that were studied, in particular, by Gliozzi et al. [84], who specifically applied the analysis to the growth of clusters of the gel phase at the expense of the fluid phase in Langmuir monolayers. In these works the physical parameters are T and $\Delta\mu$. The role of disequilibrium is obvious; temperature, on the other hand, occurs indirectly, via the T-dependence of *anisotropy*.

The algorithm of [84] describes a competition between growth and rearrangement and is a modified version of Kadanoff's "pedestrian" model [81]. Particles are continuously sent in from the outside, in DLA fashion. They perform a random walk, then either stick to the growing cluster or are lost. At the same time other particles detach from the periphery of the cluster and, again, perform a random walk and either stick to the growing cluster at another place or are lost (*evaporate*).

The energy E of the cluster is given by the lattice-gas formula

$$E = -J \sum_{i,j} n_i n_j \qquad (25)$$

where n_i is 1 if site i is occupied, J is the pair interaction energy, and the sum is over pairs of nearest neighbor sites. A particle is added or removed from the cluster with a probability $\mathscr{P}$ given by the Glauber rule

$$\mathscr{P} = \frac{1}{\exp[\beta(\Delta E - \mu_{eq}\Delta N)] + 1} \qquad (26)$$

where μ_{eq} is the chemical potential for solid-vapor coexistence (for the square lattice $\mu_{eq} = -2J$, for the triangular lattice $\mu_{eq} = -3J$), $\beta = 1/k_B T$, and ΔE and ΔN (= 1 or -1) are the variations of energy and particle number.

The two random-walk processes, originating at long distances and at the periphery of the cluster, respectively, alternate in such a way that the ratio between sticking and evaporating particles is $\exp(\beta\Delta\mu)$ to 1, where $\Delta\mu$ is the disequilibrium between the two phases. Thus the growth and rearrangement processes compete with the correct rates. By construction, the resulting growth rate is $\exp(\beta\Delta\mu) - 1$, corresponding to the so-called Wilson-Frenkel law [85].

Gliozzi et al. found, at a rather well-defined temperature (or anisotropy), a morphology transition of the *tip-splitting* type [86], from the dendritic to the dense-branching morphology (DBM). Interestingly, even for large disequilibria and (relatively) high temperatures, the clusters generated in this way (contrary to what happens for simple DLA) are not ordinary fractals. Rather, they belong to the typology of *fat fractals* [79], i.e. their measure, when measured with rulers of length l, is given by

$$M(l) = M(0) + Al^\gamma \qquad (27)$$

(For ordinary, or *thin* fractals, $M(0)$ vanishes.) A further development in terms of the description of cluster growth in Langmuir monolayers took into account the important effects of long-range interactions [87–89], which have a destabilizing influence even in thermodynamic equilibrium [90, 91].

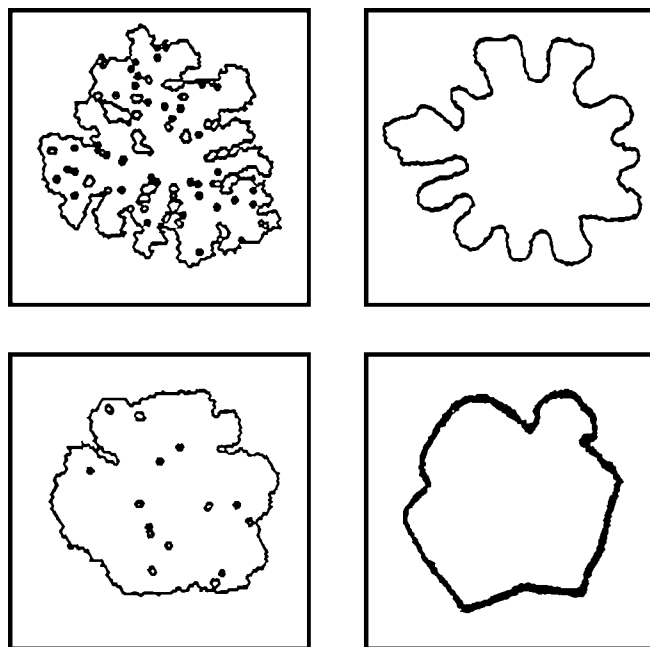
In the repulsive case [87], a remarkable agreement is found between the simulated clusters and those observed in experiments performed on clusters growing in Langmuir monolayers [92], as can be seen in Figure 9. The same shapes (compact in some cases, highly ramified in others) are found, showing that the model correctly captures the competition between random and ordering effects, although in the simulation the intensity of random behavior is determined by temperature, while in the experiments


Figure 9. Comparison between simulations and experiments [87] of lipid cluster growth at the air–water interface. The left panels show simulated clusters, while the right panels reproduce experimental clusters [92], which were made of two different lipids. The cluster of the top right panel is made of triple-chain lecithin with the third chain attached to the 1-position. The cluster in the bottom right panel is made of triple-chain lecithin with the third chain attached to the 2-position. The simulated clusters, grown by the procedure outlined in the text, are remarkably similar to the experimental ones. Reprinted with permission from [87], G. Indiveri et al., *Thin Solid Films*. 284/285, 106 (1996). © 1996, Elsevier Science.

the same effects are obtained depending on the chemistry of the amphiphilic molecules, such as on the slight difference between two kinds of triple-chain lecithin (Fig. 9).

In the attractive case, where the simulation is appropriately performed over a lattice [88] a more surprising behavior is found. Assuming a potential energy of the form

$$U = p \sum_{i,j} R_{ij}^{-\alpha} \qquad (28)$$

for small $p/k_B T$ the clusters have a typical DBM, but for very large $p/k_B T$ they take the shape of a star with branches corresponding to the lattice symmetry (e.g., a sixfold star on a triangular lattice), so that a characteristic morphology transition takes place as a function of p. Interesting results are also found as a function of the exponent α (when $p \to 0$ and $\alpha \to \infty$ the model becomes equivalent to ordinary DLA) (Fig. 10). In this case the algorithm had to be appropriately modified, the random walks taking place in a circular corona. Indeed, in the presence of long-range attractive forces it is not possible to choose the starting (or end) points for diffusion very close to the aggregate (which is permitted for DLA) since the morphology would depend on the initial conditions. The width of the corona must be chosen carefully; it turns out that a ratio of 5 to 4 between outer and inner radii gives good results.

A fairly complete analysis of morphology transitions in the (disequilibrium, anisotropy)-plane was presented by Brener et al. [93], leading to the identification of four distinct morphologies, which they call compact dendrite, fractal dendrite, compact seaweed, and fractal seaweed (where *seaweed* indicates the DBMs).

The simulations considered in the present section aim at reproducing clusters in Langmuir monolayers. However, equally important potentially will be the application of the above mentioned methods to the growth of metal clusters on metals. Such clusters exhibit very diverse forms, from compact to ramified, fat-fractal shapes [96], depending, as Bartelt and Evans [97] have shown, on the ratio between the rate of arrival of new atoms from the outside and the rate of diffusion along the periphery of the cluster. An intermediate case between Langmuir monolayers and metal adsorbates is that of self-assembled structures of, for example, thiols on gold [98], which have been the object of very interesting studies.

4. SIMULATION OF THE GROWTH OF FREE NANOCLUSTERS

Nanoclusters—nearly monodispersed particles that are generally less than 10 nm in diameter—have generated intense interest over the past decade. One reason for this is the belief that nanoclusters will have unique properties, derived in part from tha fact that these particles and their properties lie somewhere between those of bulk and single-particle species. Such "strange morsels of matter" have many fascinating potential uses, including quantum dots or computers and electronic devices, chemical sensors, light-emitting diodes, "ferrofluids" for cell separations, industrial lithography, and photochemical pattern applications such as flat-panel display. Nanoclusters also have significant potential as new types of catalysts of higher activity and selectivity. In the following section, we shall treat the growth of free nanoclusters: They can grow by condensation of a vapor, then the formed clusters can collide and coalesce. These free nanoclusters have peculiar properties, which can be preserved when they are deposited, for example by soft landing, on inert substrates. The structure of nanoclusters is one of the most fundamental properties and plays an important role to understand all aspects of their physical and chemical behaviors. Much experimental and theoretical effort has been devoted to find how the most favorable structure depends on the cluster size N. Now it is known that cluster arrangements may be different from those of the bulk: Also structures that are noncrystalline symmetries (containing for example symmetries of order five) are possible, because the constraint of translational invariance does not apply to these finite structures.

Progress in cluster physics closely follows the development of new experimental methods. Important advances in production and detection techniques for metal clusters in molecular beams provide the possibility of studying clusters in an interaction-free environment. All molecular-beam experiments on clusters need a cluster source, which is chosen on the basis of the material, and a cluster detector. Here we report a brief description of the six most important ways to produce nanoclusters [2]:

- *Seeded supersonic nozzle* sources are used mostly to produce intense cluster beams of low-boiling-point metals. These sources produce continuous beams with

p = − 0.05, α = 1/2   p = − 0.5, α = 1/2

p = − 5, α = 1/2   p = − 50, α = 1/2

Figure 10. Snapshots from simulations [88] of the aggregation model with repulsive long-range interactions, where the interaction energy between two particles i and j is given by $U_{ij} = p/R_{ij}^{\alpha}$, α is positive, and negative p correspond to attractive interactions [see Eq. (28)]. Here α is kept fixed at the value 0.5, and p is varied. Reprinted with permission from [88], G. Indiveri et al., *Physica A* 237, 217 (1999). © 1999, Elsevier Science.

reasonably narrow speed distributions. Clusters with up to several hundreds (and, under suitable conditions, with thousands) of atoms per cluster may be produced in adequate abundance. The cluster temperatures are not well known; however, larger clusters are often assumed to be near the evaporation limit.

- *Gas-aggregation* sources are particulary efficient in the production of large clusters ($N < 10,000$). The intensities are generally much lower than for nozzle sources. The overall cluster size distributions can be adjusted within rather broad limits. These sources are used for low-to-medium boiling-point materials (<2,000 K). Low cluster temperatures (<100 K) can be achieved.
- *Laser vaporization* sources produce clusters in the size range from one atom to typically several hundreds of particles per cluster. These sources are pulsed, and, although the time-averaged flux is low compared with the nozzle source, intensities within a pulse are much higher. In principle, these sources can be used for all metals to produce neutral and positively and negatively charged ionized clusters. The cluster temperatures are expected to be near or below the source temperature, depending on the supersonic expansion conditions. Then it is possible to cool down or anneal these clusters by letting them into an inert-gas atmosphere.
- *Pulsed-arc cluster-ion* sources are basically similar to laser vaporization ones. Here, however, an intense electrical discharge rather than a laser is used to produce the clusters, resulting in intense cluster-ion beams.
- *Ion sputtering* sources are used primarily to produce intense continuous beams of small singly ionized clusters of most metals. The clusters are hot, typically near the evaporation limit.
- *Liquid-metal ion* sources produce singly and multiply ionized clusters of low-melting-point metals. These clusters are hot, since in-flight evaporation and fission are observed.

The detection of a slow neutral cluster seems to be difficult, but by diffraction methods we can obtain information about cluster structure. Then clusters can be ionized for an efficient mass selective detection. An atomic ion has a detection efficiency of near unity, if it is accelerated to a kinetic energy of some keV and impinges onto a metal surface. The secondary electrons emitted can be used for further amplification. The same method is used universally to detect cluster ions. Then we can analyze the cluster beam by a mass-filter (or a quadrupole) in order to obtain mass spectra. A typical experiment consists of a well collimated electron beam with an energy of 30 to 50 keV crossing a supersonic cluster beam. The fast electrons are scattered from the atoms in the cluster, and the diffraction pattern is recorded usually on photographic film. For the interpretation, a geometrical model is constructed and the diffraction pattern calculated, remembering that the scattered intensity is the squared modulus of the Fourier transform (FT) of the scatterers with respect to the momentum transfer. In this way three pieces of information can be extracted.

- The mean geometry of the cluster.
- The mean cluster size.
- The cluster temperature.

The geometry is obtained directly from the fit of the assumed model to the experimental data. It is plausible that an icosahedron (see next section) has a different FT than a part of an fcc lattice, and so on. The larger the cluster, the narrower are the diffraction rings, such as in light diffraction from a grating with few or many grooves. The more the scatterers add their contributions coherently, the sharper the resulting pattern is. The position of an atom is described by the vector

$$\mathbf{r}(t) = \mathbf{r}_0 + \mathbf{u}(t) \qquad (29)$$

where $\mathbf{r}_0(t)$ is a constant vector pointing to an atom in the cluster, and the time dependent vector $\mathbf{u}(t)$ describes the thermally activated vibrations. An average over the thermal motion gives for the temperature dependence of the diffracted intensity

$$I(T) = I_{(T=0)} e^{-2W} \qquad (30)$$

with

$$W = \frac{1}{3} \langle u^2 \rangle q^2 \qquad (31)$$

where $\langle u^2 \rangle$ is the mean square thermal motion of the atoms from Eq. (29), and q^2 is the square of the momentum experienced by the electron beam upon scattering. The value of $\langle u^2 \rangle$ increases with temperature. The diffraction lines do not broaden but decrease exponentially in intensity according to Eq. (31).

4.1. Cluster Structures

Many kinds of nanoclusters have as their most stable forms structures based on polyhedra. They can be crystalline structures (fcc for the elements that we will consider in the following) in the sense that we can build an infinite, periodic array of them; but, since for a finite system there is no translational symmetry constraint, also noncrystalline geometries are found. The latter can show very often fivefold symmetries as those found in decahedra (Dh) or icosahedra (Ih). Here we present a brief description of the most common morphologies.

Icosahedra—They consist of 20 tetrahedra sharing a common vertex (see Fig. 11). Tetrahedra are not space-filling. Ino [99] proposed that there were small gaps in the regions separating the tetrahedra. For this reason, icosahedral particles are often called multitwinned particles since they can be thought of as tetrahedra each having twin boundaries with its neighbor. Alternatively, the tetrahedra might distort, as they are packed together so that they fill the entire volume of the icosahedron. A Mackay [100] Ih is structured in shells, as in an onion-like structure. An Ih with k shells has

$$N_{Ih}(k) = \frac{10}{3} k^3 - 5k^2 + \frac{11}{3} k - 1 \qquad (32)$$
Figure 11. Icosahedra are noncrystalline structures with six fivefold symmetry axes, having two fivefold symmetry vertices each. Around these vertices, 20 close-packed triangular facets are arranged. The icosahedral shape is quasispherical with a close-packed surface, and optimizes the surface/volume ratio very well. In nanoclusters, icosahedra can be obtained by arranging subsequent shells of atoms around a central one (Mackay icosahedra). Here we represent the fifth-shell icosahedron, which has 309 atoms: from left to right this icosahedron is given in top view, side view, and along a fivefold symmetry axis.

atoms (so that the series of magic numbers is 1, 13, 55, 147...) and presents 20 triangular facets of side k. Each facet has a (111) geometry. Icosahedral clusters, as we said before, if they continue to grow, will never become crystals. They possess 12 fivefold symmetry axes. This is a symmetry operation not consistent with the translational symmetry found in crystals. The icosahedral packing has many favorable attributes. The Ih has the highest symmetry of all discrete point groups. Each of 20 triangular faces of an Ih can be constructed with close-packed spheres [(111)-facets]. But the icosahedron is a highly strained structure. The interatomic distances between shells are smaller than those within a shell. For this reason, icosahedral packing is found only in relatively small clusters having a high surface-to-volume ratio.

Marks decahedra—They are the other very common noncrystalline structures with a fivefold symmetry axis. A decahedron consists of a pentagonal bipyramid where some vertices are cut in order to have a more spherical structure (see Fig. 12). Alternatively, a Dh can be thought of as five tetrahedra sharing a common edge. It is possible to

Figure 12. As icosahedra, also decahedra are noncrystalline structures with fivefold symmetries. Decahedra present a single fivefold axis, corresponding to two fivefold vertices. A decahedron is obtained by joining two pentagonal pyramids at their basis. This kind of decahedron has ten triangular close-packed facets, but its shape is far from being spherical. A better structure can be obtained by truncating the sides in such a way that rectangular facets are exposed, and forming reentrances exposing further close-packed facets. In this way a Marks decahedron is obtained. The Marks decahedron of $N = 146$ atoms is shown: from left to right, top view (along the fivefold axis), side view, and a different representation of the top view, which shows that atoms are perfectly arranged in columns from this perspective. This decahedron has $(m, n, p) = (3, 2, 2)$: m is the length of the horizontal side of the rectangular facets (see the middle panel) in number of atoms; n is the length of the vertical side of the rectangular facets; p is the depth of the reentrance (see the left panel), with $p = 1$ corresponding to no reentrance at all.

arrange spheres in decahedral arrangement having a shell structure. The next Dh is formed by placing a large overlapping umbrella on top of the previous member of the set. Since it is energetically favorable to truncate a decahedron in order to make it more spherical, these truncations expose (100) facets that are not close-packed and that have a correspondingly high surface energy. The degree of truncation can be varied in order to minimize the total energy for a given material. The best solution to this problem was given by Marks [101]. He introduced three indices (m, n, p), which characterize unambiguously decahedra. m and n are the length of the sides of the (100) facets of the truncation, perpendicular and parallel to the fivefold axis, respectively; p is the depth of the Marks reentrance ($p = 1$ corresponds to no reentrance, i.e., to the Ino decahedron [102]). A (m, n, p) Marks Dh has $h = m + n + 2p - 3$ atoms along its symmetry axis and a total number of atoms $N_{Dh}(m, n, p)$ given by

$$
\begin{aligned}
N_{Dh}&(m,n,p) \\
&= \frac{1}{6}\{30p^3 - 135p^2 + 207p - 102 \\
&\quad + [5m^3 + (30p - 45)m^2 + (60(p^2 - 3p) + 136)m] \\
&\quad + n[15m^2 + (60p - 75)m + 3(10p^2 - 30p) + 66]\} - 1
\end{aligned}
$$

(33)

fcc polyhedra—Starting from the octahedron, better fcc polyhedra are obtained truncating symmetrically the six vertexes, thus obtaining square and hexagonal (triangular in the case of cuboctahedra) facets (see Fig. 13). In the following we characterize a given truncated octahedron (TO) by two indexes: n_l is the length of the edge of the complete octahedron; n_{cut} is the number of layers cut at each vertex. A TO has a number of atoms

$$
N_{TO}(n_l, n_{cut}) = \frac{1}{3}(2n_l^3 + n_l) - 2n_{cut}^3 - 3n_{cut}^2 - n_{cut}
$$
(34)

and square facets with edges of $n_{cut} + 1$ atoms. Concerning the (111) hexagonal facets, they are not in general regular hexagons. In fact, three edges of the hexagons are in common with square facets, having thus $n_{cut} + 1$ atoms, while the remaining three edges have $n_l - 2n_{cut}$ atoms. Regular hexagons are thus possible if $n_l = 3n_{cut} + 1$; in the following the TO with regular hexagonal facets will be referred to as
Figure 13. Truncated octahedra (TO). These are fcc polyhedra that are obtained truncating the vertices of an octahedron, which is simply a square-basis bipyramid. When the truncation is not too deep, the TO present hexagonal and square facets, as in the first, second, and third figure from the left. When the truncation gets deeper and deeper, the hexagonal facets decrease in size at the expense of the square facets, until the hexagonal facets are transformed into triangular facets. In this case, the structure is called cuboctahedron (at right).

regular TO. On the other hand, cuboctahedra are characterized by $n_l = 2n_{cut} + 1$, which gives energetically unfavorable clusters with large (100) facets and triangular (111) facets; by substituting this relation into Eq. (34), and comparing with Eq. (32), one finds that a cuboctahedron with a given n_{cut} has the same number of atoms as an Ih with $k = n_{cut} + 1$. The most favorable TO can be found by means of the geometrical Wulff construction [1], which minimizes the surface energy, as shown in several metallic systems in [103].

In order to distinguish the different cluster structures, we have implemented the common neighbor analysis (CNA) method [104]. Briefly, in this method each pair of nearest neighbors (NN) is classified by a triplet of integers (r, s, t) where r is the number of common nearest neighbors, s is the number of nearest-neighbor bonds among the r common nearest neighbors, and t is the length of the longest chain that can be formed with the s bonds. Monitoring the signatures $(r, s, t) = (5, 5, 5), (4, 2, 1), (4, 2, 2)$, we can distinguish whether the cluster is still molten and how its structure is classified. (In Table 3, one can find typical values of these CNA-signatures for molten, Ih, Dh, and fcc clusters.)

4.2. Growth Models

Before dealing with the modeling of growth processes, we wish to spend some words to justify the use of MD simulations to study the growth of nanoaggregates. In typical experiments performed in inert gas aggregation sources, one has

- experimental time scale: $t_{exp}^C \sim$ ms and
- sizes: $d^C \sim$ several nm,

while in the case of epitaxial crystal growth the same parameters are $t_{exp}^{MBE} \sim$ minutes (hours!) and $d^{MBE} \sim \mu$m. In the

Table 3. Comparison of several nanocluster structures, pertaining to the three different structural motifs (icosahedral, decahedral and fcc), with respect to the most significant CNA signatures [104].

N	Structure	N_5	$P(5, 5, 5)$	$P(4, 2, 1)$	$P(4, 2, 2)$
75	(2,2,2) m-Dh	5	1.25	28.2	20.4
100	(3,1,2) m-Dh	5	0.92	27.6	19.6
101	(2,3,2) m-Dh	6	1.12	33.7	20.2
146	(3,2,2) m-Dh	6	0.75	39.6	18.7
192	(3,3,2) m-Dh	7	0.66	45.3	18.2
212	(2,2,3) m-Dh	7	0.60	44.7	16.4
238	(3,4,2) m-Dh	8	0.61	48.6	18.0
247	(4,2,2) m-Dh	7	0.51	47.2	16.9
268	(2,3,3) m-Dh	8	0.54	48.6	15.8
318	(4,3,2) m-Dh	8	0.45	52.5	16.3
55	Ih	5	10.3	0.00	38.5
147	Ih	7	5.17	17.2	38.8
309	Ih	9	3.10	31.0	34.9
561	Ih	11	2.06	41.2	30.9
116	TO	—	0.00	60.5	0.00
201	TO	—	0.00	64.6	0.00
225	TO	—	0.00	61.8	0.00
314	TO	—	0.00	68.0	0.00

Note: Size N, type of structure, length of the fivefold symmetry axes N_5 (in atoms), and percentages P of the occurrences of the CNA signatures (5, 5, 5), (4, 2, 1), and (4, 2, 2).

case of small systems (N is up to several hundred particles) with the present computational resources it is possible to simulate up to $t_{sim} \sim 10^{-5}$ s, which is comparable with experimental time scales; while in the case of MBE only $t_{sim} \sim 10^{-8}$ s can be reached, eight order of magnitude faster than the experimental time scale. Thus, in the case of free clusters, since the system size is small and the time scale is short, MD is a very good tool. If the interparticle potential is reliable, MD simulations offer an accurate and detailed description of the growth process, which allows us to single out the key microscopic mechanisms leading to structural transformations. Contrary to KMC, MD does not imply restrictive choices about the possible processes or the assumption of some rate theory, such as TST, to hold.

The first step to analyzing in detail the growth of free nanoaggregates is to study their lowest energy sequences. Different groups [105–107] suggested several methods, from genetic algorithms to Basin hopping to searching the global minimum (or very good local minima) at a given size N. This often is not sufficient to understand the structures found in experiments. Then it is necessary to include the effect of temperature on clusters. Thus, the problem is to find the minimum free-energy structures. But sometimes taking into account entropic effects is not enough, because the growth time is finite and the system is not able to explore all its configurational space. In other words, since the experimental time of building up of nanosystems is short, the kinetics of the growth process are of fundamental importance to understanding the experimental data. There are two alternative models of obtaining solid clusters, built in contact with a thermal bath, at the end of the growth process. Clusters can grow in the solid state by subsequent additions of single particles on a small seed. Alternatively, clusters can be grown as liquid droplets and then solidify after the growth is completed. From the point of view of simulations, the first approach corresponds to a growth at fixed T and increasing N; while in the second case N is kept fixed and T is lowered to freeze the liquid droplet. In typical conditions, solid-state growth is strongly out of equilibrium.

4.3. Solid-State Growth

The modeling of a growth process through solid states is very close to the DLA method. In fact, we can image that the building up of a cluster is due to the deposition of adatoms onto a small solidified seed, which is in contact with an inert gas, which thermalizes and carries the seeds. Then, when the incoming adatom adsorbs on a cluster, it is free to move on the surface, to reach and attach on islands or steps (as happens on a flat surface), as seen in Figure 1. Desorption is allowed, even if in the case of metallic cluster has never been seen, while for clusters of C_{60} molecules it can take place at high temperatures [108], because these clusters do not melt but sublimate. In order to simulate the presence of the inert gas, canonical MD simulations are needed, introducing for example an Andersen thermostat, as described previously (see [7] for details). The average collision frequency of the thermostat ν must be chosen according to two opposite needs: ν has to be high enough in order to have an efficient thermostat, but it must not be

too large because the thermostat must not influence the diffusive properties [110]. Free nanoclusters growth simulations are started from a small seed (seven atoms in the case of silver below), and further particles are deposited one by one at intervals τ_{sim}, by choosing the incoming particle on a random point on a large sphere centered around the cluster center of mass and directing its velocity towards the cluster. The initial position of the adatom is far enough to ensure that there are no interactions with the atoms of the aggregate. The initial velocity of the deposited adatom is chosen as the average velocity at T_{ev} corresponding to a typical evaporation temperature of the material; but this is not so important, since the kinetic energy has to be compared with the adsorption energy, which is about 1–2 eV. In between two subsequent depositions, all the atoms of the cluster are thermalized at a given temperature T, and they are free to move following Newton's equations.

The parameters of this model are the temperature T of the thermal bath and the time interval τ between two subsequent depositions, which is the inverse of the adatom flux ϕ^M. An estimate of the experimental adatom flux ϕ^M on the cluster is given by

$$\phi^M = \frac{P A_{eff}}{\sqrt{2\pi m_M k_B T}} \qquad (35)$$

where m_M is the mass of the atom, A_{eff} is the effective area of the cluster, P is the pressure of the vapor, and T is the experimental growth temperature. Below we summarize the growth simulation results for different systems.

4.3.1. Silver Clusters

In the case of silver the simulations were performed by Baletto et al. [4, 111]; the parameters were chosen in this way [4]: time interval $\tau = 1/\phi^M$ in the range 2.1–98 ns; simulation temperature T between 350 and 650 K. The experimental time scale in IGA sources is of the order of one atom every $\sim 10^2$ ns, as seen by putting in Eq. (35) typical values for Ag such as $P \sim 3$ mbar, $m_M = m_{Ag}$, with $R \sim 2$–3 nm, $T \in 300$–500 K (for details see [109]). simulations are started from a seed of 7 atoms. The experimental data by Reinhard et al. [3] were in disagreement with any thermodynamics calculations, showing a great abundance of small decahedra and few small icosahedra, while icosahedra were (very surprisingly) the most frequent structures at large sizes. fcc clusters were found if the growth took place at high T. The growth simulations by Baletto et al. [110, 4, 111] have shown that this can be explained in terms of kinetic effects. Small (2 nm of diameter) metastable decahedra are grown at intermediate temperatures because of a kinetic trapping phenomenon in stable smaller Dh (reentrant morphology transition [4]). The large metastable icosahedra are then obtained by growth above the small decahedra (see the sequences in Fig. 14). In fact, a small decahedron is a fragment of a larger icosahedron. The latter grows readily if islands on hcp stacking are nucleated on the starting decahedron [111, 112]. This solid–solid transformation of a Dh into an Ih (sstDI) takes place because it is always more convenient to adsorb an island onto a decahedron on hcp stacking than on fcc stacking, since fcc adsorption sites between two neighboring (111) facets are unstable for single adatoms.
Figure 14. Snapshots at different sizes (given in the figure) from simulations of Ag clusters growth, with a flux of one atom each 7 ns, but at different temperatures. Sequence (a) is at low T (400 K). At 55 atoms a perfect Ih is obtained; then the Ih transforms into a Dh, which is a perfect (2, 2, 2) Marks Dh at 75 atoms. The deposition of further atoms causes the nucleation of islands in hcp stacking and the formation of the Ih at 147 atoms, which grows shell by shell to form larger metastable Ih. Sequence (b) is at intermediate T (450 K). Up to 75 atoms it is analogous to (a), but the addition of further atoms continues the growth of a Dh structure up to 147 atoms. Dh are the most stable structures up to about 100 atoms, and, at this T, kinetic energy is high enough to achieve structural optimization up to this size. After this size, there is a kinetic trapping phenomenon in Dh structures, which ends up above 150 atoms, again because of the transformation into an Ih, which is metastable in this case and then grows shell by shell. Sequence (b) is in complete agreement with the experiments in [3], where small Dh and large Ih were produced. Sequence (c) is at high T (600 K). The cluster is liquid up to 135 atoms, and then solidifies into the most stable structure in this size range, which is an Ih. After that, the growth keeps on following the thermodynamics predictions, giving Dh at larger sizes. Sequence (d) is at even higher T (650 K) and shows the formation of an fcc cluster at large sizes. We underline that at sizes around 150 atoms, there is an intermediate T range where metastable Dh are grown (reentrant morphology transition [4]).

The formation of an hcp island breaks the decahedral symmetry and so the Dh grows towards an Ih. The sstDI is the key ingredient to explain the experimental results: from small decahedra, larger icosahedra are grown, which can then grow further in a shell-by-shell mode preserving their symmetry. The sstDI is a very peculiar example of complete structural transformation, since it has a clear kinetic origin and occurs only through solid states. On the contrary, the reverse transformation of an Ih into a Dh takes place only via the melting of the Ih. Finally, the growth simulations have shown that fcc clusters can be obtained at high temperatures, again in agreement with the experimental results.

4.3.2. Aluminum Clusters

The growth of aluminum clusters has been studied by Valkealahti and Manninen [113] by means of MD simulations, with the aim of explaining the observation of clusters of octahedral shape (see Fig. 13), thus exposing only (111) facets [114–116]. In their simulations, the starting cluster is a

TO of 586 atoms. After having calculated the energy barriers for the most relevant diffusion processes of adatoms and dimers above the cluster surface, Valkealahti and Manninen performed growth simulations by depositing atoms one by one (up to a total of 201), with a much faster deposition rate (one atom each 0.5 ns) than the rates of the above-discussed silver cluster growth simulations [4]. The cluster temperature was kept constant by a thermostat, and simulations were performed in a range around 400 K. Even such a fast deposition rate was however sufficient to demonstrate the possibility of transforming a TO into an octahedron by a growth process. In fact, the deposited adatoms can diffuse fast on the (111) facets, and when they reach the border close to a (100) facet, they can exchange easily with an edge atom, which is then trapped on the (100) facet. The reverse process (exchange from a (100) to a (111) facet) is very difficult because the adsorption energy is much more favorable on (100) than on (111) facets. The accumulation of atoms on (100) facets leads naturally to the formation of an octahedron exposing (111) facets only.

4.3.3. Gold Clusters

A simulation procedure of the same kind as the one of Valkealahti and Manninen for aluminum (see previous section) was applied to the growth of gold TO by Baletto et al. [110], starting from a TO of 201 atoms and depositing with rates of one atom each ns and of one atom each 25 ns. Also in the case of gold, the transformation of the TO into an octahedron can take place easily, because the diffusion processes lead the adatoms to reach the (100) facets, where adsorption is by far more favorable. In comparison, the growth of silver octahedra starting from a TO is still possible, but somewhat more difficult than for gold [110].

4.3.4. Core-Shell Silver/Copper and Silver/Palladium Clusters

The growth of bimetallic clusters in the core-shell geometry has been studied by F. Baletto et al. [117] by the same procedure described above [4, 111]. The systems silver/copper and silver/palladium were considered. In both cases, silver has the tendency to segregate at the surface [118]. Thus, starting either with a palladium or with a copper cluster as a core, and depositing silver atoms above it, there is hope to cover the core by a well-defined silver shell. The aim is to build up a single-layer silver shell. This layer will be strained, due to the size mismatch with the core atoms. Strained overlayers are interesting for catalytic applications [119], especially when obtained above nanoclusters that have a large surface/volume ratio. The simulations by Baletto et al. have indeed shown that sharply defined silver shells with a thickness of a single layer can be grown in a wide range of temperatures. Intermixing between silver and palladium or copper atoms is weak. There is however a difference between the two systems: On palladium cores, the best layers are grown at low T, because the increase of T causes the appearance of some intermixing; on copper cores, the tendency of silver to segregate is so strong that intermixing is always negligible, and the increase of temperature leads to the growth of better shells because diffusion processes are more efficient in eliminating growth defects.

4.3.5. Clusters of C_{60} Molecules

The growth of clusters of C_{60} molecules was studied experimentally several years ago [120], and the mass spectra showed magic numbers sequences related to clusters of icosahedral symmetry, up to sizes around 100 molecules. Subsequent calculations by different methods (see [121] for a summary) were however in complete disagreement with the experimental results, since the lowest energy clusters are icosahedra up to sizes of about 15 molecules, and then, either decahedral or close-packed clusters are preferred. This discrepancy was attributed to the fact that the experiments were performed on charged clusters, while the calculations considered neutral clusters. However, the repetition of the experiments with neutral clusters [122] has given again the growth of icosahedral clusters. Close-packed and decahedral clusters can be obtained only after annealing at high T [122]. The simulations by F. Baletto et al. [123] explained the experimental results by showing that the growth of large metastable icosahedra is due to kinetic trapping effects. During the growth process, small fragments of larger icosahedra are formed around sizes of 20–25 molecules. These fragments are still the lowest-energy structures. Adding further molecules, the cluster remains trapped in a pathway which leads to the completion of the large icosahedron. This is metastable, but with a very long lifetime. Due to a problem of time scales, these simulations were however not able to obtain the close-packed and the decahedral clusters after annealing. Further simulations by Branz et al. [124] showed that the transformation of metastable icosahedra into the most stable structures should be possible, but they have forced their simulated clusters to keep their size constant, not allowing cluster dissolution by evaporation.

