Preface

The Encyclopedia of Algorithms provides researchers, students, and practitioners of algorithmic research with a mechanism to efficiently and accurately find the names, definitions, and key results of important algorithmic problems. It also provides further readings on those problems.

This *encyclopedia* covers a broad range of algorithmic areas; each area is summarized by a collection of entries. The entries are written in a clear and concise structure so that they can be readily absorbed by the readers and easily updated by the authors. A typical encyclopedia entry is an in-depth mini-survey of an algorithmic problem written by an expert in the field. The entries for an algorithmic area are compiled by area editors to survey the representative results in that area and can form the core materials of a course in the area.

This 2nd edition of the encyclopedia contains a wide array of important new research results. Highlights include works in tile self-assembly (nanotechnology), bioinformatics, game theory, Internet algorithms, and social networks. Overall, more than 70 % of the entries in this edition and new entries are updated.

This reference work will continue to be updated on a regular basis via a live site to allow timely updates and fast search. Knowledge accumulation is an ongoing community project. Please take ownership of this body of work. If you have feedback regarding a particular entry, please feel free to communicate directly with the author or the area editor of that entry. If you are interested in authoring a future entry, please contact a suitable area editor. If you have suggestions on how to improve the Encyclopedia as a whole, please contact me at kao@northwestern.edu. The credit of this Encyclopedia goes to the area editors, the entry authors, the entry reviewers, and the project editors at Springer, including Melissa Fearon, Michael Hermann, and Sylvia Blago.

About the Editor

Ming-Yang Kao is a Professor of Computer Science in the Department of Electrical Engineering and Computer Science at Northwestern University. He has published extensively in the design, analysis, and applications of algorithms. His current interests include discrete optimization, bioinformatics, computational economics, computational finance, and nanotechnology. He serves as the Editor-in-Chief of Algorithmica.

He obtained a B.S. in Mathematics from National Taiwan University in 1978 and a Ph.D. in Computer Science from Yale University in 1986. He previously taught at Indiana University at Bloomington, Duke University, Yale University, and Tufts University. At Northwestern University, he has served as the Department Chair of Computer Science. He has also cofounded the Program in Computational Biology and Bioinformatics and served as its Director. He currently serves as the Head of the EECS Division of Computing, Algorithms, and Applications and is a Member of the Theoretical Computer Science Group.

2008; Mosca

Problem Definition

The Abelian hidden subgroup problem is the problem of finding generators for a subgroup K of an Abelian group G, where this subgroup is defined implicitly by a function $f : G \to X$, for some finite set X. In particular, f has the property that $f(v) = f(w)$ if and only if the cosets (we are assuming additive notation for the group operation here.) $v+K$ and $w+K$ are equal. In other words, f is constant on the cosets of the subgroup K and distinct on each coset.

It is assumed that the group G is finitely generated and that the elements of G and X have unique binary encodings. The binary assumption is only for convenience, but it is important to have unique encodings (e.g., in [22] Watrous uses a quantum state as the unique encoding of group elements). When using variables g and h (possibly with subscripts), multiplicative notation is used for the group operations. Variables x and y (possibly with subscripts) will denote integers with addition. The boldface versions $\mathbf{x}$ and $\mathbf{y}$ will denote *tuples* of integers or binary strings.

By assumption, there is computational means of computing the function f, typically a circuit or "black box" that maps the encoding of a value g to the encoding of $f(g)$. The theory of reversible computation implies that one can turn a circuit for computing $f(g)$ into a reversible circuit for computing $f(g)$ with a modest increase in the size of the circuit. Thus, it will be assumed that there is a reversible circuit or black box that maps $(g, \mathbf{z}) \mapsto (g, \mathbf{z} \oplus f(g))$, where $\oplus$ denotes the bit-wise XOR (sum modulo 2), and $\mathbf{z}$ is any binary string of the same length as the encoding of $f(g)$.

Quantum mechanics implies that any reversible gate can be extended linearly to a unitary operation that can be implemented in the model of quantum computation. Thus, it is assumed that there is a quantum circuit or

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

black box that implements the unitary map $U_f : |g\rangle|\mathbf{z}\rangle \mapsto |g\rangle|\mathbf{z} \oplus f(g)\rangle$.

Although special cases of this problem have been considered in classical computer science, the general formulation as the hidden subgroup problem seems to have appeared in the context of quantum computing, since it neatly encapsulates a family of black-box problems for which quantum algorithms offer an exponential speedup (in terms of query complexity) over classical algorithms. For some explicit problems (i.e., where the black box is replaced with a specific function, such as exponentiation modulo N), there is a conjectured exponential speedup.

Abelian Hidden Subgroup Problem:

Input: Elements $g_1, g_2, \ldots, g_n \in G$ that generate the Abelian group G. A black box that implements $U_f : |m_1, m_2, \ldots, m_n\rangle|\mathbf{y}\rangle \mapsto |m_1, m_2, \ldots, m_n\rangle|f(g) \oplus \mathbf{y}\rangle$ where $g = g_1^{m_1} g_2^{m_2} \ldots g_n^{m_n}$ and K is the hidden subgroup corresponding to f.

Output: Elements $h_1, h_2, \ldots, h_l \in G$ that generate K.

Here we use multiplicative notation for the group G in order to be consistent with Kitaev's formulation of the Abelian stabilizer problem. Most of the applications of interest typically use additive notation for the group G.

It is hard to trace the precise origin of this general formulation of the problem, which simultaneously generalizes "Simon's problem" [20], the order-finding problem (which is the quantum part of the quantum factoring algorithm [18]), and the discrete logarithm problem.

One of the earliest generalizations of Simon's problem, order-finding problem, and discrete logarithm problem, which captures the essence of the Abelian hidden subgroup problem, is the *Abelian stabilizer problem* which was solved by Kitaev using a quantum algorithm in his 1995 paper [14] (and also appears in [15, 16]).

Let G be a group acting on a finite set X. That is, each element of G acts as a map from X to X in such a way that for any two elements $g, h \in G$, $g(h(z)) = (gh)(z)$ for all $z \in X$. For a particular element $z \in X$, the set of elements that fix z (i.e., the elements $g \in G$ such that $g(z) = z$) form a subgroup. This subgroup is called the stabilizer of z in G, denoted $St_G(z)$.

Abelian Stabilizer Problem:

Input: Elements $g_1, g_2, \ldots, g_n \in G$ that generate the group G. An element $z \in X$. A black box that implements $U_{(G,X)} : |m_1, m_2, \ldots, m_n\rangle|z\rangle \mapsto |m_1, m_2, \ldots, m_n\rangle|g(z)\rangle$ where $g = g_1^{m_1} g_2^{m_2} \ldots g_n^{m_n}$.

Output: Elements $h_1, h_2, \ldots, h_l \in G$ that generate $St_G(z)$.

Let f_z denote the function from G to X that maps $g \in G$ to $g(z)$. One can implement U_{f_z} using $U_{(G,X)}$. The hidden subgroup corresponding to f_z is $St_G(z)$. Thus, the Abelian stabilizer problem is a special case of the Abelian hidden subgroup problem.

One of the subtle differences (discussed in Appendix 6 of [12]) between the above formulation of the Abelian stabilizer problem and the Abelian hidden subgroup problem is that Kitaev's formulation gives a black box that for any $g, h \in G$ maps $|m_1, \ldots, m_n\rangle|f_z(h)\rangle \mapsto |m_1, \ldots, m_n\rangle|f_z(hg)\rangle$, where $g = g_1^{m_1} g_2^{m_2} \ldots g_n^{m_n}$. The algorithm given by Kitaev is essentially one that estimates eigenvalues of shift operations of the form $|f_z(h)\rangle \mapsto |f_z(hg)\rangle$. In general, these shift operators are not explicitly needed, and it suffices to be able to compute a map of the form $|\mathbf{y}\rangle \mapsto |f_z(h) \oplus \mathbf{y}\rangle$ for any binary string $\mathbf{y}$.

Generalizations of this form have been known since shortly after Shor presented his factoring and discrete logarithm algorithms (e.g., [23] presents the hidden subgroup problem for a large class of finite Abelian groups or more generally in [11] for finite Abelian groups presented as a product of finite cyclic groups. In [17] the natural Abelian hidden subgroup algorithm is related to eigenvalue estimation.)

Other problems which can be formulated in this way include:

Deutsch's Problem:

Input: A black box that implements $U_f : |x\rangle|b\rangle \mapsto |x\rangle|b \oplus f(x)\rangle$, for some function f that maps $\mathbb{Z}_2 = \{0, 1\}$ to $\{0, 1\}$.

Output: "constant" if $f(0) = f(1)$ and "balanced" if $f(0) \neq f(1)$.

Note that $f(x) = f(y)$ if and only if $x - y \in K$, where K is either $\{0\}$ or $\mathbb{Z}_2 = \{0, 1\}$. If $K = \{0\}$, then f is $1-1$ or "balanced," and if $K = \mathbb{Z}_2$, then f is constant [5,6].

Simon's Problem:

Input: A black box that implements $U_f : |\mathbf{x}\rangle|\mathbf{b}\rangle \mapsto |\mathbf{x}\rangle|\mathbf{b} \oplus f(\mathbf{x})\rangle$ for some function f from $\mathbb{Z}_2^n$ to some set X (which is assumed to consist of binary strings of some fixed length) with the property that $f(\mathbf{x}) = f(\mathbf{y})$ if and only if $\mathbf{x} - \mathbf{y} \in K = \{\mathbf{0}, \mathbf{s}\}$ for some $\mathbf{s} \in \mathbb{Z}_2^n$.
Output: The "hidden" string $\mathbf{s}$.

The decision version allows $K = \{\mathbf{0}\}$ and asks whether K is trivial. Simon [20] presents an efficient algorithm for solving this problem and an exponential lower bound on the query complexity. The solution to the Abelian hidden subgroup problem is a generalization of Simon's algorithm.

Key Results

Theorem (ASP) There exists a quantum algorithm that, given an instance of the Abelian stabilizer problem, makes $n + O(1)$ queries to $U_{(G,X)}$ and uses poly(n) other elementary quantum and classical operations, with probability at least $\frac{2}{3}$ output values $h_1, h_2, \ldots, h_l$ such that $St_G(z) = \langle h_1\rangle \oplus \langle h_2\rangle \oplus \cdots \langle h_l\rangle$.

Kitaev first solved this problem (with a slightly higher query complexity, because his eigenvalue estimation procedure was not optimal). An eigenvalue estimation procedure based on the Quantum Fourier Transform achieves the $n + O(1)$ query complexity [5].

Theorem (AHSP) There exists a quantum algorithm that, given an instance of the Abelian hidden subgroup problem, makes $n+O(1)$ queries to U_f and uses poly(n) other elementary quantum and classical operations, with probability at least $\frac{2}{3}$ output values $h_1, h_2, \ldots, h_l$ such that $K = \langle h_1\rangle \oplus \langle h_2\rangle \oplus \cdots \langle h_l\rangle$.

In some cases, the success probability can be made 1 with the same complexity, and in general the success probability can be made $1 - \epsilon$ using $n + O(\log(1/\epsilon))$ queries and poly$(n, \log(1/\epsilon))$ other elementary quantum and classical operations.

Applications

Most of these applications in fact were known before the Abelian stabilizer problem or hidden subgroup problem were formulated.

Finding the order of an element in a group: Let a be an element of a group H (which does *not* need to be Abelian), and let r be the smallest positive integer so that $a^r = 1$.

Consider the function f from $G = \mathbb{Z}$ to the group H where $f(x) = a^x$ for some element a of H. Then $f(x) = f(y)$ if and only if $x - y \in r\mathbb{Z}$. The hidden subgroup is $K = r\mathbb{Z}$ and a generator for K gives the order r of a.

Finding the period of a periodic function: Consider a function f from $G = \mathbb{Z}$ to a set X with the property that for some positive integer r, we have $f(x) = f(y)$ if and only if $x - y \in r\mathbb{Z}$. The hidden subgroup of f is $K = r\mathbb{Z}$ and a generator for K gives the period r.

Order finding is a special case of period finding and was also solved by Shor's algorithm [18].

Discrete Logarithms: Let a be an element of a group H (which does *not* need to be Abelian), with $a^r = 1$, and suppose $b = a^k$ from some unknown k. The integer k is called the *discrete logarithm of b to the base a*. Consider the function f from $G = \mathbb{Z}_r \times \mathbb{Z}_r$ to H satisfying $f(x_1, x_2) = a^{x_1} b^{x_2}$. Then $f(x_1, x_2) = f(y_1, y_2)$ if and only if $(x_1, x_2) - (y_1, y_2) \in \{(t, -tk), t = 0, 1, \ldots, r - 1\}$ which is the subgroup $\langle(1, -k)\rangle$ of $\mathbb{Z}_r \times \mathbb{Z}_r$. Thus, finding a generator for the hidden subgroup K will give

the discrete logarithm k. Note that this algorithm works for H equal to the multiplicative group of a finite field, or the additive group of points on an elliptic curve, which are groups that are used in public-key cryptography.

Recently, Childs and Ivanyos [3] presented an efficient quantum algorithm for finding **discrete logarithms in semigroups**. Their algorithm makes use of the quantum algorithms for period finding and discrete logarithms as subroutines.

Hidden Linear Functions: Let σ be some permutation of $\mathbb{Z}_N$ for some integer N. Let h be a function from $G = \mathbb{Z} \times \mathbb{Z}$ to $\mathbb{Z}_N$, $h(x, y) = x + ay \mod N$. Let $f = \sigma \circ h$. The hidden subgroup of f is $\langle(-a, 1)\rangle$. Boneh and Lipton [1] showed that even if the linear structure of h is hidden (by σ), one can efficiently recover the parameter a with a quantum algorithm.

Self-Shift-Equivalent Polynomials: Given a polynomial P in l variables $X_1, X_2, \ldots, X_l$ over $\mathbb{F}_q$, the function f that maps $(a_1, a_2, \ldots, a_l) \in \mathbb{F}_q^l$ to $P(X_1 - a_1, X_2 - a_2, \ldots, X_l - a_l)$ is constant on cosets of a subgroup K of $\mathbb{F}_q^l$. This subgroup K is the set of shift-self-equivalences of the polynomial P. Grigoriev [10] showed how to compute this subgroup.

Decomposition of a Finitely Generated Abelian Group: Let G be a group with a unique binary representation for each element of G, and assume that the group operation, and recognizing if a binary string represents an element of G or not, can be done efficiently.

Given a set of generators $g_1, g_2, \ldots, g_n$ for a group G, output a set of elements $h_1, h_2, \ldots, h_l$, $l \leq n$, from the group G such that $G = \langle g_1\rangle \oplus \langle g_2\rangle \oplus \ldots \oplus \langle g_l\rangle$. Such a generating set can be found efficiently [2] from generators of the hidden subgroup of the function that maps $(m_1, m_2, \ldots, m_n) \mapsto g_1^{m_1} g_2^{m_2} \ldots g_n^{m_n}$.

This simple algorithm directly leads to an algorithm for computing the class group and class number of a quadratic number field, as pointed out by Watrous [22] in his paper that shows how to compute the order of solvable groups. Computing the class group of a more general number field is a much more difficult task: this and related problems have been successfully tackled in a series of elegant work summarized in ▸ Quantum Algorithms for Class Group of a Number Field.

Such a decomposition of Abelian groups was also applied by Friedl, Ivanyos, and Santha [9] to test if a finite set with a binary operation is an Abelian group, by Kedlaya [13] to compute the zeta function of a genus g curve over a finite field $\mathbb{F}_q$ in time polynomial in g and q, and by Childs, Jao, and Soukharev [4] in order to construct elliptic curve isogenies in subexponential time.

Discussion: What About Non-Abelian Groups?

The great success of quantum algorithms for solving the Abelian hidden subgroup problem leads to the natural question of whether it can solve the hidden subgroup problem for non-Abelian groups. It has been shown that a polynomial number of queries suffice [8]; however, in general there is no bound on the overall computational complexity (which includes other elementary quantum or classical operations).

This question has been studied by many researchers, and efficient quantum algorithms can be found for some non-Abelian groups. However, at present, there is no efficient algorithm for most non-Abelian groups. For example, solving the HSP for the symmetric group would directly solve the graph automorphism problem.

Abstract Voronoi Diagrams

Rolf Klein
Institute for Computer Science, University of Bonn, Bonn, Germany

Keywords

Abstract Voronoi diagram; Bisector; Computational geometry; Metric; Voronoi diagram

Years and Authors of Summarized Original Work

2009; Klein, Langetepe, Nilforoushan

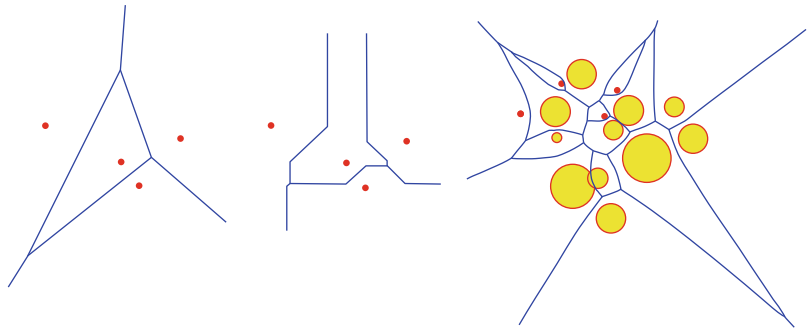
Problem Definition

Concrete Voronoi diagrams are usually defined for a set S of sites p that exert influence over the points z of a surrounding space M. Often, influence is measured by distance functions $d_p(z)$ that are associated with the sites. For each p, its *Voronoi region* is given by

$$\mathrm{VR}(p,S) = \{z \in M;\ d_p(z) < d_q(z) \text{ for all } q \in S \setminus \{p\}\},$$

and the *Voronoi diagram* $V(S)$ of S is the decomposition of M into Voronoi regions; compare the entry ▸ Voronoi Diagrams and Delaunay Triangulations of this Encyclopedia.

Quite different Voronoi diagrams result depending on the particular choices of space, sites, and distance measures; see Fig. 1. A great number of other types of Voronoi diagrams can be found in the monographs [1] and [14]. In each



Abstract Voronoi Diagrams, Fig. 1 Voronoi diagrams of points in the Euclidean and Manhattan metric and of disks (or additively weighted points) in the Euclidean plane

case, one wants to quickly compute the Voronoi diagram, because it contains a lot of distance information about the sites. However, the classical algorithms for the standard case of point sites in the Euclidean plane do not apply to more general situations.

To free us from designing individual algorithms for each and every special case, we would like to find a unifying concept that provides structural results and efficient algorithms for generalized Voronoi diagrams. One possible approach studied in [5,6] is to construct the lower envelope of the 3-dimensional graphs of the distance functions $d_p(z)$, whose projection to the XY-plane equals the Voronoi diagram.

Key Results

A different approach is given by *abstract Voronoi diagrams* that are not based on the notions of sites and distance measures (as their definitions vary anyway). Instead, AVDs are built from *bisecting curves* as primary objects [7].

Let $S = \{p, q, r, \ldots\}$ be a set of n indices, and for $p \neq q \in S$, let $J(p,q) = J(q,p)$ denote an unbounded curve that bisects the plane into two unbounded open domains $D(p,q)$ and $D(q,p)$. We require that each $J(p,q)$ is mapped to a closed Jordan curve through the north pole, under stereographic projection to the sphere. Now we define Voronoi regions by

$$\mathrm{VR}(p,S) := \bigcap_{q \in S \setminus \{p\}} D(p,q)$$

and the abstract Voronoi diagram by

$$V(S) := \mathbf{R}^2 \setminus \bigcup_{p \in S} \mathrm{VR}(p,S).$$

The system $\mathbf{J}$ of the curves $J(p,q)$ is called *admissible* if the following axioms are fulfilled for every subset T of S of size three.

A1. Each Voronoi region $\mathrm{VR}(p,T)$ *is pathwise connected.*

A2. Each point of $\mathbf{R}^2$ *lies in the closure of a Voronoi region* $\mathrm{VR}(p,T)$.

These combinatorial properties should not be too hard to check in a concrete situation because only triplets of sites need to be inspected. Yet, they form a strong foundation, as was shown in [8]. The following fact is crucial for the proof of Theorem 1. It also shows that AVDs can be seen as lower envelopes of surfaces in dimension 3.

Lemma 1 *For all* p,q,r *in* S, *we have* $D(p,q) \cap D(q,r) \subset D(p,r)$. *Consequently, for each point* $z \in \mathbf{R}^2$ *not contained in any curve of* $\mathbf{J}$, *the relation*

$$p <_z q \;:\Leftrightarrow\; z \in D(p,q)$$

is an ordering of the sites in S *at* z.

Theorem 1 *If* $\mathbf{J}$ *is admissible, then axioms A1 and A2 hold for all subsets* T *of* S. *Moreover, the abstract Voronoi diagram* $V(S)$ *is a planar graph of size* $O(n)$.

Of the classical algorithm for constructing Voronoi diagrams, the randomized incremental construction method works best for abstract Voronoi diagrams [8, 10].

Theorem 2 *If* **J** *is admissible, then* $V(S)$ *can be constructed in an expected number of* $O(n \log n)$ *many steps and in expected linear space.*

Here basic operations like computing an intersection of two bisecting curves are counted as one step.

Applications

To show that a concrete type of Voronoi diagram is under the roof of abstract Voronoi diagrams, one needs to prove that its bisector system is admissible.

Let d be a metric in the plane that enjoys the following properties. Each d-disk contains a Euclidean disk and vice versa; for any two points a, b, there exists a point c different from a and b such that $d(a,b) = d(a,c) + d(c,b)$ holds; for any two points a, b, their metric bisector

$$B_d(a,b) = \{z \in \mathbf{R}^2;\ d(a,z) = d(b,z)\}$$

is itself a curve that maps to a closed Jordan curve through the north pole by stereographic projection to the sphere, or, in case $B_d(p,q)$ contains 2-dimensional pieces, its boundary consists of two such curves.

The first two properties ensure that any two points can be connected by a d-straight path along which d-distances add up. The third condition ensures that we can choose from $B_d(p,q)$ suitable bisecting curves. Let us call metric d *very nice* if also a fourth condition is fulfilled. Given three points a, p_0, p_1, there exist d-straight paths from a to p_0 and from a to p_1 that have only point a in common, or each d-straight path from a to p_i contains p_{1-i} for $i = 0$ or $i = 1$. All *convex distance functions (gauges)* are very nice.

Theorem 3 *Very nice metrics have admissible point bisector curves.*

Other applications of AVDs include points with additive weights, both the regular and the Hausdorff Voronoi diagram of disjoint convex sites with respect to a convex distance function, and some types of city Voronoi diagrams; see [1] for further details.

Generalizations

How to *dynamize* abstract Voronoi diagrams has been studied in [12]. Special cases of *3-dimensional* abstract Voronoi diagrams have been discussed in [11]; they include all convex distance functions whose unit spheres are ellipsoids. It is well known that for the vertices of a *convex polygon*, the Voronoi diagram can be constructed in linear time. This result has been generalized to AVDs in [9] and [4]. In [3] the *path-connectedness* of abstract Voronoi regions (axiom A1) has been relaxed. If a region of three sites can have up to s connected components, the abstract Voronoi diagram can still be constructed in expected time $O(s^2 n \sum_{j=3}^{n} m_j/j)$, where m_j denotes the average number of faces per region in any subdiagram of j sites from S.

In an *order-k Voronoi diagram*, all points of space M are placed in one region that shares the same k nearest sites in S. For $k = n-1$, this concept has been generalized to furthest site abstract Voronoi diagrams in [13]. Here the furthest (or inverse) region of $p \in S$ is the intersection of all domains $D(q, p)$, where $q \in S \setminus \{p\}$. If all regular Voronoi regions are nonempty, then the furthest site AVD is a tree of size $O(n)$, even though some regions may be disconnected.

General order-k abstract Voronoi diagrams have been studied in [2]. If all regular Voronoi regions are nonempty and if bisecting curves are in general position, a tight upper complexity bound of $2k(n-k)$ can be shown. Fortunately, the nonemptiness of the regular regions need only be tested for all subsets of S of size 4.

Problem Definition

Most classic machine learning methods depend on the assumption that humans can annotate all the data available for training. However, many modern machine learning applications (including image and video classification, protein sequence classification, and speech processing) have massive amounts of unannotated or unlabeled data. As a consequence, there has been tremendous interest both in machine learning and its application areas in designing algorithms that most efficiently utilize the available data while minimizing the need for human intervention. An extensively used and studied technique is *active learning*, where the algorithm is presented with a large pool of unlabeled examples (such as all images available on the web) and can interactively ask for the

labels of examples of its own choosing from the pool, with the goal to drastically reduce labeling effort.

Formal Setup

We consider *classification problems* (such as classifying images by who is in them or classifying emails as spam or not), where the goal is to predict a label y based on its corresponding input vector x. In the standard machine learning formulation, we assume that the data points (x, y) are drawn from an unknown underlying distribution D_{XY} over $X \times Y$; X is called the feature (instance) space and $Y = \{0, 1\}$ is the label space. The goal is to output a hypothesis function h of small error (or small 0/1 loss), where $\text{err}(h) = \mathbb{P}_{(x,y)\sim D_{XY}}[h(x) \neq y]$. In the passive learning setting, the learning algorithm is given a set of labeled examples $(x_1, y_1), \ldots, (x_m, y_m)$ drawn i.i.d. from D_{XY} and the goal is to output a hypothesis of small error by using only a polynomial number of labeled examples. In the *realizable* case [10] (PAC learning), we assume that the true label of any example is determined by a deterministic function of the features (the so-called target function) that belongs to a known concept class C (e.g., the class of linear separators, decision trees, etc.). In the *agnostic* case [10, 13], we do not make the assumption that there is a perfect classifier in C, but instead we aim to compete with the best function in C (i.e., we aim to identify a classifier whose error is not much worse than $opt(C)$, the error of the best classifier in C). Both in the realizable and agnostic settings, there is a well-developed theory of Sample Complexity [13], quantifying in terms of the so-called *VC-dimension* (a measure of complexity of a concept class) how many training examples we need in order to be confident that a rule that does well on training data is a good rule for future data as well.

In the active learning setting, a set of labeled examples $(x_1, y_1), \ldots, (x_m, y_m)$ is also drawn i.i.d. from D_{XY}; the learning algorithm is permitted direct access to the sequence of x_i values (unlabeled data points), but has to make a label request to obtain the label y_i of example x_i. The hope is that we can output a classifier of small error by using many fewer label requests than in passive learning by actively directing the queries to informative examples (while keeping the number of unlabeled examples polynomial).

It has been long known that, in the realizable case, active learning can sometimes provide an exponential improvement in label complexity over passive learning. The canonical example [6] is learning threshold classifiers ($X = [0, 1]$ and $C = \{\mathbf{1}_{[0,a]} \mid a \in [0, 1]\}$). Here we can actively learn with only $\tilde{O}(\log(1/\epsilon))$ label requests by using a simple binary search-like algorithm as follows: we first draw $N = \tilde{O}((1/\epsilon)\log(1/\delta))$ unlabeled examples, then do binary search to find the transition from label 1 to label 0, and with only $O(\log(N))$ queries we can correctly infer the labels of all our examples; we finally output a classifier from C consistent with all the inferred labels. By standard VC-dimension based bounds for supervised learning [13], we are guaranteed to output an ϵ-accurate classifier. On the other hand, for passive learning, we provably need $\Omega(1/\epsilon)$ labels to output a classifier of error at most ϵ with constant probability, yielding the exponential reduction in label complexity.

Key Results

While in the simple threshold concept class described above active learning always provides huge improvements over passive learning, things are more delicate in more general scenarios. In particular, both in the realizable and in the agnostic case, it has been shown that for more general concept spaces, in the worst case over all data-generating distributions, the label complexity of active learning equals that of passive learning. Thus, much of the literature was focused on identifying non-worst case, natural conditions about the relationship between the data distribution and the target, under which active learning provides improvements over passive. Below, we discuss three approaches, under which active learning has been shown to reduce the label complexity: disagreement-based

techniques, margin-based techniques and cluster-based techniques.

Disagreement-Based Active Learning

Disagreement-based active learning was the first method to demonstrate the feasibility of *agnostic active learning* for general concept classes. The general algorithmic framework of disagreement-based active learning in the presence of noise was introduced with the A^2 algorithm by Balcan et al. [2]. Subsequently, several researchers have proposed related disagreement-based algorithms with improved sample complexity, e.g., [5, 8, 11].

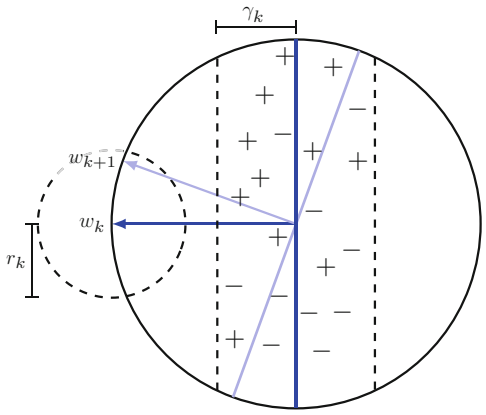
At a high level, A^2 operates in rounds. It maintains a set of candidate classifiers from the concept class C and in each round queries labels aiming to efficiently reduce this set to only few high-quality candidates. More precisely, in round i, A^2 considers the set of surviving classifiers $C_i \subseteq C$, and asks for the labels of a few random points that fall in the *region of disagreement* of C_i. Formally, the region of disagreement of a set of classifiers C_i is $\mathrm{DIS}(C_i) = \{x \in X \mid \exists f, g \in C_i : f(x) \neq g(x)\}$. Based on these queried labels from $\mathrm{DIS}(C_i)$, to obtain C_{i+1}, the algorithm then throws out hypotheses that are suboptimal. The key ingredient is that A^2 *only* throws out hypotheses, for which it is *statistically confident* that they are suboptimal.

Balcan et al. [2] show that A^2 provides exponential improvements in the label sample complexity in terms of the $1/\epsilon$-parameter when the noise rate η is sufficiently small, both for learning thresholds and for learning homogeneous linear separators in R^d, one of the most widely used and studied classes in machine learning. Following up on this, Hanneke [9] provided a generic analysis of the A^2 algorithm that applies to *any concept class*. This analysis quantifies the label complexity of A^2 in terms of the so-called *disagreement coefficient* of the class C. The disagreement coefficient is a distribution-dependent sample complexity measure that quantifies how fast the region of disagreement of the set of classifiers at distance r of the optimal classifier collapses as a function r. In particular, [9] showed that the label complexity of the A^2 algorithm is $O\left(\theta^2\left(\frac{\nu^2}{\epsilon^2}+1\right)(d\log(1/\epsilon)+\log(1/\delta))\log(1/\epsilon)\right)$, where ν is the best error rate of a classifier in C, d is the VC-dimension of C, and θ is the disagreement-coefficient. As an example, for homogeneous linear separators, we have $\theta = \theta(\sqrt{d})$ under uniform marginal over the unit ball. Here, the disagreement-based analysis yields a label complexity of $\tilde{O}\left(d^2\frac{\nu^2}{\epsilon^2}\log(1/\epsilon)\right)$ in the agnostic case and $\tilde{O}\left(d^{3/2}\log(1/\epsilon)\right)$ in the realizable case.

Margin-Based Active Learning

While the disagreement-based active learning line of work provided the first general understanding of the sample complexity benefits with active learning for arbitrary concept classes, it suffers from two main drawbacks: (1) methods and analyses developed in this context are often suboptimal in terms of label complexity, since they take a conservative approach and query even points on which there is only a small amount of uncertainty, (2) the methods are computationally inefficient. *Margin-based* active learning is a technique that overcomes both the above drawbacks for learning homogeneous linear separators under log-concave distributions. The technique was first introduced by Balcan et al. [3] and further developed by Balcan et al. [4], and Awasthi et al. [1].

At a high level, like disagreement-based methods, the margin-based active learning algorithm operates in rounds, in which a number of labels are queried in some subspace of the domain and a set of candidate classifiers for the next round is identified. The crucial idea to reduce the label complexity is to design a *more aggressive querying strategy* by carefully choosing where to query instead of querying in all of the current disagreement region. Concretely, in round k the algorithm has a *current hypothesis* w_k, and the set of candidate classifiers for the next round consists of all homogeneous halfspaces that lie in a *ball of radius* r_k *around* w_k (in terms of their angle with w_k). The algorithm then queries points for labels near the decision boundary of w_k; that is, it only queries points



Active Learning – Modern Learning Theory, Fig. 1 The margin-based active learning algorithm after iteration k. The algorithm samples points within margin γ_k of the current weight vector w_k and then minimizes the hinge loss over this sample subject to the constraint that the new weight vector w_{k+1} is within distance r_k from w_k

that are within a *margin* γ_k of w_k; see Fig. 1. To obtain w_{k+1}, the algorithm finds a loss minimizer among the current set of candidates with respect to the queried examples of round k. In the realizable case, this is done by 0/1-loss minimization. In the presence of noise, to obtain a computationally efficient procedure, the margin-based technique minimizes a convex surrogate loss.

Balcan et al. [3] and Balcan and Long [4] showed that by localizing aggressively, namely by setting the margin parameter to $\gamma_k = \Theta(\frac{1}{2^k})$, one can actively learn with only $\tilde{O}(d\log(1/\epsilon))$ label requests in the realizable case, when the underlying distribution is isotropic log-concave. A key idea of their analysis is to decompose, in round k, the error of a candidate classifier w as its error outside margin γ_k of the current separator plus its error inside margin γ_k, and to prove that for the above parameters, a small constant error inside the margin suffices to reduce the overall error by a constant factor. For the constant error inside the margin only $\theta(d)$ labels need to be queried, and since in each round the overall error gets reduced by a constant factor, $O(\log(1/\epsilon))$ rounds suffice to reduce the error to ϵ, yielding the label complexity of $\tilde{O}(d\log(1/\epsilon))$. Passive learning here provably requires $\Omega(d/\epsilon)$ labeled examples. Thus, the dependence on $1/\epsilon$ is exponentially improved, but without increasing the dependence on d (as in the disagreement-based method for this case, see above).

Building on this work, [1] gave the first *polynomial-time* active learning algorithm for learning linear separators to error ϵ in the presence of agnostic noise (of rate $O(\epsilon)$) when the underlying distribution is an isotropic log-concave distribution in R^d. They proposed to use a normalized hinge loss minimization (with normalization factor τ_k) for selecting the next classifier w_{k+1} in round k. Awasthi et al. [1] show that by setting the parameters appropriately (namely, $\tau_k = \Theta(1/2^k)$ and $r_k = \Theta(1/2^k)$), the algorithm again achieves error ϵ using only $O(\log(1/\epsilon))$ rounds, with $O(d^2)$ label requests per round. This yields a query complexity of $\text{poly}(d, \log 1/\epsilon)$. The key ingredient for the analysis of this computationally efficient version in the noisy setting is proving that by constraining the search for w_{k+1} to vectors within a ball of radius r_k around w_k, the hinge-loss acts as a sufficiently faithful proxy for the 0/1-loss.

A recent work [14] proposes an elegant generalization of [3, 4] to more general concept spaces and shows an analysis that is always tighter than disagreement-based active learning (though their results are not computationally efficient).

Cluster-Based Active Learning

The methods described above (disagreement-based and margin-based active learning) use active label queries to efficiently identify a classifier from the concept class C with low error. An alternative approach to agnostic active learning is to design active querying methods that efficiently find a (approximately) correct labeling of the unlabeled input sample. Here, "correct labeling" refers to the hidden labels y_i in the sample $(x_1, y_1), \ldots, (x_m, y_m)$ from the distribution D_{XY} (as defined in the formal setup section). The so labeled sample can then be used as input to a passive learning algorithm to learn an arbitrary concept class.

Cluster-based active learning is a method for the latter approach and was introduced by Dasgupta and Hsu [7]. The idea is to use

a hierarchical clustering (cluster tree) of the unlabeled data, and check the clusters for label homogeneity by starting at the root of the tree (the whole data set) and working towards the leaves (single data points). The label homogeneity of a cluster is estimated by choosing data points for label query uniformly at random from the cluster. If a cluster is considered label homogeneous (with sufficiently high confidence), all remaining unlabeled points in that cluster are labeled with the majority label. If a cluster is detected to be label heterogeneous, it is split into its children in the cluster tree and processed later. The key insight in [7] is that since the cluster tree is fixed before any labels were seen, the induced labeled subsample of a child cluster can be considered a sample that was chosen uniformly at random from the points in that child-cluster. Thus, the algorithm can reuse labels from the parent cluster without introducing any sampling bias. The label efficiency of this paradigm crucially depends on the quality of input hierarchical clustering. Intuitively, if the cluster tree has a small pruning with label homogeneous clusters, the procedure will make only few label queries.

Urner et al. [12] proved label complexity reductions with this paradigm under a distributional assumption. They analyze a version (PLAL) of the above paradigm that uses hierarchical clusterings induced by *spatial trees* on the domain $[0,1]^d$ and provide label query bounds in terms of the *Probabilistic Lipschitzness* of the underlying data-generating distribution. Probabilistic Lipschitzness quantifies a marginal-label relatedness in the sense of close points being likely to have the same label. For a distribution with deterministic labels ($\Pr[Y = 1 \mid X = x] \in \{0,1\}$ for all x), the Probabilistic Lipschitzness is a function ϕ that bounds, as a function of λ, the mass of points x for which both labels 0 and 1 occur in the ball $B_\lambda(x)$.

Urner et al. [12] show that, independently of the any data assumptions, (with probability $1-\delta$) PLAL labels a $(1-\epsilon)$-fraction of the input points correctly. They further show that using PLAL as a preprocedure, if the data-generating distribution has deterministic labels and its Probabilistic Lipschitzness is bounded by $\phi(\lambda) = \lambda^n$ for some $n \in \mathbb{N}$, then classes C of bounded VC-dimension on domain $X = [0,1]^d$ can be learned with $\tilde{O}\left(\left(\frac{1}{\epsilon}\right)^{\frac{n+2d}{n+d}}\right)$ many labels, while any passive proper learner (i.e., a passive learner that outputs a function from C) requires to see $\Omega(1/\epsilon^2)$ many labels. Further, [12] show that PLAL can be used to reduce the number of labels needed for nearest neighbor classification (i.e., labeling a test point by the label of its nearest point in the sample) from $\Omega\left(\left(\frac{1}{\epsilon}\right)^{1+\frac{d-1}{n}}\right)$ to $\tilde{O}\left(\left(\frac{1}{\epsilon}\right)^{1+\frac{d^2}{n(n+d)}}\right)$.

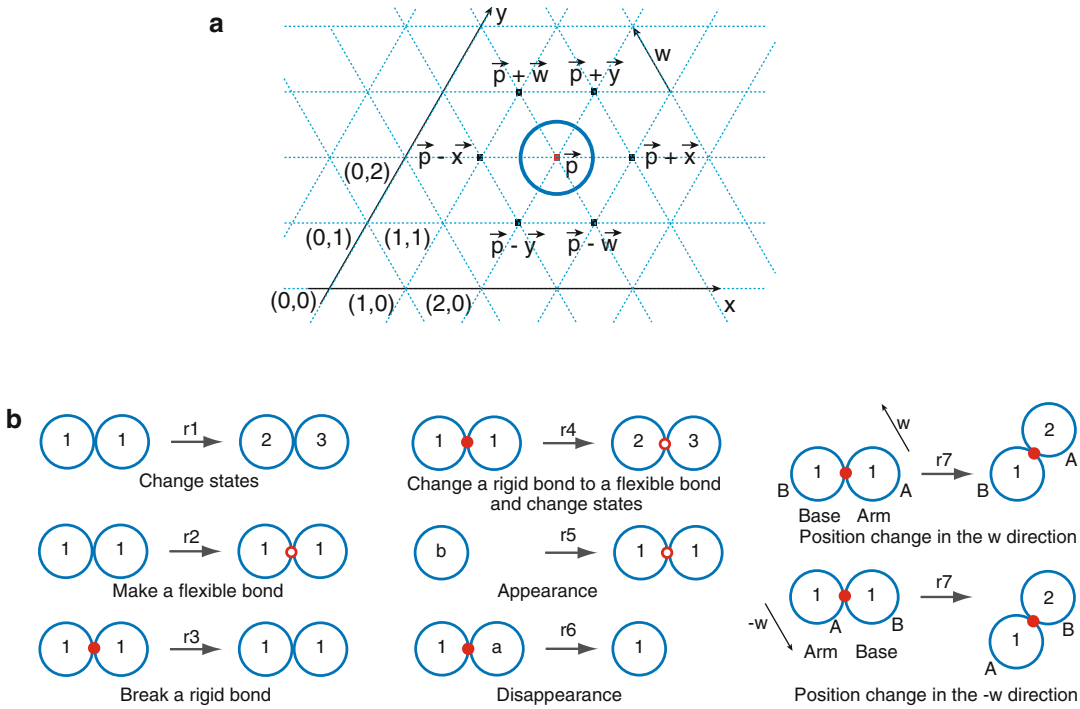
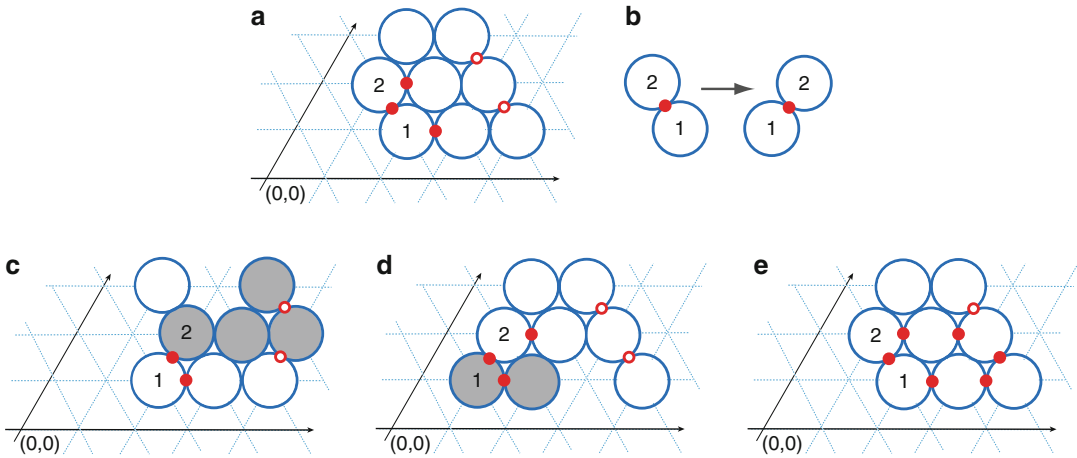
Problem Definition

In the theory of molecular-scale self-assembly, large numbers of simple interacting components are designed to come together to build complicated shapes and patterns. Many models of self-assembly, such as the abstract Tile Assembly Model [6], are cellular automata-like crystal growth models. Indeed such models have given rise to a rich theory of self-assembly as described elsewhere in this encyclopedia. In biological organisms we frequently see much more sophisticated growth processes, where self-assembly is combined with active molecular components that change internal state and even molecular motors that have the ability to push and pull large structures around. Molecular engineers are now beginning to design and build molecular-scale DNA motors and active self-assembly systems [2]. We wish to understand, at a high level of abstraction, the ultimate computational capabilities and limitations of such molecular-scale rearrangement and growth. The nubot model, put forward in [8], is akin to an asynchronous nondeterministic cellular automaton augmented with nonlocal rigid-body movement. Unit-sized monomers are placed on a 2D triangular grid. Monomers undergo state changes, appear, and disappear using local rules, as shown in Fig. 1. However, there is also a nonlocal aspect to the model: rigid-body movement that comes in two forms, movement rules and random agitations.

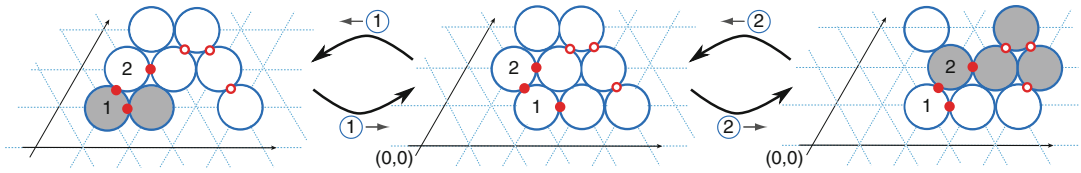
A *movement rule* r, consisting of a pair of monomer states A, B and two unit vectors, is a programmatic way to specify unit-distance translation of a set of monomers in one step. See Fig. 2 for an example. If A and B are in a prescribed orientation, one is nondeterministically chosen to move unit distance in a prescribed direction. The rule r is applied in a rigid-body fashion: roughly speaking, if A is to move right, it pushes anything immediately to its right and pulls any monomers that are bound to its left which in turn push and pull other monomers, all in one step. The rule may not be applicable if it is blocked (i.e., if movement of A would force B to also move), which is analogous to the fact that an arm cannot push its own shoulder. The other, somewhat related, form of movement is called *agitation*: at every point in time, every monomer on the grid may move unit distance in any of the six directions, at unit rate for each (monomer, direction) pair. An agitating monomer will push or pull any monomers that it is adjacent to, in a way that preserves rigid-body structure and all in



Active Self-Assembly and Molecular Robotics with Nubots, Fig. 1 Overview of the nubot model. (**a**) A nubot configuration showing a single nubot monomer on the triangular grid. (**b**) Examples of nubot monomer rules. Rules r1–r6 are local cellular automaton-like rules, whereas r7 effects a nonlocal movement that may translate other monomers as shown in Fig. 2. Monomers continuously undergo agitation, as shown in Fig. 3. A flexible bond is depicted as an empty *red circle* and a rigid bond is depicted as a *solid red disk* (from [8])



Active Self-Assembly and Molecular Robotics with Nubots, Fig. 2 Movement rule. (**a**) Initial configuration. (**b**) Movement rule with one of two results depending on the choice of arm or base. (**c**) Result if the monomer with state 2 is the arm or (**d**) monomer with state 1 is the arm. The shaded monomers are the movable set. The affect on rigid (*filled red disks*), flexible (*hollow red circles*), and null bonds is shown. (**e**) A configuration for which the movement rule is blocked: movement of 1 or 2 would force the other to move; hence the rule is not applicable (from [3])



Active Self-Assembly and Molecular Robotics with Nubots, Fig. 3 Example agitations. Starting from the centre configuration, there are 48 possible agitations (8 monomers, 6 directions each) each with equal probability. The right configuration is the result of agitation of the monomer in state 2 in direction →, the left is the result of the agitation of the monomer in state 1 in direction ←. The shaded monomers are the agitation set – monomers that are moved by the agitation (from [4])

one step as shown in Fig. 3. Unlike movement, agitations are never blocked. Rules are applied asynchronously and in parallel. Taking its time model from stochastic chemical kinetics, a nubot system evolves as a continuous time Markov process.

For intuition, we describe motion in terms of pushing and pulling. However movement and agitation are actually intended to model a nanoscale environment with diffusion, Brownian motion, convection, turbulent flow, cytoplasmic streaming, and other uncontrolled inputs of energy that interact monomers in all directions, moving large molecular assemblies in a random fashion (i.e., agitation) and allowing motors to simply latch and unlatch large assemblies into position (i.e., the movement rule).

Key Results

Assembling simple structures, namely, lines and squares, has proven to be a fruitful way to explore the power of the nubot model for a few reasons. Firstly, it helps us develop a number of techniques and intuitions for the model. Secondly, lines and squares get used again and again in more general results that show the full power of the model. Thirdly, the efficiency of assembling simple shapes has been a de facto benchmark problem for a number of self assembly models (although this benchmark often does not give the full story). In a variety of models, such as the abstract Tile Assembly Model, cellular automata, and some robotics models, it takes time $\Omega(n)$ to assemble a length n line. In the nubot model this is achieved in merely $O(\log n)$ expected time and $O(\log n)$ states.

Theorem 1 ([8]) *For each $n \in \mathbb{N}$, there is a set of nubot rules $\mathcal{N}_n^{\text{line}}$ such that starting from a single monomer $\mathcal{N}_n^{\text{line}}$ assembles a length n line in $O(\log n)$ expected time, $n \times 2$ space, and $O(\log n)$ states.*

One can trade time for states by giving a slightly slower method with fewer states:

Theorem 2 ([3]) *There is a set of nubot rules $\mathcal{N}^{\text{line}}$ such that for each $n \in \mathbb{N}$, from a line of $O(\log n)$ "binary" monomers (each in state 0 or 1), $\mathcal{N}^{\text{line}}$ assembles a length n line in $O(\log^2 n)$ expected time, $n \times O(1)$ space, and $O(1)$ states.*

An $n \times n$ square can be built by growing a horizontal line and then n vertical lines, showing that assembly of squares with nubots is exponentially faster than the $\Theta(n)$ expected time seen in the abstract Tile Assembly Model [1]:

Theorem 3 ([8]) *For each $n \in \mathbb{N}$, there is a set of nubot rules $\mathcal{N}_n^{\text{square}}$ such that starting from a single monomer, $\mathcal{N}_n^{\text{square}}$ assembles a $n \times n$ square in $O(\log n)$ expected time, $n \times n$ space, and $O(\log n)$ states.*

The results above, and all of those in [3, 8], crucially make use of the rigid-body movement rule: the ability for a single monomer to control the movement of large objects quickly and at a time and place of the programmer's choosing. However, in a molecular-scale environment, molecular motion is happening in a largely uncontrolled and fundamentally random manner, all of the time. The *agitation nubot* model does

not have the movement rule, but instead permits such uncontrolled random agitation (movement). Although this form of movement is challenging to control in a precise manner, the following result shows we can use it to achieve sublinear expected time growth of a length n line in only $O(n)$ space:

Theorem 4 ([4]) *There is a set of nubot rules $\mathcal{N}_{\text{line}}$, such that $\forall n \in \mathbb{N}$, starting from a line of $\lfloor \log_2 n \rfloor + 1$ monomers, each in state 0 or 1, $\mathcal{N}_{\text{line}}$ in the agitation nubot model assembles an $n \times 1$ line in $O(n^{1/3} \log n)$ expected time, $n \times 5$ space, and $O(1)$ monomer states.*

For a square we can do much better, achieving polylogarithmic expected time:

Theorem 5 ([4]) *There is a set of nubot rules $\mathcal{N}_{\text{square}}$, such that $\forall n \in \mathbb{N}$, starting from a line of $\lfloor \log_2 n \rfloor + 1$ monomers, each in state 0 or 1, $\mathcal{N}_{\text{square}}$ in the agitation nubot model assembles an $n \times n$ square in $O(\log^2 n)$ expected time, $n \times n$ space, and $O(1)$ monomer states.*

This section concludes with three results on general-purpose computation and shape construction with the nubot model. First we have a computability-theoretic result: any finite computable connected shape can be quickly self-assembled.

Theorem 6 ([8]) *An arbitrary connected computable 2D shape of size $\leq \sqrt{n} \times \sqrt{n}$ can be assembled in expected time $O(\log^2 n + t(|n|))$ using $O(s + \log n)$ states. Here, $t(|n|)$ is the time required for a program-size s Turing machine to compute, given a pixel index as a binary string of length $|n| = \lfloor \log_2 n \rfloor + 1$, whether or not the pixel is present in the shape.*

For complicated computable shapes the construction for Theorem 6 necessarily requires computation workspace outside of the shape's bounding box. The next result is of a more resource-bounded style and, roughly speaking, states that 2D patterns with efficiently computable pixel colors can be assembled using nubots in merely polylogarithmic expected time while staying inside the pattern's bounding box.

Theorem 7 ([8]) *An arbitrary finite computable 2D pattern of size $\leq n \times n$, where $n = 2^p$, $p \in \mathbb{N}$, with pixels whose color is computable on a polynomial time $O(|n|^\ell)$ (inputs are binary strings of length $|n| = O(\log n)$), linear space $O(|n|)$, program-size s Turing machine, can be assembled in expected time $O(\log^{\ell+1} n)$, with $O(s + \log n)$ monomer states and without growing outside the pattern borders.*

The results cited so far can be used to compare the nubot model to other models of self-assembly and tell us that nubots build shapes and patterns in a fast parallel manner. The next result quantifies this parallelism in terms of a well-known parallel model from computational complexity theory: NC is the class of problems solved by uniform polylogarithmic depth and polynomial-size Boolean circuits.

Theorem 8 ([3]) *For each language $L \in$ NC, there is a set of nubot rules $\mathcal{N}_L$ that decides L in polylogarithmic expected time, constant number of monomer states, and polynomial space in the length of the input string of binary monomers (in state 0 or 1). The output is a single binary monomer.*

This result stands in contrast to sequential machines like Turing machines, that cannot read all of an n-bit input string in polylogarithmic time, and "somewhat parallel" models like cellular automata and the abstract Tile Assembly Model, that cannot have all of n bits influence a single output bit decision in polylogarithmic time [5]. Thus, adding the nubot rigid-body movement primitive to an asynchronous nondeterministic cellular automaton drastically increases its parallel processing abilities.

Open Problems

Some future research directions are discussed here and in [3, 4, 8]. It remains as future work to look at other topics such as fault tolerance, self-healing, dynamical tasks, or systems that continuously respond to the environment.

The Complexity of Assembling Lines

Theorem 1 states that a line can be grown in expected time $O(\log n)$, space $O(n) \times O(1)$, and $O(\log n)$ states, and Theorem 2 trades time for states to get expected time $O(\log^2 n)$, space $O(n) \times O(1)$, and $O(1)$ states. What is the complexity (expected time $\times$ states) of assembling a line in the nubot model? Is it possible to meet the lower bound of expected time $\times$ states $= \Omega(\log n)$? In this problem, the input should be a set of monomers with space $\times$ states $= O(\log n)$.

Computational Power

Theorem 8 gives a lower bound on the computational complexity of the nubot model. What is the exact power of polylogarithmic expected time nubots? The answer may differ on whether we begin from a small collection of monomers (as in Theorem 8) or a large prebuilt structure. One challenge, for the upper bound, involves finding better Turing machine space, or circuit depth, bounds on computing multiple applications of the movable set on a large nubots grid.

Synchronization and Composition of Nubot Algorithms

Synchronization is a method to quickly send signals using nonlocal rigid-body motion [3, 8]. The nubot model is asynchronous, but synchronization can be used to set discrete stages, or checkpoints, during a complicated construction. This in turn facilitates composition of nubot algorithms (run algorithm 1, synchronize, run algorithm 2, synchronize, etc.) and many of the results cited here use it for exactly that reason. However, synchronization-less constructions often exhibit a kind of independence where growth proceeds everywhere in parallel, without waiting on signals from distant components. Such systems are highly distributed, easy to analyze, and perhaps more amenable to laboratory implementation. Intuitively, this seems like the right way to program molecules. The proof of Theorem 7 does not use synchronization which shows that without it a very general class of (efficiently) computable patterns can be grown and indeed the proof gives methods to compose nubot algorithms without resorting to synchronization. It remains as future work to formalize both this notion of synchronization-less "independence" and what we mean by "composition" of nubot algorithms. What conditions are necessary and sufficient for composition of nubot algorithms? What classes of shapes and patterns can be assembled using without synchronization or other forms of rapid long-range communication?

Agitation Versus the Movement Rule

Is it possible to simulate the movement rule using agitation? More formally, is it the case that for each nubot program $\mathcal{N}$, there is an agitation nubot program $\mathcal{A}_{\mathcal{N}}$, that acts just like $\mathcal{N}$ but with some $m \times m$ scale-up in space, and a k factor slowdown in time, where m and k are (constants) independent of $\mathcal{N}$ and its input? As motivation, note that every self-assembled molecular-scale structure was made under conditions where random jiggling of monomers is a dominant source of movement! Our question asks if we can *programmably exploit* this random molecular motion to build structures quicker than without it.

Intrinsic Universality and Simulation

Is the nubot model intrinsically universal? Specifically, does there exist a set of monomer rules U, such that any nubot system $\mathcal{N}$ can be simulated by "seeding" U with a suitable initial configuration? Here the simulation should have a spatial scale factor m that is a function of the number of states in the simulated system $\mathcal{N}$. Is the agitation nubot model intrinsically universal? Our hope would be that simulation could be used to tease apart the power of different notions of movement (e.g., to understand if nubot-style movement is weaker or stronger than other notions of robotic movement), in the way it has been used to characterize and separate the power of other self-assembly models [7].

Brownian Nubots

With nubots, under agitation, or multiple parallel movement rules, larger objects move faster. This is intended to model an environment with uncontrolled and rapid fluid flows. But in Brownian motion, larger objects move slower: what is the power of nubots with such a rate model, for

example, with rate equal to object size? Although assembly in such a model may be slower than with the usual model, many of the same programming principles should apply, and indeed it will still be possible to assemble objects in a parallel distributed fashion.

Technique for constructing approximation

Years and Authors of Summarized Original Work

1986; Du, Pan, Shing

Problem Definition

Adaptive partition is one of major techniques to design polynomial-time approximation algorithms, especially polynomial-time approximation schemes for geometric optimization problems. The framework of this technique is to put the input data into a rectangle and partition this rectangle into smaller rectangles by a sequence of cuts so that the problem is also partitioned into smaller ones. Associated with each adaptive partition, a feasible solution can be constructed recursively from solutions in smallest rectangles to bigger rectangles. With dynamic programming, an optimal adaptive partition is computed in polynomial time.

Historical Note

The adaptive partition was first introduced to the design of an approximation algorithm by Du et al. [4] with a guillotine cut while they studied the minimum edge-length rectangular partition (MELRP) problem. They found that if the partition is performed by a sequence of guillotine cuts, then an optimal solution can be computed in polynomial time with dynamic programming. Moreover, this optimal solution can be used as a pretty good approximation solution for the original rectangular partition problem. Both Arora [1] and Mitchell et al. [12,15] found that the cut does not need to be completely guillotine. In other words, the dynamic programming can still run in polynomial time if subproblems have some relations but the number of relations is small. As the number of relations goes up, the approximation solution obtained approaches the optimal one, while the run time, of course, goes up. They also found that this technique can be applied to many geometric optimization problems to obtain polynomial-time approximation schemes.

Key Results

The MELRP was proposed by Lingas et al. [10] as follows: Given a rectilinear polygon possibly with some rectangular holes, partition it into rectangles with minimum total edge length. Each hole may be degenerated into a line segment or a point.

There are several applications mentioned in [10] for the background of the problem: process control (stock cutting), automatic layout systems for integrated circuit (channel definition), and architecture (internal partitioning into offices). The *minimum edge-length* partition is a natural goal for these problems since there is a certain amount of waste (e.g., sawdust) or expense incurred (e.g., for dividing walls in the office) which is proportional to the sum of edge lengths drawn. For very large-scale integration (VLSI) design, this criterion is used in the MIT placement and interconnect (PI) system to divide the routing region up into channels – one finds that this produces large "natural-looking" channels with a minimum of channel-to-channel interaction to consider.

They showed that while the MELRP in general is nondeterministic polynomial-time (NP)-hard, it can be solved in time $O(n^4)$ in the hole-free case, where n is the number of vertices in the input rectilinear polygon. The polynomial algorithm is essentially a dynamic programming based on the fact that there always exists an optimal solution satisfying the property that every cut line passes through a vertex of the input polygon or holes (namely, every maximal cut segment is incident to a vertex of input or holes).

A naive idea to design an approximation algorithm for the general case is to use a forest connecting all holes to the boundary and then to solve the resulting hole-free case in $O(n^4)$ time. With this idea, Lingas [9] gave the first constant-bounded approximation; its performance ratio is 41.

Motivated by a work of Du et al. [6] on application of dynamic programming to optimal routing trees, Du et al. [4] initiated an idea of adaptive partition. They used a sequence of guillotine cuts to do rectangular partition; each guillotine cut breaks a connected area into at least two parts. With dynamic programming, they were able to show that a minimum-length guillotine rectangular partition (i.e., one with minimum total length among all guillotine partitions) can

be computed in $O(n^5)$ time. Therefore, they suggested using the minimum-length guillotine rectangular partition to approximate the MELRP and tried to analyze the performance ratio. Unfortunately, they failed to get a constant ratio in general and only obtained an upper bound of 2 for the performance ratio in an NP-hard special case [7]. In this special case, the input is a rectangle with some points inside. Those points are holes. The following is a simple version of the proof obtained by Du et al. [5].

Theorem 1 *The minimum-length guillotine rectangular partition is an approximation with performance ratio 2 for the MELRP.*

Proof Consider a rectangular partition P. Let $proj_x(P)$ denote the total length of segments on a horizontal line covered by vertical projection of the partition P.

A rectangular partition is said to be covered by a guillotine partition if each segment in the rectangular partition is covered by a guillotine cut of the latter. Let $guil(P)$ denote the minimum length of the guillotine partition covering P and $length(P)$ denote the total length of rectangular partition P. It will be proved by induction on the number k of segments in P that

$$guil(P) \le 2 \cdot length(P) - proj_x(P).$$

For $k = 1$, one has $guil(P) = length(P)$. If the segment is horizontal, then one has $proj_x(P) = length(P)$ and hence

$$guil(P) = 2 \cdot length(P) - proj_x(P).$$

If the segment is vertical, then $proj_x(P) = 0$ and hence

$$guil(P) < 2 \cdot length(P) - proj_x(P).$$

Now, consider $k \ge 2$. Suppose that the initial rectangle has each vertical edge of length a and each horizontal edge of length b. Consider two cases.

Case 1. There exists a vertical segment s having length greater than or equal to $0.5a$. Apply a guillotine cut along this segment s. Then the remainder of P is divided into two parts, P_1 and P_2, which form rectangular partition of two resulting small rectangles, respectively. By induction hypothesis,

$$guil(P_i) \le 2 \cdot length(P_i) - proj_x(P_i)$$

for $i = 1, 2$. Note that

$$\begin{aligned} guil(P) &\le guil(P_1) + guil(P_2) + a, \\ length(P) &= length(P_1) + length(P_2) \\ &\quad + length(s), \\ proj_x(P) &= proj_x(P_1) + proj_x(P_2). \end{aligned}$$

Therefore,

$$guil(P) \le 2 \cdot length(P) - proj_x(P).$$

Case 2. No vertical segment in P has length greater than or equal to $0.5a$. Choose a horizontal guillotine cut which partitions the rectangle into two equal parts. Let P_1 and P_2 denote rectangle partitions of the two parts, obtained from P. By induction hypothesis,

$$guil(P_i) \le 2 \cdot length(P_i) - proj_x(P_i)$$

for $i = 1, 2$. Note that

$$\begin{aligned} guil(P) &= guil(P_1) + guil(P_2) + b, \\ length(P) &\ge length(P_1) + length(P_2), \\ proj_x(P) &= proj_x(P_1) = proj_x(P_2) = b. \end{aligned}$$

Therefore,

$$guil(P) \le 2 \cdot length(P) - proj_x(P).$$

Gonzalez and Zheng [8] improved this upper bound to 1.75 and conjectured that the performance ratio in this case is 1.5. □

Applications

In 1996, Arora [1] and Mitchell et al. [12, 14, 15] found that the cut does not necessarily have to be completely guillotine in order to have a polynomial-time computable optimal solution for such a sequence of cuts. Of course, the number of connections left by an incomplete guillotine cut should be limited. While Mitchell et al. developed the m-guillotine subdivision technique, Arora employed a "portal" technique. They also found that their techniques can be used for not only the MELRP, but also for many geometric optimization problems [1–3, 12–15].

Open Problems

One current important submicron step of technology evolution in electronics interconnects has become the dominating factor in determining VLSI performance and reliability. Historically a problem of interconnects design in VLSI has been very tightly intertwined with the classical problem in computational geometry: Steiner minimum tree generation. Some essential characteristics of VLSI are roughly proportional to the length of the interconnects. Such characteristics include chip area, yield, power consumption, reliability, and timing. For example, the area occupied by interconnects is proportional to their combined length and directly impacts the chip size. Larger chip size results in reduction of yield and increase in manufacturing cost. The costs of other components required for manufacturing also increase with the increase of the wire length. From the performance angle, longer interconnects cause an increase in power dissipation, degradation of timing, and other undesirable consequences. That is why finding the minimum length of interconnects consistent with other goals and constraints is such an important problem at this stage of VLSI technology.

The combined length of the interconnects on a chip is the sum of the lengths of individual signal nets. Each signal net is a set of electrically connected terminals, where one terminal acts as a driver and other terminals are receivers of electrical signals. Historically, for the purpose of finding an optimal configuration of interconnects, terminals were considered as points on the plane, and a routing problem for individual nets was formulated as a classical Steiner minimum tree problem. For a variety of reasons, VLSI technology implements only rectilinear wiring on the set of parallel planes, and, consequently, with few exceptions, only a rectilinear version of the Steiner tree is being considered in the VLSI domain. This problem is known as the RSMT.

Further progress in VLSI technology resulted in more factors than just length of interconnects gaining importance in selection of routing topologies. For example, the presence of obstacles led to reexamination of techniques used in studies of the rectilinear Steiner tree, since many classical techniques do not work in this new environment. To clarify the statement made above, we will consider the construction of a rectilinear Steiner minimum tree in the presence of obstacles.

Let us start with a rectilinear plane with obstacles defined as rectilinear polygons. Given n points on the plane, the objective is to find the shortest rectilinear Steiner tree that interconnects them. One already knows that a polynomial-time approximation scheme for RSMT without obstacles exists and can be constructed by adaptive partition with application of either the portal or the m-guillotine subdivision technique. However, both the m-guillotine cut and the portal techniques do not work in the case that obstacles exist. The portal technique is not applicable because obstacles may block the movement of the line that crosses the cut at a portal. The m-guillotine cut could not be constructed either, because obstacles may break down the cut segment that makes the Steiner tree connected.

In spite of the facts stated above, the RSMT with obstacles may still have polynomial-time approximation schemes. Strong evidence was given by Min et al. [11]. They constructed a polynomial-time approximation scheme for the problem with obstacles under the condition that the ratio of the longest edge and the shortest edge of the minimum spanning tree is bounded by a constant. This design is based on the classical nonadaptive partition approach. All of the above

make us believe that a new adaptive technique can be found for the case with obstacles.

Additive Spanners

Shiri Chechik
Department of Computer Science, Tel Aviv University, Tel Aviv, Israel

Keywords

Approximate shortest paths; Spanners; Stretch factor

Years and Authors of Summarized Original Work

2013; Chechik

Problem Definition

A spanner is a subgraph of a given graph that faithfully preserves the pairwise distances of that graph. Formally, an (α, β) spanner of a graph $G = (V, E)$ is a subgraph H of G such that for any pair of nodes x, y, $\mathbf{dist}(x, y, H) \leq \alpha \cdot \mathbf{dist}(x, y, G) + \beta$, where $\mathbf{dist}(x, y, H')$ for a subgraph H' is the distance of the shortest path from s to t in H'. We say that the spanner is *additive* if $\alpha = 1$, and if in addition $\beta = O(1)$, we say that the spanner is *purely additive*. If $\beta = 0$, we say that the spanner is *multiplicative*; otherwise, we say that the spanner is *mixed*.

Key Results

This section presents a survey on spanners with a special focus on additive spanners.

Graph spanners were first introduced in [12, 13] in the late 1980s and have been extensively studied since then.

Spanners are used as a key ingredient in many distributed applications, e.g., synchronizers [13], compact routing schemes [6, 14, 17], broadcasting [11], etc.

Much of the work on spanners considers multiplicative spanners. A well-known theorem on multiplicative spanners is that one can efficiently construct a $(2k-1,0)$ spanner with $O\left(n^{1+1/k}\right)$ edges [2]. Based in the girth conjecture of Erdős [10], this size-stretch ratio is conjectured to be optimal.

The problem of additive spanners was also extensively studied, but yet several key questions remain open. The girth conjecture does not contradict the existence of $(1,2k-2)$ spanners of size $O\left(n^{1+1/k}\right)$, or in fact any (α,β) spanners of size $O\left(n^{1+1/k}\right)$ such that $\alpha+\beta=2k-1$ with $\alpha\geq 1$ and $\beta>0$.

The first construction for purely additive spanners was introduced by Aingworth et al. [1]. It was shown in [1] how to efficiently construct a $(1,2)$ spanner, or a 2-*additive* spanner for short, with $O\left(n^{3/2}\right)$ edges (see also [8, 9, 16, 19] for further follow-up). Later, Baswana et al. [3, 4] presented an efficient construction for 6-additive spanners with $O\left(n^{4/3}\right)$ edges. Woodruff [21] further presented another construction for 6-additive spanners with $\tilde{O}\left(n^{4/3}\right)$ edges with improved construction time. Chechik [7] recently presented a new algorithm for $(1,4)$-additive spanners with $\tilde{O}\left(n^{7/5}\right)$ edges. These are the only three constructions known for purely additive spanners. Interestingly, Woodruff [20] presented lower bounds for additive spanners that match the girth conjecture bounds. These lower bounds do not rely on the correctness of the conjecture. More precisely, Woodruff [20] showed the existence of graphs for which any spanner of size $O\left(k^{-1}n^{1+1/k}\right)$ must have an additive stretch of at least $2k-1$.

In the absence of additional purely additive spanners, attempts were made to seek sparser spanners with nonconstant additive stretch. Bollobás et al. [5] showed how to efficiently construct a $\left(1,n^{1-2\delta}\right)$ spanner with $O\left(2^{1/\delta}n^{1+\delta}\right)$ edges for any $\delta>0$. Later, Baswana et al. in [3,4] improved this additive stretch to $\left(1,n^{1-3\delta}\right)$, and in addition, Pettie [15] improved the stretch to $\left(1,n^{9/16-7\delta/8}\right)$ (the latter is better than the former for every $\delta<7/34$).

Chechik [7] recently further improved the stretch for a specific range of δ. More specifically, Chechik presented a construction for additive spanners with $\tilde{O}\left(n^{1+\delta}\right)$ edges and $\tilde{O}\left(n^{1/2-3\delta/2}\right)$ additive stretch for any $3/17\leq\delta<1/3$. Namely, [7] decreased the stretch for this range to the root of the best previously known additive stretch.

Sublinear additive spanners, that is, spanners with additive stretch that is sublinear in the distances, were also studied. Thorup and Zwick [19] showed a construction of a $O\left(kn^{1+1/k}\right)$ size spanner such that for every pair of nodes s and t, the additive stretch is $O\left(d^{1-1/k}+2^k\right)$, where $d=\mathbf{dist}(s,t)$ is the distance between s and t. This was later improved by Pettie [15] who presented an efficient spanner construction with $O\left(kn^{1+\frac{(3/4)^{k-2}}{7-2(3/4)^{k-2}}}\right)$ size and $O\left(kd^{1-1/k}+k^k\right)$ additive stretch, where $d=\mathbf{dist}(s,t)$. Specifically, for $k=2$, the size of the spanner is $O\left(n^{6/5}\right)$ and the additive stretch is $O\left(\sqrt{d}\right)$.

Chechik [7] slightly improved the size of Pettie's [15] sublinear additive spanner with additive stretch $O(\sqrt{d})$ from $O\left(n^{1+1/5}\right)$ to $\tilde{O}\left(n^{1+3/17}\right)$.

Open Problems

A major open problem in the area of additive spanners is on the existence of purely additive spanners with $O\left(n^{1+\delta}\right)$ for any $\delta>0$. In particular, proving or disproving the existence of a spanner of size $O\left(n^{4/3-\epsilon}\right)$ for some constant ϵ with constant or even polylog additive stretch would be a major breakthrough.

Adwords Pricing

Tian-Ming Bu
Software Engineering Institute, East China Normal University, Shanghai, China

Keywords

Adword auction; Convergence; Dynamics; Equilibrium; Mechanism design

Years and Authors of Summarized Original Work

2007; Bu, Deng, Qi

Problem Definition

The model studied here is the same as that which is first presented in [10] by Varian. For some keyword, $\mathcal{N} = \{1, 2, \ldots, N\}$ advertisers bid $\mathcal{K} = \{1, 2, \ldots, K\}$ advertisement slots ($K < N$) which will be displayed on the search result page from top to bottom. The higher the advertisement is positioned, the more conspicuous it is and the more clicks it receives. Thus for any two slots $k_1, k_2 \in \mathcal{K}$, if $k_1 < k_2$, then slot k_1's click-through rate (CTR) c_{k_1} is larger than c_{k_2}. That is, $c_1 > c_2 > \cdots > c_K$, from top to bottom, respectively. Moreover, each bidder $i \in \mathcal{N}$ has privately known information, v^i, which represents the expected return of per click to bidder i.

According to each bidder i's submitted bid b^i, the auctioneer then decides how to distribute the advertisement slots among the bidders and how much they should pay for per click. In particular, the auctioneer first sorts the bidders in decreasing order according to their submitted bids. Then the highest slot is allocated to the first bidder, the second highest slot is allocated to the second bidder, and so on. The last $N - K$ bidders would lose and get nothing. Finally, each winner would be charged on a per-click basis for the next bid in the descending bid queue. The losers would pay nothing.

Let b_k denote the kth highest bid in the descending bid queue and v_k the true value of the kth bidder in the descending queue. Thus if bidder i got slot k, i's payment would be $b_{k+1} \cdot c_k$. Otherwise, his payment would be zero. Hence, for any bidder $i \in \mathcal{N}$, if i were on slot $k \in \mathcal{K}$, his/her utility (payoff) could be represented as

$$u_k^i = (v^i - b_{k+1}) \cdot c_k$$

Unlike one-round sealed-bid auctions where each bidder has only one chance to bid, the adword auction allows bidders to change their bids any time. Once bids are changed, the system refreshes the ranking automatically and instantaneously. Accordingly, all bidders' payment and utility are also recalculated. As a result, other bidders could then have an incentive to change their bids to increase their utility and so on.

Definition 1 (Adword Pricing)

INPUT: The CTR for each slot, each bidder's expected return per click on his/her advertising
OUTPUT: The stable states of this auction and whether any of these stable states can be reached from any initial states

Key Results

Let $\mathbf{b}$ represent the bid vector $(b^1, b^2, \ldots, b^N)$. $\forall i \in \mathcal{N}$, $\mathcal{O}^i(\mathbf{b})$ denotes bidder i's place in the descending bid queue. Let $\mathbf{b}^{-i} = (b^1, \ldots, b^{i-1}, b^{i+1}, \ldots, b^N)$ denote the bids of all other bidders except i. $\mathcal{M}^i(\mathbf{b}^{-i})$ returns a set defined as

$$\mathcal{M}^i(\mathbf{b}^{-i}) = \arg \max_{b^i \in [0, v^i]} \left\{ u^i_{\mathcal{O}^i(b^i, \mathbf{b}^{-i})} \right\} \quad (1)$$

Definition 2 (Forward-Looking Best-Response Function) Given $\mathbf{b}^{-i}$, suppose $\mathcal{O}^i(\mathcal{M}^i(\mathbf{b}^{-i}), \mathbf{b}^{-i}) = k$, then bidder i's forward-looking response function $\mathcal{F}^i(\mathbf{b}^{-i})$ is defined as

$$\mathcal{F}^i(\mathbf{b}^{-i}) = \begin{cases} v^i - \frac{c_k}{c_{k-1}}(v^i - b_{k+1}) & 2 \le k \le K \\ v^i & k = 1 \text{ or } k > K \end{cases} \quad (2)$$

Definition 3 (Forwarding-Looking Equilibrium) A forward-looking best-response function-based equilibrium is a strategy profile $\hat{\mathbf{b}}$ such that

$$\forall i \in \mathcal{N}, \hat{\mathbf{b}}^i \in \mathcal{F}^i(\hat{\mathbf{b}}^{-i})$$

Definition 4 (Output Truthful (Kao et al., 2006, Output truthful versus input truthful: a new concept for algorithmic mechanism design, unpublished) [7]) For any instance of adword auction and the corresponding equilibrium set $\mathcal{E}$, if $\forall \mathbf{e} \in \mathcal{E}$ and $\forall i \in \mathcal{N}$, $\mathcal{O}^i(\mathbf{e}) = \mathcal{O}^i(v^1, \ldots, v^N)$, then the adword auction is *output truthful* on $\mathcal{E}$.

Theorem 1 *An adword auction is output truthful on* $\mathcal{E}_{forward-looking}$.

Corollary 1 *An Adword auction has a unique forward-looking Nash equilibrium.*

Corollary 2 *Any bidder's payment under the forward-looking Nash equilibrium is equal to his/her payment under the VCG mechanism for the auction.*

Corollary 3 *For adword auctions, the auctioneer's revenue in a forward-looking Nash equilibrium is equal to his/her revenue under the VCG mechanism for the auction.*

Definition 5 (Simultaneous Readjustment Scheme) In a simultaneous readjustment scheme, all bidders participating in the auction

will use forward-looking best-response function $\mathcal{F}$ to update their current bids simultaneously, which turns the current stage into a new stage. Then based on the new stage, all bidders may update their bids again.

Theorem 2 *An adword auction may not always converge to a forward-looking Nash equilibrium under the simultaneous readjustment scheme even when the number of slots is 3. But the protocol converges when the number of slots is 2.*

Definition 6 (Round-Robin Readjustment Scheme) In the round-robin readjustment scheme, bidders update their biddings one after the other, according to the order of the bidder's number or the order of the slots.

Theorem 3 *An adword auction may not always converge to a forward-looking Nash equilibrium under the round-robin readjustment scheme even when the number of slots is 4. But the protocol converges when the number of slots is 2 or 3.*

1 Readjustment Scheme: Lowest-First$(K, j, b_1, b_2, \cdots, b_N)$

if $(j = 0)$ **then**
  exit
end if
Let i be the ID of the bidder whose current bid is b_j (and equivalently, b^i).
Let $h = \mathcal{O}^i(\mathcal{M}^i(\mathbf{b}^{-i}), \mathbf{b}^{-i})$.
Let $\mathcal{F}^i(\mathbf{b}^{-i})$ be the best response function value for Bidder i.
Re-sort the bid sequence. (So h is the slot of the new bid $\mathcal{F}^i(\mathbf{b}^{-i})$ of Bidder i.)
if $(h < j)$ **then**
  call Lowest-First $(K,j,b_1,b_2,\cdots,b_N)$,
else
  call Lowest-First$(K,h-1,b_1,b_2,\cdots,b_N)$
end if

Theorem 4 *Adword auctions converge to a forward-looking Nash equilibrium in finite steps with a* lowest-first *adjustment scheme.*

Theorem 5 *Adword auctions converge to a forward-looking Nash equilibrium with probability 1 under a randomized readjustment scheme.*

Applications

Online adword auctions are the fastest growing form of advertising. Many search engine companies such as Google and Yahoo! make huge profits on this kind of auction. Because advertisers can change their bids anytime, such auctions can reduce the advertisers' risk. Further, because the advertisement is only displayed to those people who are really interested in it, such auctions can reduce the advertisers' investment and increase their return on investment.

For the same model, Varian [10] focuses on a subset of Nash equilibria, called *Symmetric Nash Equilibria*, which can be formulated nicely and dealt with easily. Edelman et al. [8] study *locally envy-free* equilibria, where no player can improve his/her payoff by exchanging bids with the player ranked one position above him/her. Coincidently, locally envy-free equilibrium is equal to symmetric Nash equilibrium proposed in [10]. Further, the revenue under the forward-looking Nash equilibrium is the same as the lower bound under Varian's symmetric Nash equilibria and the lower bound under Edelman et al.'s locally envy-free equilibria. In [6], Cary et al. also study the dynamic model's equilibria and convergence based on the *balanced bidding strategy* which is actually the same as the *forward-looking best-response function* in [4]. Cary et al. explore the convergence properties under two models, a *synchronous* model which is the same as *simultaneous readjustment scheme* in [4] and an *asynchronous* model which is

the same as *randomized readjustment scheme* in [4].

In addition, there are other models for adword auctions. Abrams [1] and Bu et al. [5] study the model under which each bidder could submit his/her daily budget, even the maximum number of clicks per day, in addition to the price per click. Both [9] and [3] study bidders' behavior of bidding on several keywords. Aggarwal et al. [2] studies the model where the advertiser not only submits a bid but additionally submits which positions he/she is going to bid for.

Open Problems

The speed of convergence still remains open. Does the dynamic model converge in polynomial time under randomized readjustment scheme? Even more, are there other readjustment scheme that converge in polynomial time?