4.4. Liquid-State Growth Followed by Freezing

Liquid-state growth implies that solidification takes place after growth. Simulations are performed starting from a liquid droplet of N particles, and then, after a thermalization at such high temperature to ensure that the cluster is liquid, T is lowered. In order to mimic a thermal contact with a cold inert gas, the cluster should be cooled down at a slow rate r_c. For example, the cluster can be cooled down is small steps δT at each time interval δt so $r_c = \delta T / \delta t$. How does one choose the cooling rate? In an inert-gas atmosphere, one can estimate that a cluster of radius R and area $A_{eff} = 4\pi R^2$ collides with gas atoms with a frequency ϕ_{exp}^G given by

$$\phi_{exp}^G \sim \frac{P_G A_{eff}}{\sqrt{2\pi m_G k_B T_G}} \tag{36}$$

where P_G and T_G are, respectively, the pressure and the temperature of the inert gas of mass m_g, and k_B is the Boltzmann constant. In the harmonic approximation, the energy loss is given by

$$\frac{\delta T}{\delta t} \sim \phi_{exp}^G \frac{\delta E}{3Nk_B} \tag{37}$$

where δE is the energy transfer at each collision, and since $N \sim R^3$ we obtain $(\delta T / \delta t) \sim (1/R)$. From [125], we can

estimate that the loss for each collision with a helium atom is $\delta E \sim 5$–10 meV. Using typical parameters for the gas ($P_g \sim 3$ mbar, $T_g \sim 300$ K) and considering a cluster of $R \sim 1$ nm, we have $(\delta T/\delta t) \sim 10^{-1}$ K/ns or even less. This is the procedure adopted in [130], where slow rates, close to the experimental ones, were adopted. However, in many cases the cooling rates of simulations are much faster than the experimental ones (see [126–129]).

4.4.1. Silver Clusters

In Ref. [130], Baletto et al. considered several free silver clusters with size N in the range 130–310 atoms and, in addition, at icosahedral magic numbers 147, 309, 561, and 923. Different slow cooling rates were employed (choosing $\delta T = 2.5$ K and the cooling rate between 0.1 and 5 K/ns), and, independently of that, particles presented always a well-defined structure. At small sizes (around 2–3 nm), Ih clusters are very common, around the magic size of 147 atoms and in the wide range $N \sim 245$–310. On the other hand, decahedral particles are the most frequent structures at sizes $N \sim 170$–240. fcc clusters are found, at intermediate cooling rates, at $N > 200$ atoms, especially around 280, but their percentage decreases if the cooling rate is decreased. By freezing a silver nanodroplet of a diameter around 2 nm, the probability to solidify as an icosahedron is quite high. At magic icosahedral numbers, we find that Mackay icosahedra are not always obtained. In fact, already at 561 atoms nonicosahedral particles are preferentially obtained, and at $N = 923$ it is very unlikely to find icosahedral structures, especially if the cooling rate is slow. Indeed, at $N = 147$ there is 100% of Ih structures, while at $N = 923$, there is only $\sim 10\%$. On increasing the cluster size, it is more and more difficult to grow large icosahedra by freezing on a liquid droplet. From these results, it follows that entropic effects [131] probably cause the appearance of some icosahedra after freezing the droplets of 923 atoms, but they are not sufficient to make the icosahedron the most favorable structure at that size. These findings are not in agreement with the experimental data of [3], where Dh structures are dominant at small sizes ($d \sim 2$ nm) and a great abundance of large icosahedra ($d \sim 10$ nm) is found. Therefore, the experimental data are in much better agreement with the previously reported simulations of the solid-state growth [110, 4, 111, 112] than with the results of liquid state growth followed by freezing. The conclusion is that in an inert-gas atmosphere, the silver vapor condenses, some seeds are formed, and the particles grow as solid from these seeds because of collisions between them, or by deposition of atoms from the metallic vapor, but it is more unlikely that silver nanoparticles are grown as liquid nanodroplets.

4.4.2. Gold Clusters

The solidification of gold nanoclusters has been simulated by Chushak and Bartell [126] by a rather different method with respect to Baletto et al. [130]. In their MD simulations, they start from high T liquid clusters of sizes of 459, 1,157, and 3,943 atoms. The clusters are then cooled very fast (5×10^4 K/ns) down to about 700 K, were production runs of 1 ns are performed. After that, clusters are further cooled down to 300 K, again with a fast rate (300 K/ns). The result of this procedure is that icosahedral clusters are preferentially produced, even if close-packed or decahedral clusters should be more stable in these sizes (see for example [103]). The production of icosahedra during freezing is due to the width of the icosahedral funnel [107] with respect of the funnel leading to close-packed structures on the potential-energy surface. This preference for icosahedral structures is especially seen at fast cooling rates (compare with the above results for silver [130]), and again, is more evident for the smallest cluster than for the others.

4.4.3. Nickel Clusters

Yue Qi et al. [129] studied the freezing of several Ni clusters of different sizes (from 336 to 8,007 atoms) by MD simulations. They performed heating and cooling cycles: Starting from a solid cluster at low T they raised the temperature until the cluster melted, and after that, they cooled down to solidify the cluster again. During these cycles, the temperature was varied at a fast rate, of 4×10^3 K/ns. The freezing of the clusters produced icosahedral clusters at sizes below 500 atoms and fcc clusters at larger sizes. Due to the fast cooling rate, these resolidified clusters contained a rather large number of defects, with extended region with a disordered character. Also the results of Yue Qi et al. [129] confirm the tendency to form icosahedral clusters only at small sizes after freezing a liquid droplet, in agreement with the previous cases.

4.4.4. Lead Clusters

The solidification of lead clusters by MD simulations was studied first by Lim et al. [132]; they considered a single cluster of about 8,000 atoms, obtaining an icosahedron after fast quenching, in disagreement with the energetic calculations that indicated cuboctahedra as the most favorable clusters [133]. Hendy and Hall [128] performed a more systematic study of the solidification of liquid lead droplets. In their procedure, the droplet is quenched suddenly below the cluster melting point at this size, and then equilibrated for 10 ns. In the size range between 600 and 4,000 atoms, their freezing simulations produced icosahedra with a reconstructed surface, which were shown to be lower in energy than any other known structure of the same size. (We remark however that global optimization at these sizes is unfeasible.) The freezing of larger clusters (around 6,000 atoms) produced fcc structures, even though with several stacking faults forming a narrow band with hcp structure. The production of lead Ih clusters is in agreement with the experimental observation of icosahedral particles of diameter between 3 and 6 nm by Hyslop et al. [134].

4.4.5. Lennard–Jones Clusters

Lennard–Jones clusters are good models for noble-gas nanoparticles, for example for argon clusters, which have been extensively studied in experiments [135]. Their solidification has been studied by Ikeshoji et al. [127] by MD simulations, taking into account two possible ways to cool down the cluster: by a thermostat or by evaporation of atoms. This second possibility must be taken into account for these systems. In fact, Lennard–Jones systems exhibit a rather narrow temperature range for the existence of liquid structures.

Therefore, the evaporation of atoms is still likely at temperatures that are slightly above the melting temperature of the cluster. For metallic systems, the temperature range where the liquid is stable is so wide that solidification by evaporation is practically negligible. Ikeshoji et al. considered 380 clusters in the size range between 160 and 2,200 atoms, and found that there is a transition at increasing size from icosahedra to a variety of different structures (Dh, fcc, hcp, and Ih). The transition does not depend on the cooling method, either evaporation or thermostat, and takes place around size 450. This is lower than the transition size (750 atoms) observed in experiments on argon clusters [135], but it is closer than any estimate based on total energy optimization.

4.4.6. Parahydrogen Clusters

An important issue concerning the freezing of a cluster concerns the way by which solidification is taking place inside the cluster itself. An interesting case for studying this phenomenon is related to parahydrogen nanoclusters, which are at present widely studied because they could be superfluid [136, 24, 137]. In such aggregates, the principal antagonist of superfluidity is solidification. This was recently studied by Levi and Mazzarello [138, 139], who investigated under what conditions solidification either cannot occur at all, or would occur only in times much longer than the lifetime of the cluster. Due to surface melting effects (enhanced by van der Waals forces, via the Hamaker contribution to the free energy [140]), the exterior layers of the cluster do not solidify. As far as the inner core is concerned, the solidification times depend strongly on the exact values of the parameters; they also depend strongly on the thickness of the molten layer. Nucleation implies a barrier, which in principle can be overcome either by thermal fluctuations (at relatively high T) or by tunneling (at very low T). Tunneling in a system with an infinite, or very large, number of degrees of freedom (which can be treated in terms of a small number of macroscopic variables) was introduced in the context of phase transitions, by Lifshitz and Kagan [141]. Two terms in the macroscopic kinetic energy are relevant here. One refers to the liquid motions when a portion of liquid is replaced by the denser solid phase, the other to the motion of the individual molecules across the interface. In both cases the nucleation times can be exceedingly long. More recently, the solidification of parahydrogen clusters containing a foreign, nonspherical molecule at their centers (e.g., OCS, as in the Göttingen experiment [137]), was studied [139]. The foreign molecule a) partly replaces the solid phase, b) imposes a nonspherical symmetry to the solid–liquid interface, c) furnishes a template for solidification, and d) promotes solidification via its van der Waals attraction, which is the most important effect. As a result, the solidification times are drastically reduced with respect to the case of pure hydrogen clusters. This study was used to discuss, from the point of view of solidification, the experiment of the Göttingen group [137], where strong indications in favor of hydrogen superfluidity were found by studying the spectrum of an OCS molecule, surrounded by hydrogen molecules at the center of a helium cluster. The disappearance at 0.15 K of the Q-branch in the spectrum was interpreted as disappearance of the drag of hydrogen by the OCS rotations at low temperatures, hence as superfluidity of the former.

4.5. Coalescence of Nanoclusters

Understanding coalescence is of primary importance for understanding the structure of cluster-assembled materials. These materials can be grown by the low-energy deposition of preformed clusters containing hundreds or thousands of particles on a surface. The structure of the resulting film depends crucially on the diffusion properties of the deposited clusters. By thermodynamic considerations, it is evident that clusters deposited on a surface will tend to coalesce and to form larger drops. The kinetics of this process is not known in detail, but there are some theoretical studies about the coalescence of unsupported clusters. Constant-temperature MD simulations allow us to study the coalescence of free clusters, but at the same time the coalescence events here can be relevant to supported clusters in the case that they are loosely bound to the substrate. The coalescence process can present differences if it takes place between two liquid clusters, one liquid and one solid cluster, or two solid clusters. In order to simulate the process, the starting point configuration consists of two fully equilibrated clusters, which are placed in contact with one another (i.e., along the z axis) at a distance of approach roughly equal to the nearest-neighbor distance for the material. The initial angular momentum is set to zero. For like clusters, the initial positions are chosen in order to allow rotations of clusters with respect to one another by a random angle; indeed, it is expected that coalescence will proceed differently if two facets are in contact than if a facet of one cluster is in contact with a vertex of the other. In the following, the results of simulations by Lewis et al. [142] of coalescence of gold clusters are summarized.

- **Coalescence of liquid–liquid clusters**. In this case, the two small clusters rapidly coalesce into a single essentially spherical cluster. The radii of gyration of the coalescing clusters of N atoms are $\rho_{g\alpha} = (1/N) \sum_{i=1}^{N} (\alpha_i - \alpha_{cm})$, where $\alpha = x, y, z$, and α_{cm} are the coordinates of the center of mass of the cluster, and their average is

$$\rho_g = \sqrt{\sum_\alpha \rho_{g\alpha}^2} \qquad (38)$$

Analyzing the evolution in time of all three radii of gyration, it is found that they converge to the overall average on a time scale of several tens of ps. It is important to note that coalescence into a spherical cluster proceeds by deformation of the two clusters in such a way as to optimize the contact surface, i.e. without interdiffusion of one cluster into—or onto—the other. The coalescence of two liquid clusters is essentially a collective phenomenon, involving hydrodynamics flow driven by surface tension forces. Of course, on longer time scales, since the cluster is liquid, diffusion takes over and there is intermixing of the two initial clusters.

- **Coalescence of liquid–solid clusters**. The analysis of the radii for the system (liquid cluster of 767 against a solid cluster of 1505) reveals that coalescence proceeds in two stages. First maximizing the contact surface, an extremely rapid approach of the two clusters is observed, taking place on a time of about 100 ps, which is of the same order of magnitude for coalescence of

two liquid clusters. The cluster is far from spherical but has a faceted ovoidal shape. This rapid approach is followed by a slow "sphericization" of the system driven by surface diffusion on time scales of several hundreds of ns, which is much longer than the sintering time predicted by macroscopic theories of sintering for two soft spheres. The rapid changes seen at short times are due to elastic and plastic deformations; at long times the presence of facets slows down the diffusion [110].

- **Coalescence of solid–solid clusters**. The case of two solid clusters of 1055 atoms is considered. At the beginning, the coalescence seems to proceeds faster here than it did for the liquid–solid case, but the sphericization is slower. However, we can expect that the overall coalescence is faster in the case of liquid–solid clusters. The internal structure seems to be a single domain. On the other hand, considering clusters different in size (i.e., 767 and 1,505) it is found that the internal structure is complex and presents grains. Thus we can conclude that the coalescence of two solid clusters depends strongly on their sizes, while this should not be observed in previous cases.

5. CONCLUSIONS

The study of the nanoworld presently takes enormous benefit from the interplay of experiments and computer simulations. Indeed, when tackling real problems, with the aim to explain quantitatively the experimental outcomes about specific systems, analytical techniques are very often not feasible, and the only way to interpret the experimental data relies on simulations. Thus experiments are interpreted with the help of simulations, which can also suggest new experiments, as in the case of Pt/Pt(111) growth, which in turn stimulate further simulations.

In this article we have given an overview of the most widely employed computational techniques for studying the growth of nanosystems. We have also shown specific examples where these techniques have been employed successfully to explain puzzling experimental data.

Ab initio calculations can provide activation energy barriers for complicated processes in a large variety of systems. The advantages of this technique are its versatility (almost all systems can be studied in the same framework) and its accuracy. The drawback is its computational costs, which allow neither time-dependent simulations on a scale which can be significant for growth processes, nor the study of systems with thousands of atoms. Moreover, since the calculation of each energy barrier is cumbersome, one must decide in advance which processes are significant and which are not. If this task is accomplished, the set of *ab initio* barriers is a very good basis to build up a kinetic Monte Carlo simulation.

Molecular dynamics simulations with interatomic potentials can reach much longer time scales, and on larger sizes. MD simulations give a detailed microscopic description of diffusive and growth processes, and, apart from the choice of an appropriate interatomic potential, they do not require any specific assumption about the kinetics of the system under study. Therefore, when they can be used, they are the most appropriate tool for studying growth phenomena

at the microscopic level. MD simulations can be employed to study free nanocluster growth in realistic conditions, following for example complicated transformations between noncrystalline structures. Moreover, they allow a complete study of diffusion processes without any a priori assumption about the choice of the significant processes. This technique requires the development of reliable interatomic potentials. There is no general recipe for this, but accurate atom–atom potentials have been developed for many systems, for example noble gases, several simple and transition metals, and noble metals. MD simulations are however not well-suited to simulate epitaxial crystal growth, because the time scale is too long and terraces are too large. Accelerated MD techniques are promising for bridging the time scale gap. However, at the moment they are useful only for rather small systems at very low temperatures. Moreover, they rely on the assumption of some specific rate theory, which is not universally valid.

Kinetic Monte Carlo simulations can reach the correct sizes and the time scales of epitaxial crystal growth. KMC modeling is based on a large set of assumptions (coarse graining in time and space, choice of a limited set of possible processes, choice of their rates), so that its predictive power may in some cases be rather weak. In particular, the choice of the set of the significant processes may require some skill. However, in the literature, there are several examples of successful application of KMC simulations to explain experimental data.

We have shown that computer simulations have already played a very important role in the investigation of the nanoworld. Since computer power is increasing at a fast rate, we expect that simulation methods will extend their range of applicability in the near future, so that their help in explaining experiments and in designing new materials at the nanoscale will become more and more important.

GLOSSARY

ab initio   A calculation or simulation that computes the atomic motions from first principles, following quantum mechanics and avoiding the introduction of fitting parameters.

Coalescence   The process by which two clusters unite to form one larger cluster.

Growth   The process by which a cluster, starting from a small seed, increases in size by incorporating additional atoms or molecules.

Molecular dynamics   A simulation that computes the atomic motions within a given (possibly many-body) potential, solving exactly the Lagrange equations.

Monte Carlo   A simulation that treats a physical system in terms of a Markovian stochastic process. In equilibrium Monte Carlo, only the minimal energy and the corresponding atomic positions are sought; kinetic Monte Carlo, on the contrary, attempts to really simulate the atomic motions.

Nanoclusters   Aggregates of a small number of atoms or molecules (typically less than 10,000) held together by metallic, chemical, or van der Waals forces.

Solidification (also called freezing) The process by which a cluster, formerly liquid, goes over, totally or partially, to the solid phase.

High-Field Conduction in Nanostructures

R. D. Gould

Keele University, Keele, UK

CONTENTS

1. INTRODUCTION

We can conceive, in the not too distant future, the fabrication of integrated electronic circuits where the feature size of individual components is reduced to the order of nanometers. These nanostructures will require fabrication methods that are either currently only under the initial stages of investigation or even totally unknown. Already nanosized objects may be manipulated using self-assembly and scanning probe microscopy, but the problem remains of how to build functional devices [1]. The mode of operation of such devices is also questionable at the present time, and the assumption that bulk properties will transfer to the nanoscale is very unlikely to be justified. Quantum-mechanical interactions will inevitably be of paramount importance. However, whatever the fabrication methods used and the details of the electronic interactions within the individual nanostructures, it is clear that contacts will be required in order to provide biasing and device control. Furthermore, the one type of nanostructure (admittedly with nanometer dimensions in only one direction) that has been extensively investigated to date is based on thin films. A film of thickness 100 nm having a potential difference of 1 V applied between its surfaces would experience an electric field of 10^7 V m^{-1}, approaching the dielectric breakdown strength of many materials. As we move into the realm of nanostructures, dimensions of only a few nanometers will become commonplace, consequently with even higher electric fields developed. It is likely that voltage levels will have to be restricted considerably in order to avoid damage and premature failure. Nevertheless, it is evident that high-field conduction mechanisms, which have previously been identified in many thin film structures, will become the norm rather than the exception as at present. High-field conduction processes have been previously reviewed by several authors in the context of metal-dielectric-metal layers [2–4]. Of particular interest in the present context is that phthalocyanine films, one of the earliest investigated organic semiconductors, exhibit a wide variety of such high-field conduction processes [5]. The basic phthalocyanine molecule is exceptionally stable for an organic structure, is planar, and is well suited to an important role in future organic nanostructures. High-field conduction processes are also well-known in many conventional inorganic, thin-film semiconductor materials, particularly the cadmium compounds [6], which are beginning to be investigated in the field on nanotechnology. Layer-by-layer growth of CdSe-based nanocrystalline LEDs has already been reported [7].

In keeping with these comments, the review covers the physics of the established high-field conduction processes which occur under steady direct current (DC) bias, plus where appropriate, some speculation concerning conduction processes that may become increasingly important as nanotechnology progresses. Alternating current (AC) processes are excluded from the review on the grounds of simplicity. There is no detailed description of thin film deposition, nanostructure fabrication, and assembly processes or current prototype devices, most of which are fully described elsewhere in this encyclopedia. The major emphasis is on the physics of the high-field processes that will underpin the operation of future nanodevices; although at present, these relate primarily to one-dimensional cases in metal-dielectric-metal systems, it is extremely likely that in a nanostructure, a full three-dimensional theoretical analysis of these processes will be required. The theory for this has not been developed at the present time, but it is clear that the starting point will be the solution of one of the four Maxwell equations

of electromagnetism, namely, Gauss's law, which in principle allows us to calculate the electric field F at any point in the structure. This is implicit in Poisson's equation, which relates the gradient of the electric field to the local volume charge density. In conjunction with the current-density equations, which also include the diffusion component of current density resulting from carrier concentration gradients and the carrier continuity equations, a derivation of the theoretical current density-voltage (J-V) characteristics should be possible. These three sets of equations are the basis for present day semiconductor device operation [4] and in a suitably modified form, which takes into account effects such as the inclusion of microscopic fields and quantum-mechanical behavior, will also be important in the development of the theory of nanoelectronic devices.

Following this introduction, Section 2 briefly covers the basic electromagnetic equations mentioned above. They are presented in the general three-dimensional form using vector operator notation; these are the fundamental equations that will be the basis of the applications of nanostructures in electronics. The equation for the electric field at a distance x from the center of a charged sphere of radius a is discussed as the basis for speculation that the electric field in nanostructures will be extremely high, especially in localized regions. The simpler, one-dimensional form of Poisson's equation, as conventionally used in deriving the J-V characteristics for thin film structures, is then presented. Section 3 describes the types of contact commonly presented to dielectric films, particularly, but not exclusively in metal-dielectric-metal systems. This is particularly germane, since the conduction processes that occur in the dielectric are heavily influenced by the external contacts, in terms of factors such as the barrier height at the interface, and the variation of space charge density within the dielectric. This discussion is restricted to metal-dielectric contacts, and does not cover internal barriers such as semiconductor-semiconductor junctions and grain boundaries. Speculation on the form of these in nanostructures is unlikely to be of value, considering the current state of the art, and can await experimental results on nanostructures with internal barriers.

The main body of the discussion focuses on the various high-field conduction mechanisms previously identified in thin film structures, and which are likely to carry over in some form to nanostructures. These are covered in Sections 4 to 7. The origin of the mechanisms, and a derivation of the expected J-V characteristics, are given where appropriate, together with a small selection of experimental results from the literature specifically chosen to illustrate the processes. Neither the theoretical derivations or the experimental results described are expected to be typical of what may in due course be observed in three-dimensional nanostructures, but both will offer hints of how progress may be achieved in this field. In Section 4, the thermionic emission process is described. This process results from the fact that in a metal at a given temperature, due to electron energies following a Fermi-Dirac distribution, there will be some electrons with energies sufficient to escape over the surface potential barrier. In the presence of an electric field, the potential barrier is effectively lowered, and the resulting current collected at a second electrode is voltage-dependent.

This is known as the Schottky effect. For very thin dielectric regions, typically up to about 10 nm only, the possibility of direct quantum-mechanical tunneling between the two electrodes is significant. Various aspects of the tunneling process are discussed in Section 5. In Section 6, the important mechanism of space-charge-limited conduction (SCLC) is described. This arises from the presence of a space charge reservoir at the interfacial region resulting from the use of ohmic contacts. Various different J-V characteristics can result, depending on whether such a charge is condensed in traps, and if so on their specific energy distribution. Depending primarily on the dielectric film thickness, the space charge is present either only at the contacts (in thicker films) or over the entire thickness (in thinner films). In nanostructures, the latter is likely to be the more important case. The Poole–Frenkel effect, a process similar in some ways to the Schottky effect, is discussed in Section 7. This results from the lowering of internal potential barriers due to the applied field, which results in an increased number of carriers entering the conduction (or valence) band. The field-lowering properties of the Schottky and Poole–Frenkel effects are very similar, including the basic dependencies of the J-V characteristics; these similarities and some differences are outlined. Impurity conduction (or hopping) is not addressed in this discussion, as activation energies are very low and it is rarely considered as a high-field process. This occurs when impurity centers are sufficiently close to each other to enable hopping of carriers between individual sites. In Section 8, some speculations concerning filamentary conduction are given. Although large scale filaments, of the type known to exist in various thin film structures, would almost certainly be impossible to control in nanostructures, smaller filaments of the type proposed by Dearnaley et al. [8], could possibly be exploited in a new class of nanodevices. Finally, in Section 9, these various mechanisms are briefly compared and their relevance in nanostructures is assessed.

For comparability between different works, most quantities have been quoted in the SI system of units, but other convenient units such as the electron-Volt (eV) are also used where this aids clarity. When work was originally presented using non-SI units, these have normally been converted. The main emphasis in this review is on the physics of the high-field processes that dominate the electrical conductivity of dielectric films and how such processes may prove important in nanoelectronic devices.

2. ELECTROMAGNETIC FUNDAMENTALS

The most important electromagnetic consideration in the possible functioning of nanodevices appears at present to be Gauss's law and the related Poisson's equation. Gauss's law allows us to calculate the electric field for a given charge distribution, although the equation is often very difficult or even impossible to solve for nontrivial situations. Nevertheless, it gives us an insight into the intensity of the electric field that may be expected within nanostructures. Poisson's equation directly relates the potential to the charge distribution in the structure which, in conjunction with the current density equations and the carrier continuity equations mentioned in Section 1, allows the J-V characteristics to

be calculated in simple cases with known boundary conditions. We should note that the following discussion is based on the conventional macroscopic description of electromagnetism. The delineation between the macroscopic and microscopic electromagnetic approach clearly depends on the details of the situation considered, but a distance of 10 nm has been considered plausible for the absolute lower limit of the macroscopic domain [9]. For smaller distances, the microscopic approach is generally necessary. Jackson [9] has shown how the macroscopic Maxwell equations can be derived by considering a spacial average of the microscopic equations. He has also discussed the need for a quantum-mechanical treatment for calculations of the electric field at the surface of a conductor, quoting the results of such a calculation involving the solution of the many-electron problem in which the ions of the conductor are approximated by a continuous constant charge density. The excess electron charge is seen to be confined within a region of ±0.2 nm of the surface of the ionic distribution. This demonstrates the ultimate need for a sophisticated, quantum-mechanical treatment for the smallest of nanodevices. However, in this discussion we restrict ourselves to the macroscopic equations of electromagnetism, with the proviso that below 10 nm distances or so, these will probably be inadequate.

We first consider Gauss's law in a dielectric

$$\oint \mathbf{D} \cdot d\mathbf{S} = Q \tag{1}$$

where $d\mathbf{S}$ is a surface element perpendicular to the electric displacement field $\mathbf{D}$ at any point on a closed surface $\mathbf{S}$ enclosing a total charge Q. The relationship between $\mathbf{D}$ and the electric field $\mathbf{F}$ may be taken as

$$\mathbf{D} = \varepsilon_r \varepsilon_0 \mathbf{F} \tag{2}$$

where ε_r is the relative permittivity of the material and $\varepsilon_0 = 8.85 \times 10^{-12}$ F m^{-1} is the permittivity of free space; Eq. (2) is a constitutive equation of the medium. This applies particularly for linear, isotropic, homogeneous media, and neglects electric quadrupole and higher moment densities in the medium. Furthermore, $\mathbf{D}$ is always parallel to $\mathbf{F}$. For our estimates of electric fields in nanostructures, this approximation is perfectly adequate. In our medium, Eq. (1) then reduces to

$$\oint \mathbf{F} \cdot d\mathbf{S} = \frac{Q}{\varepsilon_r \varepsilon_0} \tag{3}$$

We then consider a conducting sphere of radius a embedded in the dielectric. The treatment below is based on that of Duffin [10] for a conducting sphere in vacuum, but similar treatments are given in many books on electromagnetism. The conducting sphere will carry all its charge Q on its surface, and from the symmetry of the sphere there will be a uniform charge per unit area (area charge density) σ over the surface of the sphere, where $\sigma = Q/4\pi a^2$. To find the electric field $\mathbf{F}$ at a distance r from the center of the sphere, we consider a second sphere of radius r ($r \geq a$) concentric with the charged sphere. From the symmetry of the system, the electric field F is the same at all points on the surface of the second sphere and is directed radially outwards. The outward flux over the surface of the sphere will then

be $\oint \mathbf{F} \cdot d\mathbf{S} = 4\pi r^2 F$. When substituted into the Gauss's law expression of Eq. (3), this yields

$$F = \frac{Q}{4\pi \varepsilon_r \varepsilon_0 r^2} \tag{4}$$

for the electric field at any point a distance $r \geq a$ from the center of the charged sphere. In particular, the field at the surface of the charged sphere F_s, where $r = a$, is

$$F_s = \frac{Q}{4\pi \varepsilon_r \varepsilon_0 a^2} = \frac{\sigma}{\varepsilon_r \varepsilon_0} \tag{5}$$

where we have also used the earlier charge density expression. The potential V can be obtained from the electric field F of Eq. (4) using $V = -\int F\, dr$, and the surface potential V_s of the charged sphere is then given by

$$V_s = \frac{Q}{4\pi \varepsilon_r \varepsilon_0 a} = aF_s = \frac{a\sigma}{\varepsilon_r \varepsilon_0} \tag{6}$$

This equation demonstrates that if we were to have a series of spheres having varying radii, but all charged to the same potential, the electric field just outside the surface and also the surface area charge density are inversely proportional to a, the radius of curvature. This result carries over to the more realistic situation, where we have a single conductor with a varying radius of curvature. The electric field and the area charge density are higher in regions having a small radius of curvature, and this leads to the conclusion that because of the small size of nanostructures, and therefore the smaller radii of curvature, the electric field will be particularly high in certain regions and able to sustain a high-field conduction process. These regions are as likely to be present by accident (e.g., asperities and voids) as by design.

Using some of the above results, the field can be estimated in some nanostructures. The calculations are, of course, at best order of magnitude estimates of the field values, in view of the assumptions made, and the fact that the above theory is based on macroscopic rather than microscopic fields. Consider first a conductive region in contact with a dielectric. The conductive region is at a potential of 1 V and the radius of curvature of the conductor $a = 1$ μm. Both of these values are likely to be large in the context of nanostructures, but are typical of values in very-large-scale integration (VLSI) technology. The dielectric is assumed to have a value of relative permittivity $\varepsilon_r = 3.9$, which corresponds to silicon dioxide, SiO_2 [11]. Using these values, Eq. (6) predicts an electric field at the boundary of the conductor with the dielectric of 10^6 V m^{-1}. At a distance of 1 μm away from the radius of curvature in the dielectric ($r = 2$ μm), Eq. (4) predicts an electric field of 2.5×10^5 V m^{-1}. Although these values are not as high as the field of 10^7 V m^{-1} in the 100 nm-thick film mentioned in Section 1, they are bordering on the field intensity necessary for high-field conduction processes. Conversely, if we consider a nanostructure where the radius of curvature is 10 nm, fields at the conductor/dielectric interface of 10^8 V m^{-1} and 10^7 V m^{-1} are obtained for potentials of 1 V and 0.1 V, respectively. These and smaller radii of curvature lead to local high fields that would clearly support the operation of high-field conduction processes. Thus, in nanostructures, control of the

radius of curvature of conducting regions could determine whether or not high-field conduction processes occur. As smaller structures are contemplated, the existence of high fields in the structures would become inevitable.

Having laid the foundations for the inevitability of high fields in nanostructures, we now turn our attention to Poisson's equation, which is the starting point for deriving the J-V characteristics in such regions. Gauss's law of Eq. (1), which is presented in the integral form, can by the application of Gauss's theorem be written in the corresponding differential form as

$$\nabla \cdot \mathbf{D} = \rho(x, y, z) \tag{7}$$

where $\rho(x, y, z)$ represents the charge per unit volume (or the volume charge density) at the point (x, y, z). The differential form is in general more easy to work with, and encapsulates the behavior of the field at a *point* in space, rather than over a closed surface. Furthermore, the integral form of this and the other Maxwell equations are only solvable for highly symmetric situations. The differential forms, although they may not be solvable analytically for a general shape, lend themselves to computational numerical solutions. If we make the assumption that Eq. (2) is still valid, Eq. (7) becomes

$$\nabla \cdot \mathbf{F} = \frac{\rho(x, y, z)}{\varepsilon_r \varepsilon_0} \tag{8}$$

We now consider the definition of the electric field $\mathbf{F}$ as the negative gradient of the potential V, or

$$\mathbf{F} = -\nabla V \tag{9}$$

Substitution of this into Eq. (8) gives

$$\nabla \cdot \nabla V = \nabla^2 V = -\frac{\rho(x, y, z)}{\varepsilon_r \varepsilon_0} \tag{10}$$

which is the three-dimensional form of Poisson's equation. In the absence of a charge density when $\rho = 0$, Poisson's equation reduces to $\nabla^2 V = 0$, which is Laplace's equation. The vector operator ∇^2 is known as the Laplacian operator, and in Cartesian coordinates is

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \tag{11}$$

If the charge density varies in one direction only, say the x-direction, Poisson's equation itself reduces to

$$\frac{d^2 V}{dx^2} = \frac{dF}{dx} = -\frac{\rho(x)}{\varepsilon_r \varepsilon_0} \tag{12}$$

This is the form that is used in the discussion on contacts and in the derivation of some of the J-V characteristics in the following sections.

In this section, the basic macroscopic equations of electromagnetism relevant to nanostructures have been presented, and the case made for the existence of very high fields in nanostructures even at relatively low voltage levels. Although Maxwell's equations, the current density equations and the carrier continuity equations, are likely to be

the basis for a suitable theoretical treatment of currents in nanostructures, it is almost certain that a solution of the microscopic Maxwell's equations will be required in any rigorous theory, and that a full quantum-mechanical treatment will be required in the limit. For dimensions greater than about 10 nm, it is assumed that the macroscopic approach will hold reasonably well. Most of the work to date concerning contacts and high-field conduction that is reviewed in the following sections falls into this category, although quantum mechanics form the basis of most of the mechanisms described. In particular, tunneling is a purely quantum-mechanical process and can take place across a maximum distance of about 10 nm.

3. CONTACTS

The electrical contact made to a dielectric (either semiconductor or insulator) can drastically influence the dominant type of conductivity that occurs. Simmons [2] has classified the conduction processes within the dielectric as either bulk-limited or electrode-limited. For bulk-limited conductivity, the electrodes are largely irrelevant, in that the charge carriers are generated in the bulk, normally by thermal or optical excitation. In this case, the purpose of the electrodes is merely to supply a potential leading to a drift current in the bulk. In electrode-limited conductivity, the electrode/dielectric interface acts as a potential barrier to charge injection from the contacts, and becomes the limiting impedance to charge flow. Contacts are normally classified as ohmic or blocking, with an intermediate type known as a neutral contact. An ohmic contact has been defined by Rhoderick [12] as a contact, which has a sufficiently low resistance for the current to be determined by the resistance of the bulk semiconductor (or current-voltage characteristic of a device), rather than by the properties of the contact. In its most rudimentary form, the type of contact formed at a metal/dielectric interface depends on the relative values of the metal work function ψ_m and that of the dielectric (semiconductor or insulator) ψ_i. In equilibrium, the vacuum and Fermi levels of the metal and the dielectric must be continuous across the interface. If no potential is applied across the interface, the Fermi level must not only be continuous but also flat; otherwise a current would flow across the junction, contrary to experience. At a sufficient distance away from the interface within the bulk of the dielectric, the energy difference between the vacuum and Fermi levels must be equal to the bulk dielectric work function ψ_i. In the absence of surface states, the height of the potential barrier at the interface φ_0 is given by

$$\varphi_0 = \psi_m - \chi \tag{13}$$

where χ is the dielectric electron affinity. This expression was first stated explicitly by Mott [13], although Schottky [14] gave the first model for what has now become known as a Schottky barrier. The expression represents the difference between the Fermi level on the metal side of the junction and the bottom of the conduction band on the dielectric side. It is therefore a measure of the energy required to excite an electron in the metal into the dielectric conduction band. Although this expression is valid for both ohmic and

blocking contact, we shall see later that φ_0 is only relevant in limiting the current in the latter case. In Figure 1 [2], energy band diagrams of both ohmic and blocking contacts are shown, in which the relationship of Eq. (13) is clearly evident.

It has been previously pointed out by Simmons [2] that the class of conductivity (bulk- or electrode-limited) is primarily governed by the type of contact, and not by the value of φ_0. We mainly consider conduction by electrons rather than by holes. In insulators [2] and in wide bandgap semiconductors [6], this is almost universally true owing to the lower hole mobilities and their immobilization by trapping effects. In any case, in the occasional cases of p-type conductivity, the conditions relating to the various workfunction values are reversed [12].

The various types of contact are illustrated in Figure 1 [2], together with the basic conditions for their formation in terms of the metal and dielectric workfunctions for the case of electron injection. Ohmic contacts occur in this case when $\psi_m < \psi_i$. Electrons are injected from the electrode into the dielectric in order to comply with thermal equilibrium requirements (equality of the Fermi levels). This is illustrated in Figures 1(a) and 1(b). Figure 1(a) shows the situation before the metal is in contact with the dielectric, where the vacuum levels of both materials are aligned. F represents the Fermi levels, and since the workfunction represents the difference between the vacuum level and the Fermi level for each material, the dielectric Fermi level is below that of the metal. The injected electrons penetrate a distance λ_0 into the dielectric conduction band, and constitute a negative space charge region, termed an accumulation region. An equal amount of positive charge accumulates on the surface of the electrode in order to satisfy the requirement of charge neutrality, and the interaction between these two sets of charges establishes a varying electric field within the accumulation region. Because the Fermi level represents an occupation probability, this must remain constant for any junction in the absence of an applied voltage. However, since the band structure of the dielectric must remain effectively unaltered in the bulk region, which is shielded from the electrode by the accumulation region, it therefore results in upward band bending of the conduction band edges. In this region, the accumulation region acts as a reservoir of charge, which can supply electrons to the dielectric as required by the bias conditions. The conduction process is limited by the rate at which electrons can flow into the bulk of the dielectric and not by the rate at which they are supplied by the electrode [2] and is therefore bulk-limited for ohmic contacts.

Various workers have attempted to calculate the thickness of the space-charge region and derive expressions for the potential or electric field in situations where $\psi_m < \psi_i$. Perhaps the earliest was that of Mott and Gurney [15], who solved Poisson's equation (Eq. (12)) in one direction for the case of an electron density which decayed exponentially with the potential ψ, subject to boundary conditions including a constant, fixed electron density at the metal electrode, and a zero field in the bulk of the dielectric. This work established that for the space-charge region to be of a thickness up to 10 nm, the value of $\psi_m - \chi$ must be 0.1 eV or less. A later and extremely useful theoretical treatment was also provided by Simmons [16]. This assumed that the charge density in the space-charge region $\rho(x)$ decreases exponentially with the potential energy of the dielectric conduction band edge above the electrode Fermi level ψ such that

$$\rho(x) = eN_c \exp\left(-\frac{\psi}{kT}\right) \tag{14}$$

where ψ is shown in Figure 1(b) [2], N_c represents the effective density of states in the dielectric conduction band, e is the electronic charge, k is Boltzmann's constant, and T is the absolute temperature. This is the starting point for the solution of Poisson's equation given in Eq. (12), which becomes

$$\frac{dF}{dx} = \frac{1}{e}\frac{d^2\psi}{dx^2} = -\frac{eN_c}{\varepsilon_r\varepsilon_0}\exp\left(-\frac{\psi}{kT}\right) \tag{15}$$

Integrating with respect to x, subject to the boundary conditions that $d\psi/dx = 0$ at $\psi = \psi_i - \chi$ (i.e., the electric field becomes zero at the boundary of the accumulation region) yields

$$\frac{d\psi}{dx} = \left(\frac{2e^2kTN_c}{\varepsilon_r\varepsilon_0}\right)^{1/2}\left[\exp\left(-\frac{\psi}{kT}\right) - \exp\left(-\frac{\psi_i - \chi}{kT}\right)\right]^{1/2} \tag{16}$$

Integrating again, and using the boundary conditions that $\psi = \psi_m - \chi$ at $x = 0$ according to Eq. (13) and $\psi = \psi_i - \chi$ at $x = \lambda_0$ gives

$$\lambda_0 = \left(\frac{2kT\varepsilon_r\varepsilon_0}{e^2N_c}\right)^{1/2}$$
$$\times \left\{\frac{\pi}{2} - \sin^{-1}\left[\exp\left(-\frac{\psi_i - \psi_m}{2kT}\right)\right]\right\}\exp\left(\frac{\psi_i - \chi}{2kT}\right) \tag{17}$$

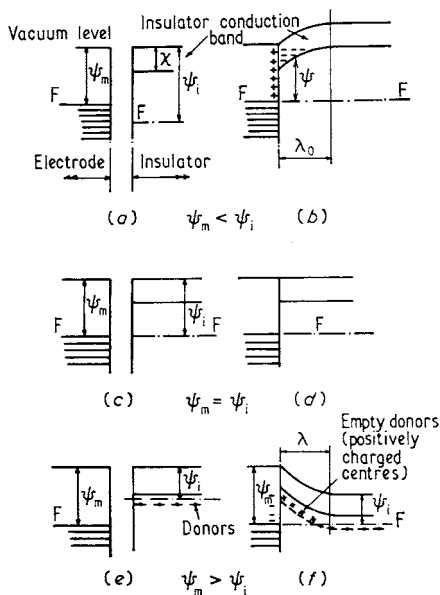

Figure 1. Contacts. Energy band diagrams showing the requirements and type of contacts for the case of an ohmic contact (a), (b), a neutral contact (c), (d) and a blocking contact (e), (f). F indicates the Fermi level. Reprinted with permission from [2], J. G. Simmons, *J. Phys. D: Appl. Phys.* 4, 613 (1971). © 1971, Institute of Physics Publishing Ltd.

which reduces in the usual case where $\psi_i - \psi_m > 4kT$, to

$$\lambda_0 \approx \frac{\pi}{2} \left(\frac{2kT\varepsilon_r\varepsilon_0}{e^2 N_c} \right)^{1/2} \exp\left(\frac{\psi_i - \chi}{2kT} \right) \qquad (18)$$

Expressions for the field at the interface ($x = 0$) and for the total space charge per unit area in the accumulation region are also derived in [16]. For a good ohmic contact, a value of $\lambda_0 = 16$ nm was calculated for $\psi_m - \chi = 0.1$ eV, reasonably close to the value predicted earlier [15]. For the case of an insulator with N_t shallow electron traps positioned at an energy E_t below the bottom of the conduction band, this expression is modified to [2]

$$\lambda_0 = \frac{\pi}{2} \left(\frac{2kT\varepsilon_r\varepsilon_0}{e^2 N_t} \right)^{1/2} \exp\left(\frac{\psi_i - \chi - E_t}{2kT} \right) \qquad (19)$$

Calculations show that $\lambda_0 \geq 10$ nm for virtually all situations, except for very high trap concentrations. This implies that in nanostructures, where traps are very unlikely to be easily controllable, the accumulation region established at ohmic contacts will probably envelop the entire structure. This is likely to encourage SCLC as discussed in Section 6.

Blocking contacts occur in principle when $\psi_m > \psi_i$. Electrons flow from the dielectric to the metal electrode on contact, which is the opposite situation to that which takes place with ohmic contacts. The region where the electrons have been removed becomes a positive space-charge region, which is termed a depletion region because of the absence of majority carriers (electrons in this case). A corresponding negative charge is located on the electrode, and the interaction of these charges leads to an electric field in the depletion region. This situation is illustrated in Figure 1(e) and 1(f), and results in the conduction band edge in the dielectric bending downwards until it reaches a point where the Fermi level in the bulk of the dielectric lies ψ_i below the vacuum level, such that the region beyond the depletion region retains the bulk dielectric band structure. In this case, the current through the dielectric is limited by the rate of flow of electrons over the interfacial potential barrier whose height is given by Eq. (13). Note that there is no reservoir of mobile charge in the depletion region, as there is in the case of an accumulation region in an ohmic contact, and so the excitation of electrons over the potential barrier becomes the rate-limiting process. In this case, therefore, the conduction is electrode-limited. Such contacts are also frequently termed Schottky barriers, as much of the early theory concerning them was performed by Schottky [14, 17].

The analysis for blocking contacts, where $\psi_m > \psi_i$, is similar to the familiar analysis of p-n junctions in semiconductor theory. Mott and Gurney [15] derived an expression for the depletion region width, which is essentially the same as that currently used today, using what is known as the depletion approximation [12]. More sophisticated treatments of the depletion region at a blocking contact have been performed by various workers. A general expression for the barrier height was obtained by Cowley and Sze [4, 18], assuming an intimate contact and an interfacial layer between the metal and a semiconductor. The interfacial layer was supposed to be transparent to electrons and able to withstand a potential across it. Surface states were included in the analysis,

whose density is a property of the semiconductor surface, but independent of the metal. Rhoderick [12] has given an exact analysis of the electric field in a Schottky barrier. Copious information concerning blocking contacts is given in the standard text on rectifying semiconducting contacts by Henisch [19]. For the purposes of the present discussion, the depletion approximation is sufficient, and we follow the treatment followed by Simmons [16]. It is assumed that the dielectric contains a concentration of donors N_d below the conduction band edge, as shown in Figure 1(f) [2]. Assuming the donors are uniformly distributed and completely ionized from the interface to the full extent of the depletion region, a depth λ_0, the space charge density in the depletion region is constant, that is, $\rho(x) = eN_d$, and Poisson's Eq. (12) becomes

$$\frac{d^2\psi}{dx^2} = \frac{e^2 N_d}{\varepsilon_r\varepsilon_0} \qquad (20)$$

Integrating with respect to x gives

$$\frac{d\psi}{dx} = \frac{e^2 N_d}{\varepsilon_r\varepsilon_0}(x - \lambda_0) \qquad (21)$$

where the integration constant is determined by the fact that $d\psi/dx = 0$ at $x = \lambda_0$. Integrating again and using the fact that $\psi = \psi_m - \chi$ at $x = 0$, as in the case of the ohmic contact, we obtain

$$\psi = \frac{e^2 N_d}{\varepsilon_r\varepsilon_0} \left(\frac{x^2}{2} - \lambda_0 x \right) + (\psi_m - \chi) \qquad (22)$$

Finally, using $\psi = \psi_i - \chi$ at $x = \lambda_0$ we obtain the thickness of the depletion region

$$\lambda_0 = \left[\frac{2(\psi_m - \psi_i)\varepsilon_r\varepsilon_0}{e^2 N_d} \right]^{1/2} \qquad (23)$$

Calculations using this expression [2] for $\psi_m - \psi_i = 2$ eV and $\varepsilon_r = 5$ show that N_d needs to be of the order of 10^{25} m^{-3} to reduce λ_0 to the order of 10 nm, and therefore the depletion region is likely to cover the whole nanostructure for undoped and moderately doped dielectrics.

A neutral contact is intermediate between an ohmic and a blocking contact. In this case, $\psi_m = \psi_i$ and the Fermi levels line up automatically on contact, with no flow of charge across the interface. In this case, neither an accumulation region nor a depletion region is established, and there is no band bending as shown in Figures 1(c) and 1(d) [2]. At low applied biases, such a contact behaves as if it is ohmic; however, at higher biases the maximum current that the electrode can supply is limited by the saturated thermionic (Richardson) current over the potential barrier, and ohmic conduction ceases.

The previous discussion has shown that, in principle, the type of contact formed depends on the relative values of ψ_m and ψ_i. A seriously complicating factor, however, is the existence of surface states. These are additional energy levels located at the surfaces, that is at interfaces, that are absent in the bulk of the dielectric. They are due to the effects of dangling bonds or impurities at the interface and to the curtailment of long-range order in this region [3]. Equation (13)

does not apply directly in the presence of a significant number of surface states. In nanoelectronic structures, control of surface states will be of paramount importance. The existence of impurities may well be controlled using advanced assembly techniques, but the presence of dangling bonds will depend on the detailed surface chemistry, and the absence of long-range order will be felt internally as well as at interfaces, owing to the nanoscale dimensions. It is clear that surface state control, or even exploitation, will be a key feature in the development of nanoscale devices.

Such considerations are complicated by the fact that electronic devices (nano or otherwise) generally require at least two contacts. The interaction of the two contact regions has previously been considered for metal-dielectric-metal thin film systems in terms of the width of the accumulation or depletion regions and the dielectric layer thickness [2, 16]. When two ohmic contacts are provided, and the film thickness d is less than the total extent of the two accumulation regions (i.e., $d < 2\lambda_0$ for zero-applied bias), there is insufficient charge within the accumulation regions to screen the interior of the dielectric from the conditions at the interfaces. In this case, the dielectric conduction band does not become flat in the interior as shown in Figure 1(b) [2], remaining curved throughout the dielectric; thus, an electric field exists throughout the entire dielectric, even in the absence of a bias. In contrast to the situation shown in Figure 1(b) [2], the highest point of the bottom of the conduction band is less than $\psi_i - \chi$ above the Fermi level. A space charge is therefore present throughout the dielectric and swamps the indigenous charge. Space-charge-limited conductivity, as described in Section 6, is thus a strong contender for the dominant conduction process under these circumstances. Indeed, it has been previously stressed that overlapping accumulation regions are required in order to observe good SCLC [2]. Such a situation is highly likely in the case of nanodevices, where the dimensions are small and the accumulation regions are likely to penetrate throughout the dielectric. Conversely, if $d > 2\lambda_0$, the accumulation regions do not overlap—the bulk of the dielectric is screened from the interfaces and absent of space charge. There is no electric field in the interior region, and it is the indigenous charge that keeps the bottom of the conduction band at a height $\psi_i - \chi$ above the Fermi level. However, as noted earlier, this situation is unlikely to occur in nanoscale devices. When two blocking contacts are provided, overlap of depletion (rather than accumulation) regions occurs if $d < 2\lambda_0$. When this takes place, the conduction band also bends, but in the opposite sense to that for two ohmic contacts. In this case, there is a positive space charge in the interior of the dielectric—an electric field is also present throughout and the bottom of the conduction band is higher than $\psi_i - \chi$ above the Fermi level. The dielectric is depleted of electrons throughout its extent and an electrode-limited conduction process will occur. As with the case of two ohmic contacts, the situation where $d > 2\lambda_0$ is improbable in nanodevices, although if it should occur the bottom of the conduction band would be $\psi_i - \chi$ above the Fermi level in the interior, and would be effectively screened from the surfaces.

An interesting and nontrivial effect takes place when two dissimilar neutral contacts are used with an insulator. If the workfunctions of the two electrodes are denoted by ψ_{m1} and

ψ_{m2}, respectively ($\psi_{m2} > \psi_{m1}$), the difference in the potential barrier heights at the two electrodes is $\psi_{m2} - \psi_{m1}$. This difference gives rise to an intrinsic electric field F_{in} given by

$$F_{in} = \frac{\psi_{m2} - \psi_{m1}}{ed} \tag{24}$$

which is the result of a transfer of charge between the two electrodes. Electrons from the electrode of lower workfunction (electrode 1) transfer to the electrode with the higher workfunction (electrode 2), which gives a positive surface charge on electrode 1 and a negative surface charge on electrode 2. The intensity of this field can be substantial. For instance, if $(\psi_{m2} - \psi_{m1})/e = 1$ V and $d = 2$ nm, the value of $F_{in} = 5 \times 10^8$ V m^{-1} [2], and even for our limiting assumption that $d = 10$ nm, results in a field value of 10^8 V m^{-1}. When a voltage V is applied between the electrodes, the total field F in the dielectric is given by

$$F = F_{in} + \frac{V}{d} = \frac{(\psi_{m2} - \psi_{m1})/e + V}{d} \tag{25}$$

Thus, depending on the polarity of the applied voltage, the total field is either increased above or reduced below F_{in}. If the electrode of higher workfunction is negatively biased, the insulator will be able to withstand greater applied voltages before dielectric breakdown. This effect could be useful in the avoidance of dielectric breakdown in nanodevices. The intrinsic field can be determined by investigating the breakdown voltage of metal-insulator-metal junctions as a function of voltage bias [20].

It has been argued that in metal-dielectric-metal structures, the type of contact is given in principle by the relative values of the metal and dielectric workfunctions, while the potential barrier between the electrode Fermi level and the conduction band of the dielectric is given by Eq. (13). Where present, surface states can override these considerations and entirely determine the contact behavior. A space-charge region of negative (ohmic contact) or positive (blocking contact) charge is established within the dielectric. For the case of ohmic contacts, the accumulation region is likely to extend to a distance of at least 10 nm, and may be the dominant effect in determining the conduction process observed. Overlapping accumulation regions will lead to SCLC. For blocking contacts, the depletion region is also likely to extend across entire nanostructures, particularly for undoped and moderately doped dielectrics, and will lead to an electrode-limited process. Even neutral contacts can give rise to extremely high internal fields, without the application of applied voltages. It may be possible to exploit this effect to mitigate dielectric breakdown and failure mechanisms.

Within the last few years, several experiments have been performed concerned with the ultimate prospects of nanoscale devices, and in particular, the quantization of conductance in such devices. Of particular relevance is the use of quantum point contacts, which are normally metallic structures just a few nanometers wide; such contacts are formed by using a scanning tunneling microscope (STM) tip, which is gradually retracted from a metallic surface. Ohnishi et al. [21] have used a gold STM tip which was slowly withdrawn from a gold island. A gold bridge formed between the substrate and tip during withdrawal of the tip;

electron microscope images showed rows of gold atoms in this region. Parallel with the imaging, electrical measurements showed that the conductance was quantized in units of $2e^2/h$ ($\sim$13 kΩ^{-1}), where e is the electronic charge and h is Planck's constant. This value was observed to correspond to a single strand of gold atoms, while that of a double strand was twice as large. Yanson et al. [22] performed similar electrical measurements and determined the same quantized conductance values by making measurements of conductance as a function of electrode displacement. They were able to stretch a metallic wire of single gold atoms up to a distance of 2 nm. Contacts made to nanodevices will probably be larger than this, consisting of several parallel metallic chains, although quantum behavior is still probable. Particularly interesting is the fact that chains of metallic atoms, that is, what are presently termed nanowires, were originally proposed many years ago by Dearnaley et al. [8] in metal-insulator-metal structures which showed electroforming as described in Section 8. From this point of view, electroforming may be ascribed to a solid-state analogue of the nano-contact experiments, in which the metallic chains are established during the electroforming process owing to extremely high electric fields at asperities with a small radius of curvature, as suggested by Eq. (6). However, as yet there are no convincing images of such metallic filaments of nanometer dimensions in metal-insulator-metal structures. The stability of filaments (nanowires) in solid-state structures should be greater than in vacuum, owing to the rigidity of the structures and effective heat-conduction mechanisms. The quantum-mechanical effects described will inevitably become of overwhelming importance as nanostructures decrease in size towards their theoretical limit. Nevertheless, it is likely that the traditional contact properties discussed earlier will still remain relevant in the larger structures, while allowing for the fact that accumulation and depletion regions will dominate the conductivity.

4. THE SCHOTTKY EFFECT

The initial approach to deriving the J-V characteristics of metal-semiconductor or insulator-metal tunnel structures has been given in the form of a generalized current density equation by several workers [23–25]. Simmons [2] has used the form of this equation for the parabolic electron energy-momentum relation and the free-electron mass m in each of the three regions (i.e., the cathode, the insulator or semiconductor, and the anode) as a starting point to obtain both the Schottky-effect current density and the tunneling current density. The form used is [2, 25]

$$J = \frac{4\pi em}{h^3} \int_0^\infty dE(f_c(E) - f_a(E)) \int_0^E P(E_x)\,dE_x \quad (26)$$

where e is the electronic charge, h is Planck's constant, $P(E_x)$ is the electron transmission probability across the dielectric, and E_x is the "x-directed" electron energy. f_c and f_a represent the Fermi-Dirac distribution function for electrons in the cathode and the anode, respectively:

$$f_c = \frac{1}{1 + \exp\left(\frac{E-E_f}{kT}\right)} \quad \text{and} \quad f_a = \frac{1}{1 + \exp\left(\frac{E+eV-E_f}{kT}\right)} \quad (27)$$

where k is Boltzmann's constant, E is the electron energy, E_f is the Fermi energy of the cathode, and V is the voltage difference between the cathode and anode.

Providing the potential barrier is too thick to allow tunneling (Section 5) to occur, and also that the concentration of allowed states in the forbidden gap of the dielectric is too small to allow impurity conduction (or hopping) to occur, the current that flows through the dielectric is limited by the rate at which electrons are thermally excited over the interfacial potential barrier from the Fermi level in the cathode to the bottom of the dielectric conduction band, φ. Simmons [2] has argued that the current density expression in this case can be derived from Eq. (26) by replacing the lower limit in the integral over dE_x by φ and the transmission function $P(E_x)$ by 1. On performing the integration, the following expression is obtained:

$$J = \frac{4\pi mek^2T^2}{h^3} \exp\left(-\frac{\varphi}{kT}\right) \equiv AT^2 \exp\left(-\frac{\varphi}{kT}\right) \quad (28)$$

This expression is known as the Richardson saturated thermionic emission equation when φ is independent of the applied voltage, so J depends only on the barrier height and the temperature T. A is called the Richardson constant, whose theoretical value is 1.2×10^6 A m^{-2} K^{-2}.

Equation (28) can also be derived using slightly different (but equivalent) approaches [3, 4, 12], often in connection with the behavior of Schottky-barrier diodes. An example of the classic derivation is given by Levine [26], and considers electrons to be emitted only in the x-direction. Assuming an electron's energy to be entirely kinetic, this leads to the inequality

$$v_x > \left(\frac{2(E_f + \varphi)}{m}\right)^{1/2} \quad (29)$$

where v_x is the velocity component along the positive x-direction. The problem is basically that of calculating the number of electrons at a given temperature which have the required velocities. The derivation starts from the general expression for the number of electrons dn with a velocity in the interval v to $v + dv$

$$dn = \rho(v)f(v)\,dv_x\,dv_y\,dv_z \quad (30)$$

where $\rho(v) = (2m/h)^3$ is the density of states for electrons, $f(v)$ is the Fermi-Dirac occupation probability which is f_c of Eq. (27), and v_x, v_y, and v_z are the three velocity components. The total energy of an electron E is

$$E = \frac{1}{2}m\left(v_x^2 + v_y^2 + v_z^2\right) \quad (31)$$

The total current density is obtained by multiplying Eq. (30) by ev_x, and integrating over v_x from the lower limit given by Eq. (29) to ∞, and over v_y and v_z from $-\infty$ to $+\infty$; Eq. (28) results from this integration.

The above discussion and Eq. (28) imply that the current density emitted into the dielectric is not field-dependent. However, this is not true, owing primarily to the image-force effect. When an electron is emitted, the metal surface at the interface becomes positively charged (polarized) as a result

of the loss of the electron. Therefore, there is an attractive force between the electron and the polarized electrode, with a corresponding electric field established. The electric field is directed perpendicular to the electrode, and under these conditions, the field and the potential can be calculated as if there were a positive charge located at a mirror image position behind the electrode. If the electron is a distance x in front of the electrode, the positive image charge is a distance x behind it, so that charges are separated by a perpendicular distance $2x$. Coulomb's law then allows us to calculate the magnitude of force on the electron as $e^2/4\pi\varepsilon_r\varepsilon_0(2x)^2 = e^2/16\pi\varepsilon_r\varepsilon_0 x^2$ towards the surface of the electrode, where ε_r is the high-frequency value since the electron spends only a very short time near the cathode during emission. Since this force is attractive, its sign is negative. The potential energy φ_{im}, relative to that of an electron at infinity due to the image force, then becomes

$$\varphi_{im} = -\frac{e^2}{16\pi\varepsilon_r\varepsilon_0 x} \tag{32}$$

This expression is not valid *at* the electrode surface, since it becomes $-\infty$ at that point, but it is considered to be applicable when $x > x_0$, and the potential is assumed to be linear for $x < x_0$ [16, 27]. This technicality need not concern us here. Thus, when the image force is taken into consideration, the potential barrier that an electron needs to overcome in order to be emitted into the dielectric conduction band is, for $x > x_0$, given by $\varphi_0 - \varphi_{im}$. When an electric field F is applied, it conspires with the image force to lower the potential barrier by adding a further third term $-eFx$ to the potential barrier term. The potential step $\varphi(x)$ with an electric field applied, and in the presence of an image force, then becomes

$$\varphi(x) = \varphi_0 - \frac{e^2}{16\pi\varepsilon_r\varepsilon_0 x} - eFx \tag{33}$$

for a neutral contact. The case for a blocking contact has been covered by Simmons [2], but will not be discussed further here. This expression clearly depends on x and has a maximum value. Providing an electron has sufficient energy to surmount this maximum, it is emitted into the dielectric. Differentiation shows that this maximum occurs at

$$x_m = \left(\frac{e}{16\pi\varepsilon_r\varepsilon_0 F}\right)^{1/2} \tag{34}$$

and that the maximum value of $\varphi(x) = \varphi_0 - (e^3/4\pi\varepsilon_r\varepsilon_0)^{1/2}F^{1/2}$. The effective barrier height φ is then field-dependent and given by

$$\varphi = \varphi_0 - \Delta\varphi_S \tag{35}$$

where

$$\Delta\varphi_S = \beta_S F^{1/2} \tag{36}$$

represents the amount of field lowering of the potential barrier, and β_S is called the Schottky field-lowering coefficient given by

$$\beta_S = \left(\frac{e^3}{4\pi\varepsilon_r\varepsilon_0}\right)^{1/2} \tag{37}$$

The current density in the presence of a field is then obtained by substituting Eqs. (35) to (37) into Eq. (28) to yield

$$J = AT^2\exp\left(-\frac{\varphi_0}{kT}\right)\exp\left(\frac{\beta_S F^{1/2}}{kT}\right) \tag{38}$$

This expression was first obtained by Schottky in 1914 and is known as the Richardson-Schottky equation [28]. Providing the electric field applied across the dielectric is reasonably uniform, the J-V characteristic is then

$$J = AT^2\exp\left(-\frac{\varphi_0}{kT}\right)\exp\left(\frac{\beta_S V^{1/2}}{kTd^{1/2}}\right) \tag{39}$$

where d represents the dielectric thickness. Thus, Schottky emission is indicated by a linear plot of $\ln J$ against $V^{1/2}$ and the gradient of such a plot is determined by β_S, which in turn depends on the permittivity of the dielectric.

The Schottky effect has been observed in a wide range of insulators and semiconductors, both organic and inorganic. Emtage and Tantraporn [29] observed this mechanism in Al-Al_2O_3-Al and Al-GeO_2-Al structures, although some of their work was also performed on gold films in contact with polymerized silicon oil. Pollack [30] observed Schottky emission through 30 nm-thick reactively evaporated Al_2O_3 layers having Pb electrodes. In addition to observing a $\ln I \propto V^{1/2}$ dependence at fixed temperatures of 241 K and 273 K, the temperature dependence of the phenomenon was also investigated, and it was shown that gradients of the curves over a range of temperatures increased linearly with reciprocal temperature $1/T$ as also predicted by Eq. (39). Below 235 K, the temperature dependence of the gradient was minimal, and it was therefore suggested that tunneling was dominant at lower temperatures. In Ta-Ta_2O_5-Au samples prepared by electron beam evaporation and plasma oxidation [31], Schottky emission was observed when the Ta electrode was biased negatively, and tunneling when it was biased positively. More recently, Schottky emission has been observed in many insulating films having various different metal contacts.

The Schottky effect has also been reported in organic metal phthalocyanine (MPc) films, which are invariably p-type semiconductors [5]; the Schottky effect occurs for hole injection at the blocking contact. Examples of such systems are Al-H_2Pc-Al [32] and Al-CuPc-Al [33]. In CuPc films [34] and in ZnPc films [35] with at least one Al electrode, the Schottky effect was also identified, but was attributed to an aluminum oxide interfacial layer at the interface. Wilson and Collins [36] found behavior consistent with Eq. (39) for planar CuPc films with Al electrodes, deducing a depletion region width of 96 nm. Hassan and Gould [37] found experimental values of the field-lowering coefficient several times higher than the theoretical value of $\beta_S = 2 \times 10^{-5}$ eV $m^{1/2}$ $V^{-1/2}$ in CuPc films with a positively biased Al electrode. However, this was reconciled by adopting the explanation of Wilson and Collins [36] that most of the applied voltage is dropped over a depletion region of thickness d_S and assuming the theoretical value of β_S. Values of $d_S = 120$ nm and $\varphi_0 = 0.88$ eV were determined for an annealed sample. For hole injection from the Pb electrode in Au-CuPc-Pb structures, enhanced values of the

field-lowering coefficient were similarly found, and were satisfactorily explained in terms of a Schottky barrier region at the injecting electrode [38]. In triclinic PbPc films with one Al electrode and one Au electrode, both Ahmad and Collins [39] and Shafai and Gould [40] used a similar Schottky barrier analysis to derive consistent values of the Schottky barrier width of 50 nm with slightly different barrier heights of 1.11 eV [39] and 1.0 eV [40].

In films of the compound semiconductor CdS, Zuleeg [41] used dissimilar ohmic In contacts and Au blocking contacts. Ohmic conductivity was observed for both polarities at low voltages, but under reverse bias (Au injecting electrode), a field-lowering conduction process was observed, as shown in Figure 2 [41], where the logarithm of the current is proportional to the square root of the applied voltage. This figure is typical of a sample showing the Schottky effect. The behavior could, in principle, be either the Schottky effect or the Poole–Frenkel effect (Section 7), but Schottky emission was indicated in this case using differential capacitance measurements, giving a Schottky barrier height of 0.88 eV, which is close to that obtained for gold contacts to grown CdS single crystals. Field-lowering behavior has also been observed in cadmium arsenide (Cd_3As_2) films having a bottom Ag electrode and a top electrode of either Ag, Al, or Au [42]. The simple barrier-height model [13, 14] is unlikely to be applicable in this case, owing to the very low bandgap of Cd_3As_2 [6], but there was a good correlation with the experimental field-lowering coefficient and the value of β_S predicted by Eq. (37) for the relative permittivity value of 12 for Cd_3As_2. There appeared to be a gradual transition from the Schottky effect to the Poole–Frenkel effect as the film thickness increased, and the effect of the injecting electrode/Cd_3As_2 interface became less significant.

The basic Schottky emission process, under the influence of an applied field as given by Eq. (39), has been observed in many metal/dielectric systems. As will be seen in Section 7, a similar J-V dependence is also observed for the Poole–Frenkel effect, although in principle it is possible to distinguish between these on the basis of the different expressions for the field-lowering coefficient. However, in practice, this is often inconclusive, and it is normally better to first determine the type of contact; if blocking, then the Schottky effect is probably responsible and if ohmic the conductivity is likely to be via the Poole–Frenkel effect. The existence of a Schottky barrier can be determined using differential capacitance measurements [41], and Poole–Frenkel conduction, being bulk-limited, is not sensitive to the electrode species. Hence, experiments using a range of contacts with different workfunctions can be used to distinguish between these two effects. In some cases, the Schottky effect is influenced by an interfacial oxide layer [34, 35], while in some organic materials the field-lowering coefficient is somewhat higher than the theoretical value, implying that most of the applied voltage is dropped over a depletion region [36–40].