Algorithm DC-TREE for *k*-Servers on Trees

Marek Chrobak
Computer Science, University of California, Riverside, CA, USA

Keywords

Competitive analysis; K-server problem; On-line algorithms; Trees

Years and Authors of Summarized Original Work

1991; Chrobak, Larmore

Problem Definition

In the *k-Server Problem*, one wishes to schedule the movement of k-servers in a metric space $\mathbb{M}$, in response to a sequence $\varrho = r_1, r_2, \ldots, r_n$ of *requests*, where $r_i \in \mathbb{M}$ for each i. Initially, all the servers are located at some initial configuration $X_0 \subseteq \mathbb{M}$ of k points. After each request r_i is issued, one of the k-servers must move

to r_i. A *schedule* specifies which server moves to each request. The *cost* of a schedule is the total distance traveled by the servers, and our objective is to find a schedule with minimum cost.

In the *online* version of the k-Server Problem, the decision as to which server to move to each request r_i must be made before the next request r_{i+1} is issued. In other words, the choice of this server is a function of requests $r_1, r_2, \ldots, r_i$. It is quite easy to see that in this online scenario, it is not possible to compute an optimal schedule for each request sequence, raising the question of how to measure the accuracy of such online algorithms. A standard approach to doing this is based on competitive analysis. If $\mathcal{A}$ is an online k-server algorithm denote by $cost_{\mathcal{A}}(\varrho)$ the cost of the schedule produced by $\mathcal{A}$ on a request sequence ϱ, and by $opt(\varrho)$ the cost of the optimal schedule. $\mathcal{A}$ is called *R-competitive* if $cost_{\mathcal{A}}(\varrho) \leq R \cdot opt(\varrho) + B$, where B is a constant that may depend on $\mathbb{M}$ and X_0. The smallest such R is called the *competitive ratio* of $\mathcal{A}$.

The k-Server Problem was introduced by Manasse, McGeoch, and Sleator [7, 8], who proved that there is no online R-competitive algorithm for $R < k$, for any metric space with at least $k + 1$ points. They also gave a 2-competitive algorithm for $k = 2$ and formulated what is now known as the *k-Server Conjecture*, which postulates that there exists a k-competitive online algorithm for all k. Koutsoupias and Papadimitriou [5, 6] proved that the so-called *Work-Function Algorithm* has competitive ratio at most $2k - 1$, which to date remains the best upper bound known.

Efforts to prove the k-Server Conjecture led to discoveries of k-competitive algorithms for some restricted classes of metric spaces, including Algorithm DC-TREE for trees [3] presented in this entry. (See [1, 2, 4] for other examples.) A *tree* is a metric space defined by a connected acyclic graph whose edges are treated as line segments of arbitrary positive lengths. This metric space includes both the tree's vertices and the points on the edges, and the distances are measured along the (unique) shortest paths.

Key Results

Let $\mathbb{T}$ be a tree, as defined above. Given the current server configuration $S = \{s_1, \ldots, s_k\}$, where s_j denotes the location of server j, and a request point r, the algorithm will move several servers, with one of them ending up on r. For two points $x, y \in \mathbb{T}$, let $[x, y]$ be the unique path from x to y in $\mathbb{T}$. A server j is called *active* if there is no other server in $[s_j, r] - \{s_j\}$, and j is the minimum-index server located on s_j (the last condition is needed only to break ties).

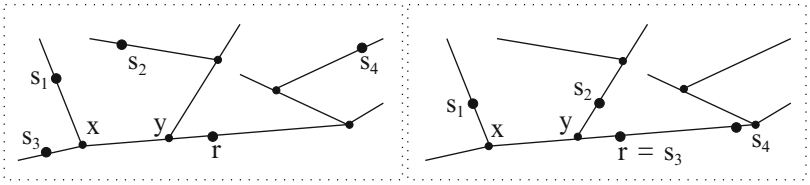
Algorithm DC-TREE. On a request r, move all active servers, continuously and with the same speed, towards r, until one of them reaches the request. Note that during this process some active servers may become inactive, in which case they halt. Clearly, the server that will arrive at r is the one that was closest to r at the time when r was issued.

More formally, denoting by s_j the variable representing the current position of server j, the algorithm serves r as follows:

while $s_j \neq r$ for all j **do**
  let $\delta = \frac{1}{2} \min_{i<j} \{d(s_i, s_j) + d(s_i, r) - d(s_j, r)\}$
  move each active server s_j by distance δ towards r

The example below shows how DC-TREE serves a request r (Fig. 1).

The competitive analysis of Algorithm DC-TREE is based on a potential argument. The cost of Algorithm DC-TREE is compared to that of an adversary who serves the requests with her own servers. Denoting by A the configuration of the adversary servers at a given step, define the potential by $\Phi = k \cdot D(S, A) + \sum_{i<j} d(s_i, s_j)$, where $D(S, A)$ is the cost of the minimum matching between S and A. At each step, the adversary first moves one of her servers to r. In this substep the potential increases by at most k times the increase of the adversary's cost. Then, Algorithm DC-TREE serves the request. One can show that then the sum of Φ and DC-TREE's cost does not increase. These two facts, by amortization over



Algorithm DC-TREE for *k*-Servers on Trees, Fig. 1 Algorithm DC-TREE serving a request on r. The configuration before r is issued is on the left; the configuration after the service is completed is on the right. At first, all servers are active. When server 3 reaches point x, server 1 becomes inactive. When server 3 reaches point y, server 2 becomes inactive

the whole request sequence, imply the following result [3]:

Theorem 1 ([3]) *Algorithm* DC-TREE *is* k*-competitive on trees.*

Applications

The k-Server Problem is an abstraction of various scheduling problems, including emergency crew scheduling, caching in multilevel memory systems, or scheduling head movement in 2-headed disks. Nevertheless, due to its abstract nature, the k-server problem is mainly of theoretical interest.

Algorithm DC-TREE can be applied to other spaces by "embedding" them into trees. For example, a uniform metric space (with all distances equal 1) can be represented by a star with arms of length $1/2$, and thus Algorithm DC-TREE can be applied to those spaces. This also immediately gives a k-competitive algorithm for the *caching problem*, where the objective is to manage a two-level memory system consisting of a large main memory and a cache that can store up to k memory items. If an item is in the cache, it can be accessed at cost 0, otherwise it costs 1 to read it from the main memory. This caching problem can be thought of as the k-server problem in a uniform metric space where the server positions represent the items residing in the cache. This idea can be extended further to the *weighted caching* [4], which is a generalization of the caching problem where different items may have different costs. In fact, if one can embed a metric space $\mathbb{M}$ into a tree with distortion bounded by δ, then Algorithm DC-TREE yields a δk-competitive algorithm for $\mathbb{M}$.

Open Problems

The k-Server Conjecture – whether there is a k-competitive algorithm for k-servers in any metric space – remains open. It would be of interest to prove it for some natural special cases, for example the plane, either with the Euclidean or Manhattan metric. (A k-competitive algorithm for the Manhattan plane for $k = 2, 3$ servers is known [1], but not for $k \geq 4$).

Very little is known about online *randomized* algorithms for k-servers. In fact, even for $k = 2$ it is not known if there is a randomized algorithm with competitive ratio smaller than 2.

Algorithmic Cooling

Tal Mor
Department of Computer Science, Technion – Israel Institute of Technology, Haifa, Israel

Keywords

Cooling; Data compression; Nuclear magnetic resonance; Quantum computing; Spin cooling; State initialization

Years and Authors of Summarized Original Work

1999; Schulman, Vazirani
2002; Boykin, Mor, Roychowdhury, Vatan, Vrijen

Problem Definition

The fusion of concepts taken from the fields of quantum computation, data compression, and thermodynamics has recently yielded novel algorithms that resolve problems in nuclear magnetic resonance and potentially in other areas as well, algorithms that "cool down" physical systems.

- A leading candidate technology for the construction of quantum computers is nuclear magnetic resonance (NMR). This technology has the advantage of being well established for other purposes, such as chemistry and medicine. Hence, it does not require new and exotic equipment, in contrast to ion traps and optical lattices, to name a few. However, when using standard NMR techniques, (not only for quantum computing purposes) one has to live with the fact that the state can only be initialized in a very noisy manner: The particles' spins point in mostly random directions, with only a tiny bias towards the desired state.

  The key idea of Schulman and Vazirani [27] is to combine the tools of both data compression and quantum computation, to suggest a *scalable* state initialization process, a "molecular-scale heat engine." Based on Schulman and Vazirani's method, Boykin, Mor, Roychowdhury, Vatan, and Vrijen [4] then developed a new process, "heat-bath algorithmic cooling," to significantly improve the state initialization process, by opening the system to the environment. Strikingly, this offered a way to put to good use the phenomenon of decoherence, which is usually considered to be the villain in quantum computation. These two methods are now sometimes called "closed-system" (or "reversible"), algorithmic cooling, and "open-system" algorithmic cooling, respectively.
- The far-reaching consequence of this research lies in the possibility of reaching beyond the potential implementation of remote-future quantum computing devices. An efficient technique to generate ensembles of spins that are highly polarized by external magnetic fields is considered to be a Holy Grail in NMR spectroscopy. Spin-half nuclei have steady-state polarization biases that increase inversely with temperature; therefore, spins exhibiting polarization biases above their thermal-equilibrium biases are considered *cool*. Such cooled spins present an improved signal-to-noise ratio if used in NMR spectroscopy or imaging.

  Existing spin-cooling techniques are limited in their efficiency and usefulness. Algorithmic cooling is a promising new spin-cooling approach that employs data compression methods in *open systems*.

It reduces the entropy of spins to a point far beyond Shannon's entropy bound on reversible entropy manipulations, thus increasing their polarization biases. As a result, it is conceivable that the open-system algorithmic cooling technique could be harnessed to improve on *current uses of NMR* in areas such as chemistry, material science, and even medicine, since NMR is at the basis of MRI – magnetic resonance imaging.

Basic Concepts

Loss-Less In-Place Data Compression

Given a bit string of length n, such that the probability distribution is known and far enough from the uniform distribution, one can use data compression to generate a shorter string, say of m bits, such that the entropy of each bit is much closer to one. As a simple example, consider a four-bit string which is distributed as follows: $p_{0001} = p_{0010} = p_{0100} = p_{1000} = 1/4$, with p_i the probability of the string i. The probability of any other string value is exactly zero, so the probabilities sum up to one. Then, the bit string can be compressed, via a lossy compression algorithm, into a 2-bit string that holds the binary description of the location of "1" in the above four strings. One can also envision a similar process that generates an output which is of the same length n as the input, but such that the entropy is compressed via a loss-less, in-place, data compression into the last two bits. For instance, logical gates that operate on the bits can perform the permutation $0001 \rightarrow 0000$, $0010 \rightarrow 0001$, $0100 \rightarrow 0010$, and $1000 \rightarrow 0011$, while the other input strings transform to output strings in which the two most significant bits are not zero; for instance, $1100 \rightarrow 1010$. One can easily see that the entropy is now fully concentrated on the two least significant bits, which are useful in data compression, while the two most significant bits have zero entropy.

In order to gain some intuition about the design of logical gates that perform entropy manipulations, one can look at a closely related scenario which was first considered by von Neumann. He showed a method to extract fair coin flips, given a biased coin; he suggested taking a pair of biased coin flips, with results a and b, and using the value of a conditioned on $a \neq b$. A simple calculation shows that $a = 0$ and $a = 1$ are now obtained with equal probabilities, and therefore, the entropy of coin a is increased in this case to 1. The opposite case, the probability distribution of a given that $a = b$, results in a highly determined coin flip, namely, a (conditioned) coin flip with a higher bias or lower entropy. A gate that flips the value of b if (and only if) $a = 1$ is called a controlled NOT gate. If after applying such a gate $b = 1$ is obtained, this means that $a \neq b$ prior to the gate operation; thus, now the entropy of a is 1. If, on the other hand, after applying such a gate $b = 0$ is obtained, this means that $a = b$ prior to the gate operation; thus, the entropy of a is now lower than its initial value.

Spin Temperature, Polarization Bias, and Effective Cooling

In physics, two-level systems, namely, systems that possess only binary values, are useful in many ways. Often it is important to initialize such systems to a pure state "0" or to a probability distribution which is as close as possible to a pure state "0." In these physical two-level systems, a data compression process that brings some of them closer to a pure state can be considered as "cooling." For quantum two-level systems, there is a simple connection between temperature, entropy, and population probability. The population difference between these two levels is known as the polarization bias, ϵ. Consider a single spin-half particle – for instance, a hydrogen nucleus – in a constant magnetic field. At equilibrium with a thermal heat-bath, the probability of this spin to be up or down (i.e., parallel or antiparallel to the field direction) is given by $p_\uparrow = \frac{1+\epsilon}{2}$ and $p_\downarrow = \frac{1-\epsilon}{2}$. The entropy H of the spin is $H(\text{single}-\text{bit}) = H(1/2 + \epsilon/2)$ with $H(P) \equiv -P \log_2 P - (1-P)\log_2(1-P)$ measured in bits. The two pure states of a spin-half nucleus are commonly written as $|\uparrow\rangle \equiv$"0" and $|\downarrow\rangle \equiv$"1"; the $|\rangle$ notation will be clarified elsewhere. (Quantum Computing entries in this encyclopedia.) The polarization bias of the spin at

thermal equilibrium is given by $\epsilon = p_\uparrow - p_\downarrow$. For such a physical System, the bias is obtained via a quantum statistical mechanics argument, $\epsilon = \tanh\left(\frac{\hbar\gamma B}{2K_B T}\right)$, where $\hbar$ is Planck's constant, B is the magnetic field, γ is the particle-dependent gyromagnetic constant,(This constant, γ, is thus responsible for the difference in equilibrium polarization bias [e.g., a hydrogen nucleus is 4 times more polarized than a carbon isotope ^{13}C nucleus, but about 10^3 less polarized than an electron spin].) K_B is Boltzman's coefficient, and T is the thermal heat-bath temperature. For high temperatures or small biases $\epsilon \approx \frac{\hbar\gamma B}{2K_B T}$; thus, the bias is inversely proportional to the temperature. Typical values of ϵ for spin-half nuclei at room temperature (and magnetic field of $\sim$10 T) are 10^{-5}–10^{-6}, and therefore, most of the analysis here is done under the assumption that $\epsilon \ll 1$. The spin temperature at equilibrium is thus $T = \frac{\text{Const}}{\epsilon}$, and its (Shannon) entropy is $H = 1 - (\epsilon^2/\ln 4)$.

A spin temperature out of thermal equilibrium is still defined via the same formulas. Therefore, when a system is moved away from thermal equilibrium, achieving a greater polarization bias is equivalent to cooling the spins, *without cooling the system*, and to decreasing their entropy. The process of increasing the bias (reducing the entropy) without increasing the temperature of the thermal bath is known as "effective cooling." After a typical period of time, termed the thermalization time or relaxation time, the bias will gradually revert to its thermal equilibrium value; yet during this process, typically in the order of seconds, the effectively cooled spin may be used for various purposes as described in section "Applications."

Consider a molecule that contains n adjacent spin-half nuclei arranged in a line; these form the bits of the string. These spins are initially at thermal equilibrium due to their interaction with the environment. At room temperature, the bits at thermal equilibrium are not correlated to their neighbors on the same string: more precisely, the correlation is very small and can be ignored. Furthermore, in a liquid state one can also neglect the interaction between strings (between molecules). It is convenient to write the probability distribution of a single spin at thermal equilibrium using the "density-matrix" notation

$$\rho_\epsilon = \begin{pmatrix} p_\uparrow & 0 \\ 0 & p_\downarrow \end{pmatrix} = \begin{pmatrix} (1+\epsilon)/2 & 0 \\ 0 & (1-\epsilon)/2 \end{pmatrix}, \tag{1}$$

since these two-level systems are of a quantum nature (namely, these are quantum bits – qubits) and, in general, can also have states other than just a classical probability distribution over "0" and "1." The classical case will now be considered, where ρ contains only diagonal elements, and these describe a conventional probability distribution. At thermal equilibrium, the state of $n = 2$ uncorrelated qubits that have the same polarization bias is described by the density matrix $\rho_{\text{init}}^{\{n=2\}} = \rho_\epsilon \otimes \rho_\epsilon$, where $\otimes$ means tensor product. The probability of the state "00," for instance, is then $(1+\epsilon)/2 \times (1+\epsilon)/2 = (1+\epsilon)^2/4$, etc. Similarly, the initial state of an n-qubit system of this type, at thermal equilibrium, is

$$\rho_{\text{init}}^{\{n\}} = \rho_\epsilon \otimes \rho_\epsilon \otimes \cdots \otimes \rho_\epsilon. \tag{2}$$

This state represents a thermal probability distribution, such that the probability of the classical state "000…0" is $P_{000\ldots0} = (1+\epsilon_0)^n/2^n$, etc. In reality, the initial bias is not the same on each qubit,(Furthermore, individual addressing of each spin during the algorithm requires a slightly different bias for each.) but as long as the differences between these biases are small (e.g., all qubits are of the same nucleus), these differences can be ignored in a discussion of an idealized scenario.

Key Results

Molecular-Scale Heat Engines

Schulman and Vazirani (SV) [27] identified the importance of in-place loss-less data compression and of the low-entropy bits created in that process: physical two-level systems (e.g., spin-half nuclei) may be similarly cooled by data compression algorithms. SV analyzed the cooling of such a system using various tools of data compression. A loss-less compression of an n-bit binary string distributed according to the thermal

equilibrium distribution, Eq. 2, is readily analyzed using information-theoretical tools: In an ideal compression scheme (not necessarily realizable), with sufficiently large n, all randomness – and hence all the entropy – of the bit string is transferred to $n - m$ bits; the remaining m bits are thus left, with extremely high probability, at a known deterministic state, say the string "000...0." The entropy H of the entire system is $H(\text{system}) = nH(\text{single} - \text{bit}) = nH(1/2 + \epsilon/2)$. Any compression scheme cannot decrease this entropy; hence, Shannon's source coding entropy bound yields $m \leq n[1 - H(1/2 + \epsilon/2)]$. A simple leading-order calculation shows that m is bounded by (approximately) $\frac{\epsilon^2}{2\ln 2}n$ for small values of the initial bias ϵ. Therefore, with typical $\epsilon \sim 10^{-5}$, molecules containing an order of magnitude of 10^{10} spins are required to cool a single spin close to zero temperature.

Conventional methods for NMR quantum computing are based on unscalable state initialization schemes [7, 14] (e.g., the "pseudo-pure-state" approach) in which the signal-to-noise ratio falls exponentially with n, the number of spins. Consequently, these methods are deemed inappropriate for future NMR quantum computers. SV [27] were first to employ tools of information theory to address the scaling problem; they presented a compression scheme in which the number of cooled spins scales well (namely, a constant times n). SV also demonstrated a scheme approaching Shannon's entropy bound, for very large n. They provided detailed analyses of three cooling algorithms, each useful for a different regime of ϵ values.

Some ideas of SV were already explored a few years earlier by Sørensen [29], a physical chemist who analyzed effective cooling of spins. He considered the entropy of several spin systems and the limits imposed on cooling these systems by polarization transfer and more general polarization manipulations. Furthermore, he considered spin-cooling processes in which only unitary operations were used, wherein unitary matrices are applied to the density matrices; such operations are realizable, at least from a conceptual point of view. Sørensen derived a stricter bound on unitary cooling, which today bears his name. Yet, unlike SV, he did not infer the connection to data compression or advocate compression algorithms.

SV named their concept "molecular-scale heat engine." When combined with conventional polarization transfer (which is partially similar to a SWAP gate between two qubits), the term "reversible polarization compression (RPC)" is more descriptive.

Heat-Bath Algorithmic Cooling

The next significant development came when Boykin, Mor, Roychowdhury, Vatan, and Vrijen (hereinafter referred to as BMRVV), invented a new spin-cooling technique, which they named *Algorithmic cooling* [4] or more specifically heat-bath algorithmic cooling in which the use of controlled interactions with a heat bath enhances the cooling techniques much further. Algorithmic cooling (AC) expands the effective cooling techniques by exploiting entropy manipulations in *open systems*. It combines RPC steps (When the entire process is RPC, namely, any of the processes that follow SV ideas, one can refer to it as reversible AC or closed-system AC, rather than as RPC.) with fast relaxation (namely, thermalization) of the *hotter spins*, as a way of pumping entropy outside the system and cooling the system *much beyond Shannon's entropy bound*. In order to pump entropy out of the system, AC employs regular spins (here called computation spins) together with rapidly relaxing spins. The latter are auxiliary spins that return to their thermal equilibrium state very rapidly. These spins have been termed "reset spins," or, equivalently, reset bits. The controlled interactions with the heat bath are generated by polarization transfer or by standard algorithmic techniques (of data compression) that transfer the entropy onto the reset spins which then lose this excess entropy into the environment.

The ratio $R_{\text{relax}-\text{times}}$, between the relaxation time of the computation spins and the relaxation time of the reset spins, must satisfy $R_{\text{relax}-\text{times}} \gg 1$. This condition is vital if one wishes to perform many cooling steps on the system to obtain significant cooling.

In a pure information-theoretical point of view, it is legitimate to assume that the only restriction on ideal RPC steps is Shannon's entropy bound; then the equivalent of Shannon's entropy bound, when an ideal open-system AC is used, is that all computation spins can be cooled down to zero temperature, that is to $\epsilon = 1$. Proof: repeat the following till the entropy of all computation spins is exactly zero: (i) push entropy from computation spins into reset spins and (ii) let the reset spins cool back to room temperature. Clearly, each application of step (i), except the last one, pushes the same amount of entropy onto the reset spins, and then this entropy is removed from the system in step (ii). Of course, a realistic scenario must take other parameters into account such as finite relaxation-time ratios, realistic environment, and physical operations on the spins. Once this is done, cooling to zero temperature is no longer attainable. While finite relaxation times and a realistic environment are system dependent, the constraint of using physical operations is conceptual.

BMRVV therefore pursued an algorithm that follows some physical rules; it is performed by unitary operations and reset steps and still bypass Shannon's entropy bound, by far. The BMRVV cooling algorithm obtains significant cooling beyond that entropy bound by making use of very long molecules bearing hundreds or even thousands of spins, because its analysis relies on the law of large numbers.

Practicable Algorithmic Cooling

The concept of algorithmic cooling then led to practicable algorithms [13] for cooling *small molecules*. In order to see the impact of practicable algorithmic cooling, it is best to use a different variant of the entropy bound. Consider a system containing n spin-half particles with total entropy higher than $n - 1$, so that there is no way to cool even one spin to zero temperature. In this case, the entropy bound is a result of the compression of the entropy into $n - 1$ fully random spins, so that the remaining entropy on the last spin is minimal. The entropy of the remaining single spin satisfies $H(\text{single}) \geq 1 - n\epsilon^2/\ln 4$; thus, at most, its polarization can be improved to

$$\epsilon_{\text{final}} \leq \epsilon\sqrt{n}\,. \tag{3}$$

The practicable algorithmic cooling (PAC), suggested by Fernandez, Lloyd, Mor, and Roychowdhury in [13], indicated potential for a near-future application to NMR spectroscopy. In particular, it presented an algorithm named PAC2 which uses any (odd) number of spins n, such that one of them is a reset spin, and $(n-1)$ are computation spins. PAC2 cools the spins such that the coldest one can (approximately) reach a bias amplification by a factor of $(3/2)^{(n-1)/2}$. The approximation is valid as long as the final bias $(3/2)^{(n-1)/2}\ \epsilon$ is much smaller than 1. Otherwise, a more precise treatment must be done. This proves an exponential advantage of AC over the best possible reversible AC, as these reversible cooling techniques, e.g., of [27, 29], are limited to improve the bias by no more than a factor of $\sqrt{n}$. PAC can be applied for small n (e.g., in the range of 10–20), and therefore, it is potentially suitable for near-future applications [9, 13, 19] in chemical and biomedical usages of NMR spectroscopy.

It is important to note that in typical scenarios, the initial polarization bias of a reset spin is higher than that of a computation spin. In this case, the bias amplification factor of $(3/2)^{(n-1)/2}$ is relative to the larger bias, that of the reset spin.

Exhaustive Algorithmic Cooling

Next, AC was analyzed, wherein the cooling steps (reset and RPC) are repeated an arbitrary number of times. This is actually an idealization where an unbounded number of reset and logic steps can be applied without error or decoherence, while the computation qubits do not lose their polarization biases. Fernandez [12] considered two computation spins and a single reset spin (the least significant bit, namely, the qubit at the right in the tensor-product density-matrix notation) and analyzed optimal cooling of this system. By repeating the reset and compression

exhaustively, he realized that the bound on the final biases of the three spins is approximately $\{2, 1, 1\}$ in units of ϵ, the polarization bias of the reset spin.

Mor and Weinstein generalized this analysis further and found that $n-1$ computation spins and a single reset spin can be cooled (approximately) to biases according to the Fibonacci series: $\{\ldots 34, 21, 13, 8, 5, 3, 2, 1, 1\}$. The computation spin that is further away from the reset spin can be cooled up to the relevant Fibonacci number F_n. That approximation is valid as long as the largest term times ϵ is still much smaller than 1. Schulman then suggested the "partner pairing algorithm" (PPA) and proved the optimality of the PPA among all *classical and quantum* algorithms. These two algorithms, the Fibonacci AC and the PPA, led to two joint papers [25, 26], where upper and lower bounds on AC were also obtained. The PPA is defined as follows: repeat these two steps until cooling sufficiently close to the limit: (a) RESET, applied to a reset spin in a system containing $n-1$ computation spins and a single (the LSB) reset spin, and (b) SORT, a permutation that sorts the 2^n diagonal elements of the density matrix by decreasing order, so that the MSB spin becomes the coldest. Two important theorems proven in [26] are:

(1) Lower bound: When $\epsilon 2^n \gg 1$ (namely, for long enough molecules), Theorem 3 in [26] promises that $n - \log(1/\epsilon)$ cold qubits can be extracted. This case is relevant for scalable NMR quantum computing.
(2) Upper bound: Section 4.2 in [26] proves the following theorem: No algorithmic cooling method can increase the probability of any basis state to above $\min\{2^{-n}e^{2^n\epsilon}, 1\}$, wherein the initial configuration is the completely mixed state (the same is true if the initial state is a thermal state).

More recently, Elias, Fernandez, Mor, and Weinstein [9] analyzed more closely the case of $n < 15$ (at room temperature), where the coldest spin (at all stages) still has a polarization bias much smaller than 1. This case is most relevant for near-future applications in NMR spectroscopy. They generalized the Fibonacci-AC to algorithms yielding higher-term Fibonacci series, such as the tribonacci (also known as 3-term Fibonacci series), $\{\ldots 81, 44, 24, 13, 7, 4, 2, 1, 1\}$, etc. The ultimate limit of these multi-term Fibonacci series is obtained when each term in the series is the sum of all previous terms. The resulting series is precisely the exponential series $\{\ldots 128, 64, 32, 16, 8, 4, 2, 1, 1\}$, so the coldest spin is cooled by a factor of 2^{n-2}. Furthermore, a leading-order analysis of the upper bound mentioned above (Section 4.2 in Ref. [26]) shows that no spin can be cooled beyond a factor of 2^{n-1}; see Corollary 1 in [9].

Other Results

For several other theoretical results dealing with relevant algorithms and with the connection to thermodynamics, see [11, 15, 17, 21]. For several popular "News and Views" discussions of AC in Nature, see [18, 22, 24].

Applications

The two major far-future and near-future applications are already described in section "Problem Definition." It is important to add here that although the specific algorithms analyzed so far for AC are usually classical, their practical implementation via an NMR spectrometer must be done through analysis of universal quantum computation, using the specific gates allowed in such systems. Therefore, AC could yield the first near-future application of quantum computing devices.

AC may also be useful for cooling various other physical systems; for several examples (theoretical and experimental), see [2, 16, 28, 30, 31], since state initialization is a common problem in physics in general and in quantum computation in particular.

Open Problems

A main open problem in practical AC is technological; can the ratio of relaxation

times be increased so that many cooling steps may be applied onto relevant NMR systems? Other methods, for instance, a spin-diffusion mechanism [3, 23], may also be useful for various applications.

Another interesting open problem is whether the ideas developed during the design of AC can also lead to applications in classical information theory.

Last but not least, in the context of building scalable quantum computers, it is interesting to study if AC can become a practical tool for advancing the non-conventional model of quantum computing called the one pure qubit (or one clean qubit) model as suggested in [1, 8] and to study if AC can be useful for designing fault-tolerant quantum computers as suggested in [20].

Experimental Results

Various ideas of AC had already led to several experiments using 3–4 qubit quantum computing devices in NMR (AC used in other systems was mentioned earlier in section "Applications"):

(1) An experiment [6] that implemented a single RPC step.
(2) Two experiments [5, 10] in which entropy-conservation bounds (which apply in any closed system) were bypassed. The second one [10] was done on bio-molecules – amino acids.
(3) A full AC experiment [3] that includes the initialization of three carbon nuclei to the bias of a hydrogen spin, followed by a single compression step on these three carbons. This work was later on extended also to multi-cycle AC [23].

Algorithmic Mechanism Design

Ron Lavi

Years and Authors of Summarized Original Work

1999; Nisan, Ronen

Problem Definition

Mechanism design is a sub-field of economics and game theory that studies the construction of social mechanisms in the presence of selfish agents. The nature of the agents dictates a basic contrast between the social planner, that aims to reach a socially desirable outcome, and the agents, that care only about their own private utility. The underlying question is how to incentivize the agents to cooperate, in order to reach the desirable social outcomes.

In the Internet era, where computers act and interact on behalf of selfish entities, the connection of the above to algorithmic design suggests itself: suppose that the input to an algorithm is kept by selfish agents, who aim to maximize their own utility. How can one design the algorithm so that the agents will find it in their best interest to cooperate, and a close-to-optimal outcome will be outputted? This is different than classic distributed computing models, where agents are either "good" (meaning obedient) or "bad" (meaning faulty, or malicious, depending on the context). Here, no such partition is possible. It is simply assumed that all agents are utility maximizers. To illustrate this, let us describe a motivating example:

A Motivating Example: Shortest Paths

Given a weighted graph, the goal is to find a shortest path (with respect to the edge weights) between a given source and target nodes. Each edge is controlled by a selfish entity, and the weight of the edge, w_e is private information of that edge. If an edge is chosen by the algorithm to be included in the shortest path, it will incur a cost which is minus its weight (the cost of communication). Payments to the edges are allowed, and the total utility of an edge that participates in the shortest path and gets a payment p_e is assumed to be $u_e = p_e - w_e$. Notice that the shortest path is *with respect to the true weights of the agents, although these are not known to the designer.*

Assuming that each edge will act in order to maximize its utility, how can one choose the

path and the payments? One option is to ignore the strategic issue all together, ask the edges to simply report their weights, and compute the shortest path. In this case, however, an edge dislikes being selected, and will therefore prefer to report a very high weight (much higher than its true weight) in order to decrease the chances of being selected. Another option is to pay each selected edge its reported weight, or its reported weight plus a small fixed "bonus". However in such a case all edges will report lower weights, as being selected will imply a positive gain.

Although this example is written in an algorithmic language, it is actually a mechanism design problem, and the solution, which is now a classic, was suggested in the 1970's. The chapter continues as follows: First, the abstract formulation for such problems is given, the classic solution from economics is described, and its advantages and disadvantages for algorithmic purposes are discussed. The next section then describes the new results that algorithmic mechanism design offers.

Abstract Formulation

The framework consists of a set A of alternatives, or outcomes, and n players, or agents. Each player i has a valuation function $v_i: A \to \Re$ that assigns a value to each possible alternative. This valuation function belongs to a domain V_i of all possible valuation functions. Let $V = V_1 \times \cdots \times V_n$, and $V_{-i} = \prod_{j \neq i} V_j$. Observe that this generalizes the shortest path example of above: A is all the possible $s-t$ paths in the given graph, $v_e(a)$ for some path $a \in A$ is either $-w_e$ (if $e \in a$) or zero.

A *social choice function* $f: V \to A$ assigns a socially desirable alternative to any given profile of players' valuations. This parallels the notion of an algorithm. A *mechanism* is a tuple $M = (f, p_1, \ldots, p_n)$, where f is a social choice function, and $p_i: V \to \Re$ (for $i = 1, \ldots, n$) is the price charged from player i. The interpretation is that the social planner asks the players to reveal their true valuations, chooses the alternative according to f as if the players have indeed acted truthfully, and in addition rewards/punishes the players with the prices. These prices should induce "truthfulness" in the following strong sense: no matter what the other players declare, it is always in the best interest of player i to reveal her true valuation, as this will maximize her utility. Formally, this translates to:

Definition 1 (Truthfulness) M is "truthful" (in dominant strategies) if, for any player i, any profile of valuations of the other players $v_{-i} \in V_{-i}$, and any two valuations of player i $v_i, v_i' \in V_i$,

$$v_i(a) - p_i(v_i, v_{-i}) \geq v_i(b) - p_i(v_i', v_{-i})$$

where $f(v_i, v_{-i}) = a$ and $f(v_i', v_{-i}) = b$.

Truthfulness is quite strong: a player need not know anything about the other players, even not that they are rational, and still determine the best strategy for her. Quite remarkably, there exists a truthful mechanism, even under the current level of abstraction. This mechanism suits all problem domains, where the social goal is to maximize the "social welfare":

Definition 2 (Social welfare maximization) A social choice function $f: V \to A$ maximizes the social welfare if $f(v) \in \text{argmax}_{a \in A} \sum_i v_i(a)$, for any $v \in V$.

Notice that the social goal in the shortest path domain is indeed welfare maximization, and, in general, this is a natural and important economic goal. Quite remarkably, there exists a general technique to construct truthful mechanisms that implement this goal:

Theorem 1 (Vickrey–Clarke–Groves (VCG)) *Fix any alternatives set A and any domain V, and suppose that $f: V \to A$ maximizes the social welfare. Then there exist prices p such that the mechanism (f, p) is truthful.*

This gives "for free" a solution to the shortest path problem, and to many other algorithmic problems. The great advantage of the VCG scheme is its generality: it suits *all* problem domains. The disadvantage, however, is that the method is tailored to social welfare maximization. This turns out to be restrictive,

especially for algorithmic and computational settings, due to several reasons: (i) different algorithmic goals: the algorithmic literature considers a variety of goals, including many that cannot be translated to welfare maximization. VCG does not help us in such cases. (ii) computational complexity: even if the goal is welfare maximization, in many settings achieving exactly the optimum is computationally hard. The CS discipline usually overcomes this by using approximation algorithms, but VCG will not work with such algorithm – reaching exact optimality is a necessary requirement of VCG. (iii) different algorithmic models: common CS models change "the basic setup", hence cause unexpected difficulties when one tries to use VCG (for example, an online model, where the input is revealed over time; this is common in CS, but changes the implicit setting that VCG requires). This is true even if welfare maximization is still the goal.

Answering any one of these difficulties requires the design of a non-VCG mechanism. What analysis tools should be used for this purpose? In economics and classic mechanism design, average-case analysis, that relies on the knowledge of the underlying distribution, is the standard. Computer science, on the other hand, usually prefers to avoid strong distributional assumptions, and to use worst-case analysis. This difference is another cause to the uniqueness of the answers provided by algorithmic mechanism design. Some of the new results that have emerged as a consequence of this integration between Computer Science and Economics is next described. Many other research topics that use the tools of algorithmic mechanism design are described in the entries on Adword Pricing, Competitive Auctions, False Name Proof Auctions, Generalized Vickrey Auction, Incentive Compatible Ranking, Mechanism for One Parameter Agents Single Buyer/Seller, Multiple Item Auctions, Position Auctions, and Truthful Multicast.

There are two different but closely related research topics that should be mentioned in the context of this entry. The first is the line of works that studies the "price of anarchy" of a given system. These works analyze *existing* systems, trying to quantify the loss of social efficiency due to the selfish nature of the participants, while the approach of algorithmic mechanism design is to understand how new systems should be designed. For more details on this topic the reader is referred to the entry on Price of Anarchy. The second topic regards the algorithmic study of various equilibria computation. These works bring computational aspects into economics and game theory, as they ask what equilibria notions are reasonable to assume, if one requires computational efficiency, while the works described here bring game theory and economics into computer science and algorithmic theory, as they ask what algorithms are reasonable to design, if one requires the resilience to selfish behavior. For more details on this topic the reader is referred (for example) to the entry on Algorithms for Nash Equilibrium and to the entry on General Equilibrium.

Key Results

Problem Domain 1: Job Scheduling

Job scheduling is a classic algorithmic setting: n jobs are to be assigned to m machines, where job j requires processing time p_{ij} on machine i. In the game-theoretic setting, it is assumed that each machine i is a selfish entity, that incurs a cost p_{ij} from processing job j. Note that the payments in this setting (and in general) may be negative, offsetting such costs. A popular algorithmic goal is to assign jobs to machines in order to minimize the "makespan": $\max_i \sum_{j \text{ is assigned to } i} p_{ij}$. This is different than welfare maximization, which translates in this setting to the minimization of $\sum_i \sum_{j \text{ is assigned to } i} p_{ij}$, further illustrating the problem of different algorithmic goals. Thus the VCG scheme cannot be used, and new methods must be developed.

Results for this problem domain depend on the specific assumptions about the structure of the processing time vectors. In the *related machines* case, $p_{ij} = p_j/s_i$ for any $i\,j$, where the p_j's are public knowledge, and the only secret parameter of player i is its *speed*, s_i.

Theorem 2 ([3, 22]) *For job scheduling on related machines, there exists a truthful exponential-time mechanism that obtains the optimal makespan, and a truthful polynomial-time mechanism that obtains a 3-approximation to the optimal makespan.*

More details on this result are given in the entry on Mechanism for One Parameter Agents Single Buyer. The bottom line conclusion is that, although the social goal is different than welfare maximization, there still exists a truthful mechanism for this goal. A non-trivial approximation guarantee is achieved, even under the additional requirement of computational efficiency. However, this guarantee does not match the best possible without the truthfulness requirement, since in this case a PTAS is known.

Open Question 1 *Is there a truthful PTAS for makespan minimization in related machines?*

If the number of machines is fixed then [2] give such a truthful PTAS.

The above picture completely changes in the move to the more general case of *unrelated machines*, where the p_{ij}'s are allowed to be arbitrary:

Theorem 3 ([13, 30]) *Any truthful scheduling mechanism for unrelated machines cannot approximate the optimal makespan by a factor better than* $1+\sqrt{2}$ *(for deterministic mechanisms) and* $2-1/m$ *(for randomized mechanisms).*

Note that this holds regardless of computational considerations. In this case, switching from welfare maximization to makespan minimization results in a strong impossibility. On the possibilities side, virtually nothing (!) is known. The VCG mechanism (which minimizes the total social cost) is an m-approximation of the optimal makespan [32], and, in fact, nothing better is currently known:

Open Question 2 *What is the best possible approximation for truthful makespan minimization in unrelated machines?*

What caused the switch from "mostly possibilities" to "mostly impossibilities"? Related machines is a single-dimensional domain (players hold only one secret number), for which truthfulness is characterized by a simple monotonicity condition, that leaves ample flexibility for algorithmic design. Unrelated machines, on the other hand, are a multi-dimensional domain, and the algorithmic conditions implied by truthfulness in such a case are harder to work with. It is still unclear whether these conditions imply real mathematical impossibilities, or perhaps just pose harder obstacles that can be in principle solved. One multi-dimensional scheduling domain for which possibility results are known is the case where $p_{ij} \in \{L_j, H_j\}$, where the "low" 's and "high" 's are fixed and known. This case generalizes the classic multi-dimensional model of restricted machines ($p_{ij} \in \{p_j, \infty\}$), and admits a truthful 3-approximation [27].

Problem Domain 2: Digital Goods and Revenue Maximization

In the E-commerce era, a new kind of "digital goods" have evolved: goods with no marginal production cost, or, in other words, goods with unlimited supply. One example is songs being sold on the Internet. There is a sunk cost of producing the song, but after that, additional electronic copies incur no additional cost. How should such items be sold? One possibility is to conduct an *auction*. An auction is a one-sided market, where a monopolistic entity (the auctioneer) wishes to sell one or more items to a set of buyers.

In this setting, each buyer has a privately known value for obtaining one copy of the good. Welfare maximization simply implies the allocation of one good to every buyer, but a more interesting question is the question of revenue maximization. How should the auctioneer design the auction in order to maximize his profit? Standard tools from the study of revenue-maximizing auctions (This model was not explicitly studied in classic auction theory, but standard results from there can be easily adjusted to this setting.) suggest to simply declare a price-per-buyer, determined by the probability distribution of the buyer's value, and make a take-it-or-leave-it offer.

However, such a mechanism needs to know the underlying distribution. Algorithmic mechanism design suggests an alternative, worst-case result, in the spirit of CS-type models and analysis.

Suppose that the auctioneer is required to sell all items in the same price, as is the case for many "real-life" monopolists, and denote by $F(\vec{v})$ the maximal revenue from a fixed-price sale to bidders with values $\vec{v} = v_1, \ldots v_n$, *assuming that all values are known*. Reordering indexes so that $v_1 \geq v_2 \geq \cdots \geq v_n$, let $F(\vec{v}) = \max_i i \cdot v_i$. The problem is, of-course, that in fact *nothing* about the values is known. Therefore, a truthful auction that extracts the players' values is in place. Can such an auction obtain a profit that is a constant fraction of $F(\vec{v})$, for any $\vec{v}$ (i.e., in the worst case)? Unfortunately, the answer is provably no [17]. The proof makes use of situations where the entire profit comes from the highest bidder. Since there is no potential for competition among bidders, a truthful auction cannot force this single bidder to reveal her value.

Luckily, a small relaxation in the optimality criteria significantly helps. Specifically, denote by $F^{(2)}(\vec{v}) = \max_{i \geq 2} i \cdot v_i$ (i.e., the benchmark is the auction that sells to at least two buyers).

Theorem 4 ([17, 20]) *There exists a truthful randomized auction that obtains an expected revenue of at least $F^{(2)}/3.25$, even in the worst-case. On the other hand, no truthful auction can approximate $F^{(2)}$ within a factor better than 2.42.*

Several interesting formats of distribution-free revenue-maximizing auctions have been considered in the literature. The common building block in all of them is the random partitioning of the set of buyers to random subsets, analyzing each set separately, and using the results on the other sets. Each auction utilizes a different analysis on the two subsets, which yields slightly different approximation guarantees. Aggarwal et al. [1] describe an elegant method to derandomize these type of auctions, while losing another factor of 4 in the approximation. More details on this problem domain can be found in the entry on Competitive Auctions.

Problem Domain 3: Combinatorial Auctions

Combinatorial auctions (CAs) are a central model with theoretical importance and practical relevance. It generalizes many theoretical algorithmic settings, like job scheduling and network routing, and is evident in many real-life situations. This new model has various pure computational aspects, and, additionally, exhibits interesting game theoretic challenges. While each aspect is important on its own, obviously only the integration of the two provides an acceptable solution.

A combinatorial auction is a multi-item auction in which players are interested in *bundles* of items. Such a valuation structure can represent substitutabilities among items, complementarities among items, or a combination of both. More formally, m items (Ω) are to be allocated to n players. Players value subsets of items, and $v_i(S)$ denotes i's value of a bundle $S \subseteq \Omega$. Valuations additionally satisfy: (i) monotonicity, i.e., $v_i(S) \leq v_i(T)$ for $S \subseteq T$, and (ii) normalization, i.e., $v_i(\emptyset) = 0$. The literature has mostly considered the goal of maximizing the social welfare: find an allocation $(S_1, \ldots, S_n)$ that maximizes $\sum_i v_i(S_i)$.

Since a general valuation has size exponential in n and m, the representation issue must be taken into account. Two models are usually considered (see [11] for more details). In the *bidding languages* model, the bid of a player represents his valuation is a concise way. For this model it is NP-hard to approximate the social welfare within a ratio of $\Omega(m^{1/2-\epsilon})$, for any $\epsilon > 0$ (if "single-minded" bids are allowed; the exact definition is given below). In the *query access* model, the mechanism iteratively queries the players in the course of computation. For this model, any algorithm with polynomial communication cannot obtain an approximation ratio of $\Omega(m^{1/2-\epsilon})$ for any $\epsilon > 0$. These bounds are tight, as there exist a deterministic $\sqrt{m}$-approximation with polynomial computation and communication. Thus, for the general valuation structure, the computational status by itself is well-understood.

The basic incentives issue is again well-understood: VCG obtains truthfulness. Since

VCG requires the exact optimum, which is NP-hard to compute, the two considerations therefore clash, when attempting to use classic techniques. Algorithmic mechanism design aims to develop new techniques, to integrate these two desirable aspects.

The first positive result for this integration challenge was given by [29], for the special case of "single-minded bidders": each bidder, i, is interested in a specific bundle S_i, for a value v_i (any bundle that contains S_i is worth v_i, and other bundles have zero value). Both v_i, S_i are private to the player i.

Theorem 5 ([29]) *There exists a truthful and polynomial-time deterministic combinatorial auction for single-minded bidders, which obtains a $\sqrt{m}$-approximation to the optimal social welfare.*

A possible generalization of the basic model is to assume that each item has B copies, and each player still desires at most one copy from each item. This is termed "multi-unit CA". As B grows, the integrality constraint of the problem reduces, and so one could hope for better solutions. Indeed, the next result exploits this idea:

Theorem 6 ([7]) *There exists a truthful and polynomial-time deterministic multi-unit CA, for $B \geq 3$ copies of each item, that obtains $O(B \cdot m^{1/(B-2)})$-approximation to the optimal social welfare.*

This auction copes with the representation issue (since general valuations are assumed) by accessing the valuations through a "demand oracle": given per-item prices $\{p_x\}_{x \in \Omega}$, specify a bundle S that maximizes $v_i(S) - \sum_{x \in S} p_x$.

Two main drawbacks of this auction motivate further research on the issue. First, as B gets larger it is reasonable to expect the approximation to approach 1 (indeed polynomial-time algorithms with such an approximation guarantee do exist). However here the approximation ratio does not decrease below $O(\log m)$ (this ratio is achieved for $B = O(\log m)$). Second, this auction does not provide a solution to the original setting, where $B = 1$, and, in general for small B's the approximation factor is rather high. One way to cope with these problems is to introduce randomness:

Theorem 7 ([26]) *There exists a truthful-in-expectation and polynomial-time randomized multi-unit CA, for any $B \geq 1$ copies of each item, that obtains $O(m^{1/(B+1)})$-approximation to the optimal social welfare.*

Thus, by allowing randomness, the gap from the standard computational status is being completely closed. The definition of truthfulness-in-expectation is the natural extension of truthfulness to a randomized environment: the *expected* utility of a player is maximized by being truthful.

However, this notion is strictly weaker than the deterministic notion, as this implicitly implies that players care only about the expectation of their utility (and not, for example, about the variance). This is termed "the risk-neutrality" assumption in the economics literature. An intermediate notion for randomized mechanisms is that of "universal truthfulness": the mechanism is truthful given any fixed result of the coin toss. Here, risk-neutrality is no longer needed. Dobzinski et al. [15] give a universally truthful CA for $B = 1$ that obtains an $O(\sqrt{m})$-approximation. Universally truthful mechanisms are still weaker than deterministic truthful mechanisms, due to two reasons: (i) It is not clear how to actually create the correct and exact probability distribution with a deterministic computer. The situation here is different than in "regular" algorithmic settings, where various derandomization techniques can be employed, since these in general does not carry through the truthfulness property. (ii) Even if a natural randomness source exists, one cannot improve the quality of the actual output by repeating the computation several times (using the the law of large numbers). Such a repetition will again destroy truthfulness. Thus, exactly because the game-theoretic issues are being considered in parallel to the computational ones, the importance of determinism increases.

Open Question 3 *What is the best-possible approximation ratio that deterministic and*

truthful combinatorial auctions can obtain, in polynomial-time?

There are many valuation classes, that restrict the possible valuations to some reasonable format (see [28] for more details). For example, sub-additive valuations are such that, for any two bundles $S, T, \subseteq \Omega$, $v(S \cup T) \leq v(S) + v(T)$. Such classes exhibit much better approximation guarantees, e.g., for sub-additive valuation a polynomial-time 2-approximation is known [16]. However, no polynomial-time truthful mechanism (be it randomized, or deterministic) with a constant approximation ratio, is known for any of these classes.

Open Question 4 *Does there exist polynomial-time truthful constant-factor approximations for special cases of CAs that are NP-hard?*

Revenue maximization in CAs is of-course another important goal. This topic is still mostly unexplored, with few exceptions. The mechanism [7] obtains the same guarantees with respect to the optimal revenue. Improved approximations exist for multi-unit auctions (where all items are identical) with budget constrained players [12], and for unlimited-supply CAs with single-minded bidders [6].

The topic of Combinatorial Auctions is discussed also in the entry on Multiple Item Auctions.

Problem Domain 4: Online Auctions

In the classic CS setting of "online computation", the input to an algorithm is not revealed all at once, before the computation begins, but gradually, over time (for a detailed discussion see the many entries on online problems in this book). This structure suits the auction world, especially in the new electronic environments. What happens when players arrive over time, and the auctioneer must make decisions facing only a subset of the players at any given time?

The integration of online settings, worst-case analysis, and auction theory, was suggested by [24]. They considered the case where players arrive one at a time, and the auctioneer must provide an answer to each player *as it arrives*, without knowing the future bids. There are k identical items, and each bidder may have a distinct value for every possible quantity of the item. These values are assumed to be marginally decreasing, where each marginal value lies in the interval $[\underline{v}, \bar{v}]$. The private information of a bidder includes both her valuation function, and her arrival time, and so a truthful auction need to incentivize the players to arrive on time (and not later on), and to reveal their true values. The most interesting result in this setting is for a large k, so that in fact there is a continuum of items:

Theorem 8 ([24]) *There exists a truthful online auction that simultaneously approximates, within a factor of* $O(\log(\bar{v}/\underline{v}))$*, the optimal offline welfare, and the offline revenue of VCG. Furthermore, no truthful online auction can obtain a better approximation ratio to either one of these criteria (separately).*

This auction has the interesting property of being a "posted price" auction. Each bidder is not required to reveal his valuation function, but, rather, he is given a price for each possible quantity, and then simply reports the desired quantity under these prices.

Ideas from this construction were later used by [10] to construct *two*-sided online auction markets, where multiple sellers and buyers arrive online.

This approximation ratio can be dramatically improved, to be a constant, 4, if one assumes that (i) there is only one item, and (ii) player values are i.i.d from some fixed distribution. No a–priori knowledge of this distribution is needed, as neither the mechanism nor the players are required to make any use of it. This work, [19], analyzes this by making an interesting connection to the class of "secretary problems".

A general method to convert online algorithms to online mechanisms is given by [4]. This is done for one item auctions, and, more generally, for one parameter domains. This method is competitive both with respect to the welfare and the revenue.

The revenue that the online auction of Theorem 8 manages to raise is competitive only with respect to VCG's revenue, which may be far from optimal. A parallel line of works is concerned with revenue maximizing auctions. To achieve good results, two assumptions need to be made: (i) there exists an unlimited supply of items (and recall from section "Problem Domain 2: Digital Goods and Revenue Maximization" that $F(v)$ is the offline optimal monopolistic fixed-price revenue), and (ii) players cannot lie about their arrival time, only about their value. This last assumption is very strong, but apparently needed. Such auctions are termed here "value-truthful", indicating that "time-truthfulness" is missing.

Theorem 9 ([9]) *For any $\epsilon > 0$, there exists a value-truthful online auction, for the unlimited supply case, with expected revenue of at least $(F(v))/(1+\epsilon) - O(h/\epsilon^2)$.*

The construction exploits principles from learning theory in an elegant way. Posted price auctions for this case are also possible, in which case the additive loss increases to $O(h \log\log h)$. Hajiaghayi et al. [19] consider fully-truthful online auctions for revenue maximization, but manage to obtain only very high (although fixed) competitive ratios. Constructing fully-truthful online auctions with a close-to-optimal revenue remains an open question. Another interesting open question involves multi-dimensional valuations. The work [24] remains the only work for players that may demand multiple items. However their competitive guarantees are quite high, and achieving better approximation guarantees (especially with respect to the revenue) is a challenging task.

Advanced Issues

Monotonicity

What is the general way for designing a truthful mechanism? The straight-forward way is to check, for a given social choice function f, whether truthful prices exist. If not, try to "fix" f. It turns out, however, that there exists a more structured way, an *algorithmic* condition that will imply the *existence* of truthful prices. Such a condition shifts the designer back to the familiar territory of algorithmic design. Luckily, such a condition do exist, and is best described in the abstract social choice setting of section "Problem Definition":

Definition 3 ([8, 23]) A social choice function $f : V \to A$ is "weakly monotone" (W-MON) if for any i, $v_{-i} \in V_{-i}$, and any $v_i, v_i' \in V_i$, the following holds. Suppose that $f(v_i, v_{-i}) = a$, and $f(v_i', v_{-i}) = b$. Then $v_i'(b) - v_i(b) \geq v_i'(a) - v_i(a)$.

In words, this condition states the following. Suppose that player i changes her declaration from v_i to v_i', and this causes the social choice to change from a to b. Then it must be the case that i's value for b has increased in the transition from v_i to v_i' no-less than i's value for a.

Theorem 10 ([35]) *Fix a social choice function $f : V \to A$, where V is convex, and A is finite. Then there exist prices p such that $M = (f, p)$ is truthful if and only if f is weakly monotone.*

Furthermore, given a weakly monotone f, there exists an explicit way to determine the appropriate prices p (see [18] for details).

Thus, the designer should aim for weakly monotone algorithms, and need not worry about actual prices. But how difficult is this? For single-dimensional domains, it turns out that W-MON leaves ample flexibility for the algorithm designer. Consider for example the case where every alternative has a value of either 0 (the player "loses") or some $v_i \in \Re$ (the player "wins" and obtains a value v_i). In such a case, it is not hard to show that W-MON reduces to the following monotonicity condition: if a player wins with v_i, and increases her value to $v_i' > v_i$ (while v_{-i} remains fixed), then she must win with v_i' as well. Furthermore, in such a case, the price of a winning player must be set to the infimum over all winning values.

Impossibilities of truthful design

It is fairly simple to construct algorithms that satisfy W-MON for single-dimensional domains, and a variety of positive results were obtained for such domains, in classic mechanism design, as well as in algorithmic mechanism design. But how hard is it to satisfy W-MON for multi-dimensional domains? This question is yet unclear, and seems to be one of the challenges of algorithmic mechanism design. The contrast between single-dimensionality and multi-dimensionality appears in all problem domains that were surveyed here, and seems to reflect some inherent difficulty that is not exactly understood yet. Given a social choice function f, call f *implementable* (in dominant strategies) if there exist prices p such that $M = (f, p)$ is truthful. The basic question is then *what forms of social choice functions are implementable.*

As detailed in the beginning, the welfare maximizing social choice function is implementable. This specific function can be slightly generalized to allow weights, in the following way: fix some non-negative real constants $\{w_i\}_{i=1}^n$ (not all are zero) and $\{\gamma_a\}_{a\in A}$, and choose an alternative that maximizes the *weighted* social welfare, i.e., $f(v) \in \text{argmax}_{a\in A} \sum_i w_i v_i(a) + \gamma_a$. This class of functions is sometimes termed "affine maximizers". It turns out that these functions are also implementable, with prices similar in spirit to VCG. In the context of the above characterization question, one sharp result stands out:

Theorem 11 ([34]) *Fix a social choice function $f : V \to A$, such that (i) A is finite, $|A| \geq 3$, and f is onto A, and (ii) $V_i = \Re^A$ for all i. Then f is implementable (in dominant strategies) if and only if it is an affine maximizer.*

The domain V that satisfies $V_i = \Re^A$ for all i is term an "unrestricted domain". The theorem states that, if the domain is unrestricted, at least three alternatives are chosen, and the set A of alternatives is finite, then nothing besides affine maximizers can be implemented!

However, the assumption that the domain is unrestricted is very restrictive. All the above example domains exhibit some basic combinatorial structure, and are therefore restricted in some way. And as discussed above, for many restricted domains the theorem is simply not true. So what *is* the possibilities – impossibilities border? As mentioned above, this is an unsolved challenge. Lavi, Mu'alem, and Nisan [23] explore this question for Combinatorial Auctions and similar restricted domains, and reach partial answers. For example:

Theorem 12 ([23]) *Any truthful combinatorial auction or multi-unit auction among two players, that must always allocate all items, and that approximates the welfare by a factor better than 2, must be an affine maximizer.*

Of-course, this is far from being a complete answer. What happens if there are more than two players? And what happens if it is possible to "throw away" part of the items? These questions, and the more general and abstract characterization question, are all still open.

Alternative solution concepts

In light of the conclusions of the previous section, a natural thought would be to re-examine the *solution concept* that is being used. Truthfulness relies on the strong concept of dominant strategies: for each player there is a unique strategy that maximizes her utility, no matter what the other players are doing. This is very strong, but it fits very well the worst-case way of thinking in CS. What other solution concepts can be used? As described above, randomization, and truthfulness-in-expectation, can help. A related concept, again for randomized mechanisms, is truthfulness with high probability. Another direction is to consider mechanisms where players cannot improve their utility *too much* by deviating from the truth-telling strategy [21].

Algorithm designers do not care so much about actually reaching an equilibrium point, or finding out what will the players play – the major concern is to guarantee the optimality of the solution, taking into account the strategic behavior of the players. Indeed, one way of doing this is to guarantee a good equilibrium point. But there is

no reason to rule out mechanisms where several acceptable strategic choices for the players exist, provided that the approximation will be achieved *in each of these choices*.

As a first attempt, one is tempted to simply let the players try and improve the basic result by allowing them to lie. However, this can cause unexpected dynamics, as each player chooses her lies under some assumptions about the lies of the others, etc. etc. To avoid such an unpredictable situation, it is important to insist on using rigorous game theoretic reasoning to explain exactly why the outcome will be satisfactory.

The work [31] suggests the notion of "feasibly dominant" strategies, where players reveal the possible lies they consider, and the mechanism takes this into account. By assuming that the players are computationally bounded, one can show that, instead of actually "lying", the players will prefer to reveal their true types plus all the lies they might consider. In such a case, since the mechanism has obtained the true types of the players, a close-to-optimal outcome will be guaranteed.

Another definition tries to capture the initial intuition by using the classic game-theoretic notion of undominated strategies:

Definition 4 ([5]) A mechanism M is an "algorithmic implementation of a c-approximation (in undominated strategies)" if there exists a set of strategies, D, such that (i) M obtains a c-approximation for any combination of strategies from D, in polynomial time, and (ii) For any strategy not in D, there exists a strategy in D that weakly dominates it, and this transition is polynomial-time computable.

By the second condition, it is reasonable to assume that a player will indeed play *some* strategy in D, and, by the first condition, it does not matter what tuple of strategies in D will actually be chosen, as any of these will provide the approximation. This transfers some of the burden from the game-theoretic design to the algorithmic design, since now a guarantee on the approximation should bu provided for a larger range of strategies. Babaioff et al. [5] exploit this notion to design a deterministic CA for multi-dimensional players that achieves a close-to-optimal approximation guarantee. A similar-in-spirit notion, although a weaker one, is the notion of "Set-Nash" [25].

Applications

One of the popular examples to a "real-life" combinatorial auction is the spectrum auction that the US government conducts, in order to sell spectrum licenses. Typical bids reflect values for different spectrum ranges, to accommodate different geographical and physical needs, where different spectrum ranges may complement or substitute one another. The US government invests research efforts in order to determine the best format for such an auction, and auction theory is heavily exploited. Interestingly, the US law guides the authorities to allocate these spectrum ranges in a way that will maximize *the social welfare*, thus providing a good example for the usefulness of this goal.

Adword auctions are another new and fast-growing application of auction theory in general, and of the new algorithmic auctions in particular. These are auctions that determine the advertisements that web-search engines place close to the search results they show, after the user submits her search keywords. The interested companies compete, for every given keyword, on the right to place their ad on the results' page, and this turns out to be the main source of income for companies like Google. Several entries in this book touch on this topic in more details, including the entries on Adwords Pricing and on Position Auctions.

A third example to a possible application, in the meanwhile implemented only in the academic research labs, is the application of algorithmic mechanism design to pricing and congestion control in communication networks. The existing fixed pricing scheme has many disadvantages, both with respect to the needs of efficiently allocating the available resources, and with respect to the new opportunities of the Internet companies to raise more revenue due to specific types of

traffic. Theory suggests solutions to both of these problems.

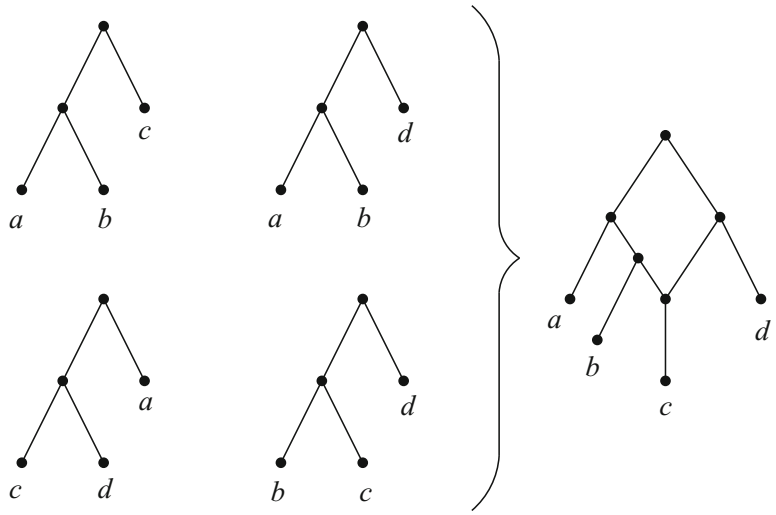
Problem Definition

A *phylogenetic tree* is a binary, rooted, unordered tree whose leaves are distinctly labeled. A *phylogenetic network* is a generalization of a phylogenetic tree formally defined as a rooted, connected, directed acyclic graph in which (1) each node has outdegree at most 2; (2) each node has indegree 1 or 2, except the root node which has indegree 0; (3) no node has both indegree 1 and outdegree 1; and (4) all nodes with outdegree 0 are labeled by elements from a finite set L in such a way that no two nodes are assigned the same label. Nodes of outdegree 0 are referred to as *leaves* and are identified with their corresponding elements in L. Nodes with indegree 2 are called *reticulation nodes*. For any phylogenetic network N, let $\mathcal{U}(N)$ be the undirected graph obtained from N by replacing each directed edge by an undirected edge. N is said to be a *galled phylogenetic network* (*galled network*, for short) if all cycles in $\mathcal{U}(N)$ are node-disjoint. Galled networks are also known in the literature as *topologies with independent recombination events* [15], *galled-trees* [6], and *level*-1 *phylogenetic networks* [2, 5, 7, 9, 10, 14].

A phylogenetic tree with exactly three leaves is called a *rooted triplet*. The unique rooted triplet on a leaf set $\{x, y, z\}$ in which the lowest common ancestor of x and y is a proper descendant of the lowest common ancestor of x and z (or equivalently, where the lowest common ancestor of x and y is a proper descendant of the lowest common ancestor of y and z) is denoted by $xy|z$. For any phylogenetic network N, the rooted triplet $xy|z$ is said to be *consistent* with N if N contains three leaves labeled by x, y, and z



Algorithms for Combining Rooted Triplets into a Galled Phylogenetic Network, Fig. 1 A dense set $\mathcal{T} = \{ab|c, ab|d, cd|a, bc|d\}$ of rooted triplets with leaf set $\{a, b, c, d\}$ and a galled phylogenetic network that is consistent with $\mathcal{T}$. Note that this solution is not unique

as well as two internal vertices w and z such that there are four directed paths of nonzero length from w to a, from w to b, from z to w, and from z to c that are vertex-disjoint except for in the vertices w and z. A set $\mathcal{T}$ of rooted triplets is *consistent* with N if every rooted triplet in $\mathcal{T}$ is consistent with N. See Fig. 1 for an example.

Denote the set of leaves in any phylogenetic network N by $\Lambda(N)$, and for any set $\mathcal{T}$ of rooted triplets, define $\Lambda(\mathcal{T}) = \bigcup_{t_i \in \mathcal{T}} \Lambda(t_i)$. A set $\mathcal{T}$ of rooted triplets is *dense* if for each $\{x, y, z\} \subseteq \Lambda(\mathcal{T})$, at least one of the three possible rooted triplets $xy|z$, $xz|y$, and $yz|x$ belongs to $\mathcal{T}$. Observe that if $\mathcal{T}$ is dense, then $|\mathcal{T}| = \Theta(|\Lambda(\mathcal{T})|^3)$. Jansson and Sung introduced the following problem in [10].

Problem 1 Given a set $\mathcal{T}$ of rooted triplets, output a galled network N with $\Lambda(N) = \Lambda(\mathcal{T})$ such that N and $\mathcal{T}$ are consistent, if such a network exists; otherwise, output *null*.

A natural optimization version of Problem 1 is:

Problem 2 Given a set $\mathcal{T}$ of rooted triplets, output a galled network N with $\Lambda(N) = \Lambda(\mathcal{T})$ that is consistent with the maximum possible number of rooted triplets belonging to $\mathcal{T}$.

A generalization of Problem 1 studied by He et al. in [8] involves *forbidden* rooted triplets and is defined as follows.

Problem 3 Given two sets $\mathcal{T}$ and $\mathcal{F}$ of rooted triplets, output a galled network N with $\Lambda(N) = \Lambda(\mathcal{T}) \cup \Lambda(\mathcal{F})$ such that (1) N and $\mathcal{T}$ are consistent and (2) N is not consistent with any rooted triplet belonging to $\mathcal{F}$; if no such network exists, output *null*.

Below, we write $L = \Lambda(\mathcal{T})$ and $n = |L|$.

Key Results

As shown in [11], Problem 1 can be solved in (optimal) $O(|\mathcal{T}|) = O(n^3)$ time for dense inputs:

Theorem 1 ([11]) *Given any dense set $\mathcal{T}$ of rooted triplets with leaf set L, a galled network consistent with $\mathcal{T}$ (if one exists) can be constructed in $O(n^3)$ time, where $n = |L|$.*

The algorithm referred to in Theorem 1 was extended by van Iersel and Kelk [14] as follows.

Theorem 2 ([14]) *Given any dense set $\mathcal{T}$ of rooted triplets with leaf set L, a galled network consistent with $\mathcal{T}$ (if one exists) that contains as few reticulation nodes as possible can be constructed in $O(n^5)$ time, where $n = |L|$.*

For the more general case of nondense inputs, Problem 1 becomes harder:

Theorem 3 ([11]) *The problem of determining if there exists a galled network that is consistent*

with an input nondense set $\mathcal{T}$ of rooted triplets is NP-hard.

Since not all sets of rooted triplets are consistent with a galled network, it is of interest to consider Problem 2. It follows from Theorem 3 that Problem 2 is also NP-hard for nondense inputs, and this motivates polynomial-time approximation algorithms. Say that an algorithm for Problem 2 is an *f-approximation algorithm* if it always returns a galled network N such that $\frac{N(\mathcal{T})}{|\mathcal{T}|} \geq f$, where $N(\mathcal{T})$ is the number of rooted triplets in $\mathcal{T}$ that are consistent with N. Define the nonlinear recurrence relation $S(n) = \max_{1 \leq a \leq n} \left\{ \binom{a}{3} + 2 \cdot \binom{a}{2} \cdot (n-a) + a \cdot \binom{n-a}{2} + S(n-a) \right\}$ for $n > 0$ and $S(0) = 0$. It was shown in [4] that $\lim_{n \to \infty} \frac{S(n)}{3\binom{n}{3}} = \frac{2(\sqrt{3}-1)}{3} \approx 0.488033\ldots$ and that $\frac{S(n)}{3\binom{n}{3}} > \frac{2(\sqrt{3}-1)}{3} \approx 0.488033\ldots$ for all $n > 2$. The following theorem was proved by Byrka et al. in [2].

Theorem 4 ([2]) *There exists an $\frac{S(n)}{3\binom{n}{3}}$-approximation algorithm for Problem 2 that runs in $O(n^3 + n|\mathcal{T}|)$ time.*

A matching negative bound is:

Theorem 5 ([11]) *For any $f > \lim_{n \to \infty} \frac{S(n)}{3\binom{n}{3}}$, there exists a set $\mathcal{T}$ of rooted triplets such that no galled network can be consistent with at least a factor of f of the rooted triplets in $\mathcal{T}$. (Thus, no f-approximation algorithm for Problem 2 is possible.)*

For Problem 3, Theorem 3 immediately implies NP-hardness by taking $\mathcal{F} = \emptyset$. The following positive result is known for the optimization version of Problem 3.

Theorem 6 ([8]) *There exists an $O(|L|^2|\mathcal{T}|(|\mathcal{T}| + |\mathcal{F}|))$-time algorithm for inferring a galled network N that guarantees $|N(\mathcal{T})| - |N(\mathcal{F})| \geq \frac{5}{12} \cdot (|\mathcal{T}| - |\mathcal{F}|)$, where $L = \Lambda(\mathcal{T}) \cup \Lambda(\mathcal{F})$.*

Finally, we remark that the analogous version of Problem 1 of inferring a phylogenetic *tree* consistent with all the rooted triplets in an input set (when such a tree exists) can be solved in polynomial time with a classical algorithm by Aho et al. [1] from 1981. Similarly, for Problem 2, to infer a phylogenetic tree consistent with as many rooted triplets from an input set of rooted triplets as possible is NP-hard and admits a polynomial-time 1/3-approximation algorithm, which is optimal in the sense that there exist certain inputs for which no tree can achieve a factor larger than 1/3. See, e.g., [3] for a survey of known results about maximizing rooted triplet consistency for trees. On the other hand, more complex network structures such as the *level-k phylogenetic networks* [5] permit a higher percentage of the input rooted triplets to be embedded; in the extreme case, if there are no restrictions on the reticulation nodes at all, then a sorting network-based construction yields a phylogenetic network that is trivially consistent with every rooted triplet over L [10]. A number of efficient algorithms for combining rooted triplets into higher level networks have been developed; see, e.g., [2,7,14] for further details and references.

Applications

Phylogenetic networks are used by scientists to describe evolutionary relationships that do not fit the traditional models in which evolution is assumed to be treelike. Evolutionary events such as horizontal gene transfer or hybrid speciation (often referred to as *recombination events*) which suggest convergence between objects cannot be represented in a single tree but can be modeled in a phylogenetic network as internal nodes having more than one parent (i.e., reticulation nodes). The phylogenetic network is a relatively new tool, and various fast and reliable methods for constructing and comparing phylogenetic networks are currently being developed.

Galled networks form an important class of phylogenetic networks. They have attracted special attention in the literature [5, 6, 15] due to their biological significance (see [6]) and their simple, almost treelike, structure. When the number of recombination events is limited and most of the recombination events have occurred recently, a galled network may suffice to accurately describe the evolutionary process under study [6]. The motivation behind the

rooted triplet approach taken here is that a highly accurate tree for each cardinality-three subset of the leaf set can be obtained through maximum likelihood-based methods or Sibley-Ahlquist-style DNA-DNA hybridization experiments (see [13]). The algorithms mentioned above can be used as the merging step in a divide-and-conquer approach for constructing phylogenetic networks analogous to the quartet method paradigm for inferring unrooted phylogenetic trees [12] and other supertree methods. We consider dense input sets in particular because this case can be solved in polynomial time.

Open Problems

The approximation factor given in Theorem 4 is expressed in terms of the number of rooted triplets in the input $\mathcal{T}$, and Theorem 5 shows that it cannot be improved. However, if one measures the quality of the approximation in terms of a galled network N_{OPT} that is consistent with the maximum possible number of rooted triplets from $\mathcal{T}$, Theorem 4 can be far from optimal. An open problem is to determine the polynomial-time approximability and inapproximability of Problem 2 when the approximation ratio is defined as $\frac{N(\mathcal{T})}{N_{OPT}(\mathcal{T})}$ instead of $\frac{N(\mathcal{T})}{|\mathcal{T}|}$.

Another research direction is to develop fixed-parameter polynomial-time algorithms for Problem 1. The level of the constructed network, the number of allowed reticulation nodes, or some measure of the density of the input set of rooted triplet might be suitable parameters.

All Pairs Shortest Paths in Sparse Graphs

Problem Definition

Given a communications network or road network, one of the most natural algorithmic questions is how to determine the shortest path from one point to another. The *all pairs* shortest path problem (APSP) is, given a directed graph $G = (V, E, l)$, to determine the distance and shortest path between every pair of vertices, where $|V| = n$, $|E| = m$, and $l : E \to \mathbb{R}$ is the edge length (or weight) function. The output is in the form of two $n \times n$ matrices: $D(u, v)$ is the distance from u to v and $S(u, v) = w$ if (u, w) is the first edge on a shortest path from u to v. The APSP problem is often contrasted with the *point-to-point* and *single source* (SSSP) shortest path problems. They ask for, respectively, the shortest path from a given source vertex to a given target vertex and all shortest paths from a given source vertex.

Definition of Distance

If ℓ assigns only non-negative edge lengths then the definition of distance is clear: $D(u, v)$ is the length of the minimum length path from u to v, where the length of a path is the total length of its constituent edges. However, if ℓ can assign negative lengths then there are several sensible notations of distance that depend on how negative length cycles are handled. Suppose that a cycle C has negative length and that $u, v \in V$ are such that C is reachable from u and v reachable from C. Because C can be traversed an arbitrary number of times when traveling from u to v, there is no shortest path from u to v using a finite number of edges. It is sometimes assumed a priori that G has no negative length cycles; however it is cleaner to define $D(u, v) = -\infty$ if there is no finite shortest path. If $D(u, v)$ is defined to be the length of the shortest *simple* path (no repetition of vertices) then the problem becomes NP-hard. (If all edges have length -1 then $D(u, v) = -(n-1)$ if and only if G contains a Hamiltonian path [7] from u to v.) One could also define distance to be the length of the shortest path without repetition of edges.

Classic Algorithms

The Bellman-Ford algorithm solves SSSP in $O(mn)$ time and under the assumption that edge lengths are non-negative, Dijkstra's algorithm solves it in $O(m + n \log n)$ time. There is a well known $O(mn)$-time shortest path preserving transformation that replaces any length function with a non-negative length function. Using this transformation and n runs of Dijkstra's algorithm gives an APSP algorithm running in $O(mn + n^2 \log n) = O(n^3)$ time. The Floyd-Warshall algorithm computes APSP in a more

direct manner, in $O(n^3)$ time. Refer to [4] for a description of these algorithms. It is known that APSP on complete graphs is asymptotically equivalent to (min, +) matrix multiplication [1], which can be computed by a non-uniform algorithm that performs $O(n^{2.5})$ numerical operations [6].

Integer-Weighted Graphs

Much recent work on shortest paths assume that edge lengths are integers in the range $\{-C, \ldots, C\}$ or $\{0, \ldots, C\}$. One line of research reduces APSP to a series of standard matrix multiplications. These algorithms are limited in their applicability because their running times scale linearly with C. There are faster SSSP algorithms for both non-negative edge lengths and arbitrary edge lengths. The former exploit the power of RAMs to sort in $o(n \log n)$ time and the latter are based on the *scaling* technique. See Zwick [20] for a survey of shortest path algorithms up to 2001.

Key Results

Pettie's APSP algorithm [12] adapts the *hierarchy* approach of Thorup [16] (designed for undirected, integer-weighted graphs) to general real-weighted directed graphs. Theorem 1 is the first improvement over the $O(mn+n^2 \log n)$ time bound of Dijkstra's algorithm on arbitrary real-weighted graphs.

Theorem 1 *Given a real-weighted directed graph, all pairs shortest paths can be solved in* $O(mn + n^2 \log\log n)$ *time.*

This algorithm achieves a logarithmic speedup through a trio of new techniques. The first is to exploit the necessary similarity between the SSSP trees emanating from nearby vertices. The second is a method for computing discrete approximate distances in real-weighted graphs. The third is a new hierarchy-type SSSP algorithm that runs in $O(m + n \log\log n)$ time when given suitably accurate approximate distances.

Theorem 1 should be contrasted with the time bounds of other hierarchy-type APSP algorithms [11, 14, 16].

Theorem 2 ([14], 2005) *Given a real-weighted undirected graph, APSP can be solved in* $O(mn \log\alpha(m, n))$ *time.*

Theorem 3 ([16], 1999) *Given an undirected graph* $G(V, E, l)$*, where* ℓ *assigns integer edge lengths in the range* $\{-2^{w-1}, \ldots, 2^{w-1} - 1\}$*, APSP can be solved in* $O(mn)$ *time on a RAM with w-bit word length.*

Theorem 4 ([13], 2002) *Given a real-weighted directed graph, APSP can be solved in polynomial time by an algorithm that performs* $O(mn \log\alpha(m, n))$ *numerical operations, where* α *is the inverse-Ackermann function.*

A secondary result of [12, 14] is that no *hierarchy-type* shortest path algorithm can improve on the $O(m + n \log n)$ running time of Dijkstra's algorithm.

Theorem 5 *Let* G *be an input graph such that the ratio of the maximum to minimum edge length is* r*. Any hierarchy-type SSSP algorithm performs* $\Omega(m + \min\{n \log n, n \log r\})$ *numerical operations if* G *is directed and* $\Omega(m + \min\{n \log n, n \log\log r\})$ *if* G *is undirected.*

Applications

Shortest paths appear as a subproblem in other graph optimization problems; the minimum weight perfect matching, minimum cost flow, and minimum mean-cycle problems are some examples. A well known commercial application of shortest path algorithms is finding efficient routes on road networks; see, for example, Google Maps, MapQuest, or Yahoo Maps.

Open Problems

The longest standing open shortest path problems are to improve the SSSP algorithms of Dijkstra's and Bellman-Ford on *real*-weighted graphs.

Problem 1 Is there an $o(mn)$ time SSSP or point-to-point shortest path algorithm for arbitrarily weighted graphs?

Problem 2 Is there an $O(m) + o(n \log n)$ time SSSP algorithm for directed, non-negatively weighted graphs? For undirected graphs?

A partial answer to Problem 2 appears in [14], which considers undirected graphs. Perhaps the most surprising open problem is whether there is any (asymptotic) difference between the complexities of the all pairs, single source, and point-to-point shortest path problems on arbitrarily weighted graphs.

Problem 3 Is point-to-point shortest paths easier than all pairs shortest paths on arbitrarily weighted graphs?

Problem 4 Is there a truly subcubic APSP algorithm, i.e., one running in time $O(n^{3-\epsilon})$? In a recent breakthrough on this problem, Williams [19] gave a new APSP algorithm running in $n^3/2^{\Theta(\sqrt{\log n/\log\log n})}$ time. Vassilevska Williams and Williams [17] proved that a truly subcubic algorithm for APSP would imply truly subcubic algorithms for other graph problems.

Experimental Results

See [5, 8, 15] for recent experiments on SSSP algorithms. On sparse graphs the best APSP algorithms use repeated application of an SSSP algorithm, possibly with some precomputation [15]. On dense graphs cache-efficiency becomes a major issue. See [18] for a cache conscious implementation of the Floyd-Warshall algorithm.

The trend in recent years is to construct a linear space data structure that can quickly answer exact or approximate point-to-point shortest path queries; see [2, 6, 9, 10].

Data Sets

Problem Definition

The all pairs shortest path (APSP) problem is to compute shortest paths between all pairs of vertices of a directed graph with nonnegative real numbers as edge costs. Focus is given on shortest distances between vertices, as shortest paths can be obtained with a slight increase of cost. Classically, the APSP problem can be solved in cubic time of $O(n^3)$. The problem here is to achieve a sub-cubic time for a graph with small integer costs.

A directed graph is given by $G = (V, E)$, where $V = \{1, \ldots, n\}$, the set of vertices, and E is the set of edges. The cost of edge $(i, j) \in E$ is denoted by d_{ij}. The (n, n)-matrix D is one whose (i, j) element is d_{ij}. It is assumed for simplicity that $d_{ij} > 0$ and $d_{ii} = 0$ for all $i \neq j$. If there is no edge from i to j, let $d_{ij} = \infty$. The cost, or distance, of a path is the sum of costs of the edges in the path. The length of a path is the number of edges in the path. The shortest distance from vertex i to vertex j is the minimum cost over all paths from i to j, denoted by d^*_{ij}. Let $D^* = \{d^*_{ij}\}$. The value of n is called the size of the matrices.

Let A and B are (n, n)-matrices. The three products are defined using the elements of A and B as follows: (1) Ordinary matrix product over a ring $C = AB$ (2) Boolean matrix product $C = A \cdot B$ (3) Distance matrix product $C = A \times B$, where

$$(1)\ c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj}, \quad (2)\ c_{ij} = \bigvee_{k=1}^{n} a_{ik} \wedge b_{kj},$$

$$(3)\ c_{ij} = \min_{1 \le k \le n} \{a_{ik} + b_{kj}\}.$$

The matrix C is called a product in each case; the computational process is called multiplication, such as distance matrix multiplication. In those

three cases, k changes through the entire set $\{1,\ldots,n\}$. A partial matrix product of A and B is defined by taking k in a subset I of V. In other words, a partial product is obtained by multiplying a vertically rectangular matrix, $A(*,I)$, whose columns are extracted from A corresponding to the set I, and similarly a horizontally rectangular matrix, $B(I,*)$, extracted from B with rows corresponding to I. Intuitively, I is the set of check points k, when going from i to j.

The best algorithm [11] computes (1) in $O(n^\omega)$ time, where $\omega = 2.373$. This was recently achieved as improvement from $\omega = 2.376$ in [4] after more than two decades of interval. We use $\omega = 2.376$ to describe Zwick's result in this article. Three decimal points are carried throughout this article. To compute (2), Boolean values 0 and 1 in A and B can be regarded as integers and use the algorithm for (1), and convert nonzero elements in the resulting matrix to 1. Therefore, this complexity is $O(n^\omega)$. The witnesses of (2) are given in the witness matrix $W = \{w_{ij}\}$ where $w_{ij} = k$ for some k such that $a_{ik} \wedge b_{kj} = 1$. If there is no such k, $w_{ij} = 0$. The witness matrix $W = \{w_{ij}\}$ for (3) is defined by $w_{ij} = k$ that gives the minimum to c_{ij}. If there is an algorithm for (3) with $T(n)$ time, ignoring a polylog factor of n, the APSP problem can be solved in $\tilde{O}(T(n))$ time by the repeated squaring method, described as the repeated use of $D \leftarrow D \times D$ $O(\log n)$ times.

The definition here of computing shortest paths is to give a witness matrix of size n by which a shortest path from i to j can be given in $O(\ell)$ time where ℓ is the length of the path. More specifically, if $w_{ij} = k$ in the witness matrix $W = \{w_{ij}\}$, it means that the path from i to j goes through k. Therefore, a recursive function path(i,j) is defined by (path(i,k), k, path(k,j)) if path$(i,j) = k > 0$ and nil if path$(i,j) = 0$, where a path is defined by a list of vertices excluding endpoints. In the following sections, k is recorded in w_{ij} whenever k is found such that a path from i to j is modified or newly set up by paths from i to k and from k to j. Preceding results are introduced as a framework for the key results.

Alon-Galil-Margalit Algorithm

The algorithm by Alon, Galil, and Margalit [1] is reviewed. Let the costs of edges of the given graph be ones. Let $D^{(\ell)}$ be the ℓ-th approximate matrix for D^* defined by $d_{ij}^{(\ell)} = d_{ij}^*$ if $d_{ij}^* \le \ell$, and $d_{ij}^{(\ell)} = \infty$ otherwise. Let A be the adjacency matrix of G, that is, $a_{ij} = 1$ if there is an edge (i,j), and $a_{ij} = 0$, otherwise. Let $a_{ii} = 1$ for all i. The algorithm consists of two phases. In the first phase, $D^{(\ell)}$ is computed for $\ell = 1,\ldots,r$, by checking the (i,j) element of $A^\ell = \{a_{ij}^\ell\}$. Note that if $a_{ij}^\ell = 1$, there is a path from i to j of length ℓ or less. Since Boolean matrix multiplication can be computed in $O(n^\omega)$ time, the computing time of this part is $O(rn^\omega)$.

In the second phase, the algorithm computes $D^{(\ell)}$ for $\ell = r, \lceil \frac{3}{2}r \rceil, \left\lceil \frac{3}{2}\lceil \frac{3}{2}r \rceil \right\rceil, \ldots, n'$ by repeated squaring, where n' is the smallest integer in this sequence of ℓ such that $\ell \ge n$. Let $T_{i\alpha} = \{j | d_{ij}^{(\ell)} = \alpha\}$ and $I_i = T_{i\alpha}$ such that $|T_{i\alpha}|$ is minimum for $\lceil \ell/2 \rceil \le \alpha \le \ell$. The key observation in the second phase is that it is only needed to check k in I_i whose size is not larger than $2n/\ell$, since the correct distances between $\ell+1$ and $\lceil 3\ell/2 \rceil$ can be obtained as the sum $d_{ik}^{(\ell)} + d_{kj}^{(\ell)}$ for some k satisfying $\lceil \ell/2 \rceil \le d_{ik}^{(\ell)} \le \ell$. The meaning of I_i is similar to I for partial products except that I varies for each i. Hence, the computing time of one squaring is $O(n^3/\ell)$. Thus, the time of the second phase is given with $N = \lceil \log_{3/2} n/r \rceil$ by $O\left(\sum_{s=1}^{N} n^3/((3/2)^s r)\right) = O(n^3/r)$. Balancing the two phases with $rn^\omega = n^3/r$ yields $O(n^{(\omega+3)/2}) = O(n^{2.688})$ time for the algorithm with $r = O(n^{(3-\omega)/2})$.

Witnesses can be kept in the first phase in time polylog of n by the method in [2]. The maintenance of witnesses in the second phase is straightforward.

When a directed graph G whose edge costs are integers between 1 and M is given, where M is a positive integer, the graph G can be expanded to G' by creating up to $M-1$ new vertices for each vertex and replacing each edge by up to M edges with unit cost. Obviously, the problem for G can be solved by applying the above algorithm to G',

which takes $O\left((Mn)^{(\omega+3)/2}\right)$ time. This time is sub-cubic when $M < n^{0.116}$. The maintenance of witnesses has an extra polylog factor in each case.

For undirected graphs with unit edge costs, $\tilde{O}(n^{\omega})$ time is known in Seidel [9].

Takaoka Algorithm

When the edge costs are bounded by a positive integer M, a better algorithm can be designed than in the above as shown in Takaoka [10]. Romani's algorithm [7] for distance matrix multiplication is reviewed briefly.

Let A and B be (n, m) and (m, n) distance matrices whose elements are bounded by M or infinite. Let the diagonal elements be 0. A and B are converted into A' and B' where $a'_{ij} = (m+1)^{M-a_{ij}}$, if $a_{ij} \neq \infty, 0$, otherwise, and $b'_{ij} = (m+1)^{M-b_{ij}}$, if $b_{ij} \neq \infty, 0$, otherwise.

Let $C' = A'B'$ be the product by ordinary matrix multiplication and $C = A \times B$ be that by distance matrix multiplication. Then, it holds that

$$c'_{ij} = \sum_{k=1}^{m} (m+1)^{2M-(a_{ik}+b_{kj})},$$

$$c_{ij} = 2M - \lfloor \log_{m+1} c'_{ij} \rfloor.$$

This distance matrix multiplication is called (n, m)-Romani. In this section, the above multiplication is used with square matrices, that is, (n, n)-Romani is used. In the next section, the case where $m < n$ is dealt with.

C can be computed with $O(n^{\omega})$ arithmetic operations on integers up to $(n+1)^M$. Since these values can be expressed by $O(M \log n)$ bits and Schönhage and Strassen's algorithm [8] for multiplying k-bit numbers takes $O(k \log k \log\log k)$ bit operations, C can be computed in $O(n^{\omega} M \log n \log(M \log n) \log\log (M \log n))$ time, or $\tilde{O}(Mn^{\omega})$ time.

The first phase is replaced by the one based on (n, n)-Romani and the second phase is modified based on path lengths, not distances.

Note that the bound M is replaced by ℓM in the distance matrix multiplication in the first phase. Ignoring polylog factors, the time for the first phase is given by $\tilde{O}(n^{\omega} r^2 M)$. It is assumed that M is $O(n^k)$ for some constant k. Balancing this complexity with that of second phase, $O(n^3/r)$, yields the total computing time of $\tilde{O}(n^{(6+\omega)/3} M^{1/3})$ with the choice of $r = O(n^{(3-\omega)/3} M^{-1/3})$. The value of M can be almost $O(n^{0.624})$ to keep the complexity within sub-cubic.

Key Results

Zwick improved the Alon-Galil-Margalit algorithm in several ways. The most notable is an improvement of the time for the APSP problem with unit edge costs from $O(n^{2.688})$ to $O(n^{2.575})$. The main accelerating engine in Alon-Galil-Margalit [1] was the fast Boolean matrix multiplication and that in Takaoka [10] was the fast distance matrix multiplication by Romani, both powered by the fast matrix multiplication of square matrices.

In this section, the engine is the fast distance matrix multiplication by Romani powered by the fast matrix multiplication of rectangular matrices given by Coppersmith [3] and Huang and Pan [5]. Suppose the product of (n, m) matrix and (m, n) matrix can be computed with $O(n^{\omega(1,\mu,1)})$ arithmetic operations, where $m = n^{\mu}$ with $0 \leq \mu \leq 1$. Several facts such as $O(n^{\omega(1,1,1)}) = O(n^{2.376})$ and $O(n^{\omega(1,0.294,1)}) = \tilde{O}(n^2)$ are known. To compute the product of (n, n) square matrices, $n^{1-\mu}$ matrix multiplications are needed, resulting in $O(n^{\omega(1,\mu,1)+1-\mu})$ time, which is reformulated as $O(n^{2+\mu})$, where μ satisfies the equation $\omega(1, \mu, 1) = 2\mu + 1$. Also, the upper bound of $\omega(1, \mu, 1)$ is given by

$$\omega(1, \mu, 1) = 2, \text{ if } 0 \leq \mu \leq \alpha$$

$$\omega(1, \mu, 1) = 2 + (\omega - 2)(\mu - \alpha)/(1 - \alpha), \text{ if } \alpha \leq \mu \leq 1$$

The best known value for μ, when [12] was published, was $\mu = 0.575$, derived from the above formulae, $\alpha > 0.294$ and $\omega < 2.376$. So, the time becomes $O(n^{2.575})$, which is not as

good as $O(n^{2.376})$. Thus, we use the algorithm for rectangular matrices in the following.

The above algorithm for rectangular matrix multiplication is incorporated into (n,m)-Romani with $m = n^{\mu}$ and $M = n^t$, and the computing time of $\tilde{O}(Mn^{\omega(1,\mu,1)})$. The next step is how to incorporate (n,m)-Romani into the APSP algorithm. The first algorithm is a monophase algorithm based on repeated squaring, similar to the second phase of the algorithm in [1]. To take advantage of rectangular matrices in (n,m)-Romani, the following definition of the bridging set is needed, which plays the role of the set I in the partial distance matrix product in section "Problem Definition."

Let $\delta(i,j)$ be the shortest distance from i to j, and $\eta(i,j)$ be the minimum length of all shortest paths from i to j. A subset I of V is an ℓ-bridging set if it satisfies the condition that if $\eta(i,j) \geq \ell$, there exists $k \in I$ such that $\delta(i,j) = \delta(i,k) + \delta(k,j)$. I is a strong ℓ-bridging set if it satisfies the condition that if $\eta(i,j) \geq \ell$, there exists $k \in I$ such that $\delta(i,j) = \delta(i,k) + \delta(k,j)$ and $\eta(i,j) = \eta(i,k) + \eta(k,j)$. Note that those two sets are the same for a graph with unit edge costs.

Note that if $(2/3)\ell \leq \mu(i,j) \leq \ell$ and I is a strong $\ell/3$-bridging set, there is a $k \in I$ such that $\delta(i,j) = \delta(i,k) + \delta(k,j)$ and $\mu(i,j) = \mu(i,k) + \mu(k,j)$. With this property of strong bridging sets, (n,m)-Romani can be used for the APSP problem in the following way. By repeated squaring in a similar way to Alon-Galil-Margalit, the algorithm computes $D^{(\ell)}$ for $\ell = 1, \lceil \frac{3}{2} \rceil, \left\lceil \frac{3}{2} \left\lceil \frac{3}{2} \right\rceil \right\rceil, \ldots, n'$, where n' is the first value of ℓ that exceeds n, using various types of set I described below. To compute the bridging set, the algorithm maintains the witness matrix with extra polylog factor in the complexity. In [12], there are three ways for selecting the set I. Let $|I| = n^r$ for some r such that $0 \leq r \leq 1$.

1. Select $9n \ln n/\ell$ vertices for In from V at random. In this case, it can be shown that the algorithm solves the APSP problem with high probability, i.e., with $1 - 1/n^c$ for some constant $c > 0$, which can be shown to be 3. In other words, I is a strong $\ell/3$-bridging set with high probability. The time T is dominated by (n,m)-Romani. It holds that $T = \tilde{O}(\ell M n^{\omega(1,r,1)})$, since the magnitude of matrix elements can be up to ℓM. Since $m = O(n \ln n/\ell) = n^r$, it holds that $\ell = \tilde{O}(n^{1-r})$, and thus $T = O(Mn^{1-r}n^{\omega(1,r,1)})$. When $M = 1$, this bound on r is $\mu = 0.575$, and thus $T = O(n^{2.575})$. When $M = n^t \geq 1$, the time becomes $O(n^{2+\mu(t)})$, where $t \leq 3 - \omega = 0.624$ and $\mu = \mu(t)$ satisfies $\omega(1,\mu,1) = 1 + 2\mu - t$. It is determined from the best known $\omega(1,\mu,1)$ and the value of t. As the result is correct with high probability, this is a randomized algorithm.
2. Consider the case of unit edge costs here. In (1), the computation of witnesses is an extra thing, i.e., not necessary if only shortest distances are needed. To achieve the same complexity in the sense of an exact algorithm, not a randomized one, the computation of witnesses is essential. As mentioned earlier, maintenance of witnesses, that is, matrix W, can be done with an extra polylog factor, meaning the analysis can be focused on Romani within the $\tilde{O}$-notation. Specifically, I is selected as an $\ell/3$-bridging set, which is strong with unit edge costs. To compute I as an $O(\ell)$-bridging set, obtain the vertices on the shortest path from i to j for each i and j using the witness matrix W in $O(\ell)$ time. After obtaining those n^2 sets spending $O(\ell n^2)$ time, it is shown in [12] how to obtain a $O(\ell)$-bridging set of $O(n \ln n/\ell)$ size within the same time complexity. The process of obtaining the bridging set must stop at $\ell = n^{1/2}$ as the process is too expensive beyond this point, and thus, the same bridging set is used beyond this point. The time before this point is the same as that in (1) and that after this point is $\tilde{O}(n^{2.5})$. Thus, this is a two-phase algorithm.
3. When edge costs are positive and bounded by $M = n^t > 0$, a similar procedure can be used to compute an $O(\ell)$-bridging set of $O(n \ln n/\ell)$ size in $\tilde{O}(\ell n^2)$ time. Using the bridging set, the APSP problem can be solved in $\tilde{O}(n^{2+\mu(t)})$ time in a similar way to (1).

The result can be generalized into the case where edge costs are between $-M$ and M within the same time complexity by modifying the procedure for computing an ℓ-bridging set, provided there is no negative cycle. The details are shown in [12].

Applications

The eccentricity of a vertex v of a graph is the greatest distance from v to any other vertices. The diameter of a graph is the greatest eccentricity of any vertices. In other words, the diameter is the greatest distance between any pair of vertices. If the corresponding APSP problem is solved, the maximum element of the resulting matrix is the diameter.

Open Problems

Recently, LeGall [6] discovered an algorithm for multiplying rectangular matrices with $\omega(1, 0.530, 1) < 2.060$, which gives the upper bound $\mu < 0.530$. This improves the complexity of APSP with unit edge costs from $O(n^{2.575})$ by Zwick to $O(n^{2.530})$ in the same framework as that of Zwick in this article. Two major challenges are stated here among others. The first is to improve the complexity of $\tilde{O}(n^{2.530})$ for the APSP with unit edge costs.

The other is to improve the bound of $M < O(n^{0.624})$ for the complexity of the APSP with integer costs up to M to be sub-cubic.

Problem Definition

All-distances sketches (The term *least element lists* was used in [3]; the terms MV/D lists and Neighborhood summaries were used in [6].) are randomized summary structures of the distance relations of nodes in a graph. The graph can be directed or undirected, and edges can have uniform or general nonnegative weights.

Preprocessing Cost

A set of sketches, ADS(v) for each node v, can be computed efficiently, using a near-linear number of edge traversals. The sketch sizes are well concentrated, with logarithmic dependence on the total number of nodes.

Supported Queries

The sketches support approximate distance-based queries, which include:

- ***Distance distribution***: The query specifies a node v and value $d \geq 0$ and returns the cardinality $|N_d(v)|$ of the d-neighborhood of v $N_d(v) = \{u \mid d_{vu} \leq d\}$, where d_{uv} is the shortest path distance from u to v. We are interested in estimating $|N_d(v)|$ from ADS(v).

  A related property is the *effective diameter* of the graph, which is a quantile of the distance distribution of all node pairs; we are interested in computing an estimate efficiently.
- ***Closeness centrality*** (distance-decaying) is defined for a node v, a monotone nonincreasing function $\alpha(x) \geq 0$ (where $\alpha(+\infty) \equiv 0$), and a nonnegative function $\beta(u) \geq 0$:

$$C_{\alpha,\beta}(v) = \sum_u \alpha(d_{vu})\beta(u) \,. \tag{1}$$

  The function α specifies the decay of relevance with distance and the function β weighs nodes based on metadata to focus on a topic or property of relevance. Neighborhood cardinality is a special case obtained using $\beta \equiv 1$ and $\alpha(x) = 1$ if $x \leq d$ and $\alpha(x) = 0$ otherwise. The number of reachable nodes from v is obtained using $\alpha(x) \equiv 1$. Also studied were exponential decay $\alpha(x) = 2^{-x}$ with distance [10], the (inverse) harmonic mean of distances $\alpha(x) = 1/x$ [1, 14], and general decay functions [4,6]. We would like to estimate $C_{\alpha,\beta}(v)$ from ADS(v).
- ***Closeness similarity*** [8] relates a pair of nodes based on the similarity of their distance relations to all other nodes.

$$\underset{\alpha,\beta}{\mathrm{SIM}}(v,u) = \frac{\sum_j \alpha(\max\{d_{u,j}, d_{v,j}\})\beta(j)}{\sum_j \alpha(\min\{d_{u,j}, d_{v,j}\})\beta(j)} \,. \tag{2}$$

  We would like to estimate $\mathrm{SIM}_{\alpha,\beta}(v,u) \in [0,1]$ from ADS(v) and ADS(u).
- ***Timed influence*** of a seed set S of nodes depends on the set of distances from S to other nodes. Intuitively, when edge lengths model transition times, the distance is the "elapsed time" needed to reach the node from S. Influence is higher when distances are shorter:

$$\underset{\alpha,\beta}{\mathrm{INF}}(S) = \sum_j \alpha(\min_{i \in S} d_{ij})\beta(j) \,. \tag{3}$$

  We would like to estimate $\mathrm{INF}_{\alpha,\beta}(S)$ from the sketches $\{\mathrm{ADS}(v) \mid v \in S\}$.
- ***Approximate distance oracles:*** For two nodes v, u, use ADS(u) and ADS(v) to estimate $d_{u,v}$.

Key Results

We provide a precise definition of ADSs, overview algorithms for scalable computation, and finally discuss estimators.

Definition

The ADS of a node v, ADS(v), is a set of node ID and distance pairs (u, d_{vu}). The included nodes are a sample of the nodes reachable from v. The sampling is such that the inclusion probability of a node is inversely proportional to its Dijkstra rank (nearest neighbor rank). That is, the probability that the ith closest node is sampled is proportional to $1/i$.

The ADSs are defined with respect to random mappings/permutations r of the set of all nodes

and come in three flavors: bottom-k, k-mins, and k-partition. The integer parameter k determines a tradeoff between the sketch size and computation time on one hand and the information and estimate quality on the other. For simplicity, we assume here that distances d_{vu} are unique for different u (using tie breaking). We use the notation $\Phi_{<u}(v)$ for the set of nodes that are closer to node v than node u and $\pi_{vu} = 1 + |\Phi_{<u}(v)|$ for the *Dijkstra rank* of u with respect to v (u is the π_{vu} closest node from v). For a set N and a numeric function $r : N$, the function $\mathrm{k}_r\mathrm{th}(N)$ returns the kth smallest value in the range of r on N. If $|N| < k$, then we define $\mathrm{k}_r\mathrm{th}(N)$ to be the supremum of the range of r.

A *bottom-k* ADS [3,7] is defined with respect to a single random permutation r. ADS(v) includes a node u if and only if the rank $r(u)$ is one of the k smallest ranks among nodes that are at least as close to v:

$$u \in \mathrm{ADS}(v) \iff r(u) < \mathrm{k}_r\mathrm{th}(\Phi_{<u}(v)). \quad (4)$$

A *k-partition* ADS (implicit in) [2] is defined with respect to a random partition $\mathrm{BUCKET} : V \to [k]$ of the nodes to k subsets and a random permutation r. ADS(v) includes u if and only if u has the smallest rank among nodes in its bucket that are at least as close to v.

$$u \in \mathrm{ADS}(v) \iff r(u) < \min\left\{ r(h) \mid \begin{array}{l} \mathrm{BUCKET}(h) = \mathrm{BUCKET}(u) \\ \wedge\, h \in \Phi_{<u}(v) \end{array} \right\}.$$

A *k-mins* ADS [3,15] is k bottom-1 ADSs, defined with respect to k independent permutations.

It is often convenient to specify the ranks $r(j)$ and (for k-partition ADSs) the bucket $\mathrm{BUCKET}(j)$ using random hash functions, so they are readily available from the node ID. The same randomization is used for all nodes, which results in the sketches being coordinated. This means that a node sampled in one sketch is more likely to be included in other sketches. Coordination is an artifact of scalable computation of the sketches but also facilitates more accurate similarity and influence queries.

Relation to MinHash Sketches

All-distances sketches are related to MinHash sketches: ADS(v) is the union of the MinHash sketches of the neighborhoods $N_d(v)$, for all possible values of d. We explain how a MinHash sketch of a neighborhood $N_d(v)$ can be obtained from ADS(v). From a k-mins ADS, we obtain a k-mins MinHash sketch of $N_d(v)$, which includes for each of the k permutations r the value $x \leftarrow \min_{u \in N_d(v)} r(u)$. Note that x is the minimum rank of a node of distance at most d in the respective bottom-1 ADS defined for r. The k minimum rank values $x^{(t)}$ $t \in [k]$ we obtain from the different permutations are the k-mins MinHash sketch of $N_d(v)$. We now consider obtaining a bottom-k MinHash sketch of $N_d(v)$ from a bottom-k ADS(v). The MinHash sketch of $N_d(v)$ includes the k nodes of minimum rank in $N_d(v)$, which are also the k nodes of minimum rank in ADS(v) within distance at most d. Finally, a k-partition MinHash sketch of $N_d(v)$ is similarly obtained from a k-partition ADS by taking, for each bucket $i \in [k]$, the smallest rank value of a node in bucket i that is in $N_d(v)$. This is also the smallest value in ADS(v) over nodes in bucket i that have distance at most d from v.

Direction

For directed graphs, influence, centrality, and closeness similarity queries can be defined with respect to either forward or reversed distances. Accordingly, we can separately consider for each node v the *forward* ADS and the *backward* ADS of each node, which are defined respectively using forward or reverse paths from v.

Node Weights

All the ADS flavors can be extended to be with respect to specified node weights $\beta(v) \geq 0$ [3,4]. This makes queries formulated with respect to the weights more efficient.

Algorithms

There are two meta-approaches for scalable computation of an ADS set. The first approach,

PRUNEDDIJKSTRA (Algorithm 1), performs pruned applications of Dijkstra's single-source shortest paths algorithm (BFS when unweighted) [3, 7]. The second approach, DP (implicit in [2, 15]), applies to unweighted graphs and is based on dynamic programming or Bellman-Ford shortest paths computation. LOCALUPDATES (Algorithm 2) [4] extends DP to weighted graphs. LOCALUPDATES is node-centric and is appropriate for MapReduce or similar platforms, but can incur more overhead than PRUNEDDIJKSTRA. The algorithms are presented for bottom-k sketches, but both approaches can be easily adopted to work with all three ADS flavors.

Algorithm 1: ADS set for G via PRUNEDDIJKSTRA

```
1 for u by increasing r(u) do
2     Perform Dijkstra from u on G^T (the transpose graph)
3     foreach scanned node v do
4         if |{(x, y) ∈ ADS(u) | y < d_vu}| = k then
5             prune Dijkstra at v
6         else
7             ADS(v) ← ADS(v) ∪ {(r(u), d_vu)}
```

Both PRUNEDDIJKSTRA and DP can be performed in $O(km \log n)$ time (on unweighted graphs) on a single processor in main memory, where n and m are the number of nodes and edges in the graph. These algorithms maintain a partial ADS for each node, as entries of node ID and distance pairs. ADS(v) is initialized with the pair $(v, 0)$. The basic operation we use is *edge relaxation*: when relaxing (v, u), ADS(v) is updated using ADS(u). For bottom-k, the relaxation modifies ADS(v) when ADS(u) contains a node i such that $r(i)$ is smaller than the kth smallest rank among nodes in ADS(v) with distance at most $d_{ui} + w_{vu}$ from v. Both PRUNEDDIJKSTRA and DP perform relaxations in an order which guarantees that inserted entries are part of the final ADS, that is, there are no other nodes that are both closer and have lower rank: PRUNEDDIJKSTRA iterates over all nodes in increasing rank, runs Dijkstra's algorithm from the node on the transpose graph, and prunes at nodes when the ADS is not updated. DP performs iterations, where in each iteration, all edges (v, u), such that ADS(v) was updated in the previous step, are relaxed. Therefore, entries are inserted by increasing distance.

Algorithm 2: ADS set for G via LOCALUPDATES

```
   // Initialization
1  for u do
2      ADS(u) ← {(r(u), 0)}
   // Propagate updates (r, d) at node u
3  if (r, d) is added to ADS(u) then
4      foreach y | (u, y) ∈ G do
5          send (r, d + w(u, y)) to y
   // Process update (r, d) received at u
6  if node u receives (r, d) then
7      if r < k^th_x{(x, y) ∈ ADS(u) | y < d} then
8          ADS(u) ← ADS(u) ∪ {(r(v), d)}
       // Clean-up ADS(u)
9      for entries (x, y) ∈ ADS(u) | y > d by increasing y do
10         if x > k^th_h{(h, z) ∈ ADS(u) | z < y} then
11             ADS(u) ← ADS(u) \ (x, y)
```

Estimation

Distance Distribution

Neighborhood cardinality queries for a node v, and $d \geq 0$ can be estimated with a small relative error from ADS(v). The generic estimator extracts a MINHASH sketch of the neighborhood $N_d(v)$ from ADS(v) and applies a MINHASH cardinality estimator to this sketch. This approach was used in [3, 7, 15]. A nearly optimal estimator, the Historic Inverse Probability (HIP) estimator [4], has a factor 2 improvement in variance by using all information in the ADS instead of just the MINHASH sketch. HIP works by considering for each entry (u, d) in the sketch, the *HIP threshold probability*, which is the prob-

ability, under randomly drawn rank for the node u, but fixing ranks of all other nodes, that the entry is included in the sketch. The entry then obtains an adjusted weight that is the inverse of the HIP threshold probability. Neighborhood cardinality can be estimated by the sum of the adjusted weights of ADS entries that fall in the neighborhood.

Closeness Centrality (Distance-Decaying)

$C_{\alpha,\beta}(v)$ can be estimated from ADS(v) with a small relative error when the set of ADSs is computed with respect to β. Estimators using MINHASH sketches were given in [6]. The tighter HIP estimator in [4] simply sums, over entries $(u, d) \in$ ADS(v), the product of the adjusted weight of the entry and $\alpha(d)\beta(u)$.

Closeness Similarity and Influence

When the sketches are computed with respect to β, the closeness similarity of two nodes u and v can be estimated from ADS(u) and ADS(v) within a small additive ϵ [8]. The influence of a set of nodes S can be estimated from $\{\text{ADS}(v) \mid v \in S\}$ to within a small relative error [9]. These estimators are instances of the L* estimator [5] applied with the HIP inclusion probabilities [4].

Approximate Distance Oracles

An upper bound on the distance of two nodes u, v can be computed from ADS(u) and ADS(v) [8]. This is done by looking at the minimum, over nodes h that are in the intersection ADS(u) $\cap$ ADS(v), of $d_{uh} + d_{hv}$. When the graph is undirected, the oracle has worst-case quality guarantees that match the distance oracle of [16] (oracle time can be improved by looking only at nodes in the few ADS entries that correspond to $k = 1$). We note that observed quality in practice (using the full oracle) tends to have a small relative error [8].

Applications

Massive graphs, with billions of edges, are prevalent and model web graphs and social networks. Centralities, similarities, influence, and distances are basic data analysis tasks on these graphs. ADSs are a powerful tool for scalable analysis of very large graphs.

Extensions

An ADS can be viewed as a MINHASH sketch constructed from a stream, where all updates are recorded. This means that the HIP estimator [4] can be applied for distinct counting on streams, obtaining improved performance over estimators applied to the MINHASH sketch alone [11, 12].

In a graph context, ADS(v) is a recording of all updates to a MINHASH sketch obtained by sweeping through nodes in increasing distance from v. More generally, we can construct ADS for other settings and apply the same estimation machinery. One example is Euclidean distances [6, 13]. Another example is constructing a *combined ADS* of multiple graphs for the application of timed influence oracles [9].

Problem Definition

A parameterized problem is a language $L \subseteq \Sigma^* \times \mathbb{N}$. Such a problem is said to be *fixed-parameter tractable* if there is an algorithm that decides if $(x,k) \in L$ in time $f(k)|X|^{O(1)}$. For attacking an intractable problem within the multivariate algorithmic framework, a necessary first step is to identify some reasonable parameters. The relevance of an FPT algorithm will depend on the quality of the choice of parameters. The first objective is of a practical concern: the choice of parameter should not "cheat," that is, it should be a choice that leads to tractability in the context of instances that are relevant to real-world applications. On the other hand, the parameter should also lend a perspective that is useful to the algorithm designer, usually by providing additional structural insights, thereby making an otherwise unwieldy problem manageable. Finally, the parameter itself should be accessible, in the sense that it should either typically accompany the input or be easy to compute from the input.

For a combinatorial optimization problem, the size of the desired solution is a natural parameter. For a minimization problem, it is usually reasonable to assume that this parameter is also small in practice. For a maximization problem, the *dual* parameter, which is the difference from the best possible upper bound on the optimum, is also a natural choice. For example, consider the problem of satisfying at least k clauses of a CNF formula. Here, the standard parameter would be k, while the dual parameter would be $(m-k)$: in other words, can we satisfy *all but* k clauses in the formula? In the rest of this section, we broadly describe the other possibilities for parameters.

Structural Parameterizations

Structural parameters are a considered attempt at acknowledging that various aspects of an instance influence its complexity. A classic example is ML-type checking [11], which is an NP-complete problem but can be resolved in time $O(2^k)n^{O(1)}$, where k is the maximum nesting depth of the

input program. Fortunately, nesting depths of most programs are no more than four or five; the algorithm proposed is entirely adequate for real-world instances.

Since every problem context is inherently suggestive of several possible parameters, we are only able to describe a few illustrative examples. In the context of graph problems, *width parameters* such as treewidth, cliquewidth, and rankwidth have enjoyed immense success. The notion of *treewidth* is particularly popular because of a number of real-world instances that are known to exhibit small treewidth, and on the other hand, the theoretical foundations of algorithms on graphs of bounded treewidth are extremely well established and actively developed (see, e.g., [3, Chapter 7]). An analogous notion for treewidth for directed graphs remains elusive, although several proposals with varying merits exist in the literature [7].

Special graph classes, such as interval graphs, chordal graphs, planar graphs, and so on, have been extensively studied, and most hard problems turn out to be tractable on these classes. For an arbitrary graph, one might hope that the tractability carries over if the graph is "close enough" to being, say, a chordal graph. An increasingly popular program involves considering distance-to-$\mathcal{C}$ parameterizations, where $\mathcal{C}$ is a class of graphs on which the problem of interest is easily solvable. For instance, we might let k be the size of a smallest subset of vertices whose removal makes the input graph a member of $\mathcal{C}$. Other measures of closeness, using operations like addition, removal, or contraction of edges, are also frequently considered.

In the context of satisfiability and constraint satisfaction also, the notion of distance from tractable subclasses has garnered much attention in recent times. This is formalized by the notion of *backdoors*, which are subsets of variables whose "removal" makes the formula tractable (for instance, one of the Schaefer classes). Much work has been done with backdoors as parameters for determining satisfiability, and we refer the reader to [9].

Above or Below Guarantee Parameterizations

Consider the standard parameterization of VERTEX COVER: given a graph $G = (V, E)$ on n vertices, decide whether G has a vertex cover of size at most k. The best-known algorithm for vertex cover is due to Chen et al. [1] and runs in time $O(1.2852^k + kn)$. Observe that if G has a matching of size μ, then any vertex cover also has size at least μ. In particular, if G has a perfect matching, then all vertex covers of G have $\Omega(n)$ edges, and even the FPT algorithms for the standard parameter will be obliged to spend time that is exponential in n.

Mahajan and Raman [13] consider the following alternative parameterization: does G have a vertex cover of size at most $\mu + k$? Note that the parameter k here is the size of the vertex cover *above* the matching size. Since the matching size is a guaranteed lower bound on the vertex cover size, this problem is referred to as the ABOVE GUARANTEE VERTEX COVER problem. Just as one can parameterize above guaranteed values, one can consider parameterizations below guaranteed values. A classic example is the following variant of VERTEX COVER: given a planar graph $G = (V, E)$ on n vertices and an integer parameter k, does G admit a vertex cover of size $\lfloor 3n/4 \rfloor - k$?

Key Results

One of the earliest attempts at parameterizing by the size of the vertex cover was made in [4]. Various graph layout problems were considered, where it turned out that a small vertex cover led to a very convenient structure for formulating a linear program. For many of these problems, it is not known if they are FPT parameterized by treewidth, and some are hard even on graphs of bounded treewidth (indeed, BANDWIDTH is NP-hard even on trees). This justifies the need for a stronger structural parameter, and in these examples, vertex cover turned out to be a very fruitful parameterization.

These examples led to a broader theme, namely, the "complexity ecology of parameters"

program, which was proposed in [5]. The theoretical foundations of this program were further established and surveyed in [6]. An immediate concern is that of how one formalizes the structural parameterization in question. Along the lines of [6], we distinguish the following possible objectives from the formalization:

1. The complexity of verifying and then exploiting a bounded parameter value
2. The complexity of exploiting structure that is guaranteed, but not given explicitly (a "promise" problem)
3. The complexity of exploiting structure that is explicitly provided along with the input, as a "witness"

The first setting is the most general but also the most computationally restrictive, as it puts the burden of discovering the structure also on the algorithm. This definition makes the study of parameters like bandwidth and cliquewidth prohibitive, as these are hard to determine even in the parameterized framework. On the other hand, while the other two notions are increasingly relaxed, the premise of a promise or the availability of witnesses in real-world witnesses remains a concern. We point the reader to [6] for a detailed discussion of the precise formalisms and their respective merits and trade-offs.

One of the major theoretical themes with alternate parameterizations is the exercise of identifying *meta-theorems* that explain the influence of the parameter over a large class of problems, usually specified in an appropriate logic. A cornerstone result of this kind is Courcelle's theorem, establishing that a problem expressible in Monadic Second Order Logic is FPT when parameterized by treewidth and the size of the formula [2]. Several generalizations of Courcelle's theorem have since been proposed, and many of them are surveyed in [10]. More recent work also establishes a similar result in the context of kernelization and parameters like vertex cover [8].

There is a rich literature that evidences the growing consideration of alternate parameterizations for optimization problems in varied contexts. As a concluding example, we turn our attention to [14], which serves to illustrate the scale at which it is possible to execute an exercise in understanding a question from several perspectives. Given two graphs H and G, the SUBGRAPH ISOMORPHISM problem asks if H is isomorphic to a subgraph of G. In [14], a framework is developed involving ten relevant parameters for each of H and G (such as treewidth, maximum degree, number of components, and so on). The generic question addressed in this work is if the problem admits an algorithm with running time:

$$f_1(p_1, p_2, \ldots, p_\ell) \cdot n^{f_2(p_{\ell+1}, \ldots, p_k)},$$

where each of $p_1, \ldots, p_k$ is one of the ten parameters depending only on H or G. We refer the reader to Figure 1 in [14] for a concise tabulation of the results. Notably, *all* combinations of questions (the number of which runs into the billions) are answered by a set of 28 of positive and negative results.

There are many examples of problems that are parameterized away from guaranteed bounds. We note that parameterizing vertex cover above the LP optimum has attracted considerable interest because a number of fundamental problems including Above Guarantee Vertex Cover, Odd Cycle Transversal, Split Vertex Deletion, and Almost 2-SAT reduce to this problem. Indeed, for many of these problems, the fastest algorithms at the time of this writing are obtained by reducing these problems to vertex cover parameterized above the LP optimum [12].

Open Problems

We direct the reader to the excellent survey [6] for several open problems concerning specific combinations of parameters for particular problems. In an applied context, an interesting possibility is to investigate if parameters can be learned from large samples of data.

Problem Definition

While the competitive ratio [19] is the most common metric in online algorithm analysis and it has led to a vast amount of knowledge in the field, there are numerous known applications in

which the competitive ratio produces unsatisfactory results. Far too often, it leads to unrealistically pessimistic measures including the failure to distinguish between algorithms that have vastly differing performance under any practical characterization in practice. Because of this there, has been extensive research in alternatives to the competitive ratio, with a renewed effort in the period from 2005 to the present date.

The competitive ratio metric can be derived from the observation that an online algorithm, in essence, computes a partial solution to a problem using incomplete information. Then, it is only natural to quantify the performance drop due to this absence of information. That is, we compare the quality of the solution obtained by the online algorithm with the one computed in the presence of full information, namely, that of the offline optimal OPT, in the *worst case*. More formally,

Definition 1 An online algorithm $\mathcal{A}$ is said to have (asymptotic) competitive ratio c if $\mathcal{A}(\sigma) \leq c \cdot \text{OPT}(\sigma) + b$ for all input sequences σ and fixed constants b and c.

The early literature considered only algorithms with constant competitive ratio, and all others are termed as algorithms with *unbounded* competitive ratio. However, it is easy to extend this definition to a $C(n)$-competitive algorithm as follows:

Definition 2 An online algorithm $\mathcal{A}$ is said to have (asymptotic) competitive ratio $C(n)$ if $\mathcal{A}(\sigma) \leq C(n) \cdot \text{OPT}(\sigma) + b$ for all σ and a fixed constant b. When $b = 0$, $C(n)$ is termed the *absolute* competitive ratio.

A natural expectation would be that the performance of OPT reflects both knowledge of the future and the inherent structure of the specific instance being solved, and hence, an online algorithm with optimal competitive ratio must handle most if not all instances in an efficient manner. Unfortunately, for most problems, the worst-case nature of the competitive ratio leads to algorithms of varying degrees of sophistication having the same equally bad competitive ratio. As a consequence the competitive ratio leads to "equivalence" for online algorithms with vastly differing performance in practice.

In the next sections we discuss the main alternatives to and refinements of the competitive ratio and highlight their relative benefits and drawbacks.

Key Results

Relative Worst-Order Ratio

The relative worst-order ratio [8, 10, 11] combines some desirable properties of two earlier measures, namely, the max/max ratio [6] and the random order ratio [15]. Using this measure we can directly compare two online algorithms. Informally, for a given sequence, it considers the worst-case ordering of that sequence for each algorithm and compares their behavior as a ratio on these orderings. Then it finds among all sequences (not just reorderings) the one that maximizes the ratio above in the worst-case performance.

Let $\mathcal{A}$ and $\mathcal{B}$ be online algorithms for an online minimization problem and let $\mathcal{A}(I)$ be the cost of $\mathcal{A}$ on an input sequence $I = (i_1, i_2, \ldots, i_n)$. Denote by I_σ the sequence obtained by applying a permutation σ to I, i.e., $I_\sigma = (i_{\sigma_1}, \ldots, i_{\sigma_n})$. Define $\mathcal{A}_W(I) = \min_\sigma \mathcal{A}(I_\sigma)$.

Definition 3 ([11]) Let $S_1(c)$ and $S_2(c)$ be the statements about algorithms $\mathcal{A}$ and $\mathcal{B}$ defined in the following way:

$S_1(c)$: There exists a constant b such that $\mathcal{A}_W(I) \leq c \cdot \mathcal{B}_W(I) + b$ for all I.

$S_2(c)$: There exists a constant b such that $\mathcal{A}_W(I) \geq c \cdot \mathcal{B}_W(I) - b$ for all I.

The relative worst-order ratio $WR_{\mathcal{A},\mathcal{B}}$ of an online algorithm $\mathcal{A}$ to algorithm $\mathcal{B}$ is defined if $S_1(1)$ or $S_2(1)$ holds. In this case $\mathcal{A}$ and $\mathcal{B}$ are said to be comparable. If $S_1(1)$ holds, then $WR_{\mathcal{A},\mathcal{B}} = \sup\{r | S_2(r)\}$, and if $S_2(r)$ holds, then $WR_{\mathcal{A},\mathcal{B}} = \inf\{r | S_1(r)\}$.

$WR_{\mathcal{A},\mathcal{B}}$ can be used to compare the qualities of $\mathcal{A}$ and $\mathcal{B}$. If $WR_{\mathcal{A},\mathcal{B}} = 1$, then these two

algorithms have the same quality with respect to this measure. The magnitude of difference between $WR_{\mathcal{A},\mathcal{B}}$ and 1 reflects the difference between the behavior of the two algorithms. For a minimization problem, $\mathcal{A}$ is better than $\mathcal{B}$ with respect to this measure if $WR_{\mathcal{A},\mathcal{B}} < 1$ and vice versa. Boyar and Favrholdt showed that the relative worst-order ratio is transitive [8].

Note that we can also compare the online algorithm $\mathcal{A}$ to an optimal offline algorithm OPT. The *worst-order ratio* of $\mathcal{A}$ is defined as $WR_{\mathcal{A}} = WR_{\mathcal{A},\mathrm{OPT}}$. For some problems, OPT is the same for all order of requests on a given input sequence, and hence, the worst-order ratio is the same as the competitive ratio. However, for other problems such as paging the order does matter for OPT.

In [10], three online algorithms (FIRST-FIT, BEST-FIT, and WORST-FIT) for two variants of the seat reservation problem [9] are compared using the relative worst-order ratio. The relative worst-order ratio when applied to paging algorithms can be used to differentiate LRU which is strictly better than FWF with respect to the worst-order ratio, while they have the same competitive ratio [11]. Similarly, [11] proposes a new paging algorithm, retrospective LRU (RLRU), and shows that it is better than LRU under this measure while not under the competitive ratio.

Loose Competitiveness

Loose competitiveness was first proposed in [22] and later modified in [25]. It attempts to obtain a more realistic measure by observing that first, in many real online problems, we can ignore those input sequences on which the online algorithm incurs a cost less than a certain threshold and, second, many online problems have a second resource parameter (e.g., size of cache, number of servers) and the input sequences are independent of these parameters. In contrast, in competitive analysis, the adversary can select sequences tailored against those parameters. For example, for caching the worst-case input with competitive ratio k can only be constructed by the adversary if it is aware of the size k of the cache. However, in practice the competitive ratios of many online paging algorithms have been observed to be constant [25], i.e., independent of k.

In loose competitiveness we consider an adversary that is oblivious to the parameter by requiring it to give a sequence that is bad for most values of the parameter rather than just a specific bad value of the parameter. Let $\mathcal{A}_k(I)$ denote the cost of an algorithm $\mathcal{A}$ on an input sequence I, when the parameter of the problem is k.

Definition 4 ([25]) An algorithm $\mathcal{A}$ is (ϵ,δ)-loosely c-competitive if, for any input sequence I and for any n, at least $(1-\delta)n$ of the values $k \in \{1,2,\ldots,n\}$ satisfy $\mathcal{A}_k(I) \le \max\{c \cdot \mathrm{OPT}_k(I), \epsilon\,|I|\}$.

Therefore, we ignore the input sequences I which cost less than $\epsilon\,|I|$. Also we require the algorithm to be good for at least $(1-\delta)$ fraction of the possible parameters. For each online problem, we can select the appropriate constants ϵ and δ. The following result shows that by this modification of the competitive analysis, we can obtain paging algorithms with constant performance ratios.

Theorem 1 ([25]) *Every k-competitive paging algorithm is (ϵ,δ)-loosely c-competitive for any $0 < \epsilon, \delta < 1$, and $c = (e/\delta)\ln(e/\epsilon)$, where e is the base of the natural logarithm.*

Diffuse Adversary Model

The diffuse adversary model [16] tries to refine the competitive ratio by restricting the set of legal input sequences. In the diffuse adversary model, the input is generated according to a distribution belonging to a member of a class Δ of distributions.

Definition 5 Let $\mathcal{A}$ be an online algorithm for a minimization problem and let Δ be a class of distributions for the input sequences. Then $\mathcal{A}$ is c-competitive against Δ, if there exists a constant b, such that $\mathcal{E}_{I\in D}\mathcal{A}(I) \le c\cdot\mathcal{E}_{I\in D}\mathrm{OPT}(I)+b$, for every distribution $D \in \Delta$, where $\mathcal{A}(I)$ denotes the cost of $\mathcal{A}$ on the input sequence I and the expectations are taken over sequences that are picked according to D.

In other words, for a given algorithm A, the adversary selects the distribution D in Δ that

leads to its worst-case performance in that family. If Δ is highly restrictive, then A knows more about the distribution of input sequences and the power of adversary is more constrained. When Δ contains all possible distributions, then the competitive analysis against Δ is the same as the standard competitive ratio.

Computing the actual competitive ratio of both deterministic and randomized paging algorithms against Δ_ϵ is studied in [23, 24]. An estimation of the optimal competitive ratio for several algorithms (such as LRU and FIFO) within a factor of 2 is given. Also it is observed that around the threshold $\epsilon \approx 1/k$, the best competitive ratios against Δ_ϵ are $\Theta(\ln k)$. The competitive ratios rapidly become constant for values of ϵ less than the threshold. For $\epsilon = \omega(1/k)$, i.e., values greater than the threshold, the competitive ratio rapidly tends to $\Theta(k)$ for deterministic algorithms while it remains unchanged for randomized algorithms.

Note that we can also model locality of reference using the diffuse adversary model by considering only those distributions that are consistent with distributions obeying a locality of reference principle. In particular Dorrigiv et al. showed that for the list update problem MTF is optimal in expected cost under any probability distribution that has locality of reference monotonicity, i.e., a recently accessed item has equal or larger probability of being accessed than a less recently accessed item [14].

Bijective Analysis

Bijective analysis and average analysis [3] build upon the framework of locality of reference by [1]. These models directly compare two online algorithms without appealing to the concept of the offline "optimal" cost. In addition, these measures do not evaluate the performance of the algorithm on a single "worst-case" request, but instead use the cost that the algorithm incurs on each and all request sequences. Informally, bijective analysis aims to pair input sequences for two algorithms $\mathcal{A}$ and $\mathcal{B}$ using a bijection in such a way that the cost of $\mathcal{A}$ on input σ is no more than the cost of $\mathcal{B}$ on the image of σ, for all request sequences σ of the same length. In this case, intuitively, $\mathcal{A}$ is no worse than $\mathcal{B}$. On the other hand, average analysis compares the average cost of the two algorithms over all request sequences of the same length. For an online algorithm $\mathcal{A}$ and an input sequence σ, let $\mathcal{A}(\sigma)$ be the cost incurred by $\mathcal{A}$ on σ. Denote by I_n the set of all input sequences of length n.

We say that an online algorithm $\mathcal{A}$ is *no worse* than an online algorithm $\mathcal{B}$ according to bijective analysis if there exists an integer $n_0 \geq 1$ so that for each $n \geq n_0$, there is a bijection $b : \mathcal{I}_n \leftrightarrow \mathcal{I}_n$ satisfying $\mathcal{A}(\sigma) \leq \mathcal{B}(b(\sigma))$ for each $\sigma \in \mathcal{I}_n$. We denote this by $\mathcal{A} \preceq_b \mathcal{B}$.

We say that an online algorithm $\mathcal{A}$ is *no worse* than an online algorithm $\mathcal{B}$ according to average analysis if there exists an integer $n_0 \geq 1$ so that for each $n \geq n_0$, $\sum_{I \in \mathcal{I}_n} \mathcal{A}(I) \leq \sum_{I \in \mathcal{I}_n} \mathcal{B}(I)$. We denote this by $\mathcal{A} \preceq_a \mathcal{B}$.

Under both bijective analysis and average analysis alone, all *lazy* algorithms (including LRU and FIFO, but not FWF) are in fact strongly equivalent. This is evidence of an inherent difficulty to separate these algorithms in any general unrestricted setting. Their superiority is seemingly derived from the well-known observation that input sequences for paging and several other problems show locality of reference [12, 13]. This means that when a page is requested, it is more likely to be requested in the near future. Therefore, several models for paging with locality of reference have been proposed.

Hence, the need to combine bijective analysis with an assumption of locality of reference model such as concave analysis. In this model a request sequence has high locality of reference if the number of distinct pages in a window of size n is small.

Using this measure Angelopoulos et al. [3] show that LRU is never outperformed in any possible subpartition on the request sequence space induced by concave analysis, while it always outperforms *any other paging algorithm* in at least one subpartition of the sequence space. This result proves separation between LRU and all other algorithms and provides theoretical backing to the observation that LRU is preferable in practice. This is the first deterministic theoretical

model to provide full separation between LRU and all other algorithms. Recently this result was strengthened by Angelopolous and Schweitzer [2] where they showed that the separation also holds under the stricter bijective analysis (as opposed to average analysis) using the concave analysis framework.

Smoothed Competitiveness

Some algorithms that have very bad *worst-case* performance behave very well in practice. One of the most famous examples is the simplex method. This algorithm has a very good performance in practice but it has exponential worst-case running time. *Average case* analysis of algorithms can somehow explain this behavior, but sometimes there is no basis to the assumption that the inputs to an algorithm are random.

Smoothed analysis of algorithms [21] tries to explain this intriguing behavior without assuming anything about the distribution of the input instances. In this model, we randomly perturb (smoothen) the input instances according to a probability distribution f and then analyze the behavior of the algorithm on these perturbed (smoothed) instances. For each input instance $\check{I}$, we compute the neighborhood $N(\check{I})$ of $\check{I}$ which contains the set of all perturbed instances that can be obtained from $\check{I}$. Then we compute the expected running time of the algorithm over all perturbed instances in this neighborhood. The smoothed complexity of the algorithm is the maximum of this expected running time over all the input instances. Intuitively, an algorithm with a bad worst-case performance can have a good smoothed performance if its worst-case instances are isolated. Spielman and Teng show [21] that the simplex algorithm has polynomial smoothed complexity. Several other results are known about the smoothed complexity of the algorithms [4, 7, 18, 20].

Becchetti et al. [5] introduced *smoothed competitive analysis* which mirrors competitive analysis except that we consider the cost of the algorithm on randomly perturbed adversarial sequences. As in the analysis of the randomized online algorithms, we can have either an *oblivious adversary* or an *adaptive adversary*. The smoothed competitive ratio of an online algorithm $\mathcal{A}$ for a minimization problem can be formally defined as follows.

Definition 6 ([5]) The *smoothed competitive ratio* of an algorithm $\mathcal{A}$ is defined as

$$c = \sup_{\check{I}} \mathcal{E}_{I \leftarrow N(\check{I})} \left[\frac{\mathcal{A}(I)}{OPT(I)} \right],$$

where the supremum is taken over all input instances $\check{I}$ and the expectation is taken over all instances I that are obtainable by smoothening the input instance $\check{I}$ according to f in the neighborhood $N(\check{I})$.

In [5], they use the smoothed competitive ratio to analyze the MULTI-LEVEL FEEDBACK(MLF) algorithm for processor scheduling in a time-sharing multitasking operating system. This algorithm has very good practical performance, but its competitive ratio is very bad and obtains strictly better ratios using the smooth competitive analysis than with the competitive ratio.

Search Ratio

The search ratio belongs to the family of measures in which the offline OPT is weakened. It is defined only for the specific case of geometric searches in an unknown terrain for a target of unknown position. Recall that the competitive ratio compares against an all-knowing OPT; indeed, for geometric searches in the competitive ratio framework, the OPT is simply a shortest path algorithm, while the online search algorithm has intricate methods for searching. The search ratio instead considers the case where OPT knows the terrain but not the position of the target. That is, the search ratio compares two search algorithms, albeit one more powerful than the other. By comparing two instances of like objects, the search ratio can be argued to be a more meaningful measure of the quality of an online search algorithm. Koutsopias et al. show that searching in trees results the same large competitive ratio regardless of the search strategy, yet under the search ratio framework, certain algorithms are far superior to others [17].

Problem Definition

Let $\mathcal{A}$ be an enumeration algorithm. Suppose that $\mathcal{A}$ is a recursive type algorithm, i.e., composed of a subroutine that recursively calls itself several times (or none). Thus, the recursion structure of the algorithm forms a tree. We call the subroutine or the execution of the subroutine an *iteration*. We here assume that an iteration does not include the computation done in the recursive calls generated by itself. We regard a series of subroutines of different types as an iteration if they form a nested recursion. We simply write the set of all iterations of an execution of $\mathcal{A}$ by $\mathcal{X}$.

When an iteration X recursively calls an iteration Y, X is called the *parent* of Y, and Y is called a *child* of X. The *root iteration* is that with no parent. For non-root iteration X, its parent is unique and is denoted by $P(X)$. The set of the children of X is denoted by $C(X)$. The parent-child relation between iterations forms a tree structure called a *recursion tree*, or an *enumeration tree*. An iteration is called a *leaf iteration* if it has no child and an *inner iteration* otherwise.

For iteration X, an upper bound of the execution time (the number of operations) of X is denoted by $T(X)$. Here we exclude the computation for the output process from the computation time. We remind that $T(X)$ is the time for local execution time and thus does not include the computation time in the recursive calls generated by X. For example, when $T(X) = O(n^2)$, $T(X)$ is written as cn^2 for some constant c. T^* is the maximum $T(X)$ among all leaf iterations X. Here, T^* can be either constant or a polynomial of the input size. If X is an inner iteration, let $\overline{T}(X) = \sum_{Y \in C(X)} T(Y)$.

Key Results

We explain methods to amortize the computation time of iterations that only requires a local condition and give simple algorithms which achieves nontrivial time complexity. On enumeration algorithms, it is very hard to grasp the global structures of the computation and the recursion tree that is coming from the hardness of estimating the number of iterations in a branch. Instead of that, we approach from local amortization from parent and children. When we go deep in a recursion tree, the number of iterations tends to increase exponentially, and the size of the input of each iteration often decreases on the other hand. Motivated by this observation, we amortize the computation time by moving the computation time of each iteration to its children from the top to bottom, so that the long computation time on upper levels is diffused.

Amortization by Children

Suppose that each iteration X takes $O((|C(X)|+1)T)$ time. Note that this implies that a leaf iteration takes $O(T)$ time. Then, the total computation time of the algorithm is $O(T \sum_{X \in \mathcal{X}} |C(X)| + 1) = O(T(|\mathcal{X}| + \sum_{X \in \mathcal{X}} |C(X)|) = O(T|\mathcal{X}|)$, since any iteration is a child of at most one iteration. Hence, an iteration takes $O(T)$ time on average. Let us see an example on the following algorithm for enumerating all subsets of $\{1, \ldots, n\}$.

We can confirm that the algorithm correctly enumerates all subsets without duplications, and an iteration X takes $O(|C(X)|)$ time, except for the output process. Without amortization, the time complexity is $O(n)$ for each iteration, but the above amortization reduces it to $O(1)$. Note that the output process is shortened by outputting each subset by the difference from the previously output subset, and by this the accumulated computation time for output process is also bounded by $O(1)$ for each subset. This amortization technique is common in many algorithms. Further, in the enumeration of spanning trees, the time

Algorithm EnumSubset (S, x)**:**

```
1 output S
2 for i := x + 1 to n; call EnumSubset
  (S ∪ {i}, i + 1)
```

complexity is amortized by not only the children but also the grandchildren [3]. More sophisticated amortization is used in [1, 2] for path connecting given two vertices and subtrees of size k.

Push-Out Amortization

When the computation time of an iteration X is not proportional $|C(X)|$, the above amortization does not work. In such cases, *push-out* amortization [4–6] can work. We amortize the computation time by charging the computation time of iterations near by the root of the recursion to those in bottom levels, by recursively moving the computation time from an iteration to its children from top to down. The move is done in the following push-out rule.

Push-out rule (PO rule): Suppose that iteration X receives a computation time of $S(X)$ from its parent; thus X has computation time of $S(X) + T(X)$ in total. Then, we fix $\frac{\beta}{\alpha-1}(|C(X)|+1)T^*$ of the computation time to X and charge (push-out) the remaining computation time of quantity $S(X) + T(X) - \frac{\beta}{\alpha-1}(|C(X)| + 1)T^*$ to its children. Each child Z of X receives computation time proportional to $T(Z)$, that is, $S(Z) = (S(X) + T(X) - \frac{\beta}{\alpha-1}(|C(X)| + 1)T^*)\frac{T(Z)}{\overline{T}(X)}$.

After the moves in this rule from the top to bottom of the recursion tree, each inner iteration has $O((|C(X)| + 1)T^*)$ computation time, thus $O(T^*)$ time per iteration. Moreover, when the following push-out condition holds for any non-leaf iteration X, each leaf iteration receives computation time of $O(T^*)$ from its parent; thus the computation time per iteration is bounded by $O(T^*)$. Suppose that $\alpha > 1$ and $\beta \geq 0$ are two constants.

Push-Out Condition (PO Condition)
$\overline{T}(X) \geq \alpha T(X) - \beta(|C(X)| + 1)T^*$

Intuitively, this means that $\overline{T}(X) \geq \alpha T(X)$ holds after the assignment of the computation time of $\alpha\beta(|C(X)| + 1)T^*$ to children and the remaining to itself, the inequation. Thus, the computation time of one level of recursion intuitively increases as the depth, unless there are not so many leaf iterations. These suggest that the total computation time spent by middle-level iterations is relatively short compared to that by leaf iterations.

Theorem 1 *If any inner iteration of an enumeration algorithm satisfies PO condition, the amortized computation time of an iteration is* $O(T^*)$.

Proof We state by induction that when we charge computation time with PO rule, from the root iteration to the leaf iterations, each iteration X satisfies $S(X) \leq T(X)/(\alpha - 1)$. The root iteration satisfies this condition. Suppose that an iteration X satisfies it. Then, for any child Z of X, we have

$$\begin{aligned} S(Z) &= (S(X) + T(X) - \frac{\beta}{\alpha-1}(|C(X)| + 1)T^*)\frac{T(Z)}{\overline{T}(X)} \\ &\leq (T(X)/(\alpha-1) + T(X) - \frac{\beta}{\alpha-1}(|C(X)| + 1)T^*)\frac{T(Z)}{\overline{T}(X)} \\ &= \frac{\alpha T(X) - \beta(|C(X)| + 1)T^*}{\overline{T}(X)} \times \frac{T(Z)}{\alpha-1}. \end{aligned}$$

Therefore, any leaf iteration receives $O(T^*)$ time from its parent, and the statement holds.

Since PO condition is satisfied, $\overline{T}(X) \geq \alpha T(X) - \beta(|C(X)| + 1)T^*$. Thus,

$$\frac{\alpha T(X) - \beta(|C(X)| + 1)T^*}{\overline{T}(X)}\frac{T(Z)}{\alpha-1} \leq \frac{T(Z)}{\alpha-1}.\square$$

Matching Enumeration

Let us see an example of designing algorithms so that push-out amortization does work. The problem is the enumeration of matchings in an undirected graph $G = (V, E)$. A *matching* is an edge set $M \subseteq E$ such that any vertex is incident to at most one edge in M. A straightforward

way to enumerate all matchings is to choose an edge e and enumerate matchings including e and enumerate matchings not including e, recursively. This algorithm yields the time complexity of $O(|V|)$ for each matching.

We here consider another way for the enumeration. We choose a vertex v of the maximum degree and partition the problem into enumeration of matchings including e_1, matchings including e_2, ..., matchings including e_k, and matchings including none of $e_1, \ldots, e_k$. Here $e_1, \ldots, e_k$ are the edges incident to v. Since any matching has at most one edge incident to v, this algorithm is complete and makes no duplication. The algorithm is described as follows. Note that $G \setminus \{v\}$ denotes the graph obtained by removing vertex v and edges incident to v from G.

Algorithm EnumMatching $(G = (V, E), M)$**:**

1 **if** $E = \emptyset$ **then output** M; **return**
2 choose a vertex v having the maximum degree in G
3 **call** EnumMatching $(G \setminus \{v\}, M)$
4 **for** each edge $e = (v, u)$, **call** EnumMatching $(G \setminus \{u, v\}, M \cup \{e\})$

$G \setminus \{u, v\}$ is obtained from $G \setminus \{u', v\}$ in $O(d(u) + d(u'))$ time, where $d(u)$ and $d(u')$ are the degrees of u and u', respectively. From this, the computation time in step 4 is bounded by the sum of degrees of all vertices adjacent to v. Here $T(X) = c|E|$ for some c, except for the output process. Note that $|E|$ is the number of edges in the graph given to X.

The input graph of the child generated in step 3 has $|E| - d(v)$ edges and that in step 4 has $|E| - d(v) - d(u) + 1$ edges. Thus, when $d(v) < |E|/4$, we have $\overline{T}(X) = c((|E| - d(v)) + (|E| - d(v) - d(u) + 1)) \geq 1.25c|E|$. When $d(v) \geq |E|/4$, $|C(X)| \geq |E|/4$. Thus, PO condition holds by setting $\alpha = 1.25$ and choosing a certain β. The output process can be shorten as the subset enumeration.

Theorem 2 *Matchings of a graph can be enumerated in $O(1)$ time for each matching.*

Elimination Ordering

An *elimination ordering* is a sequence of elements obtained by iteratively removing an element from an object G with keeping a property satisfied, until the object will be empty. Examples are perfect elimination ordering and perfect sequence. The former is the removal sequence of simplicial vertices from a chordal graph, and the latter is the removal sequence of cliques from a connected chordal graph. Elimination orderings can be enumerated by a simple algorithm as follows.

Algorithm EnumElim (G, S)**:**

1 **if** $G = \emptyset$ **then output** S; **return**
2 **for** each element e of G that can be removed, **call** EnumElim $(G \setminus \{e\}, S \cup \{e\})$

Here we assume that $T(X) = \text{poly}(|G|)$ except for output process. The decision problem of removing an element from G is naturally considered to be solved in $O(\text{poly}(|G|))$ time; thus this assumption is natural.

Theorem 3 *If any G of size larger than some constant c has at least two removable elements, elimination orderings are enumerated in $O(1)$ time for each.*

Proof The statement means that each iteration has at least two children, if its computation time is not constant. For sufficiently large constant δ, we always have $\text{poly}(|G|) \leq 2\text{poly}(|G| - 1)$ for any $|G| > \delta$. This implies that PO condition always holds for these iterations. □

AMS Sketch

Graham Cormode
Department of Computer Science, University of Warwick, Coventry, UK

Keywords

Euclidean norm; Second-moment estimation; Sketch; Streaming algorithms

Years and Authors of Summarized Original Work

1996; Alon, Matias, Szegedy

Problem Definition

Streaming algorithms aim to summarize a large volume of data into a compact summary, by maintaining a data structure that can be incrementally modified as updates are observed. They allow the approximation of particular quantities. The AMS sketch is focused on approximating the sum of squared entries of a vector defined by a stream of updates. This quantity is naturally related to the Euclidean norm of the vector and so has many applications in high-dimensional geometry and in data mining and machine learning settings that use vector representations of data.

The data structure maintains a linear projection of the stream (modeled as a vector) with a number of randomly chosen vectors. These random vectors are defined implicitly by simple hash functions, and so do not have to be stored explicitly. Varying the size of the sketch changes the accuracy guarantees on the resulting estimation. The fact that the summary is a linear projection means that it can be updated flexibly, and sketches can be combined by addition or subtraction, yielding sketches corresponding to the addition and subtraction of the underlying vectors.

Key Results

The AMS sketch was first proposed by Alon, Matias, and Szegedy in 1996 [1]. Several refinements or variants have subsequently appeared in the literature, for example, in the work of Thorup and Zhang [4]. The version presented here works by using hashing to map each update to one of t counters rather than taking the average of t repetitions of an "atomic" sketch, as was originally proposed. This hash-based variation is often referred to as the "fast AMS" summary.

Data Structure Description

The AMS summary maintains an array of counts which are updated with each arriving item. It gives an estimate of the ℓ_2-norm of the vector v that is induced by the sequence of updates. The estimate is formed by computing the norm of each row and taking the median of all rows. Given parameters ε and δ, the summary uses space $O(1/\varepsilon^2 \log 1/\delta)$ and guarantees with probability of at least $1 - \delta$ that its estimate is within relative ε-error of the true ℓ_2-norm, $\|v\|_2$.

Initially, v is taken to be the zero vector. A stream of updates modifies v by specifying an index i to which an update w is applied, setting $v_i \leftarrow v_i + w$. The update weights w can be positive or negative.

The AMS summary is represented as a compact array C of $d \times t$ counters, arranged as d rows of length t. In each row j, a hash function h_j maps the input domain U uniformly to $\{1, 2, \ldots t\}$. A second hash function g_j maps elements from U uniformly onto $\{-1, +1\}$. For the analysis to hold, we require that g_j is *four-wise* independent. That is, over the random choice of g_j from the set of all possible hash functions, the probability that any four distinct items from

the domain that get mapped to $\{-1, +1\}^4$ is uniform: each of the 16 possible outcomes is equally likely. This can be achieved by using polynomial hash functions of the form $g_j(x) = 2((ax^3 + bx^2 + cx + d \mod p) \mod 2) - 1$, with parameters a, b, c, d chosen uniformly from the prime field p.

The sketch is initialized by picking the hash functions to be used and initializing the array of counters to all zeros. For each update operation to index i with weight w (which can be either positive or negative), the item is mapped to an entry in each row based on the hash functions h and the update applied to the corresponding counter, multiplied by the corresponding value of g. That is, for each $1 \leq j \leq d$, $h_j(i)$ is computed, and the quantity $wg_j(i)$ is added to entry $C[j, h_j(i)]$ in the sketch array. Processing each update therefore takes time $O(d)$, since each hash function evaluation takes constant time.

The sketch allows an estimate of $\|v\|_2^2$, the squared Euclidean norm of v, to be obtained. This is found by taking the sums of the squares of the rows of the sketch and in turn finding the median of these sums. That is, for row j, it computes $\sum_{k=1}^{t} C[j,k]^2$ as an estimate and takes the median of these d estimates. The query time is linear in the size of the sketch, $O(td)$, as is the time to initialize a new sketch. Meanwhile, update operations take time $O(d)$.

The analysis of the algorithm follows by considering the produced estimate as a random variable. The random variable can be shown to be correct in expectation: its expectation is the desired quantity, $\|v\|_2^2$. This can be seen by expanding the expression of the estimator. The resulting expression has terms $\sum_i v_i^2$ but also terms of the form $v_i v_j$ for $i \neq j$. However, these "unwanted terms" are multiplied by either $+1$ or -1 with equal probability, depending on the choice of the hash function g. Therefore, their expectation is zero, leaving only $\|v\|_2$. To show that it is likely to fall close to its expectation, we also analyze the variance of the estimator and use Chebyshev's inequality to argue that with constant probability, each estimate is close to the desired value. Then, taking the median of sufficient repetitions amplifies this constant probability to be close to certainty.

This analysis shows that the estimate is between $(1 - \varepsilon)\|v\|_2^2$ and $(1 + \varepsilon)\|v\|_2^2$. Taking the square root of the estimate gives a result that is between $(1 - \varepsilon)^{1/2}\|v\|_2$ and $(1 + \varepsilon)^{1/2}\|v\|_2$, which means it is between $(1 - \varepsilon/2)\|v\|_2$ and $(1 + \varepsilon/2)\|v\|_2$.

Note that since the updates to the AMS sketch can be positive or negative, it can be used to measure the Euclidean distance between two vectors v and u: we can build an AMS sketch of v and one of $-u$ and merge them together by adding the sketches. Note also that a sketch of $-u$ can be obtained from a sketch of u by negating all the counter values.

Applications

The sketch can also be applied to estimate the inner product between a pair of vectors. A similar analysis shows that the inner product of corresponding rows of two sketches (formed with the same parameters and using the same hash functions) is an unbiased estimator for the inner product of the vectors. This use of the summary to estimate the inner product of vectors was described in a follow-up work by Alon, Matias, Gibbons, and Szegedy [2], and the analysis was similarly generalized to the fast version by Cormode and Garofalakis [3]. The ability to capture norms and inner products in Euclidean space means that these sketches have found many applications in settings where there are high-dimensional vectors, such as machine learning and data mining.

Analyzing Cache Behaviour in Multicore Architectures

Alejandro López-Ortiz[1] and Alejandro Salinger[2]
[1]David R. Cheriton School of Computer Science, University of Waterloo, Waterloo, ON, Canada
[2]Department of Computer Science, Saarland University, Saarbücken, Germany

Keywords

Cache; Chip multiprocessor; Multicore; Online algorithms; Paging

Years and Authors of Summarized Original Work

2010; Hassidim
2012; López-Ortiz, Salinger

Problem Definition

Multicore processors are commonly equipped with one or more levels of cache memory, some of which are shared among two or more cores. Multiple cores compete for the use of shared caches for fast access to their program's data, with the cache usage patterns of a program running on one core, possibly affecting the cache performance of programs running on other cores.

Paging

The management of data across the various levels of the memory hierarchy of modern computers is abstracted by the paging problem. Paging models a two-level memory system with a small and fast memory – known as cache – and a large and slow memory. Data is transferred between the two levels of memory in units known as pages. The input to the problem is a sequence of page requests that must be made available in cache as they are requested. If the currently requested page is already present in the cache, then this is known as a *hit*. Otherwise a *fault* occurs, and the requested page must be brought from slow memory to cache, possibly requiring the eviction of a page currently residing in the cache. An algorithm for this problem must decide, upon each request that results in a fault with a full cache, which page to evict in order to minimize the number of faults. Since the decision of which page to evict must be taken without information of future requests, paging is an online problem.

The most popular framework to analyze the performance of online algorithms is competitive analysis [10]: an algorithm A for a minimization problem is said to be c-competitive if its cost is at most c times that of an optimal algorithm that knows the input in advance. Formally, let $A(r)$ and $\mathrm{OPT}(r)$ denote the costs of A and the optimal algorithm OPT on an input r. Then A is c-competitive if for all inputs r, $A(r) \leq c \cdot \mathrm{OPT}(r) + \beta$, where β is a constant that does not depend on r. The infimum of all such values c is known as A's *competitive ratio*.

Traditional paging algorithms, like least recently used (LRU), evict the page currently

in cache that was least recently accessed, or first-in-first-out (FIFO), evict the page currently in the cache that was brought in the earliest, have an optimal competitive ratio equal to the cache size. Other optimal eviction policies are flush-when-full (FWF) and Clock (see [2] for definitions).

Paging in Multicore Caches

The paging problem described above can be extended to model several programs running simultaneously with a shared cache. For a multicore system with p cores sharing one cache, the multicore paging problem consists of a set r of p request sequences $r_1, \ldots r_p$ to be served with one shared cache of size k pages. At any timestep, at most p requests from different processors can arrive and must be served in parallel. A paging algorithm must decide which pages to evict when a fault occurs on a full cache.

The general model we consider for this problem was proposed by Hassidim [6]. This model defines the fetching time τ of a page as the ratio between a cache miss and a cache hit. A sequence of requests that suffers a page fault must wait τ timesteps for the page to be fetched into the cache, while other sequences that incur hits can continue to be served. In addition, paging algorithms can decide on the schedule of request sequences, choosing to serve a subset of the sequences and delay others. In this problem, the goal of a paging algorithm is to minimize the makespan. López-Ortiz and Salinger [8] proposed a slightly different model in which paging algorithms are not allowed to make scheduling decisions and must serve requests as they arrive. Furthermore, instead of minimizing the makespan, they propose two different goals: minimize the number of faults and decide if each of the sequences can be served with a number of faults below a given threshold. We consider both these settings here and the following problems:

Definition 1 (Min-Makespan) Given a set r of request sequences $r_1, \ldots, r_p$ to be served with a cache of size k, minimize the timestep at which the last request among all sequences is served.

Definition 2 (Min-Faults) Given a set r of requests $r_1, \ldots, r_p$ to be served with a cache of size k, minimize the total number of faults when serving r.

Definition 3 (Partial-Individual-Faults) Given a set r of requests $r_1, \ldots, r_p$ to be served with a cache of size k, a timestep t, and a bound b_i for each sequence, decide whether r can be served such that at time t the number of faults on r_i is at most b_i for all $1 \leq i \leq p$.

Key Results

Online Paging

For both the models of Hassidim and López-Ortiz and Salinger ,no online algorithm has been shown to be competitive, while traditional algorithms that are competitive in the classic paging setting are not competitive in the multicore setting. Hassidim shows that LRU and FIFO have a competitive ratio in the Min-Makespan problem of $\Theta(\tau)$, which is the worst possible for any online algorithm in this problem.

In the following, k is the size of the shared cache of an online algorithm, and h is the size of the shared cache of the optimal offline.

Theorem 1 ([6]) *For any $\alpha > 1$, the competitive ratio of LRU (or FIFO) is $\Theta(\tau/\alpha)$, when $h = k/\alpha$. In particular, if we give LRU a constant factor resource augmentation, the ratio is $\Theta(\tau)$. There is a setting with this ratio with just $\lceil \alpha \rceil + 1$ cores.*

The bad competitive ratio stems from the ability of the offline algorithm to schedule sequences one after the other one so that each sequence can use the entire cache. Meanwhile, LRU or FIFO will try to serve all sequences simultaneously, not having enough cache to satisfy the demands of any sequence. A similar result is shown in [8] for the Min-Faults problem, even in the case in which the optimal offline cannot explicitly schedule the input sequences. In this case, given a set of request sequences that alternate periods of high and low cache demand, the optimal offline algorithm can delay some sequences through faults in

order to align periods of high demands of some sequences with periods of low demands of others and with a total cache demand below capacity. As in the previous lower bound, traditional online algorithms will strive to serve all sequences simultaneously, incurring only faults in periods of high demand.

Theorem 2 ([8]) *Let A be any of LRU, FIFO, Clock, or FWF, let $p \geq 4$, let n be the total length of request sequences, and assume $\tau > 1$. The competitive ratio of A is at least $\Omega(\sqrt{n\tau/k})$ when the optimal offline's cache is $h \geq k/2 + 3p/2$. If A has no resource augmentation, the competitive ratio is at least $\Omega(\sqrt{n\tau p/k})$.*

These results give light about the characteristics required by online policies to achieve better competitive ratios. López-Ortiz and Salinger analyzed paging algorithms for Min-Faults , separating the cache partition and the eviction policy aspects. They defined partitioned strategies as those that give a portion of the cache to each core and serve the request sequences with a given eviction policy exclusively with the given part of the cache. The partition can be static or dynamic. They also define shared strategies as those in which all requests are served with one eviction policy using a global cache. The policies considered in Theorems 1 and 2 above are examples of shared strategies.

If a cache partition is determined externally by a scheduler or operating system, then traditional eviction policies can achieve a good performance when compared to the optimal eviction policy with the same partition. More formally,

Theorem 3 *Let A be any marking or conservative paging algorithm and B be any dynamically conservative algorithm [9] (these classes include LRU, FIFO, and Clock). Let S and D be any static and dynamic partition functions and let OPT_s and OPT_d denote the optimal eviction policies given S and D, respectively. Then, for all inputs r, $A(r) \leq k \cdot OPT_s(r)$ and $B(r) \leq pk \cdot OPT_d(r)$.*

The result above relies on a result by Peserico [9] which states that dynamically conservative policies are k-competitive when the size of the cache varies throughout the execution of the cache instance.

When considering a strategy as a partition plus eviction policy, it should not be a surprise that a strategy involving a static partition cannot be competitive. In fact, even a dynamic partition that does not change the sizes of the parts assigned to its cores often enough cannot be competitive. There are sequences for which the optimal static partition with the optimal paging policy in each part can incur a number of faults that is arbitrarily large compared to an online shared strategy using LRU. A similar result applies to dynamic partitions that change a sublinear number of times. These results suggest that in order to be competitive, an online strategy needs to be either shared or partitioned with a partition that changes often.

Offline Paging

We now consider the offline multicore paging problem. Hassidim shows that Min-Makespan is NP-hard for $k = p/3$ and [7] extends it to arbitrary k and p. In the model without scheduling of [8], Partial-Individual-Faults, a variant of the fault minimization problem, is also shown to be NP-hard. It is not known, however, whether Min-Faults is NP-hard as well. Interestingly, Partial-Individual-Faults remains NP-hard when $\tau = 1$ (and hence a fault does not delay the affected sequence with respect to other sequences). In contrast, in this case, Min-Faults can be solved simply by evicting the page that will be requested furthest in the future, as in classic paging. On the positive side, the following property holds for both Min-Makespan and Min-Faults (on disjoint sequences).

Theorem 4 *There exist optimal algorithms for Min-Makespan and Min-Faults that, upon a fault, evict the page that is the furthest in the future for some sequence.*

This result implies that multicore paging reduces to determining the optimal dynamic partition of the cache: upon a fault, the part of the cache of one sequence is reduced (unless this sequence is the same as the one which incurred the fault), and the page whose next request is

furthest is the future in this sequence should be evicted.

Finally, in the special case of a constant number of processors p and constant delay τ, Min-Makespan admits a polynomial time approximation scheme (PTAS), while Min-Faults and Partial-Individual-Faults admit exact polynomial time algorithms.

Theorem 5 ([6]) *There exists an algorithm that, given an instance of Min-Makespan with optimal makespan m, returns a solution with makespan $(1+\epsilon)m$. The running time is exponential on p, τ, and $1/\epsilon$.*

Theorem 6 ([8]) *An instance of Min-Faults with p requests of total length n, with $p = O(1)$ and $\tau = O(1)$ can be solved in time $O(n^{k+p}\tau^p)$.*

Theorem 7 ([8]) *An instance of Partial-Individual-Faults with p requests of total length n, with $p = O(1)$ and $\tau = O(1)$, can be solved in time $O(n^{k+2p+1}\tau^{p+1})$.*

Other Models

Paging with multiple sequences with a shared cache has also been studied in other models [1,3–5], even prior to multicores. In these models, request sequences may be interleaved; however, only one request is served at a time and all sequences must wait upon a fault affecting one sequence.

In the application-controlled model of Cao et al. [3], each process has full knowledge of its request sequence, while the offline algorithm also knows the interleaving of requests. As opposed to the models in [6, 8], the interleaving is fixed and does not depend on the decisions of algorithms. It has been shown that for p sequences and a cache of size k, no online deterministic algorithm can have a competitive ratio better than $p+1$ in the case where sequences are disjoint [1] and $\frac{p}{2}\log\left(\frac{4(k+1)}{3p}\right)$ otherwise [7]. On the other hand, there exist algorithms with competitive ratios $2(p+1)$ [1, 3] and $\max\{10, p+1\}$ [7] for the disjoint case, and $2p(\ln(ek/p)+1)$ [7] for the shared case.

Open Problems

Open problems in multicore paging are finding competitive online algorithms, determining the exact complexity of Min-Faults, obtaining approximation algorithms for Min-Makespan for a wider range of parameters, and obtaining faster exact offline algorithms for Min-Faults and Partial-Individual-Faults. Another challenge in multicore paging is concerned with modeling the right features of the multicore architecture while enabling the development of meaningful algorithms. Factors to consider are cache coherence, limited parallelism in other shared resources (such as bus bandwidth), different cache associativities, and others.