A good indication as to whether the Schottky effect may be observed in nanoscale devices may be obtained from Eq. (34), which gives the dependence of the position of the maximum in the potential barrier height x_m below the metal/dielectric interface. Simple calculations show that for $\varepsilon_r = 4$ (a typical insulator), this will occur at a depth of approximately 3 nm for a field of 10^7 V m^{-1} and 1 nm for a field of 10^8 V m^{-1}. Higher values of ε_r, such as those applicable to most semiconductors, reduces the value of x_m still further. For all practical purposes, x_m will generally be less than 10 nm from the interface and the Schottky effect should therefore be observable in most metal/dielectric combinations having the appropriate workfunction/electron affinity combinations. However, tunneling through the potential barrier, rather than field-assisted emission over it, may well be more probable, particularly in structures with dimensions less than 10 nm.

5. TUNNELING

Tunneling is an extremely important conduction process that follows directly from the quantum-mechanical description of particles, such as electrons, in terms of a wave-function $\psi(x)$. The product $\psi(x)\psi^*(x)\,dx$ represents the probability of finding an electron with wave-function $\psi(x)$, whose complex conjugate is $\psi^*(x)$, in the range x to $x + dx$. Effectively, this means that an electron can tunnel through a potential barrier, without the need to surmount the potential barrier as in the case of the Schottky effect. However, for practical purposes, the value of $\psi(x)\psi^*(x)\,dx$ is nonzero only for very small values of x, that is, those less than a maximum of about 10 nm. Consequently, the tunneling process only takes place across very narrow potential barriers.

Early work on tunneling continued on from the initial development of quantum mechanics in the 1920s. The first work of relevance in the present context is that of Fowler and Nordheim [43] who derived an expression (the Fowler–Nordheim equation) for the tunnel emission current from a metal in a high electric field. This equation is still directly relevant to tunnel currents for relatively large applied voltages, and appears as the limiting high-voltage case in the comprehensive model of tunneling developed by Simmons [44]. Expressions for the tunnel current between two metal

Figure 2. The Schottky effect. Reverse current measurements (Au negative) in an evaporated Au-CdS-In diode of thickness 2.7 μm showing the Schottky effect above 4 V. Reproduced with permission from [41], R. Zuleeg, *Solid State Electron.* 6, 645 (1963). © 1963, Elsevier Science.

electrodes were first derived by Frenkel [45]. Other major contributions to the theory of tunneling were by Sommerfield and Bethe [46] and Holm [47], who derived expressions for low and high voltages, and for intermediate voltages, respectively. Stratton [25] expressed the tunneling current density in terms of Eq. (26) and derived expressions for an arbitrary-shaped potential barrier, while Simmons [44] derived a series of expressions applicable over four alternative voltage ranges.

The approach given below follows that of the Simmons model. The starting point is effectively Eq. (26) and the Wentzel–Kramer–Brillouin (WKB) approximation for the tunneling probability $P(E_x)$, an approach also followed by Stratton [25]. The WKB approximation is [44, 48]

$$P(E_x) = \exp\left\{-\frac{4\pi}{h}\int_{s_1}^{s_2}[2m(\varphi(x)-E_x)]^{1/2}\,dx\right\} \quad (40)$$

where $\varphi(x)$ represents the varying height of the potential barrier and s_1 and s_2 represent the limits of the barrier at the Fermi level, with the width of the barrier $\Delta s = s_2 - s_1$. In view of the complexity of the mathematical derivation, it is not appropriate to give it fully here. The full derivation of the J-V characteristics is given by Simmons [44], and summaries have also been given elsewhere [2, 3, 16]. The generalized tunneling characteristic, applicable for all voltage ranges and barrier shapes, becomes

$$J = J_0\left\{\bar{\varphi}\exp(-A\bar{\varphi}^{1/2}) - (\bar{\varphi}+eV)\exp[-A(\bar{\varphi}+eV)^{1/2}]\right\} \quad (41)$$

where

$$A = \frac{4\pi\beta\Delta s(2m)^{1/2}}{h} \quad \text{and} \quad J_0 = \frac{e}{2\pi h(\beta\Delta s)^2} \quad (42)$$

In these expressions, $\bar{\varphi}$ represents the mean barrier height above the Fermi level of the negatively biased electrode and β is a function of barrier shape, which is approximately unity.

Equation (41) is particularly useful in that it can be applied to a potential barrier of any shape, provided the mean barrier height $\bar{\varphi}$ and the barrier width Δs are known. It may be interpreted as the difference between two currents, one flowing from the first to the second electrode, and the other in the reverse direction. Simmons applied Eqs. (41) and (42) to the case of a rectangular potential barrier, as considered in earlier work [46, 47]. It is thus relatively simple to calculate $\bar{\varphi}$ and Δs in this case. For very low applied voltage ($V \approx 0$), $\bar{\varphi} \approx \varphi_0$, the energy difference between the Fermi level of the negative electrode and the bottom of the dielectric conduction band as given by Eq. (13), and $\Delta s = d$, the electrode spacing. The J-V characteristic is then described by

$$J = \left(\frac{3e^2}{2h^2 d}\right)(2m\varphi_0)^{1/2}V\exp\left[-\frac{4\pi d}{h}(2m\varphi_0)^{1/2}\right] \quad (43)$$

Thus, at very low voltages, Ohm's law is followed. For intermediate voltages, $(V < \varphi_0/e)$, $\bar{\varphi} \approx \varphi_0 - eV/2$, $\Delta s = d$ and we obtain

$$J = \left(\frac{e}{2\pi h d^2}\right)$$
$$\times\left\{\left(\varphi_0 - \frac{eV}{2}\right)\exp\left[-\frac{4\pi d}{h}(2m)^{1/2}\left(\varphi_0 - \frac{eV}{2}\right)^{1/2}\right]\right.$$
$$\left.-\left(\varphi_0 + \frac{eV}{2}\right)\exp\left[-\frac{4\pi d}{h}(2m)^{1/2}\left(\varphi_0 + \frac{eV}{2}\right)^{1/2}\right]\right\} \quad (44)$$

For high voltages ($V > \varphi_0/e$), $\bar{\varphi} \approx \varphi_0/2$ and $\Delta s = d\varphi_0/eV$. In this case, the value of the factor $\beta = 23/24$ and the J-V characteristic becomes

$$J = \left(\frac{2.2e^3 V^2}{8\pi h\varphi_0 d^2}\right)$$
$$\times\left\{\exp\left[-\frac{8\pi d}{2.96heV}(2m)^{1/2}\varphi_0^{3/2}\right] - \left(1 + \frac{2eV}{\varphi_0}\right)\right.$$
$$\left.\times\exp\left[-\frac{8\pi d}{2.96heV}(2m)^{1/2}\varphi_0^{3/2}\left(1 + \frac{2eV}{\varphi_0}\right)^{1/2}\right]\right\} \quad (45)$$

For very high voltages ($V > (\varphi_0 + E_f)/kT$), the Fermi level of the second electrode lies below the bottom of the conduction band of the first electrode, and electrons cannot tunnel from the second to the first electrode. The second term in Eq. (45) becomes negligible and we obtain

$$J = \frac{2.2e^3 V^2}{8\pi h\varphi_0 d^2}\exp\left[-\frac{8\pi d}{2.96heV}(2m)^{1/2}\varphi_0^{3/2}\right] \quad (46)$$

The last equation is similar to the Sommerfield–Bethe [46] relationship for high voltages, except for the factor of 2.2 and the replacement of 3 by 2.96 in the denominator of the exponential. These differences were considered negligible, in consideration of the dominant influence of the exponential term. Equation (46) is also substantially equivalent to the well-known Fowler–Nordheim equation [43], which has been observed many times in the literature.

An interesting point regarding tunneling is that there is no significant temperature-dependence in any of the four voltage ranges. This is a distinctive feature of tunneling, which allows it to be distinguished from other conduction processes, such as the Schottky effect. There is, in fact, a slight quadratic dependence, with the current density at a temperature T, $J(T)$, related to its value at 0 K, $J(0)$, by the approximate expression [2] $J(T) = J(0)(1 + \alpha T^2)$. For typical values of $\bar{\varphi} = 2$ eV and $\Delta s = 2$ nm, the value of $\alpha = 6 \times 10^{-7}$, and there is little difference between the current density at absolute zero and at room temperature.

Tunneling has been observed in a wide variety of structures. Fisher and Giaever [49] made measurements of currents in Al-Al$_2$O$_3$-Al structures produced by oxidation, and compared their J-V characteristics with the tunneling model of Holm [47]. There was good qualitative agreement, with the films showing ohmic conduction at low voltages and an exponential dependence of current on voltage at higher voltages. However, they were only able to obtain quantitative agreement by assuming the electron effective

mass in the insulator to be about 1/9 of the free electron mass; later, Mead [50] showed that the results were actually influenced by electric field penetration into the electrodes. Mayerhofer and Ochs [51] investigated very thin films of Al_2O_3 and BeO, again finding ohmic and faster-than-exponential dependences of current on voltage at lower and higher voltages, respectively. Tunneling was thought to be directly from metal to metal electrode at low voltages and directly into the insulator conduction band at higher voltages. Pollack and Morris [52] also made measurements on thermally grown Al_2O_3 films on Al; however, they used a wide variety of different evaporated counter electrodes. They compared their measurements with the model of Simmons [44] described above for similar metal electrodes, and in view of their varying counter electrodes, also with an extended model version of the Simmons model for dissimilar electrodes [53]. They found a remarkable correlation with the model at room temperature over nine decades of current, thus substantially verifying the model. Lenzlinger and Snow [54] later studied tunneling in thermally grown SiO_2 films on Si of a thickness 65–500 nm. The electrodes were of either Al or Ag. Since the films were relatively thick, it was necessary to apply high voltages to reduce the Fermi-level barrier thickness to that suitable for tunneling. Thus, the conditions for Eq. (46) were essentially fulfilled. Data were plotted in the form of a Fowler–Nordheim plot, $\log(J/V^2)$ against $1/F$ (or d/V) and were shown to give excellent linear behavior over five orders of magnitude of current. The measured currents were somewhat lower than predicted by the theory, probably due to trapping effects, and the slopes of the curves implied effective mass values of $0.48m$ for Ag, $0.39m$ for Al, and $0.42m$ for Si, where m is the free electron mass. Since these early experimental verifications of the tunneling models, it has been observed in many insulating systems.

Although tunneling is normally associated with current flow through insulators, it may also be observed in semiconductors. Perhaps the prime example of this at present is the tunnel diode, which consists of a p-n junction in which both semiconducting regions are degenerate, and the Fermi level is located within one of the allowed bands, rather than in the forbidden band. Tunneling can occur across the depletion region at any point where there are occupied energy levels on one side of the junction and unoccupied levels on the other side. The varying alignment of such regions as the applied voltage varies, changes the probability of the tunneling process, and leads to a differential negative resistance region in the J-V characteristic, which is useful in oscillators and other high-frequency applications. The theory and experimental characteristics of contemporary tunnel diodes is fully described in the literature [4]. Due to the requirement for semiconductor doping, p-n junctions of a similar type are unlikely to be fabricated as nanostructures, and will not be further discussed. In copper phthalocyanine (CuPc) thin films with indium electrodes, it was observed that a very sharp increase in the current density occurred when an applied voltage of approximately 1 V was exceeded [55]. However, this feature only occurred when the substrate electrode was biased positive, notwithstanding the fact that both electrodes were of the same metal. It had been suggested earlier by Wilson and Collins [36] that oxidation of

indium contacts during deposition was likely to occur, and that tunneling might therefore take place. Although it was considered unlikely that such an oxide layer would exceed a thickness of about 1.5 nm, and therefore would be unlikely to dominate the overall conductivity, it was suggested that such a layer may modify the character of the In/CuPc interface, allowing tunneling to occur to the valence band, since CuPc is p-type. Simmons [56] had proposed that a modified Fowler–Nordheim expression may be applicable for tunneling through the interfacial barrier when the electric field was sufficiently high to reduce the barrier width to about 5 nm. Data in this region were therefore analyzed in terms of a Fowler–Nordheim plot ($\log(I/V^2)$ against $1/V$), which according to Eq. (46) gives a linear dependence. This is illustrated in Figure 3 [55], and is typical of plots obtained with Fowler–Nordheim tunneling. The figure shows two curves, the first for a simple In-CuPc-In sample (A) and the second for a sample that also incorporated an "edge-thickening" insulating layer to avoid localized high fields and a potential dielectric breakdown originating at the edge of the bottom electrode (B). Assuming a tunneling thickness of 5 nm, barrier heights of 0.36 eV and 0.27 eV were determined for the samples of type A and B, respectively. The current density drawn was, however, considerably lower than that predicted by Eq. (46). This may be due to two effects: first, the effective tunneling area may be a factor of as low as 10^{-5} times the geometric area [57]; second, Geppart [58] has shown that in the presence of space charge and traps there is a
Figure 3. Tunneling. Fowler–Nordheim plots for evaporated In-copper phthalocyanine-In sandwich structures of thickness 1.2 μm. Type A samples were simple sandwich structures, whereas type B samples had an additional insulating "edge-thickening" layer to avoid preferential dielectric breakdown. The curves yield barrier heights of 0.36 eV (type A) and 0.27 eV (type B) assuming tunneling thicknesses of 5 nm. Reproduced with permission from [55], A. K. Hassan and R. D. Gould, *J. Phys. D: Appl. Phys.* 22, 1162 (1989). © 1989, Institute of Physics Publishing Ltd.

significant decrease in the current density. A further example of tunneling in semiconductors is given by Canali et al. [59] for CdTe who found a linear dependence of the logarithm of the drift mobility on inverse electric field ($1/F$) for $F > 1.2 \times 10^6$ V m^{-1}, which was consistent with tunneling.

The theory of tunneling was developed following the initial development of quantum mechanics. Since the Fowler–Nordheim expression was first derived [43], the tunneling theory has been extended to cover a wide range of potential barriers, including those of arbitrary shape with similar [44] and dissimilar [53] electrodes. There is excellent agreement between experiment and theory for insulators, and tunneling behavior is also observed in both organic and inorganic semiconductors, in addition to the well-known case of tunneling across the depletion region in the degenerate semiconductor junctions of tunnel diodes.

In nanostructures, it is unlikely that semiconductor doping control will initially prove sufficient for the fabrication of useful devices. However, thin insulators of nanoscale dimensions are likely to be utilized in nanoelectronic devices as carrier tunnel injectors. In view of the low thickness, dielectric breakdown will probably be a problem, unless voltage levels are restricted, and Ohm's law behavior as predicted by Eq. (43) is probable. The type of tunneling observed is unlikely to be well-described by a rectangular potential barrier, and the theory needs to encompass nanoscale dimensions in more than one direction. As devices become smaller, the probability of direct tunneling into the allowed band of a dielectric will probably be greater than that of Schottky emission, particularly for grown oxides, which may be only a few nanometers thick.

6. SPACE-CHARGE-LIMITED CONDUCTION

When there is an appreciable space-charge concentration in a dielectric, carriers passing through the space-charge region are affected by it in a similar way to electrons emitted from the cathode in a vacuum tube (Child's Law). The first derivation of the J-V characteristic for space-charge limited currents in solids was performed by Mott and Gurney [14] in 1940. They assumed that the space-charge region extended throughout the dielectric; furthermore, the effects of traps were not considered in the original theory. In Mott and Gurney's derivation, the effect of carrier diffusion is considered, but discarded later in the derivation as negligible. Lamb [3] followed the earlier derivation, but included the effect of dielectric permittivity. The equivalent, but simpler, derivation of Simmons [16] ignores diffusion from the outset, but includes the permittivity of the dielectric. This approach is also followed here.

The total current density is given by

$$J = \rho(x)\mu F \qquad (47)$$

where $\rho(x)$ is the space-charge density, μ is the carrier mobility, and F is the electric field. If the effects of diffusion currents are also included, there is an additional term $-De(dn/dx)$ added to the right-hand side of the equation, where D is the diffusion coefficient and n is the number of

carriers per unit volume. Using Poisson's equation to substitute from Eq. (12) for $\rho(x)$, we obtain

$$J = -\mu \varepsilon_r \varepsilon_0 F \frac{dF}{dx} \qquad (48)$$

Integrating, subject to the boundary conditions that $F = 0$ at $x = 0$, gives

$$F = -\frac{dV}{dx} = \left(\frac{2Jx}{\mu \varepsilon_r \varepsilon_0}\right)^{1/2} \qquad (49)$$

Further integration, subject to the boundary conditions that V is zero at $x = 0$ and V at $x = d$ (at the opposite side of the dielectric), yields

$$J = \frac{9}{8}\varepsilon_r \varepsilon_0 \mu \frac{V^2}{d^3} \qquad (50)$$

This classic SCLC expression predicts that the current density is proportional to the square of the applied voltage and also inversely proportional to the cube of the dielectric thickness. Both these variations have been observed in structures showing SCLC. However, Eq. (50) also predicts that there is no temperature-dependence, and implies values of the current density far in excess of those observed experimentally. This discrepancy can be resolved by discounting the trap-free SCLC expression and considering the situation where traps are present in the dielectric. This was first considered by Rose [60], who considered the case of a set of shallow traps of concentration N_t positioned at an energy E_t below the bottom of the conduction band. Using Fermi-Dirac statistics, it is simple to show that the ratio of free-to-trapped charge is given by

$$\theta = \frac{N_c}{N_t} \exp\left(-\frac{E_t}{kT}\right) \qquad (51)$$

The current is then carried only by the free charge and the current density in Eq. (50) is reduced by the factor θ to give [16, 60]

$$J = \frac{9}{8}\varepsilon_r \varepsilon_0 \mu \theta \frac{V^2}{d^3} \qquad (52)$$

This has essentially the same form as Eq. (50). The factor θ, however, has the effect of reducing the current density value below that for the trap-free case. Depending on the circumstances, θ may have a value of less than 10^{-5}. A second feature that becomes apparent is that there is an exponential dependence of θ on $1/T$, that is, θ is thermally activated, and therefore in the presence of shallow traps, there is a $J \propto \exp(-E_t/kT)$-dependence. Thus, the trap depth may be determined from a plot of $\ln J$ against $1/T$ at a constant voltage and the trap concentration calculated from Eq. (51).

The conductivity in samples containing traps distributed in energy was also tackled by Rose [60], who considered both traps distributed exponentially and uniformly. The first case was shown to follow a $J \propto V^n$-dependence, where $n \geq 2$, and the second to follow a $J \propto \exp(\alpha V)$-dependence, where α is a constant. For the exponential trap distribution, where the trap concentration per unit energy range at an energy E

below the conduction band edge $N(E)$, may be represented by

$$N(E) = N_0 \exp\left(-\frac{E}{kT_t}\right) \tag{53}$$

where N_0 is the trap concentration at the conduction band edge and T_t is a temperature parameter describing the distribution, Lampert [61] has derived a J-V characteristic given by

$$J \sim e\mu N_c \left(\frac{\varepsilon_r \varepsilon_0 V}{e N_0 kT_t}\right)^l \frac{V^{l+1}}{d^{2l+1}} \tag{54}$$

for n-type conductivity, where l represents the ratio T_t/T. A similar expression is applicable for p-type conductivity [5]. There is, therefore, a power-law dependence of J on V, with $J \propto V^n$, where $n = l + 1$. The dependence on thickness is $J \propto d^{-(2l+1)}$ and the temperature-dependence is via the power law, since $l = T_t/T$. Such dependencies have been widely observed in the literature [61]. J-V characteristics corresponding to a uniform trap distribution have been rarely observed, and will not therefore be further discussed.

It should be noted that at low voltages, Ohm's law is almost universally obeyed, with a transition to SCLC at a transition voltage V_t. Derivations of expressions for V_t, both for the trap-free case and for the case of a single shallow trap level are given by Lampert [61]. The transition voltage between ohmic conduction and SCLC for the case of an exponential trap distribution has also been derived [62]. Lampert [61] has discussed the situation where all the traps become filled, and the J-V characteristic then follows the trap-free law above a voltage V_{TFL}, corresponding to the trap-filled limit. It has also been shown that for SCLC dominated by an exponential trap distribution, measurements of J as a function of temperature at constant applied voltage in the SCLC region may be used to determine the mobility and trap concentration [63]. This is a useful method where the mobility is low and Hall-effect measurements are difficult to perform. The case of double injection (holes from one electrode and electrons from the other) has been considered, and leads in some cases to negative resistance behavior [3, 61]. However, these references to the theory and practice of SCLC currents are beyond the scope of this discussion, and will not be referred to further. Additional information on many of these aspects of SCLC is given in the standard text of Lampert and Mark [64].

Space-charge-limited conduction has been observed in some insulators and in many different semiconductors. Much of the earlier work was performed on CdS, which has been described as the workhorse of the SCLC field [61]. Much of this was performed on thin single crystals of the material [65–67]. In this early work, there was clear evidence of a shallow-trap square-law, followed by a rapid current rise over several orders of magnitude at the trap-filled limit. Amorphous selenium was shown to exhibit SCLC when provided with hole-injecting Te contacts [68]. In Sb_2S_3 dielectric films with bismuth ohmic contacts, Budinas et al. [69] observed SCLC having square-law behavior. In accordance with the theory, the current was initially ohmic before showing the square-law dependence. At high voltages, a rapidly increasing current was evident, suggestive of trap filling. Furthermore, V_t was found to be proportional to d^2, and J was found to be proportional to d^{-3} at constant voltage. All of these observed dependences implied SCLC and have since been confirmed in many different materials.

The phthalocyanines have been particularly fruitful in exhibiting SCLC. Perhaps the earliest measurements showing SCLC in these organic materials are those of Delacote et al. [70] on Al-CuPc-Au structures, where at low voltage an ohmic hole current was observed, followed by exponential behavior implying a uniform trap distribution as suggested by Lampert [61]. Sussman [71] made an extensive series of measurements on CuPc films with Au electrodes. It was proven that the material was p-type, and after an ohmic region a power law with exponent n in the range 2.6–4.0 was observed. The value of n decreased with increasing temperature T, since $n = 1 + (T_t/T)$. He also reported an inverse power-law dependence of current on thickness, as was also predicted by Eq. (54). Since the publication of this work SCLC, dominated by both discrete trap levels (Eqs. (51) and (52)) and by an exponential trap distribution (Eqs. (53) and (54)), has been observed in many phthalocyanine materials. Their properties have been tabulated elsewhere [5]. In general, these materials are p-type, having a thermally generated hole concentration in the range of 10^{16}–10^{18} m^{-3}. Trap concentrations for a single trap level are in the range 5×10^{16}–7.1×10^{25} m^{-3} and for an exponential distribution 6×10^{20}–9.3×10^{26} m^{-3}. Activation energies for discrete trap levels vary between the different phthalocyanines, having typical values of 0.77 eV [38] and 0.62 eV [72] in CuPc, 0.42 eV in PbPc [40], 0.58 eV in NiPc [73], and 0.45 eV (fresh) and 0.69 eV (annealed) in CoPc [74]. Such values are probably a function of the central metal atom in the molecule and the oxygen content. Trap concentrations and carrier mobility have been measured in CuPc films as a function of the ratio of evaporation background pressure to deposition rate [75] as suggested previously [63].

In CdS thin films, like the single crystals mentioned earlier, SCLC has also been observed. In samples having an ohmic In and a blocking Au contact, Zuleeg [41] observed SCLC under forward bias (In injecting electrode) with a single trap level, although at higher voltage levels, a $J \propto V^3$ dependence suggested that an exponential trap distribution was also present. Zuleeg and Muller [76] also noted a $J \propto d^{-3}$ dependence in agreement with that expected from Eq. (52). Space-charge-limited conduction dominated by a single trap level in coevaporated CdS films, also with In electrodes, has been investigated by Pizzarello [77], who used measurements of V_{TFL} to determine a trap concentration of 2.5×10^{20} m^{-3}. CdTe films similarly show SCLC behavior. In n-type CdTe films, ohmic conduction was observed at low voltages, whereas at higher voltages the current followed an exponential dependence on voltage [78, 79]. The theoretical model of Rose [60] for a uniform trap distribution was modified, and substantial agreement between this and the experimental results was obtained. In Ni-CdTe-Au structures, a $J \propto V^2$ dependence was observed when the Ni electrode was biased negative, indicative of a single trap level [80] and consistent with Eq. (52). These results are shown in Figure 4 [80], and are typical of those for samples showing
Figure 4. Space-charge-limited conduction. V^2 dependence of current on voltage in an electrodeposited Ni-CdTe-Au sandwich structure of thickness approximately 1 μm showing SCLC for temperatures of 273–338 K. Reproduced with permission from [80], B. M. Basol and O. M. Stafsudd, *Solid State Electron.* 24, 121 (1981). © 1981, Elsevier Science.

SCLC. They are plotted logarithmically, and all have similar gradients of approximately 2. Furthermore, the figure also shows that the current density increases systematically with temperature over the whole temperature range of 273–338 K. The same workers observed a $J \propto d^{-3}$ dependence, thus confirming SCLC. In evaporated CdTe films, with both electrodes of Al, similar ohmic and single trap-level behavior was observed [81]. However, at higher voltages, there was a $J \propto d^n$ dependence, with n in the range 6.0–6.5, changing to 11–12, suggesting an exponential trap distribution may also be apparent. Similar studies have also shown ohmic conduction and SCLC dominated by an exponential trap distribution, without the intermediate single trap level behavior [82]. Both the J-V and J-d dependencies were as predicted by Eq. (54). Measurements on similar samples [83] using a method proposed previously [63], where the dependence of J on $1/T$ was measured for several different applied voltages, yielded values of the mobility of $(4$–$8) \times 10^{-2}$ m^2 V^{-1} s^{-1} and the trap concentration of $(1.4$–$4.2) \times 10^{24}$ m^{-3}. CdSe films similarly show SCLC. Some samples have shown behavior dominated by a single trap level only [84, 85], while others additionally showed behavior dominated by an exponential trap distribution [86–88]. The differences appear to depend on the differing deposition methods and processing used.

Space-charge-limited conduction is observed in many thin film systems, but it is restricted to structures having at least one ohmic contact. For n-type conduction, this implies that $\psi_m < \psi_i$, although the influence of surface states cannot be neglected. It has also been argued that the accumulation regions in nanostructures are likely to envelop the entire structure (Eq. (18)) and is likely to be a dominant influence on the conductivity. The type of SCLC observed will clearly depend on the nanostructure architecture. Trap-free behavior is clearly possible for perfectly assembled nanostructures with no impurities. The addition of impurities in a controlled manner could be sufficient to immobilize nearly all of the injected charge by trapping effects. Nanostructures are unlikely to be large enough to accommodate a sufficient number of impurities to approximate an exponential trap distribution, and therefore a single trap level giving a $J \propto V^2$ dependence, is more probable. However, the influence of added impurities will probably be disproportionate to their number, as only one impurity atom in a structure containing 100 atoms would correspond to a trap concentration of about 10^{28} m^{-3}. As nanostructure sizes inevitably decrease, quantum effects will probably become apparent, considerably modifying any observed SCLC behavior.

7. THE POOLE–FRENKEL EFFECT

The Poole–Frenkel effect is a bulk-limited process, which may be considered as the bulk analogue of the Schottky effect [16]. Since it is a bulk property, at low fields the current density is determined only by the conductivity and the applied field, and may be written as

$$J = \sigma_0 F \tag{55}$$

where σ_0 represents the low-field conductivity. In a bulk insulator or wide bandgap semiconductor without impurities, the contribution of holes to σ_0 may be considered negligible, and

$$\sigma_0 = e\mu N_c \exp\left(-\frac{E_g}{2kT}\right) \tag{56}$$

where μ is the mobility and N_c is the effective density of states in the conduction band. It is clear that if these two equations only are considered, the current density is proportional only to the voltage at a given temperature, and that therefore Ohm's law is followed.

Frenkel [89] proposed that in the presence of a high electric field, the ionization potential of the atoms in the solid E_g would be lowered by an amount depending on the electric field, in the same way as the potential barrier at a contact may be lowered by the Schottky effect. The potential barrier $\varphi(x)$ for thermal excitation is assumed to follow a coulombic form, and is lowered by application of the high field.

The potential barrier for excitation into the conduction band is then given by

$$\varphi(x) = \varphi_0 - \frac{e^2}{4\pi\varepsilon_r\varepsilon_0 x} - eFx \tag{57}$$

where φ_0 is the ionization energy. This expression is similar to Eq. (33) for the Schottky effect. However, in the case of the Poole–Frenkel effect, an image force with characteristic distance $2x$ is not present, and the x in the above equation represents the distance of the electron from the emitting center. A maximum in this expression occurs at

$$x_m = \left(\frac{e}{4\pi\varepsilon_r\varepsilon_0 F}\right)^{1/2} \tag{58}$$

which on substituting into Eq. (57), leads to a reduced ionization energy given by

$$\varphi = \varphi_0 - \Delta\varphi_{PF} \tag{59}$$

where

$$\Delta\varphi_{PF} = \beta_{PF}F^{1/2} \tag{60}$$

represents the amount of field lowering of the barrier at the center, and β_{PF} is the Poole–Frenkel field-lowering coefficient given by

$$\beta_{PF} = \left(\frac{e^3}{\pi\varepsilon_r\varepsilon_0}\right)^{1/2} = 2\beta_S \tag{61}$$

In principle, therefore, the Poole–Frenkel field-lowering coefficient is twice that of the Schottky value given by Eq. (37). If we then replace E_g by $E_g - \Delta\varphi_{PF}$ in Eq. (56), Eq. (55) becomes

$$J = J_0 \exp\left(\frac{\beta_{PF}F^{1/2}}{2kT}\right) = J_0 \exp\left(\frac{\beta_{PF}V^{1/2}}{2kTd^{1/2}}\right) \tag{62}$$

where $J_0 = \sigma_0 F$ is the low field current density. Simmons [2] has pointed out that although $\Delta\varphi_{PF} = 2\Delta\varphi_S$, the coefficient of $F^{1/2}$ in Eqs. (38) and (62) is the same for both effects, owing to the additional factor of 2 in the denominator of Eq. (62). In thin films, however, Mead [90] has argued that since, for the case of an insulator, traps are almost universally present, the current density in thin films containing shallow traps is given by

$$J = J_0 \exp\left(\frac{\beta_{PF}F^{1/2}}{kT}\right) = J_0 \exp\left(\frac{\beta_{PF}V^{1/2}}{kTd^{1/2}}\right) \tag{63}$$

In thin films, Eq. (63) is therefore normally associated with the Poole–Frenkel effect rather than Eq. (62). In principle, if Eq. (63) is followed, this may be distinguished from the Schottky effect of Eq. (39) by the value of the field-lowering coefficient derived from a $\ln J \propto V^{1/2}$ plot. However, this is not true if Eq. (62) is followed. Furthermore, many modified Poole–Frenkel expressions may be found in the literature, having different coefficients of $F^{1/2}$, which makes the assignment of the type of conductivity even more problematic. For instance, when a material contains donor levels below the Fermi level and shallow neutral traps [91], the coefficient

of $F^{1/2}/kT$ is one half the value given by Eq. (61). Moreover, in the presence of a nonuniform electric field, having a maximum value of $\alpha^2 F$ where $\alpha > 1$, the Poole–Frenkel field-lowering coefficient is enhanced by the factor α [92]. The fact remains, however, that like the Schottky effect the Poole–Frenkel effect is indicated by a linear $\ln J \propto V^{1/2}$ dependence, although distinguishing between the two effects is particularly difficult.

Poole–Frenkel conductivity has been observed in many wide bandgap oxide films, including anodized Ta_2O_5 and silicon monoxide (SiO) [90, 93–95]; the interpretation of some of these results has been questioned, and alternatively classified as Schottky emission when the correct high-frequency permittivity values are used in the analysis [91]. In SiO films, good agreement with Eq. (63) was obtained, but the value of β_{PF} was greater than the theoretical value [96]; such discrepancies have been discussed by Jonscher [97]. Further work on SiO films established that this is indeed Poole–Frenkel behavior [98], as the characteristics were symmetric over five orders of applied bias, irrespective of different combinations of metal electrodes, and therefore inconsistent with the Schottky mechanism. Another very important microelectronic device material in which Poole–Frenkel conductivity has been observed is silicon nitride (Si_3N_4) [99]. Metal-insulator-semiconductor (MIS) diodes were fabricated on a degenerate Si substrate, by reacting $SiCl_4$ and NH_3 at 1000 °C to produce a Si_3N_4 film. An evaporated gold layer completed the structure. At low values of electric field, the J-V characteristic was asymmetric, with a higher current carried when the Au electrode was positive. This asymmetry was attributed to differences in the barrier heights at the gold-nitride and the nitride-silicon interfaces. At high fields, exceeding approximately 4×10^8 V m^{-1}, typical Poole–Frenkel behavior was observed with linear $\ln J - V^{1/2}$ behavior apparent over nearly four decades of current. For a given field, it was found that the characteristics of current density versus field were essentially independent of the film thickness, device area, electrode materials, and polarity, strongly indicating that the conductivity was bulk controlled, rather than electrode controlled as in the Schottky effect.