2003; Mehlhorn, Sanders

Problem Definition

The problem considered here is *multiple sequence access via cache memory*. Consider the following pattern of memory accesses. k sequences of data, which are stored in disjoint arrays and have a total length of N, are accessed as follows:

for $t := 1$ to N do
  select a sequence $s_i \in \{1, \ldots k\}$
  work on the current element of sequence s_i
  advance sequence s_i to the next element.

The aim is to obtain exact (not just asymptotic) closed form upper and lower bounds for this problem. Concurrent accesses to multiple sequences of data are ubiquitous in algorithms. Some examples of algorithms which use this paradigm are distribution sorting, k-way merging, priority queues, permuting, and FFT. This entry summarizes the analyses of this problem in [5, 8].

Caches, Models, and Cache Analysis

Modern computers have hierarchical memory which consists of registers, one or more levels of caches, main memory, and external memory devices such as disks and tapes. Memory size increases, but the speed decreases with distance from the CPU. Hierarchical memory is designed to improve the performance of algorithms by exploiting temporal and spatial locality in data accesses.

Caches are modeled as follows. A cache has m *blocks* each of which holds B data elements. The capacity of the cache is $M = mB$. Data is transferred between one level of cache and the next larger and slower memory in blocks of B elements. A cache is organized as $s = m/a$ *sets* where each set consists of a blocks. Memory at address xB, referred to as memory block x, can only be placed in a block in set $x \bmod s$. If $a = 1$, the cache is said to be *direct mapped*, and if $a = s$, it is said to be *fully associative*.

If memory block x is accessed and it is not in cache, then a *cache miss* occurs, and the data in memory block x is brought into cache, incurring a performance penalty. In order to accommodate block x, it is assumed that the least recently used (LRU) or the first used (FIFO) block from the cache set $x \bmod s$ is evicted, and this is referred to as the *replacement strategy*. Note that a block may be evicted from a set, even though there may be unoccupied blocks in other sets.

Cache analysis is performed for the number of cache misses for a problem with N data elements. To read or write N data elements, an algorithm must incur $\Omega(N/B)$ cache misses. These are the *compulsory* or *first reference misses*. In the multiple sequence access via cache memory problem, for given values of M and B, one aim is to find the largest k such that there are $O(N/B)$ cache misses for the N data accesses. It is interesting to analyze cache misses for the important case of direct mapped cache and for the general case of set-associative caches.

A large number of algorithms have been designed on the external memory model [11], and these algorithms optimize the number of data transfers between main memory and disk. It seems natural to exploit these algorithms

to minimize cache misses, but due to the limited associativity of caches, this is not straightforward. In the external memory model, data transfers are under programmer control, and the multiple sequence access problem has a trivial solution. The algorithm simply chooses $k \leq M_e/B_e$, where B_e is the block size and M_e is the capacity of the main memory in the external memory model. For $k \leq M_e/B_e$, there are $O(N/B_e)$ accesses to external memory. Since caches are hardware controlled, the problem becomes nontrivial. For example, consider the case where the starting addresses of $k > a$ equal length sequences map to the ith element of the same set, and the sequences are accessed in a round-robin fashion. On a cache with an LRU or FIFO replacement strategy, all sequence accesses will result in a cache miss. Such pathological cases can be overcome by randomizing the starting addresses of the sequences.

Related Problems

A very closely related problem is where accesses to the sequences are interleaved with accesses to a small working array. This occurs in applications such as distribution sorting or matrix multiplication.

Caches can emulate external memory with an optimal replacement policy [3, 10]; however, this requires some constant factor more memory. Since the emulation techniques are software controlled and require modification to the algorithm, rather than selection of parameters, they work well for fairly simple algorithms [6].

Key Results

Theorem 1 ([5]) *Given an a-way set-associative cache with m cache blocks, $s = m/a$ cache sets, cache blocks size B, and LRU or FIFO replacement strategy. Let U_a denote the expected number of cache misses in any schedule of N sequential accesses to k sequences with starting addresses that are at least $(a+1)$-wise independent:*

$$U_1 \leq k + \frac{N}{B}\left(1 + (B-1)\frac{k}{m}\right), \tag{1}$$

$$U_1 \geq \frac{N}{B}\left(1 + (B-1)\frac{k-1}{m+k-1}\right), \tag{2}$$

$$U_a \leq k + \frac{N}{B}\left(1 + (B-1)\left(\frac{k\alpha}{m}\right)^a + \frac{1}{m/(k\alpha)-1} + \frac{k-1}{s-1}\right) \tag{3}$$

$$\text{for } k \leq \frac{m}{\alpha},$$

$$U_a \leq k + \frac{N}{B}\left(1 + (B-1)\left(\frac{k\beta}{m}\right)^a + \frac{1}{m/(k\beta)-1}\right) \tag{4}$$

$$\text{for } k \leq \frac{m}{2\alpha},$$

$$U_a \geq \frac{N}{B}\left(1 + (B-1)P_{\text{tail}}\left(k-1, \frac{1}{s}, a\right)\right) - kM, \tag{5}$$

$$U_a \geq \frac{N}{B}\left(1 + (B-1)\left(\frac{(k-a)\alpha}{m}\right)^a \left(1 - \frac{1}{-}s\right)^k\right) - kM, \tag{6}$$

where $\alpha = \alpha(a) = a/(a!)^{1/a}$, $P_{\text{tail}}(n, p, a) = \sum_{i \geq a} \binom{n}{i} p^i (1-p)^{n-i}$ *is the cumulative binomial probability, and* $\beta := 1 + \alpha(\lceil ax \rceil)$ *where* $x = x(a) = \inf\{0 < z < 1 : z + z/\alpha(\lceil az \rceil) = 1\}$.

Here $1 \leq \alpha < e$ and $\beta(1) = 2$, $\beta(\infty) = 1 + e \approx 3.71$. This analysis assumes that an adversary schedules the accesses to the sequences. For the lower bound, the adversary initially advances sequence s_i for $i = 1 \ldots k$ by X_i elements, where the X_i is chosen uniformly and independently from $\{0, M-1\}$. The adversary then accesses the sequences in a round-robin manner.

The k in the upper bound accounts for a possible extra block that may be accessed due to randomization of the starting addresses. The $-kM$ term in the lower bound accounts for the fact that cache misses cannot be counted when the adversary initially winds forwards the sequences.

The bounds are of the form $pN + c$, where c does not depend on N and p is called the *cache miss probability*. Letting $r = k/m$, the ratio between the number of sequences and the number of cache blocks, the bounds for the cache miss probabilities in Theorem 1 become [5]

$$p_1 \leq (1/B)(1 + (B-1)r), \tag{7}$$

$$p_1 \geq (1/B)\left(1 + (B-1)\frac{r}{1+r}\right), \tag{8}$$

$$p_a \leq (1/B)(1 + (B-1)(r\alpha)^a + r\alpha + ar) \quad \text{for } r \leq \frac{1}{\alpha}, \tag{9}$$

$$p_a \leq (1/B)(1 + B - 1)(r\beta)^a + r\beta \text{ for } r \leq \frac{1}{2\beta} \tag{10}$$

$$p_a(1/B)\left(1 + (B-1)(r\alpha)^a\left(1 - \frac{1}{s}\right)^k\right). \tag{11}$$

The $1/B$ term accounts for the compulsory or first reference miss, which must be incurred in order to read a block of data from a sequence. The remaining terms account for *conflict misses*, which occur when a block of data is evicted from cache before all its elements have been scanned. Conflict misses can be reduced by restricting the number of sequences. As r approaches zero, the cache miss probabilities approach $1/B$. In general, inequality (4) states that the number of cache misses is $O(N/B)$ if $r \leq 1/(2\beta)$ and $(B-1)(r\beta)^a = O(1)$. Both of these conditions are satisfied if $k \leq m/\max(B^{1/a}, 2\beta)$. So, there are $O(N/B)$ cache misses provided $k = O(m/B^{1/a})$.

The analysis shows that for a direct-mapped cache, where $a = 1$, the upper bound is a factor of $r + 1$ above the lower bound. For $a \geq 2$, the upper bounds and lower bounds are close if $(1 - 1/s)^k \approx$ and $(\alpha + \alpha)r \ll 1$, and both these conditions are satisfied if $k \ll s$.

Rahman and Raman [8] obtain closer upper and lower bounds for average case cache misses assuming the sequences are accessed uniformly randomly on a direct-mapped cache. Sen and Chatterjee [10] also obtain upper and lower bounds assuming the sequences are randomly accessed. Ladner, Fix, and LaMarca have analyzed the problem on direct-mapped caches on the independent reference model [4].

Multiple Sequence Access with Additional Working Set

As stated earlier in many applications, accesses to sequences are interleaved with accesses to an additional data structure, a *working set*, which determines how a sequence element is to be treated. Assuming that the working set has size at most sB and is stored in contiguous memory locations, the following is an upper bound on the number of cache misses:

Theorem 2 ([5]) *Let* U_a *denote the bound on the number of cache misses in Theorem 1 and define* $U_0 = N$. *With the working set occupying* w *conflict-free memory blocks, the expected number of cache misses arising in the* N *accesses to the sequence data, and any number of accesses to the working set, is bounded by* $w + (1 - w/s)U_a + 2(w/s)U_{a-1}$.

On a direct-mapped cache, for $i = 1, \ldots, k$, if sequence i is accessed with probability p_i independently of all previous accesses and is followed by an access to element i of the working set, then the following are upper and lower bounds for the number of cache misses:

Theorem 3 ([8]) *In a direct-mapped cache with m cache blocks, each of B elements, if sequence i, for $i = , \ldots, k$, is accessed with probability p_i and block j of the working set, for $j = , \ldots, k/B$, is accessed with probability P_j, then the expected number of cache misses in N sequence accesses is at most $N(p_s + p_w) + k(1 + 1/B)$, where*

$$p_s \leq \frac{1}{B} + \frac{k}{mB} + \frac{B-1}{mB} \sum_{i=1}^{k} \left(\sum_{j=1}^{k/B} \frac{p_i P_j}{p_i + P_j} + \frac{B-1}{B} \sum_{j=1}^{k} \frac{p_i p_j}{p_i + p_j} \right),$$

$$p_w \leq \frac{k}{B^2 m} + \frac{B-1}{mB} \sum_{i=1}^{k/B} \sum_{j=1}^{k} \frac{P_i p_j}{P_i p_j}.$$

Theorem 4 ([8]) *In a direct-mapped cache with m cache blocks each of B elements, if sequence i, for $i = 1, \ldots, k$, is accessed with probability $p_i \geq 1/m$, then the expected number of cache misses in N sequence accesses is at least $Np_s + k$, where*

$$p_s \geq \frac{1}{B} + \frac{k(2m-k)}{2m^2} + \frac{k(k-3m)}{2Bm^2} - \frac{1}{2Bm} - \frac{k}{2B^2 m} + \frac{B(k-m) + 2m - 3k}{Bm^2} \sum_{i=1}^{k} \sum_{j=1}^{k} \frac{(p_i)^2}{p_i + p_j}$$
$$+ \frac{(B-1)^2}{B^3 m^2} \sum_{i=1}^{k} p_i \left[\sum_{j=1}^{k} \frac{p_i(1 - p_i - p_j)}{(p_i + p_j)^2} - \frac{B-1}{2} \sum_{j=1}^{k} \sum_{l=1}^{k} \frac{p_i}{p_i + p_j + p_l - p_j p_l} \right] - O(e^{-B}).$$

The lower bound ignores the interaction with the working set, since this can only increase the number of cache misses.

In Theorems 3 and 4, p_s is the probability of a cache miss for a sequence access, and in Theorem 3, p_w is the probability of a cache miss for an accesses to the working set.

If the sequences are accessed uniformly randomly, then using Theorems 3 and 4, the ratio between the upper and lower bound is $3/(3 - r)$, where $r = k/m$. So for uniformly random data, the lower bound is within a factor of about $3/2$ of the upper bound when $k \leq m$ and is much closer when $k \ll m$.

Applications

Numerous algorithms have been developed on the external memory model which access multiple sequences of data, such as merge sort, distribution sort, priority queues, and radix sorting. These analyses are important as they allow initial parameter choices to be made for cache memory algorithms.

Open Problems

The analyses assume that the starting addresses of the sequences are randomized, and current approaches to allocating random starting addresses waste a lot of virtual address space [5]. An open problem is to find a good online scheme to randomize the starting addresses of arbitrary length sequences.

Experimental Results

The cache model is a powerful abstraction of real caches; however, modern computer architectures have complex internal memory hierarchies, with

registers, multiple levels of caches, and *translation lookaside buffers* (TLB). Cache miss penalties are not of the same magnitude as the cost of disk accesses, so an algorithm may perform better by allowing conflict misses to increase in order to reduce computation costs and compulsory misses, by reducing the number of passes over the data. This means that in practice, cache analysis is used to choose an initial value of k which is then fine-tuned for the platform and algorithm [1,2,6,7,9,12,13].

For distribution sorting, in [6], a heuristic was considered for selecting k, and equations for approximate cache misses were obtained. These equations were shown to be very accurate in practice.

Problem Definition

Given a geometric graph in d-dimensional space, it is useful to preprocess it so that distance queries, exact or approximate, can be answered efficiently. Algorithms that can report distance queries in constant time are also referred to as "distance oracles." With unlimited preprocessing time and space, it is clear that exact distance oracles can be easily designed. This entry sheds light on the design of approximate distance oracles with limited preprocessing time and space for the family of geometric graphs with constant dilation.

Notation and Definitions

If p and q are points in $\mathcal{R}^d$, then the notation $|pq|$ is used to denote the Euclidean distance between p and q; the notation $\delta_G(p,q)$ is used to denote the Euclidean length of a shortest path between p and q in a geometric network G. Given a constant $t > 1$, a graph G with vertex set S is a t-spanner for S if $\delta_G(p,q) \leq t|pq|$ for any two points p and q of S. A t-spanner network is said to have *dilation* (or *stretch factor*) t. A $(1+\varepsilon)$-approximate shortest path between p and q is defined to be any path in G between p and q having length Δ, where $\delta_G(p,q) \leq \Delta \leq (1+\varepsilon)\delta_G(p,q)$. For a comprehensive overview of geometric spanners, see the book by Narasimhan and Smid [14].

All networks considered in this entry are simple and undirected. The model of computation used is the traditional algebraic computation tree model with the added power of indirect addressing. In particular, the algorithms presented here do not use the non-algebraic floor function as a unit-time operation. The problem is formalized below.

Problem 1 (Distance Oracle) Given an arbitrary real constant $\epsilon > 0$, and a geometric graph G in d-dimensional Euclidean space with constant dilation t, design a data structure that answers $(1+\epsilon)$-approximate shortest path length queries in constant time.

The data structure can also be applied to solve several other problems. These include (a) the problem of reporting approximate distance queries between vertices in a planar polygonal domain with "rounded" obstacles, (b) query versions of *closest pair* problems, and (c) the efficient computation of the approximate dilations of geometric graphs.

Survey of Related Research

The design of efficient data structures for answering distance queries for general (non-geometric) networks was considered by Thorup and Zwick [17] (unweighted general graphs), Baswanna and Sen [3] (weighted general graphs, i.e., arbitrary metrics), and Arikati et al. [2] and Thorup [16] (weighted planar graphs).

For the geometric case, variants of the problem have been considered in a number of papers (for a recent paper, see, e.g., Chen et al. [5]). Work on the approximate version of these variants can also be found in many articles (for a recent paper, see, e.g., Agarwal et al. [1]). The focus of this entry is the results reported in the work of Gudmundsson et al. [10–13]. Similar results on distance oracles were proved subsequently for *unit disk graphs* [7]. Practical implementations of distance oracles in geometric networks have also been investigated [15].

Key Results

The main result of this entry is the existence of approximate distance oracle data structures for geometric networks with constant dilation (see Theorem 4 below). As preprocessing, the network is "pruned" so that it only has a linear number of edges. The data structure consists of

a series of "cluster graphs" of increasing coarseness, each of which helps answer approximate queries for pairs of points with interpoint distances of different scales. In order to pinpoint the appropriate cluster graph to search in for a given query, the data structure uses the bucketing tool described below. The idea of using cluster graphs to speed up geometric algorithms was first introduced by Das and Narasimhan [6] and later used by Gudmundsson et al. [9] to design an efficient algorithm to compute $(1+\varepsilon)$-spanners. Similar ideas were explored by Gao et al. [8] for applications to the design of mobile networks.

Pruning

If the input geometric network has a superlinear number of edges, then the preprocessing step for the distance oracle data structure involves efficiently "pruning" the network so that it has only a linear number of edges. The pruning may result in a small increase of the dilation of the spanner. The following theorem was proved by Gudmundsson et al. [12].

Theorem 1 *Let $t > 1$ and $\varepsilon' > 0$ be real constants. Let S be a set of n points in $\mathcal{R}^d$, and let $G = (S, E)$ be a t-spanner for S with m edges. There exists an algorithm to compute in $O(m + n \log n)$ time, a $(1+\varepsilon')$-spanner of G having $O(n)$ edges and whose weight is $O(wt(MST(S)))$.*

The pruning step requires the following technical theorem proved by Gudmundsson et al. [12].

Theorem 2 *Let S be a set of n points in $\mathcal{R}^d$, and let $c \geq 7$ be an integer constant. In $O(n \log n)$ time, it is possible to compute a data structure $D(S)$ consisting of:*

1. *A sequence $L_1, L_2, \ldots, L_\ell$ of real numbers, where $\ell = O(n)$, and*
2. *A sequence $S_1, S_2, \ldots, S_\ell$ of subsets of S such that $\sum_{i=1}^{\ell} |S_i| = O(n)$,*

such that the following holds. For any two distinct points p and q of S, it is possible to compute in $O(1)$ time an index i with $1 \leq i \leq \ell$ and two points x and y in S_i such that (a) $L_i/n^{c+1} \leq |xy| < L_i$ and (b) both $|px|$ and $|qy|$ are less than $|xy|/n^{c-2}$.

Despite its technical nature, the above theorem is of fundamental importance to this work. In particular, it helps to deal with networks where the interpoint distances are not confined to a polynomial range, i.e., there are pairs of points that are very close to each other and very far from each other.

Bucketing

Since the model of computation assumed here does not allow the use of floor functions, an important component of the algorithm is a "bucketing tool" that allows (after appropriate preprocessing) constant-time computation of a quantity referred to as BINDEX, which is defined to be the floor of the logarithm of the interpoint distance between any pair of input points.

Theorem 3 *Let S be a set of n points in $\mathcal{R}^d$ that are contained in the hypercube $(0, n^k)^d$, for some positive integer constant k, and let ε be a positive real constant. The set S can be preprocessed in $O(n \log n)$ time into a data structure of size $O(n)$, such that for any two points p and q of S, with $|pq| \geq 1$, it is possible to compute in constant time the quantity $\text{BINDEX}_\varepsilon(p, q) = \lfloor \log_{1+\varepsilon} |pq| \rfloor$.*

The constant-time computation mentioned in Theorem 3 is achieved by reducing the problem to one of answering least common ancestor queries for pairs of nodes in a tree, a problem for which constant-time solutions were devised most recently by Bender and Farach-Colton [4].

Main Results

Using the bucketing and the pruning tools, and using the algorithms described by Gudmundsson et al. [13], the following theorem can be proved.

Theorem 4 *Let $t > 1$ and $\varepsilon > 0$ be real constants. Let S be a set of n points in $\mathcal{R}^d$, and let $G = (S, E)$ be a t-spanner for S with m edges. The graph G can be preprocessed into a data structure of size $O(n \log n)$ in time $O(mn \log n)$,*

such that for any pair of query points $p, q \in S$, it is possible to compute a $(1+\varepsilon)$-approximation of the shortest path distance in G between p and q in $O(1)$ time. Note that all the big-Oh notations hide constants that depend on d, t, and ε.

Additionally, if the traditional algebraic model of computation (without indirect addressing) is assumed, the following weaker result can be proved.

Theorem 5 *Let S be a set of n points in $\mathcal{R}^d$, and let $G = (S, E)$ be a t-spanner for S, for some real constant $t > 1$, having m edges. Assuming the algebraic model of computation, in $O(m \log\log n + n \log^2 n)$ time, it is possible to preprocess G into a data structure of size $O(n \log n)$, such that for any two points p and q in S, a $(1+\varepsilon)$-approximation of the shortest-path distance in G between p and q can be computed in $O(\log\log n)$ time.*

Applications

As mentioned earlier, the data structure described above can be applied to several other problems. The first application deals with reporting distance queries for a planar domain with polygonal obstacles. The domain is further constrained to be t-rounded, which means that the length of the shortest obstacle-avoiding path between any two points in the input point set is at most t times the Euclidean distance between them. In other words, the visibility graph is required to be a t-spanner for the input point set.

Theorem 6 *Let $\mathcal{F}$ be a t-rounded collection of polygonal obstacles in the plane of total complexity n, where t is a positive constant. One can preprocess $\mathcal{F}$ in $O(n \log n)$ time into a data structure of size $O(n \log n)$ that can answer obstacle-avoiding $(1+\varepsilon)$-approximate shortest path length queries in time $O(\log n)$. If the query points are vertices of $\mathcal{F}$, then the queries can be answered in $O(1)$ time.*

The next application of the distance oracle data structure includes query versions of *closest pair* problems, where the queries are confined to specified subset(s) of the input set.

Theorem 7 *Let $G = (S, E)$ be a geometric graph on n points and m edges, such that G is a t-spanner for S, for some constant $t > 1$. One can preprocess G in time $O(m + n \log n)$ into a data structure of size $O(n \log n)$ such that given a query subset S' of S, a $(1+\varepsilon)$-approximate closest pair in S' (where distances are measured in G) can be computed in time $O(|S'| \log |S'|)$.*

Theorem 8 *Let $G = (S, E)$ be a geometric graph on n points and m edges, such that G is a t-spanner for S, for some constant $t > 1$. One can preprocess G in time $O(m + n \log n)$ into a data structure of size $O(n \log n)$ such that given two disjoint query subsets X and Y of S, a $(1+\varepsilon)$-approximate bichromatic closest pair (where distances are measured in G) can be computed in time $O((|X| + |Y|) \log(|X| + |Y|))$.*

The last application of the distance oracle data structure includes the efficient computation of the approximate dilations of geometric graphs.

Theorem 9 *Given a geometric graph on n vertices with m edges, and given a constant C that is an upper bound on the dilation t of G, it is possible to compute a $(1+\varepsilon)$-approximation to t in time $O(m + n \log n)$.*

Open Problems

Two open problems remain unanswered:

1. Improve the space utilization of the distance oracle data structure from $O(n \log n)$ to $O(n)$.
2. Extend the approximate distance oracle data structure to report not only the approximate distance but also the approximate shortest path between the given query points.

Problem Definition

The Problem and the Model

A static data structure problem consists of a set of data D, a set of queries Q, a set of answers A, and a function $f : D \times Q \to A$. The goal is to store the data succinctly, so that any query can be answered with only a few probes to the data structure. *Static membership* is a well-studied problem in data structure design [2, 6, 9, 10, 16, 17, 23].

Definition 1 (Static Membership) In the static membership problem, one is given a subset S of at most n keys from a universe $U = \{1, 2, \ldots, m\}$. The task is to store S so that queries of the form "Is u in S?" can be answered by making few accesses to the memory.

A natural and general model for studying any data structure problem is the *cell probe model* proposed by Yao [23].

Definition 2 (Cell Probe Model) An (s, w, t) cell probe scheme for a static data structure problem $f : D \times Q \to A$ has two components: a storage scheme and a query scheme. The storage scheme stores the data $d \in D$ as a Table $T[d]$ of s cells, each cell of word size w bits. The storage scheme is deterministic. Given a query $q \in Q$, the query scheme computes $f(d, q)$ by making at most t probes to $T[d]$, where each probe reads one cell at a time, and the probes can be adaptive. In a deterministic cell probe scheme, the query scheme is deterministic. In a randomized cell probe scheme, the query scheme is randomized and is allowed to err with a small probability.

Buhrman et al. [3] study the complexity of the static membership problem in the *bitprobe* model. The bitprobe model is a variant of the cell probe model in which each cell holds just a single bit. In other words, the word size w is 1. Thus, in this model, the query algorithm is given bitwise access to the data structure. The study of the membership problem in the bitprobe model was initiated by Minsky and Papert in their book *Perceptrons* [16]. However, they were interested in *average*-case upper bounds for this problem, while this work studies *worst*-case bounds for the membership problem.

Observe that if a scheme is required to store sets of size at most n, then it must use at least $\lceil \log \sum_{i \le n} \binom{m}{i} \rceil$ number of bits. If $n \le m^{1-\Omega(1)}$, this implies that the scheme must store $\Omega(n \log m)$ bits (and therefore use $\Omega(n)$ cells). The goal in [3] is to obtain a scheme that answers queries, uses only constant number of bitprobes, and at the same time uses a table of $O(n \log m)$ bits.

Related Work

The static membership problem has been well studied in the cell probe model, where each cell is capable of holding one element of the universe. That is, $w = O(\log m)$. In a seminal paper, Fredman, Komlós, and Szemerédi [10] proposed a scheme for the static membership problem in the cell probe model with word size $O(\log m)$ that used a constant number of probes and a table of size $O(n)$. This scheme will be referred to as the FKS scheme. Thus, up to constant factors, the FKS scheme uses optimal space and number of cell probes. In fact, Fiat et al. [9], Brodnik and Munro [2], and Pagh [17] obtain schemes that use space (in bits) that is within a small additive term of $\lceil \log \sum_{i \le n} \binom{m}{i} \rceil$ and yet answer queries by reading at most a constant number of cells. Despite all these fundamental results for the membership problem in the cell probe model, very little was known about the bitprobe complexity of static membership prior to the work in [3].

Key Results

Buhrman et al. investigate the complexity of the static membership problem in the bitprobe model. They study

- Two-sided error randomized schemes that are allowed to err on positive instances as well as negative instances (i.e., these schemes can say "No" with a small probability when the query element u is in the set S and "Yes" when it is not).
- One-sided error randomized schemes where the errors are restricted to negative instances alone (i.e., these schemes never say "No" when the query element u is in the set S);
- Deterministic schemes in which no errors are allowed.

The main techniques used in [3] are based on 2-colorings of special set systems that are related to r-cover-free family of sets considered in [5, 7, 11]. The reader is referred to [3] for further details.

Randomized Schemes with Two-Sided Error

The main result in [3] shows that there are randomized schemes that use *just one bitprobe* and

yet use space close to the information theoretic lower bound of $\Omega(n \log m)$ bits.

Theorem 1 *For any $0 < \epsilon \leq \frac{1}{4}$, there is a scheme for storing subsets S of size at most n of a universe of size m using $O\left(\frac{n}{\epsilon^2} \log m\right)$ bits so that any membership query "Is $u \in S$?" can be answered with error probability at most ϵ by a randomized algorithm which probes the memory at just one location determined by its coin tosses and the query element u.*

Note that randomization is allowed only in the query algorithm. It is still the case that for each set S, there is exactly one associated data structure $T(S)$. It can be shown that deterministic schemes that answer queries using a single bitprobe need m bits of storage (see the remarks following Theorem 4). Theorem 1 shows that, by allowing randomization, this bound (for constant ϵ) can be reduced to $O(n \log m)$ bits. This space is within a constant factor of the information theoretic bound for n sufficiently small. Yet, the randomized scheme answers queries using a single bitprobe.

Unfortunately, the construction above does not permit us to have sub-constant error probability and still use optimal space. Is it possible to improve the result of Theorem 1 further and design such a scheme? Buhrman et al. [3] shows that this is not possible: if ϵ is made sub-constant, then the scheme must use more than $n \log m$ space.

Theorem 2 *Suppose $\frac{n}{m^{1/3}} \leq \epsilon \leq \frac{1}{4}$. Then, any two-sided ϵ-error randomized scheme which answers queries using one bitprobe must use space $\Omega\left(\frac{n}{\epsilon \log(1/\epsilon)} \log m\right)$.*

Randomized Schemes with One-Sided Error

Is it possible to have any savings in space if the query scheme is expected to make only one-sided errors? The following result shows it is possible if the error is allowed only on negative instances.

Theorem 3 *For any $0 < \epsilon \leq \frac{1}{4}$, there is a scheme for storing subsets S of size at most n of a universe of size m using $O\left(\left(\frac{n}{\epsilon}\right)^2 \log m\right)$ bits so that any membership query "Is $u \in S$?" can be answered with error probability at most ϵ by a randomized algorithm which makes a single bitprobe to the data structure. Furthermore, if $u \in S$, the probability of error is 0.*

Though this scheme does not operate with optimal space, it still uses significantly less space than a bitvector. However, the dependence on n is quadratic, unlike in the two-sided scheme where it was linear. Buhrman et al. [3] shows that this scheme is essentially optimal: there is necessarily a quadratic dependence on $\frac{n}{\epsilon}$ for any scheme with one-sided error.

Theorem 4 *Suppose $\frac{n}{m^{1/3}} \leq \epsilon \leq \frac{1}{4}$. Consider the static membership problem for sets S of size at most n from a universe of size m. Then, any scheme with one-sided error ϵ that answers queries using at most one bitprobe must use $\Omega\left(\frac{n^2}{\epsilon^2 \log(n/\epsilon)} \log m\right)$ bits of storage.*

Remark 1 One could also consider one-probe one-sided error schemes that only make errors on positive instances. That is, no error is made for query elements *not* in the set S. In this case, [3] shows that randomness does not help at all: such a scheme must use m bits of storage.

The following result shows that the space requirement can be reduced further in one-sided error schemes if more probes are allowed.

Theorem 5 *Suppose $0 < \delta < 1$. There is a randomized scheme with one-sided error $n^{-\delta}$ that solves the static membership problem using $O\left(n^{1+\delta} \log m\right)$ bits of storage and $O\left(\frac{1}{\delta}\right)$ bitprobes.*

Deterministic Schemes

In contrast to randomized schemes, Buhrman et al. show that deterministic schemes exhibit a time-space tradeoff behavior.

Theorem 6 *Suppose a deterministic scheme stores subsets of size n from a universe of size m using s bits of storage and answers membership queries with t bitprobes to memory. Then, $\binom{m}{n} \leq \max_{i \leq nt} \binom{2s}{i}$.*

This tradeoff result has an interesting consequence. Recall that the FKS hashing scheme is

a data structure for storing sets of size at most n from a universe of size m using $O(n \log m)$ bits, so that membership queries can be answered using $O(\log m)$ bitprobes. As a corollary of the tradeoff result, [3] show that the FKS scheme makes an optimal number of bitprobes, within a constant factor, for this amount of space.

Corollary 1 *Let $\epsilon > 0, c \geq 1$ be any constants. There is a constant $\delta > 0$ so that the following holds. Let $n \leq m^{1-\epsilon}$ and let a scheme for storing sets of size at most n of a universe of size m as data structures of at most $cn \log m$ bits be given. Then, any deterministic algorithm answering membership queries using this structure must make at least $\delta \log m$ bitprobes in the worst case.*

From Theorem 6, it also follows that any deterministic scheme that answers queries using t bitprobes must use space at least $\Omega\left(tm^{1/t}n^{1-1/t}\right)$ in the worst case. The final result shows the existence of schemes which almost match the lower bound.

Theorem 7 *1. There is a nonadaptive scheme that stores sets of size at most n from a universe of size m using $O\left(ntm^{\frac{2}{t+1}}\right)$ bits and answers queries using $2t+1$ bitprobes. This scheme is non-explicit.*

2. *There is an explicit adaptive scheme that stores sets of size at most n from a universe of size m using $O\left(m^{1/t}n \log m\right)$ bits and answers queries using $O(\log n + \log\log m) + t$ bitprobes.*

Power of Few Bitprobes

In this section, we highlight some of recent results for this problem subsequent to [3] and encourage the reader to read the corresponding references for more details. Most of these results focus on the power of deterministic schemes with a small number of bitprobes.

Let $S(m,n,t)$ denote the minimum number of bits of storage needed by a deterministic scheme that answers queries using t (adaptive) bitprobes. In [3], it was shown that $S(m,n,1) = m$ and $S(m,n,5) = o(m)$ for $n = o\left(m^{1/3}\right)$ (Theorem 7, Part 1). This leads us to a natural question: Is $S(m,n,t) = o(m)$ for $t = 2, 3$, and 4 and under what conditions on n?

Initial progress for the case $t = 2$ was made by [18] who considered the simplest case: $n = 2$. They showed that $S(m,2,2) = O\left(m^{2/3}\right)$. It was later shown in [19] that $S(m,2,2) = \Omega\left(m^{4/7}\right)$. The upper bound result of [18] was improved upon by the authors of [1] who showed that $S(m,n,2) = o(m)$ if $n = o(\log m)$. Interestingly, a matching lower bound was shown recently in [12]: $S(m,n,2) = o(m)$ only if $n = o(\log m)$.

Strong upper bounds were obtained by [1] for the case $t = 3$ and $t = 4$. They showed that $S(m,n,3) = o(m)$ whenever $n = o(m)$. They also showed that $S(m,n,4) = o(m)$ for $n = o(m)$ even if the four bitprobes are nonadaptive. Recently, it was shown in [14] that $S(m,2,3) \leq 7m^{2/5}$. This work focuses on explicit schemes for $n = 2$ and $t \geq 3$.

Finally, we end with two remarks. Our problem for the case $n = \Theta(m)$ has been studied by Viola [22]. A recent result of Chen, Grigorescu, and de Wolf [4] studies our problem in the presence of adversarial noise.

Applications

The results in [3] have interesting connections to questions in coding theory and communication complexity. In the framework of coding theory, the results in [3] can be viewed as constructing locally decodable source codes, analogous to the locally decodable channel codes of [13]. Theorems 1–4 can also be viewed as giving tight bounds for the following communication complexity problem (as pointed out in [15]): Alice gets $u \in \{1,\ldots,m\}$, Bob gets $S \subseteq \{1,\ldots,m\}$ of size at most n, and Alice sends a single message to Bob after which Bob announces whether $u \in S$. See [3] for further details.

Approximate distance oracle; Graphs; Query time; Shortest paths

Years and Authors of Summarized Original Work

2013; Wulff-Nilsen

Problem Definition

This problem is concerned with obtaining a compact data structure capable of efficiently reporting approximate shortest path distance queries in a given undirected edge-weighted graph $G = (V, E)$. If the query time is independent (or nearly independent) of the size of G, we refer to the data structure as an *approximate distance oracle* for G. For vertices u and v in G, we denote by $d_G(u, v)$ the shortest path distance between u and v in G. For a given *stretch* parameter $\delta \geq 1$, we call the oracle *δ-approximate* if for all vertices u and v in G, $d_G(u, v) \leq \tilde{d}_G(u, v) \leq \delta d_G(u, v)$, where $\tilde{d}_G(u, v)$ is the output of the query for u and v. Hence, we allow estimates to be stretched by a factor up to δ but not shrunk.

Key Results

A major result in the area of distance oracles is due to Thorup and Zwick [4]. They gave, for every integer $k \geq 1$, a $(2k-1)$-approximate distance oracle of size $O\left(kn^{1+1/k}\right)$ and query time $O(k)$, where n is the number of vertices of the graph. This is constant query time when k is constant. Corresponding approximate shortest paths can be reported in time proportional to their length. Mendel and Naor [3] asked the question of whether query time can be improved to a universal constant (independent also of k) while keeping both size and stretch small. They obtained $O\left(n^{1+1/k}\right)$ size and $O(1)$ query time at the cost of a constant-factor increase in stretch to $128k$. Unlike the oracle of Thorup and Zwick, Mendel and Naor's oracle is not path reporting.

In [5], it is shown how to improve the query time of Thorup-Zwick to $O(\log k)$ without increasing space or stretch. This is done while keeping essentially the same data structure but applying binary instead of linear search in so-called bunch structures that were introduced by Thorup and Zwick [4]; the formal definition will be given below. Furthermore, it is shown in [5] how to improve the stretch of the oracle of Mendel and Naor to $(2+\epsilon)k$ for an arbitrarily small constant $\epsilon > 0$ while keeping query time constant (bounded by $1/\epsilon$). This improvement is obtained without an increase in space except for large values of k close to $\log n$ (only values of k less than $\log n$ are interesting since the Mendel-Naor oracle has optimal $O(n)$ space and $O(1)$ query time for larger values). Below, we sketch the main ideas in the improvement of Thorup-Zwick and of Mendel-Naor, respectively.

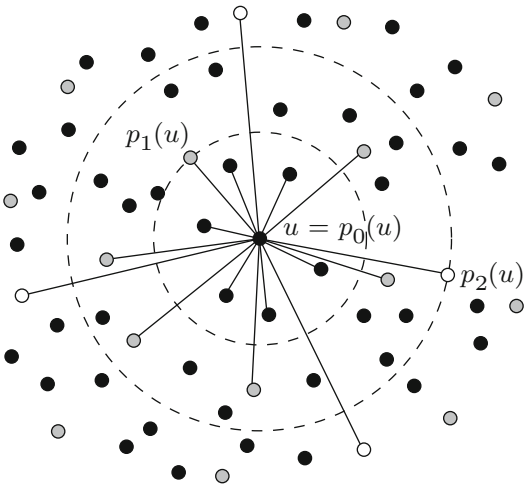
Oracle with $O(\log k)$ Query Time

The oracle of Thorup and Zwick keeps a hierarchy of sets of sampled vertices $V = A_0 \supseteq A_1 \supseteq A_2 \ldots \supseteq A_k = \emptyset$, where for $i = 1, \ldots, k-1$, A_i is obtained by picking each element of A_{i-1} independently with probability $n^{-1/k}$. Define $p_i(u)$ as the vertex in A_i closest to u. The oracle precomputes and stores for each vertex $u \in V$ the *bunch* B_u, defined as

$$B_u = \bigcup_{i=0}^{k-1} \{v \in A_i \setminus A_{i+1} | d_G(u,v) < d_G(u, p_{i+1}(u))\}.$$

See Fig. 1 for an illustration of a bunch. The distance $d_G(u,v)$ for each $v \in B_u$ is precomputed as well.

Now, to answer a query for a vertex pair (u,v), the oracle performs a linear search through bunches B_u and B_v. Pseudocode is given in Fig. 2. It is clear that query time is $O(k)$, and it can be shown that the estimate output in line 6 has stretch $2k-1$.



Approximate Distance Oracles with Improved Query Time, Fig. 1 A bunch B_u in a complete Euclidean graph with $k = 3$. *Black vertices* belong to A_0, *grey vertices* to A_1, and *white vertices* to A_2. Line segments connect u to vertices of B_u

```
Algorithm dist_k(u, v)
1. w ← p_0(u); j ←0
2. while w ∉ B_v
3.     j ← j + 1
4.     (u, v) ← (v, u)
5.     w ← p_j(u)
6. return d_G(w, u) + d_G(w, v)
```

Approximate Distance Oracles with Improved Query Time, Fig. 2 Answering a distance query, starting at sample level i

We can improve query time to $O(\log k)$ by instead doing binary search in the bunch structures. A crucial property of the Thorup-Zwick oracle is that every time the test in line 2 succeeds, $d_G(u, p_j(u))$ increases by at most $d_G(u, v)$, and this is sufficient to prove $2k - 1$ stretch. In particular, if the test succeeds two times in a row, $d_G(u, p_{j+2}(u)) - d_G(u, p_j(u)) \leq 2d_G(u, v)$, where j is even. If we can check that $d_G(u, p_{j'+2}(u)) - d_G(u, p_{j'}(u)) \leq 2d_G(u, v)$ for all smaller even indices j', we may start the query algorithm at index j instead of index 0. Since we would like to apply binary search, pick j to be (roughly) $k/2$. It suffices to check only one inequality, namely, the one with the largest value $d_G(u, p_{j'+2}(u)) - d_G(u, p_{j'}(u))$. Note that this value depends only on u and k, so we can precompute the index j' with this largest value. In the query phase, we can check in $O(1)$ time whether $d_G(u, p_{j'+2}(u)) - d_G(u, p_{j'}(u)) \leq 2d_G(u, v)$. If the test succeeds, we can start the query at j, and hence, we can recurse on indices between j and $k - 1$. Conversely, if the test fails, it means that the test in line 2 fails for either j' or $j' + 1$. Hence, the query algorithm of Thorup and Zwick terminates no later than at index $j' + 1$, and we can recurse on indices between 0 and $j' + 1$. In both cases, the number of remaining indices is reduced by a factor of at least 2. Since each recursive call takes $O(1)$ time, we thus achieve $O(\log k)$ query time.

Since the improved oracle is very similar to the Thorup-Zwick oracle, it is path reporting, i.e., it can report approximate paths in time proportional to their length.

Oracle with Constant Query Time

The second oracle in [5] can be viewed as a hybrid between the oracles of Thorup-Zwick and of Mendel-Naor. An initial estimate is obtained by querying the Mendel-Naor oracle. This estimate has stretch at most $128k$, and it is refined in subsequent iterations until the desired stretch $(2 + \epsilon)k$ is obtained. In each iteration, the current estimate is reduced by a small constant factor greater than 1 (depending on ϵ). Note that after a constant number of iterations, the estimate will be below the desired stretch, but it needs to be ensured that it is not below the shortest path distance.

In each iteration, the hybrid algorithm attempts to start the Thorup-Zwick query algorithm at a step corresponding to this estimate. If this can be achieved, only a constant number of steps of this query algorithm need to be executed before the desired stretch is obtained. Conversely, if the hybrid algorithm fails to access the Thorup-Zwick oracle in any iteration, then by a property of the bunch structures, it is shown that the current estimate is not below the shortest path distance. Hence, the desired stretch is again obtained.

An important property of the Mendel-Naor oracle needed above is that the set d_{MN} of all different values the oracle can output has size bounded by $O\left(n^{1+1/k}\right)$. This is used in the hybrid algorithm as follows. In a preprocessing step, values from d_{MN} are ordered in a list $\mathcal{L}$ together with additional values corresponding to the intermediate estimates that the hybrid algorithm can consider in an iteration. Updating the estimate in each iteration then corresponds to a linear traversal of part of $\mathcal{L}$. Next, each vertex p_i of each bunch structure B_u of the Thorup-Zwick oracle is associated with the value in the list closest to $d_G(u, p_i)$. For each element of $\mathcal{L}$, a hash table is kept for the bunch vertices associated with that element. It can be shown that this way of linking the oracle of Thorup-Zwick and Mendel-Naor achieves the desired.

Applications

The practical need for efficient algorithms to answer the shortest path (distance) queries in graphs has increased significantly over the years, in large part due to emerging GPS navigation technology and other route planning software. Classical algorithms like Dijkstra do not scale well as they may need to explore the entire graph just to answer a single query. As road maps are typically of considerable size, obtaining compact distance oracles has received a great deal of attention from the research community.

Open Problems

A widely believed girth conjecture of Erdős [2] implies that an oracle with stretch $2k-1$, size $O\left(n^{1+1/k}\right)$, and query time $O(1)$ would be optimal. Obtaining such an oracle (preferably one that is path reporting) is a main open problem in the area. Some progress has recently been made: Chechik [1] gives an oracle (not path reporting) with stretch $2k-1$, size $O\left(kn^{1+1/k}\right)$, and $O(1)$ query time.

Approximate Matching

Ran Duan
Institute for Interdisciplinary Information Sciences, Tsinghua University, Beijing, China

Keywords

Approximation algorithms; Maximum matching

Years and Authors of Summarized Original Work

1973; Hopcroft, Karp
1980; Micali, Vazirani
2014; Duan, Pettie

Problem Definition

In graph theory, a *matching* in a graph is a set of edges without common vertices, while a *perfect matching* is one in which all vertices are associated with matching edges. In a graph $G = (V, E, w)$, where V is the set of vertices, E is the set of edges, and $w : E \to \mathbb{R}$ is the edge weight function, the *maximum matching* problem determines the matching M in G which maximizes $w(M) = \sum_{e \in M} w(e)$. Note that a maximum matching is not necessarily perfect. The *maximum cardinality matching (MCM)* problem means the maximum matching problem for $w(e) = 1$ for all edges. Otherwise, it is called the *maximum weight matching (MWM)*.

Algorithms for Exact MWM

Although the maximum matching problem has been studied for decades, the computational complexity of finding an optimal matching remains quite open. Most algorithms for graph matchings use the concept of augmenting paths. An alternating path (or cycle) is one whose edges alternate between M and $E \backslash M$. An alternating path P is *augmenting* if P begins and ends at free vertices, that is, $M \oplus P \stackrel{\text{def}}{=} (M \backslash P) \cup (P \backslash M)$ is a matching with cardinality $|M \oplus P| = |M| + 1$. Therefore, the basic algorithm finds the maximum cardinality matching by finding an augmenting path in the graph and adding it the matching each time, until no more augmenting paths exist. The running time for the basic algorithm will be $O(mn)$ where $m = |E|$ and $n = |V|$. The major improvement over this for bipartite graphs is the Hopcroft-Karp algorithm [10]. It finds a maximal set of vertex disjoint shortest augmenting paths in each step and shows that the length of shortest augmenting paths will increase each time. The running time of the Hopcroft-Karp algorithm is $O(m\sqrt{n})$. Its corresponding algorithm for general graphs is given by Micali and Vazirani [14].

For the maximum weight matching (MWM) and maximum weight perfect matching (MWPM), the most classical algorithm is the Hungarian algorithm [12] for bipartite graphs and the Edmonds algorithm for general graphs [6, 7].

For fast implementations, Gabow and Tarjan [8] gave bit-scaling algorithms for MWM in bipartite graphs running in $O(m\sqrt{n}\log(nN))$ time, where the edge weights are integers in $[-N,\ldots,N]$. Then, they also gave its corresponding algorithm for general graphs [9]. Extending [15], Sankowski [18] gave an $O(Nn^{\omega})$ MWM algorithm for bipartite graphs (here, $\omega \leq 2.373$ denotes the exponential of the complexity of fast matrix multiplication (FMM) [2, 20]), while Huang and Kavitha [11] obtained a similar time bound for general graphs. We can see these time complexities are still far from linear, which shows the importance of fast approximation algorithms.

Approximate Matching

Let a δ-MWM be a matching whose weight is at least a δ fraction of the maximum weight matching, where $0 < \delta \leq 1$, and let δ-MCM be defined analogously.

It is well known that the *greedy* algorithm – iteratively chooses the maximum weight edge not incident to previously chosen edges – produces a $\frac{1}{2}$-MWM. A straightforward implementation of this algorithm takes $O(m \log n)$ time. Preis [3,17] gave a $\frac{1}{2}$-MWM algorithm running in linear time. Vinkemeier and Hougardy [19] and Pettie and Sanders [16] proposed several $\left(\frac{2}{3}-\epsilon\right)$-MWM algorithms (see also [13]) running in $O(m \log \epsilon^{-1})$ time; each is based on iteratively improving a matching by identifying sets of short weight-augmenting paths and cycles.

Key Results

Approximate Maximum Cardinality Matching

In fact, the Hopcroft-Karp algorithm [10] for bipartite graphs and Micali-Vazirani [14] algorithm for general graphs both imply a $(1-\epsilon)$-MCM algorithm in $O(\epsilon^{-1}m)$ time. We can search for a maximal set of vertex disjoint shortest augmenting paths for k steps, and the matching obtained is a $\left(1-\frac{1}{k+1}\right)$-MCM.

Theorem 1 ([10, 14]) *In a general graph G, the $(1-\epsilon)$-MCM algorithm can be found in time $O(\epsilon^{-1}m)$.*

Approximate Maximum Weighted Matching

In 2014, Duan and Pettie [5] give the first $(1-\epsilon)$-MWM algorithm for arbitrary weighted graphs whose running time is linear. In particular, we show that such a matching can be found in $O(m\epsilon^{-1}\log\epsilon^{-1})$ time, improving a preliminary result of $O(m\epsilon^{-2}\log^3 n)$ running time by the authors in 2010 [4]. This result leaves little room for improvement. The main results are given in the following two theorems:

Theorem 2 ([5]) *In a general graph G with integer edge weights between $[0, N]$, a $(1-\epsilon)$-MWM can be computed in time $O(m\epsilon^{-1}\log N)$.*

Theorem 3 ([5]) *In a general graph G with real edge weights, a $(1-\epsilon)$-MWM can be computed in time $O(m\epsilon^{-1}\log\epsilon^{-1})$.*

Unlike previous algorithms of approximation ratios of $1/2$ [3, 17] or $2/3$ [16, 19], the new algorithm does not find weight-augmenting paths and cycles directly, but follows a primal-dual relaxation on the linear programming formulation of MWM. This relaxed complementary slackness approach relaxes the constraint of the dual variables by a small amount, so that the iterative process of the dual problem will converge to an approximate solution much more quickly. While it takes $O(\sqrt{n})$ iterations of augmenting to achieve a perfect matching, we proved that we only need $O(\log N/\epsilon)$ iterations to achieve a $(1-\epsilon)$-approximation. Also, we make the relaxation "dynamic" by shrinking the relaxation when the dual variables decrease by one half, so that finally the relaxation is at most ϵ times the edge weight on each matching edge and very small on each nonmatching edge, which gives an approximate solution.

Applications

Graph matching is a fundamental combinatorial problem that has a wide range of applications in

many fields, and it can also be building blocks of other algorithms, such as the Christofides algorithm [1] for approximate traveling salesman problem. The approximate algorithm for maximum weight matching described above has linear running time, much faster than the Hungarian algorithm [12] and Edmonds [6,7] algorithm. It is also much simpler than the Gabow-Tarjan scaling algorithms [8,9] of $\tilde{O}(m\sqrt{n})$ running time. Thus, it has a great impact both in theory and in real-world applications.

Approximate Regular Expression Matching

Gonzalo Navarro
Department of Computer Science, University of Chile, Santiago, Chile

Keywords

Regular expression matching allowing errors or differences

Years and Authors of Summarized Original Work

1995; Wu, Manber, Myers

Problem Definition

Given a *text string* $T = t_1 t_2 \ldots t_n$ and a *regular expression* R of length m denoting language, $\mathcal{L}(R)$ over an alphabet Σ of size σ, and given a *distance function* among strings d and a *threshold* k, the *approximate regular expression matching (AREM)* problem is to find all the text positions that finish a so-called approximate occurrence of R in T, that is, compute the set $\{j, \exists i, 1, \leq i \leq j, \exists P \in \mathcal{L}(R), d(P, t_i, \ldots, t_j) \leq k\}$ T, R, and k are given together, whereas the algorithm can be tailored for a specific d.

This entry focuses on the so-called weighted edit distance, which is the minimum sum of weights of a sequence of operations converting one string into the other. The operations are insertions, deletions, and substitutions of characters. The weights are positive real values associated to each operation and characters involved. The weight of deleting a character c is written $w(c \rightarrow \varepsilon)$, that of inserting c is written $w(\varepsilon \rightarrow c)$, and that of substituting c by $c \neq c'$ is written $w(c \rightarrow c')$. It is assumed $w(c \rightarrow c) = 0$ for all $c \in \Sigma \cup \varepsilon$ and the triangle inequality, that is, $w(x \rightarrow y) + w(y \rightarrow z) \geq w(x \rightarrow z)$ for any $x, y, z, \in \Sigma \cup \{\varepsilon\}$. As the distance may be asymmetric, it is also fixed that $d(A,B)$ is the cost of converting A into B. For simplicity and practicality, $m = o(n)$ is assumed in this entry.

Key Results

The most versatile solution to the problem [3] is based on a graph model of the distance computation process. Assume the regular expression R is converted into a nondeterministic finite automaton (NFA) with $O(m)$ states and transitions using Thompson's method [8]. Take this automaton as a directed graph $G(V,E)$ where edges are labeled by elements in $\Sigma \cup \{\varepsilon\}$. A directed and weighted graph $\mathcal{G}$ is built to solve the AREM problem. $\mathcal{G}$ is formed by putting $n+1$ copies of $G, G_0, G_1, \ldots, G_n$ and connecting them with weights so that the distance computation reduces to finding shortest paths in $\mathcal{G}$.

More formally, the nodes of $\mathcal{G}$ are $\{v_i, v \in V, 0 \leq i \leq n\}$, so that v_i is the copy of node $v \in V$ in graph G_i . For each edge $u \xrightarrow{c} v$ in $E, c \in \Sigma \cup \varepsilon$, the following edges are added to graph $\mathcal{G}$:

$$u_i \rightarrow v_i, \quad \text{with weight } w(c \rightarrow \varepsilon), \quad 0 \leq i \leq n.$$

$$u_i \rightarrow u_{i+1}, \quad \text{with weight } w(\varepsilon \rightarrow t_{i+1}), \quad 0 \leq i \leq n.$$

$$u_i \rightarrow v_{i+1}, \quad \text{with weight } w(c \rightarrow t_{i+1}), \quad 0 \leq i \leq n.$$

Assume for simplicity that G has initial state s and a unique final state f (this can always be arranged). As defined, the shortest path in $\mathcal{G}$ from s_0 to f_n gives the smallest distance between T and a string in $\mathcal{L}(R)$. In order to adapt the graph to the AREM problem, the weights of the edges between s_i and s_{i+1} are modified to be zero.

Then, the AREM problem is reduced to computing shortest paths. It is not hard to see that $\mathcal{G}$ can be topologically sorted so that all the paths to nodes in G_i are computed before all those to G_{i+1}. This way, it is not hard to solve this shortest path problem in $O(mn\log m)$ time and $O(m)$ space. Actually, if one restricts the problem to the particular case of *network expressions*, which are regular expressions without Kleene closure, then G has no loops and the shortest path computation can be done in $O(mn)$ time, and even better on average [2].

The most delicate part in achieving $O(mn)$ time for general regular expressions [3] is to prove that, given the types of loops that arise in the NFAs of regular expressions, it is possible to compute the distances correctly within each G_i by (a) computing them in a topological order of G_i without considering the *back edges* introduced by Kleene closures, (b) updating path costs by using the back edges once, and (c) updating path

costs once more in topological order ignoring back edges again.

Theorem 1 (Myers and Miller [3]) *There exists an $O(mn)$ worst-case time solution to the AREM problem under weighted edit distance.*

It is possible to do better when the weights are integer-valued, by exploiting the unit-cost RAM model through a four-Russian technique [10]. The idea is as follows. Take a small subexpression of R, which produces an NFA that will translate into a small subgraph of each G_i . At the time of propagating path costs within this automaton, there will be a counter associated to each node (telling the current shortest path from s_0). This counter can be reduced to a number in $[0, k + 1]$, where $k + 1$ means "more than k." If the small NFA has r states, $r\lceil \log_2(k + 2)\rceil$ bits are needed to fully describe the counters of the corresponding subgraph of G_i. Moreover, given an initial set of values for the counters, it is possible to precompute all the propagation that will occur within the same subgraph of G_i, in a table having $2^{r\lceil \log_2(k+2)\rceil}$ entries, one per possible configuration of counters. It is sufficient that $r < \alpha \log_{k+2} n$ for some $\alpha < 1$ to make the construction and storage cost of those tables $o(n)$. With the help of those tables, all the propagation within the subgraph can be carried out in constant time. Similarly, the propagation of costs to the same subgraph at G_{i+1} can also be precomputed in tables, as it depends only on the current counters in G_i and on text character t_{i+1}, for which there are only σ alternatives.

Now, take all the subtrees of R of maximum size not exceeding r and preprocess them with the technique above. Convert each such subtree into a leaf in R labeled by a special character a_A, associated to the corresponding small NFA A. Unless there are consecutive Kleene closures in R, which can be simplified as $R^{**} = R^*$, the size of R after this transformation is $O(m/r)$. Call R' the transformed regular expression. One essentially applies the technique of Theorem 1 to R', taking care of how to deal with the special leaves that correspond to small NFAs. Those leaves are converted by Thompson's construction into two nodes linked by an edge labeled a_A. When the path cost propagation process reaches the source node of an edge labeled a_A with cost c, one must update the counter of the initial state of NFA A to c (or $k + 1$ if $c > k$). One then uses the four-Russians table to do all the cost propagation within A in constant time and finally obtain, at the counter of the final state of A, the new value for the target node of the edge labeled a_A in the top-level NFA. Therefore, all the edges (normal and special) of the top-level NFA can be traversed in constant time, so the costs at G_i can be obtained in $O(mn/r)$ time using Theorem 1. Now one propagates the costs to G_{i+1}, using the four-Russians tables to obtain the current counter values of each subgraph A in G_{i+1}.

Theorem 2 (Wu et al. [10]) *There exists an $O(n + mn/\log_{k+2} n)$ worst-case time solution to the AREM problem under weighted edit distance if the weights are integer numbers.*

Applications

The problem has applications in computational biology, to find certain types of motifs in DNA and protein sequences. See [1] for a more detailed discussion. In particular, PROSITE patterns are limited regular expressions rather popular to search protein sequences. PROSITE patterns can be searched for with faster algorithms in practice [7]. The same occurs with other classes of complex patterns [6] and network expressions [2].

Open Problems

The worst-case complexity of the AREM problem is not fully understood. It is of course $\Omega(n)$, which has been achieved for $m\log(k + 2) = O(\log n)$, but it is not known how much can this be improved.

Experimental Results

Some experiments are reported in [5]. For small m and k, and assuming all the weights are 1

(except $w(c \rightarrow c) = 0$), bit-parallel algorithms of worst-case complexity $O(k\,n(m/\log n)^2)$ [4,9] are the fastest (the second is able to skip some text characters, depending on R). For arbitrary integer weights, the best choice is a more complex bit-parallel algorithm [5] or the four-Russians based one [10] for larger m and k. The original algorithm [3] is slower, but it is the only one supporting arbitrary weights.

URL to Code

A recent and powerful software package implementing AREM is *TRE* (http://laurikari.net/tre), which supports edit distance with different costs for each type of operation. Older packages offering efficient AREM are *agrep* [9] (https://github.com/Wikinaut/agrep) for simplified weight choices and *nrgrep* [4] (http://www.dcc.uchile.cl/~gnavarro/software).

Cross-References

- Approximate String Matching is a simplification of this problem, and the relation between graph $\mathcal{G}$ here and matrix C there should be apparent.
- Regular Expression Matching is the simplified case where exact matching with strings in $\mathcal{L}(R)$ is sought.

Problem Definition

Given a *text string* $T = t_1 t_2 \ldots t_n$ and a *pattern string* $P = p_1 p_2 \ldots p_m$, both being sequences over an alphabet Σ of size σ, and given a *distance function* among strings d and a *threshold* k, the *approximate string matching (ASM)* problem is to find all the text positions that finish the so-called approximate occurrence of P in T, that is, compute the set $\{j, \exists i, 1 \leq i \leq j, d(P, t_i \ldots t_j) \leq k\}$. In the sequential version of the problem, T, P,

and k are given together, whereas the algorithm can be tailored for a specific d.

The solutions to the problem vary widely depending on the distance d used. This entry focuses on a very popular one, called *Levenshtein distance* or *edit distance*, defined as the minimum number of character insertions, deletions, and substitutions necessary to convert one string into the other. It will also pay some attention to other common variants such as *indel distance*, where only insertions and deletions are permitted and is the dual of the *longest common subsequence lcs* ($d(A,B) = |A| + |B| - 2 \cdot lcs(A,B)$), and *Hamming distance*, where only substitutions are permitted.

A popular generalization of all the above is the *weighted edit distance*, where the operations are given positive real-valued weights and the distance is the minimum sum of weights of a sequence of operations converting one string into the other. The weight of deleting a character c is written $w(c \rightarrow \varepsilon)$, that of inserting c is written $w(\varepsilon \rightarrow c)$, and that of substituting c by $c' \neq c$ is written $w(c \rightarrow c')$. It is assumed $w(c \rightarrow c) = 0$ and the triangle inequality, that is, $w(x \rightarrow y) + w(y \rightarrow z) \geq w(x \rightarrow z)$ for any $x, y, z, \in \sum \cup \{\varepsilon\}$. As the distance may now be asymmetric, it is fixed that $d(A,B)$ is the cost of converting A into B. Of course, any result for weighted edit distance applies to edit, Hamming, and indel distances (collectively termed *unit-cost edit distances*) as well, but other reductions are not immediate.

Both worst- and average-case complexity are considered. For the latter, one assumes that pattern and text are randomly generated by choosing each character uniformly and independently from Σ. For simplicity and practicality, $m = o(n)$ is assumed in this entry.

Key Results

The most ancient and versatile solution to the problem [13] builds over the process of computing weighted edit distance. Let $A = a_1 a_2 \ldots a_m$ and $B = b_1 b_2 \ldots b_n$ be two strings. Let $C[0 \ldots m, 0 \ldots n]$ be a matrix such that $C[i,j] = d(a_1 \ldots a_i, b_1 \ldots b_j)$. Then, it holds $C[0,0] = 0$ and

$$C[i,j] = \min(C[i-1,j] + w(a_i \rightarrow \varepsilon), C[i,j-1] + w(\varepsilon \rightarrow b_j), C[i-1,j-1] + w(a_i \rightarrow b_j)),$$

where $C[i,-1] = C[-1,j] = \infty$ is assumed. This matrix is computed in $O(mn)$ time and $d(A,B) = C[m,n]$. In order to solve the approximate string matching problem, one takes $A = P$ and $B = T$ and sets $C[0,j] = 0$ for all j, so that the above formula is used only for $i > 0$.

Theorem 1 (Sellers 1980 [13]) *There exists an $O(mn)$ worst-case time solution to the ASM problem under weighted edit distance.*

The space is $O(m)$ if one realizes that C can be computed column-wise and only column $j-1$ is necessary to compute column j. As explained, this immediately implies that searching under unit-cost edit distances can be done in $O(mn)$ time as well. In those cases, it is quite easy to compute only part of matrix C so as to achieve $O(kn)$ average-time algorithms [14].

Yet, there exist algorithms with lower worst-case complexity for weighted edit distance. By applying a Ziv-Lempel parsing to P and T, it is possible to identify regions of matrix C corresponding to substrings of P and T that can be computed from other previous regions corresponding to similar substrings of P and T [5].

Theorem 2 (Crochemore et al. 2003 [5]) *There exists an $O(n + mn/\log_\sigma n)$ worst-case time solution to the ASM problem under weighted edit distance. Moreover, the time is $O(n + mnh/\log n)$, where $0 \leq h \leq \log \sigma$ is the entropy of T.*

This result is very general, also holding for computing weighted edit distance and local similarity (see section on "Applications"). For the case of edit distance and exploiting the unit-cost RAM model, it is possible to do better. On one hand, one can apply a four-Russian technique: All the possible blocks (submatrices of C) of

size $t \times t$, for $t = O(\log_\sigma n)$, are precomputed, and matrix C is computed block-wise [9]. On the other hand, one can represent each cell in matrix C using a constant number of bits (as it can differ from neighboring cells by ± 1) so as to store and process several cells at once in a single machine word [10]. This latter technique is called *bit-parallelism* and assumes a machine word of $\Theta(\log n)$ bits.

Theorem 3 (Masek and Paterson 1980 [9]; Myers 1999 [10]) *There exist* $O(n + mn/(\log_\sigma n)^2)$ *and* $O(n + mn/\log n)$ *worst-case time solutions to the ASM problem under edit distance.*

Both complexities are retained for indel distance, yet not for Hamming distance.

For unit-cost edit distances, the complexity can depend on k rather than on m, as $k < m$ for the problem to be nontrivial, and usually k is a small fraction of m (or even $k = o(m)$). A classic technique [8] computes matrix C by processing in constant time diagonals $C[i + d, j + d], 0 \leq d \leq s$, along which cell values do not change. This is possible by preprocessing the suffix trees of T and P for lowest common ancestor queries.

Theorem 4 (Landau and Vishkin 1989 [8]) *There exists an* $O(kn)$ *worst-case time solution to the ASM problem under unit-cost edit distances.*

Other solutions exist which are better for small k, achieving time $O(n(1 + k^4/m))$ [4]. For the case of Hamming distance, one can achieve improved results using convolutions [1].

Theorem 5 (Amir et al. 2004 [1]) *There exist* $O(n\sqrt{k \log k})$ *and* $O(n(1+k^3/m)\log k)$ *worst-case time solution to the ASM problem under Hamming distance.*

The last result for edit distance [4] achieves $O(n)$ time if k is small enough ($k = O(m^{1/4})$). It is also possible to achieve $O(n)$ time on unit-cost edit distances at the expense of an exponential additive term on m or k: The number of different columns in C is independent of n, so the transition from every possible column to the next can be precomputed as a finite-state machine.

Theorem 6 (Ukkonen 1985 [14]) *There exists an* $O(n+m\min(3^m, m(2m\sigma)^k))$ *worst-case time solution to the ASM problem under edit distance.*

Similar results apply for Hamming and indel distance, where the exponential term reduces slightly according to the particularities of the distances.

The worst-case complexity of the ASM problem is of course $\Omega(n)$, but it is not known if this can be attained for any m and k. Yet, the average-case complexity of the problem is known.

Theorem 7 (Chang and Marr 1994 [3]) *The average-case complexity of the ASM problem is* $\Theta(n(k + \log_\sigma m)/m)$ *under unit-cost edit distances.*

It is not hard to prove the lower bound as an extension to Yao's bound for exact string matching [15]. The lower bound was reached in the same paper [3], for $k/m < 1/3 - O\left(1/\sqrt{\sigma}\right)$. This was improved later to $k/m < 1/2 - O\left(1/\sqrt{\sigma}\right)$ [6] using a slightly different idea. The approach is to precompute the minimum distance to match every possible text substring (block) of length $O(\log_\sigma m)$ inside P. Then, a text window is scanned backwards, block-wise, adding up those minimum precomputed distances. If they exceed k before scanning all the window, then no occurrence of P with k errors can contain the scanned blocks, and the window can be safely slid over the scanned blocks, advancing in T. This is an example of a *filtration* algorithm, which discards most text areas and applies an ASM algorithm only over those areas that cannot be discarded.

Theorem 8 (Fredriksson and Navarro 2004 [6]) *There exists an optimal-on-average solution to the ASM problem under edit distance, for any* $k/m \leq \frac{1-e/\sqrt{\sigma}}{2-e/\sqrt{\sigma}} = 1/2 - O\left(1/\sqrt{\sigma}\right)$.

The result applies verbatim to indel distance. The same complexity is achieved for Hamming distance, yet the limit on k/m improves to $1 - 1/\sigma$. Note that, when the limit k/m is reached, the average complexity is already $\Theta(n)$. It is not clear up to which k/m limit could one achieve linear time on average.

Applications

The problem has many applications in computational biology (to compare DNA and protein sequences, recovering from experimental errors, so as to spot mutations or predict similarity of structure or function), text retrieval (to recover from spelling, typing, or automatic recognition errors), signal processing (to recover from transmission and distortion errors), and several others. See a survey [11] for a more detailed discussion.

Many extensions of the ASM problem exist, particularly in computational biology. For example, it is possible to substitute whole substrings by others (called *generalized edit distance*), swap characters in the strings (*string matching with swaps or transpositions*), reverse substrings (*reversal distance*), have variable costs for insertions/deletions when they are grouped (*similarity with gap penalties*), and look for any pair of substrings of both strings that are sufficiently similar (*local similarity*). See, for example, Gusfield's book [7], where many related problems are discussed.

Open Problems

The worst-case complexity of the problem is not fully understood. For unit-cost edit distances, it is $\Theta(n)$ if $m = O(\min(\log n, (\log_\sigma n)^2))$ or $k = O(\min(m^{1/4}, \log_{m\sigma} n))$. For weighted edit distance, the complexity is $\Theta(n)$ if $m = O(\log_\sigma n)$. It is also unknown up to which k/m value can one achieve $O(n)$ average time; up to now this has been achieved up to $k/m = 1/2 - O\left(1/\sqrt{\sigma}\right)$.

Experimental Results

A thorough survey on the subject [11] presents extensive experiments. Nowadays, the fastest algorithms for edit distance are in practice filtration algorithms [6, 12] combined with bit-parallel algorithms to verify the candidate areas [2, 10]. Those filtration algorithms work well for small enough k/m; otherwise, the bit-parallel algorithms should be used stand-alone. Filtration algorithms are easily extended to handle multiple patterns searched simultaneously.

Problem Definition

Identification of periodic structures in words (variants of which are known as *tandem repeats, repetitions, powers*, or *runs*) is a fundamental algorithmic task (see entry ▸ Squares and Repetitions). In many practical applications, such as DNA sequence analysis, considered repetitions admit a certain variation between copies of the repeated pattern. In other words, repetitions under interest are *approximate tandem repeats* and not necessarily exact repeats only.

The simplest instance of an approximate tandem repeat is an *approximate square*. An approximate square in a word w is a subword uv, where u and v are within a given distance k according to some distance measure between words, such as Hamming distance or edit (also called Levenshtein) distance. There are several ways to define approximate tandem repeats as successions of approximate squares, i.e., to generalize to the approximate case the notion of arbitrary periodicity (see entry ▸ Squares and Repetitions). In this entry, we discuss three different definitions of approximate tandem repeats. The first two are built upon the Hamming distance measure, and the third one is built upon the edit distance.

Let $h(\cdot,\cdot)$ denote the Hamming distance between two words of equal length.

Definition 1 A word $r[1\ldots n]$ is called a K-*repetition* of period p, $p \le n/2$, iff $h(r[1\ldots n-p], r[p+1\ldots n]) \le K$.

Equivalently, a word $r[1\ldots n]$ is a K-repetition of period p, if the number of mismatches, i.e., the number of i such that $r[i] \neq r[i+p]$, is at most K. For example, *ataa atta ctta ct* is a 2-repetition of period 4. *atc atc atc atg atg atg atg atg* is a 1-repetition of period 3, but *atc atc atc att atc atc atc att* is not.

Definition 2 A word $r[1\ldots n]$ is called a K-*run*, of period p, $p \le n/2$, iff for every $i \in [1\ldots n-2p+1]$, we have $h(r[i\ldots i+p-1], r[i+p, i+2p-1]) \le K$.

A K-run can be seen as a sequence of approximate squares uv such that $|u| = |v| = p$ and u and v differ by at most K mismatches. The total number of mismatches in a K-run is not bounded.

Let $ed(\cdot,\cdot)$ denote the edit distance between two strings.

Definition 3 A word r is a K-*edit* repeat if it can be partitioned into consecutive subwords, $r = v' w_1 w_2 \ldots w_\ell v''$, $\ell \ge 2$, such that

$$ed(v', w_1') + \sum_{i=1}^{\ell-1} ed(w_i, w_{i+1}) + ed(w_\ell'', v'') \le K,$$

where w'_1 is some suffix of w_1 and w''_ℓ is some prefix of w_ℓ.

A K-edit repeat is a sequence of "evolving" copies of a pattern such that there are at most K insertions, deletions, and mismatches, overall, between all consecutive copies of the repeat. For example, the word $r = caagct\ cagct\ ccgct$ is a 2-edit repeat.

When looking for tandem repeats occurring in a word, it is natural to consider *maximal* repeats. Those are the repeats extended to the right and left as much as possible provided that the corresponding definition is still verified. Note that the notion of maximality applies to K-repetitions, to K-runs, and to K-edit repeats.

Under the Hamming distance, K-runs provide the weakest "reasonable" definition of approximate tandem repeats, since it requires that every square it contains cannot contain more than K mismatch errors, which seems to be a minimal reasonable requirement. On the other hand, K-repetition is the strongest such notion as it limits by K the *total* number of mismatches. This provides an additional justification that finding these two types of repeats is important as they "embrace" other intermediate types of repeats. Several intermediate definitions have been discussed in [9, Section 5].

In general, each K-repetition is a part of a K-run of the same period, and every K-run is the union of all K-repetitions it contains. Observe that a K-run can contain as many as a linear number of K-repetitions with the same period. For example, the word $(000\ 100)^n$ of length $6n$ is a 1-run of period 3, which contains $(2n - 1)$ 1-repetitions. In general, a K-run r contains $(s - K + 1)$ K-repetitions of the same period, where s is the number of mismatches in r.

Example 1 The following Fibonacci word contains three 3-runs of period 6. They are shown in regular font, in positions aligned with their occurrences. Two of them are identical and contain each four 3-repetitions, shown in italic for the first run only. The third run is a 3-repetition in itself.

Key Results

Given a word w of length n and an integer K, it is possible to find all K-runs, K-repetitions, and K-edit repeats within w in the following time and space bounds:

- K **-runs** can be found in time $O(nK \log K + S)$ (S the output size) and working space $O(n)$ [9].
- K **-repetitions** can be found in time $O(nK \log K + S)$ and working space $O(n)$ [9].
- K **-edit repeats** can be found in time $O(nK \log K \log(n/K) + S)$ and working space $O(n + K^2)$ [14, 19].

All three algorithms are based on similar algorithmic tools that generalize corresponding techniques for the exact case [4, 15, 16] (see [10] for a systematic presentation). The first basic tool is a generalization of the *longest extension functions* [16] that, in the case of Hamming distance, can be exemplified as follows. Given a word w, we want to compute, for each position p and each $k \leq K$, the quantity $\max\{j \mid h(w[1 \ldots j], w[p \ldots p + j - 1]) \leq k\}$. Computing all those values can be done in time $O(nK)$ using a method based on the suffix tree and the computation of the *lowest common ancestor* described in [7].

The second tool is the Lempel-Ziv factorization used in the well-known compression method. Different variants of the Lempel-Ziv factorization of a word can be computed in linear time [7, 18].

The algorithm for computing K-repetitions from [9] can be seen as a direct generalization of

the algorithm for computing maximal repetitions (runs) in the exact case [8, 15]. Although based on the same basic tools and ideas, the algorithm [9] for computing K-runs is much more involved and uses a complex "bootstrapping" technique for assembling runs from smaller parts.

The algorithm for finding the K-edit repeats uses both the recursive framework and the idea of the *longest extension functions* of [16]. The longest common extensions, in this case, allow up to K edit operations. Efficient methods for computing these extensions are based upon a combination of the results of [12] and [13]. The K-edit repeats are derived by combining the longest common extensions computed in the forward direction with those computed in the reverse direction.

Applications

Tandemly repeated patterns in DNA sequences are involved in various biological functions and are used in different practical applications.

Tandem repeats are known to be involved in regulatory mechanisms, e.g., to act as binding sites for regulatory proteins. Tandem repeats have been shown to be associated with recombination hotspots in higher organisms. In bacteria, a correlation has been observed between certain tandem repeats and virulence and pathogenicity genes.

Tandem repeats are responsible for a number of inherited diseases, especially those involving the central nervous system. Fragile X syndrome, Kennedy disease, myotonic dystrophy, and Huntington's disease are among the diseases that have been associated with triplet repeats.

Examples of different genetic studies illustrating abovementioned biological roles of tandem repeats can be found in introductive sections of [1, 6, 11]. Even more than just genomic elements associated with various biological functions, tandem repeats have been established to be a fundamental mutational mechanism in genome evolution [17].

A major practical application of short tandem repeats is based on the interindividual variability in copy number of certain repeats occurring at a single locus. This feature makes tandem repeats a convenient tool for genetic profiling of individuals. The latter, in turn, is applied to pedigree analysis and establishing phylogenetic relationships between species, as well as to forensic medicine [3].

Open Problems

The definition of K-edit repeats is similar to that of K-repetitions (for the Hamming distance case). It would be interesting to consider other definitions of maximal repeats over the edit distance. For example, a definition similar to the K-run would allow up to K edits between each pair of neighboring periods in the repeat. Other possible definitions would allow K errors between *any* pair of copies of a repeat, or between *all pairs* of copies, or between some *consensus* and each copy.

In general, a *weighted* edit distance scheme is necessary for biological applications. Known algorithms for tandem repeats based on a weighted edit distance scheme are not feasible, and thus, only heuristics are currently used.

URL to Code

The algorithms described in this entry have been implemented for DNA sequences and are publicly available. The Hamming distance algorithms (K-runs and K-repetitions) are part of the *mreps* software package, available at http://mreps.univ-mlv.fr/ [11]. The K-edit repeat software, *TRED*, is available at http://tandem.sci.brooklyn.cuny.edu/ [19]. The implementations of the algorithms are coupled with postprocessing filters, necessary due to the nature of biological sequences.

In practice, software based on heuristic and statistical methods is largely used. Among them, TRF (http://tandem.bu.edu/trf/trf.html) [1] is the most popular program used by the bioinformatics community. Other programs include ATRHunter (http://bioinfo.cs.technion.ac.il/atrhunter/) [20]

and TandemSWAN (http://favorov.bioinfolab.net/swan/) [2]. STAR (http://atgc.lirmm.fr/star/) [5] is another software, based on an information-theoretic approach, for computing approximate tandem repeats of a prespecified pattern.

Approximating Fixation Probabilities in the Generalized Moran Process

George B. Mertzios
School of Engineering and Computing Sciences, Durham University, Durham, UK

Keywords

Approximation algorithm; Evolutionary dynamics; Fixation probability; Markov-chain Monte Carlo; Moran process

Years and Authors of Summarized Original Work

2014; Diaz, Goldberg, Mertzios, Richerby, Serna, Spirakis

Problem Definition

Population and evolutionary dynamics have been extensively studied, usually with the assumption that the evolving population has no spatial structure. One of the main models in this area is the Moran process [17]. The initial population

contains a single "mutant" with fitness $r > 0$, with all other individuals having fitness 1. At each step of the process, an individual is chosen at random, with probability proportional to its fitness. This individual reproduces, replacing a second individual, chosen uniformly at random, with a copy of itself.

Lieberman, Hauert, and Nowak introduced a generalization of the Moran process, where the members of the population are placed on the vertices of a connected graph which is, in general, directed [13, 19]. In this model, the initial population again consists of a single mutant of fitness $r > 0$ placed on a vertex chosen uniformly at random, with each other vertex occupied by a nonmutant with fitness 1. The individual that will reproduce is chosen as before, but now one of its neighbors is randomly selected for replacement, either uniformly or according to a weighting of the edges. The original Moran process can be recovered by taking the graph to be an unweighted clique.

Several similar models describing particle interactions have been studied previously, including the SIR and SIS epidemic models [8, Chapter 21], the voter model, the antivoter model, and the exclusion process [1, 7, 14]. Related models, such as the decreasing cascade model [12, 18], have been studied in the context of influence propagation in social networks and other models have been considered for dynamic monopolies [2]. However, these models do not consider different fitnesses for the individuals.

In general, the Moran process on a finite, connected, directed graph may end with all vertices occupied by mutants or with no vertex occupied by a mutant – these cases are referred to as *fixation* and *extinction*, respectively – or the process may continue forever. However, for undirected graphs and strongly connected digraphs, the process terminates almost surely, either at fixation or extinction. At the other extreme, in a directed graph with two sources, neither fixation nor extinction is possible. In this work we consider finite undirected graphs. The *fixation probability* for a mutant of fitness r in a graph G is the probability that fixation is reached and is denoted $f_{G,r}$.

Key Results

The fixation probability can be determined by standard Markov chain techniques. However, doing so for a general graph on n vertices requires solving a set of 2^n linear equations, which is not computationally feasible, even numerically. As a result, most prior work on computing fixation probabilities in the generalized Moran process has either been restricted to small graphs [6] or graph classes where a high degree of symmetry reduces the size of the set of equations – for example, paths, cycles, stars, and complete graphs [3–5] – or has concentrated on finding graph classes that either encourage or suppress the spread of the mutants [13, 16].

Because of the apparent intractability of exact computation, we turn to approximation. Using a potential function argument, we show that, with high probability, the Moran process on an undirected graph of order n reaches absorption (either fixation or extinction) within $\mathcal{O}(n^6)$ steps if $r = 1$ and $\mathcal{O}(n^4)$ and $\mathcal{O}(n^3)$ steps when $r > 1$ and $r < 1$, respectively. Taylor et al. [20] studied absorption times for variants of the generalized Moran process, but, in our setting, their results only apply to the process on regular graphs, where it is equivalent to a biased random walk on a line with absorbing barriers. The absorption time analysis of Broom et al. [3] is also restricted to cliques, cycles, and stars. In contrast to this earlier work, our results apply to all connected undirected graphs.

Our bound on the absorption time, along with polynomial upper and lower bounds for the fixation probability, allows the estimation of the fixation and extinction probabilities by Monte Carlo techniques. Specifically, we give a *fully polynomial randomized approximation scheme* (FPRAS) for these quantities. An FPRAS for a function $f(X)$ is a polynomial-time randomized algorithm g that, given input X and an error bound ε, satisfies $(1-\varepsilon)f(X) \leqslant g(X) \leqslant (1+\varepsilon)f(X)$ with probability at least $\frac{3}{4}$ and runs in time polynomial in the length of X and $\frac{1}{\varepsilon}$ [11].

For the case $r < 1$, there is no polynomial lower bound on the fixation probability so only the extinction probability can be approximated

by this technique. Note that, when $f \ll 1$, computing $1 - f$ to within a factor of $1 \pm \varepsilon$ does not imply computing f to within the same factor.

Bounding the Fixation Probability

In the next two lemmas, we provide polynomial upper and lower bounds for the fixation probability of an arbitrary undirected graph G. Note that the lower bound of Lemma 1 holds only for $r \geqslant 1$. Indeed, for example, the fixation probability of the complete graph K_n is given by $f_{K_n,r} = (1 - \frac{1}{r})/(1 - \frac{1}{r^n})$ [13, 19], which is exponentially small for any $r < 1$.

Lemma 1 *Let $G = (V, E)$ be an undirected graph with n vertices. Then $f_{G,r} \geqslant \frac{1}{n}$ for any $r \geqslant 1$.*

Lemma 2 *Let $G = (V, E)$ be an undirected graph with n vertices. Then $f_{G,r} \leqslant 1 - \frac{1}{n+r}$ for any $r > 0$.*

Bounding the Absorption Time

In this section, we show that the Moran process on a connected graph G of order n is expected to reach absorption in a polynomial number of steps. To do this, we use the potential function given by

$$\phi(S) = \sum_{x \in S} \frac{1}{\deg x}$$

for any state $S \subseteq V(G)$ and we write $\phi(G)$ for $\phi(V(G))$. Note that $1 < \phi(G) < n$ and that $\phi(\{x\}) = 1/\deg x \leqslant 1$ for any vertex $x \in V$.

First, we show that the potential strictly increases in expectation when $r > 1$ and strictly decreases in expectation when $r < 1$.

Lemma 3 *Let $(X_i)_{i \geqslant 0}$ be a Moran process on a graph $G = (V, E)$ and let $\emptyset \subset S \subset V$. If $r \geqslant 1$, then*

$$\mathbb{E}[\phi(X_{i+1}) - \phi(X_i) \mid X_i = S] \geqslant \left(1 - \frac{1}{r}\right) \cdot \frac{1}{n^3},$$

with equality if and only if $r = 1$. For $r < 1$,

$$\mathbb{E}[\phi(X_{i+1}) - \phi(X_i) \mid X_i = S] < \frac{r-1}{n^3}.$$

To bound the expected absorption time, we use martingale techniques. It is well known how to bound the expected absorption time using a potential function that decreases in expectation until absorption. This has been made explicit by Hajek [9] and we use the following formulation based on that of He and Yao [10]. The proof is essentially theirs but is modified to give a slightly stronger result.

Theorem 1 *Let $(Y_i)_{i \geqslant 0}$ be a Markov chain with state space Ω, where Y_0 is chosen from some set $I \subseteq \Omega$. If there are constants $k_1, k_2 > 0$ and a nonnegative function $\psi : \Omega \to \mathbb{R}$ such that*

- *$\psi(S) = 0$ for some $S \in \Omega$,*
- *$\psi(S) \leqslant k_1$ for all $S \in I$ and*
- *$\mathbb{E}[\psi(Y_i) - \psi(Y_{i+1}) \mid Y_i = S] \geqslant k_2$ for all $i \geqslant 0$ and all S with $\psi(S) > 0$,*

then $\mathbb{E}[\tau] \leqslant k_1/k_2$, where $\tau = \min\{i : \psi(Y_i) = 0\}$.

Using Theorem 1, we can prove the following upper bounds for the absorption time τ in the cases where $r < 1$ and $r > 1$, respectively.

Theorem 2 *Let $G = (V, E)$ be a graph of order n. For $r < 1$ and any $S \subseteq V$, the absorption time τ of the Moran process on G satisfies*

$$\mathbb{E}[\tau \mid X_0 = S] \leqslant \frac{1}{1-r} n^3 \phi(S).$$

Theorem 3 *Let $G = (V, E)$ be a graph of order n. For $r > 1$ and any $S \subseteq V$, the absorption time τ of the Moran process on G satisfies*

$$\begin{aligned}\mathbb{E}[\tau \mid X_0 = S] &\leqslant \frac{r}{r-1} n^3 \big(\phi(G) - \phi(S)\big) \\ &\leqslant \frac{r}{r-1} n^4.\end{aligned}$$

The case $r = 1$ is more complicated as Lemma 3 shows that the expectation is constant. However, this allows us to use standard martingale techniques and the proof of the following is partly adapted from the proof of Lemma 3.4 in [15].

Theorem 4 *The expected absorption time for the Moran process* $(X_i)_{i\geqslant 0}$ *with* $r = 1$ *on a graph* $G = (V, E)$ *is at most* $n^4(\phi(G)^2 - \mathbb{E}[\phi(X_0)^2])$.

Approximation Algorithms

We now have all the components needed to present our fully polynomial randomized approximation schemes (FPRAS) for the problem of computing the fixation probability of a graph, where $r \geqslant 1$, and for computing the extinction probability for all $r > 0$. In the following two theorems, we give algorithms whose running times are polynomial in n, r, and $\frac{1}{\varepsilon}$. For the algorithms to run in time polynomial in the length of the input and thus meet the definition of FPRAS, r must be encoded in unary.

Theorem 5 *There is an FPRAS for* MORAN FIXATION, *for* $r \geqslant 1$.

Proof (sketch) The algorithm is as follows. If $r = 1$ then we return $\frac{1}{n}$. Otherwise, we simulate the Moran process on G for $T = \lceil \frac{8r}{r-1} Nn^4 \rceil$ steps, $N = \lceil \frac{1}{2}\varepsilon^{-2} n^2 \ln 16 \rceil$ times and compute the proportion of simulations that reached fixation. If any simulation has not reached absorption (fixation or extinction) after T steps, we abort and immediately return an error value.

Note that each transition of the Moran process can be simulated in $\mathcal{O}(1)$ time. Maintaining arrays of the mutant and nonmutant vertices allows the reproducing vertex to be chosen in constant time, and storing a list of each vertex's neighbors allows the same for the vertex where the offspring is sent. Therefore, the total running time is $\mathcal{O}(NT)$ steps, which is polynomial in n and $\frac{1}{\varepsilon}$, as required.

For $i \in \{1, \ldots, N\}$, let $X_i = 1$ if the ith simulation of the Moran process reaches fixation and $X_i = 0$ otherwise. Assuming all simulation runs reach absorption, the output of the algorithm is $p = \frac{1}{N}\sum_i X_i$. □

Note that this technique fails for disadvantageous mutants ($r < 1$) because there is no analogue of Lemma 1 giving a polynomial lower bound on $f_{G,r}$. As such, an exponential number of simulations may be required to achieve the desired error probability. However, we can give an FPRAS for the extinction probability for all $r > 0$. Although the extinction probability is just $1 - f_{G,r}$, there is no contradiction because a small relative error in $1 - f_{G,r}$ does not translate into a small relative error in $f_{G,r}$ when $f_{G,r}$ is, itself, small.

Theorem 6 *There is an FPRAS for* MORAN EXTINCTION *for all* $r > 0$.

Proof (sketch) The algorithm and its correctness proof are essential as in the previous theorem. If $r = 1$, we return $1 - \frac{1}{n}$. Otherwise, we run $N = \lceil \frac{1}{2}\varepsilon^{-2}(r + n)^2 \ln 16 \rceil$ simulations of the Moran process on G for $T(r)$ steps each, where

$$T(r) = \begin{cases} \lceil \frac{8r}{r-1} Nn^4 \rceil & \text{if } r > 1 \\ \lceil \frac{8}{1-r} Nn^3 \rceil & \text{if } r < 1. \end{cases}$$

If any simulation has not reached absorption within $T(r)$ steps, we return an error value; otherwise, we return the proportion p of simulations that reached extinction. □

It remains open whether other techniques could lead to an FPRAS for MORAN FIXATION when $r < 1$.

2004; Bartal, Fakcharoenphol, Rao, Talwar

Problem Definition

This problem is to construct a random tree metric that probabilistically approximates a given arbitrary metric well. A solution to this problem is useful as the first step for numerous approximation algorithms because usually solving problems on trees is easier than on general graphs. It also finds applications in on-line and distributed computation.

It is known that tree metrics approximate general metrics badly, e.g., given a cycle C_n with n nodes, any tree metric approximating this graph metric has distortion $\Omega(n)$ [17]. However, Karp [15] noticed that a random spanning tree of C_n approximates the distances between any two nodes in C_n well in expectation. Alon, Karp, Peleg, and West [1] then proved a bound of $\exp(O(\sqrt{\log n \log\log n}))$ on an average distortion for approximating any graph metric with its spanning tree.

Bartal [2] formally defined the notion of probabilistic approximation.

Notations

A graph $G = (V, E)$ with an assignment of nonnegative weights to the edges of G defines a metric space (V, d_G) where for each pair $u, v \in V$, $d_G(u, v)$ is the shortest path distance between u and v in G. A metric (V, d) is a *tree metric* if there exists some tree $T = (V', E')$ such that $V \subseteq V'$ and for all $u, v \in V$, $d_T(u, v) = d(u, v)$. The metric (V, d) is also called a metric induced by T.

Given a metric (V, d), a distribution $\mathcal{D}$ over tree metrics over V *α-probabilistically approximates* d if every tree metric $d_T \in \mathcal{D}$, $d_T(u, v) \geq d(u, v)$ and $\mathrm{E}_{d_T \in \mathcal{D}}[d_T(u, v)] \leq \alpha \cdot d(u, v)$, for every $u, v \in V$. The quantity α is referred to as the *distortion* of the approximation.

Although the definition of probabilistic approximation uses a distribution $\mathcal{D}$ over tree metrics, one is interested in a procedure that constructs a random tree metric distributed according to $\mathcal{D}$, i.e., an algorithm that produces a random tree metric that probabilistically approximates a given metric. The problem can be formally stated as follows.

Problem (APPROX-TREE)
INPUT: a metric (V, d)
OUTPUT: a tree metric (V, d_T) sampled from a distribution $\mathcal{D}$ over tree metrics that α-probabilistically approximates (V, d).

Bartal then defined a class of tree metrics, called hierarchically well-separated trees (HST), as follows. A *k-hierarchically well-separated tree* (k-HST) is a rooted weighted tree satisfying two properties: the edge weight from any node to each of its children is the same, and the edge weights along any path from the root to a leaf are decreasing by a factor of at least k. These properties are important to many approximation algorithms.

Bartal showed that any metric on n points can be probabilistically approximated by a set of k-HST's with $O(\log^2 n)$ distortion, an improvement from $\exp(O(\sqrt{\log n \log\log n}))$ in [1]. Later Bartal [3], following the same approach as in Seymour's analysis on the Feedback Arc Set problem [18], improved the distortion down to $O(\log n \log\log n)$. Using a rounding procedure of Calinescu, Karloff, and Rabani [5], Fakcharoenphol, Rao, and Talwar [9] devised an algorithm that, in expectation, produces a tree with $O(\log n)$ distortion. This bound is tight up to a constant factor.

Key Results

A tree metric is closely related to graph decomposition. The randomized rounding procedure of Calinescu, Karloff, and Rabani [5] for the 0-extension problem decomposes a graph into pieces with bounded diameter, cutting each edge with probability proportional to its length and a ratio between the numbers of nodes at certain distances. Fakcharoenphol, Rao, and Talwar [9] used the CKR rounding procedure to decompose the graph recursively and obtained the following theorem.

Theorem 1 *Given an n-point metric (V, d), there exists a randomized algorithm, which runs in time $O(n^2)$, that samples a tree metric from the distribution $\mathcal{D}$ over tree metrics that $O(\log n)$-probabilistically approximates (V, d). The tree is also a 2-HST.*

The bound in Theorem 1 is tight, as Alon et al. [1] proved the bound of an $\Omega(\log n)$ distortion when (V, d) is induced by a grid graph. Also note that it is known (as folklore) that even embedding a line metric onto a 2-HST requires distortion $\Omega(\log n)$.

If the tree is required to be a k-HST, one can apply the result of Bartal, Charikar, and Raz [4] which states that any 2-HST can be $O(k/\log k)$-probabilistically approximated by k-HST, to obtain an expected distortion of $O(k \log n/\log k)$.

Finding a distribution of tree metrics that probabilistically approximates a given metric has a dual problem that is to find a single tree T with small average weighted stretch. More specifically, given weight c_{uv} on edges, find a tree metric d_T such that for all $u, v \in V d_T(u, v) \geq d(u, v)$ and $\sum_{u,v\in V} c_{uv} \cdot d_T(u, v) \leq \alpha \sum_{u,v\in V} c_{uv} \cdot d(u, v)$.

Charikar, Chekuri, Goel, Guha, and Plotkin [6] showed how to find a distribution of $O(n \log n)$ tree metrics that α-probabilistically approximates a given metric, provided that one can solve the dual problem. The algorithm in Theorem 1 can be derandomized by the method of conditional expectation to find the required tree metric with $\alpha = O(\log n)$. Another algorithm based on modified region growing techniques is presented in [9], and independently by Bartal.

Theorem 2 *Given an n-point metric (V, d), there exists a polynomial-time deterministic algorithm that finds a distribution $\mathcal{D}$ over $O(n \log n)$ tree metrics that $O(\log n)$-probabilistically approximates (V, d).*

Note that the tree output by the algorithm contains Steiner nodes, however Gupta [10] showed how to find another tree metric without Steiner nodes while preserving all distances within a constant factor.

Applications

Metric approximation by random trees has applications in on-line and distributed computation, since randomization works well against oblivious adversaries, and trees are easy to work with and maintain. Alon et al. [1] first used tree embedding to give a competitive algorithm for the k-server problem. Bartal [3] noted a few problems in his paper: metrical task system, distributed paging, distributed k-server problem, distributed queuing, and mobile user.

After the paper by Bartal in 1996, numerous applications in approximation algorithms have been found. Many approximation algorithms work for problems on tree metrics or HST metrics. By approximating general metrics with these metrics, one can turn them into algorithms for general metrics, while, usually, losing only a factor of $O(\log n)$ in the approximation factors. Sample problems are metric labeling, buy-at-bulk network design, and group Steiner trees. Recent applications include an approximation algorithm to the Unique Games [12], information network design [13], and oblivious network design [11].

The SIGACT News article [8] is a review of the metric approximation by tree metrics with more detailed discussion on developments and techniques. See also [3, 9], for other applications.

Open Problems

Given a metric induced by a graph, some application, e.g., solving a certain class of linear systems, does not only require a tree metric, but a tree metric induced by a spanning tree of the graph. Elkin, Emek, Spielman, and Teng [7] gave an algorithm for finding a spanning tree with average distortion of $O(\log^2 n \log\log n)$. It remains open if this bound is tight.

Problem Definition

The diameter of a graph is the largest distance between its vertices. Closely related to the diameter is the radius of the graph. The center of a graph is a vertex that minimizes the maximum distance to all other nodes, and the radius is the distance from the center to the node furthest from it. Being able to compute the diameter, center, and radius of a graph efficiently has become an increasingly important problem in the analysis of large networks [11]. For general weighted graphs the only known way to compute the exact diameter and radius is by solving the all-pairs shortest paths problem (APSP). Therefore, a natural question is whether it is possible to get faster diameter and radius algorithms by settling for an approximation. For a graph G with diameter D, a c-approximation of D is a value $\hat{D}$ such that $\hat{D} \in [D/c, D]$. The question is whether a c-approximation can be computed in sub-cubic time.

Key Results

For *sparse* directed or undirected unweighted graphs, the best-known algorithm (ignoring polylogarithmic factors) for APSP, diameter, and radius does breadth-first search (BFS) from every node and hence runs in $O(mn)$ time, where m is the number of edges in the graph. For dense directed *unweighted* graphs, it is possible to compute both the diameter and the radius using fast matrix multiplication (this is folklore; for a recent simple algorithm, see [5]), thus obtaining $\tilde{O}(n^{\omega})$ time algorithms, where $\omega < 2.38$ is the matrix multiplication exponent [4, 9, 10] and n is the number of nodes in the graph.

A 2-approximation for both the diameter and the radius of an undirected graph can be obtained in $O(m + n)$ time using BFS from an arbitrary node. For APSP, Dor et al. [6] show that any $(2 - \epsilon)$-approximation algorithm in unweighted undirected graphs running in $T(n)$ time would imply an $O(T(n))$ time algorithm for Boolean matrix multiplication (BMM). Hence a priori it could be that $(2 - \epsilon)$-approximating the diameter and radius of a graph may also require solving BMM.

Aingworth et al. [1] showed that this is not the case by presenting a sub-cubic $(2 - \epsilon)$-approximation algorithm for the diameter in both directed and undirected graphs that does not use fast matrix multiplication. Their algorithm

computes in $\tilde{O}(m\sqrt{n} + n^2)$ time an estimate $\hat{D}$ such that $\hat{D} \in [\lfloor 2D/3 \rfloor, D]$. Berman and Kasiviswanathan [2] showed that for the radius problem the approach of Aingworth et al. can be used to obtain in $\tilde{O}(m\sqrt{n} + n^2)$ time an estimate $\hat{r}$ that satisfies $r \in [\hat{r}, 3/2r]$, where r is the radius of the graph. For weighted graphs the algorithm of Aingworth et al. [1] guarantees that the estimate $\hat{D}$ satisfies $\hat{D} \in [\lfloor \frac{2}{3} \cdot D \rfloor - (M-1), D]$, where M is the maximum edge weight in the graph.

Roditty and Vassilevska Williams [8] gave a Las Vegas algorithm running in expected $\tilde{O}(m\sqrt{n})$ time that has the same approximation guarantee as Aingworth et al. for the diameter and the radius. They also showed that obtaining a $(\frac{3}{2} - \epsilon)$-approximation algorithm running in $O(n^{2-\delta})$ time in sparse undirected and unweighted graphs for constant $\epsilon, \delta > 0$ would be difficult, as it would imply a fast algorithm for CNF Satisfiability, violating the widely believed Strong Exponential Time Hypothesis of Impagliazzo, Paturi, and Zane [7].

Chechik et al. [3] showed that it is possible to remove the additive error while still keeping the running time (in terms of n) subquadratic for sparse graphs. They present two *deterministic* algorithms with $\frac{3}{2}$-approximation for the diameter, one running in $\tilde{O}(m^{\frac{3}{2}})$ time and one running in $\tilde{O}(mn^{\frac{3}{2}})$ time.

Open Problems

The main open problem is to understand the relation between the diameter computation and the APSP problem. Is there a truly sub-cubic time algorithm for computing the exact diameter or can we show sub-cubic equivalence between the exact diameter computation and APSP problem?

Another important open problem is to find an algorithm that distinguishes between graphs of diameter two to graphs of diameter three in sub-cubic time. Alternatively, can we show that it is sub-cubic equivalent to the problem of exact diameter?

Problem Definition

Spin systems are well-studied objects in statistical physics and applied probability. An instance of a spin system is an undirected graph $G = (V, E)$ of n vertices. A *configuration* of a two-state spin system, or simply just *two-spin system* on G, is an assignment $\sigma : V \to \{0, 1\}$ of two *spin states* "0" and "1" (sometimes called "–" and "+" or seen as two colors) to the vertices of G. Let $\mathbf{A} = \begin{bmatrix} A_{0,0} & A_{0,1} \\ A_{1,0} & A_{1,1} \end{bmatrix}$ be a nonnegative symmetric matrix which specifies the local interactions between adjacent vertices and $\mathbf{b} = \begin{bmatrix} b_0 \\ b_1 \end{bmatrix}$ a nonnegative vector which specifies preferences of individual vertices over the two spin states. For each configuration $\sigma \in \{0, 1\}^V$, its weight is then given by the following product:

$$w(\sigma) = \prod_{\{u,v\} \in E} A_{\sigma(u),\sigma(v)} \prod_{v \in V} b_{\sigma(v)}.$$

The *partition function* $Z_{\mathbf{A},\mathbf{b}}(G)$ of a two-spin system on G is defined to be the following exponential summation over all possible configurations:

$$Z_{\mathbf{A},\mathbf{b}}(G) = \sum_{\sigma \in \{0,1\}^V} w(\sigma).$$

Up to normalization, $\mathbf{A}$ and $\mathbf{b}$ can be described by three parameters, so that one can assume that $\mathbf{A} = \begin{bmatrix} \beta & 1 \\ 1 & \gamma \end{bmatrix}$ and $\mathbf{b} = \begin{bmatrix} \lambda \\ 1 \end{bmatrix}$, where $\beta, \gamma \geq 0$ are the *edge activities* and $\lambda > 0$ is the *external field*. Since the roles of the two spin states are symmetric, it can be further assumed that $\beta \leq \gamma$ without loss of generality. Therefore, a two-spin system is completely specified by the three parameters (β, γ, λ) where it holds that $0 \leq \beta \leq \gamma$ and $\lambda > 0$. The resulting partition function is written as $Z_{(\beta,\gamma,\lambda)}(G) = Z_{\mathbf{A},\mathbf{b}}(G)$ and as $Z(G)$ for short if the parameters are clear from the context.

The two-spin systems are classified according to their parameters into two families with distinct physical and computational properties: the *ferromagnetic* two-spin systems ($\beta\gamma > 1$) in which neighbors favor agreeing spin states and the *antiferromagnetic* two-spin systems ($\beta\gamma < 1$) in which neighbors favor disagreeing spin states. Two-spin systems with $\beta\gamma = 1$ are trivial in both physical and computational senses and thus are usually not considered. The model of two-spin systems covers some of the most extensively studied statistical physics models as special cases, as well as being accepted in computer science as a framework for counting problems, for examples:

- When $\beta = 0$, $\gamma = 1$, and $\lambda = 1$, the $Z_{(\beta,\gamma,\lambda)}(G)$ gives the number of independent sets (or vertex covers) of G.
- When $\beta = 0$ and $\gamma = 1$, the $Z_{(\beta,\gamma,\lambda)}(G)$ is the partition function of the hardcore model with fugacity λ on G.
- When $\beta = \gamma$, the $Z_{(\beta,\gamma,\lambda)}(G)$ is the partition function of the Ising model with edge activity β and external field λ on G.

Given a set of parameters (β, γ, λ), the computational problem Two-Spin(β, γ, λ) is the problem of computing the value of the partition function $Z_{(\beta,\gamma,\lambda)}(G)$ when the graph G is given as input. This problem is known to be #P-hard except for the trivial cases where $\beta\gamma = 1$ or $\beta = \gamma = 0$ [1]. Therefore, the main focus here is the efficient approximation algorithms for Two-Spin(β, γ, λ). Formally, a fully polynomial-time approximation scheme (FPTAS) is an algorithm which takes G and any $\varepsilon > 0$ as input and outputs a number $\hat{Z}$ satisfying $Z(G)\exp(-\varepsilon) \leq \hat{Z} \leq Z(G)\exp(\varepsilon)$ within time polynomial in n and $1/\varepsilon$; and a fully

polynomial-time randomized approximation scheme (FPRAS) is its randomized relaxation in which randomness is allowed and the above accuracy of approximation is required to be satisfied with high probability.

For many important two-spin systems (e.g., independent sets, antiferromagnetic Ising model), it is NP-hard to approximate the partition function on graphs of unbounded degrees. In these cases, the problem is further refined to consider the approximation algorithms for TWO-SPIN(β, γ, λ) on graphs with *bounded maximum degree*. In addition, in order to study the approximation algorithms on graphs which has bounded average degree or on special classes of lattice graphs, the approximation of partition function is studied on classes of graphs with bounded *connective constant*, a natural and well-studied notion of average degree originated from statistical physics.

Therefore, the main problem of interest is to characterize the regimes of parameters (β, γ, λ) for which there exist efficient approximation algorithms for TWO-SPIN(β, γ, λ) on classes of graphs with bounded maximum degree $\Delta_{\max}$, or on classes of graphs with bounded connective constant Δ, or on all graphs.

Key Results

Given a two-spin system on graph $G = (V, E)$, a natural probability distribution μ over all configurations $\sigma \in \{0, 1\}^V$, called the *Gibbs measure*, can be defined by $\mu(\sigma) = \frac{w(\sigma)}{Z(G)}$, where $w(\sigma) = \prod_{\{u,v\}\in E} A_{\sigma_u,\sigma_v} \prod_{v\in V} b_{\sigma_v}$ is the weight of σ and the normalizing factor $Z(G)$ is the partition function.

The Gibbs measure defines a marginal distribution at each vertex. Suppose that a configuration σ is sampled according to the Gibbs measure μ. Let p_v denote the probability of vertex v having spin state "0" in σ; and for a fixed configuration $\tau_\Lambda \in \{0, 1\}^\Lambda$ partially specified over vertices in $\Lambda \subset V$, let $p_v^{\tau_\Lambda}$ denote the probability of vertex v having spin state "0" conditioning on that the configuration of vertices in Λ in σ is as specified by τ_Λ.

The marginal probability plays a key role in computing the partition function. Indeed, the marginal probability $p_v^{\tau_\Lambda}$ itself is a quantity of main interest in many applications such as probabilistic inference. In addition, due to the standard procedure of self-reduction, an FPTAS for the partition function $Z(G)$ can be obtained if the value of $p_v^{\tau_\Lambda}$ can be approximately computed with an additive error ε in time polynomial in both n and $1/\varepsilon$. This reduces the problem of approximating the partition function (with multiplicative errors) to approximating the marginal probability (with additive errors), which is achieved either by rapidly mixing random walks or by recursions exhibiting a decay of correlation.

Ferromagnetic Two-Spin Systems

For the ferromagnetic case, the problem TWO-SPIN(β, γ, λ) is considered for $\beta\gamma > 1$ and without loss of generality for $\beta \le \gamma$.

In a seminal work [3], Jerrum and Sinclair gave an FPRAS for approximately computing the partition function of the ferromagnetic Ising model, which is the TWO-SPIN(β, γ, λ) problem with $\beta = \gamma > 1$.

The algorithm uses the Markov chain Monte Carlo (MCMC) method; however very interestingly, it does not directly apply the random walk over configurations of two-spin system since such random walk might have a slow mixing time. Instead, it first transforms the two-spin system into configurations of the so-called "subgraphs world": each such configuration is a subgraph of G. A random walk over the subgraph configurations is applied and proved to be rapidly mixing for computing the new partition function defined over subgraphs, which is shown to be equal to the partition function $Z(G)$ of the two-spin system. This equivalence is due to that this transformation between the "spins world" and the "subgraphs world" is actually a holographic transformation, which is guaranteed to preserve the value of the partition function.

The result of [3] can be stated as the following theorem.

Theorem 1 *If $\beta = \gamma > 1$ and $\lambda > 0$, then there is an FPRAS for* TWO-SPIN(β, γ, λ).

The algorithm actually works for a stronger setting where the external fields are local (vertices have different external fields) as long as the external fields are homogeneous (all have the same preference over spin states).

For the two-spin system with general β and γ, one can translate it to the Ising model where $\beta = \gamma$ by delegating the effect of the general β, γ to the degree-dependent effective external fields. This extends the FPRAS for the ferromagnetic Ising model to certain regime of ferromagnetic two-spin systems, stated as follows.

Theorem 2 ([2, 6]) *If $\beta < \gamma$, $\beta\gamma > 1$, and $\lambda \leq \gamma/\beta$, then there is an FPRAS for* TWO-SPIN(β, γ, λ).

If one is restricted to the deterministic algorithms for approximating the partition function, then a deterministic FPTAS is known for a strictly smaller regime, implicitly stated in the following theorem.

Theorem 3 ([7]) *There is a continuous monotonically increasing function $\Gamma(\gamma)$ defined on $[1, +\infty)$ satisfying (1) $\Gamma(1) = 1$, (2) $1 < \Gamma(\gamma) < \gamma$ for all $\gamma > 1$, and (3) $\lim_{\gamma \to +\infty} \frac{\Gamma(\gamma)}{\gamma} = 1$, such that there is an FPTAS for* TWO-SPIN(β, γ, λ) *if $\beta\gamma > 1$, $\beta \leq \Gamma(\gamma)$, and $\lambda \leq 1$.*

This deterministic FPTAS uses the same holographic transformation from two-spin systems to the "subgraphs world" as in [3], and it approximately computes the marginal probability defined in the subgraphs world by a recursion. The accuracy of the approximation is guaranteed by the decay of correlation. This technique is more extensively and successfully used for the antiferromagnetic two-spin systems.

On the other hand, assuming certain complexity assumptions, it is unlikely that for every ferromagnetic two-spin system its partition function is easy to approximate.

Theorem 4 ([6]) *For any $\beta < \gamma$ with $\beta\gamma > 1$, there is a λ_0 such that* TWO-SPIN(β, γ, λ) *is* #BIS*-hard for all $\lambda \geq \lambda_0$.*

Antiferromagnetic Two-Spin Systems

For the antiferromagnetic case, the problem TWO-SPIN(β, γ, λ) is considered for $\beta\gamma < 1$ and without loss of generality for $\beta \leq \gamma$.

In [2], a heatbath random walk over spin configurations is applied to obtain an FPRAS for TWO-SPIN(β, γ, λ) for a regime of antiferromagnetic two-spin systems.

The regime of antiferromagnetic two-spin systems whose partition function is efficiently approximable is characterized by the *uniqueness condition*.

Given parameters (β, γ, λ) and $d \geq 1$, the *tree recursion* $f(x)$ is given by

$$f(x) = \lambda \left(\frac{\beta x + 1}{x + \gamma} \right)^d. \tag{1}$$

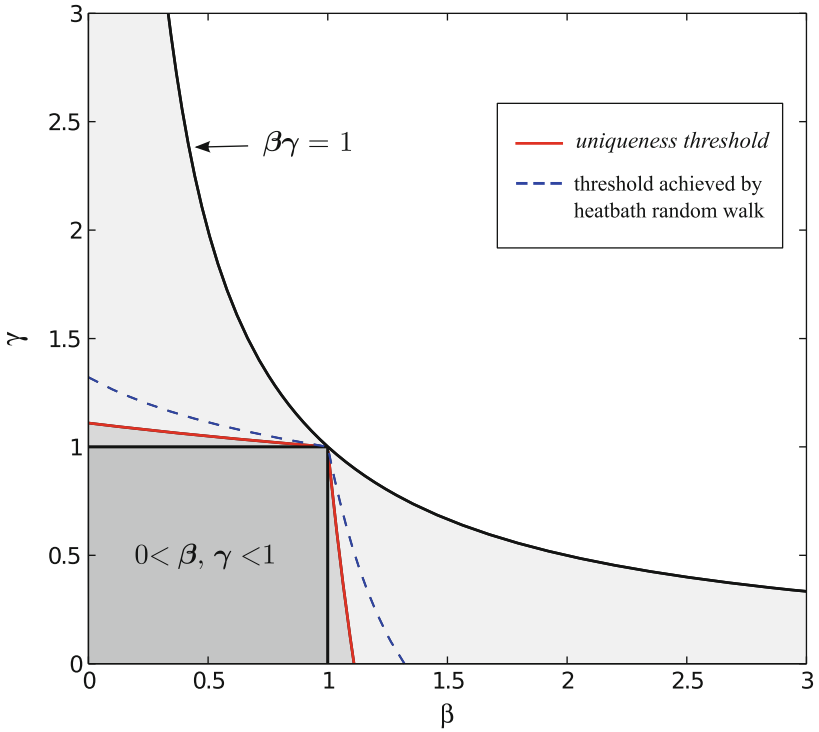
For antiferromagnetic (β, γ, λ), the function $f(x)$ is decreasing in x; thus, there is a unique positive fixed point $\hat{x}$ satisfying $\hat{x} = f(\hat{x})$. Consider the absolute derivative of $f(x)$ at the fixed point:

$$\left| f'(\hat{x}) \right| = \frac{d(1 - \beta\gamma)\hat{x}}{(\beta\hat{x} + 1)(\hat{x} + \gamma)}.$$

Definition 1 Let $0 \leq \beta \leq \gamma$, $\beta\gamma < 1$, and $d \geq 1$. The *uniqueness condition* UNIQUE$(\beta, \gamma, \lambda, d)$ is satisfied if $|f'(\hat{x})| < 1$; and the condition NON-UNIQUE$(\beta, \gamma, \lambda, d)$ is satisfied if $|f'(\hat{x})| > 1$.

The condition UNIQUE$(\beta, \gamma, \lambda, d)$ holds if and only if the dynamical system (1) converges to its unique fixed point $\hat{x}$ at an exponential rate. The name uniqueness condition is due to that UNIQUE$(\beta, \gamma, \lambda, d)$ implies the uniqueness of the Gibbs measure of two-spin system of parameters (β, γ, λ) on the Bethe lattice (i.e., the infinite d-regular tree) and NON-UNIQUE$(\beta, \gamma, \lambda, d)$ implies that there are more than one such measures (Fig. 1).

Efficient approximation algorithms for TWO-SPIN(β, γ, λ) are discovered for special cases of antiferromagnetic two-spin systems within the uniqueness regime, including the hardcore model [12], the antiferromagnetic Ising model [8], and the antiferromagnetic two-spin



Approximating the Partition Function of Two-Spin Systems, Fig. 1 The regime of (β, γ) for which the uniqueness condition UNIQUE$(\beta, \gamma, \lambda, d)$ holds for $\lambda = 1$ and for all integer $d \geq 1$

systems without external field [4], and finally for all antiferromagnetic two-spin systems within the uniqueness regime [5].

Theorem 5 ([5]) *For* $0 \leq \beta \leq \gamma$ *and* $\beta\gamma < 1$, *there is an FPTAS for* TWO-SPIN(β, γ, λ) *on graphs of maximum degree at most* $\Delta_{\max}$ *if* UNIQUE$(\beta, \gamma, \lambda, d)$ *holds for all integer* $1 \leq d \leq \Delta_{\max} - 1$.

This algorithmic result for graphs of bounded maximum degree can be extended to graphs of unbounded degrees.

Theorem 6 ([4, 5]) *For* $0 \leq \beta \leq \gamma$ *and* $\beta\gamma < 1$, *there is an FPTAS for* TWO-SPIN(β, γ, λ) *if* UNIQUE$(\beta, \gamma, \lambda, d)$ *holds for all integer* $d \geq 1$.

All these algorithms follow the framework introduced by Weitz in his seminal work [12]. In this framework, the marginal probability $p_v^{\tau\Lambda}$ is computed by applying the tree recursion (1) on the *tree of self-avoiding walks*, (In fact, (1) is the recursion for the ratio $p_v^{\tau\Lambda}/(1 - p_v^{\tau\Lambda})$ of marginal probabilities.) which enumerates all paths originated from vertex v. Then, a decay of correlation, also called the *spatial mixing* property, is verified, so that a truncated recursion tree of polynomial size is sufficient to provide the required accuracy for the estimation of the marginal probability. For graphs of unbounded degrees, a stronger notion of decay of correlation, called the *computationally efficient correlation decay* [4], is verified to enforce the same cost and accuracy even when the branching number of the recursion tree is unbounded.

On the other hand, for antiferromagnetic two-spin systems in the nonuniqueness regime, the partition function is hard to approximate.

Theorem 7 ([11]) *Let* $0 \leq \beta \leq \gamma$ *and* $\beta\gamma < 1$. *For any* $\Delta_{\max} \geq 3$, *unless* $NP = RP$, *there does not exist an FPRAS for* TWO-SPIN(β, γ, λ) *on graphs of maximum degree at most* $\Delta_{\max}$ *if* NON-UNIQUE$(\beta, \gamma, \lambda, d)$ *holds for some integer* $1 \leq d \leq \Delta_{\max} - 1$.

Altogether, this gives a complete classification of the approximability of partition function of antiferromagnetic two-spin systems except for the uniqueness threshold.

Algorithms for Graphs with Bounded Connective Constant

The *connective constant* is a natural and well-studied notion of the average degree of a graph, which, roughly speaking, measures the growth rate of the number of self-avoiding walks in the graph as their length grows. As a quantity originated from statistical physics, the connective constant has been especially well studied for various infinite regular lattices. In order to suit the algorithmic applications, the definition of connective constant was extended in [9] to families of finite graphs.

Given a vertex v in a graph G, let $N(v, l)$ denote the number of self-avoiding walks of length ℓ in G which start at v.

Definition 2 ([9]) Let $\mathcal{G}$ be a family of finite graphs. The connective constant of $\mathcal{G}$ is at most Δ if there exist constants a and c such that for any graph $G = (V, E)$ in $\mathcal{G}$ and any vertex v in G, it holds that $\sum_{i=1}^{\ell} N(v, i) \leq c\Delta^{\ell}$ for all $\ell \geq a \log |V|$.

The connective constant has a natural interpretation as the "average arity" of the tree of self-avoiding walks.

For certain antiferromagnetic two-spin systems, it is possible to establish the desirable decay of correlation on the tree of self-avoiding walks with bounded average arity instead of maximum arity, and hence the arity d in the uniqueness condition $\text{UNIQUE}(\beta, \gamma, \lambda, d)$ can be replaced with the connective constant Δ. The algorithmic implication of this is stated as the following theorem.

Theorem 8 ([10]) *For the following two cases:*

- *(The hardcore model) $\beta = 0$ and $\gamma = 1$;*
- *(The antiferromagnetic Ising model with zero field) $\beta = \gamma < 1$ and $\lambda = 1$;*

there exists an FPTAS for $\text{TWO-SPIN}(\beta, \gamma, \lambda)$ *on graphs of connective constant at most Δ if* $\text{UNIQUE}(\beta, \gamma, \lambda, \Delta)$ *holds.*

For the two-spin systems considered by this theorem, it holds that $\text{UNIQUE}(\beta, \gamma, \lambda, \Delta)$ implies $\text{UNIQUE}(\beta, \gamma, \lambda, d)$ for all $1 \leq d \leq \Delta$.

The connective constant of a graph of maximum degree $\Delta_{\max}$ is at most $\Delta_{\max} - 1$, but the connective constant of a family of graphs can be much smaller than this crude bound. For example, though the maximum degree of a graph drawn from the Erdös-Rényi model $G(n, d/n)$ is $\Theta(\log n / \log \log n)$ with high probability, the connective constant of such a graph is at most $d(1 + \varepsilon)$ with high probability for any fixed $\varepsilon > 0$. Therefore, for the considered two-spin systems, the algorithm in Theorem 8 works on strictly more general families of graphs than that of Theorem 5.

Approximation Schemes for Bin Packing

Nikhil Bansal

Keywords

Cutting-stock problem

Years and Authors of Summarized Original Work

1982; Karmarker, Karp

Problem Definition

In the bin-packing problem, the input consists of a collection of items specified by their sizes. There are also identical bins, which without loss of generality can be assumed to be of size 1, and the goal is to pack these items using the minimum possible number of bins.

Bin packing is a classic optimization problem, and hundreds of its variants have been defined and studied under various settings such as average case analysis, worst-case off-line analysis, and worst-case online analysis. This note considers the most basic variant mentioned above under the off line model where all the items are given in advance. The problem is easily seen to be NP-hard by a reduction from the partition problem. In fact, this reduction implies that unless P = NP, it is impossible to determine in polynomial time whether the items can be packed into two bins or whether they need three bins.

Notations

The input to the bin-packing problem is a set of n items I specified by their sizes $s_1, \ldots, s_n$, where each s_i is a real number in the range (0,1]. A subset of items $S \subseteq I$ can be packed feasibly in a bin if the total size of items in S is at most 1. The goal is to pack all items in I into the minimum number of bins. Let $\mathrm{OPT}(I)$ denote the value of the optimum solution and $\mathrm{Size}(I)$ the total size of all items in I. Clearly, $\mathrm{OPT}(I) \geq \lceil \mathrm{Size}(I) \rceil$.

Strictly speaking, the problem does not admit a polynomial-time algorithm with an approximation guarantee better than 3/2. Interestingly, however, this does not rule out an algorithm that requires, say, $\mathrm{OPT}(I) + 1$ bins (unlike other optimization problems, making several copies of a small hard instance to obtain a larger hard instance does not work for bin packing). It is more meaningful to consider approximation guarantees in an asymptotic sense. An algorithm is called an asymptotic ρ approximation if the number of bins required by it is $\rho \cdot \mathrm{OPT}(I) + O(1)$.

Key Results

During the 1960s and 1970s, several algorithms with constant factor asymptotic and absolute approximation guarantees and very efficient running times were designed (see [1] for a survey). A breakthrough was achieved in 1981 by de la Vega and Lueker [3], who gave the first polynomial-time asymptotic approximation scheme.

Theorem 1 ([3]) *Given any arbitrary parameter $\epsilon > 0$, there is an algorithm that uses $(1 + \epsilon)OPT(I) + O(1)$ bins to pack I. The running*

time of this algorithm is $O(n \log n) + (1 + \epsilon)^{O(1/\epsilon)}$.

The main insight of de la Vega and Lueker [3] was to give a technique for approximating the original instance by a simpler instance where large items have only $O(1)$ distinct sizes. Their idea was simple. First, it suffices to restrict attention to large items, say, with size greater than ε. These can be called I_b. Given an (almost) optimum packing of I_b, consider the solution obtained by greedily filling up the bins with remaining small items, opening new bins only if needed. Indeed, if no new bins are needed, then the solution is still almost optimum since the packing for I_b was almost optimum. If additional bins are needed, then each bin, except possibly one, must be filled to an extent $(1 - \epsilon)$, which gives a packing using $\text{Size}(I)/(1 - \epsilon) + 1 \leq \text{OPT}(I)/(1 - \epsilon) + 1$ bins. So it suffices to focus on solving I_b almost optimally. To do this, the authors show how to obtain another instance I' with the following properties. First, I' has only $O(1/\epsilon^2)$ distinct sizes, and second, I' is an approximation of I_b in the sense that $\text{OPT}(I_b) \geq \text{OPT}(I')$, and moreover, any solution of I' implies another solution of I_b using $O(\epsilon \cdot \text{OPT}(I))$ additional bins. As I' has only $1/\epsilon^2$ distinct item sizes, and any bin can obtain at most $1/\epsilon$ such items, there are at most $O\left(1/\epsilon^2\right)^{1/\epsilon}$ ways to pack a bin. Thus, I' can be solved optimally by exhaustive enumeration (or more efficiently using an integer programming formulation described below).

Later, Karmarkar, and Karp [4] proved a substantially stronger guarantee.

Theorem 2 ([4]) *Given an instance I, there is an algorithm that produces a packing of I using* $\text{OPT}(I) + O(\log^2 \text{OPT}(I))$ *bins. The running time of this algorithm is* $O(n^8)$.

Observe that this guarantee is significantly stronger than that of [3] as the additive term is $O(\log^2 \text{OPT})$ as opposed to $o(\epsilon \cdot \text{OPT})$. Their algorithm also uses the ideas of reducing the number of distinct item sizes and ignoring small items, but in a much more refined way. In particular, instead of obtaining a rounded instance in a single step, their algorithm consists of a logarithmic number of steps where in each step they round the instance "mildly" and then solve it partially.

The starting point is an exponentially large linear programming (LP) relaxation of the problem commonly referred to as the configuration LP. Here, there is a variable x_S corresponding to each subset of items S that can be packed feasibly in a bin. The objective is to minimize $\sum_S x_S$ subject to the constraint that for each item i, the sum of x_S over all subsets S that contain i is at least 1. Clearly, this is a relaxation as setting $x_S = 1$ for each set S corresponding to a bin in the optimum solution is a feasible integral solution to the LP. Even though this formulation has exponential size, the separation problem for the dual is a knapsack problem, and hence the LP can be solved in polynomial time to any accuracy (in particular within an accuracy of 1) using the ellipsoid method. Such a solution is called a fractional packing. Observe that if there are n_i items each of size exactly s_i, then the constraints corresponding to i can be "combined" to obtain the following LP:

$$\begin{aligned} & \min \sum_S x_S \\ \text{s.t.} \quad & \sum_S a_{S,i} x_S \geq n_i \qquad \forall \text{item sizes } i \\ & x_S \geq 0 \qquad\qquad \forall \text{ feasible sets } S. \end{aligned}$$

Here, $a_{S,i}$ is the number of items of size s_i in the feasible S. Let $q(I)$ denote the number of distinct sizes in I. The number of nontrivial constraints in LP is equal to $q(I)$, which implies that there is a basic optimal solution to this LP that has only $q(I)$ variables set nonintegrally. Karmarkar and Karp exploit this observation in a very clever way. The following lemma describes the main idea.

Lemma 1 *Given any instance J, suppose there is an algorithmic rounding procedure to obtain another instance J' such that J' has* $\text{Size}(J)/2$ *distinct item sizes and J and J' are related in the following sense: given any fractional packing of J using ℓ bins gives a fractional packing of J' with at most ℓ bins, and given any packing of J' using ℓ' bins gives a packing of J using $\ell' + c$*

bins, where c is some fixed parameter. Then, J can be packed using $\mathrm{OPT}(J) + c \cdot \log(\mathrm{OPT}(J))$ *bins.*

Proof Let $I_0 = I$ and let I_1 be the instance obtained by applying the rounding procedure to I_0. By the property of the rounding procedure, $\mathrm{OPT}(I) \leq \mathrm{OPT}(I_1) + c$ and $\mathrm{LP}(I_1) \leq \mathrm{LP}(I)$. As I_1 has $\mathrm{Size}(I_0)/2$ distinct sizes, the LP solution for I_1 has at most $\mathrm{Size}(I_0)/2$ fractionally set variables. Remove the items packed integrally in the LP solution, and consider the residual instance I_1'. Note that $\mathrm{Size}(I_1') \leq \mathrm{Size}(I_0)/2$. Now, again apply the rounding procedure to I_1' to obtain I_2 and solve the LP for I_2. Again, this solution has at most $\mathrm{Size}(I_1')/2 \leq \mathrm{Size}(I_0)/4$ fractionally set variables and $\mathrm{OPT}(I_1') \leq \mathrm{OPT}(I_2) + c$ and $\mathrm{LP}(I_2) \leq \mathrm{LP}(I_1')$. The above process is repeated for a few steps. At each step, the size of the residual instance decreases by a factor of at least two, and the number of bins required to pack I_0 increases by additive c. After $\log(\mathrm{Size}(I_0))(\approx \log(\mathrm{OPT}(I)))$ steps, the residual instance has size $O(1)$ and can be packed into $O(1)$ additional bins. □

It remains to describe the rounding procedure. Consider the items in nondecreasing order $s_1 \geq s_2 \geq \cdots \geq s_n$ and group them as follows. Add items to current group until its size first exceeds 2. At this point, close the group and start a new group. Let $G_1, \ldots, G_k$ denote the groups formed and let $n_i = |G_i|$, setting $n_0 = 0$ for convenience. Define I' as the instance obtained by rounding the size of n_{i-1} largest items in G_i to the size of the largest item in G_i for $i = 1, \ldots, k$. The procedure satisfies the properties of Lemma 1 with $c = O(\log n_k)$ (left as an exercise to the reader). To prove Theorem 2, it suffices to show that $n_k = O(\mathrm{Size}(I))$. This is done easily by ignoring all items smaller than $1/\mathrm{Size}(I)$ and filling them in only in the end (as in the algorithm of de la Vega and Lueker).

In the case when the item sizes are not too small, the following corollary is obtained.

Corollary 1 *If all the item sizes are at least δ, it is easily seen that $c = O(\log 1/\delta)$, and the above algorithm implies a guarantee of* $\mathrm{OPT} + O(\log(1/\delta) \cdot \log \mathrm{OPT})$, *which is* $\mathrm{OPT} + O(\log\ \mathrm{OPT})$ *if δ is a constant.*

Recently, Rothvoss gave the first improvement to the result of Karmarkar and Karp and improve their additive guarantee from $\mathrm{O}(\log^2 \mathrm{Opt})$ to O(log Opt log log Opt). His algorithm also uses the configuration LP solution and is based on several new ideas and recent developments. First is the connection of bin packing to a problem in discrepancy theory known as the k-permutation problem. Second are the recently developed algorithmic approaches for addressing discrepancy minimization problems.

In addition to these, a key idea in Rothvoss' algorithm is to glue several small items contained in a configuration into a new large item. For more details, we refer the reader to [5].

Applications

The bin-packing problem is directly motivated from practice and has many natural applications such as packing items into boxes subject to weight constraints, packing files into CDs, packing television commercials into station breaks, and so on. It is widely studied in operations research and computer science. Other applications include the so-called cutting-stock problems where some material such as cloth or lumber is given in blocks of standard size from which items of certain specified size must be cut. Several variations of bin packing, such as generalizations to higher dimensions, imposing additional constraints on the algorithm and different optimization criteria, have also been extensively studied. The reader is referred to [1, 2] for excellent surveys.

Open Problems

Except for the NP-hardness, no other hardness results are known, and it is possible that a polynomial-time algorithm with guarantee OPT + 1 exists for the problem. Resolving this is a key open question. A promising approach seems to be via the configuration LP (considered above).

In fact, no instance is known for which the additive gap between the optimum configuration LP solution and the optimum integral solution is more than 1. It would be very interesting to design an instance that has an additive integrality gap of two or more.

1999: Mitchell
1998; Rao, Smith

Problem Definition

Geometric network optimization is the problem of computing a network in a geometric space (e.g., the Euclidean plane), based on an input of geometric data (e.g., points, disks, polygons/polyhedra) that is optimal according to an objective function that typically involves geometric measures, such as Euclidean length, perhaps in addition to combinatorial metrics, such as the number of edges in the network. The desired network is required to have certain properties, such as being connected (or k-connected), having a specific topology (e.g., forming a path/cycle), spanning at least a certain number of input objects, etc.

One of the most widely studied optimization problems is the traveling salesperson problem (TSP): given a set S of n *sites* (e.g., cities), and distances between each pair of sites, determine a route or *tour* of minimum length that visits every member of S. The (symmetric) TSP is often formulated in terms of a graph optimization problem on an edge-weighted complete graph K_n, and the goal is to determine a Hamiltonian cycle (a cycle visiting each vertex exactly once), or a *tour*, of minimum total weight. In geometric settings, the sites are often points in the plane with distances measured according to the Euclidean metric.

The TSP is known to be NP-complete in graphs and NP-hard in the Euclidean plane. Many methods of combinatorial optimization, as well as heuristics, have been developed and applied successfully to solving to optimality instances of TSP; see Cook [7]. Our focus here is on provable approximation algorithms.

In the context of the TSP, a minimization problem, a c-approximation algorithm is an algorithm guaranteed to yield a solution whose objective function value (length) is guaranteed to be at most c times that of an optimal solution. A *polynomial-time approximation scheme* (PTAS) is a family of c-approximation algorithms, with $c = 1 + \varepsilon$, that runs in polynomial (in input size) time for any fixed $\varepsilon > 0$. A *quasi-polynomial-time approximation scheme* (QPTAS) is an approximation scheme, with factor $c = 1 + \varepsilon$ for any fixed $\varepsilon > 0$, whose running time is *quasi-polynomial*, $2^{O((\log n)^C)}$, for some C.

In the Euclidean *Steiner minimum spanning tree* (SMST) problem, the objective is to compute a minimum total length tree that spans all of the input points S, allowing nodes of the tree to be at points of the Euclidean space other than S (such points are known as *Steiner points*). The Euclidean SMST is known to be NP-hard, even in the plane.

Key Results

A simple 2-approximation algorithm for TSP follows from a "doubling" of a minimum spanning tree, assuming that the distances obey the triangle inequality. By augmenting the minimum spanning tree with a minimum-weight matching on the odd-degree nodes of the tree, Christofides obtained a 1.5-approximation for TSP with triangle inequality. This is the currently best-known approximation for general metric spaces; an outstanding open conjecture is that a 4/3-approximation (or better) may be possible. It is known that the TSP in a general metric space is APX-complete, implying that, unless P = NP, no PTAS exists, in general.

Research has shown that "geometry helps" in network optimization problems. Geometric structure has played a key role in solving combinatorial optimization problems. There are problems that are NP-hard in their abstract generality, yet are solvable exactly in polynomial time in geometric settings (e.g., maximum TSP in polyhedral metrics), and there are problems for which we have substantially better, or more efficient, approximation algorithms in geometric settings (e.g., TSP).

As shown by Arora [1] and Mitchell [10] in papers originally appearing in 1996, geometric instances of TSP and SMST have special structure that allows for the existence of a PTAS. Arora [1] gives a randomized algorithm that, with probability 1/2, yields a $(1 + \varepsilon)$-approximate tour in time $n(\log n)^{O(\sqrt{d}/\varepsilon)^{d-1}}$ in Euclidean d-space. Rao and Smith [14] obtain a deterministic algorithm with running time $2^{(d/\varepsilon)^{O(d)}} n + (d/\varepsilon)^{O(d)} n \log n$. This $O(n \log n)$ bound (for fixed d, ε) matches the $\Omega(n \log n)$ lower bound in the decision tree bound. In the real RAM model, with atomic floor or mod function, Bartal and Gottlieb [3] give a randomized linear-time PTAS that, with probability $1 - e^{-O(n^{1/3d})}$, computes a $(1 + \varepsilon)$-approximation to an optimal tour in time $2^{(d/\varepsilon)^{O(d)}} n$. The exponential dependence on d in the PTAS bounds is essentially best possible, since Trevisan has shown that if $d \geq \log n$, it is NP-hard to obtain a $(1 + \varepsilon)$-approximation.

A key insight of Rao and Smith is the application of the concept of "spanners" to the approximation schemes. A connected subgraph G of the complete Euclidean graph, joining every pair of points in S (within Euclidean d-dimensional space), is said to be a *t-spanner* for S if all points of S are nodes of G and, for any points $u, v \in S$, the length of a shortest path in G from u to v is at most t times the Euclidean distance, $d_2(u, v)$. It is known that for any point set S and $t > 1$, t-spanners exist and can be calculated in time $O(n \log n)$, with the property that the t-spanner is *lightweight*, meaning that the sum of its edge lengths is at most a constant factor (depending on d and t) greater than the Euclidean length of a minimum spanning tree on S.

Overview of Methods

The PTAS techniques are based on structure theorems showing that an optimal solution can be "rounded" to a "nearby" solution, of length at most a factor $(1 + \varepsilon)$ longer, that falls within a special class of recursively "nice" solutions for which optimization via dynamic programming

can be done efficiently, because the interface between adjacent subproblems is "small" combinatorially. Arora's algorithm [1] is randomized, as is that of Rao and Smith [14]; both can be derandomized. The m-guillotine method (Mitchell [10]) is directly a deterministic method; however, the proof of its structure theorem is effectively an averaging argument.

Arora's Dissection Method

Arora [1, 2] gives a method based on geometric dissection using a quadtree (or its octtree analogue in d dimensions). On the boundary of each quadtree square are m equally spaced points ("portals"); a *portal-respecting tour* is one that crosses the boundaries of squares only at portals. Using an averaging argument based on a randomly shifted quadtree that contains the bounding square of S, Arora proves structure theorems, the simplest of which shows that, when $m > (\log n)/\epsilon$, the expected length of a shortest portal-respecting tour, T, is at most $(1+\epsilon)$ times the length of an optimal tour. Within a quadtree square, T consists of at most m disjoint paths that together visit all sites within the square. Since the interface data specifying a subproblem has size $2^{O(m)}$, dynamic programming computes a shortest portal-respecting tour in time $2^{(O(m)}$ per quadtree square, for overall time $2^{O((\log n)/\epsilon)} = n^{O(1/\epsilon)}$. An improved, near-linear (randomized) running time is obtained via a stronger structure theorem, based on "(m,k)-light" tours, which are portal respecting and enter/leave each square at most k times (with $k = O(1/\varepsilon)$). Rao and Smith's improvement uses the observation that it suffices to restrict the algorithm to use edges of a $(1+\varepsilon)$-spanner.

The m-Guillotine Method

The m-guillotine method of Mitchell [10] is based on the notion of an *m-guillotine structure*. A geometric graph G in the plane has the m-guillotine structure if the following holds: either (1) G has $O(m)$ edges or (2) there exists a *cut* by an axis-parallel line ℓ such that the intersection of ℓ with the edge set of G has $O(m)$ connected components and the subgraphs of G on each side of the cut recursively also have the m-guillotine structure. The m-guillotine structure is defined in dimensions $d > 2$ as well, using hyperplane cuts orthogonal to the coordinate axes.

The m-guillotine structure theorem in 2 dimensions states that, for any positive integer m, a set E of straight line segments in the plane is either m-guillotine already or is "close" to being m-guillotine, in that there exists a superset, $E_m \supset E$ that has m-guillotine structure, where E_m is obtained from E by adding a set of axis-parallel segments (*bridges*, or *m-spans*) of total length at most $O(\varepsilon|E|)$. The proof uses a simple charging scheme.

The m-guillotine method originally (1996) yielded a PTAS for TSP and related problems in the plane, with running time $n^{O(1/\epsilon)}$; this was improved (1997) to $n^{O(1)}$. With the injection of the idea of Rao and Smith [14] to employ spanners, the m-guillotine method yields a simple, deterministic $O(n \log n)$ time PTAS for TSP and related problems in fixed dimension $d \geq 2$. The steps are the following: (a) construct (in $O(n \log n)$ time) a spanner, T; (b) compute its m-guillotine superset, T_m, by standard sweep techniques (in time $O(n \log n)$); and (c) use dynamic programming (time $O(n)$) applied to the recursive tree associated with T_m, to optimize over spanning subgraphs of T_m.

Generalizations to Other Metrics

The PTAS techniques described above have been significantly extended to variants of the Euclidean TSP. While we do not expect that a PTAS exists for general metric spaces (because of APX-hardness), the methods can be extended to a very broad class of "geometric" metrics known as *doubling metrics*, or metric spaces of bounded *doubling dimension*. A metric space $\mathcal{X}$ is said to have *doubling constant* c_d if any ball of radius r can be covered by c_d balls of radius $r/2$; the logarithm of c_d is the *doubling dimension* of $\mathcal{X}$. Euclidean d-space has doubling dimension $O(d)$. Bartal, Gottlieb, and Krauthgamer [4] have given a PTAS for TSP in doubling metrics, improving on a prior QPTAS.

For the discrete metric space induced by an edge-weighted planar graph, the TSP has a linear-time PTAS. The *subset TSP* for edge-weighted

planar graphs, in which there is a subset $S \subseteq V$ of the vertex set V that must be visited, also has an efficient ($O(n \log n)$ time) PTAS; this implies a PTAS for the *geodesic metric* for TSP on a set S of sites in a polygonal domain in the plane, with distances given by the (Euclidean) lengths of geodesic shortest paths between pairs of sites.

Applications to Network Optimization

The approximation schemes we describe above have been applied to numerous geometric network optimization problems, including the list below. We do not give references for most of the results summarized below; see the surveys [2, 11, 12] and Har-Peled [9].

1. A PTAS for the Euclidean Steiner minimum spanning tree (SMST) problem.
2. A PTAS for the Euclidean minimum Steiner forest problem, in which one is to compute a minimum-weight forest whose connected components (Steiner trees) span given (disjoint) subsets $S_1, \ldots, S_K \subset S$ of the sites, allowing Steiner points.
3. A PTAS for computing a minimum-weight k-connected spanning graph of S in Euclidean d-space.
4. A PTAS for the *k-median problem*, in which one is to determine k *centers*, among S, in order to minimize the sum of the distances from the sites S to their nearest center points.
5. A PTAS for the *minimum latency problem* (MLP), also known as the *deliveryman problem* or the *traveling repairman problem*, in which one is to compute a tour on S that minimizes the sum of the "latencies" of all points, where the *latency* of a point p is the length of the tour from a given starting point to the point p. The PTAS of Sitters [15] runs in time $n^{O(1/\epsilon)}$, improving the prior QPTAS.
6. A PTAS for the k-TSP (and k-MST), in which one is to compute a shortest tour (tree) spanning at least k of the n sites of S.
7. A QPTAS for degree-bounded spanning trees in the plane.
8. A QPTAS for the capacitated vehicle routing problem (VRP) [8], in which one is to compute a minimum-length collection of tours, each visiting at most k sites of S. A PTAS is known for some values of k.
9. A PTAS for the *orienteering problem*, in which the goal is to maximize the number of sites visited by a length-bounded tour [6].
10. A PTAS for *TSP with Neighborhoods* (TSPN), in which each site of the input set S is a connected region of d-space (rather than a point), and the goal is to compute a tour that visits each region. The TSPN has a PTAS for regions in the plane that are "fat" and are weakly disjoint (no point lies in more than a constant number of regions) [13]. Chan and Elbassioni [5] give a QPTAS for fat, weakly disjoint regions in doubling metrics. For TSPN with disconnected regions, the problem is that of the "group TSP" (also known as "generalized TSP" or "one-of-a-set TSP"), which, in general metrics, is much harder than TSP; even in the Euclidean plane, the problem is NP-hard to approximate to within any constant factor for finite point sets and is NP-hard to approximate better than a fixed constant for visiting point pairs.
11. A PTAS for the *milling* and *lawnmowing* problems, in which one is to compute a shortest path/tour for a specified cutter so that all points of a given region R in the plane is swept over by the cutter head while keeping the cutter fully within the region R (milling), or allowing the cutter to sweep over points outside of region R (lawnmowing).
12. A PTAS for computing a minimum-length cycle that separates a given set of "red" points from a given set of "blue" points in the Euclidean plane.
13. A QPTAS for the *minimum-weight triangulation* (MWT) problem of computing a triangulation of the planar point set S in order to minimize the sum of the edge lengths. The MWT has been shown to be NP-hard.

14. A PTAS for the minimum-weight Steiner convex partition problem in the plane, in which one is to compute an embedded planar straight-line graph with convex faces whose vertex set contains the input set S.

Open Problems

A prominent open problem in approximation algorithms for network optimization is to determine if approximations better than factor 3/2 can be achieved for the TSP in general metric spaces.

Specific open problems for geometric network optimization problems include:

1. Is there a PTAS for minimum-weight triangulation (MWT) in the plane? (A QPTAS is known.)
2. Is there a PTAS for capacitated vehicle routing, for all k?
3. Is there a PTAS for Euclidean minimum spanning trees of bounded degree (3 or 4)? (A QPTAS is known for degree-3 trees.)
4. Is there a PTAS for TSP with Neighborhoods (TSPN) for connected disjoint regions in the plane?
5. Is there a PTAS for computing a minimum-weight t-spanner of a set of points in a Euclidean space?

Finally, can PTAS techniques be implemented to be competitive with other practical methods for TSP or related network optimization problems?

Approximation Schemes for Makespan Minimization

Asaf Levin
Faculty of Industrial Engineering and Management, The Technion, Haifa, Israel

Keywords

Approximation scheme; Load balancing; Parallel machine scheduling

Years and Authors of Summarized Original Work

1987, 1988; Hochbaum, Shmoys

Problem Definition

Non-preemptive makespan minimization on m uniformly related machines is defined as follows. We are given a set $M = \{1, 2, \ldots, m\}$ of m machines where each machine i has a speed s_i such that $s_i > 0$. In addition we are given a set of jobs $J = \{1, 2, \ldots, n\}$, where each job j has a positive size p_j and all jobs are available for processing at time 0. The jobs need to be partitioned into m subsets $S_1, \ldots, S_m$, with S_i being the subset of jobs assigned to machine i, and each such (ordered) partition is a feasible solution to the problem. Processing job j on machine i takes $\frac{p_j}{s_i}$ time units. For such a solution (also known as a schedule), we let $L_i = (\sum_{j \in S_i} p_j)/s_i$ be the *completion time* or *load* of machine i. The *work* of machine i is $W_i = \sum_{j \in S_i} p_j = L_i \cdot s_i$, that is, the total size of the jobs assigned to i. The *makespan* of the schedule is defined as $\max\{L_1, L_2, \ldots, L_m\}$, and the goal is to find a schedule that minimizes the makespan. We also consider the problem on identical machines, that is, the special case of the above problem in which $s_i = 1$ for all i (in this special case, the work and the load of a given machine are always the same).

Key Results

A PTAS (polynomial-time approximation scheme) is a family of polynomial-time algorithms such that for all $\epsilon > 0$, the family has an algorithm such that for every instance of the makespan minimization problem, it returns a feasible solution whose makespan is at most $1 + \epsilon$ times the makespan of an optimal solution to the same instance. Without loss of generality, we can assume that $\epsilon < \frac{1}{5}$.

The Dual Approximation Framework and Common Preprocessing Steps

Using a guessing step of the optimal makespan, and scaling the sizes of all jobs by the value of the optimal makespan, we can assume that the optimal makespan is in the interval $[1, 1 + \epsilon)$ and it suffices to construct a feasible solution whose makespan is at most $1 + c\epsilon$ for a constant c (then scaling ϵ before applying the algorithm will give the claimed result). This assumption can be made since we can find in polynomial time two values LB and UB such that the optimal makespan is in the interval $[LB, UB]$ and $\frac{UB}{LB}$ is at most some constant (or even at most an exponential function of the length of the binary encoding of the input), then using a constant (or polynomial) number of iterations, we can find the minimum integer power of $1 + \epsilon$ for which the algorithm below will succeed to find a schedule with makespan at most $1 + c\epsilon$ times the optimal makespan. This approach is referred to as the *dual approximation method* [7,8].

From now on, we assume that the optimal makespan is in the interval $[1, 1 + \epsilon)$. The next step is to round up the size of each job to the next integer power of $1 + \epsilon$ and to round down the speed of each machine to the next integer power of $1 + \epsilon$. That is, the rounded size of job j is $p'_j = (1 + \epsilon)^{\lceil \log_{1+\epsilon} p_j \rceil}$ and the rounded speed of machine i is $s'_i = (1 + \epsilon)^{\lfloor \log_{1+\epsilon} s_i \rfloor}$. Note that this rounding does not decrease the makespan of any feasible solution and increase the optimal makespan by a multiplicative factor of at most $(1 + \epsilon)^2$. Thus, in the new instance that we call *the rounded instance*, the makespan

of an optimal solution is in the interval $[1, (1+\epsilon)^3)$. We observe that if the original instance to the makespan minimization problem was for the special case of identical machines, so does the rounded instance. The next steps differ between the PTAS for identical machines and its generalization for related machines.

The Case of Identical Machines

We define a job to be *small* if its rounded size is at most ϵ, and otherwise it is *large*. The large jobs instance is the instance we obtain from the rounded instance by removing all small jobs. The first observation is that it is sufficient to design an algorithm for finding a feasible solution to the large jobs instance whose makespan is at most $1 + c\epsilon$ where $c \geq 5$ is some constant. This is so, because we can apply this algorithm on the large jobs instance and obtain a schedule of these large jobs. Later, we add to the schedule the small jobs one by one using the list scheduling heuristic [5]. In the analysis, there are two cases. In the first one, adding the small jobs did not increase the makespan of the resulting schedule, and in this case our claim regarding the makespan of the output of the algorithm clearly holds. In the second case, the makespan increased by adding the small jobs, and we consider the last iteration in which such increase happened. In that last iteration, the load of one machine was increased by the size of the job assigned in this iteration, that is by at most ϵ, and before this iteration its load was smaller than $\frac{\sum_j p'_j}{m} \leq (1+\epsilon)^3$, where the inequality holds because the makespan of a feasible solution cannot be smaller than the average load of the machines. The claim now follows using $(1+\epsilon)^3 + \epsilon \leq 1 + 5\epsilon$ as $\epsilon < \frac{1}{5}$.

The large jobs instance has a compact representation. There are m identical machines and jobs of at most $O(\log_{1+\epsilon} \frac{1}{\epsilon})$ distinct sizes. Note that each machine has at most $\frac{2}{\epsilon}$ large jobs assigned to it (in any solution with makespan smaller than 2), and thus there are a constant number of different schedules of one machine when we consider jobs of the same size as identical jobs. A schedule of one machine in a solution to the large jobs instance is called the *configuration of the machine*. Now, we can either perform a dynamic programming algorithm that assigns large jobs to one machine after the other while recalling in each step the number of jobs of each size that still need to be assigned (as done in [7]) or use an integer program of fixed dimension [9] to solve the problem of assigning all large jobs to configurations of machines while having at most m machines in the solution and allowing only configurations corresponding to machines with load at most $(1+\epsilon)^3$ as suggested by Shmoys (see [6]).

We refer to [1, 2], and [10] for PTASs for other load balancing problems on identical machines.

The Case of Related Machines

Here, we still would like to consider separately the large jobs and the small jobs; however, a given job j can be large for one machine and small for another machine (it may even be too large for other machines, that is, processing it on such machine may take a period of time that is longer than the makespan of an optimal solution). Thus, for a given job j, we say that it is *huge* for machine i if $\frac{p_j}{s_i} > (1+\epsilon)^3$, it is *large* for machine i if $\epsilon < \frac{p_j}{s_i} \leq (1+\epsilon)^3$, and otherwise it is *small* for machine i. A configuration of machine i is the number of large jobs of each rounded size that are assigned to machine i (observe that similarly to the case of identical machines, the number of sizes of large jobs for a given machine is a constant) as well as approximate value of the total size of small jobs assigned to machine i, that is a value Δ_i such that the total size of small jobs assigned to machine i is in the interval $\left((\Delta_i - 1)\epsilon \cdot \frac{1}{s_i}, \Delta_i \epsilon \cdot \frac{1}{s_i}\right]$. Note that the vector of configurations of machines defines some information about the schedule, but it does not give a one-to-one assignment of small jobs to the machines.

Once again, [8] suggested to use dynamic programming for assigning jobs to the machines by traversing the machines from the slowest one to the fastest one and, for each machine, decide the number of large jobs of each size as well as an approximate value of the total size of small

jobs (for that machine) assigned to it. That is, the dynamic programming decides the configuration of each machine. To do so, it needs to recall the number of large jobs (with respect to the current machine) that are still not assigned, as well as the total size of small jobs (with respect to the current machine) that are still not assigned (this total size is a rounded value). At a postprocessing step, the jobs assigned as large jobs by the solution for the dynamic programming are scheduled accordingly, while the other jobs are assigned as small jobs as follows.

We assign the small jobs to the machines while traversing the machines from slowest to fastest and assigning the small jobs from the smallest to largest. At each time we consider the current machine i and the prefix of unassigned small jobs that are small with respect to the current machine. Denote by Δ_i the value of this parameter according to the solution of the dynamic programming. Due to the successive rounding of the total size of unassigned small jobs, we will allow assignments of a slightly larger total size of small jobs to machine i. So we will assign the small jobs one by one as long as their total size is at most $\frac{(\Delta_i+4)\epsilon}{s_i}$. If at some point there are no further unassigned small jobs that are small for machine i, we move to the next machine, otherwise we assign machine i small jobs (for machine i) of total size of at least $\frac{(\Delta_i+3)\epsilon}{s_i}$. This suffices to guarantee the feasibility of the resulting solution (i.e., all jobs are assigned) while increasing the makespan only by a small amount.

We refer to [3] and [4] for PTASs for other load balancing problems on related machines.

Problem Definition

Many NP-hard graph problems become easier to approximate on planar graphs and their generalizations. (A graph is *planar* if it can be drawn in the plane (or the sphere) without crossings. For definitions of other related graph classes, see the entry on ▸ Bidimensionality (2004; Demaine, Fomin, Hajiaghayi, Thilikos).) For example, a *maximum independent set* asks to find a maximum subset of vertices in a graph that induce no edges. This problem is inapproximable in general graphs within a factor of $n^{1-\epsilon}$ for any $\epsilon > 0$ unless NP = ZPP (and inapproximable within $n^{1/2-\epsilon}$ unless P = NP), while for planar graphs, there is a 4-approximation (or simple 5-approximation) by taking the largest color class in a vertex 4-coloring (or 5-coloring). Another is *minimum dominating set*, where the goal is to find a minimum subset of vertices such that every vertex is either in or adjacent to the subset. This problem is inapproximable in general graphs within $\epsilon \log n$ for some $\epsilon > 0$ unless P = NP, but as we will see, for planar graphs, the problem admits a *polynomial-time approximation scheme* (PTAS): a collection of $(1 + \epsilon)$-approximation algorithms for all $\epsilon > 0$.

There are two main general approaches to designing PTASs for problems on planar graphs and their generalizations: the separator approach and the Baker approach.

Lipton and Tarjan [15, 16] introduced the first approach, which is based on planar separators. The first step in this approach is to find a separator of $O(\sqrt{n})$ vertices or edges, where n is the size of the graph, whose removal splits the graph into two or more pieces each of which is a constant fraction smaller than the original graph. Then, recurse in each piece, building a recursion tree of separators, and stop when the pieces have some constant size such as $1/\epsilon$. The problem can be solved on these pieces by brute force, and then it remains to combine the solutions up the recursion tree. The induced error can often be bounded in terms of the total size of all separators, which in turn can be bounded by ϵn. If the optimal solution is at least some constant factor times n, this approach often leads to a PTAS.

There are two limitations to this planar-separator approach. First, it requires that the optimal solution be at least some constant factor times n; otherwise, the cost incurred by the separators can be far larger than the desired optimal solution. Such a bound is possible in some problems after some graph pruning (linear kernelization), e.g., independent set, vertex cover, and forms of the traveling salesman problem. But, for example, Grohe [12] states that the dominating set is a problem "to which the technique based on the separator theorem does not apply." Second, the approximation algorithms resulting from planar separators are often impractical because of large constant factors. For example, to achieve an approximation ratio of just 2, the base case requires exhaustive solution of graphs of up to $2^{2,400}$ vertices.

Baker [1] introduced her approach to address the second limitation, but it also addresses the first limitation to a certain extent. This approach is based on decomposition into overlapping subgraphs of bounded outerplanarity, as described in the next section.

Key Results

Baker's original result [1] is a PTAS for a maximum independent set (as defined above) on planar graphs, as well as the following list of problems on planar graphs: maximum tile salvage, partition into triangles, maximum H-matching, minimum vertex cover, minimum dominating set, and minimum edge-dominating set.

Baker's approach starts with a planar embedding of the planar graph. Then it divides vertices into *layers* by iteratively removing vertices on the outer face of the graph: layer j consists of the vertices removed at the jth iteration. If one now removes the layers congruent to i modulo k, for any choice of i, the graph separates into connected components each with at most k consecutive layers, and hence the graph becomes k-outerplanar. Many NP-complete problems can be solved on k-outerplanar graphs for fixed k using dynamic programming (in particular, such graphs

have bounded treewidth). Baker's approximation algorithm computes these optimal solutions for each choice i of the congruence class of layers to remove and returns the best solution among these k solutions. The key argument for maximization problems considers the optimal solution to the full graph and argues that the removal of one of the k congruence classes of layers must remove at most a $1/k$ fraction of the optimal solution, so the returned solution must be within a $1 + 1/k$ factor of optimal. A more delicate argument handles minimization problems as well. For many problems, such as maximum independent set, minimum dominating set, and minimum vertex cover, Baker's approach obtains a $(1 + \epsilon)$-approximation algorithms with a running time of $2^{O(1/\epsilon)}n^{O(1)}$ on planar graphs.

Eppstein [10] generalized Baker's approach to a broader class of graphs called graphs of *bounded local treewidth*, i.e., where the treewidth of the subgraph induced by the set of vertices at a distance of at most r from any vertex is bounded above by some function $f(r)$ independent of n. The main differences in Eppstein's approach are replacing the concept of bounded outerplanarity with the concept of bounded treewidth, where dynamic programming can still solve many problems, and labeling layers according to a simple breadth-first search. This approach has led to PTASs for hereditary maximization problems such as maximum independent set and maximum clique, maximum triangle matching, maximum H-matching, maximum tile salvage, minimum vertex cover, minimum dominating set, minimum edge-dominating set, minimum color sum, and subgraph isomorphism for a fixed pattern [6, 8, 10]. Frick and Grohe [11] also developed a general framework for deciding any property expressible in first-order logic in graphs of bounded local treewidth.

The foundation of these results is Eppstein's characterization of minor-closed families of graphs with bounded local treewidth [10]. Specifically, he showed that a minor-closed family has bounded local treewidth if and only if it excludes some *apex graph*, a graph with a vertex whose removal leaves a planar graph. Unfortunately, the initial proof of this result brought Eppstein's approach back to the realm of impracticality, because his bound on local treewidth in a general apex-minor-free graph is doubly exponential in r : $2^{2O(r)}$. Fortunately, this bound could be improved to $2^{O(r)}$ [3] and even the optimal $O(r)$ [4]. The latter bound restores Baker's $2^{O(1/\epsilon)}n^{O(1)}$ running time for $(1 + \epsilon)$-approximation algorithms, now for all apex-minor-free graphs.

Another way to view the necessary decomposition of Baker's and Eppstein's approaches is that the vertices or edges of the graph can be split into any number k of pieces such that deleting any one of the pieces results in a graph of bounded treewidth (where the bound depends on k). Such decompositions in fact exist for arbitrary graphs excluding any fixed minor H [9], and they can be found in polynomial time [6]. This approach generalizes the Baker-Eppstein PTASs described above to handle general H-minor-free graphs.

This decomposition approach is effectively limited to *deletion-closed* problems, whose optimal solution only improves when deleting edges or vertices from the graph. Another decomposition approach targets *contraction-closed* problems, whose optimal solution only improves when contracting edges. These problems include classic problems such as dominating set and its variations, the traveling salesman problem, subset TSP, minimum Steiner tree, and minimum-weight c-edge-connected submultigraph. PTASs have been obtained for these problems in planar graphs [2, 13, 14] and in bounded-genus graphs [7] by showing that the edges can be decomposed into any number k of pieces such that contracting any one piece results in a bounded-treewidth graph (where the bound depends on k).

Applications

Most applications of Baker's approach have been limited to optimization problems arising from "local" properties (such as those definable in first-order logic). Intuitively, such local properties can be decided by locally checking every constant-

size neighborhood. In [5], Baker's approach is generalized to obtain PTASs for nonlocal problems, in particular, connected dominating set. This generalization requires the use of two different techniques. The first technique is to use an ε-fraction of a constant-factor (or even logarithmic-factor) approximation to the problem as a "backbone" for achieving the needed nonlocal property. The second technique is to use subproblems that overlap by $\Theta(\log n)$ layers instead of the usual $\Theta(1)$ in Baker's approach.

Despite this advance in applying Baker's approach to more general problems, the planar-separator approach can still handle some different problems. Recall, though, that the planar-separator approach was limited to problems in which the optimal solution is at least some constant factor times n. This limitation has been overcome for a wide range of problems [5], in particular obtaining a PTAS for feedback vertex set, to which neither Baker's approach nor the planar-separator approach could previously apply. This result is based on evenly dividing the optimum solution instead of the whole graph, using a relation between treewidth and the optimal solution value to bound the treewidth of the graph, thus obtaining an $O(\sqrt{\mathrm{OPT}})$ separator instead of an $O(\sqrt{n})$ separator. The $O(\sqrt{\mathrm{OPT}})$ bound on treewidth follows from the bidimensionality theory described in the entry on ▸ Bidimensionality (2004; Demaine, Fomin, Hajiaghayi, Thilikos). We can divide the optimum solution into roughly even pieces, without knowing the optimum solution, by using existing constant-factor (or even logarithmic-factor) approximations for the problem. At the base of the recursion, pieces no longer have bounded size but do have bounded treewidth, so fast fixed-parameter algorithms can be used to construct optimal solutions.

Open Problems

An intriguing direction for future research is to build a general theory for PTASs of subset problems. Although PTASs for subset TSP and Steiner tree have recently been obtained for planar graphs [2, 14], there remain several open problems of this kind, such as subset feedback vertex set, group Steiner tree, and directed Steiner tree.

Another instructive problem is to understand the extent to which Baker's approach can be applied to nonlocal problems. Again there is an example of how to modify the approach to handle the nonlocal problem of connected dominating set [5], but, for example, the only known PTAS for feedback vertex set in planar graphs follows the separator approach.

Problem Definition

Nash [15] introduced the concept of Nash equilibria in noncooperative games and proved that any game possesses at least one such equilibrium. A well-known algorithm for computing a Nash equilibrium of a 2-player game is the Lemke-Howson algorithm [13]; however, it has exponential worst-case running time in the number of available pure strategies [18].

Daskalakis et al. [5] showed that the problem of computing a Nash equilibrium in a game with 4 or more players is *PPAD*-complete; this result was later extended to games with 3 players [8]. Eventually, Chen and Deng [3] proved that the problem is *PPAD*-complete for 2-player games as well.