Poole–Frenkel conduction in a structure incorporating a phthalocyanine was reported in In-CuPc-SiO$_x$-In structures [55], but was proven to be dominated by the insulating SiO$_x$ region. In oxygen-doped CuPc films, with a positively biased Al electrode and a negatively biased gold electrode, a slightly enhanced value of β_{PF} was determined [37] and attributed to a nonuniform electric field distribution as proposed previously [92]. In annealed films, the measured value of the field-lowering coefficient was in reasonably good agreement with the theoretical value. Similar agreement was observed in Au-CuPc-Pb samples [38]. Au-PbPc-Al samples showed two different values of the field-lowering coefficient [40], that at high voltages was consistent with Poole–Frenkel conductivity in the presence of a nonuniform field, while the lower voltage value was consistent with the Schottky effect. Similar results on the same system had, however, been interpreted in terms of the Schottky effect with two different barrier widths [39], although the presence of the Poole–Frenkel effect was not totally ruled out. Both Schottky and Poole–Frenkel behavior were observed in PbPc films containing oxygen in which both electrodes were gold [100].

Poole–Frenkel conductivity has been reported in radio frequency (rf)-sputtered CdS films sandwiched between Al and Au electrodes [101, 102]. A clear dependence of $\ln I$ on $V^{1/2}$ was observed, and this was symmetric with respect to the applied field, and therefore tended to discount the possibility of Schottky emission. However, detailed calculations of the value of the field-lowering coefficient were not performed. The process has also been observed by several groups in CdTe films [59, 92, 103, 104], although in one case the material was intentionally doped [104]. The earliest work was performed on compensated bulk samples [59], in which the mobility was found to vary linearly with $F^{1/2}$. The experimental value of β_{PF} was reasonably close to the theoretical value, although at fields greater than 1.2×10^6 V m^{-1}, the Poole–Frenkel effect gave way to tunneling. In Al-CdTe-Al thin film samples, Poole–Frenkel type behavior was observed consistently over a temperature range from 0 °C to 108 °C. However, the value of the field-lowering coefficient increased from 4.95×10^{-5} eV m$^{1/2}$ V$^{-1/2}$ at 0 °C to 7.70×10^{-5} eV m$^{1/2}$ V$^{-1/2}$ at 108 °C, and was of the order of twice that expected for the Poole–Frenkel effect in CdTe. However, the Schottky effect was discounted, since the field lowering did not appear to depend on the electrode workfunction, when the injecting electrode was replaced by either In or Ag. These results, which appear typical of those associated with the Poole–Frenkel effect, are shown in Figure 5 [103]. The apparent discrepancy between the experimental and theoretical values of β_{PF} was resolved by adopting the suggestion of Jonscher and Ansari [98] that

electrons produced by thermal ionization at donor-like centers could hop between the sites as the result of thermal activation. When the data were reinterpreted according to this model, there was good agreement between the theoretical and experimental values of β_{PF}, and a barrier of height 0.15 eV between hopping sites was deduced, which was attributed to Cd vacancies. Similar linear $\ln J \propto V^{1/2}$ characteristics were obtained on the same system in which the experimental β_{PF} value also exceeded the theoretical value [92]; measurements of the gradients of these characteristics as a function of $1/T$ also generated experimental β_{PF} values, which were consistent with those determined from the J-V characteristics. It was suggested that the similarity between the results of this work [92] and that of the earlier work [103] could be related to individual centers experiencing an electric field greater than the mean field in samples where the electric field was nonuniform, and an approximate expression to account for such characteristics was presented. It was also observed that p-type CdTe films, which had been deliberately doped with PbCl$_2$, showed a change in conductivity type from SCLC to Poole–Frenkel [104], which may be related either to the inclusion of Poole–Frenkel centers owing to the doping process or to the establishment of a nonuniform electric field. Evidence of Poole–Frenkel conductivity has also been reported in CdSe films [88] with either two Au electrodes or one Al and one Au electrode. Again, measured values of β_{PF} were somewhat in excess of the theoretical value and were associated with a nonuniform electric field. In Cd$_3$As$_2$ films [42] with various electrode combinations, there was also evidence for Poole–Frenkel conductivity in thicker films, although the Schottky effect was thought to be responsible for conductivity in thinner films.

There is thus a considerable amount of evidence for Poole–Frenkel conductivity in many different insulators and semiconductors. The basic J-V characteristic expected for this type of conductivity may, in principle, be distinguished from that for the Schottky effect in thin film systems which contain shallow traps by the differing values of the field-lowering coefficients, where $\beta_{PF} = 2\beta_S$. However, there are several complicating factors. Even in such films that contain, for instance, donor levels below the Fermi level [91] or which have a nonuniform electric field [92], the effective value of the field-lowering coefficient is modified. Thus, distinguishing Poole–Frenkel from Schottky emission is not a simple task, and a more meaningful assignment needs to include a consideration of whether the conductivity is bulk- or electrode-limited. This may be informed by determining whether or not the J-V characteristics are symmetric using dissimilar electrodes, or by using capacitance measurements to obtain Schottky barrier heights as a controlling feature of the conductivity.

In the context of nanoelectronics, it is likely that in practice the type of Poole–Frenkel conductivity will follow Eq. (62) rather than Eq. (63), since at least in the foreseeable future most samples are likely to be assembled from pure elemental semiconductors. Samples of nano-sized dimensions consisting of compound semiconductors are very unlikely to show simple behavior owing to discontinuities at the surface boundary and other crystal imperfections. An estimate of the lateral extent of the region across

Figure 5. The Poole–Frenkel effect. Linear dependence of the logarithm of current on the square root of the applied voltage in an evaporated Al-CdTe-Al sandwich structure of thickness 722.5 nm at 0 °C (bottom curve), 30 °C, 55 °C, 80 °C, and 108 °C (top curve). The behavior was identified with a form of the Poole–Frenkel effect. Reproduced with permission from [103], S. Gogoi and K. Barua, *Thin Solid Films* 92, 227 (1982). © 1982, Elsevier Science.

which field-assisted ionization might occur can be obtained from Eq. (58). By comparison with Eq. (34), this will be twice the value obtained for the Schottky effect at the same field with the same dielectric, or about 6 nm for a field of 10^7 V m^{-1} and 2 nm for 10^8 V m^{-1}, where $\varepsilon_r = 4$. For silicon, a lower value would result, owing to the higher value of ε_r, and would allow several Poole–Frenkel emission centers to operate within the volume of a nanostructure. It is unclear, however, whether these would dominate the electrical conductivity, or what the ultimate form of the J-V characteristic might be; to answer this would require a quantum-mechanical analysis.

8. FILAMENTARY CONDUCTION

For some considerable time, negative resistance and electron emission effects have been observed in metal-insulator-metal (MIM) sandwich systems that have undergone an electroforming process. Providing the insulator (or semiconductor in many cases) is reasonably thin (typically a few tens of nanometers), the application of a voltage bias of the order of several volts under vacuum conditions results in the structure undergoing an essentially irreversible electroforming process. Prior to electroforming, such samples normally exhibit one of the high-field mechanisms described in Sections 4–7, but following it the conductivity is enhanced by several orders of magnitude, and voltage-controlled differential negative resistance (VCNR) behavior is observed. Early experiments were performed on insulators, such as SiO$_x$ sandwiched between Al and Au electrodes [105] or on anodized Al$_2$O$_3$ with an evaporated Au counter electrode [106]. Initial models of the electroforming process and conductivity in such samples involved, for instance, SCLC in an impurity band of localized states introduced during electroforming and located near the center of the bandgap [107], or the injection of ions from the anode (Au in this case) to form a broad impurity band [105]. Neither of these models involved localized conduction in the form of filaments, a mechanism which was originally proposed by Dearnaley et al. [108]. This model assumed that microscopic filaments were established during the electroforming process that spanned the insulating region between the two electrodes, and that the subsequent negative resistance behavior was a consequence of filament rupture owing to heat dissipation. Since this early work, electroforming has been observed in an extremely wide variety of materials, and has been extensively reviewed in the literature [8, 109–111].

Electrical conductivity through narrow channels was first suggested by Dearnaley [112] in chemically unsaturated oxides. This was developed into a theory of the oxide-coated cathode [113] and its efficient emission properties. Generally, it was suggested that at favorable points on the metal-insulator interface, the high electric field will encourage filament growth in which oxygen vacancies migrate to the filament tip, enabling it to grow. Equation (6) demonstrates that at a region of small radius of curvature, for example, at structural imperfections or at the ends of existing filaments, the electric field will be particularly intense and therefore conducive to filament growth. Thus, we have a simple mechanism both for the initiation of filaments and for their propagation through the insulator. It is clear, however, that such

a process may also occur in other materials where oxygen vacancies are not present, and in such cases the filaments are likely to contain metal originating from the electrodes [111].

The original model of filamentary conduction as first proposed by Dearnaley et al. [108] remains the basis of current understanding, although modifications to the model and various refinements have been proposed. It was assumed that conduction through individual filaments follows Ohm's law; furthermore, in any particular electroformed structure there are a very large number of filaments (roughly estimated at 5×10^6 cm^{-2} or 5×10^{10} m^{-2}). Such filaments were considered to be essentially noninteracting, except via thermal processes. Since the conduction in the individual filaments follows Ohm's law, the individual electrical behavior of a filament is governed by the filament resistance, ρ. However, ρ varies between individual filaments, and for a given electroformed sample, the assembly of filaments may be described by a probability distribution of filament resistances $P(\rho)$, where

$$\int_0^\infty P(\rho)\,d\rho = 1 \tag{64}$$

The range of integration is clearly from $0 \to \infty$ in the general case, although the lower and upper limits may be replaced by other values depending on the physical properties of the assumed filament distribution. The first calculated distribution of filament resistances was approximately triangular, as shown in Figure 6 [108]. ρ_t and ρ_u represent, respectively, the minimum and maximum values of ρ in the distribution.

Since the filaments are effectively connected in parallel between the two electrodes, the total current through the

Figure 6. Filamentary conduction. The simple triangular probability distribution of filament resistances, ρ, assumed as an approximation to the calculated distribution deduced from experimental current-voltage behavior. electroformed sample can be obtained by summing the currents through the individual filaments and is given by

$$I = \int_{\rho_{\min}}^{\infty} \frac{V}{\rho} P(\rho) \, d\rho \qquad (65)$$

where $\rho_{\min}$ represents the minimum resistance of a filament remaining conductive at the voltage V. The crucial part of the theory, which causes the negative resistance behavior, is the fact that as the voltage applied increases the value of $\rho_{\min}$ also increases, that is, individual filaments either cease to conduct or fracture, as a response to the applied voltage. The exact mechanism for this is of secondary importance, as long as lower resistance filaments cease to conduct at lower voltages than higher resistance filaments. In the original model, and in much of the subsequent work, it is assumed that the process is thermal, and that filaments cease to conduct when a local temperature $T_{\max}$ is reached. Solution of the steady state heat flow equation for the filament, where α characterizes the Joule heating of the filaments and τ_c characterizes the cooling by conduction, yields an expression for $\rho_{\min}$ as

$$\rho_{\min} = \frac{\tau_c \alpha V^2}{T_{\max} - T_0} \qquad (66)$$

where T_0 represents the temperature of the environment surrounding the filaments. For the case of cylindrical filaments of radius d and length L cooling to a cylindrical sink of radius D and temperature T_0, the product $\tau \alpha_c$ is given by

$$\tau_c \alpha = \frac{\ln(D/d)}{2\pi K L} \qquad (67)$$

where K (W m^{-2} K^{-1}) is the thermal conductivity of the insulator.

Using simple arguments and typical values of thermal conductivity, it was concluded that $(T_{\max} - T_0) \sim 1000$ K, $d \sim 1$ nm, and the mean resistance per filament is about 2.5×10^7 Ω. Since this initial work, many variations to the original assumptions have been considered. A wide variety of different filament probability distributions $P(\rho)$ have been investigated, including uniform, parabolic, and bimodal triangular distributions [114], with rather good agreement observed for the parabolic distribution. Radial, as well as cylindrical symmetry in the heat flow, was also considered [115], and it was shown that in both cases the voltage V_p, at which filaments of resistance ρ will cease to conduct, is given by

$$V_p = \beta \rho^{1/2} \qquad (68)$$

where β is determined by the heat flow symmetry. For the case of radial heat flow symmetry, for instance, where the filament resistance is assumed to be dominated by weak spots, the filaments are effectively isolated from each other. It was early recognized that the filament conductivity was unlikely to be ohmic, and Sutherland [116] investigated the case where the current $I \propto I_0 \sinh(V/V_0)$, where I_0 and V_0 are constants. It has also been suggested that cooling in electroformed structures may take place through the top electrode [117], when biased at the higher potential, since the thermal conductivity of the metal electrode is much higher than that of the unformed insulator regions. Nevertheless, even with this departure from the more localized heat conduction symmetry, an appropriate value of β in Eq. (68) was derived to account for the situation. These workers also suggested that a normal probability distribution of filament resistances was more fundamental than those investigated previously, and that both the triangular and the parabolic distributions were merely approximations to this [118]. Normal probability distributions of filament radii [119] and cross-sectional area [120] have also been investigated. It has been shown recently [121] that Monte Carlo techniques offer a good method for investigating more complex situations, such as those requiring multivariate probability distributions. This technique has been tested for the case of the normal probability density distributions of filament resistances and radii, and is anticipated to become ubiquitous for investigation of filaments in the case of nonohmic filamentary conduction.

Although the above discussion of filamentary conduction assumes that it is a thermal process that causes the filaments to fracture, since individual filaments of this type have not been unequivocally observed, this is by no means certain. Dearnaley et al. [108] considered that the localized regions in which filaments are initiated to be of size $R < 2$ nm, and that filaments were therefore unlikely to be observed microscopically. Bräuer et al. [122] also concluded more recently that direct observation of filaments having nanometer dimensions, where the length is much greater than the thickness or width, would not be possible with existing experimental methods. Only when filaments can be isolated from each other, such that a single or a small number of filaments can be investigated directly, will such questions be answered. It is not impossible with conventional technology to fabricate MIM samples of area $A = 2 \times 10^{-11}$ m^2, which would correspond on average to the estimated filament area density of 5×10^{10} m^{-2}, and may be expected to contain typically one filament. Required feature size at the metallic contact would be of the order of $\sqrt{A}$, or a few micrometers. It is possible that by electroforming such structures, individual filaments could be formed and their electrical characteristics investigated. Owing to the estimated filament radius $d \sim 1$ nm, it is entirely possible that they may show quantized conductance effects, as have recently been observed in metallic chain structures investigated using a STM [21, 22], and discussed in Section 3.

Electroforming may well be a suitable method to fabricate nanowires (or quantum wires) within a solid structure. For ballistic electron transport along a narrow channel, the conductance G_0 is proportional to the transmission probability T for current injected from an electron reservoir at one end of the channel, and is given by the Landauer formula [123]:

$$G_0 = \frac{e^2}{h} T \qquad (69)$$

Size quantization is expected to set in when the width of the conducting channel becomes less than the Fermi wavelength of the electrons λ_F, which is of the order of 0.5 nm for metals. However, for semiconductors, and in particular for the material comprising the proposed filaments, λ_F can be larger than this because of the smaller electron density [123]. We may therefore reasonably expect quantum behavior in

filaments established during electroforming, providing their radius is of about 1 nm as estimated by Dearnaley et al. [108].

Electroforming is well known in many thin film sandwich structures, usually giving rise to negative resistance behavior. If the current is indeed carried by an assembly of filaments with radii of the order of 1 nm, it is very likely that the individual filaments will exhibit quantum behavior and act as nanowires (or quantum wires). It is therefore feasible that the electroforming process may be a relatively simple route to the fabrication of nanowires, which will facilitate investigation of their electrical properties and perhaps direct observation using one of the tunneling microscopy techniques.

9. CONCLUDING REMARKS

In this review, it has been demonstrated that in nanostructures there is a high probability of the existence of high electric fields, whether intentionally by design or as a consequence of other factors. Precautionary measures, as used in present day metal-oxide-semiconductor (MOS) devices, will be necessary to protect structures, as the existence of unwanted high electric fields, resulting from charge inhomogenieties, need to be neutralized. Such considerations will be as necessary in nanostructures having nonelectronic applications as in electronic nanodevices.

It is a direct consequence of Maxwell's equations of electromagnetism, and Gauss's law in particular, that very high electric fields are generated at regions of a small radius of curvature. In three-dimensional structures of nanoscale dimensions, there may in principle be several regions where such considerations apply and high fields are present. The existence of high fields in nanostructures therefore warrants a consideration of high field conduction processes in the design of all electronic nanostructures. In deriving the current-voltage characteristics of most of the established high-field conduction processes described in this review, Poisson's equation, which relates the localized electric field to the charge density, must be solved subject to suitable boundary conditions. At the time of writing this article, this is usually performed only in the one-dimensional case, and although this is satisfactory in establishing the current-voltage characteristic equations for potential differences applied across thin films, when three-dimensional nanostructures are seriously considered this will be inadequate and may require a full three-dimensional analysis. Furthermore, the implications of the microscopic set of Maxwell's equations will need to be assessed, and in many cases a quantum-mechanical description will be required.

Many of the conduction models described in this review involve parameters such as the carrier concentrations at the band edges, and impurity and trap concentrations. Familiar concepts, such as the assumption of an effective density of states of approximately constant energy at the conduction and valence band edges, may not be applicable in nanostructures, where the inclusion of a small number of impurities may lead to degenerate behavior. For similar reasons, in nanostructures trap concentrations resulting from imperfections may be exceptionally high, and impurity doping of

semiconductors is likely to be tactically avoided when not essential.

In all nanoelectronic devices, as with their conventional counterparts, electrical contacts will be required to introduce electric charge into the structure. Estimates derived from the conventional expressions for the widths of the accumulation region or the depletion region in the cases of ohmic and blocking contacts, respectively, show that such regions are likely to extend to a depth of at least 10 nm, and are therefore capable of encompassing entire nanostructures. Thus, the contact region cannot be considered separately from the remaining nanostructure, but becomes integral with it, and can in principle wholly determine the nanostructure conductivity. Consideration of the contact parameters, as well as doping and the other effects mentioned earlier, will be of paramount importance in the development of nanoelectronic devices. The basic features of the known high-field conduction processes in thin films are summarized below, together with some implications of their possible appearance in nanostructures.

For metal-dielectric-metal structures, a generalized current density expression is applicable, which includes the Fermi-Dirac probability distribution functions for electrons in the two electrodes and the electron transmission probability across the dielectric. In essence, the dielectric region is considered as providing a barrier to the flow of electrons between the electrodes. For relatively thick dielectrics, the current is determined by the rate at which electrons are thermally excited over the interfacial potential barrier at the injecting electrode. Due to the interplay between the contributions to the overall potential from the metal/dielectric barrier height, the image force, and the applied field, there is a maximum in the potential function inside the dielectric. The effective barrier height is lowered as the applied field is increased, and thus the current increases with the applied voltage. The location of the maximum in the potential depends on the dielectric permittivity and the applied field. For all practical purposes, this is located within 10 nm of the electrode/dielectric interface and would, in principle, permit Schottky emission providing the interfacial workfunctions are suitable. For thinner films, it is more probable that tunneling will take place through the dielectric, either directly or via excitation to the conduction or valence bands. Such structures may well find applications as injectors of carriers (electrons) in nanostructures.

For structures having an ohmic contact, space-charge-limited conductivity is a strong possibility. Since the accumulation region is likely to penetrate throughout entire nanostructures, the primary condition for SCLC is fulfilled. The type of current-voltage dependence will depend on the presence or lack of trapping centers and on their distribution in energy. For assembled nanostructures with no impurities, it is possible that behavior similar to the classic Mott–Gurney trap-free behavior will be observed, permitting high current densities. Trapping effects may be used to immobilize injected charge if it is not required. Similarly Poole–Frenkel bulk conductivity will presumably be observed, but in the absence of traps, and exhibit a current density dependence differing from that normally observed in thin films with shallow traps. Field-assisted ionization of Poole–Frenkel centers would occur over a region of approximately

twice that for the equivalent Schottky effect in the same material, and would allow the operation of several Poole–Frenkel centers in a given nanostructure. It is, however, unclear whether this would then constitute the dominating conduction mechanism, or whether an electrode-limited process would prevail.

The final high-field process that has been considered in this review is observed only after an electroforming process. Among other theories of electroforming, it has been widely argued that during electroforming a considerable number of conducting filaments are formed between the electrodes. There is considerable evidence that quantized conduction occurs in metallic chains, which may be formed by retracting an STM tip from a metallic surface. This represents a quantum point contact. There is a reasonable correlation between the dimensions predicted for conducting filaments in electroformed structures, those predicted for quantum conduction in metallic chains and experimental observations in quantum point contacts. This poses the question that individual filaments may exhibit quantum behavior. The electroforming process, which with its subsequent conductivity has been seen as a curiosity in solid state physics, may well be a suitable mechanism for forming nanowires in solids and investigating any quantum conduction behavior. Applications of electroforming in nanostuctures, whether or not electroforming involves conducting filaments, are unlikely owing to the unpredictable and time-varying currents normally observed.

To conclude, the major high field conduction processes observed in thin film structures have been reviewed, and typical examples have been cited for each of these. Owing to the decreased size of nanostructures, high fields will be an almost inevitable consequence of nanoelectronics. Both the experimental and theoretical aspects of nanostructures are in their infancy, although this encyclopedia shows that remarkable progress has been made in many areas. It is clear that some of the experimental and theoretical work concerned with thin films (nanostructures in one dimension) will carry over to the three-dimensional situation; for structures having nanodimensions in all directions, quantum effects are to be expected and the theory developed will need to be based on this. Although nanoelectronics is still in its infancy, it is based on many years of earlier work on thin films. High field conductivity is as likely to be found in nanostructures as in thin films and will play a crucial role in nanoelectronics.

GLOSSARY

Accumulation region A space-charge region at a semiconductor or insulator surface where majority carriers are accumulated following a flow of carriers into the region from the contact in order to equalize Fermi levels.

Barrier height The quantity of energy required to surmount a potential barrier.

Blocking contact A contact which can only supply carriers to a semiconductor or insulator after they have overcome a potential barrier. The contact resistance is high, since the applied potential falls largely over a low conductivity depletion region. Essentially a Schottky barrier.

Bulk-limited Determined by bulk properties of the semiconductor or insulator.

Conduction band A partially filled energy band in a semiconductor or insulator in which electrons can move freely to establish an electric current.

Constitutive equation An equation relating the electric displacement field **D** and the electric field intensity **F**, or the magnetic flux density **B** and the magnetic field intensity **H** in a particular medium.

Continuity equations Equations relating the rate of change of the concentration of charge carriers (electrons and holes) in a semiconductor or insulator to the carrier generation and recombination rates and the divergence of the current density.

Coulomb's law The force between two electric point charges is directed along the line connecting them and its magnitude is proportional to the product of the charges and inversely proportional to the permittivity of the medium in which they are situated and to the square of their separation.

Current density equations Equations relating the electron and hole current densities in a semiconductor or insulator to their concentrations, including the influences of both an electric field and carrier concentration gradients.

Dangling bond A chemical bond associated with an atom at the surface of a solid that is not linked with a second atom, but extends towards the exterior of the solid.

Depletion approximation An approximation where the majority free carrier concentration is assumed to fall *abruptly* from the value in the bulk of a semiconductor or insulator to a negligible value at the boundary of the depletion region.

Depletion region A space-charge region at a semiconductor or insulator surface where majority carriers are depleted following a flow of carriers out of the region to the contact in order to equalize Fermi levels.

Dielectric breakdown The permanent failure of a dielectric to act as an insulator, arising for instance from heat generated or electric discharges at high voltages. Following dielectric breakdown the dielectric may be short circuited or open circuited.

Differential form The expression of one of Maxwell's four equations of the electromagnetic field in terms of the vector operators $\nabla\cdot$ (divergence) or $\nabla\times$ (curl), which encapsulates the behavior of the field at a point in space.

Donor An impurity or imperfection in a semiconductor or insulator which donates electrons to the conduction band, thus increasing the electron conductivity.

Effective density of states The number of energy levels (states) per unit volume required to be placed at a specific energy within a band of allowed states which, when multiplied by the probability of occupation by the relevant type of carriers, gives the concentration of carriers in the band, e.g. the effective density of states of electrons at the bottom of the conduction band E_c or of holes at the top of the valence band E_v.

Effective mass A parameter having the dimensions of mass that is assigned to charge carriers in a solid which allows them to be considered as free carriers in an applied electric field. Effective masses are not restricted in terms of magnitude or sign.

Electrode-limited Determined by the conditions at the injecting electrode.

Electroforming A process whereby some dielectrics undergo voltage-induced structural changes, after which the electrical conductivity is drastically increased and they exhibit characterisitic VCNR, electron emission and other features.

Electron affinity The difference in energy between an electron at the bottom of the conduction band and an electron at rest outside the surface of a semiconductor or insulator, i.e. at the vacuum level.

Fermi-Dirac distribution A statistical density function specifying the probability that a member of an assembly of independent fermions, such as electrons in a semiconductor, insulator or metal, occupies a particular energy level when in a state of thermal equilibrium.

Fermi level The energy level in a solid at which the probability of occupation is 1/2, e.g. where the value of the Fermi-Dirac distribution function is 1/2 for electrons in a solid.

Field-lowering Effective lowering of a potential barrier height as a result of modifications to the potential barrier in response to an applied electric field, e.g. lowering of an image force potential barrier in the Schottky effect, or a coulombic potential barrier in the Poole–Frenkel effect.

Field-lowering coefficient A coefficient β quantifying the amount of field-lowering, e.g. the Schottky field-lowering coefficient β_S, or the Poole–Frenkel field-lowering coefficient β_{PF}.

Filament A region of relatively high electrical conductivity embedded in a medium of high resistivity, through which electrical current may flow preferentially; in particular long narrow regions connecting the electrodes in metal-insulator or semiconductor-metal structures, proposed to be established during an electroforming process.

Filamentary conduction Electrical conduction preferentially through localized high-conductivity filaments, particularly those proposed to be established during an electroforming process.

Fowler-Nordheim Pertaining to a type of quantum-mechanical tunneling behavior observed at high electric fields F, where the current density is proportional to $F^2 \exp(-1/F)$, as originally derived by Fowler and Nordheim.

Gauss's law The outward flux of the electric field intensity **F** over a closed surface **S** is equal to the algebraic sum of the conduction and polarization charges enclosed by **S** divided by the permittivity of free space ε_0; or equivalently the outward flux of the electric displacement field **D** is equal to the algebraic sum of the conduction charges enclosed by **S**.

High-field conduction Electrical conductivity operating under high-field conditions, where the concentration and/or mobility of charge carriers may be field dependent. Under these conditions the current density-voltage characteristics are distinguished by the type of conduction process, and do not generally obey Ohm's law.

Hopping An electrical conduction process sustained by hopping between impurity centers which have energy levels within the forbidden band of a compensated semiconductor or insulator. Electrons in occupied states below the Fermi level obtain energy from phonon interactions enabling them to move to unoccupied states above the Fermi level. A type of impurity conduction.

Image force The electrostatic force on an electric charge due to the polarization charge that it induces on a neighbouring conductor, which may be considered as equivalent to the attraction between the charge and its electrical image in the conductor.

Impurity conduction An electrical conduction process sustained by transfer between impurity centers which have energy levels within the forbidden band gap of a semiconductor or insulator. Hopping is usually classified as impurity conduction.

Integral form The expression of one of Maxwell's four equations of the electromagnetic field in terms of volume or surface integrals bounded by closed surfaces and paths respectively, which encapsulates the behavior of the field over the volume or surface.

Landauer formula An expression relating the conductance to the transmission probability for current injected in the case of ballistic transport in a narrow conducting region.

Laplace's equation A partial differential equation describing the variation in electric field **F** or potential V with position in the absence of an electric charge distribution, and subject to suitable boundary conditions. A special case of Poisson's equation.

Macroscopic electromagnetism This is described by the set of four classical Maxwell's equations described below. These may be derived from the equations of microscopic electromagnetism using suitable spatial and time averaging of the microscopic fields, where the derived macroscopic fields **D** and **H** are identified with contributions relating to bulk properties of the macroscopic medium.

Maxwell's equations A set of four self-consistent equations summarizing the classical space and time dependence of the electromagnetic field, and relating the electric displacement field **D**, the electric field intensity **F**, the magnetic flux density **B**, the magnetic field intensity **H**, the volume electric charge density ρ and the current density **J**. These may be expressed in either the differential form or the integral form.

Microscopic electromagnetism This is described by a set of four Maxwell's equations applying on a microscopic scale, relating the microscopic electric field intensity **f**, the microscopic magnetic flux density **b**, the microsopic charge density η and the microscopic current density **j**. At the microscopic scale there is no corresponding microscopic electric displacement field **d** or microscopic magnetic field intensity **h** as for the macroscopic description, because all the charges are included in η and **j**.

Mobile charge Charges which can move freely as a response to an electric field, i.e. electrons in the conduction band of a semiconductor or insulator. Conversely, ionized impurities are immobile charges.

Nanowire A long narrow chain of atomic dimensions.

Negative resistance The condition where the current I decreases with increasing voltage V. Strictly *differential* negative resistance, with $dI/dV < 0$ on a current-voltage characteristic.

Neutral contact A contact intermediate between ohmic and blocking contacts, possessing neither accumulation or depletion space-charge regions.

N-type Pertaining to an extrinsic semiconductor or insulator having a concentration of negative electron charge carriers greater than that of positive hole charge carriers.

Ohmic contact A contact which can readily supply carriers to a semiconductor or insulator from a reservoir of mobile charge in an accumulation region. The contact resistance is sufficiently low for the current to be determined by the bulk material and not by the contact.

Ohm's law This is obeyed when the current flowing through a specimen is directly proportional to the voltage applied across it. It is not generally applicable at high electric fields, or across junctions between different materials.

Poisson's equation A partial differential equation which describes the variation in electric field **F** or potential V with position produced by a given distribution of charge density, and subject to suitable boundary conditions.

Poole–Frenkel Pertaining to the Poole–Frenkel effect described below.

Poole–Frenkel effect Lowering of an internal potential barrier in a semiconductor or insulator between an impurity centre and the conduction or valence band edges, when it interacts with an electric field. This leads to field-assisted thermal ionization which causes an increase in the conductivity.

Potential barrier A region where a difference between potentials exists which needs to be overcome to enable carriers to pass from one region to another.

P-type Pertaining to an extrinsic semiconductor or insulator having a concentration of positive hole charge carriers greater than that of negative electron charge carriers.

Quantized conductance Conductance which only varies in discrete quantum steps.

Quantum The minimum amount by which a particular property of a system can change; pertaining to such a discrete change in the value of a property.

Quantum-mechanical Pertaining to the theory of quantum mechanics.

Quantum mechanics The contemporary theory of matter, electromagnetic radiation and their interactions, which generalizes and supercedes classical physics, particularly in the atomic and subatomic domains.

Quantum point contact A structure in which a 'neck' of atoms of width only a few atomic diameters, and comparable to the Fermi wavelength of the conduction electrons, bridges two electric contacts. They are normally metallic and formed by retraction of the tip in a scanning tunneling microscope (STM).

Quantum wire A long narrow chain, whose dimensions in two orthogonal directions are less than some appropriate property, such as the mean-free path or the electron Fermi wavelength. The latter constitutes a one-dimensional conductor.

Richardson–Schottky equation An equation relating the current density of electrons emitted from a conductor to the temperature, potential barrier height for electron emission

and the applied electric field. The potential barrier height from a metal to vacuum is equal to the metal work function, and from a metal to a semiconductor or insulator by the metal work function minus the relevant electron affinity.

Richardson's thermionic emission equation (also known as the Richardson-Dushman equation) An equation relating the current density emitted from a conductor, in the absence of an applied electric field, to the temperature and the potential barrier height for electron emission. The potential barrier height from a metal to vacuum is equal to the metal work function, and from a metal to a semiconductor or insulator by the metal work function minus the relevant electron affinity.

Scanning tunneling microscope (STM) A type of microscope in which a fine conducting tip is located close to the surface of a sample and scanned across the surface. Electrons tunnel between the tip and the sample producing an electrical signal, which is used to control the distance between the tip and the sample and produces a contour map of the surface. The method is capable of resolving individual atoms.

Schottky Pertaining to a Schottky barrier or the Schottky effect.

Schottky barrier A potential barrier at a metal/ semiconductor or insulator interface which needs to be overcome for carriers to pass between them. There is no potential barrier for the same type of carrier in the reverse direction. Essentially a blocking contact.

Schottky-barrier diode An electronic device based on a junction between a metal and a semiconductor, which allows a high current in one direction and only a small current in the reverse direction. Unlike the *pn* junction this is a unipolar device.

Schottky effect Lowering of a potential barrier between the Fermi level of a metal and the conduction or valence band edges of a semiconductor or insulator in the presence of an electric field. This leads to enhanced field-dependent thermionic emission and causes an increase in the conductivity.

Schottky emission Emission of a carrier over a Schottky barrier.

Shallow trap A trap located at an energy level above the Fermi level.

SI system of units An internationally recognized system of units (Système International d'Unités) with the metre (m), kilogram (kg), second (s), ampere (A), kelvin (K), candela (cd) and mole (mol) as base units.

Size quantization Quantization of a property owing to restriction in size in one or more dimensions, e.g. a quantum wire showing quantized conductance suffers size quantization in two dimensions when the Fermi wavelength is less than that of its diameter, and is therefore a one-dimensional conductor.