This fact emerged the computation of *approximate* Nash equilibria. There are several versions of approximate Nash equilibria that have been defined in the literature; however, the focus of this entry is on the notions of ϵ-Nash equilibrium and ϵ-well-supported Nash equilibrium. An ϵ-Nash equilibrium is a strategy profile such that no deviating player could achieve a payoff higher than the one that the specific profile gives her, plus ϵ. A stronger notion of approximate Nash equilibria is the *ϵ-well-supported Nash equilibria*; these are strategy profiles such that each player plays only approximately best-response pure strategies with nonzero probability. These are *additive* notions of approximate equilibria; the problem of computing approximate equilibria of bimatrix games using a relative notion of approximation is known to be *PPAD*-hard even for constant approximations.

Notation

For a $n \times 1$ vector x, denote by $x_1, \ldots, x_n$ the components of x and by x^T the transpose of x. Denote by e_i the column vector with 1 at the ith coordinate and 0 elsewhere. For an $n \times m$ matrix A, denote a_{ij} the element in the i-th row

and j-th column of A. Let $\mathbb{P}^n$ be the set of all probability vectors in n dimensions: $\mathbb{P}^n = \left\{ z \in \mathbb{R}^n_{\geq 0} : \sum_{i=1}^{n} z_i = 1 \right\}$.

Bimatrix Games

Bimatrix games [16] are a special case of 2-player games such that the payoff functions can be described by two real $n \times m$ matrices A and B. The n rows of A, B represent the *action set* of the first player (the *row player*), and the m columns represent the action set of the second player (the *column player*). Then, when the row player chooses action i and the column player chooses action j, the former gets payoff a_{ij}, while the latter gets payoff b_{ij}. Based on this, bimatrix games are denoted by $\Gamma = \langle A, B \rangle$.

A *strategy* for a player is any probability distribution on his/her set of actions. Therefore, a strategy for the row player can be expressed as a probability vector $x \in \mathbb{P}^n$, while a strategy for the column player can be expressed as a probability vector $y \in \mathbb{P}^m$. Each extreme point $e_i \in \mathbb{P}^n (e_j \in \mathbb{P}^m)$ that corresponds to the strategy assigning probability 1 to the i-th row (j-th column) is called a *pure strategy* for the row (column) player. A *strategy profile* (x, y) is a combination of (mixed in general) strategies, one for each player. In a given strategy profile (x, y), the players get *expected payoffs* $x^T Ay$ (row player) and $x^T By$ (column player).

If both payoff matrices belong to $[0, 1]^{m \times n}$, then the game is called a [0,1]-bimatrix (or else, *positively normalized*) game. The special case of bimatrix games in which all elements of the matrices belong to $\{0, 1\}$ is called a $\{0, 1\}$-bimatrix (or else, *win-lose*) game. A bimatrix game $\langle A, B \rangle$ is called *zero sum* if $B = -A$.

Approximate Nash Equilibria

Definition 1 (ϵ-Nash equilibrium) For any $\epsilon > 0$, a strategy profile (x, y) is an *ϵ-Nash equilibrium* for the $n \times m$ bimatrix game $\Gamma = \langle A, B \rangle$ if

1. For all pure strategies $i \in \{1, \ldots, n\}$ of the row player, $e_i^T Ay \leq x^T Ay + \epsilon$.
2. For all pure strategies $j \in \{1, \ldots, m\}$ of the column player, $x^T Be_j \leq x^T By + \epsilon$.

Definition 2 (ϵ-well-supported Nash equilibrium) For any $\epsilon > 0$, a strategy profile (x, y) is an *ϵ-well-supported Nash equilibrium* for the $n \times m$ bimatrix game $\Gamma = \langle A, B \rangle$ if

1. For all pure strategies $i \in \{1, \ldots, n\}$ of the row player,

$$x_i > 0 \Rightarrow e_i^T Ay \geq e_k^T Ay - \epsilon \ \forall k \in \{1, \ldots, n\}$$

2. For all pure strategies $j \in \{1, \ldots, m\}$ of the column player,

$$y_i > 0 \Rightarrow x^T Be_j \geq x^T Be_k - \epsilon \ \forall k \in \{1, \ldots, m\}.$$

Note that both notions of approximate equilibria are defined with respect to an additive error term ϵ. Although (exact) Nash equilibria are known not to be affected by any positive scaling, it is important to mention that approximate notions of Nash equilibria are indeed affected. Therefore, the commonly used assumption in the literature when referring to approximate Nash equilibria is that the bimatrix game is positively normalized, and this assumption is adopted in the present entry.

Key Results

The work of Althöfer [1] shows that, for *any* probability vector p, there exists a probability vector $\hat{P}$ with logarithmic supports, so that for a fixed matrix C, $\max_j |p^T Ce_j - \hat{p}^T Ce_j| \leq \epsilon$, for any constant $\epsilon > 0$. Exploiting this fact, the work of Lipton, Markakis, and Mehta [14] shows that, for any bimatrix game and for any *constant* $\epsilon > 0$, there exists an ϵ-Nash equilibrium with only logarithmic support (in the number n of available pure strategies). Consider a bimatrix game $\Gamma = \langle A, B \rangle$, and let (x, y) be a Nash equilibrium for Γ. Fix a positive integer k and form a multiset S_1 by sampling k times from the set of pure strate-

gies of the row player, independently at random according to the distribution x. Similarly, form a multiset S_2 by sampling k times from set of pure strategies of the column player according to y. Let $\hat{x}$ be the mixed strategy for the row player that assigns probability $1/k$ to each member of S_1 and 0 to all other pure strategies, and let $\hat{y}$ be the mixed strategy for the column player that assigns probability $1/k$ to each member of S_2 and 0 to all other pure strategies. Then, $\hat{x}$ and $\hat{y}$ are called *k-uniform* [14], and the following holds:

Theorem 1 ([14]) *For any Nash equilibrium (x, y) of a $n \times n$ bimatrix game and for every $\epsilon > 0$, there exists, for every $k \geq (12 \ln n)/\epsilon^2$, a pair of k-uniform strategies $\hat{x}, \hat{y}$ such that $(\hat{x}, \hat{y})$ is an ϵ-Nash equilibrium.*

This result directly yields a quasi-polynomial $(n^{O(\ln n)})$ algorithm for computing such an approximate equilibrium. Moreover, as pointed out in [1], no algorithm that examines supports smaller than about $\ln n$ can achieve an approximation better than $1/4$.

Theorem 2 ([4]) *The problem of computing a $1/n^{\Theta(1)}$-Nash equilibrium of a $n \times n$ bimatrix game is PPAD-complete.*

Theorem 2 asserts that, unless $PPAD \subseteq P$, there exists no fully polynomial time approximation scheme for computing equilibria in bimatrix games. However, this does not rule out the existence of a polynomial approximation scheme for computing an ϵ-Nash equilibrium when ϵ is an absolute constant, or even when $\epsilon = \Theta(1 - /\text{poly}(\ln n))$. Furthermore, as observed in [4], if the problem of finding an ϵ-Nash equilibrium were *PPAD*-complete when ϵ is an absolute constant, then, due to Theorem 1, all *PPAD* problems would be solved in quasi-polynomial time, which is unlikely to be the case.

Two concurrent and independent works [6, 11] were the first to make progress in providing ϵ-Nash equilibria and ϵ-well-supported Nash equilibria for bimatrix games and some *constant* $0 < \epsilon < 1$. In particular, the work of Kontogiannis, Panagopoulou, and Spirakis [11] proposes a simple linear-time algorithm for computing a $3/4$-Nash equilibrium for any bimatrix game:

Theorem 3 ([11]) *Consider any $n \times m$ bimatrix game $\Gamma = \langle A, B \rangle$, and let $a_{i1,j1} = \max_{i,j} a_{ij}$ and $b_{i2,j2} = \max_{i,j} b_{ij}$. Then the pair of strategies $(\hat{x}, \hat{y})$ where $\hat{x}_{i_1} = \hat{x}_{i_2} = \hat{y}_{j_1} = \hat{y}_{j_2} = 1/2$ is a $3/4$-Nash equilibrium for Γ.*

The above technique can be extended so as to obtain a parametrized, stronger approximation:

Theorem 4 ([11]) *Consider a $n \times m$ bimatrix game $\Gamma = \langle A, B \rangle$. Let $\lambda_1{}^*(\lambda_2{}^*)$ be the minimum, among all Nash equilibria of Γ, expected payoff for the row (column) player, and let $\lambda = \max\{\lambda_1{}^*, \lambda_2{}^*\}$. Then, there exists a $(2 + \lambda)/4$-Nash equilibrium that can be computed in time polynomial in n and m.*

The work of Daskalakis, Mehta, and Papadimitriou [6] provides a simple algorithm for computing a $1/2$-Nash equilibrium: Pick an arbitrary row for the row player, say row i. Let $j = \arg\max_{'j} b'_{ij}$. Let $k = \arg\max_{'k} a'_{kj}$. Thus, j is a best-response column for the column player to the row i, and k is a best-response row for the row player to the column j. Let $\hat{x} = 1/2e_i + 1/2e_k$ and $\hat{y} = e_j$, i.e., the row player plays row i or row k with probability $1/2$ each, while the column player plays column j with probability 1. Then:

Theorem 5 ([6]) *The strategy profile $(\hat{x}, \hat{y})$ is a $1/2$-Nash equilibrium.*

A polynomial construction (based on linear programming) of a 0.38-Nash equilibrium is presented in [7].

For the more demanding notion of well-supported approximate Nash equilibrium, Daskalakis, Mehta, and Papadimitriou [6] propose an algorithm, which, under a quite interesting and plausible graph theoretic conjecture, constructs in polynomial time a $5/6$-well-supported Nash equilibrium. However, the status of this conjecture is still unknown. In [6], it is also shown how to transform a [0,1]-bimatrix game to a $\{0, 1\}$-bimatrix game of the same size, so that each ϵ-well-supported Nash equilibrium of the resulting game is $(1+\epsilon)/2$-well-supported Nash equilibrium of the original game.

An algorithm given by Kontogiannis and Spirakis computes a $2/3$-well-supported Nash equilibrium in polynomial time [12]. Their methodology for attacking the problem is based on the solvability of zero-sum bimatrix games (via its connection to linear programming) and provides a 0.5-well-supported Nash equilibrium for win-lose games and a $2/3$-well-supported Nash equilibrium for normalized games. In [9], a polynomial-time algorithm computes an ε-well-supported Nash equilibrium with $\varepsilon < 2/3$, by extending the $2/3$-algorithm of Kontogiannis and Spirakis. In particular, it is shown that either the strategies generated by their algorithm can be tweaked to improve the approximation or that we can find a sub-game that resembles matching pennies, which again leads to a better approximation. This allows to construct a (2/3-0.004735)-well-supported Nash equilibrium in polynomial time.

Two new results improved the approximation status of ϵ-Nash equilibria:

Theorem 6 ([2]) *There is a polynomial time algorithm, based on linear programming, that provides an 0.36392-Nash equilibrium.*

The second result below, due to Tsaknakis and Spirakis, is the best till now. Based on local search, it establishes that any local minimum of a very natural map in the space of pairs of mixed strategies or its dual point in a certain minimax problem used for finding the local minimum constitutes a 0.3393-Nash equilibrium.

Theorem 7 ([19]) *There exists a polynomial time algorithm, based on the stationary points of a natural optimization problem, that provides an 0.3393-Nash Equilibrium.*

In [20], it is shown that the problem of computing a Nash equilibrium for 2-person games can be polynomially reduced to an indefinite quadratic programming problem involving the spectrum of the adjacency matrix of a strongly connected directed graph on n vertices, where n is the total number of players' strategies. Based on that, a new method is presented for computing approximate equilibria, and it is shown that its complexity is a function of the average spectral energy of the underlying graph. The implications of the strong connectedness properties on the energy and on the complexity of the method are discussed, and certain classes of graphs are described for which the method is a polynomial time approximation scheme (PTAS). The worst- case complexity is bounded by a subexponential function in the total number of strategies n.

Kannan and Theobald [10] investigate a hierarchy of bimatrix games $\langle A, B\rangle$ which results from restricting the rank of the matrix $A + B$ to be of fixed rank at most k. They propose a new model of ϵ-approximation for games of rank k and, using results from quadratic optimization, show that approximate Nash equilibria of constant rank games can be computed deterministically in time polynomial in $1/\epsilon$. Moreover, [10] provides a randomized approximation algorithm for certain quadratic optimization problems, which yields a randomized approximation algorithm for the Nash equilibrium problem. This randomized algorithm has similar time complexity as the deterministic one, but it has the possibility of finding an exact solution in polynomial time if a conjecture is valid. Finally, they present a polynomial time algorithm for *relative approximation* (with respect to the payoffs in an equilibrium) provided that the matrix $A + B$ has a nonnegative decomposition.

Applications

Noncooperative game theory and its main solution concept, i.e., the Nash equilibrium, have been extensively used to understand the phenomena observed when decision-makers interact and have been applied in many diverse academic fields, such as biology, economics, sociology, and artificial intelligence. Since however the computation of a Nash equilibrium is in general *PPAD*-complete, it is important to provide efficient algorithms for approximating a Nash equilibrium; the algorithms discussed in this entry are a first step towards this direction.

Problem Definition

The simultaneous purchase and sale of the same securities, commodities, or foreign exchange in order to profit from a differential in the price. This usually takes place on different exchanges or marketplaces and is also known as a "riskless profit."

Arbitrage is, arguably, the most fundamental concept in finance. It is a state of the variables of financial instruments such that a riskless profit can be made, which is generally believed not in existence. The economist's argument for its nonexistence is that active investment agents will exploit any arbitrage opportunity in a financial market and thus will deplete it as soon as it may arise. Naturally, the speed at which such an arbitrage opportunity can be located and be taken advantage of is important for the profit-seeking investigators, which falls in the realm of analysis of algorithms and computational complexity.

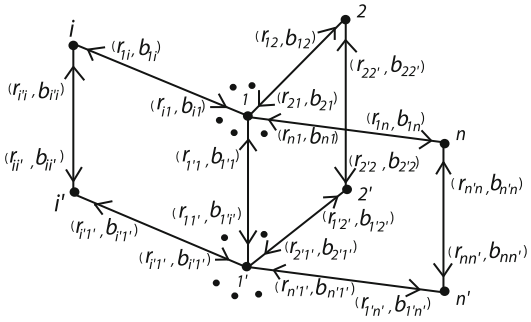
The identification of arbitrage states is, at frictionless foreign exchange market (a theoretical trading environment where all costs and restraints associated with transactions are nonexistent), not difficult at all and can be reduced to existence of arbitrage on three currencies (see [11]). In reality, friction does exist. Because of friction, it is possible that there exist arbitrage opportunities in the market but difficult to find it and to exploit it to eliminate it. Experimental results in foreign exchange markets showed that arbitrage does exist in reality. Examination of data from 10 markets over a 12-day period by Mavrides [11] revealed that a significant arbitrage opportunity exists. Some opportunities were observed to be persistent for a long time. The problem becomes worse at forward and future markets (in which future contracts in commodities are traded) coupled with covered interest rates, as observed by Abeysekera and Turtle [1] and Clinton [4]. An obvious interpretation is that the arbitrage opportunity was not immediately identified because of information asymmetry in the market. However, that is not the only factor. Both the time necessary to collect the market information (so that an arbitrage opportunity would be identified) and the time people (or computer programs) need to find the arbitrage transactions are important factors for eliminating arbitrage opportunities.

The computational complexity in identifying arbitrage, the level in difficulty measured by arithmetic operations, is different in different models of exchange systems. Therefore, to approximate an ideal exchange market, models with lower complexities should be preferred to those with higher complexities.

To model an exchange system, consider n foreign currencies: $N = \{1, 2, \ldots, n\}$. For each ordered pair (i, j), one may change one unit of currency i to r_{ij} units of currency j. Rate r_{ij} is the *exchange rate* from i to j. In an ideal market, the exchange rate holds for any amount that is exchanged. An *arbitrage opportunity* is a set of exchanges between pairs of currencies such that the net balance for each involved currency is nonnegative and there is at least one currency for which the net balance is positive. Under ideal market conditions, there is no arbitrage if and only if there is no arbitrage among any three currencies (see [11]).

Various types of *friction* can be easily modeled in such a system. Bid-offer spread may be expressed in the present mathematical format as $r_{ij}\, r_{ji} < 1$ for some $i, j \in N$. In addition, usually the traded amount is required to be in multiples of a fixed integer amount, hundreds, thousands, or millions. Moreover, different traders may bid or offer at different rates, and each for a limited amount. A more general model to describe these market *imperfections* will include, for pairs $i \neq j \in N$, l_{ij} different rates r_{ij}^k of exchanges from currency i to j up to b_{ij}^k units of currency i, $k = 1, \ldots, l_{ij}$, where l_{ij} is the number of different exchange rates from currency i to j.

A currency exchange market can be represented by a digraph $G = (V, E)$ with vertex set V and arc set E such that each vertex $i \in V$ represents currency i and each arc $a_{ij}^k \in E$ represents the currency exchange relation from i to j with rate r_{ij}^k and bound b_{ij}^k. Note that parallel arcs may occur for different exchange rates. Such a digraph is called an exchange digraph. Let $x = (x_{ij}^k)$ denote a currency exchange vector (Fig. 1).



Arbitrage in Frictional Foreign Exchange Market, Fig. 1 Digraph G_1

Problem 1 The existence of arbitrage in a frictional exchange market can be formulated as follows:

$$\sum_{j\neq i}\sum_{k=1}^{l_{ji}} \lfloor r_{ji}^k x_{ji}^k \rfloor - \sum_{j\neq i}\sum_{k=1}^{l_{ij}} x_{ij}^k \geq 0,\ i=1,\ldots,n, \tag{1}$$

at least one strict inequality holds

$$0 \leq x_{ij}^k \leq b_{ij}^k,\ 1 \leq k \leq l_{ij},\ 1 \leq i \neq j \leq n, \tag{2}$$

$$x_{ij}^k \text{ is integer},\ 1 \leq k \leq l_{ij},\ 1 \leq i \neq j \leq n. \tag{3}$$

Note that the first term in the right-hand side of (1) is the revenue at currency i by selling other currencies and the second term is the expense at currency i by buying other currencies.

The corresponding optimization problem is

Problem 2 The maximum arbitrage problem in a frictional foreign exchange market with bid-ask spreads, bound, and integrality constraints is the following integer linear programming (P):

$$\text{maximize} \sum_{i=1}^{n} w_i \sum_{j\neq i}\left(\sum_{k=1}^{l_{ji}} \lfloor r_{ji}^k x_{ji}^k \rfloor - \sum_{k=1}^{l_{ij}} x_{ij}^k\right)$$

subject to

$$\sum_{j\neq i}\left(\sum_{k=1}^{l_{ji}} \lfloor r_{ji}^k x_{ji}^k \rfloor - \sum_{k=1}^{l_{ij}} x_{ij}^k\right) \geq 0,\ i=1,\ldots,n, \tag{4}$$

$$0 \leq x_{ij}^k \leq b_{ij}^k,\ 1 \leq k \leq l_{ij},\ 1 \leq i \neq j \leq n, \tag{5}$$

$$x_{ij}^k \text{ is integer},\ 1 \leq k \leq l_{ij},\ 1 \leq i \neq j \leq n, \tag{6}$$

where $w_i \geq 0$ is a given weight for currency $i, i = 1, 2, \ldots, n$, with at least one $w_i > 0$.

Finally, consider another

Problem 3 In order to eliminate arbitrage, how many transactions and arcs in a exchange digraph have to be used for the currency exchange system?

Key Results

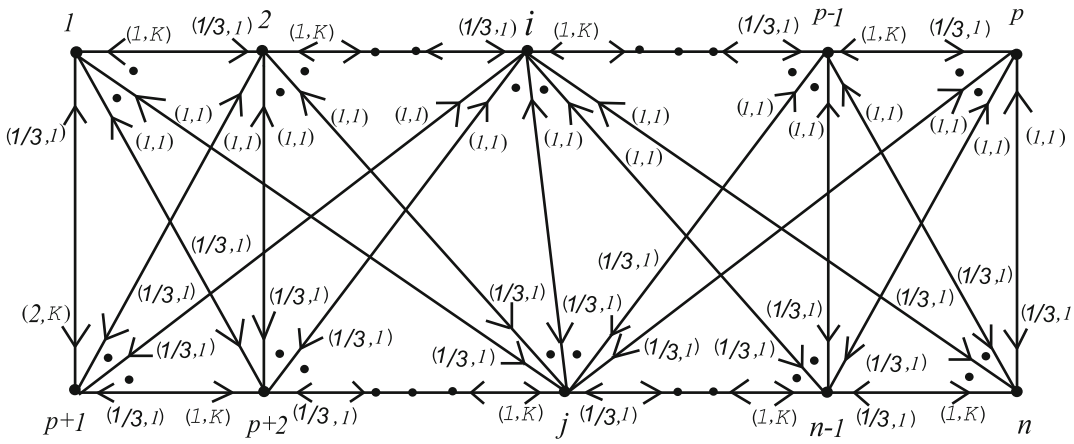
A decision problem is called nondeterministic polynomial (*NP* for short) if its solution (if one exists) can be guessed and verified in polynomial time; nondeterministic means that no particular rule is followed to make the guess. If a problem is *NP* and all other *NP* problems are polynomial-time reducible to it, the problem is *NP*-complete. And a problem is called *NP*-hard if every other problem in *NP* is polynomial-time reducible to it (Fig. 2).

Theorem 1 *It is NP-complete to determine whether there exists arbitrage in a frictional foreign exchange market with bid-ask spreads, bound, and integrality constraints even if all* $l_{ij} = 1$.

Then, a further inapproximability result is obtained.

Theorem 2 *There exists fixed* $\epsilon > 0$ *such that approximating* (P) *within a factor of* n^{ϵ} *is NP-hard even for any of the following two special cases:*

(P_1) *all* $l_{ij} = 1$ *and* $w_i = 1$.
(P_2) *all* $l_{ij} = 1$ *and all but one* $w_i = 0$.



Arbitrage in Frictional Foreign Exchange Market, Fig. 2 Digraph G_2

Now, consider two polynomially solvable special cases when the number of currencies is constant or the exchange digraph is star shaped (a digraph is star shaped if all arcs have a common vertex).

Theorem 3 *There are polynomial time algorithms for* (P) *when the number of currencies is constant.*

Theorem 4 *It is polynomially solvable to find the maximum revenue at the center currency of arbitrage in a frictional foreign exchange market with bid-ask spread, bound, and integrality constraints when the exchange digraph is star shaped.*

However, if the exchange digraph is the coalescence of a star-shaped exchange digraph and its copy, shown by Digraph G_1, then the problem becomes *NP*-complete.

Theorem 5 *It is NP-complete to decide whether there exists arbitrage in a frictional foreign exchange market with bid-ask spreads, bound, and integrality constraints even if its exchange digraph is coalescent.*

Finally, an answer to Problem 3 is as follows

Theorem 6 *There is an exchange digraph of order n such that at least* $\lfloor n/2 \rfloor \lceil n/2 \rceil - 1$ *transactions and at least* $n^2/4 + n - 3$ *arcs are in need to bring the system back to non-arbitrage states.*

For instance, consider the currency exchange market corresponding to digraph $G_2 = (V, E)$, where the number of currencies is $n = |V|$, $p = \lfloor n/ \rfloor$, and $K = n^2$.

Set

$$C = \{a_{ij} \in E | 1 \le i \le p, p+1 \le j \le n\}$$
$$\cup \{a_{1(p+1)}\} \backslash \{a_{(p+1)1}\} \cup \{a_{i(i-1)} | 2 \le i \le p\}$$
$$\cup \{a_{i(i+1)} | p+1 \le i \le n-1\}.$$

Then, $|C| = \lfloor n/2 \rfloor \lceil n/2 \rceil + n - 2 = |E| / > n^2/4 + n - 3$. It follows easily from the rates and bounds that each arc in C has to be used to eliminate arbitrage. And $\lfloor n/2 \rfloor \lceil n/2 \rceil - 1$ transactions corresponding to $\{a_{ij} \in E | 1 \le i \le p, p+1 \le j \le n\} \backslash \{a_{(p+1)1}\}$ are in need to bring the system back to non-arbitrage states.

Applications

The present results show that different foreign exchange systems exhibit quite different computational complexities. They may shed new light on how monetary system models are adopted and evolved in reality. In addition, it provides with a computational complexity point of view to the understanding of the now fast growing Internet electronic exchange markets.

Open Problems

The dynamic models involving in both spot markets (in which goods are sold for cash and delivered immediately) and futures markets are the most interesting ones. To develop good approximation algorithms for such general models would be important. In addition, it is also important to identify special market models for which polynomial time algorithms are possible even with future markets. Another interesting paradox in this line of study is why friction constraints that make arbitrage difficult are not always eliminated in reality.

Arithmetic Coding for Data Compression

Paul G. Howard[1] and Jeffrey Scott Vitter[2]
[1]Akamai Technologies, Cambridge, MA, USA
[2]University of Kansas, Lawrence, KS, USA

Keywords

Entropy coding; Statistical data compression

Years and Authors of Summarized Original Work

1994; Howard, Vitter

Problem Definition

Often it is desirable to encode a sequence of data efficiently to minimize the number of bits required to transmit or store the sequence. The sequence may be a file or message consisting of *symbols* (or *letters* or *characters*) taken from a fixed input alphabet, but more generally the sequence can be thought of as consisting of *events*, each taken from its own input set. Statistical data compression is concerned with encoding the data in a way that makes use of probability estimates of the events. Lossless compression has the property that the input sequence can be reconstructed exactly from the encoded sequence. Arithmetic

Arithmetic Coding for Data Compression, Table 1 Comparison of codes for Huffman coding, Hu-Tucker coding, and arithmetic coding for a sample 5-symbol alphabet

Symbol e_k	Prob.		Huffman		Hu-Tucker		Arithmetic
	p_k	$-\log_2 p_k$	Code	Length	Code	Length	Length
a	0.04	4.644	**1111**	4	**000**	3	4.644
b	0.18	2.474	**110**	3	**001**	3	2.474
c	0.43	1.218	**0**	1	**01**	2	1.218
d	0.15	2.737	**1110**	4	**10**	2	2.737
e	0.20	2.322	**10**	2	**11**	2	2.322

coding is a nearly optimal statistical coding technique that can produce a lossless encoding.

Problem (statistical data compression) INPUT: A sequence of m events $a_1, a_2, \ldots, a_m$. The ith event a_i is taken from a set of n distinct possible events $e_{i,1}, e_{i,2}, \ldots, e_{i,n}$, with an accurate assessment of the probability distribution P_i of the events. The distributions P_i need not be the same for each event a_i.

OUTPUT: A succinct encoding of the events that can be decoded to recover exactly the original sequence of events.

The goal is to achieve optimal or near-optimal encoding length. Shannon [10] proved that the smallest possible expected number of bits needed to encode the ith event is the *entropy* of P_i, denoted by

$$H(P_i) = \sum_{k=1}^{n} -p_{i,k} \log_2 p_{i,k}$$

where $p_{i,k}$ is the probability that e_k occurs as the ith event. An optimal code outputs $-\log_2 p$ bits to encode an event whose probability of occurrence is p.

The well-known Huffman codes [6] are optimal only among *prefix* (or *instantaneous*) codes, that is, those in which the encoding of one event can be decoded before encoding has begun for the next event. Hu-Tucker codes are prefix codes similar to Huffman codes and are derived using a similar algorithm, with the added constraint that coded messages preserve the ordering of original messages.

When an instantaneous code is not needed, as is often the case, arithmetic coding provides a number of benefits, primarily by relaxing the constraint that the code lengths must be integers: (1) The code length is optimal ($-\log_2 p$ bits for an event with probability p), even when probabilities are not integer powers of $\frac{1}{2}$. (2) There is no loss of coding efficiency even for events with probability close to 1. (3) It is trivial to handle probability distributions that change from event to event. (4) The input message to output message ordering correspondence of Hu-Tucker coding can be obtained with minimal extra effort.

As an example, consider a 5-symbol input alphabet. Symbol probabilities, codes, and code lengths are given in Table 1.

The average code length is 2.13 bits per input symbol for the Huffman code, 2.22 bits per symbol for the Hu-Tucker code, and 2.03 bits per symbol for arithmetic coding.

Key Results

In theory, arithmetic codes assign one "codeword" to each possible input sequence. The codewords consist of half-open subintervals of the half-open unit interval [0,1) and are expressed by specifying enough bits to distinguish the subinterval corresponding to the actual sequence from all other possible subintervals. Shorter codes correspond to larger subintervals and thus more probable input sequences. In practice, the subinterval is refined incrementally using the probabilities of the individual events, with bits being output as soon as they are known. Arithmetic codes almost always give better compression than prefix codes, but they lack the direct correspondence between

the events in the input sequence and bits or groups of bits in the coded output file.

The algorithm for encoding a file using arithmetic coding works conceptually as follows:

1. The "current interval" $[L, H)$ is initialized to [0,1).
2. For each event in the file, two steps are performed:
   (a) Subdivide the current interval into subintervals, one for each possible event. The size of an event's subinterval is proportional to the estimated probability that the event will be the next event in the file, according to the model of the input.
   (b) Select the subinterval corresponding to the event that actually occurs next and make it the new current interval.
3. Output enough bits to distinguish the final current interval from all other possible final intervals.

The length of the final subinterval is clearly equal to the product of the probabilities of the individual events, which is the probability p of the particular overall sequence of events. It can be shown that $\lfloor -\log_2 p \rfloor + 2$ bits are enough to distinguish the file from all other possible files.

For finite-length files, it is necessary to indicate the end of the file. In arithmetic coding, this can be done easily by introducing a special low-probability event that can be injected into the input stream at any point. This adds only $O(\log m)$ bits to the encoded length of an m-symbol file.

In step 2, one needs to compute only the subinterval corresponding to the event a_i that actually occurs. To do this, it is convenient to use two "cumulative" probabilities: the cumulative probability $P_C = \sum_{k=1}^{i-1} p_k$ and the next-cumulative probability $P_N = P_C + p_i = \sum_{k=1}^{i-1} p_k$. The new subinterval is $[L + P_C(H - L), L + P_N(H - L))$. The need to maintain and supply cumulative probabilities requires the model to have a sophisticated data structure, such as that of Moffat [7], especially when many more than two events are possible.

Modeling

The goal of modeling for statistical data compression is to provide probability information to the coder. The modeling process consists of structural and probability estimation components; each may be adaptive (starting from a neutral model, gradually build up the structure and probabilities based on the events encountered), semi-adaptive (specify an initial model that describes the events to be encountered in the data and then modify the model during coding so that it describes only the events yet to be coded), or static (specify an initial model and use it without modification during coding).

In addition there are two strategies for probability estimation. The first is to estimate each event's probability individually based on its frequency within the input sequence. The second is to estimate the probabilities collectively, assuming a probability distribution of a particular form and estimating the parameters of the distribution, either directly or indirectly. For direct estimation, the data can yield an estimate of the parameter (the variance, for instance). For indirect estimation [4], one can start with a small number of possible distributions and compute the code length that would be obtained with each; the one with the smallest code length is selected. This method is very general and can be used even for distributions from different families, without common parameters.

Arithmetic coding is often applied to text compression. The events are the symbols in the text file, and the model consists of the probabilities of the symbols considered in some context. The simplest model uses the overall frequencies of the symbols in the file as the probabilities; this is a zero-order Markov model, and its entropy is denoted H_0. The probabilities can be estimated adaptively starting with counts of 1 for all symbols and incrementing after each symbol is coded, or the symbol counts can be coded before coding the file itself and either modified during coding (a decrementing semi-adaptive code) or left unchanged (a static code). In all cases, the

code length is independent of the order of the symbols in the file.

Theorem 1 *For all input files, the code length L_A of an adaptive code with initial 1-weights is the same as the code length L_{SD} of the semi-adaptive decrementing code plus the code length L_M of the input model encoded assuming that all symbol distributions are equally likely. This code length is less than $L_S = mH_0 + L_M$, the code length of a static code with the same input model. In other words, $L_A = L_{SD} + L_M < mH_0 + L_M = L_S$.*

It is possible to obtain considerably better text compression by using higher-order Markov models. Cleary and Witten [2] were the first to do this with their PPM method. PPM requires adaptive modeling and coding of probabilities close to 1 and makes heavy use of arithmetic coding.

Implementation Issues

Incremental Output

The basic implementation of arithmetic coding described above has two major difficulties: the shrinking current interval requires the use of high-precision arithmetic, and no output is produced until the entire file has been read. The most straightforward solution to both of these problems is to output each leading bit as soon as it is known and then to double the length of the current interval so that it reflects only the unknown part of the final interval. Witten, Neal, and Cleary [11] add a clever mechanism for preventing the current interval from shrinking too much when the endpoints are close to $\frac{1}{2}$ but straddle $\frac{1}{2}$. In that case, one does not yet know the next output bit, but whatever it is, the *following* bit will have the opposite value; one can merely keep track of that fact and expand the current interval symmetrically about $\frac{1}{2}$. This follow-on procedure may be repeated any number of times, so the current interval size is always strictly longer than $\frac{1}{4}$.

Before [11] other mechanisms for incremental transmission and fixed precision arithmetic were developed through the years by a number of researchers beginning with Pasco [8]. The bit-stuffing idea of Langdon and others at IBM [9] that limits the propagation of carries in the additions serves a function similar to that of the follow-on procedure described above.

Use of Integer Arithmetic

In practice, the arithmetic can be done by storing the endpoints of the current interval as sufficiently large integers rather than in floating point or exact rational numbers. Instead of starting with the real interval [0,1), start with the integer interval $[0,N)$, N invariably being a power of 2. The subdivision process involves selecting non-overlapping integer intervals (of length at least 1) with lengths approximately proportional to the counts.

Limited-Precision Arithmetic Coding

Arithmetic coding as it is usually implemented is slow because of the multiplications (and in some implementations, divisions) required in subdividing the current interval according to the probability information. Since small errors in probability estimates cause very small increases in code length, introducing approximations into the arithmetic coding process in a controlled way can improve coding speed without significantly degrading compression performance. In the Q-Coder work at IBM [9], the time-consuming multiplications are replaced by additions and shifts, and low-order bits are ignored.

Howard and Vitter [3] describe a different approach to approximate arithmetic coding. The fractional bits characteristic of arithmetic coding are stored as state information in the coder. The idea, called *quasi-arithmetic coding*, is to reduce the number of possible states and replace arithmetic operations by table lookups; the lookup tables can be precomputed.

The number of possible states (after applying the interval expansion procedure) of an arithmetic coder using the integer interval $[0,N)$ is $3N^2/16$. The obvious way to reduce the number of states in order to make lookup tables practicable is to reduce N. Binary quasi-arithmetic coding causes an insignificant increase in the code length compared with pure arithmetic coding.

Theorem 2 *In a quasi-arithmetic coder based on full interval [0,N), using correct probability estimates, and excluding very large and very small probabilities, the number of bits per input event by which the average code length obtained by the quasi-arithmetic coder exceeds that of an exact arithmetic coder is at most*

$$\frac{4}{\ln 2}\left(\log_2 \frac{2}{e \ln 2}\right)\frac{1}{N} + O\left(\frac{1}{N^2}\right) \approx \frac{0.497}{N} + O\left(\frac{1}{N^2}\right),$$

and the fraction by which the average code length obtained by the quasi-arithmetic coder exceeds that of an exact arithmetic coder is at most

$$\left(\log_2 \frac{2}{e \ln 2}\right)\frac{1}{\log_2 N} + O\left(\frac{1}{(\log N)^2}\right) \approx \frac{0.0861}{\log_2 N} + O\left(\frac{1}{(\log N)^2}\right).$$

General-purpose algorithms for parallel encoding and decoding using both Huffman and quasi-arithmetic coding are given in [5].

Applications

Arithmetic coding can be used in most applications of data compression. Its main usefulness is in obtaining maximum compression in conjunction with an adaptive model or when the probability of one event is close to 1. Arithmetic coding has been used heavily in text compression. It has also been used in image compression in the JPEG international standards for image compression and is an essential part of the JBIG international standards for bilevel image compression. Many fast implementations of arithmetic coding, especially for a two-symbol alphabet, are covered by patents; considerable effort has been expended in adjusting the basic algorithm to avoid infringing those patents.

Open Problems

The technical problems with arithmetic coding itself have been completely solved. The remaining unresolved issues are concerned with modeling, in which the issue is how to decompose an input data set into a sequence of events, so that the set of events possible at each point in the data set can be described by a probability distribution suitable for input into the coder. The modeling issues are entirely application-specific.

Experimental Results

Some experimental results for the Calgary and Canterbury corpora are summarized in a report by Arnold and Bell [1].

Data Sets

Among the most widely used data sets suitable for research in arithmetic coding are the Calgary Corpus and Canterbury Corpus (corpus.canterbury.ac.nz) and the Pizza&Chili Corpus (pizzachili.dcc.uchile.cl or http://pizzachili.di.unipi.it).

URL to Code

A number of implementations of arithmetic coding are available on The Data Compression Resource on the Internet, www.data-compression.info/Algorithms/AC/.

Assignment Problem

Samir Khuller
Computer Science Department, University of Maryland, College Park, MD, USA

Keywords

Weighted bipartite matching

Years and Authors of Summarized Original Work

1955; Kuhn
1957; Munkres

Problem Definition

Assume that a complete bipartite graph, $G(X, Y, X \times Y)$, with weights $w(x, y)$ assigned to every edge (x, y) is given. A matching M is a subset of edges so that no two edges in M have a common vertex. A perfect matching is one in which all the nodes are matched. Assume that $|X| = |Y| = n$. The **weighted matching problem** is to find a matching with the greatest total weight, where $w(M) = \sum_{e \in M} w(e)$. Since G is a complete bipartite graph, it has a perfect matching. An algorithm that solves the weighted matching problem is due to Kuhn [4] and Munkres [6]. Assume that all edge weights are non-negative.

Key Results

Define a *feasible vertex labeling* ℓ as a mapping from the set of vertices in G to the reals, where

$$\ell(x) + \ell(y) \geq w(x, y).$$

Call $\ell(x)$ the label of vertex x. It is easy to compute a feasible vertex labeling as follows:

$$\forall y \in Y \ell(y) = 0$$

and

$$\forall x \in X \quad \ell(x) = \max_{y \in Y} w(x, y).$$

Define the **equality subgraph**, G_ℓ, to be the spanning subgraph of G, which includes all vertices of G but only those edges (x, y) that have weights such that

$$w(x, y) = \ell(x) + \ell(y).$$

The connection between equality subgraphs and maximum-weighted matchings is provided by the following theorem:

Theorem 1 *If the equality subgraph, G_ℓ, has a perfect matching, M^*, then M^* is a maximum-weighted matching in G.*

In fact, note that the sum of the labels is an upper bound on the weight of the maximum-weighted perfect matching. The algorithm eventually finds a matching and a feasible labeling

such that the weight of the matching is equal to the sum of all the labels.

High-Level Description

The above theorem is the basis of an algorithm for finding a maximum-weighted matching in a complete bipartite graph. Starting with a feasible labeling, compute the equality subgraph, and then find a maximum matching in this subgraph (here, one can ignore weights on edges). If the matching found is perfect, the process is done. If it is not perfect, more edges are added to the equality subgraph by revising the vertex labels. After adding edges to the equality subgraph, either the size of the matching goes up (an augmenting path is found) or the Hungarian tree continues to grow. (This is the structure of explored edges when one starts BFS simultaneously from all free nodes in S. When one reaches a matched node in T, one only explores the matched edge; however, all edges incident to nodes in S are explored.) In the former case, the phase terminates, and a new phase starts (since the matching size has gone up). In the latter case, the Hungarian tree grows by adding new nodes to it, and clearly, this cannot happen more than n times.

Let S be the set of free nodes in X. Grow Hungarian trees from each node in S. Let T be the nodes in Y encountered in the search for an augmenting path from nodes in S. Add all nodes from X that are encountered in the search to S.

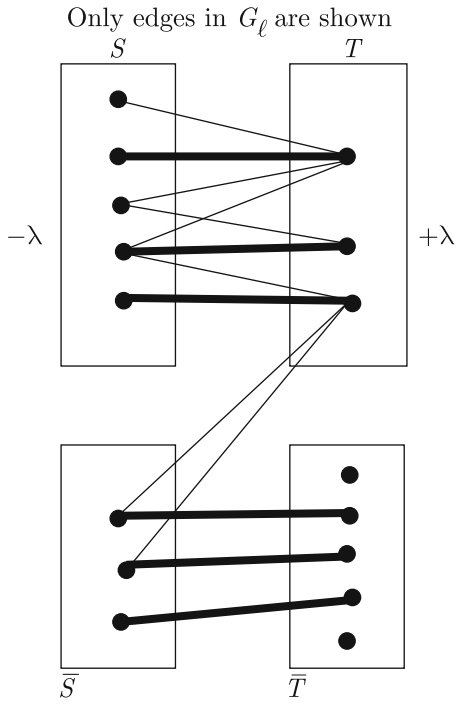
Note the following about this algorithm:

$$\overline{S} = X \backslash S.$$

$$\overline{T} = Y \backslash T.$$

$$|S| > |T|.$$

There are no edges from S to $\overline{T}$ since this would imply that one did not grow the Hungarian trees completely. As the Hungarian trees are grown in G_ℓ, alternate nodes in the search are placed into S and T. To revise the labels, take the labels in S, and start decreasing them uniformly (say, by λ), and at the same time, increase the labels in T by λ. This ensures that the edges from S to T do not leave the equality subgraph (Fig. 1).



Assignment Problem, Fig. 1 Sets S and T as maintained by the algorithm

As the labels in S are decreased, edges (in G) from S to $\overline{T}$ will potentially enter the equality subgraph, G_ℓ. As we increase λ, at some point in time, an edge enters the equality subgraph. This is when one stops and updates the Hungarian tree. If the node from $\overline{T}$ added to T is matched to a node in $\overline{S}$, both these nodes are moved to S and T, which yields a larger Hungarian tree. If the node from $\overline{T}$ is free, an augmenting path is found, and the phase is complete. One phase consists of those steps taken between increases in the size of the matching. There are at most n phases, where n is the number of vertices in G (since in each phase the size of the matching increases by 1). Within each phase, the size of the Hungarian tree is increased at most n times. It is clear that in $O(n^2)$ time, one can figure out which edge from S to $\overline{T}$ is the first to enter the equality subgraph (one simply scans all the edges). This yields an $O(n^4)$ bound on the total running time. How to implement it in $O(n^3)$ time is now shown.

More Efficient Implementation

Define the slack of an edge as follows:

$$slack\,(x, y) = \ell\,(x) + \ell\,(y) - w\,(x, y)\,.$$

Then,

$$\lambda = \min_{x \in S, y \in \overline{T}} slack\,(x, y)\,.$$

Naively, the calculation of λ requires $O(n^2)$ time. For every vertex $y \in \overline{T}$, keep track of the edge with the smallest slack, i.e.,

$$slack\,[y] = \min_{x \in S} slack\,(x, y)\,.$$

The computation of $slack[y]$ (for all $y \in \overline{T}$) requires $O(n^2)$ time at the start of a phase. As the phase progresses, it is easy to update all the *slack* values in $O(n)$ time since all of them change by the same amount (the labels of the vertices in S are going down uniformly). Whenever a node u is moved from $\overline{S}$ to S, one must recompute the slacks of the nodes in $\overline{T}$, requiring $O(n)$ time. But a node can be moved from $\overline{S}$ to S at most n times.

Thus, each phase can be implemented in $O(n^2)$ time. Since there are n phases, this gives a running time of $O(n^3)$. For sparse graphs, there is a way to implement the algorithm in $O(n(m + n \log n))$ time using min cost flows [1], where m is the number of edges.

Applications

There are numerous applications of biparitite matching, for example, scheduling unit-length jobs with integer release times and deadlines even with time-dependent penalties.

Open Problems

Obtaining a linear, or close to linear, time algorithm.

Asynchronous Consensus Impossibility

Maurice Herlihy
Department of Computer Science,
Brown University, Providence, RI, USA

Keywords

Agreement; Wait-free consensus

Years and Authors of Summarized Original Work

1985; Fischer, Lynch, Paterson

Problem Definition

Consider a distributed system consisting of a set of *processes* that communicate by sending and receiving messages. The network is a multiset of messages, where each message is addressed to some process. A process is a state machine that can take three kinds of *steps*.

- In a *send* step, a process places a message in the network.
- In a *receive* step, a process A either reads and removes from the network a message addressed to A, or it reads a distinguished *null* value, leaving the network unchanged. If a message addressed to A is placed in the network, and if A subsequently performs an infinite number of receive steps, then A will eventually receive that message.
- In a *computation* state, a process changes state without communicating with any other process.

Processes are *asynchronous*: there is no bound on their relative speeds. Processes can *crash*: they can simply halt and take no more steps. This article considers executions in which at most one process crashes.

In the *consensus* problem, each process starts with a private *input* value, communicates with the others, and then halts with a *decision* value. These values must satisfy the following properties:

- *Agreement:* all processes' decision values must agree.
- *Validity:* every decision value must be some process' input.
- *Termination:* every non-fault process must decide in a finite number of steps.

Fischer, Lynch, and Paterson showed that there is no protocol that solves consensus in any asynchronous message-passing system where even a single process can fail. This result is one of the most influential results in Distributed Computing, laying the foundations for a number of subsequent research efforts.

Terminology

Without loss of generality, one can restrict attention to *binary* consensus, where the inputs are 0 or 1. A *protocol state* consists of the states of the processes and the multiset of messages in transit in the network. An *initial state* is a protocol state before any process has moved, and a *final state* is a protocol state after all processes have finished. The *decision value* of any final state is the value decided by all processes in that state.

Any terminating protocol's set of possible states forms a tree, where each node represents a possible protocol state, and each edge represents a possible step by some process. Because the protocol must terminate, the tree is finite. Each leaf node represents a final protocol state with decision value either 0 or 1.

A *bivalent* protocol state is one in which the eventual decision value is not yet fixed. From any bivalent state, there is an execution in which the eventual decision value is 0, and another in which it is 1. A *univalent* protocol state is one in which the outcome is fixed. Every execution starting from a univalent state decides the same value. A *1-valent* protocol state is univalent with eventual decision value 1, and similarly for a *0-valent* state.

A protocol state is *critical* if

- it is bivalent, and
- if any process takes a step, the protocol state becomes univalent.

Key Results

Lemma 1 *Every consensus protocol has a bivalent initial state.*

Proof Assume, by way of contradiction, that there exists a consensus protocol for $(n+1)$ threads $A_0, \cdots, A_n$ in which every initial state is univalent. Let s_i be the initial state where processes $A_i, \cdots, A_n$ have input 0 and $A_0, \ldots, A_{i-1}$ have input 1. Clearly, s_0 is 0-valent: all processes have input 0, so all must decide 0 by the validity condition. If s_i is 0-valent, so is s_{i+1}. These states differ only in the input to process $A_i : 0$ in s_i, and 1 in s_{i+1}. Any execution starting from s_i in which A_i halts before taking any steps is indistinguishable from an execution starting from s_{i+1} in which A_i halts before taking any steps. Since processes must decide 0 in the first execution, they must decide 1 in the second. Since there

is one execution starting from s_{i+1} that decides 0, and since s_{i+1} is univalent by hypothesis, s_{i+1} is 0-valent. It follows that the state s_{n+1}, in which all processes start with input 1, is 0-valent, a contradiction. □

Lemma 2 *Every consensus protocol has a critical state.*

Proof by contradiction. By Lemma 1, the protocol has a bivalent initial state. Start the protocol in this state. Repeatedly choose a process whose next step leaves the protocol in a bivalent state, and let that process take a step. Either the protocol runs forever, violating the termination condition, or the protocol eventually enters a critical state.□

Theorem 1 *There is no consensus protocol for an asynchronous message-passing system where a single process can crash.*

Proof Assume by way of contradiction that such a protocol exists. Run the protocol until it reaches a critical state s. There must be two processes A and B such that A's next step carries the protocol to a 0-valent state, and B's next step carries the protocol to a 1-valent state.

Starting from s, let s_A be the state reached if A takes the first step, s_B if B takes the first step, s_{AB} if A takes a step followed by B, and so on. States s_A and s_{AB} are 0-valent, while s_B and s_{BA} are 1-valent. The rest is a case analysis.

Of all the possible pairs of steps A and B could be about to execute, most of them *commute*: states s_{AB} and s_{BA} are identical, which is a contradiction because they have different valences.

The only pair of steps that do not commute occurs when A is about to send a message to B (or vice versa). Let s_{AB} be the state resulting if A sends a message to B and B then receives it, and let s_{BA} be the state resulting if B receives a different message (or *null*) and then A sends its message to B. Note that every process other than B has the same local state in s_{AB} and s_{BA}. Consider an execution starting from s_{AB} in which every process other than B takes steps in round-robin order. Because s_{AB} is 0-valent, they will eventually decide 0. Next, consider an execution starting from s_{BA} in which every process other than B takes steps in round-robin order. Because s_{BA} is 1-valent, they will eventually decide 1. But all processes other than B have the same local states at the end of each execution, so they cannot decide different values, a contradiction. □

In the proof of this theorem, and in the proofs of the preceding lemmas, we construct scenarios where at most a single process is delayed. As a result, this impossibility result holds for any system where a single process can fail undetectably.

Applications

The consensus problem is a key tool for understanding the power of various asynchronous models of computation.

Open Problems

There are many open problems concerning the solvability of consensus in other models, or with restrictions on inputs.

Related Work

The original paper by Fischer, Lynch, and Paterson [8] is still a model of clarity.

Many researchers have examined alternative models of computation in which consensus can be solved. Dolev, Dwork, and Stockmeyer [5] examine a variety of alternative message-passing models, identifying the precise assumptions needed to make consensus possible. Dwork, Lynch, and Stockmeyer [6] derive upper and lower bounds for a semi-synchronous model where there is an upper and lower bound on message delivery time. Ben-Or [1] showed that introducing randomization makes consensus possible in an asynchronous message-passing system. Chandra and Toueg [3] showed that consensus becomes possible if in the presence of an oracle that can (unreliably) detect when a process has crashed. Each of the papers cited

here has inspired many follow-up papers. A good place to start is the excellent survey by Fich and Ruppert [7].

A protocol is *wait-free* if it tolerates failures by all but one of the participants. A concurrent object implementation is *linearizable* if each method call seems to take effect instantaneously at some point between the method's invocation and response. Herlihy [9] showed that shared-memory objects can each be assigned a *consensus number*, which is the maximum number of processes for which there exists a wait-free consensus protocol using a combination of read-write memory and the objects in question. Consensus numbers induce an infinite hierarchy on objects, where (simplifying somewhat) higher objects are more powerful than lower objects. In a system of n or more concurrent processes, it is impossible to construct a lock-free implementation of an object with consensus number n from an object with a lower consensus number. On the other hand, any object with consensus number n is *universal* in a system of n or fewer processes: it can be used to construct a wait-free linearizable implementation of any object.

In 1990, Chaudhuri [4] introduced the *k-set agreement* problem (sometimes called *k-set consensus*, which generalizes consensus by allowing k or fewer distinct decision values to be chosen. In particular, 1-set agreement is consensus. The question whether k-set agreement can be solved in asynchronous message-passing models was open for several years, until three independent groups [2, 10, 11] showed that no protocol exists.

Atomic Broadcast

Xavier Défago
School of Information Science, Japan Advanced Institute of Science and Technology (JAIST), Ishikawa, Japan

Keywords

Atomic multicast; Total order broadcast; Total order multicast

Years and Authors of Summarized Original Work

1995; Cristian, Aghili, Strong, Dolev

Problem Definition

The problem is concerned with allowing a set of processes to concurrently broadcast messages while ensuring that all destinations consistently deliver them in the exact same sequence, in spite of the possible presence of a number of faulty processes.

The work of Cristian, Aghili, Strong, and Dolev [7] considers the problem of atomic broadcast in a system with approximately synchronized clocks and bounded transmission and processing delays. They present successive extensions of an algorithm to tolerate a bounded number of omission, timing, or Byzantine failures, respectively.

Related Work

The work presented in this entry originally appeared as a widely distributed conference contribution [6], over a decade before being published in a journal [7], at which time the work was well-known in the research community. Since there was no significant change in the algorithms, the historical context considered here is hence with respect to the earlier version.

Lamport [11] proposed one of the first published algorithms to solve the problem of ordering broadcast messages in a distributed systems. That algorithm, presented as the core of a mutual exclusion algorithm, operates in a fully asynchronous system (i.e., a system in which there are no bounds on processor speed or communication delays), but does not tolerate failures. Although the algorithms presented here rely on physical clocks rather than Lamport's logical clocks, the principle used for ordering messages is essentially the same: message carry a timestamp of their sending time; messages are delivered in increasing order of the timestamp, using the sending processor name for messages with equal timestamps.

At roughly the same period as the initial publication of the work of Cristian et al. [6], Chang and Maxemchuck [3] proposed an atomic broadcast protocol based on a token passing protocol, and tolerant to crash failures of processors. Also, Carr [1] proposed the Tandem global update protocol, tolerant to crash failures of processors.

Cristian [5] later proposed an extension to the omission-tolerant algorithm presented here, under the assumption that the communication system consists of $f + 1$ independent broadcast channels (where f is the maximal number of faulty processors). Compared with the more general protocol presented here, its extension generates considerably fewer messages.

Since the work of Cristian, Aghili, Strong, and Dolev [7], much has been published on the problem of atomic broadcast (and its numerous variants). For further reading, Défago, Schiper, and Urbán [8] surveyed more than sixty different algorithms to solve the problem, classifying them into five different classes and twelve variants. That survey also reviews many alternative definitions and references about two hundred articles related to this subject. This is still a very active research area, with many new results being published each year.

Hadzilacos and Toueg [10] provide a systematic classification of specifications for variants of atomic broadcast as well as other broadcast problems, such as reliable broadcast, FIFO broadcast, or causal broadcast.

Chandra and Toueg [2] proved the equivalence between atomic broadcast and the *consensus* problem. Thus, any application solved by a consensus can also be solved by atomic broadcast and vice-versa. Similarly, impossibility results apply equally to both problems. For instance, it is well-known that consensus, thus atomic broadcast, cannot be solved deterministically in an asynchronous system with the presence of a faulty process [9].

Notations and Assumptions

The system G consists of n distributed processors and m point-to-point communication links. A link does not necessarily exists between every pair of processors, but it is assumed that the communication network remains connected even in the face of faults (whether processors or links). All processors have distinct names and there exists a total order on them (e.g., lexicographic order).

A component (link or processor) is said to be *correct* if its behavior is consistent with its specification, and *faulty* otherwise. The paper considers three classes of component failures, namely, omission, timing, and Byzantine failures.

- An *omission* failure occurs when the faulty component fails to provide the specified output (e.g., loss of a message).
- A *timing* failure occurs when the faulty component omits a specified output, or provides it either too early or too late.
- A *Byzantine* failure [12] occurs when the component does not behave according to its specification, for instance, by providing output different from the one specified. In particular, the paper considers authentication-detectable Byzantine failures, that is, ones that are detectable using a message authentication protocol, such as error correction codes or digital signatures.

Each processor p has access to a local clock C_p with the properties that (1) two separate clock readings yield different values, and (2) clocks are ε-synchronized, meaning that, at any real time t, the deviation in readings of the clocks of any two processors p and q is at most ε.

In addition, transmission and processing delays, as measured on the clock of a correct processor, are bounded by a known constant δ. This bound accounts not only for delays in transmission and processing, but also for delays due to scheduling, overload, clock drift or adjustments. This is called a synchronous system model.

The diffusion time $d\delta$ is the time necessary to propagate information to all correct processes, in a surviving network of diameter d with the presence of a most π processor failures and λ link failures.

Problem Definition

The problem of atomic broadcast is defined in a synchronous system model as a broadcast primitive which satisfies the following three properties: atomicity, order, and termination.

Problem 1 (Atomic broadcast)
INPUT: A stream of messages broadcast by n concurrent processors, some of which may be faulty.
OUTPUT: The messages delivered in sequence, with the following properties:

1. *Atomicity*: if any correct processor delivers an update at time U on its clock, then that update was initiated by some processor and is delivered by each correct processor at time U on its clock.
2. *Order*: all updates delivered by correct processors are delivered in the same order by each correct processor.
3. *Termination*: every update whose broadcast is initiated by a correct processor at time T on its clock is delivered at all correct processors at time $T + \Delta$ on their clock.

Nowadays, problem definitions for atomic broadcast that do not explicitly refer to physical time are often preferred. Many variants of time-free definitions are reviewed by Hadzilacos and Toueg [10] and Défago et al. [8]. One such alternate definition is presented below, with the terminology adapted to the context of this entry.

Problem 2 (Total order broadcast)
INPUT: A stream of messages broadcast by n concurrent processors, some of which may be faulty.
OUTPUT: The messages delivered in sequence, with the following properties:

1. *Validity*: if a correct processor broadcasts a message m, then it eventually delivers m.
2. *Uniform agreement*: if a processor delivers a message m, then all correct processors eventually deliver m.
3. *Uniform integrity*: for any message m, every processor delivers m at most once, and only if m was previously broadcast by its sending processor.
4. *Gap-free uniform total order*: if some processor delivers message m' after message m, then a processor delivers m' only after it has delivered m.

Key Results

The paper presents three algorithms for solving the problem of atomic broadcast, each under an increasingly demanding failure model, namely, omission, timing, and Byzantine failures. Each protocol is actually an extension of the previous one.

All three protocols are based on a classical flooding, or information diffusion, algorithm [14]. Every message carries its initiation timestamp T, the name of the initiating processor s, and an update σ. A message is then uniquely identified by (s, T). Then, the basic protocol is simple. Each processor logs every message it receives until it is delivered. When it receives a message that was never seen before, it forwards that message to all other neighbor processors.

Atomic Broadcast for Omission Failures

The first atomic broadcast protocol, supporting omission failures, considers a termination time Δ_o as follows.

$$\Delta_o = \pi\delta + d\delta + \varepsilon\,. \tag{1}$$

The delivery deadline $T + \Delta_o$ is the time by which a processor can be sure that it has received copies of every message with timestamp T (or earlier) that could have been received by some correct process.

The protocol then works as follows. When a processor initiates an atomic broadcast, it propagates that message, similar to the diffusion algorithm described above. The main exception is that every message received after the local clock exceeds the delivery deadline of that message, is discarded. Then, at local time $T + \Delta_o$, a processor delivers all messages timestamped with T, in order of the name of the sending processor. Finally, it discards all copies of the messages from its logs.

Atomic Broadcast for Timing Failures

The second protocol extends the first one by introducing a hop count (i.e., a counter incremented each time a message is relayed) to the messages. With this information, each relaying processor can determine when a message is timely, that is, if a message timestamped T with hop count h is received at time U then the following condition must hold.

$$T - h\varepsilon < U < T + h(\delta + \varepsilon)\,. \tag{2}$$

Before relaying a message, each processor checks the acceptance test above and discard the message if it does not satisfy it. The termination time Δ_t of the protocol for timing failures is as follows.

$$\Delta_t = \pi(\delta + \varepsilon) + d\delta + \varepsilon\,. \tag{3}$$

The authors point out that discarding early messages is not necessary for correctness, but ensures that correct processors keep messages in their log for a bounded amount of time.

Atomic Broadcast for Byzantine Failures

Given some text, every processor is assumed to be able to generate a signature for it, that cannot be faked by other processors. Furthermore, every processor knows the name of every other processors in the network, and has the ability to verify the authenticity of their signature.

Under the above assumptions, the third protocol extends the second one by adding signatures to the messages. To prevent a Byzantine processor (or link) from tampering with the hop count, a message is co-signed by every processor that relays it. For instance, a message signed by k processors $p_1, \ldots, p_k$ is as follows.

$$(relayed, \ldots (relayed, (first, T, \sigma, p_1, s_1), p_2, s_2)\,, \ldots p_k, s_k)$$

Where σ is the update, T the timestamp, p_1 the message source, and s_i the signature generated by processor p_i. Any message for which one of the signature cannot be authenticated is simply discarded. Also, if several updates initiated by the same processor p carry the same timestamp, this indicates that p is faulty and the corresponding updates are discarded. The remainder of the protocol is the same as the second one, where

the number of hops is given by the number of signatures. The termination time Δ_b is also as follows.

$$\Delta_b = \pi(\delta + \varepsilon) + d\delta + \varepsilon\,. \tag{4}$$

The authors insist however that, in this case, the transmission time δ must be considerably larger than in the previous case, since it must account for the time spent in generating and verifying the digital signatures; usually a costly operation.

Bounds

In addition to the three protocols presented above and their correctness, Cristian et al. [7] prove the following two lower bounds on the termination time of atomic broadcast protocols.

Theorem 1 *If the communication network G requires x steps, then any atomic broadcast protocol tolerant of up to π processor and λ link omission failures has a termination time of at least $x\delta + \varepsilon$.*

Theorem 2 *Any atomic broadcast protocol for a Hamiltonian network with n processors that tolerate $n-2$ authentication-detectable Byzantine processor failures cannot have a termination time smaller than $(n-1)(\delta + \varepsilon)$.*

Applications

The main motivation for considering this problem is its use as the cornerstone for ensuring fault-tolerance through process replication. In particular, the authors consider a *synchronous replicated storage*, which they define as a distributed and resilient storage system that displays the same content at every correct physical processor at any clock time. Using atomic broadcast to deliver updates ensures that all updates are applied at all correct processors in the same order. Thus, provided that the replicas are initially consistent, they will remain consistent. This technique, called *state-machine replication* [11, 13] or also *active replication*, is widely used in practice as a means of supporting fault-tolerance in distributed systems.

In contrast, Cristian et al. [7] consider atomic broadcast in a *synchronous* system with bounded transmission and processing delays. Their work was motivated by the implementation of a highly-available replicated storage system, with tightly coupled processors running a real-time operating system.

Atomic broadcast has been used as a support for the replication of running processes in real-time systems or, with the problem reformulated to isolate explicit timing requirements, has also been used as a support for fault-tolerance and replication in many group communication toolkits (see survey of Chockler et al. [4]).

In addition, atomic broadcast has been used for the replication of database systems, as a means to reduce the synchronization between the replicas. Wiesmann and Schiper [15] have compared different database replication and transaction processing approaches based on atomic broadcast, showing interesting performance gains.

Attribute-Efficient Learning

Jyrki Kivinen
Department of Computer Science, University of Helsinki, Helsinki, Finland

Keywords

Learning with irrelevant attributes

Years and Authors of Summarized Original Work

1987; Littlestone

Problem Definition

Given here is a basic formulation using the *online mistake-bound* model, which was used by Littlestone [9] in his seminal work.

Fix a class C of Boolean functions over n variables. To start a learning scenario, a *target function* $f_* \in C$ is chosen but not revealed to the *learning algorithm*. Learning then proceeds in a sequence of *trials*. At trial t, an input $\boldsymbol{x}_t \in \{0,1\}^n$ is first given to the learning algorithm. The learning algorithm then produces its *prediction* $\hat{y}_t$, which is its guess as to the unknown value $f_*(x_t)$. The correct value $y_t = f_*(x_t)$ is then revealed to the learner. If $y_t \neq \hat{y}_t$, the learning algorithm made a *mistake*. The learning algorithm learns C with mistake-bound m, if the number of mistakes never exceeds m, no matter how many trials are made and how f_* and $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots$ are chosen.

Variable (or attribute) X_i is *relevant* for function $f : \{0,1\}^n \to \{0,1\}$ if $f(x_1, \ldots, x_i, \ldots, x_n) \neq f(x_1, \ldots, 1 - x_i, \ldots, x_n)$ holds for some $\vec{x} \in \{0,1\}^n$. Suppose now that for some $k \leq n$, every function $f \in C$ has at most k relevant variables. It is said that a learning algorithm learns class C *attribute-efficiently*, if it learns C with a mistake-bound polynomial in k and $\log n$. Additionally, the computation time for each trial is usually required to be polynomial in n.

Key Results

The main part of current research of attribute-efficient learning stems from Littlestone's Winnow algorithm [9]. The basic version of Winnow maintains a weight vector $\boldsymbol{w}_t = (w_{t,1}, \ldots, w_{t,n}) \in \mathbb{R}^n$. The prediction for input $\boldsymbol{x}_t \in \{0,1\}^n$ is given by

$$\hat{y}_t = \operatorname{sign}\left(\sum_{i=1}^{n} w_{t,i} x_{t,i} - \theta\right)$$

where θ is a parameter of the algorithm. Initially $\boldsymbol{w}_1 = (1, \ldots, 1)$, and after trial t, each component $w_{t,i}$ is updated according to

$$w_{t+1,i} = \begin{cases} \alpha w_{t,i} & \text{if } y_t = 1,\ \hat{y}_t = 0 \text{ and } x_{t,i} = 1 \\ w_{t,i}/\alpha & \text{if } y_t = 0,\ \hat{y}_t = 1 \text{ and } x_{t,i} = 1 \\ w_{t,i} & \text{otherwise} \end{cases} \tag{1}$$

where $\alpha > 1$ is a learning rate parameter.

Littlestone's basic result is that with a suitable choice of θ and α, Winnow learns the class of monotone k-literal disjunctions with mistake-bound $O(k \log n)$. Since the algorithm changes its weights only when a mistake occurs, this bound also guarantees that the weights remain small enough for computation times to remain polynomial in n. With simple transformations, Winnow also yields attribute-efficient learning algorithms for general disjunctions and conjunctions. Various subclasses of DNF formulas and decision lists [8] can be learned, too.

Winnow is quite robust against noise, i.e., errors in input data. This is extremely important for practical applications. Remove now the assumption about a target function $f_* \in C$ satisfying $y_t = f_*(x_t)$ for all t. Define *attribute error* of a pair $(\boldsymbol{x}, y)$ with respect to a function f as the minimum Hamming distance between $\boldsymbol{x}$ and $\boldsymbol{x}'$ such that $f(\boldsymbol{x}') = y$. The attribute error of a sequence of trials with respect to f is the sum of attribute errors of the individual pairs $(\boldsymbol{x}_t, y_t)$. Assuming the sequence of trials has attribute error at most A with respect to some k-literal disjunction, Auer and Warmuth [1] show that Winnow makes $O(A+k \log n)$ mistakes. The noisy scenario can also be analyzed in terms of *hinge loss* [5].

The update rule (1) has served as a model for a whole family of *multiplicative update algorithms*. For example, Kivinen and Warmuth [7] introduce the exponentiated gradient algorithm, which is essentially Winnow modified for continuous-valued prediction, and show how it can be motivated by a relative entropy minimization principle.

Consider a function class C where each function can be encoded using $O(p(k) \log n)$ bits for some polynomial p. An example would be Boolean formulas with k relevant variables, when the size of the formula is restricted to $p(k)$ ignoring the size taken by the variables. The cardinality of C is then $|C| = 2^{O(p(k) \log n)}$. The classical halving algorithm (see [9] for discussion and references) learns any class consisting of m Boolean functions with mistake-bound $\log_2 m$ and would thus provide an attribute-efficient algorithm for such a class C. However, the running time would not be polynomial. Another serious drawback would be that the halving algorithm does not tolerate any noise. Interestingly, a multiplicative update similar to (1) has been used in Littlestone and Warmuth's weighted majority algorithm [10], and also Vovk's aggregating algorithm [14], to produce a noise-tolerant generalization of the halving algorithm.

Attribute-efficient learning has also been studied in other learning models than the mistake-bound model, such as Probably Approximately Correct learning [4], learning with uniform distribution [12], and learning with membership queries [3]. The idea has been further developed into learning with a potentially infinite number of attributes [2].

Applications

Attribute-efficient algorithms for simple function classes have a potentially interesting application as a component in learning more complex function classes. For example, any monotone k-term DNF formula over variables $x_1, \ldots, x_n$ can be represented as a monotone k-literal disjunction over 2^n variables z_A, where z_A is defined as $z_A = \prod_{i \in A} x_i$ for $A \subseteq \{1, \ldots, n\}$. Running Winnow with the transformed inputs $\boldsymbol{z} \in \{0,1\}^{2^n}$ would give a mistake-bound $O(k \log 2^n) = O(kn)$. Unfortunately the running time would be linear in 2^n, at least for a naive implementation. Khardon et al. [6] provide discouraging computational hardness results for this potential application.

Online learning algorithms have a natural application domain in signal processing. In this setting, the sender emits a true signal y_t at time t, for $t = 1, 2, 3, \ldots$. At some later time $(t + d)$, a receiver receives a signal z_t, which is a sum

of the original signal y_t and various echoes of earlier signals $y_{t'}$, $t' < t$, all distorted by random noise. The task is to recover the true signal y_t based on received signals $z_t, z_{t-1}, \ldots, z_{t-l}$ over some time window l. Currently attribute-efficient algorithms are not used for such tasks, but see [11] for preliminary results.

Attribute-efficient learning algorithms are similar in spirit to statistical methods that find sparse models. In particular, statistical algorithms that use L_1 regularization are closely related to multiplicative algorithms such as winnow and exponentiated gradient. In contrast, more classical L_2 regularization leads to algorithms that are not attribute-efficient [13].

Keywords

Automated proofs of upper bounds on the running time of splitting algorithms

Years and Authors of Summarized Original Work

2004; Gramm, Guo, Hüffner, Niedermeier

Problem Definition

This problem is concerned with the automated development and analysis of search tree algorithms. Search tree algorithms are a popular way to find optimal solutions to NP-complete problems. (For ease of presentation, only decision problems are considered; adaption to optimization problems is straightforward.) The idea is to recursively solve several smaller instances in such a way that at least one branch is a yes-

instance if and only if the original instance is. Typically, this is done by trying all possibilities to contribute to a solution certificate for a small part of the input, yielding a small local modification of the instance in each branch.

For example, consider the NP-complete CLUSTER EDITING problem: can a given graph be modified by adding or deleting up to k edges such that the resulting graph is a *cluster graph*, that is, a graph that is a disjoint union of cliques? To give a search tree algorithm for CLUSTER EDITING, one can use the fact that cluster graphs are exactly the graphs that do not contain a P_3 (a path of 3 vertices) as an induced subgraph. One can thus solve CLUSTER EDITING by finding a P_3 and splitting it into 3 branches: delete the first edge, delete the second edge, or add the missing edge. By this characterization, whenever there is no P_3 found, one already has a cluster graph. The original instance has a solution with k modifications if and only if at least one of the branches has a solution with $k-1$ modifications.

Analysis

For NP-complete problems, the running time of a search tree algorithm only depends on the size of the search tree up to a polynomial factor , which depends on the number of branches and the reduction in size of each branch. If the algorithm solves a problem of size s and calls itself recursively for problems of sizes $s-d_1,\ldots,s-d_i$, then $(d_1,\ldots,d_i)$ is called the *branching vector* of this recursion. It is known that the size of the search tree is then $O(\alpha^s)$, where the *branching number* α is the only positive real root of the *characteristic polynomial*

$$z^d - z^{d-d_1} - \cdots - z^{d-d_i}\ , \qquad (1)$$

where $d = \max\{d_1,\ldots,d_i\}$. For the simple CLUSTER EDITING search tree algorithm and the size measure k, the branching vector is (1, 1, 1) and the branching number is 3, meaning that the running time is up to a polynomial factor $O(3^k)$.

Case Distinction

Often, one can obtain better running times by distinguishing a number of cases of instances, and giving a specialized branching for each case. The overall running time is then determined by the branching number of the worst case. Several publications obtain such algorithms by hand (e.g., a search tree of size $O(2.27^k)$ for CLUSTER EDITING [4]); the topic of this work is how to automate this. That is, the problem is the following:

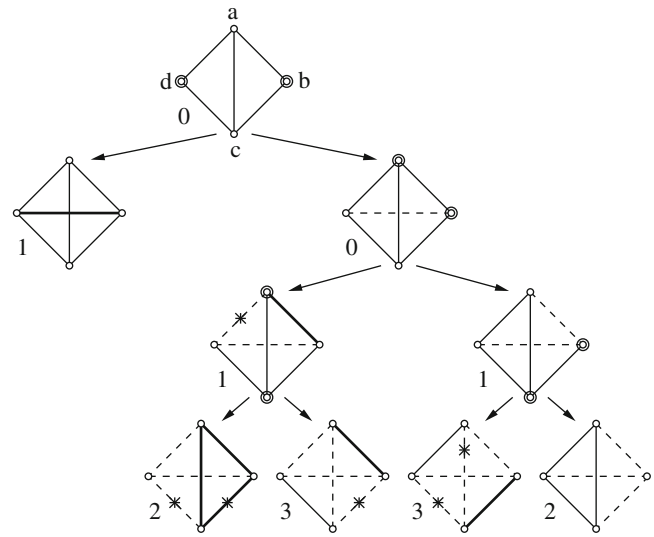
Problem 1 (Fast Search Tree Algorithm)
INPUT: An NP-hard problem $\mathcal{P}$ and a size measure $s(I)$ of an instance I of $\mathcal{P}$ where instances I with $s(I)=0$ can be solved in polynomial time.
OUTPUT: A partition of the instance set of $\mathcal{P}$ into *cases*, and for each case a branching such that the maximum branching number over all branchings is as small as possible.

Note that this problem definition is somewhat vague; in particular, to be useful, the case an instance belongs to must be recognizable quickly. It is also not clear whether an optimal search tree algorithm exists; conceivably, the branching number can be continuously reduced by increasingly complicated case distinctions.

Key Results

Gramm et al. [3] describe a method to obtain fast search tree algorithms for CLUSTER EDITING and related problems, where the size measure is the number of editing operations k. To get a case distinction, a number of subgraphs are enumerated such that each instance is known to contain at least one of these subgraphs. It is next described how to obtain a branching for a particular case.

A standard way of systematically obtaining specialized branchings for instance cases is to use a combination of *basic branching* and *data reduction rules*. Basic branching is typically a very simple branching technique, and data reduction rules replace an instance with a smaller, solution-equivalent instance in polynomial time. Applying this to CLUSTER EDITING first requires a small modification of the problem: one considers an *annotated* version, where an edge can be marked as *permanent* and a non-edge can be marked as *forbidden*. Any such annotated vertex pair cannot



Automated Search Tree Generation, Fig. 1 Branching for a CLUSTER EDITING case using only basic branching on vertex pairs (*double circles*), and applications of the reduction rules (*asterisks*). Permanent edges are marked *bold*, forbidden edges *dashed*. The *numbers* next to the subgraphs state the change of the problem size k. The branching vector is (1, 2, 3, 3, 2), corresponding to a search tree size of $O(2.27^k)$

be edited anymore. For a pair of vertices, the basic branching then branches into two cases: permanent or forbidden (one of these options will require an editing operation). The reduction rules are: if two permanent edges are adjacent, the third edge of the triangle they induce must also be permanent; and if a permanent and a forbidden edge are adjacent, the third edge of the triangle they induce must be forbidden.

Figure 1 shows an example branching derived in this way.

Using a refined method of searching the space for all possible cases and to distinguish all branchings for a case, Gramm et al. [3] derive a number of search tree algorithms for graph modification problems.

Applications

Gramm et al. [3] apply the automated generation of search tree algorithms to several graph modification problems (see also Table 1). Further, Hüffner [5] demonstrates an application of DOMINATING SET on graphs with maximum degree 4, where the size measure is the size of the dominating set.

Fedin and Kulikov [2] examine variants of SAT; however, their framework is limited in that it only proves upper bounds for a fixed algorithm instead of generating algorithms.

Skjernaa [6] also presents results on variants of SAT. His framework does not require user-provided data reduction rules, but determines reductions automatically.

Open Problems

The analysis of search tree algorithms can be much improved by describing the "size" of an instance by more than one variable, resulting in multivariate recurrences [1]. It is open to introduce this technique into an automation framework.

It has frequently been reported that better running time bounds obtained by distinguishing a large number of cases do not necessarily speed up, but in fact can slow down, a program. A careful investigation of the tradeoffs involved and a corresponding adaption of the automation frameworks is an open task.

Experimental Results

Gramm et al. [3] and Hüffner [5] report search tree sizes for several NP-complete problems. Further, Fedin and Kulikov [2] and Skjernaa [6]

Automated Search Tree Generation, Table 1 Summary of search tree sizes where automation gave improvements. "Known" is the size of the best previously published "hand-made" search tree. For the satisfiability problems, m is the number of clauses and l is the length of the formula

2013; Gaspers, Szeider

Problem Definition

In the satisfiability problem (SAT), the input is a Boolean formula in conjunctive normal form (CNF), and the question is whether the formula is satisfiable, that is, whether there exists an assignment of truth values to the variables such that the formula evaluates to true. For example, the formula

$$(x \vee \neg y) \wedge (\neg x \vee y \vee z) \wedge (x \vee \neg z) \wedge (\neg x \vee y \vee z)$$

is satisfiable since it evaluates to true if we set x, y, and z to true.

Several classes of CNF formulas are known for which SAT can be solved in polynomial time – so-called islands of tractability. For a given island of tractability C, a C-backdoor is a set of variables of a formula such that assigning truth values to these variables gives a formula in C.

Formally, let C be a class of formulas for which the recognition problem and the satisfiability problem can be solved in polynomial time. For a subset of variables $X \subseteq \mathrm{var}(F)$ of a CNF formula F, and an assignment $\alpha : X \to \{\text{true}, \text{false}\}$ of truth values to these variables, the reduced formula $F[\alpha]$ is obtained from F by removing all the clauses containing a true literal under α and removing all false literals from the remaining clauses. The notion of backdoors was introduced by Williams et al. [15], and they come in two variants:

Definition 1 ([15]) A *weak C-backdoor* of a CNF formula F is a set of variables $X \subseteq \mathrm{var}(F)$ such that there exists an assignment α to X such that $F[\alpha] \in C$ and $F[\alpha]$ is satisfiable.

Definition 2 ([15]) A *strong C-backdoor* of a CNF formula F is a set of variables $X \subseteq \mathrm{var}(F)$ such that for each assignment α to X, we have that $F[\alpha] \in C$.

There are two main computational problems associated with backdoors. In the *detection* problem, the input is a CNF formula F and an integer k, and the question is whether F has a

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

weak/strong C-backdoor of size k. In the *evaluation* problem, the input is a CNF formula F and a weak/strong C-backdoor X, and the question is whether F is satisfiable. (In the case of weak C-backdoors, one usually requires to find a satisfying assignment since every formula that has a weak C-backdoor is satisfiable.)

The size of a smallest weak/strong C-backdoor of a CNF formula F naturally defines the distance of F to C. The size of the backdoor then becomes a very relevant parameter in studying the parameterized complexity [1] of backdoor detection and backdoor evaluation.

For a base class C where #SAT (determine the number of satisfying assignments) or Max-SAT (find an assignment that maximizes the number or weight of satisfied clauses) can be solved in polynomial time, strong C-backdoors can also be used to solve these generalizations of SAT.

Key Results

While backdoor evaluation problems are fixed-parameter tractable for SAT, the parameterized complexity of backdoor detection depends on the particular island of tractability C that is considered. If weak (resp., strong) C-backdoor detection is fixed-parameter tractable parameterized by backdoor size, SAT is fixed-parameter tractable parameterized by the size of the smallest weak (resp., strong) C-backdoor. A sample of results for the parameterized complexity of backdoor detection is presented in Table 1. The considered islands of tractability are defined in Table 2.

It can be observed that restricting the input formulas to have bounded clause length can make backdoor detection more tractable. Also, weak backdoor detection is often no more tractable than strong backdoor detection; the outlier here is FOREST-backdoor detection for general CNF formulas, where the weak version is known to be W[2]-hard but the parameterized complexity of the strong variant is still open. A CNF formula belongs to the island of tractability Forest if its incidence graph is acyclic. Here, the *incidence graph* of a CNF formula F is the bipartite graph on the variables and clauses of F where a clause is incident to the variables it contains.

Backdoors to SAT, Table 2 Some islands of tractability

Island	Description
HORN	Horn formulas, i.e., CNF formulas where each clause contains at most one positive literal
2CNF	Krom formulas, i.e., CNF formulas where each clause contains at most two literals
UP	CNF formulas from which the empty formula or an empty clause can be derived by unit propagation (setting the literals in unit length clauses to true)
FOREST	Acyclic formulas, i.e., CNF formulas whose incidence graphs are forests
RHORN	Renamable Horn formulas, i.e., CNF formulas that can be made Horn by flipping literals
CLU	Cluster formulas, i.e., CNF formulas that are variable disjoint unions of hitting formulas. A formula is *hitting* if every two of its clauses have at least one variable occurring positively in one clause and negatively in the other

The width of graph decompositions constitutes another measure for the tractability of CNF formulas that is orthogonal to backdoors. For example, Fischer et al. [2] and Samer and Szeider [12] give linear-time algorithms solving #SAT for CNF formulas in $\mathcal{W}_{\leq t}$.