Space charge Charge existing in a region of space (e.g. within a solid) arising from a distribution of positively or negatively charged entities. The charge may be mobile (e.g. associated with electrons or holes) or immobile (e.g. associated with impurities or traps) and gives rise to it own electric field as described by Poisson's equation.

Space-charge-limited conduction (SCLC) A conduction process dominated by the effects of a space-charge region, which is injected into a semiconductor or insulator. The level of current drawn is strongly influenced by the presence and occupation of traps.

Surface state An electron state in a semiconductor or insulator whose wavefunction is localized in a region near the surface, and which arises from the lack of periodicity and the presence of dangling bonds at the surface.

Thermal equilibrium A state in which no net energy flow takes place between two regions; this is achieved by equilization of the Fermi levels.

Thermionic emission The emission of electrons from a conductor by thermal excitation over a potential barrier. The emitted current density is given by Richardson's thermionic emission equation in the absence of an applied electric field and by the Richardson-Schottky equation when an electric field is applied.

Thin film A thin layer of material, normally deposited on the surface of another material (the substrate) by processes such as evaporation or sputtering. In this context 'thin' means of a thickness below that at which a normal bulk property is observed, and can therefore depend on the property of interest; however it is usually below 1 μm.

Trap An impurity or imperfection in a semiconductor or insulator at which an electron or hole can be immobilized until released by thermal excitation.

Trap-filled limit The situation in materials showing space-charge-limited conduction where all the traps are filled, and therefore all additional injected charge contributes to the current. The applied voltage at which this occurs is denoted by V_{TFL}.

Tunneling A conduction process dominated by the quantum-mechanical tunnel effect, in which electrons are able to pass across a narrow region which on classical theory would require more energy than the electron possesses.

Vacuum level The energy of an electron at rest just outside the surface of a solid.

Valence band The highest electronic energy band in a semiconductor or insulator which can be filled with electrons and is located below the conduction band. If partially filled an electric current can be established.

Very-large-scale integration (VLSI) A level of integration having typically more than 10^5 devices per chip.

Voltage-controlled differential negative resistance (VCNR) A type of differential negative resistance in which the current is single-valued for a given applied voltage, with the current-voltage characteristic having an N-shaped curve. In contrast, for current-controlled differential negative resistance (CCNR) the voltage is single-valued for a given current and the current-voltage characteristic is S-shaped.

Wentzel-Kramer-Brillouin (WKB) approximation An approximate method of solving linear differential equations with slowly varying coefficients, which is useful in handling wavefunctions and energy levels, and in particular the tunneling probability.

Work function The difference in energy between the Fermi level and the energy of an electron at rest outside the surface of a solid, i.e. at the vacuum level.

HiPco Process for Single-Wall Carbon Nanotube Production

Pavel Nikolaev

G.B. Tech/NASA Johnson Space Center, Houston, Texas, USA

CONTENTS

1. INTRODUCTION

Single-walled carbon nanotubes (SWCNTs) exhibit many unique and useful physical and chemical properties [1]. Demonstrated methods for producing SWCNTs involve laser vaporization of metal-doped carbon targets [2], arc evaporation of metal-doped carbon electrodes [3], and chemical vapor deposition (CVD) of carbon-containing molecules such as C_2H_4, CH_4, and CO [4–6] on supported nanometer-sized metal particles that serve as catalysts for SWCNT growth [7]. All of these methods produce SWCNTs in milligram to gram quantities in a few hours. However, many potential applications of SWCNTs require kilogram to ton quantities. Laser vaporization and arc discharge are essentially batch techniques with rather limited potential for bulk production. Traditional CVD techniques employ catalyst supported on alumina or silica particles, which need to be separated from the nanotubes afterward, requiring time-consuming purification. Also, CVD techniques are better geared toward high-yield production of multiwall tubes or vapor-grown carbon fibers (VGCF), and yields of SWCNTs produced by CVD on supported catalyst are rather low.

Many groups have investigated gas-phase continuous-flow production of carbon fibers. These studies typically involve passing a mixture of carbon source gas and organometallic catalyst precursor molecules through a heated furnace. The organometallics decompose and react, forming metal clusters on which carbon fibers nucleate and grow. Tibbets et al. have reported gas-phase synthesis of carbon fibers (VGCF) in heated flowing mixtures of methane or hexane with organometallics such as iron pentacarbonyl [$Fe(CO)_5$] [8] and ferrocene [dicyclopentadienyl iron, $Fe(Cp)_2$] [9]. Sen and co-workers [10–12] have investigated the catalytic growth of carbon nanotubes in gas phase, both by direct pyrolysis of ferrocene and other metallocenes and by catalytic decomposition of hydrocarbons or carbon monoxide in the presence of metallocenes or $Fe(CO)_5$. In two of these studies, this group reported production of SWCNTs from mixtures of $Fe(CO)_5$ with acetylene [10] and benzene [12]. Cheng and co-workers have reported the production of SWCNT in a heated flow of benzene and ferrocene [13, 14]. Recently Ploenjes et al. reported SWCNT production in low-pressure vibrationally nonequilibrium CO excited by a continuous wave CO laser in the presence of a small amount of $Fe(CO)_5$ [15].

To date, all but one [15] investigation reporting gas-phase continuous-flow production of SWCNT relied on hydrocarbons as the carbon source molecule for nanotube growth. However, hydrocarbons pyrolyze readily on most surfaces heated above 600 to 700 °C (temperatures required for growth of SWCNT), forming graphitic deposits or amorphous carbon. Nanotubes grown in heated flows of gaseous hydrocarbons often show substantial amorphous carbon overcoating, which would need to be removed in subsequent processing steps. One may anticipate that such effects would complicate efforts to scale up production methods using hydrocarbon feedstocks.

HiPco is a new gas-phase process for single-wall carbon nanotube production discovered at Rice University in early 1998. HiPco stands for "high-pressure CO." In the HiPco process nanotubes grow in high-pressure, high-temperature flowing CO on catalytic clusters of iron. Catalyst is formed *in-situ* by thermal decomposition of iron pentacarbonyl, which is delivered intact within a cold CO flow and then rapidly mixed with hot CO in the reaction zone. Upon heating, the $Fe(CO)_5$ decomposes into atoms which condense into larger clusters. SWCNTs nucleate and grow on these particles in gas phase via CO disproportionation

(Boudouard reaction): $CO + CO \xrightarrow{Fe} CO_2 + C_{(SWCNT)}$, catalyzed by the Fe surface. The rate of the Boudouard reaction scales as a square of CO pressure, hence the importance of high pressure of CO for efficient SWCNT production.

The HiPco process is an attractive alternative to other methods of nanotube production for several reasons. It is a gas-phase process which does not employ premade catalyst particles, like other varieties of CVD techniques. It is a continuous rather than a batch process, and the current HiPco apparatus is able to run continuously for up to 2 weeks at a time, limited by the capacity of the nanotube collector. Nanotubes produced by HiPco have significant amount of Fe impurity, but Fe particles are not encased in heavy graphitic shells like in the case of arc or laser and are relatively easy to remove. Most importantly, HiPco is amenable for relatively easy scale-up by chemical engineers, and this undertaking is currently underway at Carbon Nanotechnologies Inc. in Houston, TX.

The main limitation of the HiPco process is the low rate of the Boudouard reaction. Even at 30 atm pressure, only about 1 out of 10,000 CO molecules entering the reactor is converted into nanotubes. The rest are recirculated through the reactor over and over again. Since the amount of $Fe(CO)_5$ entering the reactor is constant (~1.5 ppm) and all of it decomposes into iron particles, this results in ~5–6 at% of iron in nanotubes.

2. HIGH-PRESSURE CO (HiPco) DISCOVERY AND EARLY EXPERIMENTS

Nanotube production in gas phase in high-pressure CO was discovered and initially studied in a simple flow cell reactor consisting of a 1 in. Outside diameter thick-walled quartz flow tube contained within a tube furnace, through which reactant gases are flowed. It could withstand pressures up to 10 atm. The tube section inside the furnace was maintained between 800 and 1200 °C, while the tube entrance and exit were maintained at room temperature. The rate at which the reactant gases were heated had substantial effects on the amount and quality of SWCNT produced. In some experiments the CO and $Fe(CO)_5$ were introduced through a water-cooled injector positioned inside the quartz tube, which maintained the gases at low temperature until they were injected into the furnace, resulting in rapid heating. Around the exit of this injector could be positioned a circle of four narrow-gauge steel needles through which preheated CO was passed at high flow rate to mix with the cool flow emerging from the injector, further increasing the heating rate of the injected gas. The CO sprayed from this "showerhead" mixer was preheated by passing through a helical heat exchanger positioned within the furnace.

2.1. Feedstock and Catalyst

The gas mixture consisted of CO (1–10 atm flowing at 1-2 slm) dosed with a small amount (0–25 mTorr) of gaseous $Fe(CO)_5$. Dosing was accomplished by passing a measured fraction of the CO stream through a $Fe(CO)_5$-filled bubbler maintained at 0 °C. This produced a partial pressure

of $Fe(CO)_5$ equal to its vapor pressure of ~7 Torr, and the partial pressure of $Fe(CO)_5$ was subsequently reduced by diluting with additional CO before its introduction into the flow cell. Commercial CO will always contain a few ppm of $Fe(CO)_5$ as a contaminant, which was filtered out using an in-line catalytic purifier (Oxyzorb, Matheson) prior to introduction into flow system. Alternately, this small "background" concentration of $Fe(CO)_5$ was used directly in experiments with high CO pressure and/or low $Fe(CO)_5$ concentration because the bubbler was found to be unreliable under these conditions. The concentration of background $Fe(CO)_5$ in the CO stream, typically 2–10 ppm, was determined by measuring the total amount of iron deposited in the reactor.

Flow of $CO/Fe(CO)_5$ mixtures through the heated reactor resulted in black deposits on the walls of the quartz tube outside the furnace. These deposits consisted of SWCNT, non-nanotube carbon impurities and iron particles apparently overcoated with carbon. In control experiments using no $Fe(CO)_5$ (with the catalytic purifier in use), no iron or carbon reaction products were observed.

2.2. Temperature and Flow Velocity Study

Gas-phase iron pentacarbonyl will decompose rapidly at 250–300 °C [17]. Boudouard reaction occurs at a significant rate only at temperatures above 500 °C [18]. One may thus anticipate that the rate at which the gas mixture is heated through the temperature range of 200–500 °C will be important in determining the outcome of this process: too slow a heating rate could allow the Fe clusters to grow too large before they reach the temperature required for CO disproportionation to proceed, thus preventing SWCNT nucleation and growth in the gas phase. This was confirmed in initial experiments conducted without the cooled injector. In these experiments, 6.5 atm of unpurified CO was flowed directly through the quartz tube heated to 850 °C. It was determined that the CO contained 4–5 ppm of $Fe(CO)_5$, giving a $Fe(CO)_5$ partial pressure of 20–25 mTorr. When the flow velocity in the region of transition from room temperature to SWCNT growth temperature (about 10 cm long) was around 10–20 cm/sec, it was found that SWC-NTs were produced and deposited as thin mats or films on the cold parts of the quartz tube. Figure 1 shows transmission electron microscope (TEM) and scanning electron microscope (SEM) images of the SWCNT material from these experiments. When the flow velocity was slower,[1] 0.5–1 cm/sec, no SWCNTs were formed, and instead multiwall fibers were found deposited at the oven entrance. Approximately 3.6 mg of material was produced in 16 hours of gas flow at 1500 sccm. EDS and TGA a showed that the material contained 45% of iron atoms, or 75% iron by weight. Such a level of purity and production rate is very poor, but nevertheless this experiment demonstrated the feasibility of the gas-phase approach.

---

[1] This experiment was performed with the furnace positioned vertically, which forced a uniform gas flow. In the former experiment the furnace was positioned horizontally, and gas was drawn into the furnace much faster (10–20 cm/sec) due to formation of a convection cell.
Figure 1. TEM (a, b) and SEM (c) images of SWCNT ropes produced in a first experiment [6.5 atm CO with 5 ppm Fe(CO)$_5$ at 850 °C]. (b) and (c) Reprinted with permission from [16], P. Nikolaev et al., *Chem. Phys. Lett.*, 313, 91 (1999). © 1999, Elsevier Science.

Much more rapid heating of the CO/Fe(CO)$_5$ mixture was achieved using the cooled injector, and this setup was used to study the dependence of SWCNT production on temperature and pressure. In these experiments, CO containing 5 ppm of Fe(CO)$_5$ was flowed through the heated reactor tube at 1000 sccm for 5–15 hours. Nanotube containing material was deposited on the walls of the quartz tube and on a filter positioned downstream of the reactor. This material was collected and weighed, and the mass fraction of carbon was determined by TGA. TEM observations of the product material suggest that most of the carbon was present as SWCNT, rather than other forms such as amorphous carbon. TEM images also gave the diameter distributions of the product SWCNT. Very few tube ends were observed, implying that the tubes are long compared to their width: average tube length was estimated to be approximately one micrometer, based on the number of tube ends observed.

2.3. Process Optimization

Table 1 lists the rate of SWCNT production vs temperature at 10 atm. The highest production rate was achieved at the highest available temperature, 1200 °C. Next CO pressure was varied from 1 to 10 atm while the relative concentration of Fe(CO)$_5$ was maintained at 5 ppm and oven temperature at 1200 °C. It was found that production rate increased with

Table 1. Nanotube production rate and yield vs temperature at 10 atm pressure.

Temperature (°C)	Production rate (mg/hr)	SWCNT yield (mol%)	SWCNT yield (wt%)
850	0.68	73%	37%
1000	1.00	71%	34%
1200	1.24	79%	44%

Source: Reprinted with permission from [16], P. Nikolaev et al., *Chem. Phys. Lett.* 313, 91 (1999). © 1999, from Elsevier Science.

increasing pressure up to 10 atm, the maximum pressure that could be achieved. Table 2 lists the SWCNT production rate vs CO pressure. It was also observed that nanotubes consistently showed smaller diameters as pressure was increased. Figure 2 shows the diameter distributions observed at various pressures. Reaction at 10 atm gave tubes as small as 0.7 nm in diameter, which is about the diameter of a C$_{60}$ molecule.

Experiments with the cooled injector alone using higher Fe(CO)$_5$ concentrations did not give additional nanotube material. Instead, iron in excess of 5 ppm merely formed additional iron particles mixed in with the product material. This inefficient use of available iron could result from too small a heating rate of the CO/Fe(CO)$_5$ mixture. Therefore the "showerhead" mixer was implemented to achieve even faster heating of the injected gases. In experiments with this mixer the CO pressure was maintained at 3 atm rather than 10 atm in order to achieve higher gas flow velocities, since the net flow rate was limited by the mass-flow meter's capacity. The CO/Fe(CO)$_5$ mixture was flowed through the cooled injector at 1000 sccm, while hot gas (pure CO) was sprayed from the mixer at 5000 sccm. All showerhead mixer experiments were carried out at 1200 °C.

The showerhead allowed utilization of somewhat higher Fe(CO)$_5$ concentrations in the CO. Fe(CO)$_5$ concentrations of 8 ppm gave SWCNT production rates of up to 15 mg/hr. But more importantly, the showerhead led to much more efficient use of the available iron: 8 ppm of Fe(CO)$_5$ gave product material containing only 7 at% iron, compared to 31 at% obtained using 5 ppm Fe(CO)$_5$ with the cooled injector alone. The diameter distributions of the SWCNT from the showerhead configuration were similar to those from the cooled injector alone (Fig. 2). Clearly, the rate of heating of the CO/Fe(CO)$_5$ mixture has a substantial effect on the SWCNT material produced. Figure 3 shows TEM images of the SWCNT material produced using the cooled injector with the showerhead mixer. Note from the TEM images in both Figures 1 and 3 that SWCNTs produced

Table 2. Nanotube production rate and yield vs CO pressure at 1200 °C temperature.

Pressure (atm)	Production rate (mg/hr)	SWCNT yield (mol%)	SWCNT yield (wt%)
1	1.16	61%	25%
3	1.38	67%	30%
10	1.24	79%	44%

by this process are essentially free of amorphous carbon overcoating.

3. SECOND-GENERATION HiPco APPARATUS

The experimental setup described has four major drawbacks. First, flow rates are limited by the capacity of mass-flow meters. Second, carbon monoxide is exhausted into the atmosphere, which is quite wasteful, since only about 1 out of 10,000 carbon atoms entering reactor in the form of CO is converted into nanotubes, and all this CO has to be heated to 1200 °C. Third, the maximum pressure is limited by the strength of the quartz tube. Fourth, stainless steel parts which are not water-cooled (showerhead mixer and spiral heat exchanger) were literally falling apart in the carbon-rich, reducing atmosphere in the reactor (CO

Figure 3. TEM image of SWCNT produced in the first-generation reactor using the cooled injector with showerhead mixer [3 atm CO with 8 ppm of $Fe(CO)_5$ at 1200 °C]. Reprinted with permission from [16], P. Nikolaev et al., *Chem. Phys. Lett.* 313, 91 (1999). © 1999, Elsevier Science.

disproportionates appreciably on the steel surfaces, and the resulting carbon reacts with steel making it brittle).

3.1. Closed-Loop Reactor for High-Pressure Operation

To address these issues, a second-generation reactor was built in 1999 [19]. It is a closed-loop reactor; that is, CO is recirculated through the system using a compressor (rather than being exhausted into the atmosphere). The mass-flow meters capacities were increased to match that of the compressor, allowing net flow rate of up to 300 slm (compared to 6 slm in first-generation reactor). The pressure vessel, instead of being a quartz tube, was constructed out of aluminum, allowing pressures up to 100 atm. The materials problem was solved by having all hot parts made out of graphite or quartz.

This reactor (Fig. 4) consists of a 3-in.-diameter thin-walled quartz tube surrounded by an electrical heating element, both of which are contained within a thick-walled aluminum cylinder. The heating element itself and the space between the quartz tube and the aluminum cylinder's inner wall reside under an atmosphere of argon maintained at slightly higher pressure than that of the CO inside the quartz tube. Mixtures of $Fe(CO)_5$ and CO are injected into the reactor through an insulated, air- or water-cooled stainless steel injector tipped with a copper nozzle. Around the end of the injector was positioned a circle of orifices (the "showerhead"), through which preheated CO was sprayed to mix with and heat the cold flow emerging from the catalyst injector nozzle (Fig. 5). The showerhead CO preheater consists of a thick-walled graphite tube with six longitudinally bored, equally spaced channels. Each of the six channels contains
Figure 4. 4. Layout of the second-generation HiPco reactor. Reprinted with permission from [19], M. J. Bronikowski et al., *J. Vac. Sci. Technol. A* 19, 1800 (2001). © 2001, American Vacuum Society.

a resistively heated graphite rod. As shown in Figure 4, CO for the showerhead flows through these channels and is heated by contact with graphite rods. The heated CO passes then into the showerhead orifice circle (also machined from graphite) and is delivered into the reaction zone through the showerhead orifices. There, it collides and mixes with the cold injector flow emerging from the copper nozzle, which protrudes through the showerhead and into this reaction zone. The temperature of the heated CO passing through the showerhead, T_{SH}, was controlled by varying the current passed through the heating rods and was measured by thermocouples inserted into thermal wells in the front face of the graphite CO preheater. Note that because the hot showerhead CO mixes with the room temperature injector flow, the actual reaction temperature will be lower than T_{SH} by a calculable amount.

The highest SWCNT production rate was achieved with a showerhead consisting of a circle of orifices distributed equally around a circle, positioned with the orifices about 1 mm away from the injector nozzle, and set at an angle of 30° with respect to the injector flow (the quartz tube axis). Three, six, and eight orifices were tried, all with similar results. It should be noted here that due to the very large number of possible geometries for collision/mixing of gas jets, it is unlikely that the current showerhead/injector geometry represents the best design to accomplish Fe(CO)$_5$ heating and SWCNT formation. Attempts to optimize the showerhead design will be discussed in Section 5.1.

Figure 5. Close-up of the injector nozzle.

Fe(CO)$_5$ is introduced into the injector flow by passing a measured fraction of the CO flow through a liquid Fe(CO)$_5$-filled bubbler maintained at room temperature. The SWCNTs and iron particles are carried out of the reactor and pass through a series of filters and cooled surfaces, upon which the SWCNTs condense. Once purged of SWCNTs the CO gas passes through absorption beds containing NaOH and a molecular sieve (type 3A), which remove CO$_2$ and H$_2$O, respectively. The CO is then recirculated back through the gas flow system and reactor using a compressor (Fluitron, Y5-200); the reactor flow system thus constitutes a closed loop through which CO is continuously recycled. The gas flowing in the system can be analyzed with a gas chromatography/mass spectrometry analysis system (Varian, Saturn 2000), which is used to measure product CO$_2$ concentration in the reactor exhaust stream, carbonyl concentration in the reactant stream, and concentrations of trace gases such as H$_2$.

3.2. Standard Running Conditions

The standard running conditions are 450 psi (30 atm) of CO pressure and 1050 °C reactor (showerhead) temperature. CO is flowed through the showerhead preheater at 250 slm mass flow, while CO containing 0.25 Torr of Fe(CO)$_5$ is flowed through the injector at 42 slm. The total flow of CO through the reactor is thus 292 slm, and the ratio of showerhead flow to injector flow is 6:1. Typical run times are 24–72 h. Under these conditions, the reactor produces SWCNT material at a rate of approximately 450 mg/h. Figure 6 shows a TEM image of the typical product.

3.3. CO$_2$ Concentration as a Measure of SWCNT Production

The primary emphasis of the research involving a second-generation setup has been on optimizing the mass yield of SWCNTs per unit time with respect to available experimental variables. The behavior of the SWCNT production with

Figure 6. TEM image of the typical nanotubes produced in the second-generation HiPco reactor.

respect to such parameters also yields insight into the details of the SWCNT production mechanism.

For maximizing SWCNT production, it was found that real-time measurement of the CO_2 concentration in the gas flow exiting the reactor is a valuable tool. By varying experimental parameters while monitoring CO_2 production, it is possible to maximize CO_2 (and, hence, carbon) production with respect to any parameter. The maximum CO_2 production will correspond to the maximum production of nanotubes provided that the carbon product is in the form of nanotubes (which can be verified by microscopy), since for each CO_2 molecule there is one carbon molecule produced. Simultaneous measurements of CO_2 and $Fe(CO)_5$ pressures allow calculation of atomic carbon concentration (yield) in the resulting mixture of nanotubes and iron, according to eq. (1). $Fe(CO)_5$ in the cooled injector is diluted by a factor of 7 in the showerhead, hence the 1/7 coefficient.

$$\text{yield} = \frac{P(CO_2)}{P(CO_2) + \frac{1}{7}P(Fe(CO)_5)} \tag{1}$$

Unfortunately, the published parametric study [19] lacks such analysis and relies instead on TGA measurements exclusively.

3.4. Parametric Study of SWCNT Production

First SWCNT production was studied as a function of reaction temperature. Figure 7 gives the concentrations of CO_2 in the exhaust stream measured for various showerhead temperatures. The production of SWCNTs is very small at showerhead temperatures below 800 °C and appears to start between 850 and 900 °C. By 950 °C the SWCNT production rate is beginning to level out, reaches a maximum at 1050 °C, and then begins to fall off at higher temperatures.

CO_2 production was also investigated as a function of the concentration of $Fe(CO)_5$ in the injector gas flow. Figure 8 shows a typical result: the relative concentration of CO_2 produced as $Fe(CO)_5$ concentration was varied, at a pressure of 45 atm. It was found that CO_2 production first increases approximately linearly with increasing $Fe(CO)_5$ concentration, but that it eventually levels off. As the $Fe(CO)_5$ concentration is increased further, the CO_2 production actually
Figure 7. CO_2 yield vs reactor temperature at 30 atm pressure. Reprinted with permission from [19], M. J. Bronikowski et al., *J. Vac. Sci. Technol. A* 19, 1800 (2001). © 2001, American Vacuum Society.

Figure 8. CO_2 yield vs $Fe(CO)_5$ concentration in the injector flow at 45 atm. Values are shown relative to $Fe(CO)_5$ and CO_2 concentrations at maximum SWCNT yield (0.38 and 1.4 Torr, respectively). Numbers indicate calculated atomic fraction of carbon in the resulting mix of SWCNT and iron. Reprinted with permission from [19], M. J. Bronikowski et al., *J. Vac. Sci. Technol. A* 19, 1800 (2001). © 2001, American Vacuum Society.

decreases and only increases again at much higher concentrations. This qualitative behavior was observed for all temperature, pressure, gas flow, and heating/mixing conditions investigated and appears quite general. SEM and TEM analysis of the SWCNTs produced at very high $Fe(CO)_5$ concentrations indicated that a much larger fraction of the carbon was present as amorphous carbon or as graphitic, fullerene-like partial shells associated with the larger metal particles, rather than as additional SWCNTs. Thus, it appears that the production of SWCNTs is optimum at the initial maximum ("turnover point") in the curve of CO_2 vs $Fe(CO)_5$; excess iron over this maximum does not give more SWCNTs but instead appears to retard the growth of SWCNTs and eventually gives much carbon in undesirable forms.

Note that operating at the turnover point serves to maximize the production of SWCNTs, without consideration of Fe in the resulting mix. Superimposed on Figure 8 are atomic fractions of carbon in the resulting mix, calculated according to the expression (1). It is obvious that nanotubes with the least amount of iron (96.8 at% of C) are produced at $Fe(CO)_5$ concentration of 0.25 Torr, at the point where the CO_2 vs $Fe(CO)_5$ curve just begins to deviate from the linear dependence. Therefore $Fe(CO)_5$ pressure can be selected to produce the maximum amount of nanotubes with slightly higher Fe content (3.7 at% Fe), or a slightly lower amount of nanotubes with minimal Fe content (3.2 at% Fe). (These numbers are for 45 atm pressure and will be different for other reactor pressures.)

SWCNT production was also studied as a function of reaction pressure. At any given pressure, the CO_2 vs $Fe(CO)_5$ curve has qualitatively the same appearance as that shown in Figure 8. The maximum CO_2 concentration (at the turnover point) and the corresponding level of $Fe(CO)_5$ were found to increase as pressure was increased up to the maximum (45 atm) in an approximately linear fashion. These results are shown in Figure 9 (normalized to standard running condition, 30 atm). Superimposed on Figure 9 are atomic fractions of carbon in the resulting mix, calculated according to the expression (1). Because of the small deviations from the linear dependence in both CO_2 and $Fe(CO)_5$ curves, nanotubes with the least amount of iron
Figure 9. Maximum CO_2 produced and corresponding $Fe(CO)_5$ concentrations vs CO pressure. Values are shown relative to $Fe(CO)_5$ and CO_2 concentrations at maximum SWCNT yield at 30 atm (0.3 and 1 Torr, respectively). Numbers indicate calculated atomic fraction of carbon in the resulting mix of SWCNT and iron. Reprinted with permission from [19], M. J. Bronikowski et al., *J. Vac. Sci. Technol. A* 19, 1800 (2001). © 2001, American Vacuum Society.

are actually produced at 8 and 15 atm. Running at 30 atm produces nanotubes with the highest amount of iron. Maximum nanotube production rate was achieved at 45 atm, with the amount of iron still lower than that at 30 atm. Based on this analysis, it is not clear why 30 atm was chosen as a standard pressure, since maximum nanotube production rate is achieved at 45 atm, and nanotubes with the least amount of iron are produced at 15 atm.

4. MECHANISMS OF SWCNT GROWTH

Carbon SWCNTs have been observed to nucleate and grow from small metal clusters on supported catalysts [4, 20]. It was proposed in [19] that gas-phase nucleation and growth of SWCNTs occur in the HiPco process by an analogous mechanism: the iron carbonyl molecules decompose at high temperature to release their Fe atoms, which cluster together to form small catalytic particles from which SWCNTs nucleate and grow, all in the gas phase. Gas-phase iron pentacarbonyl decomposes rapidly above 300 °C [17]. CO disproportionation occurs at a significant rate only at temperatures above 500 °C [18]. Thus, the rate at which the gas mixture is heated through the temperature range of 300–500 °C will be important in determining the outcome of this process. If this rate is too slow, the clusters may grow too big to nucleate nanotubes. Instead, they would simply overcoat with carbon [4]. On the other hand, the per-atom binding energy for small iron clusters (2–10 atoms) is typically 1.5–2.5 eV, much less than the bulk value of 4.28 eV [21]. At temperatures where SWCNT formation occurs, such small clusters would tend to evaporate quickly. Thus, heating the gas mixture too quickly might curtail the formation of SWCNTs.

4.1. Cluster Formation and Inactivation

If one assumes that all carbonyl molecules are first stripped of CO to form atomic iron vapor and then begin to form Fe_n clusters, there appears to be a bottleneck in the cluster formation: the $Fe + Fe \rightarrow Fe_2$ reaction. Moreover, once a few

Fe_2 clusters are formed, the rest of Fe atoms would react much easier with Fe_2 than with each other. This would lead to preferred formation of large Fe clusters not suitable for SWCNT nucleation. Scott et al. have attempted to simulate numerically the relevant iron–carbon cluster kinetics in the nucleation zone of the HiPco reactor [22]. One of the interesting results which emerged from these simulations is that the Fe dimer formation occurs through other, much more effective channels:

$$Fe(CO) + Fe \rightarrow Fe_2 + CO \qquad and$$
$$Fe(CO) + Fe(CO) \rightarrow Fe_2 + 2CO \qquad (2)$$
At the same time, in addition to direct evaporation of small Fe clusters ($Fe_n \rightarrow Fe_{n-1} + Fe$), they can evaporate via carbonyl formation: $Fe_n + CO \rightarrow Fe_{n-1} + Fe(CO)$. This is relevant to the mechanism by which nanotube growth ceases. Since the per-atom binding energy of small Fe clusters is smaller than that of larger clusters, any evaporation of smaller clusters which are suitable for SWCNT nucleation will lead to growth of larger clusters, which presumably have already nucleated nanotubes. As a catalytic particle grows larger, a more and more catalytically active surface area is created, and eventually a graphitic shell or other structures not associated with the growing nanotube will begin to form on the particle. Eventually the particle will become covered with carbon, preventing the diffusion of additional CO to the particle's surface and terminating further nanotube growth. Alternately, if a growing nanotube is attached to the small cluster, it may evaporate completely too early, ceasing nanotube growth. The cessation of growth of the nucleated nanotubes would thus derive from a combination of these two effects: some nanotubes would stop growing when their attached catalyst particle evaporates or becomes too small, and some would stop when their catalyst cluster grows too large.

4.2. Discussion

The observed temperature dependence of SWCNT production is consistent with this picture. Both the decomposition of $Fe(CO)_5$ and the rate of CO disproportionation become appreciable only at high temperatures, so one expects that the SWCNT production rate will initially increase as the temperature is increased. At temperatures above 1050 °C the SWCNT production rate begins to decline. Apparently, at higher temperatures the rate of evaporation of small, active catalytic clusters is fast enough that growth of SWCNTs is strongly curtailed, overcoming gains in growth arising from faster $Fe(CO)_5$ decomposition and a greater rate of CO disproportionation.

SWCNT yield as a function of $Fe(CO)_5$ concentration can also be understood in terms of this SWCNT growth model. At low concentrations of iron, accretion of Fe onto already growing nanotubes is slow enough that the faster death of growing nanotubes is more than offset by the nucleation of additional nanotubes, as Fe concentration increases. The addition of more iron thus results simply in the formation of proportionally more nanotubes. As $Fe(CO)_5$ concentration is increased further, we see a slowing down in the rate of

SWCNT formation increase, and at sufficiently high concentrations the differential SWCNT yield can actually be negative. This behavior could indicate a concentration regime in which diminished nanotube production due to Fe accretion onto growing nanotubes exceeds increased production from formation of additional catalytic particles. Above a critical "turnover" $Fe(CO)_5$ concentration, the rate of Fe accretion becomes large enough, and the resultant shortening of a nanotube growth time severe enough, that the overall yield of SWCNTs decreases with increasing $Fe(CO)_5$ concentration. Eventually, at very high iron concentrations, the yield of carbon turns around and begins increasing again, but as mentioned, the extra carbon is in forms other than nanotubes. This behavior is qualitatively independent of pressure. Quantitatively, the turnover concentration increases as pressure increases (Fig. 9). Higher CO pressure may simply cause a greater SWCNT growth rate from a catalytic cluster, allowing the SWCNT to grow longer before its attached particle is deactivated. Alternately, higher CO pressure may give a higher nucleation rate of nanotubes from very small clusters, so that more small clusters nucleate nanotubes and fewer collide with and adsorb onto previously nucleated tubes. Results of the parametric study [19] suggest that limits on SWCNT production arise primarily from inactivation of Fe catalyst particles once they become too large. There could be other mechanisms of catalyst inactivation.