Definition 3 For every integer $t \geq 0$, $\mathcal{W}_{\leq t}$ is the class of CNF formulas whose incidence graph has treewidth at most t.

Combining backdoor and graph decomposition methods, let us now consider backdoors to $\mathcal{W}_{\leq t}$. Since FOREST $= \mathcal{W}_{\leq 1}$, weak $\mathcal{W}_{\leq t}$-backdoor detection is already W[2]-hard for $t = 1$. Fomin et al. [3] give parameterized algorithms for weak $\mathcal{W}_{\leq t}$-backdoor detection when the input formula has bounded clause length. Concerning strong $\mathcal{W}_{\leq t}$-backdoor detection for formulas with bounded clause length, Fomin et al. [3] sidestep the issue of computing a backdoor by giving a fixed-parameter algorithm, where the parameter is the size of the smallest $\mathcal{W}_{\leq t}$-backdoor, that directly solves r-SAT. The parameterized complexity of strong $\mathcal{W}_{\leq t}$-backdoor detection remains open, even for $t = 1$. However, a fixed-parameter approximation algorithm was designed by Gaspers and Szeider.

Theorem 1 ([8]) *There is a cubic-time algorithm that, given a CNF formula F and two constants $k, t \geq 0$, either finds a strong $\mathcal{W}_{\leq t}$-backdoor of size at most 2^k or concludes that F has no strong $\mathcal{W}_{\leq t}$-backdoor set of size at most k.*

Using one of the #SAT algorithms for $\mathcal{W}_{\leq t}$ [2, 12], one can use Theorem 1 to obtain a fixed-parameter algorithm for #SAT parameterized by the size of the smallest strong backdoor to $\mathcal{W}_{\leq t}$.

Corollary 1 ([8]) *There is a cubic-time algorithm that, given a CNF formula F, computes the number of satisfying assignments of F or concludes that F has no strong $\mathcal{W}_{\leq t}$-backdoor of size k for any pair of constants $k, t \geq 0$.*

In general, a fixed-parameter approximation algorithm for weak/strong C-backdoor detection is sufficient to make SAT fixed-parameter tractable parameterized by the size of a smallest weak/strong C-backdoor.

Backdoors for SAT have been considered for combinations of base classes [4, 9], and the notion of backdoors has been extended to other computational reasoning problems such as constraint satisfaction, quantified Boolean formulas, planning, abstract argumentation, and nonmonotonic reasoning; see [7]. Other variants of the notion of backdoors include deletion backdoors where variables are deleted instead of instantiated, backdoors that are sensitive to clause-learning, pseudo-backdoors that relax the requirement that the satisfiability problem for an island of tractability be solved in polynomial time, and backdoor trees; see [5].

Applications

SAT is an NP-complete problem, but modern SAT solvers perform extremely well, especially on structured and industrial instances [13].

The study of backdoors, and especially the parameterized complexity of backdoor detection problems, is one nascent approach to try and explain the empirically observed running times of SAT solvers.

Open Problems

Major open problems in the area include to determine whether

- strong FOREST-backdoor detection is fixed-parameter tractable, and whether
- strong RHORN-backdoor detection is fixed-parameter tractable for 3-CNF formulas.

Experimental Results

Experimental results evaluate running times of algorithms to find backdoors in benchmark instances, evaluate the size of backdoors of known SAT benchmark instances, compare backdoor sizes for various islands of tractability, compare backdoor sizes for various notions of backdoors, evaluate what effect preprocessing has on backdoor size, compare how backdoor sizes of random instances compare to backdoor

sizes of real-world industrial instances, and evaluate how SAT solver running times change if we force the solver to branch only on the variables of a given backdoor. The main messages are that the islands of tractability with the smallest backdoors are also those for which the backdoor detection problems are the most intractable and that existing SAT solvers can be significantly sped up on many real-world SAT instances if we feed them small backdoors. The issue is, of course, to compute these backdoors, and knowledge of the application domain, or specific SAT translations might help significantly with this task in practice. See [5] for a survey.

Problem Definition

Determination of the complexity of k-CNF satisfiability is a celebrated open problem: given a Boolean formula in conjunctive normal form with at most k literals per clause, find an assignment to the variables that satisfies each of the clauses or declare none exists. It is well known that the decision problem of k-CNF satisfiability is NP-complete for $k \geq 3$. This entry is concerned with algorithms that significantly improve the worst-case running time of the naive exhaustive search algorithm, which is $\text{poly}(n)2^n$ for a formula on n variables. Monien and Speckenmeyer [8] gave the first real improvement by giving a simple algorithm whose running time is $O(2_k^{(1-\varepsilon)n})$, with $\varepsilon_k > 0$ for all k. In a sequence of results [1, 3, 5–7, 9–12], algorithms with increasingly better running times (larger values of ε_k) have been proposed and analyzed.

These algorithms usually follow one of two lines of attack to find a satisfying solution. Backtrack search algorithms make up one class of algorithms. These algorithms were originally proposed by Davis, Logemann, and Loveland [4] and are sometimes called Davis-Putnam procedures. Such algorithms search for a satisfying assignment by assigning values to variables one by one (in some order), backtracking if a clause is made false. The other class of algorithms is based on local searches (the first guaranteed performance results were obtained by Schöning [12]). One starts with a randomly (or strategically) selected assignment and searches locally for a satisfying assignment guided by the unsatisfied clauses.

This entry presents **ResolveSat**, a randomized algorithm for k-CNF satisfiability which achieves some of the best known upper bounds. **ResolveSat** is based on an earlier algorithm of Paturi, Pudlák, and Zane [10], which is essentially a backtrack search algorithm where the variables are examined in a randomly chosen order. An analysis of the algorithm is based on the observation that as long as the formula has a satisfying assignment which is isolated from other satisfying assignments, a third of the variables are expected to occur as unit clauses as the variables are assigned in a random order. Thus, the algorithm needs to correctly guess the values of at most 2/3 of the variables. This analysis is extended to the general case by observing that either there exists an isolated satisfying assignment or there are many solutions, so the probability of guessing one correctly is sufficiently high.

ResolveSat combines these ideas with resolution to obtain significantly improved bounds [9]. In fact, **ResolveSat** obtains the best known upper bounds for k-CNF satisfiability for all $k \geq 5$. For $k = 3$ and 4, Iwama and Takami [6] obtained the best known upper bound with their randomized algorithm which combines the ideas from Schöning's local search algorithm and **ResolveSat**. Furthermore, for the promise problem of unique k-CNF satisfiability whose instances are conjectured to be among the hardest instances of k-CNF satisfiability [2], **ResolveSat** holds the best record for all $k \geq 3$. Bounds obtained by **ResolveSat** for unique k-SAT and k-SAT for $k = 3, 4, 5, 6$ are shown in Table 1. Here, these bounds are compared with those of Schöning [12], subsequently improved results based on local search [1, 5, 11], and the most recent improvements due to Iwama and Takami [6]. The upper bounds obtained by these algorithms are expressed in the form $2^{cn-o(n)}$ and the numbers in the table represent the exponent c. This comparison focuses only on the best bounds irrespective of the type of the algorithm (randomized versus deterministic).

Backtracking Based k-SAT Algorithms, Table 1 This table shows the exponent c in the bound $2^{cn-o(n)}$ for the unique k-SAT and k-SAT from the **ResolveSat** algorithm, the bounds for k-SAT from Schöning's algorithm [12], its improved versions for 3-SAT [1, 5, 11], and the hybrid version of [6]

k	unique k-SAT[9]	k-SAT[9]	k-SAT[12]	k-SAT [1,5,11]	k-SAT[6]

Notation

In this entry, a CNF Boolean formula $F(x_1, x_2, \ldots, x_n)$ is viewed as both a Boolean function and a set of clauses. A Boolean formula F is a k-CNF if all the clauses have size at most k. For a clause C, write var(C) for the set of variables appearing in C. If $v \in \text{var}(C)$, the *orientation* of v is positive if the literal v is in C and is negative if $\bar{v}$ is in C. Recall that if F is a CNF Boolean formula on variables $(x_1, x_2, \ldots, x_n)$ and a is a partial assignment of the variables, the *restriction* of F by a is defined to be the formula $F' = F\lceil_a$ on the set of variables that are not set by a, obtained by treating each clause C of F as follows: if C is set to 1 by a, then delete C and otherwise replace C by the clause C' obtained by deleting any literals of C that are set to 0 by a. Finally, a *unit clause* is a clause that contains exactly one literal.

Key Results

ResolveSat Algorithm

The **ResolveSat** algorithm is very simple. Given a k-CNF formula, it first generates clauses that can be obtained by resolution without exceeding a certain clause length. Then it takes a random order of variables and gradually assigns values to them in this order. If the currently considered variable occurs in a unit clause, it is assigned as the only value that satisfies the clause. If it occurs in contradictory unit clauses, the algorithm starts over. At each step, the algorithm also checks if the formula is satisfied. If the formula is satisfied, then the input is accepted. This subroutine is repeated until either a satisfying assignment is found or a given time limit is exceeded.

The **ResolveSat** algorithm uses the following subroutine, which takes an arbitrary assignment y, a CNF formula F, and a permutation π as input, and produces an assignment u. The assignment u is obtained by considering the variables of y in the order given by π and modifying their values in an attempt to satisfy F.

Function **Modify**(CNF formula $G(x_1, x_2, \ldots, x_n)$, permutation π of $\{1, 2, \ldots, n\}$, assignment $y) \rightarrow$ (assignment u) $G_0 = G$.**for** $i = 1$ **to** n **if** G_{i-1} contains the unit clause $x_{\pi(i)}$ **then** $u_{\pi(i)} = 1$ **else if** G_{i-1} contains the unit clause $\bar{x}_{\pi(i)}$ **then** $u_{\pi(i)} = 0$ **else** $u_{\pi(i)} = y_{\pi(i)}$ $G_i = G_{i-1}\lceil_{x\pi(i)=u\pi(i)}$ **end** /* end for loop */**return** u;

The algorithm **Search** is obtained by running **Modify** (G, π, y) on many pairs (π, y), where π is a random permutation and y is a random assignment.

Search(CNF-formula F, integer I)**repeat** I times π = uniformly random permutation of $1, \ldots, n$ y = uniformly random vector $\in \{0,1\}^n$ u = **Modify** (F, π, y); **if** u satisfies F **then** output(u); **exit**;**end**/* end repeat loop */output('Unsatisfiable');

The **ResolveSat** algorithm is obtained by combining **Search** with a preprocessing step consisting of *bounded resolution*. For the clauses C_1 and C_2, C_1 and C_2 *conflict* on variable v if one of them contains v and the other contains $\bar{v}$. C_1 and C_2 is a *resolvable pair* if they conflict on exactly one variable v. For such a pair, their *resolvent*, denoted $R(C_1, C_2)$, is the clause $C = D_1 \vee D_2$ where D_1 and D_2 are obtained by deleting v and $\bar{v}$ from C_1 and C_2. It is easy to see that any assignment satisfying C_1 and C_2 also satisfies C. Hence, if F is a satisfiable CNF formula containing the resolvable pair C_1, C_2 then the formula $F' = F \wedge R(C_1, C_2)$ has the same satisfying assignments as F. The resolvable pair C_1, C_2 is *s-bounded* if $|C_1|, |C_2| \leq s$ and $|R(C_1, C_2)| \leq s$. The following subroutine extends a formula F to a formula F_s by applying as many steps of s-bounded resolution as possible.

Resolve(CNF Formula F, integer s)$F_s = F$.**while** F_s has an s-bounded resolvable pair C_1, C_2 with $R(C_1, C_2) \notin F_s$ $F_s = F_s \wedge R(C_1, C_2)$.**return** (F_s).

The algorithm for k-SAT is the following simple combination of **Resolve** and **Search**:

ResolveSat(CNF-formula F, integer s, positive integer I)$F_s =$ **Resolve** (F, s).**Search** (F_s, I).

Analysis of ResolveSat

The running time of **ResolveSat** (F, s, I) can be bounded as follows. **Resolve** (F, s) adds at most $O(n^s)$ clauses to F by comparing pairs

of clauses, so a naive implementation runs in time $n^{3s}\text{poly}(n)$ (this time bound can be improved, but this will not affect the asymptotics of the main results). **Search** (F_s, I) runs in time $I(|F| + n^s)\text{poly}(n)$. Hence, the overall running time of **ResolveSat** (F, s, I) is crudely bounded from above by $(n^{3s} + I(|F| + n^s))\text{poly}(n)$. If $s = O(n/\log n)$, the overall running time can be bounded by $I|F|2^{O(n)}$ since $n^s = 2^{O(n)}$. It will be sufficient to choose s either to be some large constant or to be a *slowly growing* function of n. That is, $s(n)$ tends to infinity with n but is $O(\log n)$.

The algorithm **Search** (F, I) always answers "unsatisfiable" if F is unsatisfiable. Thus, the only problem is to place an upper bound on the error probability in the case that F is satisfiable. Define $\tau(F)$ to be the probability that **Modify** (F, π, y) finds some satisfying assignment. Then for a satisfiable F, the error probability of **Search** (F, I) is equal to $(1 - \tau(F))^I \le \mathrm{e}^{-I\tau(F)}$, which is at most e^{-n} provided that $I \ge n/\tau(F)$. Hence, it suffices to give good upper bounds on $\tau(F)$.

Complexity analysis of **ResolveSat** requires certain constants μ_k for $k \ge 2$:

$$\mu_k = \sum_{j=1}^{\infty} \frac{1}{j\left(j + \frac{1}{k-1}\right)}.$$

It is straightforward to show that $\mu_3 = 4 - 4\ln 2 > 1.226$ using Taylor's series expansion of $\ln 2$. Using standard facts, it is easy to show that μ_k is an increasing function of k with the limit

$$\sum_{j=1}^{\infty}(1/j^2) = (\pi^2/6) = 1.644\ldots$$

The results on the algorithm **ResolveSat** are summarized in the following three theorems.

Theorem 1

(i) *Let $k \ge 5$, and let $s(n)$ be a function going to infinity. Then for any satisfiable k-CNF formula F on n variables,*

$$\tau(F_s) \le 2^{-\left(1-\frac{\mu_k}{k-1}\right)n-o(n)}.$$

*Hence, **ResolveSat** (F, s, I) with $I = 2^{(1-\mu_k/(k-1))n+O(n)}$ has error probability $O(1)$ and running time $2^{(1-\mu_k/(k-1))n+O(n)}$ on any satisfiable k-CNF formula, provided that $s(n)$ goes to infinity sufficiently slowly.*

(ii) *For $k \ge 3$, the same bounds are obtained provided that F is uniquely satisfiable.*

Theorem 1 is proved by first considering the uniquely satisfiable case and then relating the general case to the uniquely satisfiable case. When $k \ge 5$, the analysis reveals that the asymptotics of the general case is no worse than that of the uniquely satisfiable case. When $k = 3$ or $k = 4$, it gives somewhat worse bounds for the general case than for the uniquely satisfiable case.

Theorem 2 *Let $s = s(n)$ be a slowly growing function. For any satisfiable n-variable 3-CNF formula, $\tau(F_s) \ge 2^{-0.521n}$, and so **ResolveSat** (F, s, I) with $I = n2^{0.521n}$ has error probability $O(1)$ and running time $2^{0.521n+O(n)}$.*

Theorem 3 *Let $s = s(n)$ be a slowly growing function. For any satisfiable n-variable 4-CNF formula, $\tau(F_s) \ge 2^{-0.5625n}$, and so **ResolveSat** (F, s, I) with $I = n2^{0.5625n}$ has error probability $O(1)$ and running time $2^{0.5625n+O(n)}$.*

Applications

Various heuristics have been employed to produce implementations of 3-CNF satisfiability algorithms which are considerably more efficient than exhaustive search algorithms. The **ResolveSat** algorithm and its analysis provide a rigorous explanation for this efficiency and identify the structural parameters (e.g., the width of clauses and the number of solutions), influencing the complexity.

Open Problems

The gap between the bounds for the general case and the uniquely satisfiable case when $k \in \{3, 4\}$ is due to a weakness in analysis, and it

is conjectured that the asymptotic bounds for the uniquely satisfiable case hold in general for all k. If true, the conjecture would imply that **ResolveSat** is also faster than any other known algorithm in the $k = 3$ case.

Another interesting problem is to better understand the connection between the number of satisfying assignments and the complexity of finding a satisfying assignment [2]. A strong conjecture is that satisfiability for formulas with many satisfying assignments is strictly easier than for formulas with fewer solutions.

Finally, an important open problem is to design an improved k-SAT algorithm which runs faster than the bounds presented in here for the unique k-SAT case.

Problem Definition

A network bargaining game can be represented by a graph $G = (V, E)$ along with a set of node capacities $\{c_i | i \in V\}$ and a set of edge weights

$\{w_{ij}|(i,j) \in E\}$, where V is a set of n agents, E is the set of all possible contracts, each agent $i \in V$ has a *capacity* c_i which the maximum number of contracts in which agent i may participate, and each edge $(i,j) \in E$ has a *weight* w_{ij} which represents the surplus of a possible contract between agent i and agent j which should be divided between agents i and j upon an agreement. The main goal is to find the outcome of bargaining among agents which is a set of contracts $M \subseteq E$ and the division of surplus $\{z_{ij}\}$ for all contracts in M.

Problem 1 (Computing the Final Outcome)

INPUT: *A network bargaining game* $G = (V, E)$ *along with capacities* $\{c_i|i \in V\}$ *and weights* $\{w_{ij}|(i,j) \in E\}$.

OUTPUT: *The final outcome of bargaining among agents.*

Solution Concept

Feasible Solution

The final outcome of the bargaining process might have many properties. The main one is the feasibility. A solution $(M, \{z_{ij}\})$ is *feasible* if and only if it has the following properties:

- The degree of each node i should be at most c_i in set M.
- For each edge $(i,j) \in M$, we should have $z_{ij} + z_{ji} = w_{ij}$. This means if there is a contract between agents i and j, the surplus should be divided between these two agents.
- For each edge $(i,j) \notin M$, we should have $z_{ij} = z_{ji} = 0$.

Outside Option

Given a feasible solution $(M, \{z_{ij}\})$, the *outside* option of agent is the best deal she can make outside of set M. For each edge $(i,k) \in E - M$, agent i has an outside option by offering agent k her current worst offer. In particular, if k has less than c_k contracts in M, agent i can offer agent k exactly 0, and thus the outside option of agent i regarding agent k would be w_{ik}. On the other hand, if k has exactly c_k contracts in M, agent i may offer agent k the minimum of z_{kj} for all $(k,j) \in M$, and thus the outside option of agent i regarding agent k would be $w_{ik} - \min_{(k,j)\in M}\{z_{kj}\}$. Therefore, the outside option α_i of agent i regarding solution $(M, \{z_{ij}\})$ is defined as $\alpha_i = \max_{(i,k)\in E-M}\{w_{ik} - \eta_{ik}\}$ where

$$\eta_{ik} = \begin{cases} 0 & \text{if } k \text{ has less than } c_i \text{ contracts in } M \\ \min_{(k,j)\in M}\{z_{kj}\} & \text{if } k \text{ has exactly } c_i \text{ contracts in } M \end{cases}$$

Stable Solution

A solution $(M, \{z_{ij}\})$ is *stable* if for each contract $(i,j) \in M$, we have $z_{ij} \geq \alpha_i$ and for each agent i with less than c_i contracts in M, we have $\alpha_i = 0$. Otherwise, agent i has an incentive to deviate from M and makes a contract with agent k such that $(i,k) \notin M$.

Balanced Solution

John Nash [6] proposed a solution for the outcome of bargaining process between two agents. In his solution, known as the *Nash bargaining solution*, both agents will enjoy their outside options and then divide the surplus equally. One can leverage the intuition behind the Nash bargaining solution and defines the balanced solution in the network bargaining game. A feasible solution $(M, \{z_{ij}\})$ is *balanced* if for each contract (i,j) in M, the participants divide the net surplus equally, i.e., $z_{ik} = \alpha_i + \frac{w_{ik} - \alpha_i - \alpha_j}{2}$.

Problem 2 (Computing a Stable Solution)

INPUT: *A network bargaining game* $G = (V, E)$ *along with capacities* $\{c_i|i \in V\}$ *and weights* $\{w_{ij}|(i,j) \in E\}$.

OUTPUT: *A stable solution.*

Problem 3 (Computing a Balanced Solution)

INPUT: *A network bargaining game* $G = (V, E)$ *along with capacities* $\{c_i|i \in V\}$ *and weights* $\{w_{ij}|(i,j) \in E\}$.

OUTPUT: *A balanced solution.*

Key Results

The main goal of studying the network bargaining games is to find the right outcome of the game. Stable and balanced solutions are known to be good candidates. However, they might be too large, and moreover, some network bargaining games do not have stable and balanced solutions.

Existence of Stable and Balanced Solutions

It has been proved that a network bargaining game $G = (V, E)$ with set of weights $\{w_{ij} | (i, j) \in E\}$ has at least one stable solution if and only if the following linear program for the corresponding maximum weighted matching problem has an integral optimum solution [4,5]:

$$\begin{array}{lll} \text{maximize} & \sum_{(i,j)\in E} x_{ij} w_{ij} & \\ \text{subject to} & \sum_{(i,j)\in E} x_{ij} \le c_i, & \forall i \in V \\ & x_{ij} \le 1, & \forall (i,j) \in E \end{array} \quad \text{(LP1)}$$

Kleinberg and Tardös [5] also study network bargaining games with unit capacities, i.e., $c_i = 1$ for each agent i, and show these games have at least one balanced solution if and only if they have a stable solution. Farczadi et al. [3] generalize this result and prove the same result for network bargaining games with general capacities.

Cooperative Game Theory Perspective

One can study network bargaining games from cooperative game theory perspective. A cooperative game is defined by a set of agents V and a value function $v : 2^V \to \mathcal{R}$, where $v(S)$ represents the surplus that all agents in S alone can generate. In order to consider our bargaining game as a cooperative game, we should first define a value function for our bargaining game. The value function $v(S)$ can be defined as the size of the maximum weighted c-matching of S.

Core

An outcome $\{x_i | i \in V\}$ is in core if for each subset of agents S, we have $\sum_{i\in S} x_i \ge v(S)$ and for set V we have $\sum_{i\in V} x_i = v(V)$. This means the agents should divide the total surplus $v(V)$ such that each subset of agents earns at least as much as they alone can generate.

Prekernel

Consider an outcome $\{x_i | i \in V\}$. The *power* of agent i over agent j regarding outcome $\{x_i | i \in V\}$ is defined as $s_{ij}(x) = \max\{v(S) - \sum_{i\in S} x_i | S \subseteq V, i \in S, j \in V - S\}$. An outcome $\{x_i | i \in V\}$ is in prekernel if for every two agents i and j, we have $s_{ij}(x) = s_{ji}(x)$.

Nucleolus

Consider an outcome $\{x_i | i \in V\}$. The *excess* of set S is defined as $\epsilon(S) = v(S) - \sum_{i\in S} x_i$. Let ϵ be the vector of all possible $2^{|V|}$ excesses which are sorted in nondecreasing order. The *nucleolus* is the outcome which lexicographically maximizes vector ϵ.

There is a nice connection between stable and balanced solutions in network bargaining games and core and prekernel outcomes in cooperative games [1,2]. Bateni et al. [2] prove in a bipartite network where all nodes on one side have unit capacity, the set of stable solutions and the core coincide. Moreover, they map the set of balanced solutions to the prekernel in the same setting. Note that it is shown that this equivalence cannot be extended to a general bipartite network where nodes on both sides have general capacities [2,3].

The set of stable and balanced solutions are quite large for many instances and thus may not be used for predicting the outcome of the game. Both Azar et al. [1] and Bateni et al. [2] leverage the connection between network bargaining games and cooperative games and suggest the nucleolus as a symmetric and unique solution for the outcome of a network bargaining game [1, 2]. Bateni et al. [2] also propose a polynomial-time algorithm for finding nucleolus in bipartite networks with unit capacities on one side.

Finding Stable and Balanced Solutions

Designing a polynomial-time algorithm for finding stable and balanced solutions of a network bargaining game is a well-known problem. Kleinberg and Tardös [5] were the first who studied this problem and proposed a polynomial-time

algorithm which characterizes stable and balanced solutions when all agents have unit capacities. Their solution draws connection to the structure of matchings and the Edmonds-Gallai decomposition. Bateni et al. [2] generalize this results and design a polynomial-time algorithm for bipartite graphs where all agents on one side have general capacities and the other ones have unit capacities. They leverage the correspondence between the set of balanced solutions and the intersection of the core and prekernel and use known algorithms for finding a point in prekernel to solve the problem. Last but not least, Farczadi et al. [3] propose an algorithm for computing a balanced solution for general capacities. The main idea of their solution is to reduce an instance with general capacities to a network bargaining game with unit capacities.

Open Problems

- What is the right outcome of a network bargaining game on a general graph?
- How can we compute a proper outcome of a network bargaining game on a general graph in a polynomial time?

Bend Minimization for Orthogonal Drawings of Plane Graphs

Maurizio Patrignani
Engineering Department, Roma Tre University, Rome, Italy

Keywords

Bends; Grid embedding; Network flow; Orthogonal drawings; Planar embedding

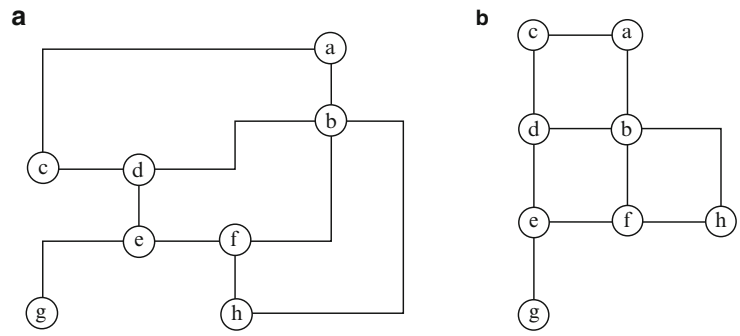
Years and Authors of Summarized Original Work

1987; Tamassia

Problem Definition

A *drawing* of a graph $G = (V, E)$ maps each vertex $v \in V$ to a distinct point of the plane and each edge $e \in E$ to a simple open Jordan curve joining its end vertices. A drawing is *planar* if the edges do not intersect. A graph is *planar* if it admits a planar drawing. A planar drawing of a graph partitions the plane into connected regions called *faces*. The unbounded face is called *external face*. Two drawings of G are *equivalent* if they induce the same circular order of the edges incident to the vertices. A *planar embedding* of G is an equivalence class of such drawings. A *plane* graph is a planar graph together with a planar embedding and the specification of the external face.

A drawing of a graph is *orthogonal* if each edge is a sequence of alternate horizontal and vertical segments. Only planar graphs of maximum degree four admit planar orthogonal drawings.



Bend Minimization for Orthogonal Drawings of Plane Graphs, Fig. 1 (**a**) An orthogonal drawing of a graph. (**b**) An orthogonal drawing of the same graph with the minimum number of bends

The points in common between two subsequent segments of the same edge are called *bends*. Figure 1 shows two orthogonal drawings of the same plane graph with seven bends and one bend, respectively.

Bend Minimization Problem

Formally, the main research problem can be defined as follows.

INPUT: *A plane graph $G = (V, E)$ of maximum degree four.*
OUTPUT: *An orthogonal drawing of G with the minimum number of bends.*

Since, given the shape of the faces, an orthogonal drawing of G with integer coordinates for vertices and bends can be computed in linear time, this problem may be alternatively viewed as that of embedding a 4-plane graph in the orthogonal grid with the minimum number of bends. Observe that if the planar embedding of the graph is not fixed, the problem of finding a minimum-bend orthogonal drawing is known to be NP-complete [9], unless the input graph has maximum degree three [5].

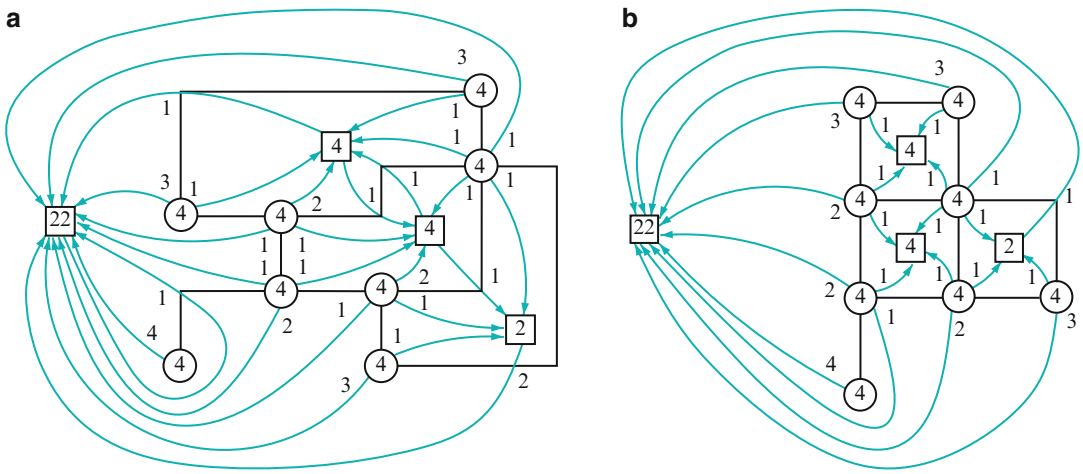
Key Results

The bend minimization problem can be solved in polynomial time by reducing it to that of finding a minimum-cost integer flow of a suitable network. Here, rather than describing the original model of [11], we describe the more intuitive model of [6].

Any orthogonal drawing of a maximum degree four plane graph $G = (V, E)$ corresponds to an integer flow in a network $\mathcal{N}(G)$ with value $4 \times n$, with $n = |V|$, where:

1. For each vertex $v \in V$, $\mathcal{N}(G)$ has a node n_v which is a source of 4 units of flow.
2. For each face f of G, $\mathcal{N}(G)$ has a node n_f which is a sink of $2\deg(f) - 4$ units if f is an internal face, or $2\deg(f) + 4$, otherwise, where $\deg(f)$ is the number of vertices encountered while traversing the boundary of face f (the same vertex may be counted multiple times).
3. For each edge $e \in E$, with adjacent faces f and g, $\mathcal{N}(G)$ has two arcs (n_f, n_g) and (n_g, n_f), both with cost 1 and lower bound 0.
4. For each vertex $v \in V$ incident to a face f of G, $\mathcal{N}(G)$ has an arc (n_v, n_f) with cost 0 and lower bound 1. Multiple incidences of the same vertex to the same face yield multiple arcs of $\mathcal{N}(G)$.

Figure 2 shows the two flows of cost 7 and 1, respectively, corresponding to the orthogonal drawings of Fig. 1. Intuitively, a flow of $\mathcal{N}(G)$ describes how 90° angles are distributed in the orthogonal drawing of G. Namely, each vertex has four 90° angles around it, hence "producing" four units of flow. The number of 90° angles needed to close a face f is given by the formula in [12], that is, $2\deg(f) - 4$ units if f is an internal face, and $2\deg(f) + 4$, otherwise. Finally, the flows traversing the edges account for their bends, where each bend allows a face



Bend Minimization for Orthogonal Drawings of Plane Graphs, Fig. 2 (**a**) The flow associated with the drawing of Fig. 1a has cost 7. (**b**) The flow associated with the drawing of Fig. 1b has cost 1

to "lose" a 90° angle and the adjacent face to "gain" it. More formally, we have the following theorem.

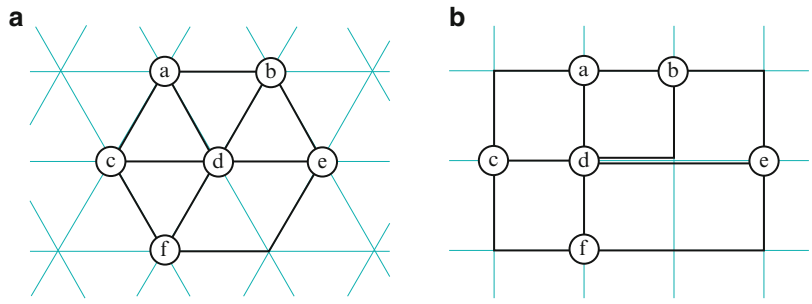
Theorem 1 *Let $G = (V, E)$ be a four-plane graph. For each orthogonal drawing of G with b bends, there exists an integer flow in $\mathcal{N}(G)$ whose value is $4 \times |V|$ and whose cost is b.*

Although several orthogonal drawings of G (e.g., with the order of the bends along edges permuted) may correspond to the same flow of $\mathcal{N}(G)$, starting from any flow, one of such drawings may be obtained in linear time. Namely, once the orthogonal shape of each face is fixed, it is possible to greedily add as many dummy edges and nodes as are needed to split the face into rectangular faces (the external face may require the addition of dummy vertices in the corners). Integer edge lengths can be consistently assigned to the sides of these rectangular faces, obtaining a grid embedding (a linear-time algorithm for doing this is described in [6]). The removal of dummy nodes and edges yields the desired orthogonal drawing. Hence, we have the following theorem.

Theorem 2 *Let $G = (V, E)$ be a four-plane graph. Given an integer flow in $\mathcal{N}(G)$ whose value is $4 \times |V|$ and whose cost is b, an orthogonal drawing of G with b bends can be found in linear time.*

Since each bend of the drawing corresponds to a unit of cost for the flow, when the total cost of the flow is minimum, any orthogonal drawing that can be obtained from it has the minimum number of bends [11].

Hence, given a plane graph $G = (V, E)$ of maximum degree four, an orthogonal drawing of G with the minimum number of bends can be computed with the same asymptotic complexity of finding a minimum-cost integer flow of $\mathcal{N}(G)$. The solution to this problem proposed in [11] is based on an iterative augmentation algorithm. Namely, starting from the initial zero flow, the final $4 \times n$ flow is computed by augmenting the flow at each of the $O(n)$ steps along a minimum-cost path. Such a path can be found with the $O(n \log n)$-implementation of Dijkstra's algorithm that exploits a priority queue. The overall $O(n^2 \log n)$ time complexity was lowered first to $O(n^{7/4}\sqrt{\log n})$ [8] and then to $O(n^{3/2})$, exploiting the planarity of the flow network [4]. However, the latter time bound is increased by an additional logarithmic factor if some edges have constraints on the number of allowed bends [4] or if the Dijkstra's algorithm for the shortest path computation is preferred with respect to the rather theoretical algorithm in [10].



Bend Minimization for Orthogonal Drawings of Plane Graphs, Fig. 3 (**a**) A drawing on the hexagonal grid. (**b**) A drawing of the same graph in the Kandinsky model

Applications

Orthogonal drawings with the minimum number of bends are of interest to VLSI circuit design, architectural floor plan layout, and aesthetic layout of diagrams used in information systems design. In particular, the orthogonal drawing standard is adopted for a wide range of diagrams, including entity-relationship diagrams, relational schemes, data-flow diagrams, flow charts, UML class diagrams, etc.

Open Problems

Several generalizations of the model have been proposed in order to deal with graphs of degree greater than four. The hexagonal grid, for example, would allow for vertices of maximum degree six (see Fig. 3a. Although the bend minimization problem is polynomial on such a grid [11], deciding edge lengths becomes NP-hard [2].

One of the most popular generalizations is the *Kandinsky* orthogonal drawing standard [7] where vertices of arbitrary degree are represented as small squares or circles of the same dimensions, while the first segments of the edges that leave a vertex in the same direction run very close together (see, e.g., Fig. 3b). Although the bend minimization problem in the Kandinsky orthogonal drawing standard has been shown to be NP-hard [3], this model is of great interest for applications. An extension of the flow model that makes it possible to solve this problem in polynomial time for a meaningful subfamily of Kandinsky orthogonal drawings has been proposed in [1]. Namely, in addition to the drawing conventions of the Kandinsky model, each vertex with degree greater than four has at least one incident edge on each side, and each edge leaving a vertex either has no bend or has its first bend on the right.

Atomic selfish flows

Years and Authors of Summarized Original Work

2005; Fotakis, Kontogiannis, Spirakis

Problem Definition

A setting is assumed in which n selfish users compete for routing their loads in a network. The network is an $s-t$ directed graph with a single source vertex s and a single destination vertex t. The users are ordered sequentially. It is assumed that each user plays after the user before her in the ordering, and the desired end result is a Pure Nash Equilibrium (PNE for short). It is assumed that, when a user plays (i.e., when she selects an $s-t$ path to route her load), the play is a best response (i.e., minimum delay), given the paths and loads of users currently in the net. The problem then is to find the class of directed graphs for which such an ordering exists so that the implied sequence of best responses leads indeed to a Pure Nash Equilibrium.

The Model

A *network congestion game* is a tuple $((w_i)_{i\in N}, G, (d_e)_{e\in E})$ where $N = \{1,\ldots,n\}$ is the set of users where user i controls w_i units of traffic demand. In *unweighted* congestion games $w_i = 1$ for $i = 1,\ldots,n$. $G(V,E)$ is a directed graph representing the communications network and d_e is the latency function associated with edge $e \in E$. It is assumed that the d_e's are non-negative and non-decreasing functions of the edge loads. The edges are called *identical* if $d_e(x) = x$, $\forall e \in E$. The model is further restricted to single-commodity network congestion games, where G has a single source s and destination t and the set of users' strategies is the set of $s-t$ paths, denoted P. Without loss of generality it is assumed that G is connected and that every vertex of G lies on a directed $s-t$ path.

A vector $P = (p_1,\ldots,p_n)$ consisting of an $s-t$ path p_i for each user i is a *pure strategies profile*. Let $l_e(P) = \sum_{i:e\in p_i} w_i$ be the load of edge e in P. The authors define *the cost* $\lambda^i_p(P)$ for user i routing her demand on path p in the profile P to be

$$\lambda^i_p(P) = \sum_{e\in p\cap p_i} d_e\left(l_e(P)\right) + \sum_{e\in p\smallsetminus p_i} d_e\left(l_e(P)+w_i\right).$$

The cost $\lambda^i(P)$ of user i in P is just $\lambda^i_{p_i}(P)$, i.e., the total delay along her path.

A pure strategies profile P is a Pure Nash Equilibrium (PNE) iff no user can reduce her total

delay by *unilaterally deviating* i.e., by selecting another $s-t$ path for her load, while all other users keep their paths.

Best Response

Let p_i be the path of user i and $P^i = (p_1, \ldots, p_i)$ be the pure strategies profile for users $1, \ldots, i$. Then the *best response* of user $i+1$ is a path p_{i+1} so that

$$p_{i+1} = avg \min_{p \in P^i} \left\{ \sum_{e \in p} \left(d_e \left(l_e \left(P^i \right) + w_{i+1} \right) \right) \right\}.$$

Flows and Common Best Response

A (feasible) flow on the set P of $s-t$ paths of G is a function $f : P \to \Re_{\geq 0}$ so that

$$\sum_{p \in P} f_p = \sum_{i=1}^{n} w_i .$$

The single-commodity network congestion game $((w_i)_{i \in N}, G, (d_e)_{e \in E})$ has the Common Best Response property if for every initial flow f (not necessarily feasible), all users have the same set of best responses with respect to f. That is, if a path p is a best response with respect to f for some user, then for all users j and all paths p'

$$\sum_{e \in p'} d_e \left(f_e + w_j \right) \geq \sum_{e \in p} d_e \left(f_e + w_j \right).$$

Furthermore, every segment π of a best response path p is a best response for routing the demand of any user between π's endpoints. It is allowed here that some users may already have contributed to the initial flow f.

Layered and Series-Parallel Graphs

A directed (multi)graph $G(V, E)$ with a distinguished source s and destination t is *layered* iff all directed $s-t$ paths have exactly the same length and each vertex lies on some directed $s-t$ path.

A multigraph is *series-parallel* with *terminals* (s, t) if

1. it is a single edge (s, t) or
2. it is obtained from two series-parallel graphs G_1, G_2 with terminals (s_1, t_1) and (s_2, t_2) by connecting them either in *series* or in *parallel*. In a series connection, t_1 is identified with s_2 and s_1 becomes s and t_2 becomes t. In a parallel connection, $s_1 = s_2 = s$ and $t_1 = t_2 = t$.

Key Results

The Greedy Best Response Algorithm (GBR)

GBR considers the users one-by-one in *non-increasing* order of weight (i.e., $w_1 \geq w_2 \geq \cdots \geq w_n$). Each user adopts her best response strategy on the set of (already adopted in the net) best responses of previous users. No user can change her strategy in the future. Formally, GBR *succeeds* if the eventual profile P is a Pure Nash Equilibrium (PNE).

The Characterization

In [3] it is shown:

Theorem 1 *If G is an $(s-t)$ series-parallel graph and the game $((w_i)_{i \in N}, G, (d_e)_{e \in E})$ has the common best response property, then GBR succeeds.*

Theorem 2 *A weighted single-commodity network congestion game in a layered network with identical edges has the common best response property for any set of user weights.*

Theorem 3 *For any single-commodity network congestion game in series-parallel networks, GBR succeeds if*

1. *The users are identical (if $w_i = 1$ for all i) and the edge-delays are arbitrary but non-decreasing or*
2. *The graph is layered and the edges are identical (for arbitrary user weights)*

Theorem 4 *If the network consists of bunches of parallel-links connected in series, then a PNE is obtained by applying GBR to each bunch.*

Theorem 5

1. *If the network is not series-parallel then there exist games where GBR fails, even for 2 identical users and identical edges.*
2. *If the network does not have the common best response property (and is not a sequence of parallel links graphs connected in series) then there exist games where GBR fails, even for 2-layered series-parallel graphs.*

Examples of such games are provided in [3].

Applications

GBR has a natural distributed implementation based on a leader election algorithm. Each player is now represented by a process. It is assumed that processes know the network and the edge latency functions. The existence of a message passing subsystem and an underlying synchronization mechanism (e.g., logical timestamps) is assumed, that allows a distributed protocol to proceed in logical rounds.

Initially all processes are active. In each round they run a leader election algorithm and determine the process of largest weight (among the active ones). This process routes its demand on its best response path, announces its strategy to all active processes, and becomes passive. Notice that each process can compute its best response locally.

Open Problems

What is the class of networks where (identical) users can achieve a PNE by a k-round repetition of a best responses sequence? What happens to weighted users? In general, how the network topology affects best response sequences? Such open problems are a subject of current research.

2011; van Iersel, Kelk
2014; Kelk, Scornavacca

Problem Definition

Recent developments in phylogenetics have provided evidences that evolutionary histories

cannot always be represented as a single tree; thus, more sophisticated representations are needed. *Phylogenetic networks* are natural extensions of phylogenetic trees that recently gathered general consensus in literature. Let Λ be a finite set of labels, representing a set of extant species (taxa). A *rooted phylogenetic* N *over* Λ (or, simply, *phylogenetic network* or *network*) is a directed acyclic connected graph $N = \langle V(N), A(N) \rangle$ containing a unique vertex with no incoming arcs, called *root* of N, and a labeling function from the set $L(N)$ of leaves of N to the set of labels Λ. The set of labels associated with the leaves of N is denoted by $\Lambda(N)$, and phylogenetic networks whose leaves are in bijection with the set of labels are called *uniquely labeled*. The undirected edges underlying the set $A(N)$ are denoted with $E(N)$.

We will discuss two important families of problems where phylogenetic networks have been introduced: consensus network computation and tree reconciliation. Other models (and the related problems) for representing and reconstructing non-treelike evolutionary scenarios are presented in [7]. The family of the consensus network computation problems asks for a single phylogenetic network (called consensus network) that best summarizes all the information provided by a collection of "structures" representing the evolutionary relationships among the set of taxa Λ. The family of tree reconciliation problems, instead, analyzes the evolution of a gene in order to either reconstruct the evolution of a set of species or infer the evolutionary scenario of the considered gene.

Observe that it is possible to topologically sort the vertices of a phylogenetic network, so that each vertex always appears after all its predecessors; hence, it is possible to define the *children*, *parents*, *ancestors*, and *descendants* of a given vertex, as usual for trees. Furthermore, as for trees, we can define the *least common ancestor* of a set of nodes. Given a subset A of nodes of a phylogenetic network N, then the least common ancestor (or, shortly, lca) of A in N is a node x of N that is an ancestor of each node in A and that is the furthest such node from the root.

Consensus Network Reconstruction

The aim of consensus network reconstruction problems is computing a unique phylogenetic network (called *consensus network*) that best summarizes all the information provided by a collection of "structures" representing the evolutionary relationships among the set of taxa Λ. Different specific computational problems have been defined in the literature depending (i) on the kind of input structures considered and (ii) on the definition of the optimality criterion used to choose the best consensus network. Simple formulations (such as *maximum agreement subtree* (MAST), *maximum compatible tree* (MCT), *maximum agreement supertree* (MASP)) compute a consensus network which is actually a phylogenetic tree. However, trees are not always sufficient for describing conflicting information and real evolutionary scenarios; hence, formulations which attempt to reconstruct phylogenetic networks have been proposed.

In terms of optimality criterion, two aims can be pursued: either finding the largest set of taxa that "share" (as defined below) a common substructure or finding the "simplest" network that represents all taxa. For measuring the complexity of a network, two natural parameters are considered: the *reticulation number* and the *level* of the network. *Reticulation* (or *hybrid*) nodes are nodes of the network with more than one parent. The *reticulation number* of a network N is defined as $|E(N)|-|V(N)|+1$ and represents how "far" the network is from a phylogenetic tree (which has reticulation number 0). If all reticulation nodes have indegree 2 (which is often assumed in the literature), then the reticulation number is equal to the number of reticulation nodes. The *level* of a network N is defined as the maximum number of reticulation nodes in a biconnected component of $\langle V(N), E(N) \rangle$ (i.e., the undirected graph obtained from the network) [6]. Phylogenetic trees are level-0 networks, while level-1 networks are often called *galled trees* [13].

In terms of kinds of input structures, several options have been studied, and, among them, the most important ones are phylogenetic networks, triplets/quartets, and clusters. When input structures are phylogenetic networks, the usual aim is to reconstruct their *maximum agreement*

subnetwork (MASN) [6], that is, a level-k phylogenetic network A (for some fixed k) uniquely labeled with a set $\Lambda' \subseteq \Lambda$ of maximum cardinality such that A is a subgraph of the topological restriction of each input network w.r.t. Λ'. The topological restriction of a uniquely labeled network N to a subset $\Lambda' \subseteq \Lambda$ of labels is defined as the network obtained by first deleting all nodes which are not on any directed path from the root to one of the leaves labeled in Λ' along with their incident edges, and then, for every node with outdegree 1 and indegree less than 2, contracting its outgoing edges. (Notice that the MAST problem is a special case of the MASN problem when $k = 0$.)

Triplets are rooted binary phylogenetic trees on exactly three species/leaves. They are generally represented as $xy|z$, indicating that the parent of x and y is a child of the parent of z. The consensus network reconstruction problem from triplets is the problem of finding, if possible, a phylogenetic network N *consistent* with each triplet given as input (or with the maximum number of them). A phylogenetic network N is said to be consistent with a triplet $xy|z$ if N contains two distinct vertices u, v and the four pairwise internally vertex-disjoint paths $u \to x$, $u \to y$, $v \to u$, $v \to z$. The resulting phylogenetic network is required to either have minimum level or have fixed level (possibly with minimum reticulation number) [18,26,27]. The related problem on *quartets* (i.e., unrooted phylogenetic trees on four species) has been also proposed [8].

Clusters are (strict) subsets of Λ. The consensus network reconstruction problem from clusters is the problems of finding a phylogenetic network N that *represents* all clusters given as input. There exist two main definitions for "represents," commonly referred to as the "hardwired" and the "softwired" definitions. A network N represents a cluster $\Lambda' \subset \Lambda$ in the *hardwired* sense if there exists an arc $(u, v) \in A(N)$ such that Λ' is exactly the set of labels associated with the leaves of a subnetwork rooted in v [16]. Instead, a network N represents a cluster $\Lambda' \subset \Lambda$ in the *softwired* sense if there exists an arc $(u, v) \in A(N)$ such that Λ' is the set of labels associated with the leaves of a subtree rooted in v obtained by removing, for each reticulation node, all edges but one directed to that node [15]. In both cases, the computational problems focus on reconstructing networks with minimum level [29].

Reconciliation of Gene Trees and Species Trees

The evolution of a family of homologous genes in a given set of species is usually represented as a phylogenetic tree, called a *gene tree*, where each label can be associated with more than one leaf, while the evolution of the considered set of species is called a *species tree*, which is a uniquely labeled tree. Due to different evolutionary events that affect gene evolution (*duplications*, *losses*, *lateral gene transfer*), the evolution represented by a gene tree and a species tree (or by two different gene trees) can be different.

Two fundamental combinatorial problems have been studied in this field: the *reconstruction* of the species tree associated with the homologous genes considered [5, 12, 21] and the *reconciliation* of a gene tree with a given species tree [3, 4, 9, 21, 23], whose goal is the inference of the evolutionary events that occurred in the genes evolution. Here, we consider only the latter problem; hence, we assume that a gene tree (or a set of gene trees) and a (correct) species tree are given.

Given a set S of taxa, a species tree T_S and a gene tree T_G are two rooted binary trees, leaf-labeled by S, with $\Lambda(T_G) \subseteq \Lambda(T_S)$. Two nodes of a tree T are comparable when one is an ancestor of the other. T_G and T_S are compared introducing a mapping $\lambda : V(T_G) \to V(T_S)$, which usually corresponds to the *least common ancestor mapping*. Three biological events are considered for gene families' evolution: *duplications*, *losses*, and *lateral gene transfers*.

A *duplication* is a copy of a given gene, after which the two copies evolve independently. A duplication occurs in an internal node g of T_G if and only if $\lambda(f(g)) = \lambda(g)$, for a child $f(g)$ of g. A *loss* of a gene in some species consists in a copy of a gene disappearing during the evolution of a given gene family. The losses can be computed from the mapping λ between T_G and T_S [21].

When duplications and losses are the only evolutionary events considered, a gene tree and a species tree are compared with a *reconciled tree* $R(T_G, T_S)$ [2,5,9–11,21,23]. The reconciled tree is a binary tree that represents an embedding of a gene tree inside a species tree, and it allows to identify when duplications and losses occur. However, when considering also *lateral gene transfers* (also called horizontal gene transfers), the scenario changes, and the evolutionary history of a gene family must be represented by a phylogenetic network. A lateral gene transfer occurs when some genetic material is transferred from a taxon to another taxon which is not a descendant of the first taxon.

In order to represent a reconciliation of a gene tree T_G and a species tree T_S considering as evolutionary events, duplications, losses, and lateral gene transfers, the definition of *duplication-transfer-loss scenario* (DTL-scenario) has been introduced [25]. Notice that other models of reconciliation have been proposed, notably [10].

Definition 1 A DTL-scenario is a tuple $\mathcal{S} = (T_S, T_G, \sigma, \lambda^*, \Sigma, \Delta, \Gamma, \Theta)$ where T_S is a species tree; T_G is gene tree; σ maps each leaf of T_G with the corresponding leaf of T_S; λ^* maps each node of T_G in a node of T_S (λ^* can be considered as a generalization of the least common ancestor mapping λ); $\{\Sigma, \Delta, \Gamma\}$ is a tripartition of the internal nodes of T_G in speciation nodes, duplication nodes, transfer nodes, respectively, while Θ is a subset of the edges of T_G; and the following properties hold:

1. For each leaf of T_G, $\lambda^*(u) = \sigma(u)$.
2. Consider a node x with children x_l and x_r, then $\lambda^*(x)$ is not a proper descendant of one of $\lambda^*(x_r)$, $\lambda^*(x_l)$, and one of $\lambda^*(x_r)$, $\lambda^*(x_l)$ is a descendant of $\lambda^*(x)$.
3. Given an edge (x, y) of T_G, then $(x, y) \in \Theta$ if and only if x is not comparable with y.
4. Given nodes x of T_G with children x_r and x_l, then:
   (a) $x \in \Gamma$ if and only if $(x, x_l) \in \Theta$ or $(x, x_r) \in \Theta$.
   (b) $x \in \Sigma$ only if $\lambda^*(x)$ is the least common ancestor of $\lambda^*(x_l)$ and $\lambda^*(x_r)$, and $\lambda^*(x_l)$ and $\lambda^*(x_r)$ are not comparable.
   (c) $x \in \Delta$ only if $\lambda^*(x)$ is an ancestor of the least common ancestor of $\lambda^*(x_l)$ and $\lambda^*(x_r)$, and $\lambda^*(x_l)$ and $\lambda^*(x_r)$ are comparable.
5. Consider two edges $(x, x') \in \Theta$ and $(y, y') \in \Theta$, with x' an ancestor of y', then $\lambda^*(x')$ is an ancestor of $\lambda^*(y)$.

The number of losses is directly inferred from a given scenario $\mathcal{S}$ [1,25].

Now, we briefly discuss the biological motivations for the conditions introduced. Condition 1 guarantees the correspondence of each leaf T_G with the corresponding species (leaf) of T_S. Condition 2 guarantees that the order on the nodes of T_G is preserved by the mapping λ^*. Condition 3 defines the edges associated with a lateral gene transfer. Condition 4 establishes that the nodes of T_G can be either associated with a lateral gene transfer (condition 4.a), with a speciation (condition 4.b, then each node x and its two children must be mapped in different nodes of T_S), or with a duplication (condition 4.c, then each node x and at least one of its two children must be mapped in the same node of T_S). The last condition (condition 5) is introduced to ensure that different lateral gene transfers are biologically meaningful, that is, those events relate coexisting species, and that if (x, x') is lateral gene transfer, then there is no lateral gene transfer (y, y'), where y is a proper ancestor of x and y' is a proper descendant of x'.

Key Results

Consensus Networks

The maximum agreement subnetwork (MASN) problem is NP-hard even if the input is composed of a binary tree and an unbounded-level network [17]. If the input is composed of two level-1 networks, the problem can be solved in time $O(n^2)$, and it is fixed-parameter tractable if the input is composed of two level-k networks (where k is the parameter) [6].

Given a set of triplets, constructing a level-k phylogenetic network consistent with all of them is NP-hard for all $k \geq 1$, while it is NP-hard

for all $k \geq 0$ if we want to construct a level-k network consistent with the maximum number of them [28]. If the input set $\mathcal{T}$ of triplets is *dense* (i.e., it contains a triplet for each cardinality three subset of taxa), then a level-k network consistent with all triplets can be found (if any) in time $O(\mathcal{T})$ for $k = 1$ [18], in time $O(\mathcal{T}^3)$ for $k = 2$ [27], and in polynomial time for any fixed k [24]. Recently, these results have been extended in order to minimize the reticulation number of the computed network [14, 26].

The reconstruction of a consensus network from a set of clusters in the hardwired sense has been tackled in [16], where an algorithm for reconstructing a phylogenetic network that represents a set $\mathcal{C}$ of clusters (and only $\mathcal{C}$) with $O(|\mathcal{C}|)$ nodes and $O(|\mathcal{C}|^2)$ edges is presented. An algorithm for reconstructing a level-1 network from clusters in the softwired sense has been shown in [15], which has been later extended in order to compute in polynomial time a level-k network or a network with reticulation number k for every fixed k [19]. An efficient algorithm for computing a level-k network (with $k \in \{1, 2\}$) representing a set of cluster in the softwired sense which also attempts to minimize the reticulation number has also been presented [29].

Reconciliation

The main combinatorial problem related to reconciliation is, given a species tree and a gene tree, the computation of a DTL-scenario of minimum cost, for some function that assigns positive cost to duplications, losses, and lateral gene transfers. The problem is known to be NP-hard [22, 25]. However, two tractable variants of the problem have been considered.

A first variant, called *cyclic DTL-scenario*, does not consider condition 5 of Definition 1. Computing a cyclic DTL-scenario of minimum cost is polynomial time solvable. First, an algorithm for cost function that assigns positive cost only to duplications and lateral gene transfers was presented [25]. Later a linear time algorithm for a general cost function (hence losses are assigned a positive cost) was given [1].

A second variant considered is the *dated version*, where nodes of the species are associated with labels that represent the divergence time and a lateral gene transfer is possible only between coexisting species. In this case, computing an acyclic DTL-scenario of minimum cost is polynomial time solvable [20].

Open Problems

The fixed parameter tractability of computing a minimum reticulation-number phylogenetic network that combines a set of nonbinary trees has not yet be assessed, and only a few attempts focus on approximate solutions. Answers to both questions could be of interest.

An interesting open problem related to the computation of a DTL-scenario of minimum cost is the investigation of the parameterized complexity for acyclic DTL-scenarios, when parameterized by the cost of the solution or by the number of lateral gene transfers. Another interesting direction for this problem is to investigate its approximation complexity.

Problem Definition

This problem concerns hypergraph dualization and generalization to poset dualization.

A *hypergraph* $\mathcal{H} = (V, \mathcal{E})$ consists of a finite collection $\mathcal{E}$ of sets over a finite set V, i.e., $\mathcal{E} \subseteq \mathcal{P}(V)$ (the powerset of V). The elements of $\mathcal{E}$ are called *hyperedges*, or simply *edges*. A hypergraph is said simple if none of its edges is contained within another. A *transversal* (or *hitting set*) of $\mathcal{H}$ is a set $T \subseteq V$ that intersects every edge of $\mathcal{E}$. A transversal is *minimal* if it does not contain any other transversal as a subset. The set of all minimal transversal of $\mathcal{H}$ is denoted by $Tr(\mathcal{H})$. The hypergraph $(V, Tr(\mathcal{H}))$ is called the *transversal hypergraph* of $\mathcal{H}$. Given a simple hypergraph $\mathcal{H}$, the hypergraph dualization problem (TRANS-ENUM for short) concerns the enumeration without repetitions of $Tr(\mathcal{H})$.

The TRANS-ENUM problem can also be formulated as a dualization problem in posets. Let $(P, \leq)$ be a poset (i.e., $\leq$ is a reflexive, antisymmetric, and transitive relation on the set P). For $A \subseteq P$, $\downarrow A$ (resp. $\uparrow A$) is the downward (resp. upward) closure of A under the relation $\leq$ (i.e., $\downarrow A$ is an ideal and $\uparrow A$ a filter of $(P, \leq)$). Two antichains $(\mathcal{B}^+, \mathcal{B}^-)$ of P are said to be dual if $\downarrow \mathcal{B}^+ \cup \uparrow \mathcal{B}^- = P$ and $\downarrow \mathcal{B}^+ \cap \uparrow \mathcal{B}^- = \emptyset$. Given an implicit description of a poset P and an antichain $\mathcal{B}^+$ (resp. $\mathcal{B}^-$) of P, the poset dualization problem (DUAL-ENUM for short) enumerates the set $\mathcal{B}^-$ (resp. $\mathcal{B}^+$), denoted by $\text{Dual}(\mathcal{B}^+) = \mathcal{B}^-$ (resp. $\text{Dual}(\mathcal{B}^-) = \mathcal{B}^+$). Notice that the function dual is self-dual or idempotent, i.e., $\text{Dual}(\text{Dual}(\mathcal{B})) = \mathcal{B}$.

TRANS-ENUM is a particular case of DUAL-ENUM. Indeed, consider P the poset $(\mathcal{P}(V), \subseteq)$ for some set V. Then for every dual set $(\mathcal{B}^+, \mathcal{B}^-)$ of P, we have $\mathcal{B}^- = Tr(\overline{\mathcal{B}^+}) = \text{Dual}(\mathcal{B}^+)$, or equivalently $\mathcal{B}^+ = \overline{Tr(\mathcal{B}^-)} = \text{Dual}(\mathcal{B}^-)$ with $\overline{\mathcal{E}} = \{V \setminus E \mid E \in \mathcal{E}\}$ where $\mathcal{E} \subseteq \mathcal{P}(V)$.

Now we ask the following question: Which posets DUAL-ENUM can be reduced to TRANS-ENUM? To do so, we introduce the notions of duality gap, convex embedding, and poset reflexion.

Let $(P, \leq P)$ and $(Q, \leq_Q)$ be two posets and $f : P \to Q$ an *injective reflection*, i.e., for all $x, y \in P, f(x) \leq_Q f(y)$ implies $x \leq_P y$. Notice that the reflection f preserves incomparability, i.e., if x and y are incomparable in P, then $f(x)$ and $f(y)$ are incomparable in Q. Therefore, for every dual set $(\mathcal{B}^+, \mathcal{B}^-)$ of P, $\text{Dual}(f(\mathcal{B}^+))$ contains $f(\mathcal{B}^-)$. The difference between the size of $\text{Dual}(f(\mathcal{B}^+))$ and the size of $f(\mathcal{B}^-)$ is a positive integer, called the *duality gap*. We speak about *weak duality* when the gap is strictly positive, *strong duality* otherwise.

Duality gaps are important in enumeration problems because they provide an upper bound on the difference between the number of enumerated solutions and the number of solutions of the original problem.

Key Results

TRANS-ENUM has been intensively studied in the last two decades, and several results show that it is equivalent to many problems in computer science area (see the paper by Eiter and Gottlob [3]). The question whether TRANS-ENUM admits an output-polynomial time algorithm is still open. In fact, despite the number of papers on TRANS-ENUM, the best known algorithm is the one by Fredman and Khachiyan [8] which runs in time $O(n^{\log(n)})$ where n is the size of the hypergraph plus the number of minimal transversals. Other results on complexity can be found in [5, 6, 11, 12, 14]. For general posets, it is shown in [7] that the dualization over the products of some posets can be done with the same complexity as TRANS-ENUM. Recently, Nourine and Petit [16] have investigated dualization problems in general posets for which the duality gap is bounded by a polynomial.

Strong Duality

The following characterization theorem of the zero gap is a reformulation of a known result in [10, 15], where the poset Q is the powerset for some set.

Theorem 1 *Let $(P, \leq_P)$ and $(Q, \leq_Q)$ be two posets. Then the duality gap is zero iff there exists a map $f : P \to Q$ such that f is a bijective embedding, i.e., for all $x, y \in P$ $f(x) \leq_Q f(y)$ iff $x \leq_P y$.*

Many instances of problems have such a property, for example, frequent itemsets, monotone Boolean functions, minimal keys, inclusion dependencies, or minimal dominating sets [10, 13, 15]. Nevertheless, the bijective embedding between two posets does not always exist. In the following we give a relaxation of the bijection embedding in order to capture some polynomial reductions between enumeration problems.

Weak Duality

Let $(P, \leq_P)$ and $(Q, \leq_Q)$ be posets. A function $f : P \to Q$ is a *convex embedding* if for all $x, y \in P$ and $z \in Q$, $x \leq_P y$ iff $f(x) \leq_Q f(y)$ and $f(x) \leq_Q z \leq_Q f(y)$ implies there exists $t \in P$ such that $f(t) = z$.

The following result can be seen as a relaxation of the bijective embedding given in Theorem 1.

Proposition 1 *Let $(P, \leq_P)$ and $(Q, \leq_Q)$ be two posets and $f : P \to Q$ a convex embedding. Then there exist two antichains $\mathcal{B}_0^+$, $\mathcal{B}_0^-$ of Q such that $P \setminus \{\bot_P\}$ is isomorphic to $Q \setminus (\downarrow \mathcal{B}_0^+ \cup \uparrow \mathcal{B}_0^-)$, where $\bot_P$ is the bottom of P if it exists. Furthermore, the duality gap is bounded by $| \mathcal{B}_0^+ | + | \mathcal{B}_0^- |$.*

Complexity

For strong duality, [10, 15] points out how the result of Fredman and Khachiyan [8] can be reused to devise an incremental quasi-polynomial time algorithm, called `Dualize and Advance`, for some pattern mining problems. For weak duality, whenever the duality gap remains polynomial in the size of the problem and $(Q, \leq_Q)$ isomorphic to $(\mathcal{P}(E), \subseteq)$ for some set E, the `Dualize and Advance` algorithm can be reused with the same complexity if the following assumptions hold:

1. The reflexion f of $(P, \leq)$ to $(\mathcal{P}(E), \subseteq)$ and its inverse is computable in polynomial time.
2. Given two elements $x, y \in P$, checking $x \leq y$ is polynomial time.

Applications

The hypergraph dualization is a crucial step in many applications in logics, databases, artificial intelligence, and pattern mining [3, 4, 8, 11, 15], especially for hypergraphs, i.e., Boolean lattices. The main application domain concerns pattern mining problems, i.e., the identification of maximal interesting patterns in database by asking membership queries (predicate) to a database. In the rest of this section, we give two examples of pattern mining problems related to DUAL-ENUM and weak duality.

Frequent Conjunctive Queries

We consider the problem statement defined in [9]. Let $\mathbf{R} = \{R_1, \ldots, R_n\}$ be a database schema, $\mathcal{D}$ the domain of $\mathbf{R}$ and $\text{sch}(\mathbf{R}) = \{R_i.A | R_i \in \mathbf{R}, A \in R_i\}$. A (simple) conjunctive query Q

over $\mathbf{R}$ is of the form $\pi_X(\sigma_F(R_1 \times \ldots \times R_n))$ ($\pi_X(\sigma_F)$ for short) where $X \subseteq \text{sch}(\mathbf{R})$ and F a conjunction of equalities of the form $R_i.A = R_j.B$ or $R_i.A = c$ with $R_i.A, R_j.B \in \text{sch}(\mathbf{R})$ and $c \in \mathcal{D}$. Let $\mathcal{Q}_r$ be the set of all possible conjunctive queries over $\mathbf{R}$. For a given database d over $\mathbf{R}$, we note $\text{Adom}(d) \subseteq \mathcal{D}$ is the active domain of d and $Q(d)$ the result of the evaluation of Q against d. We note $\mathcal{F}$ is the finite set of all possible selection formula over $\mathbf{R}$ and $\text{Adom}(d)$, i.e., $\mathcal{F} = \{\{A, B\} \mid A \neq B, A \in \mathbf{R}, B \in \mathbf{R} \cup \text{Adom}(d)\}$.

Let Q_1, Q_2 be two conjunctive queries over $\mathbf{R}$. Q_1 is *contained* in Q_2, denoted by $Q_1 \subseteq Q_2$, if for every database d over $\mathbf{R}$, $Q_1(d) \subseteq Q_2(d)$. Q_1 is *diagonally contained* in Q_2, denoted $Q_1 \subseteq^{\Delta} Q_2$, if Q_1 is contained in a projection of Q_2, i.e., $Q_1 \subseteq \pi_X(Q_2)$. The frequency of $\pi_X(\sigma_F)$ in d is defined by $|\pi_X(\sigma_F)(d)|$. A query $\pi_X(\sigma_F)$ is *frequent* in d with respect to a given threshold ϵ if $|\pi_X(\sigma_F)(d)| \geq \epsilon$. The frequency is anti-monotonic with respect to $\subseteq^{\Delta}$ [9].

Proposition 2 *Let $Q_1 = \pi_{X_1}(\sigma_{F_1})$ and $Q_2 = \pi_{X_2}(\sigma_{F_2})$ be two queries of $\mathcal{Q}_r$. Then $Q_1 \subseteq^{\Delta} Q_2$ iff $X_1 \subseteq X_2$ and $F_2 \subseteq F_1$. Equivalently, $Q_1 \subseteq^{\Delta} Q_2$ iff $X_1 \cup (\mathcal{F} \setminus F_1) \subseteq X_2 \cup (\mathcal{F} \setminus F_2)$.*

From Proposition 2, $f : \mathcal{Q}_r \to \mathcal{P}(\mathbf{R} \cup \mathcal{F})$ with $f(\pi_X(\sigma_F)) = X \cup (\mathcal{F} \setminus F)$ is a bijective embedding. Thus $\mathcal{Q}_r$ ordered under $\subseteq^{\Delta}$ is a Boolean lattice and Theorem 1 can be applied. It is interesting to consider the subclass of $\mathcal{Q}_r$ restricted to *consistent queries*, i.e., queries for which there exists at least one database such that their evaluations return values different from zero. For instance, $\sigma(B = 1 \wedge B = 2)$ and $\sigma(A = B \wedge A = 1 \wedge B = 2)$ are not consistent. Let us consider the set $\mathcal{Q}_C \subset \mathcal{Q}_r$ of all consistent queries.

Lemma 1 *Let $Q_1 = \pi_{X_1}(\sigma_{F_1})$ and $Q_2 = \pi_{X_2}(\sigma_{F_2})$ be two queries of $\mathcal{Q}_r$ such that $Q_1 \subseteq^{\Delta} Q_2$. Then if Q_2 is consistent, it implies Q_1 is consistent.*

Notice that the restriction of f to $\mathcal{Q}_C$ is still a convex embedding, but no longer bijective. More interestingly, the associated duality gap is not polynomial. Indeed, $B_0^+ = \emptyset$ but B_0^- has a size exponential in the size of $\mathbf{R} \cup \text{Adom}(d)$ since the number of selections of the form $\sigma(A_1 = A_2 \wedge \ldots \wedge A_{n-1} = A_n \wedge A_1 = v \wedge A_n = v')$ is exponential in the number of attributes.

Rigid Sequences

Let us consider sequences with or without wildcard (denoted $\star$); see, e.g., [1]. Let Σ be an alphabet and $\star \notin \Sigma$. A rigid sequence $s[n]$ is a word of size n of $(\Sigma \cup \{\star\})^*$ such that $s[1] \neq \star$ and $s[n] \neq \star$. The set of all rigid sequences of size at most n are denoted by Σ_R^n and the empty sequence by ϵ. Let $s[l], t[k] \in \Sigma_R^n$. We consider the following classical (prefix and factor) partial orders on rigid sequences:

- $s \sqsubseteq_f t$, if there exists $j \in [1 \ldots k]$ such that for every $i \in [1 \ldots l]$, either $s[i] = t[j+i-1]$ or $s[i] = \star$ (factor).
- $s \sqsubseteq_p t$, if for every $i \in [1 \ldots l]$, either $s[i] = t[i]$ or $s[i] = \star$ (prefix).

The following theorem shows that the duality gap between the dualization in prefix posets of rigid sequences and TRANS-ENUM is bounded by a polynomial in n and $|\Sigma|$.

Theorem 2 ([16]) *Let $f : (\Sigma_R^n \setminus \{\epsilon\}, \sqsubseteq_p) \to (\mathcal{P}(\{1, \ldots, n\} \times \Sigma), \subseteq)$ be a function defined by $f(s) = \{(i, s[i]) \mid s[i] \neq \star, i \leq n\}$. Then f is a convex embedding with $\mathcal{B}_0^+ = \{\{(i, x) \mid x \in \Sigma, i \in [2 \ldots n]\}\}$ and $\mathcal{B}_0^- = \{\{(1, x), (1, y)\} \mid x, y \in \Sigma, x \neq y\} \cup \{\{(1, x), (i, y), (i, z)\} \mid x, y, z \in \Sigma, y \neq z, i \in [2 \ldots n]\}$.*

Proposition 3 ([16]) *There is a poset reflection $f : (\Sigma_R^n, \sqsubseteq_f) \to (\Sigma_R^n, \sqsubseteq_p)$ with a duality gap bounded by a polynomial in n.*

Using Theorem 2 and Proposition 3, we conclude that the duality gap between the dualization in factor posets of rigid sequences and TRANS-ENUM is bounded by a polynomial the size of Σ and n [16].

Open Problems

1. The challenging question is to find an output-polynomial time algorithm for TRANS-ENUM.

2. Lattices are a particular class of posets. For example, the dualization over product of chains can be done with the same complexity as TRANS-ENUM which is equivalent to dualization in Boolean lattices. For distributive lattices class which contains Boolean lattice and the product of chains, the dualization is open.
3. Many connections have to be done between TRANS-ENUM and graph theory problems, such as minimal dominating sets [13].
4. Many problems in data mining can be formulated as dualization in posets, e.g., frequent subgraphs or frequent subtrees. An interesting direction is to identify posets for which the dualization is equivalent to TRANS-ENUM.

URLs to Code and Data Sets

Program Codes and Instances for Hypergraph Dualization can be found on the Takeaki Uno's webpage at http://research.nii.ac.jp/~uno/dualization.html. Some pattern mining problems, reducible to TRANS-ENUM with strong duality, can be found on the iZi webpage at http://liris.cnrs.fr/izi/.

Problem Definition

Over the last few years, differential privacy [5, 6] has emerged as one of the most accepted notions of statistical data privacy. At a high level differential privacy ensures that from the output of an algorithm executed on a data set of potentially sensitive records, an adversary learns "almost" the same thing about an individual irrespective of his presence or absence in the data set. Formally, differential privacy is defined below (Definition 1). Setting the privacy parameters $\epsilon < 1$ and $\delta \ll \frac{1}{n^2}$ ensures semantically meaningful privacy guarantees. For a detailed survey on the semantics of differential privacy, see [2, 3, 8, 9].

Definition 1 ((ϵ, δ)-differential privacy [5, 6]) We call two data sets D and D' (with n records from a fixed domain τ) neighboring if they differ in exactly one entry, i.e., $|D \triangle D'| = 2$. An algorithm $\mathcal{A}$ is (ϵ, δ)-differentially private if, for all neighboring data sets D and D' and for all measurable events S in the range space of $\mathcal{A}$, we have

$$\Pr[\mathcal{A}(D) \in S] \leq e^{\epsilon} \Pr[\mathcal{A}(D') \in S] + \delta.$$

Initial efforts towards designing differentially private algorithms have concentrated on settings where the algorithms enjoy the same utility guarantees for *any* data set from the domain τ^n. (See [3] for a survey on these efforts.) However, due to the pessimistic nature of these algorithms, some perform poorly in non-worst-case scenarios. With the seminal work of [11], and followed by a series of results [4, 7, 10, 12, 13], the community started focusing on designing differentially private algorithms which are more useful in non-worst-case settings, but in pessimistic scenarios may only perform as poorly as the worst case algorithms. In this entry, we provide an overview of some of the recent efforts in this line of research.

Computing the Median: A Motivating Example

To provide a flavor of the nature of these algorithms, we start with the following simple example: Given a data set $D = \{d_1, \ldots, d_n\}$ of n real numbers in $[0, R]$ (with $R \in \mathbb{R}^+$ and n being odd), the task is to compute the median of D while preserving differential privacy. Notice that in the worst case, changing one entry in D can change the median by R. So intuitively, any algorithm that does not distinguish between worst case and non-worst-case scenario will introduce an error $\Omega(R)$ in the output.

Without loss of generality, assume that $d_1 \leq \cdots \leq d_n$ and let $m = \frac{n+1}{2}$. Now it is not hard to observe that by changing one data entry in D, the median d_m can change by at most $\max\{d_m - d_{m-1}, d_{m+1} - d_m\}$, which can be potentially much smaller than R. An algorithm that takes advantage of this observation can be much more useful in non-worst-case settings as compared to an algorithm that always introduces an error of $\Theta(R)$. With this example in mind, in the following section, we define some of the notions in the differential privacy literature that capture the non-worst-case change in the output of a given computation task on neighboring data sets.

Although the median might seem to be a very simple example, but interestingly, this intuition of capturing non-worst-case change extends to a large class of problems. Especially in many machine learning settings, where even for the non-private algorithms the error guarantees are over distributional assumptions on the data [1], this intuition is very helpful in designing effective differentially private variants.

N.B. Notice that in the case of computing the average, there is no distinction between worst case and non-worst change. Hence it is not a good example for the scenarios we address in this entry.

Notions of Sensitivity

We describe some of the concepts which help us capture non-worst-case changes in the output of a given function $f : \tau^n \to \mathbb{R}$ on pairs of neighboring data sets D and D'. Later we use them to design differentially private algorithms which capture non-worst-case behavior of the data sets.

Global Sensitivity [6]

This notion of sensitivity refers to the maximum change the function f can have on any pair of neighboring data sets from the domain. Formally,

$$\mathsf{GS}(f) = \max_{D, D' \in \tau^n, |D \triangle D'| = 2} |f(D) - f(D')|. \tag{1}$$

The following algorithm in (2) is $(\epsilon, 0)$-differentially private. In the literature this is also called the *Laplace mechanism* [6]. Here $\mathsf{Lap}(\lambda)$ refers to the Laplace distribution with standard deviation $\sqrt{2}\lambda$.

$$\textbf{Output}: f(D) + \mathsf{Lap}\left(\frac{\mathsf{GS}(f)}{\epsilon}\right). \tag{2}$$

Notice that in (2) the distribution on the noise that is added is the same for all data sets. In general these style of algorithms that introduce data independent randomness have weaker utility guarantees in non-worst-case scenarios.

Local Sensitivity

While global sensitivity captures the maximum change in the output of f for any pairs of neighboring data sets, local sensitivity relaxes this notion to capture the maximum change in the output of f for any neighboring data set of a given data set D. Formally,

$$\mathsf{LS}(f, D) = \max_{D' \in \tau^n, |D \triangle D'| = 2} |f(D) - f(D')|. \tag{3}$$

With the similarity between the definitions of local sensitivity and global sensitivity, it might be tempting to use the same algorithm as (2), with the GS replaced by LS. A careful observation indicates that this algorithm cannot be (ϵ, δ)-differentially private for any non-trivial choices of ϵ and δ. Consider the following setting where the data domain is $\{0, 1\}^n$, and the function f is the median value of D. Let D be a data set with $\lfloor \frac{n}{2} - 1 \rfloor$ entries as zero, and the rest as one. When n is odd, clearly $\mathsf{LS}(D)$ equals zero. But for a data set D' formed by changing one of the zeros in D to one, $\mathsf{LS}(D')$ equals one. So, if we replace GS by LS in (2), then for D there will be zero noise added, and for D' the noise will be $\Omega(1/\epsilon)$. Differential privacy prohibits this.

The counterexample above might give an impression that local sensitivity may not be a useful concept. However, in the following and in Algorithm 2, we show that one can use local sensitivity to obtain effective differentially private algorithms which are more useful in non-worst-case scenarios.

Smooth Sensitivity [11]

In the above example, we noticed that a direct use of local sensitivity in noise addition can result in trouble. However, using a related notion called smooth sensitivity, one can obtain a variant of the algorithm in (2) which is both differentially private and respects local properties of a given data set. At a high level, smooth sensitivity is an envelope over the local sensitivity which helps avoid abrupt change in the variance of the noise on neighboring data sets. Formally,

$$\mathsf{SS}(f, D, \beta) = \max_{D' \in \tau^n} \mathsf{LS}(f, D) e^{-\beta \cdot \mathsf{dist}(D, D')/2}. \tag{4}$$

Here dist is the symmetric difference between the two data sets D and D' and $\beta > 0$ is the smoothness parameter. Following observations on smooth sensitivity will be useful for designing differentially private algorithms.

1. **Observation 1 (Envelope on LS):** $\forall D, \beta > 0, \mathsf{SS}(f, D, \beta) \geq \mathsf{LS}(f, D)$.
2. **Observation 2 (Smaller than GS):** $\forall \beta > 0, D \in \tau^n, \mathsf{SS}(f, D, \beta) \leq \mathsf{GS}(f)$.
3. **Observation 3 (Smoothness):** For all neighbors D, D', $\mathsf{SS}(f, D, \beta) \leq e^{\beta} \mathsf{SS}(f, D', \beta)$.

Key Results

Using the concepts of local sensitivity and smooth sensitivity defined in the previous section, we provide two differentially private algorithmic frameworks which respect local (non-worst-case) properties of a given data set. Later in Applications 1 and 2, we instantiate them with specific problems.

Algorithm 1: Smooth Sensitivity Based

In order to use the notion of smooth sensitivity to design a differentially private algorithm analogous to (2), we need the following properties from the noise distribution to be added to $f(D)$. Let us define the following notation: For a subset S of $\mathbb{R}$, the set $S + \Delta$ defines $\{z + \Delta : z \in S\}$, and the set $e^{\lambda} \cdot S$ defines the set $\{e^{\lambda} \cdot z : z \in S\}$.

Definition 2 (Admissible noise distribution [11]) A probability distribution h on $\mathbb{R}$ is (α, β)-admissible if, for $\alpha = \alpha(\epsilon, \delta), \beta = \beta(\epsilon, \delta)$, the following conditions hold for all $|\Delta| \leq \alpha$ and $|\lambda| \leq \beta$, and for all subsets $S \subseteq \mathbb{R}$.