5. NUMERICAL MODELING OF HiPco PROCESS

5.1. Nozzle Design

Povitsky and Salas [23, 24] have attempted to optimize the showerhead geometry by modeling the gas flow in the nozzle numerically using the FLUENT code (three-dimensional, steady–state Navier-Stokes equations combined with RNG k–ε turbulence model). They report that for the showerhead geometry with three peripheral jets described previously, the central part of the central cold jet penetrates the peripheral jets, while the peripheral part of the central jet forms a vortex in the stagnation zone between jets (Fig. 10). There are generally three types of trajectories originating in the central cold jet (Fig. 11). The first type deflects toward the nozzle axis and provide relatively slow and monotonic heating. These originate close to the nozzle axis and in-plane with peripheral jets. The second type deflects away from the nozzle axis and provide faster and monotonic heating. These originate close to the nozzle axis and in between the peripheral jets planes. The third type represents trajectories in the vortex. These originate on the periphery of the central jet and provide the fastest heating, but temperature profiles exhibit large oscillations. The heating rate is within $(0.8–1.5)\times 10^5$ K/s for the geometry described previously (30° angle between central and peripheral jets) and can be increased to $(1–2.5\times 10^5$ K/s if the angle is increased to 45°. What is probably most important is not the heating rate itself (it can be adjusted by changing mass flow rates in the nozzle), but the variations in the heating rates for different trajectory types and temperature oscillations of the third type trajectories. It is clear that gas flowing through

Figure 10. Flow field in the x–z section for the nozzle configuration with three peripheral jets positioned perpendicular to the central jet. Velocity vectors are colored with local temperature. Reprinted with permission from [24], A. Povitsky and M. D. Salas, ICASE Report 2001-4, February 2001.

the showerhead along different types of trajectories experiences widely varying temperature histories. It is possible that just one type of temperature history is optimal for nanotube production, while others simply produce unwanted iron particles. Determining the optimal temperature history and the relevant nozzle design computationally is a formidable task.

Povitsky and Salas have proposed a nozzle design with three (instead of one) central jets and three peripheral jets spaced by 60°. It all but eliminates type one trajectories and increases the heating rate to $(3.5–4.5)\times 10^5$ K/s but has not been explored experimentally yet. Another design studied in [24] is a showerhead with two peripheral jets which are

positioned perpendicular to the central jet, which produces mostly type three trajectories. This design was tried in the HiPco reactor [25] and produced very low nanotube yields, indicating that very fast heating combined with large temperature oscillations and large spread in the heating rates does not constitute optimal conditions.

Another attempt to model the gas dynamics in the HiPco nozzle has been published recently [26] by Gokcen et al. It does not take the turbulence into account. Typical Reynolds numbers are around 1000–2000, but jets are still likely to be nonlaminar due to nonparallel interaction between them. The authors approximated three-dimensional (3D) nozzle geometry with 2D axisymmetrical design; that is, peripheral hot CO is injected through an axisymmetrical circular gap, with size determined so that mass and momentum ratios of central and peripheral flows match the experimental values. This eliminates the type two trajectories mentioned and therefore the calculated flow field is probably less realistic.

5.2. Chemical Kinetics

The flow field calculated in [26] was fully coupled to the chemical kinetic model developed by Dateo et al. [27]. Authors then attempted to reproduce the results of the parametric study discussed previously [19], that is, CO$_2$ production vs temperature, overall pressure, and carbonyl partial pressure [26] (Fig. 12). The calculated CO$_2$ production vs temperature is qualitatively similar to the experiment, but it reaches maximum at 1225 K (compared to the 1325 K in experiment) and significantly underestimates the overall CO$_2$ production. A large percentage of iron exits the reactor

Figure 13. (a) Computed trajectories (*x* and *y* coordinates vs axial distance) in the standard nozzle geometry. S2 is type 1, S3 is type 2, and S0, S5, and S5, are type 3. (b) Temperature history along type 1 trajectory (S2). Reprinted with permission from [22], C. D. Scott et al., *J. Nanosci. Nanotech.* 3, 63 (2003). © 2003, American Scientific Publishers.

in the form of Fe atoms, because apparently cluster evaporation becomes significant above this temperature and competes with cluster formation and nucleation of nanotubes. This suggests that dimer dissociation and cluster evaporation rates used in the chemical kinetics modes are too high. It is also possible that the overall computed heating rates are slower than in experiment due to the choice of the nozzle geometry and failure to take turbulence into account. The qualitative behavior of CO_2 production vs CO pressure follows the experiment, except that again it is underestimated by about an order of magnitude. The computed CO_2 production vs $Fe(CO)_5$ concentration dependence does not exhibit the turnover effect seen in the experiment. Bronikowski et al. argue in [19] that CO_2 (and nanotube) production slows above turnover concentration because of Fe accretion onto existing clusters followed by inactivation. Since the kinetic model developed in [26, 27] does not take such mechanisms into account, this result is quite expected.

Scott et al. [22] have also attempted to simulate numerically the relevant iron–carbon cluster kinetics in the nucleation zone of the HiPco reactor. Several chemical kinetics models of varying degrees of complexity were developed and solved with the CHEMKIN package utilizing several sets of

rate coefficients, which are mostly similar to [26, 27]. Some coefficients were adjusted to reduce the unrealistically high Fe atom concentration at the exit in [26, 27]. The chemical model, unlike in [26], was coupled to only one type one trajectory taken from [24], which means that computed cluster distributions and CO_2 production cannot reflect the experimental values. The trajectory and its temperature history are shown in Figure 13. The resulting CO_2 and iron concentrations are shown in Figure 14. All models significantly underestimate Fe and overestimate CO_2 concentrations, which is probably due to the trajectory choice (type one trajectories provide the slowest heating rate). This may also be due to the choice of the rate coefficients for nanotube formation.

The effect of the carbonyl bond strength on the nanotube nucleation was studied computationally in [28]. The authors compared nickel and iron carbonyls as catalyst precursors using the same models as in [22]. It appears that much higher Ni–CO bond strength (170 kJ/mole) compared to that of Fe(CO) (23.9 kJ/mole) prevents dimer formation via reaction (2), thus decreasing CO_2 production by 12–22 orders of magnitude. Indeed, no nanotube formation was observed with pure $Ni(CO)_4$ as a catalyst [25].

6. CONCLUSIONS

The HiPco process has demonstrated its potential to produce single-wall carbon nanotubes inexpensively and on a large scale. Nanotubes contain significant amounts of Fe impurity (3–6 at%), which fortunately is much easier to remove compared to SWCNTs produced by other methods. The amount of nontubular carbon impurities seems to be low. The prevalence of iron in the nanotubes underscores the low efficiency of CO conversion into nanotubes. Nanotube yield can be improved by more efficient nucleation and prevention of the catalyst deactivation in the later stages of SWCNT growth. More effort is necessary to better understand the gas dynamics and cluster kinetics of the process.

GLOSSARY

Chemical vapor deposition Chemical process based on catalytically assisted decomposition of gas-phase precursor molecules.

Energy dispersive spectroscopy (EDS) A microanalytical technique that is based on the characteristic X-ray peaks that are generated when the high energy beam of the electron microscope interacts with the specimen. Each element yields a characteristic spectral fingerprint that may be used to identify the presence and relative concentration of that element within the sample.

Thermogravimetry analysis (TGA) An analytical technique that in which the mass of a substance (and/or its reaction products) is measured as a function of temperature whilst the substance is subjected to a controlled temperature program.

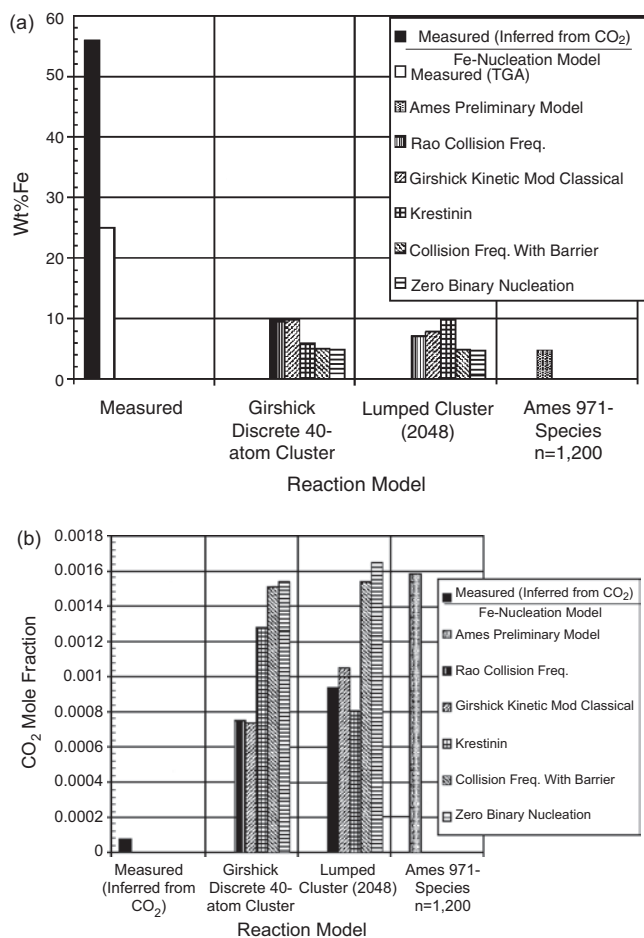

Figure 14. Iron (a) and CO_2 (b) concentration at the reactor exit, computed along single type 1 trajectory. Reprinted with permission from [22], C. D. Scott et al., *J. Nanosci. Nanotech*. 3, 63 (2003). © 2003, American Scientific Publishers.

CONTENTS

1. INTRODUCTION

Ever since the invention of the silicon solar cell in the 1940s, people have acknowledged the enormous potential that photovoltaic systems have for a large-scale electricity production. But silicon wafers are expensive, so great efforts have been focused on the development of cheaper thin-film solar cells. Such films may be purely inorganic or contain organic materials as an essential part of the device. Examples of the latter are junctions consisting of thin layers of organic donor and acceptor molecules; bulk heterojunctions in which the donor and acceptor phases exist as an interpenetrating network [1]; or dye-sensitized photoelectrochemical solar cells [2, 3], in which light absorbance occurs in metallo-organic dye molecules, but generated electrons are injected into the conduction band of a wide-bandgap semiconductor, mainly highly porous nanocrystalline TiO_2 (the so-called Grätzel cells).

Hybrid materials combine the unique properties of one or more kinds of inorganic nanoparticles with the film-forming properties of polymers. The availability of preparing thin organic/inorganic hybrid materials with various semiconducting polymers has opened the door to the construction of a new class of devices, in which both components are photovoltaically active. Most of the polymers can be processed from solution at room temperature, enabling the manufacturing of large area, flexible, and lightweight devices. A convenient way to fabricate p-n junctions is

shown to use a p-doping semiconducting polymer (poly-hexylthiophenes) and n-type II-VI semiconductor nanoparticle CdSe [4].

1.1. Bulk Heterojunction Concept

In organic semiconductors the absorbed photons generate electron-hole pairs, that can be regarded as excitons with a binding energy (0.05–1.0 eV) much higher than that of most inorganic semiconductors. In solar cells based on pristine semiconducting polymers, charge collection requires that the neutral excited states produced by photoexcitation can be separated into free charge carriers first, the so-called exciton dissociation. The generated free charges are then transported through the device to the electrodes. The charge collection is dependent on how the carriers can reach the electrodes without recombining with oppositely charged carriers in the photoactive layer.

Exciton dissociation is known to occur very efficiently at interfaces between the two organic semiconductors mixed together in a composite thin film such as a conjugated polymer and fullerene mixtures [5–7]. The photoexcited electrons will then be accepted by the material with the higher electron affinity (electron acceptor, in this case fullerene or its derivatives), and the hole by the material with the lower ionization potential, which also acts as electron donor. Many conjugated polymers are electron donors upon photoexcitation. The idea using this property in conjunction with a molecular electron acceptor to achieve long-living charge separation was based on the stability of the photoinduced excitations on the conjugated polymer. The energy gain by electron transfer from the polymer to the electron acceptor must be sufficient to overcome the coulombic exciton binding energy in the polymer to produce charge separation.

Examples of further electron acceptor materials include also cyano-substituted conjugated polymers [8, 9], tetra-cyanoanthraquinodimethanes [10], and various oligomers [11].

Efficient charge separation has been realized in two different cell configurations:

- bilayer configurations of n-type layer/ p-type polymer (vice versa)
- an interconnected network structure of p- and n-type materials

In a bilayer configuration, excitons, which are generated in the polymer layer, need to reach the donor/acceptor interface, where the charge separation occurs. Since the exciton diffusion length in organic semiconductors is usually only about ∼10 nm [12, 13], the photoactive layer in bilayer heterojunction structures is rarely thicker than 20 nm.

In the interconnected network structure, blending an electron-accepting and a hole-accepting material can result in the formation of domains close to the desired 20 nm length scale. Thus, most excitons can reach a donor-acceptor interface even in thicker devices. Replacing the flat interface by an interconnected network structure of p- and n-type materials leads to a high surface area in the whole volume for charge separation, that is, the "bulk heterojunction" (Fig. 1).

Based on interconnected networks of hole-conducting polymers (p-type) with percolating electron-conducting Buckminsterfullerene (C_{60}) derivatives (n-type), recently more than 2.5% solar power conversion efficiency in devices of less than 100 nm thickness of the absorber layer, in which only a relatively small portion of the solar light is absorbed, have been achieved [14].

In bulk heterojunction cells, the transport of the carriers to the electrodes without recombination is a more complicated problem to solve, since it requires that once the electrons and holes are separated onto different materials, each carrier type has a pathway to the appropriate electrode without needing to pass through a region of the other material. The nanoscopic morphology of the composite layers plays in this manner a fundamental role for efficient solar cell performance.

Figure 1. Formation of a bulk heterojunction in an interpenetrating donor/acceptor network.

An additional fundamental phenomenon which determines the behavior of conductivity in bulk heterojunction devices is the percolation threshold. Percolation takes place when the electron acceptor and donor concentrations reach a value high enough to provide the conduction along the connected network of each type of materials. The solubility of the n-type and p-type components in the same solvent is an important parameter for the construction of hybrid solar cells.

1.2. Nanocrystalline Semiconductors

Nanoclusters of inorganic semiconductor materials, known as nanocrystals, have been the subject of intense research in the 1990s. The primary motivation for this increased activity is related to the size-dependent new properties of these materials. For example, magnetic and semiconductor nanocrystals exhibit strongly size-dependent properties that may find applications in magnetic storage and microelectronics, key components in information technology [15–17]. The emission and absorption of semiconductor nanocrystals are tunable by size as a result of the quantum confinement effect. Also, the use of quantized nanocrystals as fluorescent or absorbing materials in optoelectronic and photovoltaic devices is an interesting and quickly developing area of research [18, 19].

There are in principle two distinct synthetic routes to create semiconductor nanostructures: physical or chemical procedure. In the "physical" approach, the particles are grown by lithographic or molecular beam techniques, whereas in the "chemical" approach, they are formed either by particle growth in various matrices or by the methods of colloidal chemistry. In this contribution, we will focus on the latter approach, which allows us to produce stable particles, which can be handled like ordinary chemical substances.

Motivated chemists have spent many years developing synthetic strategies for the preparation of nanocrystalline materials, which should have desirable chemical properties such as high crystallinity, stability against degradation, but also flexible handling properties for specific arrangement of the nanocrystals on various substrates. Nowadays, series of nanocrystals with different organic/inorganic shells, shapes, and sizes are found in the literature. Many of them are commercially available.

To exploit the full potential for the technological applications of the nanocrystalline materials, it is very important to endow them with good processing attributes. This has ultimately guided scientists toward using conventional polymers as matrix material, resulting in inorganic/organic guest-host systems generally termed "hybrid" or "composite" materials.

An important strategy was to create nanoparticles shielded by an organic ligand, the so-called "core-shell" particles. The shell can alter the dispersion characteristic of the particle by initiating attractive forces with the polymer chains, in which the particles should be homogeneously arranged. But also the stability against oxidation and against aggregation can be inhibited by tailoring the surface modification.

1.3. Hybrid Solar Cells

An effective strategy of the hybrid solar cell investigations is to fabricate blends of nanocrystals with semiconductive polymers as a photovoltaic layer. The basics of this heterojunction concept have been already described.

The investigations of inorganic semiconductor nanoparticles embedded into semiconducting polymer blends are promising materials for several reasons. The classical inorganic semiconductor materials for photovoltaic applications can have a higher absorbance coefficient and photoconductivity than organic materials mentioned earlier. Furthermore, the n- or p-type doping level of these nanocrystalline semiconductors can easily be varied by synthesis. So we can study charge transfer in composites of n-type and p-type conducting polymers with corresponding inorganic counterparts.

The first requirement in inorganic/organic hybrid solar cells is to blend a high concentration of inorganic nanoparticles into the polymer matrix, to form an interpenetrating network. Phase separation in macroscopic scale should be avoided. As discussed in Section 1.1, for an effective charge separation in electron donor/acceptor composites, the average distance between formed excitons in the two materials should be in the range of 20 nm, which determines the size of domains. For a profitable morphology of the blends, nanoscale inorganic particles should be used. To give an idea, the fullerene molecules embedded in the polymer are about <1 nm in diameter; the cluster size, however, is heavily dependent on the processing conditions. It has been shown that composite films cast from toluene solutions result in much bigger (50–500 nm scale) fullerene clusters as compared to chlorobenzene-cast films with much finer grain sizes (below 50 nm) [20, 21].

Typically, inorganic semiconductors in macroscopic dimensions, irrespective of their size, will absorb all electromagnetic radiation with an energy greater than the bandgap. However, if the particles become smaller than that of the exciton in the bulk semiconductor (typically about 10 nm), their electronic structure changes. The electronic properties of such small particles are hence more like those of a molecule than an extended solid. The electronic and optical properties of such small particles will depend not only on the material of which they are composed, but also on their size, the so-called quantum confinement effect [22–26]. The lowest energy of optical transition, among others, will increase significantly due to the quantum confinement with decreasing size of the inorganic clusters. For example, the quantized particles of $CuInS_2$ dispersed in acetonitrile can have an energy gap about 2.3 eV. In comparison to the energy gap of the bulk material, the increase is about 0.9 eV [27].

Bandgap tuning in nanoparticles can be used in realization of device architectures, such as tandem solar cells in which the different bandgaps can be obtained by modifying only one chemical compound [28, 29]. Since the energy levels of the polymers can be tuned by chemical modification of the backbone chain and the energy levels of the nanoparticles can be tuned through the size-dependent quantum confinement effects, blends of the two materials offer the possibility of tailoring optimal conditions for a solar cell,

including energy gain from charge transfer for the efficient charge separation and the spectral range of the absorbing light. In contrast to C_{60} derivatives, the bandgap of the nanoparticles lies conveniently in the visible region. Furthermore, the possibility is given, to study not only electron transfer from p-type polymer to n-type nanoparticle, but also hole transfer from the nanoparticle to the polymer after excitation in the nanoparticle.

Also, the interaction between the inorganic particle and polymer should be good enough to disperse high nanoparticle concentrations in the polymer solution and to prepare high-quality films from this solution. Contrary to the organic materials, the nanocrystals are not easily dispersed in polymer matrices. Because of the small size of the cluster, they have a high surface energy, which leads to aggregation or oxidation. Because of this reason, the synthesis of nanoparticles shielded with various organic ligands is important in determining the morphology of the polymer/nanocrystal composites.

On the other hand, the performance of nanocrystal-based devices is often limited by poor charge transport through the nanoparticle-polymer interface, since the nanocrystals are surrounded by a stabilizing shell of capping molecules. In these cases, it is possible to remove the capping molecules partly by repeated washing with organic solvents such as pyridine or cyclohexane, providing a better charge carrier exchange between nanocrystals and the conducting polymer.

Another promising technique is the modification of the nanocrystal surface with monomers or oligomers of semiconducting polymers. Subsequent co-polymerization of the nanocrystals with the matrix facilitates incorporation of the inorganic component into the semiconducting polymer and charge transport through the nanocrystal-polymer heterojunction. Details on the methods used to synthesize polymers on the nanoparticle surface can be found elsewhere [30–35]. State-of-the-art reviews for engineering particle surfaces are also given [36, 37].

In-situ formation of nanoparticles in a high-dielectric-constant polymeric medium has been realized for CuO and Cu_nS [38]. To our knowledge, no studies in photovoltaic devices have yet been reported using these methods.

The existence of concentration gradient of the n-type nanoparticles within the p-type polymer matrix may allow optimization of the topology of the heterojunction network. Introducing the gradient device morphology leads to an increase in the active area for charge separation while decreasing the charge carrier recombination during their transfer to electrodes. To obtain concentration gradient of nanoparticles, the colloid solution has to be placed on top of a polymer film. Diffusion of nanoparticles into the polymer matrix takes place with the penetration depth controlled by temperature, swelling of the polymer layer, and not at least by the size and shape of the nanocrystals. The control over the size and shape of nanoparticles is thereby an additional aspect to outline in the section below.

Because of the enormous importance of the nature of the shell molecules, the form of the particles, and the interactions with the chosen polymer matrix to construct efficient solar cells, special emphasis is given to the synthesis of the "core-shell" particles. Several strategies will be described in more detail in Section 2.

The photovoltaic performance of various inorganic/organic hybrid solar cells, prepared via spin-coating, will be the focus of this chapter. The other two common thin-film techniques, namely, electrodeposition and layer-by-layer self-assembly, are described very briefly. References are given to these techniques and to the performance of the cells prepared with these techniques for detailed information.

An efficient charge transfer from the nanocrystalline inorganic semiconductors to the conduction band of wide-bandgap semiconductors (such as TiO_2, ZnO, Ta_2O_5) in combination with high extinction coefficients of nanocrystals in the visible range makes them very attractive for dye-sensitized solar cells [39–42]. The special case of dye-sensitized photoelectrochemical solar cells would go beyond the scope of this review. We just point out the latest developments in dye-sensitized solar cells formed with semiconducting polymers.

2. METHODS

The three most common techniques [43] used for characterizing the semiconductor nanoparticles are:

1. *Optical absorption* (*or transmission*). Since the most apparent effect of quantized nanocrystals is the increasing of the bandgap, hypsochromic shift of the absorption spectra is a fast and simple indicator of the particle size.
2. *Transmission electron microscopy* (*TEM*) *together with electron diffraction* (*ED*). TEM is used to image the size, shape, and size distribution of the nanocrystals. Blended in polymer matrix, the images give information about the orientation of the particle in the polymer film and roughly about the morphology of the film. ED provides information about the stoichiometry of the particle and crystal phase.
3. *X-ray powder diffraction* (*XRD*). One very important use of XRD when dealing with nanocrystals is to estimate crystal dimensions L through the Debye–Scherrer relationship:

$$L \approx \frac{\lambda}{\Delta(2\Theta) \cdot \cos\Theta}$$

where λ is the X-ray wavelength (0.15418 nm for CuK_α radiation), $\Delta(2\Theta)$ is the peak full width at half maximum (FWHM) in radians, and Θ is the peak position. This relationship is valid only for a spherical crystal.

The size is inversely proportional to the FWHM. To be more precise, the value of FWHM depends on the length over which the periodicity of the crystal is complete (coherence length). That means, also the presence of defects in the crystal, which destroy the periodicity, can lead to broadening of the X-ray diffractions. Also a broad distribution in the crystal particle size can lead to wrong interpretation of the systems: Even if the amount of large crystals is less, they may dominate the diffraction pattern, since peak heights increase with increasing particle size. (Constant peak area for same amount of the material independent of the size, but decreasing FWHM, leads to increase of the peak heights.) Thus, the interpretation of the XRD peak broadening should be carried out with complementary methods.

2.1. Synthesis of Core-Shell Particles for Hybrid Solar Cell Applications

Nanoparticles with modified surfaces can easily be mixed with polymer materials to form thin films by several techniques such as spin-coating, doctor blade, or layer-by-layer self-assembly. The modification of the surface with an organic surfactant depends on the method by which the particle has been prepared. The nature of the organic ligand not only influences the nanoparticle distribution in the polymer matrix but also prevents more or less the aggregation and reduces the oxidative degradation. Core-shell materials have been synthesized using decomposition of organometallic compounds, colloidal chemistry, and solvothermal route.

2.1.1. Decomposition of Organometallic Compounds

CdS and CdSe have been widely studied as photoactive nanomaterials, due to the availability of precursors and ease of crystallization. The highly cited method for making CdE (E = S, Se, Te) nanocrystals is that of Murray et al. [44]. A general scheme for preparing monodisperse nanocrystals via organometallic route requires a single temporally short nucleation event followed by slower growth on the existing nuclei. This has been realized first by the pyrolysis of organometallic reagent (precursor) alkyl (dimethylcadmium) and a chalcogen source TOPSe (tri-n-octylphosphine selenid) in a hot tri-octylphosphine oxide (TOPO) matrix, which is a polar coordinating Lewis base.

The two precursors were dissolved in a liquid phase similar in nature to the matrix. The used liquid phase was tri-octylphosphine (TOP). The nucleation of CdSe nanocrystals was achieved in an inert atmosphere by the sudden introduction of the concentrated reagents in the TOPO matrix. The temperature of the TOPO is sufficient to decompose the reagents (200–350 °C), forming a supersaturation of species in solution that is relieved by nucleation of nanocrystals. Upon nucleation, the concentration of these species in solution drops below the critical concentration. Also the temperature decreases by addition of the precursors, which have been held at room temperature. Further material can only add to the existing nuclei.

During the growth of nanocrystals in the matrix, the surfactants dynamically adsorb to the growing crystals, allowing the atoms to further adsorb or de-adsorb, which controls the particle size and shape, while suppressing the aggregation. Each nanoparticle in the sample is surrounded by a TOPO layer.

Considerable efforts have been reported on the mild synthesis conditions by use of a single-molecular precursor in which the metal-chalcogen bond is already in place [45, 46]. The mild-pyrolyse method has been successfully applied to the growth of II-VI [47–51], III-V [52–57], and IV-VI [58, 59] semiconductor nanocrystals.

It is important to note that the shape of the particles depends strongly on the growth kinetics. For example, working with highly diluted suspensions leads to small nanocrystals first. Systems with mostly small nanocrystals, on the

other hand, exhibit a second growth stage: the high surface energy of small nanocrystals promotes their dissolution at the expense of the larger ones. This growth stage is known as Ostwald ripening. Such slow growth conditions favor the formation of particles with least surface energy. The resulting particle shape is spherical [60]. At higher reagent concentration, relative differences between the growth rates can lead to anisotropic shapes. Controlled growth of crystalline arrays can be further achieved by manipulation of growth kinetics. Combining surfactants with different strength of the adsorption on the particle surface can be used to vary the growth rates and synthesize anisotropic particle shapes.

The breakthrough in the morphological preparation was that the ability to assemble these colloidal particles into crystalline arrays [61–65] can be used to increase the photoconductivity of the polymer/nanoparticle blends.

Controlled formation of nanoparticles with spherical and rod shapes was realized by CdSe nanocrystals. This is possible because CdSe crystals with the wurtzite structure are intrinsically anisotropic, with a unique c-axis. If the overall growth rate by an extremely high monomer concentration is fast, growth is generally faster along the c-axis. Rods form at high growth rates by unidirectional growth of the c-axis.

The experience showed that TOPO is not a suitable surfactant for controlled growth of rodlike CdSe structures. The resulting rodlike particles are too big in three dimensions and mostly insoluble in common solvents. The blends of these particles in polymers are characterized by large-scale phase separation, which is a disadvantage for photovoltaic applications. Addition of a molecule that coordinates more strongly to cadmium has been used to control the growth rate and shape of the particles. An important discovery was that hexylphosphonic acid (HPA), which is almost always present as impurities in technical grade TOPO, accentuates the differences in the growth rates among various faces [66]. Controlled formation of CdSe nanocrystals with spherical and rod shapes was realized by the variation of the surfactant ratio of TOPO and HPA. The role of HPA seems to increase the growth rate along the c-axis. At low concentrations of HPA, spherical-shaped nanocrystals form. Intermediate amounts of HPA favor the formation of rods. Higher HPA ratios lead to the formation of arrow-shaped nanocrystals. More complex shapes such as teardrop or tetrapod-shaped crystals are produced by varying the ratio of surfactants, injection volume, and time-dependent monomer concentration [67].

Another strategy to fabricate superstructures from TOPO capped particles with a narrow size distribution is gentle destabilization of the dispersion. Attractive surface forces of nanoparticles drive self-organization and superlattice formation [68].

The crystallization of TOPO capped CdSe particles, 3.5 nm in diameter, was carried out in vertically positioned glass tubes. The toluene dispersion of the particles was slowly destabilized by diffusion of methanol, resulting in aggregation of the particles. A buffer layer of propane-2-ol between solvent-nonsolvent contact was placed, to decrease the growing rate of the particles. Single crystals grew in the form of perfectly faceted hexagonal plates. The optical behavior of these three-dimensional (3D) ordered systems,

100 μm in lateral dimensions and 20 μm in depth, was very similar to the optical behavior of individual nanoparticles.

Theoretical aspects for the kinetics of growth of solid-state nanocrystals in a liquid medium have been also reported [69].

Nanoparticles of TOPO capped II-VI materials are found to degrade in the presence of light and oxygen, forming unstable chalcogene oxide species [70]. Alternatively, TOPO has been also replaced by other organic groups such as pyridine, 4-picoline, tris (2-ethylhexyl) phosphate, and 4-(trifluoromethyl) thiophenol [71, 72]. Another way to eliminate the degradation is coating the nanoparticle surface by a layer of a higher bandgap semiconductor [73–76]. The relative stability of CdSe (CdS) nanocrystals compared to CdSe is drawn from energetic offsets between the core and shell valence bands. When the CdS shell is present, there is a possibility given, that a hole on the core nanoparticle will recombine with electrons of CdS but not degrade in the presence of oxygen. CdS capped CdSe nanocrystals have been introduced as a new class of electroluminescent materials. The light-emitting diodes of ITO/PPV (40 nm)/CdSe (CdS) (24 nm)/Mg/Ag show low operating voltages, a factor of 8 increase in quantum efficiencies, and a factor of 10 increase in lifetimes in comparison to those made by organically capped CdSe nanocrystals [77].

2.1.2. Colloidal Route

An alternative synthetic approach involves mixing the reagents at a temperature low enough to preclude any appreciable reaction. A controlled dropping of nucleation reagent initiates the reaction. As long as the temperature is adjusted to keep the rate at which the reagents react less than or equal to the dropping rate, controlled reaction conditions are given.

Because the energy of the surface is higher than in the volume, the tendency of nature is to reduce the surface-to-volume ratio, which is also the driving force of particle growth in a colloidal route after nucleation.

To stabilize the smallest particle in a dispersion, the material exchange between the particles should be hindered. This can be realized by adsorbance of charged (electrostatic forces) or bulkier surfactants (greater steric hindrance). Tailoring the ratio of the reagents concentration to that of the surfactants provides a control over the particle size. Higher surfactant-to-reagent ratios favor the formation of a smaller particle size. Surfactants in solution are only reversibly adsorbed to the surfaces of the reagents and control the particle growth. Also the chemistry of the surfactant plays an important role. For example, bulkier trioctylphosphines provide greater steric hindrance than more compact tributylphosphines, slowing the growing step [78]. The stability of the particle dispersions depends on the temperature and on the solvent. If the interaction between the surfactants and the solvent is favorable, the nanocrystals are then isolated. Introducing an additional solvent, which is miscible with the first solvent but has an unfavorable interaction with the capping group, destabilizes the particle dispersion. A controlled destabilization may lead to formation of 3D arrays, but a fast growing of the particles cause just their aggregation.

Synthesis of $CuInS_2$ (CIS) nanoparticles was performed by a colloidal route at room temperature [79]. In this synthesis, the surfactant used was triphenyl phosphite (TPP). In the first step, $InCl_3$ and CuI were suspended in a mixture of acetonitrile and TPP. The solutions were refluxed in an argon atmosphere to form TPP complexed $InCl_3$ and CuI solutions. Bis(trimethylsilyl) sulfide, which was diluted with TPP, was added for the nucleation, drop by drop to the mixture at room temperature. A remarkable dynamic color change of the solution occurs from colorless through yellow to orange and red depending on the amount of added bis(trimethylsilyl) sulfide and on the size of the formed CIS particles. The average particle size increases over time with a compensating decrease of the nanoparticle number due to the Ostwald ripening. Under cooling conditions, the dispersion is stable for ca. one month. X-ray diffraction studies performed on the product are consistent with those of the chalcopyrite structure of CIS.

2.1.3. Solvothermal Route

Using the solvothermal approach, the synthesis of III-V semiconductors has been demonstrated [80]. An advantage of this method is that the particles formed are usually crystalline and do not need post-treatment at high temperatures. Also, no organometallic precursor, which can complicate the system, and no organic stabilizers are used in this route. The nature of the solvent affects the reaction process and product quality. The synthetic route was extended to the synthesis of nanocrystalline GaN [81] and $CuInSe_2$ [82].

We synthesized $CuInSe_2$ (CISe) by the solvothermal route described by Y. Qian and co-workers. A stoichiometric mixture of elementary Se, $CuCl_2 \cdot 2H_2O$, and $InCl_3 \cdot 4H_2O$ was loaded into a 50 ml autoclave, which was then filled with anhydrous ethylenediamine up to 80% of the total volume. The experiment was performed at 180 °C for 15 h. The product was washed with water and ethanol several times in order to remove the by-product, a crystalline, undefined mixture of Cu, In, and Se beige in color. The product was black in color, which predicts the nonquantized nature of the particle. The CISe particles were elongated in shape with dimensions of about 15–60 nm [130].

Due to its strong basic capacity, an important role of the ethylenediamine is to increase the reactivity of elemental selenium forming Se^{2-} [83] and to promote the reaction between $InCl_3$ and Se forming the anions $(InSe_2)^-$. Since ethylenediamine dissolves $CuCl_2$, it can act as a bidentate ligand that could facilitate the formation of chelate complexes of $[Cu(en)_2]^+$ and likely force the $CuInSe_2$ grains to grow in one direction. When diethylamine, also a strong base ($pKa = 10.98$) but without double N-chelation, was used instead of ethylenediamine, spherical $CuInSe_2$ particles have been obtained [82]. Similar observations between the particle shape and solvent were made also for the synthesis of PbS nanoclusters [84]. These results indicate that only a bidentate solvent sustains whisker-like shapes. A major limitation of this method has been that it often leads to aggregated particles embedded in a polymer matrix. Further wet chemical synthesis methods for nanocrystalline chalcopyrites are given in [85, 86].

2.2. Thin-Film Preparation Techniques

There are three common methods to prepare films of hybrid materials: spin-coating from a solution, electrodeposition, and layer-by-layer assembly. Electrodeposition and layer-by-layer (LBL) self-assembly will be described only very briefly. References are given to these techniques and to the performance of the cells prepared with these techniques, for more information.

Hybrid solar cells fabricated via spin-coating from dispersions of CdS (CdSe) nanocrystals and semiconducting polymers are the most extensively explored systems in general. So we will describe these systems in more detail. $CuInS_2$ ($CuInSe_2$) embedded in semiconducting polymer matrices will be discussed for different photovoltaic solar cell configurations.

2.2.1. Spin-Coating

Most incorporation techniques of hybrid systems require mixing of the components in a good solvent/dispersion and spin-coating of the solution to form thin films on selected substrates. Since using semiconducting polymers as an optoelectronically active component in such hybrid systems requires optimal morphology of the film, an important issue is how to assemble nanocrystals within films. The nanocrystals consist of organic shells readily dispersible in a variety of organic solvents, and they easily form uniform films of closely packed nanocrystals by spin-casting and spin-coating. To tailor the right components for an ideal morphology of a polymer/inorganic composite film is still a challenge, which will be the target of experimental work in future.

2.2.2. Electrochemical Deposition

Films of the quantized particles can be prepared by using electrochemical deposition from nonaqueous solutions such as DMSO containing, for example, elementary chalcogen (S, Se) and a metal salt [87]. In the second step, semiconducting polymers have been electrolytically grown onto this nanocrystalline inorganic layer. Classical photovoltaic materials like CdTe [88, 89], CdS [90, 91], Cd/ZnSe [92], TiO_2 [93], $CuInS_2$ [94, 95], and $CuInSe_2$ [96] have also been nanoscale structured onto different substrates by using this technique. The experimental details can be found in [90, 91, 97, 98]. Horowitz and Garnier, who studied a polythiophene/GaAs p-n junction, reported on a hybrid solar cell fabricated by electrodeposition [99].

Schottky-type photovoltaic cells, based on polythiophene derivatives and CdTe [100] or CdS [101–103], are also reported. In these cells, the polymer is in its highly doped state and behaves like a metal. The active area for charge generation and separation may be in the inorganic layer.

Heterojunction cells consisting of n-type $CuInSe_2$ and p-type polypyrrole multilayers have been fabricated electrochemically [104].

2.2.3. Layer-by-Layer Assembly

Self-assembly is defined as the spontaneous liquid-phase adsorption of materials onto a surface. Driving forces are mostly electrostatic in nature, but they can also involve

hydrogen bonding, van der Waals, or hydrophobic interactions. The substrates, for example, ITO, silica, metal electrodes used for electro-optical applications, have surfaces with negatively charged oxides. A well-cleaned substrate is immersed into a dilute aqueous solution of an oppositely charged solution, for a time optimized for adsorption of a monolayer, rinsed, and dried. Rinsing with a solvent between the adsorption steps removes the excess solution and leaves a thin monolayer of the polyelectrolyte on the surface. The next step is the immersion of the monolayer covered substrate into a dilute dispersion of oppositely charged species (cationic/anionic polyelectrolytes or nanoparticles), also for a time of optimized adsorption of the second layer, rinsing, and drying. The cycle can be repeated to reach the desirable thickness of multilayers. Strong interpenetration of the used polymer chains makes impossible a description of the border between oppositely charged layers. In the resulting laminated structure, the two different types of semiconductors can diffuse into each other, forming a mixed layer at the interface, while still providing a percolation path to the respective electrodes. Detailed information for the fabrication techniques can be found in [105–110]. Such growth of multilayers was demonstrated for single layers of oppositely charged polyelectrodes [111] and semiconductor polymers such as water-soluble poly(p-phenylene)s [112–115] and poly(pyrrole) [115] .

The inorganic particles were usually shielded by organic layers with functional groups of dithiols, in which covalent metal-S bonds can be formed. LBL film-coating studies for nanoparticles such as CdTe, HgTe, CdSe, PbS, TiO_2, ZrO_2, Ag, Au, SiO_2, and MoO_2 have been also investigated [116–119].

The CdTe/polyaniline and CdTe/polypyrrole composites have also been produced in a second step via the treatment of electrochemically prepared polyaniline films with aqueous colloidal solutions of thiol capped nanocrystals [120] and via the electrochemical polymerization of pyrrole into the porous CdTe films [121] .

Approaches to create an electroactive interface included the incorporation of CdSe nanoparticles with 1,6-hexadecanethiol (HDT) onto a film of poly(p-phenylene-vinylene). The diodes had a good rectification and enhanced electroluminescence [122, 123]. However, the current-voltage characteristics of these cells did not originate in a p-n junction, but in a Schottky diode junction.

Composite diodes have been fabricated by self-assembling TOPO capped n-type, 2- to 4-nm CdSe particles and HDT (as a binder) onto the p-doped semiconducting polymers poly(pyrrole) (Ppy) or poly(3-methylthiophene) (PMeT). The semiconducting polymers, on the other hand, have been either layered by electrochemical deposition (PMeT) or layer by layer chemically assembled onto derivatized conducting substrates [119]. These films have shown p-n junctions in an ITO/polymer/(HDT/CdSe)₃/Al configuration.

Layer-by-layer assembly of hybrid poly(vinylpyridine)/CdSe multilayer thin films has been reported, whereas the driving force for the formation of PVP/CdSe layer was H-bond interaction between the pyridine group of the polymer and the carboxylic acid group of the surfactant surrounding the nanoparticle [124].

3. SOLAR CELLS

3.1. Hybrid Solar Cells based on CdSe-CdS Nanocrystals

Photovoltaic characteristics of CdSe and CdS core/shell particles have been most extensively explored by the group of Alivisatos et al. According to the photoluminescence quenching measurements in composite films of poly(2-methoxy,5-(2′-ethyl-hexyloxy)-p-phenylene-vinylene (MEH-PPV) and TOPO capped CdSe nanoparticles (5 nm), a charge separation at the interface between the polymer and CdSe nanoparticles has been reported [125].

Replacing the surfactant TOPO by pyridine leads to a more effective charge separation, which has been concluded because of the decrease of MEH-PPV photoluminescence efficiency to a value of ca. 0.01 by mixing CdSe in a composite film. The increase of short circuit photocurrent with increasing amount of CdSe was consistent with this picture. Photoluminescence quenching experiments have been confirmed by the observation of charge on the polymer chain in photoinduced absorption measurements [126].

By monochromatic illumination at 514 nm of an ITO/CdSe-MEH-PPV/Al cell (95 weight % CdSe) with a power intensity of 5 W/m^2, they received an open circuit voltage, V_{oc}, of 500 mV and a short circuit current of about 1 μA for a 7.3 mm^2 active area. There was a rectification ratio of 100 at $+/-3$ V in the dark and no rectification under illumination. A power conversion efficiency of 0.25% was obtained.

The low quantum efficiency is attributed to the poor transport of charges. TEM images of the films show phase separation for all composite films, unfortunately more pronounced for pyridine capped CdSe particles. Because of the structural traps in the form of incomplete pathways in the percolation network, the separated charges on different materials recombine with opposite charges before reaching the electrodes. To improve the charge collection, the film morphology should be optimized.

An idea to improve the film morphology was replacing the spherical nanocrystal particles with elongated ones. Van der Waals interactions become stronger as the contact area between two particles increases [127]. Because of this, the tendency for elongated particles to agglomerate will be stronger than that for spherical particles of the same volume. In agreement with this argument, TEM images of particles in polymer matrices show that the agglomeration domain sizes increase with increasing length of the particles (Fig. 2).

The efficient packing of larger nanocrystals may result in a decrease of charge recombination possibilities in a bulk heterojunction hybrid solar cell. Indeed, the use of nanocrystalline rods in conjunction with a regioregular poly(3-hexylthiophene) (P3HT) has resulted in almost an order of magnitude increase in power conversion efficiency, in comparison to the cell discussed above [128]. P3HT is an effective hole transport material in its regioregular form, with field effect hole mobilities up to 0.1 $cm^2 V^{-1} s^{-1}$ [129].

Solar cells were fabricated by spin-casting a solution of 90 weight % CdSe nanorods (7 × 60 nm) in P3HT onto an indium tin oxide glass substrate coated with
Figure 2. Cadmium selenide nanocrystals with aspect ratios ranging from 1 to 10. The samples, shown by transmission electron micrographs at the same scale, have dimensions (A) 7 nm × 7 nm, (B) 7 nm × 30 nm, and (C) 7 nm × 60 nm. Reprinted with permission from [4], W. Tu. Huynh et al., *Science* 295, 2425 (2002). © 2002, American Association for the Advancement of Science.

poly(ethylene dioxythiophene) doped with polystyrene sulfonic acid (PEDOT:PSS) with aluminum as counter electrode. PEDOT:PSS is a highly p-doped polymer, usually coated on the ITO electrode, to smooth the electrode surface and increase the adhesion of organic materials to form good-quality layers via spin-coating.

By monochromatic illumination at 515 nm of an ITO/PEDOT:PSS/CdSe-P3HT/Al cell with a power intensity of 0.1 mW/cm^2, they received an open circuit voltage, V_{oc}, of ca. 500 mV and a short circuit current of about 0.02 mA/cm^2. There was a rectification ratio of 10^5 in the dark. A power conversion efficiency of 6.9% is obtained (Fig. 3B). Solar cell characteristics of this 7 × 60-nm nanorod device illuminated with AM 1.5 global light, include a short circuit current of 5.7 mA/cm^2 and an open circuit voltage of 680 mV (Fig. 3C). Due to the quantization effect, the form of the photocurrent spectra changes depending on the size of the nanorods (Fig. 3D). The external quantum efficiency (IPCE), which is the percentage of electrons collected per incident photon, increases with increasing length of the nanorods from ca. 20% for 7 × 7 nm up to ca. 55% for 7 × 60 nm particles (Fig. 3A) [3].

3.2. Hybrid Solar Cells based on CuInS$_2$-CuInSe$_2$ Nanocrystals

We investigated first blends of poly (2-methoxy-5-(3′,7′-dimethyloctyloxy)-1,4-phenylene vinylene) (MDMO-PPV) and of regioregular poly (3-hexylthiophene) (P3HT) with

copper indium diselenide (CISe) and copper indium disulfide (CIS) nanocrystals [130].

The crystallographic structure of the particles was determined by powder X-ray diffraction using Cu K$_\alpha$ radiation of 1.5418 Å. Figure 4 shows the X-ray diffraction pattern of the CISe and CIS. An intense peak at $2\theta = 26.6°$ oriented along the (112) direction and other prominent peaks observed at 44.3° ((220)/(204)) and 52.3° ((312)/(116)) indicate the chalcopyrite structure of CISe. These patterns are in good agreement with JCPDS data [162].

In contrast, the upper plot shows the results of X-ray diffraction investigations performed on the CIS. The three

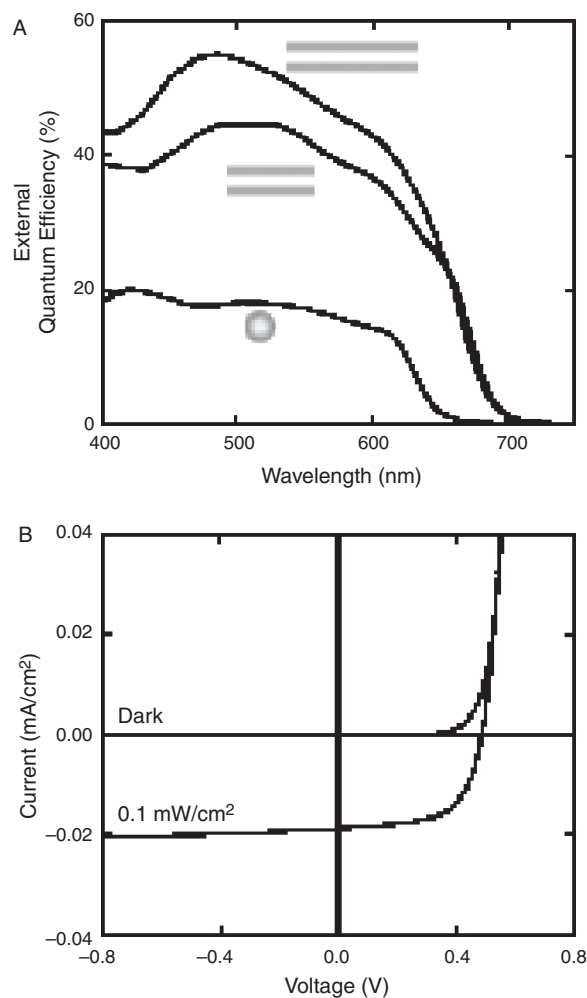

Figure 3. (A) External quantum efficiencies of 7-nm-diameter nanorods with lengths 7, 30, and 60 nm. The device structure consists of film, which was spin-cast from a pyridine-chloroform solution of 90 wt% CdSe nanorods in P3HT. The intensity is 0.084 mW/cm^2 at 515 nm. (B) The current-voltage characteristics of the 7 nm × 60 nm nanorod device exhibit rectification ratios of 10^5 in the dark and a short circuit current of 0.019 mA/cm^2 under illumination of 0.084 mW/cm^2 and at 515 nm. (C) Solar cell characteristics of this 7 nm × 60 nm nanorod device illuminated with simulated AM 1.5 global light, include a short circuit current of 5.7 mA/cm^2. (D) Photocurrent spectra for two devices with 60-nm-long nanorods with diameters 7 and 3 nm. Reprinted with permission from [4], W. U. Huynh et al., *Science* 295, 2425 (2002). © 2002, American Association for the Advancement of Science.
Figure 3. Continued.

now broad reflections at 2θ values of 27.9 (112), 46.5 (220)/(204), and 55.0 (312)/(116) are those of the chalcopyrite structure of CIS [163]. However, in the range between 15° and 35° a broad halo appears, probably due to an

Figure 4. X-ray diffractograms of CISe and CIS.

amorphous contribution. This may indicate that still TPP is present, which may not have been removed completely.

Apart from this, a comparison of the diffraction patterns clearly shows a pronounced broadening of the CIS diffraction patterns due to the Debye–Scherrer relationship (Section 2). TEM is used to image the size, shape, and size distribution of the nanocrystals [130]. CISe samples in MDMO-PPV appear to display whisker shaped particles with dimensions of at least 15×60 nm. CIS particles in P3HT matrix have also elongated forms with dimensions on the order of 5×20 nm (Fig. 5A). The preparation of the particles has been mentioned in Sections 2.1.2 and 2.1.3.

In the next step, films of $CuInS_2$ particles have been fabricated by spin-coating on the ITO electrode, which was first covered with (PEDOT:PSS). The films were homogeneous, with a roughness of about 40 nm (Fig. 5B). The CIS layer exhibits due to the quantum confinement effect, a significant hypsochromic shift of absorption relative to the bulk
A
B

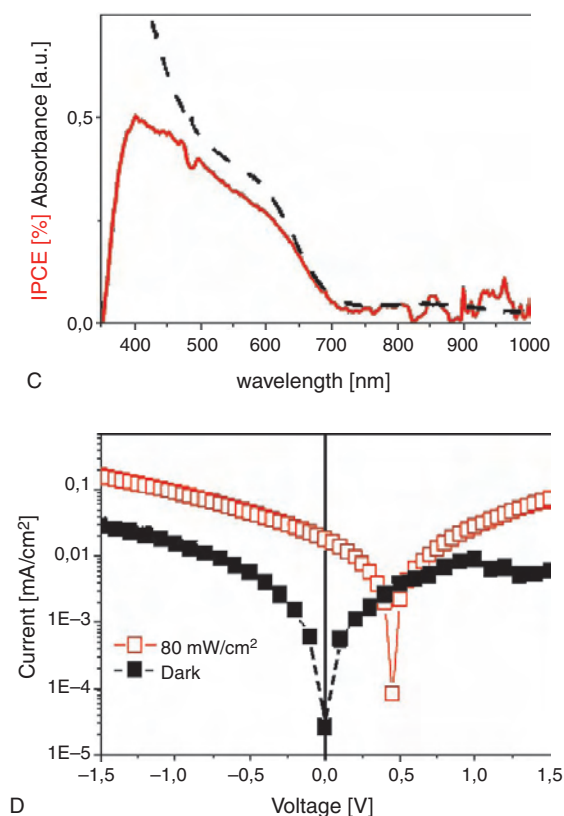
Figure 5. (A) Purely CIS nanocrystal shown by transmission electron micrographs with dimensions of ca. 5×12 nm. The particle size distribution in general depends strongly on the preparation parameters; we received particles with dimensions starting with 5×5 up to tens of nanometers. (B) Photocurrent and absorbance spectra for CIS layers show similar form with an edge at 700 nm, indicating the size quantization. (C) Atomic force micrographs of the sample, characterized by (B), show a homogeneous film with an agglomerate size of ca. 50 nm. (D) The current-voltage characteristics of the CIS device exhibit a short circuit current of 20 μA/cm^2 and 450 mV under illumination with simulated AM 1.5 global light (semilogarithmic plot).


Figure 5. Continued.

material absorption at 825 nm [131]. The absorption spectrum of films, prepared via spin-coating from a 0.06 M solution of CIS dispersions, exhibits a high shoulder at 700 nm and a weak absorbance at longer wavelengths (Fig. 5C). The IPCE onset is more or less identical with the onsets of the corresponding absorbance spectra. It is obvious that quantized CIS particles are photovoltaic active.

In the case of an ITO/PEDOT:PSS/CIS/LiF/Al photovoltaic device, a short circuit density I_{sc} of 20 μA/cm^2 and an open circuit voltage V_{oc} of 450 mV have been reported. A fill factor of about 0.25 indicates high serial resistance. However, a low rectification ratio RR at $+/-2$ V in dark conditions of 2.5 and under illumination of 6.5 indicates nonoptimized diode characteristics (Fig. 5D). Repeating the measurements and drying the films under argon leads to an improvement of the cell.

Flat interfaces formed in bilayer structures of the CIS and the nicely soluble methanofullerene, 1-(3-methoxy carbonyl)-propyl-1-1-phenyl-(6,6) C_{61} (PCBM), have shown a significant improvement in the photovoltaic performance [27]. PCBM is the electron-transporting and hole-blocking "gate" material in this bilayer configuration [132]. An additional advantage of PCBM is its solubility in toluene. TPP capped CIS particles are also slightly soluble in toluene. However, when PCBM is deposited onto a previously prepared CIS film, some swelling of the CIS layer may occur and some roughening of the formed interfaces between two layers.

The CIS//PCBM double layer exhibits a reasonable diode behavior with a typical current versus voltage I-V response

(Fig. 6). Illuminating the cell with 80 mW/cm^2 white light from a solar simulator produces an open circuit voltage, V_{oc}, of 710–790 mV and a short circuit current density of ca. 0.26 mA/cm^2. The calculated fill factor of the diode is 0.44. Conversion efficiency of 0.086% is obtained. The rectification ratio low at $+/-2$ V is 2.5 in the dark and 3.5 under illumination.

The dependence of the short circuit current on the incident light intensity, which follows a power law $I_{sc} \sim F^{\alpha}$ with a scaling exponent α, has been fitted around 0.7 for single layers of CIS. On the other hand, for the bilayer configurations CIS//PCBM, the dependence of the I_{sc} follows a power law $I_{sc} \sim F^{\alpha}$ with $\alpha \sim 0.9$.

It is obvious that in layers of TPP capped CIS, contrary to the layers consisting of TOPO capped CdS nanocrystals, a photovoltaic response can be detected without removing the organic ligand. TPP seems to be weakly bound on the inorganic core and not totally insulating the particles from each other.

The fact that particle growth occurs already by changing the viscosity of the dispersion solution leads us to the assumption that the organic shell TPP is adsorbed only reversibly on the CIS core. There might be a cooperative interaction between core, shell, and solvent. Tailoring the ratio of the concentration of organic shell to that of the correctly chosen solvent, acetonitrile provides control over the nanoparticle size, since low shell-to-solvent ratio favors the formation of bigger CIS particles. Reducing the amount of acetonitrile leads to weakening of the complexation capability of the TPP and results in a loss of size control. The absorption maximum shifts to the longer wavelengths like the bulk material. The existence of large domains in CIS and MDMO-PPV or P3HT layers, which were spin-cast from a toluene suspension, are in agreement with this argument.

We investigated a bulk heterojunction device prepared from CIS and highly p-doped poly(3,4-ethylenedioxythiophene):poly(4-styrenesulfonate) complex (PEDOT: PSS). The main point thereby was to prepare a well-percolating film, while at the same time to avoid the CIS particle-growth during the preparation [132]. The advantage of PEDOT-PSS is in this aspect its solubility in acetonitrile/TPP mixtures. PEDOT:PSS does not absorb in the visible range. Therefore it is easy to investigate the size distribution of the CIS particles by studying the absorbance behavior of CIS depending on the preparation. The aim was to form an interconnected network of the nanoparticle and of the polymer, so that the charge separation can occur at the very large interfacial area of the nanoparticle-polymer contacts. The optical and microscopic investigations on the layers of CIS-PEDOT:PSS blends showed that the nanoparticles do not grow during spin-coating from an acetonitrile dispersion of CIS and PEDOT:PSS.

In our systems, due to the high HOMO level of PEDOT:PSS ($E_{HOMO} \sim -5.0$ eV) not far from the work function of the Al electrode (~ -4.3 eV), an ohmic contact can be formed even to this electrode short circuiting the cell (Fig. 7).

By white-light illumination of an ITO/CIS-PEDOT: PSS/LiF/Al cell with a power intensity of 80 mW/cm^2, we received an open circuit voltage, V_{oc}, of 150 mV and a short circuit current density of 4 μA/cm^2. The calculated fill factor

Figure 7. Energy levels of investigated materials. The HOMO-LUMO levels of macroscopic CIS are about -5.6 eV and -4.1 eV. Because of the size distribution of the quantized CIS particles, a distribution of their energy gaps must be expected. The anticipated maximal broadening of HOMO and LUMO levels from the smallest particle up to macroscopic CIS is calculated by adding the maximal hypsochromic shift of CIS absorption in acetonitrile dispersion to the literature data of bulk CIS. However, for relatively large particles, the bandgap might be smaller than shown here. Reprinted with permission from [132], E. Arici et al., *Adv. Funct. Mater.* 13, 165 (2003). © 2003, Wiley.

Figure 6. (left) Schematic structure of bilayer devices ITO/CIS/PCBM/Al and their *I-V* characteristics in dark and under illumination with simulated AM 1.5 global light (Inset: The molecular structure of PCBM.) (right) Schematic structure of "optimized" bulk heterojunction devices ITO/CIS-PEDOT:PSS/PCBM/Al and their *I-V* characteristic in dark and under illumination with simulated AM 1.5 global light (Inset: The molecular structure of the polymer PEDOT:PSS.)
of the diode is 0.1. A conversion efficiency of only 0.003% is obtained. There is no rectification in the dark and a rectification ratio of 2.2 at $+/-2$ V under illumination [132].

In order to prevent the short circuiting contact between the hole conductor PEDOT:PSS and the electron-collecting Al electrode, a PCBM interlayer was introduced (HOMO $= -6.4$ eV, LUMO $= -4.2$ eV). Thereby a white-light illumination of the cell with a power intensity of 80 mW/cm^2 produced an open circuit voltage, V_{oc}, of 220 mV and a short circuit current density of 0.84 mA/cm^2 (Fig. 6b). The rectification ratio in the dark is 13.1 at $+/-2$ V and 11.3 under illumination.

The most significant differences between the different cell types investigated can be seen from the incident-photon-to-current-conversion efficiencies (IPCE) spectra (Fig. 8). The IPCE onsets are more or less identical with the onsets of the corresponding absorbance spectra. The photocurrent response is not limited by the absorption depth of the film. The obtained photocurrent for the CIS single layer is very poor; the photogenerated excitons mostly recombine before they can reach the electrodes. However, current generation can be significantly improved by adding PCBM as a strong electron acceptor.

Because of the ohmic contact between PEDOT:PSS and the Al electrode, the IPCE value is decreased for CIS-PEDOT:PSS monolayers as compared to the monolayer of nanocrystalline CIS. The IPCE value of CIS-PEDOT:PSS/

PCBM bilayer gives by far the best results. The holes move along the PEDOT:PSS network towards the high work function electrode ITO and the electrons, in turn, can move through the PCBM layer, where they can easily be transported to the Al electrode, whereas the holes are blocked by the high ionization energy of the PCBM HOMO level.

3.3. Hybrid Solar Cells based on TiO₂ Nanocrystals

Dye-sensitized nanocrystalline TiO₂ solar cells [2, 161] are based on a fundamentally different working principle than solar cells described in Sections 3.1 and 3.2. The semiconductor used in these devices is not photoexcited directly, in contrast to the case for the p/n photovoltaic cells. Briefly speaking, these cells consist of a nanoporous working electrode formed by a sintered film of TiO₂ semiconductor nanoparticles (10–30 nm in diameter), which serves as electron acceptor and transport layer. The TiO₂ layer is coated with a single layer of a Ru-bipyridl-based dye for light absorption and electron injection into the TiO₂ conduction band. An electrolyte solution containing the redox couple like iodide/triiodide (I^-/I_3^-) serves as redox medium to regenerate the photoexcited dye molecules by reduction. Charge separation occurs at the semiconductor/electrolyte interface. For the operation of the photoelectrochemical device, the counter electrode (Au or Pt) is sealed to the working photoelectrode with a spacer, whereas the volume between the electrodes is filled with the electrolyte solution. Photovoltaic energy conversion efficiencies as high as 10–11% at AM 1.5 standard solar spectrum have been achieved [134].

Recent efforts in dye-sensitized nanocrystalline TiO₂ solar cell research are focusing more on replacing the liquid electrolyte with solid-state analogous to eliminate problems with sealing and degradation. Early work was focused on use of solid-state p-type conductors CuI [135, 136] and CuSCN [137, 138]. Cells made in this way gave solar efficiencies of several percents, but they were not stable in air and under illumination.

Various procedures have been employed in the fabrication of solid-state dye-sensitized solar cells with p-type organic materials, that accept holes from the Ru-bipyridl-based dye cation. Triphenyldiamine, for example, is a hole conductor with high intrinsic charge carrier mobilities of about 10^{-3} cm^2 V^{-1} s^{-1} at room temperature. Nevertheless, replacing the liquid electrolyte by a triphenyldiamine layer via evaporation led to low external quantum efficiencies (IPCE) up to 0.2% [139].

For an efficient cell, organic materials placed on the top of the working electrode should penetrate into the nanoporous TiO₂ and should form a good contact to the adsorbed dye. Crystallization of the organic material is undesirable, as it would impair the formation of a good contact between the electrode and the hole conductor. Triphenyldiamine and semiconducting polymers based on triphenyldiamine have been investigated in order to understand the relationship between the film-forming properties, dye stability, and cell performance [140, 141].

The hole-conductor material containing a spiro center (a tetrahedral carbon linking two aromatic moieties), namely, 2,2′7,7′-tetrakis (N,N-di-p-methoxyphenyl-amine) 9,9′-spiro-bifluorene (spiro-OMeTAD), has been introduced as an alternative because of its relatively high glass transition temperature and amorphous film-forming properties via spin-coating. In these systems, a better electronic contact between the dye molecules and the hole conductor accompanied by increasing penetration of the solid hole conductors, leads to IPCE values up to 5% by illuminating through the working electrode. In the presence of additives, which oxidize partly the hole-conductive material and increase the amount of the free charge carriers, the maximum value of the IPCE is 33% [142]. This value is only a factor of ca. 2 lower than with liquid electrodes for the same working electrode/dye system [134].

An attractive idea is to sensitize the high-surface-area p-n heterojunction between TiO₂ and spiro-OMeTAD by using PbS quantum dots. PbS nanoparticles were formed *in-situ* on the porous TiO₂ electrode using chemical deposition techniques. These cells showed IPCE values of up to 45% [143].

An alternative approach to low molecular hole conductors is the use of polymer gel electrodes. In this case, plasticizers are used as additive during the preparation of the electrolyte to increase the chain mobility and the ionic conductivity of the electrolyte. The existence of the polymer gelling agents in the liquid electrolyte promotes its solidification afterwards [144–146]. These approaches have yielded "quasi-solid-state" devices with energy conversion efficiencies similar to those achievable with liquid electrolytes. However, the sealing of such cells remains still a problem.

The use of polymer electrolytes in such dye-sensitized photovoltaic cells exploits the advantages of ionic conduction and easy processing [147]. Polymer electrolytes comprising a poly(epichlorohydrin-co-ethylen oxide) elastomer, NaI and I₂ as mobile redox carriers, have been reported as an effective hole transporter in solid-state dye-sensitized devices. The maximum value of the IPCE reported is about 52% by illuminating through the working electrode [148, 149]. Devices have been fabricated also using

a polymer electrolyte consisting of high-molecular-mass poly(ethylene oxide) filled with titanium oxide spherical particles (20 nm in diameter), LiI, and I_2. These cells present IPCE values as high as 40% [150].

Another method to form a good penetration between the dye-sensitized working electrode and solid hole conductor is *in-situ* photoelectrochemical polymerization. This concept is realized for polypyrrole [151] and poly(3,4-ethylene-dioxythiophene) [152] based devices.

In principle, the dye can also be replaced by the semiconducting polymer layer, bringing together the functions of light absorption and charge transport in a single material. Photovoltaic studies on junctions consisting of MEH-PPV on TiO_2 have shown that on excitation of the MEH-PPV layer, electrons are injected into the conduction band of TiO_2 [153]. The maximum value of the IPCE is about 6% [154]. Comparative studies using poly(3-octylthiophene) and its derivatives have been also investigated [155–157].

One of the problems associated with conjugated polymers and nanocrystalline TiO_2 bilayers is the inefficient filling of the TiO_2 pores, which leads to charge transport limited devices. Increasing the size of the TiO_2 pores, on the other hand, leads to devices with a smaller interface for charge generation. An alternative idea is to prepare bulk heterojunction devices in which a continuous network of TiO_2 is created inside a MDMO-PPV film [158].

Using the bulk heterojunction concept, the resulting IPCE value is up to 11%. For such devices, additional processes and parameters contribute to the efficiency, including the exciton diffusion length and efficiency of the electron transfer from the polymer layer into TiO_2 [159, 160].

4. OUTLOOK

Research efforts over the last decade have led to a number of new strategies for the preparation of organic/inorganic hybrid solar cells. Earlier methods have primarily focused on achieving nanocrystalline layers of well-defined inorganic materials and covering them in a second step with a semiconductive polymer layer. A new field of scientific research has grown out of the new strategy of creating composite layers of organic/inorganic blends with huge surface areas for charge separation. More recent approaches, particularly those based on core-shell particles, have been shown to be effective in producing composite blends by easy processing techniques like spin-coating. These techniques permit remarkable control over the layer thickness, and thus the assembled components and experimental conditions can be easily manipulated to create the favorable morphology for a better performance of a hybrid solar cell. The synthetic approaches outlined provide a high level of flexibility, thus allowing the cell design to be variable. On the other hand, the morphology control of organic/inorganic blends is still in its infancy.

A number of major scientific advances in the construction of bulk heterojunction hybrid solar cells have occurred recently and many more are expected. It is envisioned that future research will, to a large extent, continue to be focused on optimizing existing approaches, as well as developing new procedures, in order to modify the surface properties of nanoparticles. An interesting extension of the core/shell nanoparticles may be the manufacturing of semiconductive polymer layers on the surfaces of nanoparticles instead of using insulating organic shells between them. Accordingly, assembling of nanoparticles into colloidal crystals is expected to be an additional strategy for the morphology control. Finally, a significant goal is the development of the long-term stability.

GLOSSARY

Bulk heterojunction Interconnected network structure created by blending of an electron-accepting and a hole-accepting material, whereas the exciton dissociation can occur at a donor-acceptor interface.

Excitons Electron-hole pairs generated in the material upon absorption of photons are the so-called excitons. Thereby an electron will be promoted from the valence band to the conduction band, leaving a positively charged "hole" behind. This hole can be thought of as the absence of an electron and acts as a particle with its own effective mass and charge in the solid, when exciton dissociation occurs.

Ostwald ripening The growth mechanism where the smaller particles dissolve and the monomer released thereby is consumed by the larger particles. As a result the average nanocrystal size increases with time and the particle concentration decreases.

Percolation Percolation takes place when the electron acceptor and donor concentrations reach the value high enough to provide the conduction along the interconnected network of each type of materials in a bulk heterojunction structure.

Size quantization The bandgap of a quantum confined semiconductor is greater than that of the parent bulk material from which it is derived. This effect is a consequence of the confinement of the electron in a three-dimensional "box" with discrete energy levels rather than in the quasi-continuous band of a bulk material. The electronic and optical properties of such small particles will depend not only on the material of which they are composed, but also on their size.