1. **Sliding property:** $\Pr_{Z \sim h}[Z \in S] \leq e^{\epsilon/2} \Pr_{Z \sim h}[Z \in S + \Delta] + \frac{\delta}{2}$.
2. **Dialation property:** $\Pr_{Z \sim h}[Z \in S] \leq e^{\epsilon/2} \Pr_{Z \sim h}\left[Z \in e^{\lambda} \cdot S\right] + \frac{\delta}{2}$.

With Definition 2 in hand, now we can define an algorithm which is analogous to (2). Let h be an (α, β)-admissible noise distribution and let Z be an independent sample from h. For a given data set D, the algorithm is as follows:

$$\textbf{Output}: f(D) + \frac{\mathsf{SS}(f, D, \beta)}{\alpha} \cdot Z. \qquad (5)$$

One can show that the above algorithm is (ϵ, δ)-differentially private [11]. An immediate question that arises: *Which natural distributions satisfy this property?* [11] showed that Laplace distribution $\frac{1}{2}e^{-|z|}$ is $\left(\epsilon/2, \frac{\epsilon}{2\ln(1/\delta)}\right)$-admissible, and $\mathcal{N}(0, 1)$ is $\left(\epsilon/\sqrt{\ln(1/\delta)}, \frac{\epsilon}{2\ln(1/\delta)}\right)$-admissible. Later we will see a concrete instantiation of (5) for the median problem.

Algorithm 2: Propose-Test-Release (PTR) Framework

In the previous section we saw a "noise-addition"-based algorithm that exploited the smooth upper bound on the local sensitivity to ensure differentially privacy. In this section, instead of obtaining a smooth bound on the local sensitivity, we seek an answer to the following question: *Given a proposed upper bound Λ on the local sensitivity of $f(D)$, how many data points (k) in D need to be changed to increase the local sensitivity beyond Λ?* If k is sufficiently large, then the algorithm uses the proposed bound Λ in (2) instead of $\mathsf{GS}(f)$; otherwise the algorithm outputs a $\perp$ and fails. Once formalized, this algorithmic paradigm can be shown to be (ϵ, δ)-differentially private. A major component in the design of algorithms using this paradigm is to come up with tight upper bounds on the local sensitivity. In Applications 1 and 2 we state two approaches for getting such bounds.

In the following, we formally introduce the propose-test-release framework. The version in Algorithm 1 is a variant of the ones appeared in [4] and [13].

Algorithm 1 Propose-test-release (PTR) framework

Input: Data set: $D \in \tau^n$, function $f : \tau^n \to \mathbb{R}$, proposed local sensitivity bound: Λ, privacy parameters: (ϵ, δ).

1: **Distance to instability:** $\mathsf{dist} \leftarrow$ Minimum $k \in [n]$ for which $\left[\max_{D', D \triangle D' = 2k} \mathsf{LS}(f, D')\right] > \Lambda$.
2: **Noisy distance to instability:** $\widetilde{\mathsf{dist}} \leftarrow \mathsf{dist} + \mathsf{Lap}\left(\frac{1}{\epsilon}\right)$.
3: **Test and release:** If $\widetilde{\mathsf{dist}} > \frac{1}{\epsilon}\log(1/\delta)$, then output Λ, else output $\perp$.

One can show that Algorithm 1 is (ϵ, δ)-differentially private. (See [13] for more details.) Additionally, by the tail properties of Laplace distribution, it is not hard to show that if $\mathsf{dist} > \frac{2}{\epsilon}\log(1/\delta)$, then with probability at least $1 - \delta$, the algorithm outputs Λ. In (6) we fit Algorithm 1 with the Laplace mechanism from (2) to obtain a differentially private estimate of $f(D)$. By the composition property of differential privacy [4, 5], the algorithm

(*PTR+Laplace mechanism*) in (6) is $(2\epsilon, \delta)$-differentially private.

$$\text{If PTR}(f, D, \Lambda, \epsilon, \delta) \neq \perp, \text{ then } \textbf{output } f(D) + \mathsf{Lap}\left(\frac{\Lambda}{\epsilon}\right), \text{ else } \textbf{fail}. \tag{6}$$

One can notice that if the proposed bound Λ is much smaller than $\mathsf{GS}(f)$, then whenever the algorithm succeeds, it would add much lesser noise to $f(D)$ as compared to (2). In Application 1 we will do a comparison between the global sensitivity based, the smooth sensitivity based, and the PTR-based algorithm for the problem of computing the median.

Application 1: Computing the Median

With the smooth sensitivity-based and the PTR-based algorithmic frameworks from the previous section in hand, we revisit the problem of computing the median. Let the data set $D = \{d_1, \ldots, d_n\} \in [0, R]^n$ with n being odd and $R \in \mathbb{R}$ being the range. W.l.o.g., assume that the entries in D are sorted in *ascending order*.

Smooth sensitivity-based algorithm for median computation. In order to use (5), we need to be able to efficiently compute the smooth sensitivity (4) of the median function for D with a given smoothness parameter β. The following theorem implies an $O(n \log n)$ algorithm for computing the smooth sensitivity.

Theorem 1 ([11]) *Let $m = \frac{n+1}{2}$. The smooth sensitivity of the median function with the smoothness parameter β is given by the following.*

$$\mathsf{SS}(\mathsf{Median}, D, \beta) = \max_{k=0,\ldots,n} \times \left(e^{-k\beta} \max_{t=0,\ldots,k+1} (d_{m+t} - d_{m+t-k-1})\right).$$

It can be computed in time $O(n \log n)$.

Once the smooth sensitivity bound is obtained, one can use it in (5) to obtain a differentially private approximation to the median of D. If Laplace distribution $(\frac{1}{2}e^{-|z|})$ is used as the noise, then set the admissible parameters $\alpha = \epsilon/2$ and $\beta = \frac{\epsilon}{2\ln(1/\delta)}$. An immediate question that arises is how does the noise added by the smooth sensitivity-based algorithm compare to the global sensitivity-based algorithm in (1). First notice that since global sensitivity is always an upper bound on smooth sensitivity, the noise added via smooth sensitivity can never be more than that via global sensitivity. Next we present a setting of the data set D where in fact the smooth sensitivity-based algorithm adds much lesser noise (and hence more accurate).

Consider the data set D where each $d_i = \frac{R \cdot i}{n}$ for all $i \in [n]$. In this case the term $A_k = \max_{t=0,\ldots,k+1} (d_{m+t} - d_{m+t-k-1}) = \frac{(k+1)R}{n}$. Thus the term $e^{-k\beta} A_k$ is maximized when $k = \frac{1}{\beta} - 1$. Assuming $\beta < 1$, the smooth sensitivity $\mathsf{SS}(\mathsf{Median}, D, \beta)$ is bounded by $\frac{R}{\beta n}$. If we use Laplace distribution in (5) to ensure (ϵ, δ)-differential privacy, then the noise that gets added to $\mathsf{Median}(D)$ is $O\left(\frac{R \log(1/\delta)}{\epsilon^2 n}\right)$. In comparison, the global sensitivity-based algorithm in (2) will add noise $O\left(\frac{R}{\epsilon}\right)$, which is much higher.

One might argue that the global sensitivity-based algorithm guarantees stronger differential privacy ($(\epsilon, 0)$ as opposed to (ϵ, δ)) and hence it is not a fair comparison. Even when one uses a more concentrated noise distribution like Gaussian distribution (which ensures (ϵ, δ)-differential privacy) instead of Laplace distribution in (2), the error still remains the same.

PTR-based algorithm for computing the median. We now instantiate the PTR-based algorithm for the same problem of computing the median. In order to do so, we first partition the real line $\mathbb{R}$ into bins of width $h = \frac{R}{n^{1/3}}$ (or any width $\frac{R}{n^{1/2+\gamma}}$ for any $\gamma > 0$). Call this set of bins $\mathcal{B}$. Additionally consider the set $\mathcal{B}_{(+h/2)}$, which is the set of bins shifted by $h/2$.

In Algorithm 1 we set the proposed sensitivity bound $\Lambda = h$. We compute the *distance to*

instability in Line 1 of Algorithm 1 by the following technique. Let k_1 be the minimum number of entries in D that needs to be changed to move the median from its bin in the set $\mathcal{B}$, and let k_2 be the corresponding minimum number for the set $\mathcal{B}_{(+h/2)}$. The distance to instability is $\mathsf{dist} \leftarrow \max\{k_1, k_2\}$. Now the rest of the algorithm follows as described for the PTR framework. The two sets of shifted bins $\mathcal{B}$ and $\mathcal{B}_{(+h/2)}$ were needed because the median might fall at the partition boundary of the bins. Notice that computing dist takes $O(n)$ time.

In terms of the utility guarantee for this algorithm, we have the following:

Theorem 2 ([4]) *Let the data set D be drawn i.i.d. from some fixed distribution $\mathcal{P}$, where the cumulative distribution function of $\mathcal{P}$ is differentiable with positive derivative at the median. Assuming the privacy parameter $\delta = 1/\mathsf{poly}(n)$, we have the following utility guarantees for the PTR-based median computation.*

$$\Pr[\mathsf{PTR}(D) = \perp] = O(e^{-\epsilon \log n})$$

and $\mathsf{PTR}(D)$ converges in probability to the median of $\mathcal{P}$ as $n \to \infty$.

Application 2: Selection from a Discrete Set

In this section we will see another application of the PTR framework. Although the exposition is fairly abstract, we will see that this tool is useful for a variety of machine learning problems, where we assume "very little" about the underlying learning algorithm. Some of the examples being sparse estimation, parameter tuning, and non-convex learning.

Given a data set $D \in \tau^n$, and a choice function $f : \tau^n \to \{S_1, \ldots, S_k\}$, the objective is to compute a differentially private approximation to $f(D)$. Here $\{S_1, \ldots, S_k\}$ form a discrete set of choices. In order to design the private algorithm, we instantiate the PTR framework in Algorithm 1, with $\Lambda = 0$ and f being the choice function. (Notice that $\Lambda = 0$ means that the output of the function does not change *at all* by changing any one entry in the data set.) If the output of the PTR framework is *not equal to* $\perp$, then output $f(D)$ exactly, and output $\perp$ otherwise. From the privacy property of the PTR framework, it follows that the above algorithm is (ϵ, δ)-differentially private. In terms of utility one can show the following.

Theorem 3 ([13]) *If the distance to instability of the choice function (Line 1 of Algorithm 1) is at least $2\log(1/\delta)$, then with probability at least $1 - \delta$, the above PTR instantiation outputs $f(D)$ exactly.*

At a high level, Theorem 3 says that if one needs to change sufficient number of entries $(2\log(1/\delta))$ in the data set D to change $f(D)$, then with high probability the PTR framework will output $f(D)$ exactly. One issue with the current instantiation of the PTR framework is that it is not clear a priori how to efficiently compute the distance to instability in Line 1 of Algorithm 1. In the following we circumvent this problem by instantiating the PTR framework with a proxy function $\hat{f}$ instead of f, for which the distance to instability is always efficiently computable. Moreover, if on a (sufficiently large) random subset D_{sub} of D, with probability at least $3/4$ one can guarantee $f(D_{\mathsf{sub}}) = f(D)$, then the PTR framework outputs $f(D)$ exactly with high probability.

Subsample and aggregate framework. The basic idea of subsample aggregate framework first appeared in [11] and the current version is from [13]. Here we use a variant of that framework for instantiating the proxy function $\hat{f}$ corresponding to f.

Let $q = \frac{\epsilon}{32\log(1/\delta)}$ and $m = \frac{\log(n/\delta)}{q^2}$. Sample data sets $D_1, \ldots, D_m$, where each D_i is generated from D by sampling each entry in D with probability q, and D_i's are i.i.d. Let S_{first} be the choice which appears maximum number of times in $\mathcal{F} = \{f(D_1), \ldots, f(D_m)\}$, and let S_{second} be the corresponding second. Let the proxy function

$\hat{f}(D)$ equal S_{first}. Let $\text{count}(S)$ be the number of times the choice S appears in $\mathcal{F}$. One can show that with probability at least $1-\delta$, the distance to instability of $\hat{f}(D)$ equals $\text{dist} \leftarrow \frac{\text{count}(S_{\text{first}})-\text{count}(S_{\text{second}})}{4mq} - 1$. From this, one can conclude that using $\hat{f}$ as the proxy for the choice function f in the PTR framework ensures $(\epsilon, 2\delta)$-differential privacy. In terms of utility, for this "proxy" instantiation of the PTR one can show the following. Notice that in both Theorems 3 and 4, there is no dependence on the number of possible choices (k).

Theorem 4 ([13]) *If for each D_i (defined above) $f(D_i) = f(D)$ with probability at least $3/4$, then with probability at least $1-2\delta$, the above instantiation of the PTR framework outputs $f(D)$ exactly.*

One of the classic setting where the above algorithms can be used in the case of model or feature selection in machine learning. A specific example is the LASSO estimator, where the PTR-based algorithm achieves the *optimal* sample complexity even under the constraint of differential privacy. (See [13] for details.) Another example is in finding the best regularization parameter for a given regression problem (Dwork and Thakurta, Differentially private parameter tuning using subsample and aggregate framework. Personal communication, 2014). Let $\Lambda = \{\lambda_1, \ldots, \lambda_k\}$ be a candidate set of regularization parameters, with each $\lambda_i \in \mathbb{R}$. The idea is to estimate the best regularization parameter from the set Λ for each of the sampled data sets $D_1, \ldots, D_m$, and use the estimation algorithm itself as the choice function f in the PTR framework.

Notice that we almost assumed nothing about the regularization parameter selection algorithm, apart from the fact that on random subsamples of the original data set D, the algorithm selects the same regularization parameter most of the times. The subsampling-based algorithm can also be used in the context of learning non-convex models while preserving differential privacy (Bilenko et al., Private and robust non-convex learning. Personal communication, 2014). For the purpose of brevity, we defer the exposition for differentially private learning with non-convex models.

Reference Notes

The global sensitivity-based and the smooth sensitivity-based algorithmic framework are due to [6] and [11] respectively. The propose-test-release (PTR) framework is initially due to [4], but the exposition in this note is from [4, 13]. The smooth sensitivity-based private median algorithm is due to [11], and the one based on PTR framework is due to [4]. The algorithm for privately selecting from a discrete set is from [13].

Problem Definition

How to effectively translate an algorithm from a distributed system model to another one?

Distributed systems come in diverse settings that are modeled by different assumptions (1) on the way processes communicate, e.g., using shared memory or messages, (2) on the fault model, (3) on synchrony assumptions, etc. Each of these parameters has a dramatic impact on the computing power of the model, and in practice, an algorithm or an impossibility result is usually tailored to a particular model and cannot be directly reused in another model.

This wide variety of models has given rise to many different impossibility theorems and numerous algorithms for many of the possible combinations of parameters that characterize them. Thus, a crucial question is the following: are there bridges between some models, i.e., is it possible to transfer an impossibility result or an algorithm from one model to another?

The Borowsky-Gafni simulation algorithm, or BG simulation, is one of the first steps toward direct translations of algorithms or impossibility results from one model to another. The BG simulation considers distributed systems made of asynchronous processes that communicate using a shared memory array. In a nutshell, this simulation allows a set of $t + 1$ asynchronous sequential processes, where up to t of them can stop during their execution, to simulate any set of $n \geq t + 1$ processes executing an algorithm that is designed to tolerate to up to t fail-stop failures.

The BG simulation has been used to prove solvability and unsolvability results for crash-prone asynchronous shared memory systems, paving the way for a more generic formal theory of reduction between problems in different models of distributed computing.

The BG-simulation algorithm is named after its authors, Elizabeth Borowsky and Eli Gafni, that introduced it as a side tool [3] in order to generalize the impossibility result of solving a weakened version of consensus, namely, k-set agreement [6]. It has been later on formalized and proven correct [4, 18] using the I/O automata formalism [17].

System Model

Processes

The simulation considers a system made of up to n asynchronous sequential processes that execute a distributed algorithm to solve a given colorless decision task, as defined below.

Failure Model

Processes may fail by stopping (crash failure). The simulation assumes that up to t processes can stop during the execution; $t < n$ is known before the execution, but the identity of processes that may crash is unknown to the simulation. This model of computation is referred to as the t-resilient model. A corner case of this model is the wait-free model where $t + 1$ processes execute concurrently and at most t of them may crash.

Communication

Processes communicate and coordinate using a reliable shared memory composed of n multiple-reader single-writer registers. Each process has the exclusive write access to one of these n registers, and processes can read all entries by invoking a *snapshot* operation, with the semantics that write and snapshot operations appear as if they are executed atomically. While using the snapshot abstraction eases the presentation of the algorithm, it has no impact on the power of the underlying computing model, since the snapshot/write model can be implemented wait-free using read/write registers [1].

Tasks

A colorless task is a distributed coordination problem in which every process p_i starts with a value, communicates with other processes, and has to decide eventually on a output value. Colorless tasks, or convergence tasks [12], are a restricted version of tasks in which a deciding process may adopt the decision value of any process, i.e., two participating processes may decide the same value. For more formal definitions of tasks using tools from algebraic topology, the reader should refer to [11].

Simulation

The simulation proceeds by executing concurrently, using $t + 1$ simulators $s_1, \ldots, s_{t+1}$, the code of $n > t$ processes that collaboratively solve a distributed colorless task. Hence, each simulator s_i is given the code of all simulated processes and handles the execution of n threads.

Key Results

Simulation of Memory

Each one of the $t + 1$ simulators s_i executes the sequential code of the n simulated processes p_j in parallel. By assumption, every simulated code is a sequence of instructions that are either (1) local processing, (2) a write operation into memory, or (3) a snapshot of the shared memory.

Every simulator s_i maintains its local view of the simulated memory for all simulated threads. These local views are synchronized between simulators by writing and reading (using snapshots) in a shared memory matrix array MEM that has one column per simulated thread and one row per *snapshot* instance.

To ensure global consistency between simulators that simulate concurrently all threads, operations on the memory must be coordinated between different simulators. This is achieved by ensuring that, for a given simulated thread, the sequence of snapshots of the memory as computed by all simulators is identical. As consensus cannot be implemented wait-free, the simulation coordinates snapshots using of a weaker form of agreement, the *safe agreement*.

The Safe-Agreement Object

Safe agreement is the most important building block of the simulation. First introduced as the *non-blocking busy-wait* agreement protocol [3], it has been further refined as safe agreement, with several blocking or non-blocking/wait-free implementations [2, 11, 14].

This weak form of agreement provides two methods to processes: *propose*(v) and *resolve*(). A participating process that proposes a value v first calls *propose*(v) once and is then allowed to make calls to *resolve*() that may return $\perp$ if safe agreement is not resolved yet or a value. In this later case, safe agreement is said to be resolved and the value returned is the decided value by the process. Formally, safe agreement is defined by three properties:

Termination: If no process crashes during the execution of *propose*(), then all processes decide, i.e., eventually all calls to *resolve*() return a non-$\perp$ value,

Validity: All processes that decide must decide a proposed value,

Agreement: All processes that decide must decide the same value.

The specification is almost identical to the one of consensus, apart from the weakened termination property. Safe agreement is wait-free solvable and thus solvable in t-resilient systems.

The crucial point of the BG simulation lies in the termination property of safe agreement: if a safe-agreement protocol cannot be resolved, i.e., if no process decides, then at least one process crashed during the call to *propose*(). Thus, a given safe-agreement instance can "capture" a calling process that crashed during the *propose* invocation.

Overview of the Simulation

The current state of the simulation and its history is thus represented by two twin data structures: (1) the shared memory matrix *MEM* that contains the consecutive memory status of all simulated threads, as seen by simulators, and (2) a matrix of safe-agreement objects SafeAgreement$[0\ldots][1\ldots n]$ with n columns, each column representing the execution advancement of one of the simulated processes, as shown in Fig. 1.

In this view, the entry at row ℓ and column i corresponds to the state of the ℓth snapshot for simulated process p_j. Hence, the "program counter" of a simulated thread p_i is the greatest row of column i that is either unresolved or resolved. In this example, simulations of threads p_2, p_4, and p_6 are stopped with unresolved safe agreement that are due to (at least) one simulator stuck in the associated *propose*() methods. The program counter of all other threads is 9.

Each simulator s_i is given the code of the n threads it has to simulate, as well as an input value of one of the threads. Conceptually, the algorithm run by simulator s_i is as follows:

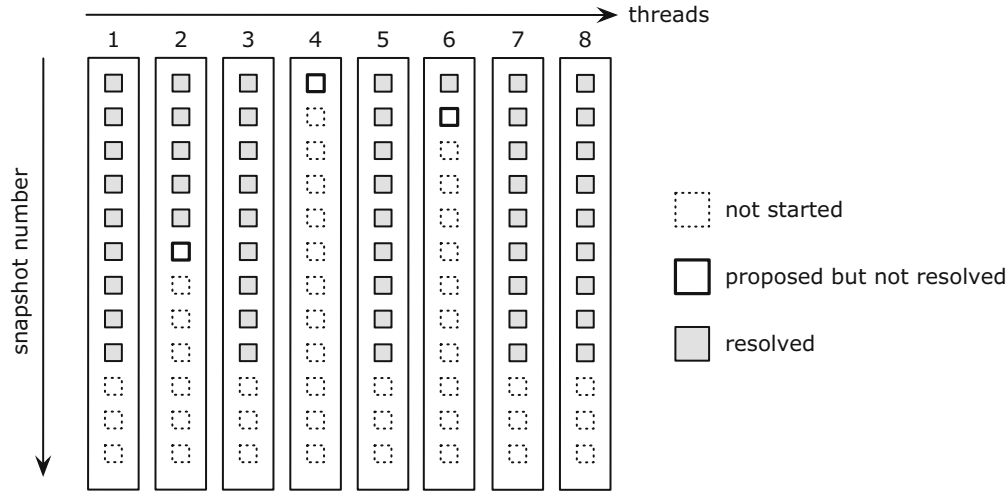
In the simulation, each *snapshot* invocation is mediated through a SafeAgreement object, lines 6 and 1. The only reason that could block the simulation of a given thread p_i is when the call to *resolve*, line 6, always returns $\perp$. By definition of the safe-agreement object, this situation can happen only when a simulator crashed during the call to *propose*() on the same safe-agreement instance: *the crash of a simulator can block the simulation of at most one simulated thread.*

Applications

The BG-simulation algorithm has been primarily used to reduce t-resilient solvability to wait-free

Algorithm 1 BG-simulation: code for a simulator s_j starting with input v

```
1:  procedure BG-SIMULATION(v)
2:      ∀i = 1...n, SafeAgreement[0][i].propose(v)
                                                          ▷ Initialization
3:      loop
4:          for i ← 1, n do                    ▷ Simulate threads in round-robin
5:              ℓ ← current program counter of p_i
6:              snap ← SafeAgreement[ℓ][i].resolve()
7:              if snap ≠ ⊥ then                          ▷ safe agreement is resolved
8:                  perform local computation using snap, write operations in local memory
9:                  execute write on behalf of p_i in MEM[ℓ][i]
10:                 if thread p_i is terminated then
11:                     return value and stop its simulation
12:                 else if at least (n − t) threads have program counter ≥ ℓ then
13:                     snap ← snapshot(MEM[ℓ])
14:                     SafeAgreement[ℓ + 1][i].propose(snap)
15:                 end if
16:             end if
17:         end for
18:     end loop
19: end procedure
```



BG Distributed Simulation Algorithm, Fig. 1 Conceptual view of advancement for snapshots of all simulated process with $n = 8$ and $t = 3$

solvability for colorless tasks, that is, tasks that are agnostic on process identities. The initial application has been made to the k-set agreement problem, in which all processes have to agree on a final set of values of size at most k. If k-set agreement was solvable in a k-resilient system of $n > k + 1$ processes, then the BG simulation of this algorithm with $k + 1$ simulators would produce a wait-free solution to k-set agreement. Since k-set agreement is not wait-free solvable for $k + 1$ processes [13, 19], it follows a contradiction.

The BG simulation presented here only applies to *colorless tasks*. Gafni [8] extended further to more general classes of tasks and provided the general characterization of t-resilient solvable tasks, similarly to the Herlihy-Shavit conditions for wait-free computability [13]. This extension has been also studied in [14, 16].

In order to study the relationship between wait-freedom and t-resilience, [5] uses objects of type $\mathcal{S}$ in addition to read/write registers and shows that for any $t < k$, t-resilient k-process consensus can be implemented with objects of type $\mathcal{S}$ and registers if and only if wait-free $(t + 1)$-process consensus can be implemented with objects of type $\mathcal{S}$ and registers. Imbs and Raynal [15] consider models equipped with registers and consensus objects and extend the results provided by BG simulation, showing equivalences between models based on the ratio between the maximum number of failures and the consensus number of consensus objects.

Chaudhuri and Reiners [7] use BG simulation to provide a characterization of the set consensus partial order, a refinement of Herlihy's consensus-based wait-free hierarchy [10]; a formal definition of *set consensus number* and a study of associated respective computing power have been later provided in [9].

Problem Definition

The theory of bidimensionality provides general techniques for designing efficient fixed-parameter algorithms and approximation algorithms for a broad range of NP-hard graph problems in a broad range of graphs. This theory applies to graph problems that are "bidimensional" in the sense that (1) the solution value for the $k \times k$ grid graph and similar graphs grows with k, typically as $\Omega(k^2)$, and (2) the solution value goes down when contracting edges and optionally when deleting edges in the graph. Many problems are bidimensional; a few classic examples are vertex cover, dominating set, and feedback vertex set.

Graph Classes

Results about bidimensional problems have been developed for increasingly general families of graphs, all generalizing planar graphs.

The first two classes of graphs relate to embeddings on surfaces. A graph is *planar* if it can be drawn in the plane (or the sphere) without crossings. A graph has *(Euler) genus* at most g if it can be drawn in a surface of Euler characteristic g. A class of graphs has *bounded genus* if every graph in the class has genus at most g for a fixed g.

The next three classes of graphs relate to excluding minors. Given an edge $e = \{v, w\}$ in a graph G, the *contraction* of e in G is the result of identifying vertices v and w in G and removing all loops and duplicate edges. A graph H obtained by a sequence of such edge contractions starting from G is said to be a *contraction* of G. A graph H is a *minor* of G if H is a subgraph of some contraction of G. A graph class C is *minor closed* if any minor of any graph in C is also a member of C. A minor-closed graph class C is *H-minor-free* if $H \notin C$. More generally, the term "H-minor-free" refers to any minor-closed graph class that excludes some fixed graph H. A *single-crossing graph* is a minor of a graph that can be drawn in the plane with at most one pair of edges crossing. A minor-closed graph class is *single-crossing-minor-free* if it excludes a fixed single-crossing graph. An *apex graph* is a graph in which the removal of some vertex leaves a planar graph. A graph class is *apex-minor-free* if it excludes some fixed apex graph.

Bidimensional Parameters

Although implicitly hinted at in [2, 5, 10, 11], the first use of the term "bidimensional" was in [3].

First, "parameters" are an alternative view on optimization problems. A *parameter* P is a function mapping graphs to nonnegative integers. The *decision problem associated with* P asks, for a given graph G and nonnegative integer k, whether $P(G) \leq k$. Many optimization problems can be phrased as such a decision problem about a graph parameter P.

Now, a parameter is $g(r)$-*bidimensional* (or just *bidimensional*) if it is at least $g(r)$ in an $r \times r$ "grid-like graph" and if the parameter does not increase when taking either minors ($g(r)$-*minor-bidimensional*) or contractions ($g(r)$-*contraction-bidimensional*). The exact definition of "grid-like graph" depends on the class of graphs allowed and whether one considers minor or contraction bidimensionality. For minor bidimensionality and for any H-minor-free graph class, the notion of a "grid-like graph" is defined to be the $r \times rgrid$, i.e., the planar graph with r^2 vertices arranged on a square grid and with edges connecting horizontally and vertically adjacent vertices. For contraction bidimensionality, the notion of a "grid-like graph" is as follows:

1. For planar graphs and single-crossing-minor-free graphs, a "grid-like graph" is an $r \times r$ grid partially triangulated by additional edges that preserve planarity.
2. For bounded-genus graphs, a "grid-like graph" is such a partially triangulated $r \times r$ grid with up to genus (G) additional edges ("handles").
3. For apex-minor-free graphs, a "grid-like graph" is an $r \times r$ grid augmented with additional edges such that each vertex is incident to $O(1)$ edges to nonboundary vertices of the grid. (Here $O(1)$ depends on the excluded apex graph.)

Contraction bidimensionality is so far undefined for H-minor-free graphs (or general graphs).

Examples of bidimensional parameters include the number of vertices, the diameter, and the size of various structures such as feedback vertex set, vertex cover, minimum maximal matching, face cover, a series of vertex-removal parameters, dominating set, edge dominating set, R-dominating set, connected dominating set, connected edge dominating set, connected R-dominating set, unweighted TSP tour (a walk in the graph visiting all vertices), and chordal completion (fill-in). For example, feedback vertex set is $\Omega(r^2)$-minor-bidimensional (and thus also contraction-bidimensional) because (1) deleting or contracting an edge preserves existing feedback vertex sets and (2) any vertex in the feedback vertex set destroys at most four squares in the $r \times r$ grid, and there are $(r-1)^2$ squares, so any feedback vertex set must have $\Omega(r^2)$ vertices. See [1, 3] for arguments of either contraction or minor bidimensionality for the other parameters.

Key Results

Bidimensionality builds on the seminal graph minor theory of Robertson and Seymour, by extending some mathematical results and building new algorithmic tools. The foundation for several results in bidimensionality is the following two combinatorial results. The first relates any bidimensional parameter to treewidth, while the second relates treewidth to grid minors.

Theorem 1 ([1, 8]) *If the parameter P is $g(r)$-bidimensional, then for every graph G in the family associated with the parameter P, $\mathrm{tw}(G) = O(g^{-1}(P(G)))$. In particular, if $g(r) = \Theta(r^2)$, then the bound becomes $\mathrm{tw}(G) = O(\sqrt{P(G)})$.*

Theorem 2 ([8]) *For any fixed graph H, every H-minor-free graph of treewidth w has an $\Omega(w) \times \Omega(w)$ grid as a minor.*

The two major algorithmic results in bidimensionality are general subexponential fixed-parameter algorithm and general polynomial-time approximation scheme (PTASs).

Theorem 3 ([1, 8]) *Consider a $g(r)$-bidimensional parameter P that can be computed on a graph G in $h(w)n^{O(1)}$ time given a tree decomposition of G of width at most w. Then there is an algorithm computing P on any graph G in P's corresponding graph class, with running time $\left[h(O(g^{-1}(k))) + 2^{O(g-1(k))}\right] n^{O(1)}$. In particular, if $g(r) = \Theta(r^2)$ and $h(w) = 2^{O(w2)}$, then this running time is subexponential in k.*

Theorem 4 ([7]) *Consider a bidimensional problem satisfying the "separation property" defined in [4, 7].*

Suppose that the problem can be solved on a graph G with n vertices in $f(n, \mathrm{tw}(G))$ time. Suppose also that the problem can be approximated within a factor of α in $g(n)$ time. For contraction-bidimensional problems, suppose further that both of these algorithms also apply to the "generalized form" of the problem defined in [4, 7]. Then there is a $(1+^2)$-approximation algorithm whose running time is $O(nf(n, O(O^2/^2)) + n^3 g(n))$ for the corresponding graph class of the bidimensional problem.

Applications

The theorems above have many combinatorial and algorithmic applications.

Applying the parameter-treewidth bound of Theorem 1 to the parameter of the number of vertices in the graph proves that every H-minor-free graph on n vertices has treewidth $O(\sqrt{n})$, thus (re)proving the separator theorem for H-minor-free graphs. Applying the parameter-treewidth bound of Theorem 1 to the parameter of the diameter of the graph proves a stronger form of Eppstein's diameter-treewidth relation for apex-minor-free graphs. (Further work shows how to further strengthen the diameter-treewidth relation to linear [6].) The treewidth-grid relation of Theorem 2 can be used to bound the gap between half-integral multicommodity flow and fractional multicommodity flow in H-minor-free graphs. It also yields an $O(1)$-approximation for treewidth in H-minor-

free graphs. The subexponential fixed-parameter algorithms of Theorem 3 subsume or strengthen all previous such results. These results can also be generalized to obtain fixed-parameter algorithms in arbitrary graphs. The PTASs of Theorem 4 in particular establish the first PTASs for connected dominating set and feedback vertex set even for planar graphs. For details of all of these results, see [4].

Open Problems

Several combinatorial and algorithmic open problems remain in the theory of bidimensionality and related concepts.

Can the grid-minor theorem for H-minor-free graphs, Theorem 2, be generalized to arbitrary graphs with a polynomial relation between treewidth and the largest grid minor? (The best relation so far is exponential.) Such polynomial generalizations have been obtained for the cases of "map graphs" and "power graphs" [9]. Good grid-treewidth bounds have applications to minor-bidimensional problems.

Can the algorithmic results (Theorems 3 and 4) be generalized to solve contraction-bidimensional problems beyond apex-minor-free graphs? It is known that the basis for these results, Theorem 1, does not generalize [1]. Nonetheless, Theorem 3 has been generalized for one specific contraction-bidimensional problem, dominating set [3].

Can the polynomial-time approximation schemes of Theorem 4 be generalized to more general algorithmic problems that do not correspond directly to bidimensional parameters? One general family of such problems arises when adding weights to vertices and/or edges, and the goal is, e.g., to find the minimum-weight dominating set. Another family of such problems arises when placing constraints (e.g., on coverage or domination) only on subsets of vertices and/or edges. Examples of such problems include Steiner tree and subset feedback vertex set.

For additional open problems and details about the problems above, see [4].

Problem Definition

In the one-dimensional bin packing problem, one is given a list $L = (a_1, a_2, \ldots, a_n)$ of items, each item a_i having a size $s(a_i) \in (0, 1]$. The goal is to pack the items into a minimum number of unit-capacity bins, that is, to partition the items into a minimum number of sets, each having total size of at most 1. This problem is NP-hard, and so much of the research on it has concerned the design and analysis of approximation algorithms, which will be the subject of this article.

Although bin packing has many applications, it is perhaps most important for the role it has played as a proving ground for new algorithmic and analytical techniques. Some of the first worst- and average-case results for approximation algorithms were proved in this domain, as well as the first lower bounds on the competitive ratios of online algorithms. Readers interested in a more detailed coverage than is possible here are directed to two relatively recent surveys [4, 11].

Key Results

Worst-Case Behavior

Asymptotic Worst-Case Ratios

For most minimization problems, the standard worst-case metric for an approximation algorithm A is the maximum, over all instances I, of the ratio $A(I)/OPT(I)$, where $A(I)$ is the value of the solution generated by A and $OPT(I)$ is the optimal solution value. In the case of bin packing, however, there are limitations to this "absolute worst-case ratio" metric. Here it is already NP-hard to determine whether $OPT(I) = 2$, and hence no polynomial-time approximation algorithm can have an absolute worst-case ratio better than 1.5 unless P = NP. To better understand the behavior of bin packing algorithms in the typical situation where the given list L requires a large number of bins, researchers thus use a more refined metric for bin packing, the *asymptotic worst-case ratio* R_A^∞. This is defined in two steps as follows.

$$R_A^n = \max\{A(L)/OPT(L) : L \text{ is a list with } OPT(L) = n\}$$

$$R_A^\infty = \limsup_{n\to\infty} R_A^n$$

The first algorithm whose behavior was analyzed in these terms was *First Fit* (FF). This algorithm envisions an infinite sequence of empty bins $B_1, B_2, \ldots$ and, starting with the first item in the input list L, places each item in turn into the first bin which still has room for it. In a technical report from 1971 which was one of the very first papers in which worst-case performance ratios were studied, Ullman [22] proved the following.

Theorem 1 ([22]) $R_{FF}^\infty = 17/10$.

In addition to FF, five other simple heuristics received early study and have served as the in-

spiration for later research. *Best Fit* (BF) is the variant of FF in which each item is placed in the bin into which it will fit with the least space left over, with ties broken in favor of the earliest such bin. Both FF and BF can be implemented to run in time $O(n \log n)$ [12]. *Next Fit* (NF) is a still simpler and linear-time algorithm in which the first item is placed in the first bin, and thereafter each item is placed in the last nonempty bin if it will fit, otherwise a new bin is started. *First Fit Decreasing* (FFD) and *Best Fit Decreasing* (BFD) are the variants of those algorithms in which the input list is first sorted into nonincreasing order by size and then the corresponding packing rule is applied. The results for these algorithms are as follows.

Theorem 2 ([12]) $R_{NF}^{\infty} = 2$.

Theorem 3 ([13]) $R_{BF}^{\infty} = 17/10$.

Theorem 4 ([12, 13]) $R_{FFD}^{\infty} = R_{BFD}^{\infty} = 11/9 = 1.222\ldots$

The above mentioned algorithms are relatively simple and intuitive. If one is willing to consider more complicated algorithms, one can do substantially better. The current best polynomial-time bin packing algorithm is very good indeed. This is the 1982 algorithm of Karmarkar and Karp [15], denoted here as "KK." It exploits the ellipsoid algorithm, approximation algorithms for the knapsack problem, and a clever rounding scheme to obtain the following guarantees.

Theorem 5 ([15]) $R_{KK}^{\infty} = 1$ *and there is a constant c such that for all lists L,*

$$KK(L) \leq OPT(L) + c \log^2(OPT(L)).$$

Unfortunately, the running time for KK appears to be worse than $O(n^8)$, and BFD and FFD remain much more practical alternatives.

Online Algorithms

Three of the abovementioned algorithms (FF, BF, and NF) are *online* algorithms, in that they pack items in the order given, without reference to the sizes or number of later items. As was subsequently observed in many contexts, the online restriction can seriously limit the ability of an algorithm to produce good solutions. Perhaps the first limitation of this type to be proved was Yao's theorem [24] that no online algorithm A for bin packing can have $R_A^{\infty} < 1.5$. The bound has since been improved to the following.

Theorem 6 ([23]) *If A is an online algorithm for bin packing, then* $R_A^{\infty} \geq 1.540\ldots$

Here the exact value of the lower bound is the solution to a complicated linear program.

Yao's paper also presented an online algorithm *Revised First Fit* (RFF) that had $R_{RFF}^{\infty} = 5/3 = 1.666\ldots$ and hence got closer to this lower bound than FF and BF. This algorithm worked by dividing the items into four classes based on size and index, and then using different packing rules (and packings) for each class. Subsequent algorithms improved on this by going to more and more classes. The current champion is the online *Harmonic++* algorithm (H++) of [21]:

Theorem 7 ([21]) $R_{H++}^{\infty} \leq 1.58889$.

Bounded-Space Algorithms

The NF algorithm, in addition to being online, has another property worth noting: no more than a constant number of partially filled bins remain open to receive additional items at any given time. In the case of NF, the constant is 1 – only the last partially filled bin can receive additional items. Bounding the number of open bins may be necessary in some applications, such as packing trucks on loading docks. The bounded-space constraint imposes additional limits on algorithmic behavior however.

Theorem 8 ([17]) *For any online bounded-space algorithm A,* $R_A^{\infty} \geq 1.691\ldots$.

The constant $1.691\ldots$ arises in many other bin packing contexts. It is commonly denoted by h_{∞} and equals $\sum_{i=1}^{\infty}(1/t_i)$, where $t_1 = 1$ and, for $i > 1$, $t_i = t_{i-1}(t_{i-1} + 1)$.

The lower bound in Theorem 8 is tight, owing to the existence of the *Harmonic*$_k$ algorithms (H_k) of [17]. H_k is a class-based algorithm in which the items are divided into classes C_h, $1 \le h \le k$, with C_k consisting of all items with size $1/k$ or smaller, and C_h, $1 \le h < k$, consisting of all a_i with $1/(h+1) < s(a_i) \le 1/h$. The items in each class are then packed by NF into a separate packing devoted just to that class. Thus, at most k bins are open at any time. In [17] it was shown that $\lim_{k\to\infty} R^{\infty}_{H_k} = h_\infty = 1.691\ldots$. This is even better than the asymptotic worst-case ratio of 1.7 for the unbounded-space algorithms FF and BF, although it should be noted that the bounded-space variant of BF in which all but the two most-full bins are closed also has $R^{\infty}_{A} = 1.7$ [8].

Average-Case Behavior

Continuous Distributions

Bin packing also served as an early test bed for studying the average-case behavior of approximation algorithms. Suppose F is a distribution on $(0, 1]$ and L_n is a list of n items with item sizes chosen independently according to F. For any list L, let $s(L)$ denote the lower bound on $OPT(L)$ obtained by summing the sizes of all the items in L. Then define

$$ER^n_A(F) = E\left[A(L_n)/OPT(L_n)\right],$$
$$ER^{\infty}_A(F) = \limsup_{n\to\infty} ER^n_A$$
$$EW^n_A(F) = E\left[A(L_n) - s(L_n)\right]$$

The last definition is included since $ER^{\infty}_A(F) = 1$ occurs frequently enough that finer distinctions are meaningful. For example, in the early 1980s, it was observed that for the distribution $F = U(0, 1]$ in which item sizes are uniformly distributed on the interval $(0, 1]$, $ER^{\infty}_{FFD}(F) = ER^{\infty}_{BFD}(F) = 1$, as a consequence of the following more-detailed results.

Theorem 9 ([16, 20]) *For* $A \in \{FFD, BFD, OPT\}$, $EW^n_A(U(0, 1]) = \Theta(\sqrt{n})$.

Somewhat surprisingly, it was later discovered that the online FF and BF algorithms also had sublinear expected waste, and hence $ER^{\infty}_A(U(0, 1]) = 1$.

Theorem 10 ([5, 19])

$$EW^n_{FF}(U(0, 1]) = \Theta(n^{2/3})$$
$$EW^n_{BF}(U(0, 1]) = \Theta(n^{1/2}\log^{3/4} n)$$

This good behavior does not, however, extend to the bounded-space algorithms NF and H_k:

Theorem 11 ([6, 18])

$$ER^{\infty}_{NF}(U(0, 1]) = 4/3 = 1.333\ldots$$
$$\lim_{k\to\infty} ER_{H_k}(U(0, 1]) = \pi^2/3 - 2 = 1.2899\ldots$$

All the above results except the last two exploit the fact that the distribution $U(0, 1]$ is symmetric about $1/2$, and hence an optimal packing consists primarily of two-item bins, with items of size $s > 1/2$ matched with smaller items of size very close to $1 - s$. The proofs essentially show that the algorithms in question do good jobs of constructing such matchings. In practice, however, there will clearly be situations where more than matching is required. To model such situations, researchers first turned to the distributions $U(0, b]$, $0 < b < 1$, where item sizes are chosen uniformly from the interval $(0, b]$. Simulations suggest that such distributions make things worse for the online algorithms FF and BF, which appear to have $ER^{\infty}_A(U(0, b]) > 1$ for all $b \in (0, 1)$. Surprisingly, they make things better for FFD and BFD (and the optimal packing).

Theorem 12 ([2, 14])

1. *For* $0 < b \le 1/2$ *and* $A \in \{FFD, BFD\}$, $EW^n_A(U(0, b]) = O(1)$.
2. *For* $1/2 < b < 1$ *and* $A \in \{FFD, BFD\}$, $EW^n_A(U(0, b]) = \Theta(n^{1/3})$.
3. *For* $0 < b < 1$, $EW^n_{OPT}(U(0, b]) = O(1)$.

Discrete Distributions

In many applications, the item sizes come from a finite set, rather than a continuous distribution like those discussed above. Thus, recently the study of average-case behavior for bin packing has turned to *discrete distributions*. Such a distribution is specified by a finite list $s_1, s_2, \ldots, s_d$ of rational sizes and for each s_i a corresponding rational probability p_i. A remarkable result of Courcoubetis and Weber [7] says the following.

Theorem 13 ([7]) *For any discrete distribution F, $EW^n_{OPT}(F)$ is either $\Theta(n)$, $\Theta(\sqrt{n})$, or $O(1)$.*

The discrete analogue of the continuous distribution $U(0, b]$ is the distribution $U\{j, k\}$, where the sizes are $1/k, 2/k, \ldots, j/k$ and all the probabilities equal $1/j$. Simulations suggest that the behavior of FF and BF in the discrete case are qualitatively similar to the behavior in the continuous case, whereas the behavior of FFD and BFD is considerably more bizarre [3]. Of particular note is the distribution $F = U\{6, 13\}$, for which $ER^{\infty}_{FFD}(F)$ is strictly greater than $ER^{\infty}_{FF}(F)$, in contrast to all the previously implied comparisons between the two algorithms.

For discrete distributions, however, the standard algorithms are all dominated by a new online algorithm called the *Sum-of-Squares* (SS) algorithm. Note that since the item sizes are all rational, they can be scaled so that they (and the bin size B) are all integral. Then at any given point in the operation of an online algorithm, the current packing can be summarized by giving, for each h, $1 \le h \le B$, the number n_h of bins containing items of total size h. In SS, one packs each item so as to minimize $\sum_{h=1}^{B-1} n_h^2$.

Theorem 14 ([9]) *For any discrete distribution F, the following hold.*

1. *If $EW^n_{OPT}(F) = \Theta(\sqrt{n})$, then $EW^n_{SS}(F) = \Theta(\sqrt{n})$.*
2. *If $EW^n_{OPT}(F) = O(1)$, then $EW^n_{SS}(F) \in \{O(1), \Theta(\log n)\}$.*

In addition, a simple modification to SS can eliminate the $\Theta(\log n)$ case of condition 2.

Applications

There are many potential applications of one-dimensional bin packing, from packing bandwidth requests into fixed-capacity channels to packing commercials into station breaks. In practice, simple heuristics like FFD and BFD are commonly used.

Open Problems

Perhaps the most fundamental open problem related to bin packing is the following. As observed above, there is a polynomial-time algorithm (KK) whose packings are within $O(\log^2(OPT))$ bins of optimal. Is it possible to do better? As far as is currently known, there could still be a polynomial-time algorithm that always gets within one bin of optimal, even if P $\neq$ NP.

Experimental Results

Bin packing has been a fertile ground for experimental analysis, and many of the theorems mentioned above were first conjectured on the basis of experimental results. For example, the experiments reported in [1] inspired Theorem 10 and 12, and the experiments in [10] inspired Theorem 14.

Problem Definition

In the *bin packing problem*, one is given a sequence of *items*, each of *size* in the range $(0, 1]$, and an infinite number of *bins*. The goal is to pack each item into some bin using as few bins as possible, under the constraint that the sum of sizes of items in each bin is at most one. In the *bin packing problem with cardinality constraints*, an additional constraint is imposed that each bin can contain at most k items.

This problem for $k = 2$ is solvable in polynomial time by reducing it to the *cardinality matching problem*. Nevertheless, this problem for $k \geq 3$ is NP-hard, since one can reduce *3-PARTITION* to it. Therefore, much work has been done on *approximation algorithms*. We remark that, in particular, it has also been of interest to design *online algorithms* that pack each item upon its arrival.

The standard performance measure of an approximation algorithm for this problem is the *asymptotic performance ratio*. For a sequence of items L and an approximation algorithm A, let $A(L)$ denote the value of the solution generated by A for L, and let $OPT(L)$ denote the value of the optimal solution for L. The asymptotic performance ratio of A is defined as

$$R_A^{\infty} = \limsup_{n \to \infty} \sup_{L} \left\{ \frac{A(L)}{OPT(L)} \;\middle|\; OPT(L) = n \right\}.$$

The bin packing problem with cardinality constraints is formally defined as follows:

Problem 1 (Bin Packing with Cardinality Constraints)
Input: *A sequence* $L = (a_1, a_2, \ldots, a_n) \in (0, 1]^n$ *and an integer* $k \geq 2$. Output: *An integer* $m \geq 1$ *and a partition of* $\{1, 2, \ldots, n\}$ *into disjoint subsets* $S_1, S_2, \ldots, S_m$ *such that (1)* m *is minimum, (2)* $\sum_{i \in S_j} a_i \leq 1$ *for all* $1 \leq j \leq m$, *and (3)* $|S_j| \leq k$ *for all* $1 \leq j \leq m$.

Key Results

Approximation Algorithms

Krause et al. [9, 10] gave approximation algorithms whose asymptotic performance ratios are all two. Kellerer and Pferschy [8] presented an improved approximation algorithm with asymptotic performance ratio $\frac{3}{2}$. Caprara et al. [3] provided an APTAS (asymptotic polynomial-time approximation scheme): a collection of approximation algorithms that, for any parameter $\varepsilon > 0$, guarantees an asymptotic performance ratio of $1 + \varepsilon$. Finally, a better polynomial-time scheme was developed:

Theorem 1 ([6]) *There exists an AFPTAS (asymptotic fully polynomial-time approximation scheme) for the bin packing problem with cardinality constraints, that is, an APTAS whose running time is polynomial in the input size and* $\frac{1}{\varepsilon}$.

Online Algorithms

An *online algorithm* is an approximation algorithm which, for each $i = 1, 2, \ldots, n$, decides into which bin to place the ith item without information on the sizes of later items or the value of n. The *First-Fit*, *Best-Fit*, and *Next-Fit* algorithms may be the most common online algorithms for the bin packing problem without cardinality constraints.

Krause et al. [9, 10] adapted the *First-Fit* algorithm to the problem with cardinality constraints and showed that its asymptotic performance ratio is at most $2.7 - \frac{12}{5k}$. The result was later improved. Some work was done for individual values of k. We thus summarize best known upper and lower bounds on the asymptotic performance ratio for each $2 \leq k \leq 6$ in Table 1. We say here that u is an *upper bound* on the asymptotic performance ratio if there exists an online algorithm A such that $R_A^{\infty} = u$. On the other hand, we say that l is a *lower bound* on the asymptotic performance ratio if $R_A^{\infty} \geq l$ holds for any online algorithm A.

Babel et al. [1] designed an online algorithm, denoted here by $BCKK$, which guarantees an

asymptotic performance ratio regardless of the value of k. For $k \geq 7$, $BCKK$ is the best so far.

Theorem 2 ([1]) *For any k, $R^{\infty}_{BCKK} = 2$.*

Recently, Dósa and Epstein [4] showed a lower bound on the asymptotic performance ratio for each $7 \leq k \leq 11$. Fujiwara and Kobayashi [7] established a lower bound for each $12 \leq k \leq 41$. Some results on the bin packing problem without cardinality constraints can be interpreted as lower bounds on the asymptotic performance ratio for large k: a lower bound of $\frac{217}{141}(\approx 1.53900)$ for $42 \leq k \leq 293$ [11] and $\frac{10,633}{6,903}(\approx 1.54034)$ for $294 \leq k \leq 2{,}057$ [2].

Bounded-Space Online Algorithms

A *bounded-space online algorithm* is an online algorithm which has only a constant number of bins available to accept given items at any time point. For example, the *Next-Fit* algorithm is a bounded-space online algorithm for the bin packing problem without cardinality constraints, since for the arrival of each new item, the algorithm always keeps a single bin which contains some item(s). All algorithms that appeared in the previous section, except *Next-Fit*, do not satisfy this property; such algorithms are sometimes called *unbounded-space online algorithms*.

For the bin packing problem with cardinality constraints, a bounded-space online algorithm called CCH_k [5] is known to be optimal, which is based on the Harmonic algorithm. Its asymptotic performance ratio is $\mathcal{R}_k = \sum_{i=1}^{k} \max\left\{\frac{1}{t_i - 1}, \frac{1}{k}\right\}$, where t_i is the sequence defined by $t_1 = 2$, $t_{i+1} = t_i(t_i - 1) + 1$ for $i \geq 1$. For example, we have $\mathcal{R}_2 = \frac{3}{2} = 1.5$, $\mathcal{R}_3 = \frac{11}{6} \approx 1.83333$, $\mathcal{R}_4 = 2$, $\mathcal{R}_5 = 2.1$, and $\mathcal{R}_6 = \frac{13}{6} \approx 2.16667$. The value of $\mathcal{R}_k$ increases as k grows and approaches $1 + \sum_{i=1}^{\infty} \frac{1}{t_i - 1} \approx 2.69103$.

Bin Packing with Cardinality Constraints, Table 1 Best known upper and lower bounds on the asymptotic performance ratio of online algorithms for $2 \leq k \leq 6$

k	Upper bound	Lower bound
2	$1 + \frac{\sqrt{5}}{5}(\approx 1.44721)$ [1]	1.42764 [7]
3	1.75 [5]	1.5 [1]
4	$\frac{71}{38}(\approx 1.86843)$ [5]	1.5 [7]
5	$\frac{771}{398}(\approx 1.93719)$ [5]	1.5 [4]
6	$\frac{287}{144}(\approx 1.99306)$ [5]	1.5 [12]

Theorem 3 ([5]) *For every k, $R^{\infty}_{CCH_k} = \mathcal{R}_k$. Besides, $R^{\infty}_{A} \geq \mathcal{R}_k$ holds for any bounded-space online algorithm A.*

Applications

In the paper by Krause et al. [9, 10], the aim was to analyze task scheduling algorithms for multiprocessor systems. Not only this but a constraint on the number of objects in a container is important in application, such as a limit to the number of files on a hard disk drive or a limit to the number of requests assigned to each node in a distributed system.

Open Problems

Many problems concerning (unbounded-space) online algorithms remain open. Even for small values of k, an optimal online algorithm has yet to be found. It is also interesting whether, for general k, there is an online algorithm whose asymptotic performance ratio is strictly smaller than two.

Problem Definition

The well-known bin packing problem [3, 8] has numerous variants [4]. Here, we consider one natural variant, called the bin packing problem with general cost structures (GCBP) [1, 2, 6]. In this problem, the action of an algorithm remains as in standard bin packing. We are given n items of rational sizes in $(0, 1]$. These items are to be assigned into unit size bins. Each bin may contain items of total size at most 1. While in the standard problem the goal is to minimize the number of used bins, the goal in GCBP is different; the cost of a bin is not 1, but it depends on the number of items actually packed into this bin. This last function is a concave function of the number of packed items, where the cost of an empty bin is zero. More precisely, the input consists of n items $I = \{1, 2, \ldots, n\}$ with sizes $1 \geq s_1 \geq s_2 \geq \cdots \geq s_n \geq 0$ and a function $f : \{0, 1, 2, \ldots, n\} \to \mathbb{R}_0^+$, where f is a monotonically nondecreasing concave function, satisfying $f(0) = 0$. The goal is to partition I into some number of sets $S_1, \ldots, S_\mu$, called bins, such that $\sum_{j \in S_i} s_j \leq 1$ for any $1 \leq i \leq \mu$, and so that $\sum_{i=1}^{\mu} f(|S_i|)$ is minimized (where $|S_i|$ denotes the cardinality of the set S_i). An instance of GCBP is defined not only by its input item sizes but also using the function f. It can be assumed that $f(1) = 1$ (by possible scaling of the cost function f). The problem is strongly NP-hard for multiple functions f, and as standard bin packing, it was studied using the asymptotic approximation ratio.

Key Results

There are two kinds of results for the problem. The first kind of results is algorithms that do not take f into account. The second kind is those that base their action on the values of f.

A class of (concave and monotonically nondecreasing) functions $\{f_q\}_{q \in \mathbb{N}}$, which was considered in [1], is the following. These are functions that grow linearly (with a slope of 1) up to an integer point q, and then, they are constant

(starting from that point). Specifically, $f_q(t) = t$ for $t \leq q$ and $f_q(t) = q$ for $t > q$. It was shown in [1] that focusing on such functions is sufficient when computing upper bounds on algorithms that act independently of the cost function. Note that $f_1 \equiv 1$, and thus GCBP with the cost function f_1 is equivalent to standard bin packing.

Before describing the results, we present a simple example showing the crucial differences between GCBP and standard bin packing. Consider the function $f = f_3$ (where $f(1) = 1$, $f(2) = 2$, and $f(k) = 3$ for $k \geq 3$). Given an integer $N \geq 1$, consider an input consisting of $3N$ items, each of size $\frac{2}{3}$, called large items, and $6N$ items, each of size $\frac{1}{6}$, called small items. An optimal solution for this input with respect to standard bin packing uses $3N$ bins, each containing one large item and two small items. This is the unique optimal solution (up to swapping positions of identical items). The cost of this solution for GCBP with the function $f = f_3$ is $9N$. Consider a solution that uses $4N$ bins, the first N bins receive six small items each, and each additional bin receives one large item. This solution is not optimal for standard bin packing, but its cost for GCBP with $f = f_3$ is $6N$.

Anily, Bramel, and Simchi-Levi [1] analyzed the worst-case performance of some natural bin packing heuristics [8], when they are applied to GCBP. They showed that many common heuristics for bin packing, such as First Fit, Best Fit, and Next Fit, do not have a finite asymptotic approximation ratio. Moreover, running the modifications of the first two heuristics after sorting the lists of items (in a nonincreasing order), i.e., applying the algorithms First Fit Decreasing and Best Fit Decreasing, leads to similar results. However, Next Fit Decreasing was shown to have an asymptotic approximation ratio of exactly 2. The algorithm Next Fit packs items into its last bin as long as this is possible and opens a new bin when necessary. Sorting the items in nondecreasing order gives a better asymptotic approximation ratio of approximately 1.691 (in this case, the three algorithms, First Fit Increasing, Best Fit Increasing, and Next Fit Increasing, are the same algorithm). It is stated in [1] that any heuristic that is independent of f has an asymptotic approximation ratio of at least $\frac{4}{3}$. An improved approximation algorithm, called MatchHalf (MH), was developed in [6]. The asymptotic approximation ratio of this algorithm does not exceed 1.5. The idea of MH is to create bins containing pairs of items. The candidate items to be packed into those bins are half of the items of size above $\frac{1}{2}$ (large items), but they can only be packed with smaller items. Naturally, the smallest large items are selected, and the algorithm tries to match them with smaller items. The remaining items and unmatched items are packed using Next Fit Increasing. Interestingly, it was shown [6] that matching a larger fraction of large items can harm the asymptotic approximation ratio.

A fully polynomial approximation scheme (asymptotic FPTAS or AFPTAS) for GCBP was given in [6]. This is a family of approximation algorithms that contains, for any $\varepsilon > 0$, an approximation algorithm whose asymptotic approximation ratio is at most $1 + \varepsilon$. The running time must be polynomial in the input and in $\frac{1}{\varepsilon}$. An AFPTAS for GCBP must use the function f in its calculations (this can be shown using the example above and similar examples and can also be deduced from the lower bound of $\frac{4}{3}$ on the asymptotic approximation ratio of an algorithm that is oblivious of f [1]). An AFPTAS for GCBP is presented in [6]. One difficulty in designing such a scheme is that the nature of packing of small items is important, unlike approximation schemes for standard bin packing, where small items can be added greedily [7, 9]. While in our problem we can impose cardinality constraints on bins (upper bounds on numbers of packed items) as in [5], still the cost function introduces major difficulties. Another ingredient of the scheme is preprocessing where some very small items are packed into relatively full bins. It is impossible to do this for all very small items as bins consisting of only such items will have a relatively large cost (as each such bin will contain a very large number of items). This AFPTAS and those of [5] require column generation as in [9] but require fairly complicated configuration linear programs.

Problem Definition

Boolean Functions

The concept of a *Boolean function* – a function whose domain is $\{0,1\}^n$ and range is $\{0,1\}$ – is central to computing. Boolean functions are used in foundational studies of complexity [7, 9] as well as the design and analysis of logic circuits [4, 13], A Boolean function can be represented using a *truth table* – an enumeration of the values taken by the function on each element of $\{0,1\}^n$. Since the truth table representation requires memory exponential in n, it is impractical for most applications. Consequently, there is a need for data structures and associated algorithms for efficiently representing and manipulating Boolean functions.

Boolean Circuits

Boolean functions can be represented in many ways. One natural representation is a *Boolean combinational circuit*, or circuit for short [6, Chapter 34]. A circuit consists of *Boolean combinational elements* connected by *wires*. The Boolean combinational elements are *gates* and *primary inputs*. Gates come in three types: NOT, AND, and OR. The NOT gate functions as follows: it takes a single Boolean-valued *input* and produces a single Boolean-valued *output* which takes value 0 if the input is 1, and 1 if the input is 0. The AND gate takes two Boolean-valued inputs and produces a single output; the output is 1 if both inputs are 1, and 0 otherwise. The OR gate is similar to AND, except that its output is 1 if one or both inputs are 1, and 0 otherwise.

Circuits are required to be acyclic. The absence of cycles implies that a Boolean assignment to the primary inputs can be unambiguously propagated through the gates in topological order. It follows that a circuit on n ordered primary inputs with a designated gate called the *primary output*

corresponds to a Boolean function on $\{0,1\}^n$. Every Boolean function can be represented by a circuit, e.g., by building a circuit that mimics the truth table.

The circuit representation is very general – any decision problem that is computable in polynomial time on a Turing machine can be computed by circuit polynomial in the instance size, and the circuits can be constructed efficiently from the Turing machine program [15]. However, the key analysis problems on circuits, namely, satisfiability and equivalence, are NP-hard [7].

Boolean Formulas

A *Boolean formula* is defined recursively: a *Boolean variable* x_i is a *Boolean formula*, and if φ and ψ are Boolean formulas, then so are $(\neg\phi)$, $(\phi \wedge \psi)$, $(\phi \vee \psi)$, $(\phi \rightarrow \psi)$, and $(\phi \leftrightarrow \psi)$. The operators $\neg, \vee, \wedge, \rightarrow, \leftrightarrow$ are referred to as *connectives*; parentheses are often dropped for notational convenience. Boolean formulas also can be used to represent arbitrary Boolean functions; however, formula satisfiability and equivalence are also NP-hard. Boolean formulas are not as succinct as Boolean circuits: for example, the parity function has linear sized circuits, but formula representations of parity are super-polynomial. More precisely, $XOR_n : \{0,1\}^n \rightarrow \{0,1\}$ is defined to take the value 1 on exactly those elements of $\{0,1\}^n$ which contain an odd number of 1s. Define the *size* of a formula to be the number of connectives appearing in it. Then for any sequence of formulas $\theta_1, \theta_2, \ldots$ such that θ_k represents XOR_k, the size of θ_k is $\Omega(k^c)$ for all $c \in Z^+$ [14, Chapters 11, 12].

A *disjunct* is a Boolean formula in which $\wedge$ and $\neg$ are the only connectives, and $\neg$ is applied only to variables; for example, $x_1 \wedge \neg x_3 \wedge \neg x_5$ is a disjunct. A Boolean formula is said to be in *Disjunctive Normal Form* (DNF) if it is of the form $D_0 \vee D_1 \vee \cdots \vee D_{k-1}$, where each D_i is a disjunct. DNF formulas can represent arbitrary Boolean functions, e.g., by identifying each input on which the formula takes the value 1 with a disjunct. DNF formulas are useful in logic design, because it can be translated directly into a PLA implementation [4]. While satisfiability of DNF formulas is trivial, equivalence is NP-hard. In addition, given DNF formulas φ and ψ, the formulas $\neg\phi$ and $\phi \wedge \psi$ are not DNF formulas, and the translation of these formulas to DNF formulas representing the same function can lead to exponential growth in the size of the formula.

Shannon Trees

Let f be a Boolean function on domain $\{0,1\}^n$. Associate the n dimensions with variables $x_0, \ldots, x_{n-1}$. Then the *positive cofactor* of f with respect to x_i, denoted by f_{x_i}, is the function on domain $\{0,1\}^n$, which is defined by

$$f_{x_i}(\alpha_0, \ldots, \alpha_{i-1}, a_i, \alpha_{i+1}, \ldots, \alpha_{n-1}) = f(\alpha_0, \ldots, \alpha_{i-1}, 1, \alpha_{i+1}, \ldots, \alpha_{n-1}).$$

The *negative cofactor* of f with respect to x_i, denoted by $f_{x_i'}$, is defined similarly, with 0 taking the place of 1 in the right-hand side.

Every Boolean function can be decomposed using Shannon's expansion theorem:

$$f(x_1, \ldots, x_n) = x_i \cdot f_{x_i} + x_i' \cdot f_{x_i'}.$$

This observation can be used to represent f by a *Shannon tree* – a kill binary tree [6, Appendix B.5] of height n, where each path to a leaf node defines a complete assignment to the n variables that f is defined over, and the leaf node holds a 0 or a 1, based on the value f takes for the assignment.

The Shannon tree is not a particularly useful representation, since the height of the tree representing every Boolean function on $\{0,1\}^n$ is n, and the tree has 2^n leaves. The Shannon tree can be made smaller by merging isomorphic subtrees and bypassing nodes which have identical children. At first glance the reduced Shannon tree representation is not particularly useful, since it entails creating the full binary tree in the first place. Furthermore, it is not clear how to efficiently perform computations on the reduced Shannon tree representation, such as equivalence checking or computing the conjunction of functions presented as reduced Shannon trees.

Bryant [5] recognized that adding the restriction that variables appear in fixed order from root to leaves greatly reduced the complexity of manipulating reduced Shannon trees. He referred to this representation as a binary decision diagram (BDD).

Key Results

Definitions

Technically, a BDD is a directed acyclic graph (DAG), with a designated root, and at most two sinks – one labeled 0, the other labeled 1. Nonsink nodes are labeled with a variable. Each nonsink node has two outgoing edges – one labeled with a 1 leading to the *1-child*, the other is a 0, leading to the *0-child*. Variables must be ordered – that is, if the variable label x_i appears before the label x_j on some path from the root to a sink, then the label x_j is precluded from appearing before x_i on any path from the root to a sink. Two nodes are *isomorphic* if both are equilabeled sinks, or they are both nonsink nodes, with the same variable label, and their 0- and 1-children are isomorphic. For the DAG to be a valid BDD, it is required that there are no isomorphic nodes, and for no nodes are its 0- and 1-children the same.

A key result in the theory of BDDs is that given a fixed variable ordering, the representation is unique up to isomorphism, i.e., if F and G are both BDDs representing $f : \{0,1\}^n \to \{0,1\}$ under the variable ordering $x_1 \prec x_2 \prec \ldots x_n$, then F and G are isomorphic.

The definition of isomorphism directly yields a recursive algorithm for checking isomorphism. However, the resulting complexity is exponential in the number of nodes – this is illustrated, for example, by checking the isomorphism of the BDD for the parity function against itself on inspection, the exponential complexity arises from repeated checking of isomorphism between pairs of nodes – this naturally suggest dynamic programming. Caching isomorphism checks reduces the complexity of isomorphism checking to $O(|F| \cdot |G|)$, where $|B|$ denotes the number of nodes in the BDD B.

BDD Operations

Many logical operations can be implemented in polynomial time using BDDs: *bdd_and* which computes a BDD representing the logical AND of the functions represented by two BDDs, *bdd_or* and *bdd_not* which are defined similarly, and *bdd_compose* which takes a BDD representing a function f, a variable v, and a BDD representing a function g and returns the BDD for f where v is substituted by g are examples.

The example of *bdd_and* is instructive – it is based on the identity $f \cdot g = x \cdot (f_x \cdot g_x) + x' \cdot (f_{x'} \cdot g_{x'})$. The recursion can be implemented directly: the base cases are when either f or g are 0 and when one or both are 1. The recursion chooses the variable v labeling either the root of the BDD for f or g, depending on which is earlier in the variable ordering, and recursively computes BDDs for $f_v \cdot g_v$ and $f_{v'} \cdot g_{v'}$; these are merged if isomorphic. Given a BDD F for f, if v is the variable labeling the root of F, the BDDs for $f_{v'}$ and f_v, respectively, are simply the 0-child and 1-child of F's root.

The implementation of *bdd_and* as described has exponential complexity because of repeated subproblems arising. Dynamic programming again provides a solution – caching the intermediate results of *bdd_and* reduced the complexity to $O(|F| \cdot |G|)$.

Variable Ordering

All symmetric functions on $\{0,1\}^n$ have a BDD that is polynomial in n, independent of the variable ordering. Other useful functions such as comparators, multiplexers, adders, and subtracters can also be efficiently represented, if the variable ordering is selected correctly. Heuristics for ordering selection are presented in [1, 2, 11]. There are functions which do not have a polynomial-sized BDD under any variable ordering – the Unction representing the n-th bit of the output of a multiplier taking two n-bit unsigned integer inputs is an example [5]. Wegener [17] presents many more examples of the impact of variable ordering.

Applications

BDDs have been most commonly applied in the context of formal verification of digital hardware [8]. Digital hardware extends the notion of circuit described above by adding *state elements* which hold a Boolean value between updates and are updated on a *clock* signal.

The gates comprising a design are often updated based on performance requirements; these changes typically are not supposed to change the logical functionality of the design. BDD-based approaches have been used for checking the equivalence of digital hardware designs [10].

BDDs have also been used for checking properties of digital hardware. A typical formulation is that a set of "good" states and a set of "initial" states are specified using Boolean formulas over the state elements; the property holds iff there is no sequence of inputs which leads a state in the initial state to a state not in the set of good states. Given a design with n registers, a set of states A in the design can be characterized by a formula φ_A over n Boolean variables: φ_A evaluates to true on an assignment to the variables iff the corresponding state is in A. The formula φ_A represents a Boolean function, and so BDDs can be used to represent sets of states. The key operation of computing the *image* of a set of states A, i.e., the set of states that can be reached on application of a single input from states in A, can also be implemented using BDDs [12].

BDDs have been used for *test generation*. One approach to test generation is to specify legal inputs using constraints, in essence Boolean formulas over the primary input and state variables. Yuan et al. [18] have demonstrated that BDDs can be used to solve these constraints very efficiently.

Logic synthesis is the discipline of realizing hardware designs specified as logic equations using gates. Mapping equations to gates is straightforward; however, in practice a direct mapping leads to implementations that are not acceptable from a performance perspective, where performance is measured by gate area or timing delay. Manipulating logic equations in order to reduce area (e.g., through constant propagation, identifying common sub-expressions, etc.), and delay (e.g., through propagating late arriving signals closer to the outputs), is conveniently done using BDDs.

Experimental Results

Bryant reported results on verifying two qualitatively distinct circuits for addition. He was able to verify on a VAX 11/780 (a 1 MIP machine) that two 64-bit adders were equivalent in 95.8 min. He used an ordering that he derived manually.

Normalizing for technology, modern BDD packages are two orders of magnitude faster than Bryant's original implementation. A large source the improvement comes from the use of the *strong canonical form*, wherein a global database of BDD nodes is maintained, and no new node is added without checking to see if a node with the same label and 0- and 1-children exists in the database [3]. (For this approach to work, it is also required that the children of any node being added be in strong canonical form.) Other improvements stem from the use of complement pointers (if a pointer has its least-significant bit set, it refers to the complement of the function), better memory management (garbage collection based on reference counts, keeping nodes that are commonly accessed together close in memory), better hash functions, and better organization of the computed table (which keeps track of subproblems that have already been encountered) [16].

Data Sets

The SIS (http://embedded.eecs.berkeley.edu/pubs/downloads/sis/) system from UC Berkeley is used for logic synthesis. It comes with a number of combinational and sequential circuits that have been used for benchmarking BDD packages.

The VIS (http://embedded.eecs.berkeley.edu/pubs/downloads/vis) system from UC Berkeley and UC Boulder is used for design verification; it uses BDDs to perform checks. The distribution includes a large collection of verification problems, ranging from simple hardware circuits to complex multiprocessor cache systems.

URL to Code

A number of BDD packages exist today, but the package of choice is CUDD (http://vlsi.colorado.edu/~fabio/CUDD/). CUDD implements all the core features for manipulating BDDs, as well as variants. It is written in C++ and has extensive user and programmer documentation.

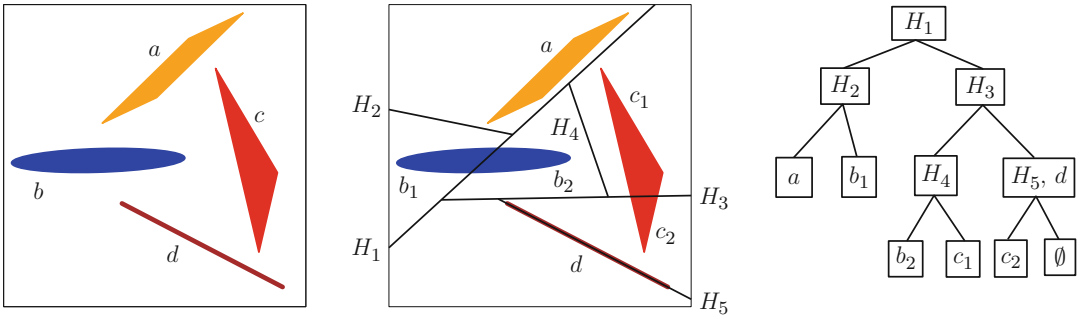
Problem Definition

The *binary space partition* (for short, *BSP*) is a scheme for subdividing the ambient space $\mathbb{R}^d$



Binary Space Partitions, Fig. 1 Three 2-dimensional convex objects and a line segment (*left*), a binary space partition with five partition lines $H_1, \ldots, H_5$ (*center*), and the corresponding BSP tree (*right*)

into open convex sets (called *cells*) by hyperplanes in a recursive fashion. Each subdivision step for a cell results in two cells, in which the process may continue, independently of other cells, until a stopping criterion is met. The binary recursion tree, also called *BSP-tree*, is traditionally used as a data structure in computer graphics for efficient rendering of polyhedral scenes. Each node v of the BSP-tree, except for the leaves, corresponds to a cell $C_v \subseteq \mathbb{R}^d$ and a partitioning hyperplane H_v. The cell of the root r is $C_r = \mathbb{R}^d$, and the two children of a node v correspond to $C_v \cap H_v^-$ and $C_v \cap H_v^+$, where H_v^- and H_v^+ denote the open half-spaces bounded by H_v. Refer to Fig. 1.

A binary space partition *for* a set of n pairwise disjoint (typically polyhedral) objects in $\mathbb{R}^d$ is a BSP where the space is recursively partitioned until each cell intersects at most one object. When the BSP-tree is used as a data structure, every leaf v stores the fragment of at most one object clipped in the cell C_v, and every interior node v stores the fragments of any lower-dimensional objects that lie in $C_v \cap H_v$.

A BSP for a set of objects has two parameters of interest: the *size* and the *height* of the corresponding BSP-tree. Ideally, a BSP partitions space so that each object lies entirely in a single cell or in a cutting hyperplane, yielding a so-called *perfect* BSP [4]. However, in most cases this is impossible, and the hyperplanes H_v partition some of the input objects into *fragments*. Assuming that the input objects are k-dimensional, for some $k \leq d$, the BSP typically stores only k-dimensional fragments, i.e., object parts clipped in leaf cells C_v or in $C_v \cap H_v$ at interior nodes.

The size of the BSP-tree is typically proportional to the number of k-dimensional fragments that the input objects are partitioned into, or the number of nodes in the tree. Given a set S of objects in $\mathbb{R}^d$, one would like to find a BSP for S with small size and/or height. The *partition complexity* of a set of objects S is defined as the minimum size of a BSP for S.

Glossary

- **Autopartition**: a class of BSPs obtained by imposing the constraint that each cut is along a hyperplane containing a facet of one of the input objects.
- **Axis-aligned BSP**: a class of BSPs obtained by imposing the constraint that each cut is orthogonal to a coordinate axis.
- **Round-robin BSP:** An axis-aligned BSP in $\mathbb{R}^d$ where any d consecutive recursive cuts are along hyperplanes orthogonal to the d coordinate axes.
- **Tiling** in $\mathbb{R}^d$: a set of interior-disjoint polyhedra that partition $\mathbb{R}^d$.
- **Axis-aligned tiling**: a set of full-dimensional boxes that partition $\mathbb{R}^d$.
- **d-dimensional box**: the cross product of d real-valued intervals.

Key Results

The theoretical study of BSPs was initiated by Paterson and Yao [10, 11].

Line Segments in the Plane

A classical result of Paterson and Yao [10] is a simple and elegant randomized algorithm, which, given n disjoint segments, produces a BSP whose expected size is $O(n \log n)$; see also [3, Ch. 12]. It was widely believed for decades that every set of n disjoint line segments in the plane admits a BSP of size $O(n)$; see e.g., [10, p. 502]; this was until Tóth proved a tight super-linear bound for this problem, first by constructing a set of segments for which any BSP must have size $\Omega(n \log n / \log \log n)$ and later by matching this bound algorithmically:

Theorem 1 ([12, 15]) *Every set of n disjoint line segments in the plane admits a BSP of size $O(n \log n / \log \log n)$. This bound is the best possible, and a BSP of this size can be computed in $O(n \log^2 n)$ time.*

Simplices in $\mathbb{R}^d$

The randomized partition technique of Paterson and Yao generalizes to higher dimensions yielding the following.

Theorem 2 ([10]) *Every set of n $(d-1)$-dimensional simplices in $\mathbb{R}^d$, where $d \geq 3$ admits a BSP of size $O(n^{d-1})$.*

While there exist n disjoint triangles in $\mathbb{R}^3$ that require a BSP of size $\Omega(n^2)$, no super-quadratic lower bound is known in any dimension d. Near-linear upper bounds are known for "realistic" input models in $\mathbb{R}^3$ such as uncluttered scenes [5] or fat axis-aligned rectangles [14].

Axis-Parallel Segments, Rectangles, and Hyperrectangles

Theorem 3 ([1, 7, 10]) *Every set of n pairwise disjoint axis-parallel line segments in the plane admits an auto-partition of size at most $2n-1$. Such a BSP can be computed using $O(n \log n)$ time and space and has the additional property that no input segment is cut more than once. The upper bound on the size is the best possible apart from lower-order terms.*

Theorem 4 ([7, 11]) *Let Γ be a collection of n line segments in $\mathbb{R}^d$, where $d \geq 3$, consisting of n_i segments parallel to the x_i-axis, for $i = 1, \ldots, d$. Then Γ admits a BSP of size at most*

$$4^{1/(d-1)}(d-1)(n_1 n_2 \ldots n_d)^{1/(d-1)} + 2n.$$

Theorem 5 ([7]) *For constants $1 \leq k \leq d-1$, every set of n axis-parallel k-rectangles in d-space admits an axis-aligned BSP of size $O(n^{d/(d-k)})$. This bound is the best possible for $k < d/2$ apart from the constant factor.*

For $k \geq d/2$, the best known upper and lower bounds do not match. No super-quadratic lower bound is known in any dimension d. In $\mathbb{R}^4$, Dumitrescu et al. [7] constructed n 2-dimensional disjoint rectangles whose partition complexity is $\Omega(n^{5/3})$.

Tilings

Already in the plane, the worst-case partition complexity of axis-aligned tilings is smaller than that for disjoint boxes. Berman, DasGupta, and Muthukrishnan [6] showed that every axis-aligned tiling of size n admits an axis-aligned BSP of size at most $2n$; apart from lower-order terms, this bound is the best possible. For higher dimensions, Hershberger, Suri, and Tóth obtained the following result.

Theorem 6 ([9]) *Every axis-aligned tiling of size n in $\mathbb{R}^d$, where $d \geq 2$, admits a round-robin BSP of size $O(n^{(d+1)/3})$. On the other hand, there exist tilings of size n in $\mathbb{R}^d$ for which every BSP has size $\Omega(n^{\beta(d)})$, where $\beta(3) = 4/3$, and $\lim_{d\to\infty} \beta(d) = (1+\sqrt{5})/2 \approx 1.618$.*

In dimensions $d = 3$, the partition complexity of axis-aligned tilings of size n is $O(n^{4/3})$, which is tight by a construction of Hershberger and Suri [8].

Applications

The initial and most prominent applications are in computer graphics: BSPs support fast *hidden-surface removal* and *ray tracing* for moving viewpoints [10]. Rendering is used for visualizing spatial opaque surfaces on the screen. A common and efficient rendering technique is the so-called *painter's algorithm*. Every object is drawn sequentially according to the *back-to-front* order, starting with the deepest object and continuing with the objects closer to the viewpoint. When

all the objects have been drawn, every pixel represents the color of the object closest to the viewpoint. Further computer graphics applications include *constructive solid geometry* and *shadow generation*. Other applications of BSP trees include *range counting*, *point location*, *collision detection*, *robotics*, *graph drawing*, and *network design*; see, for instance, [13] and the references therein.

In the original setting, the input objects of the BSP were assumed to be static. Recent research on BSPs for moving objects can be seen in the context of *kinetic data structures* (KDS) of Basch, Guibas, and Hershberger [2]. In this model, objects move continuously along a given trajectory (flight plan), typically along a line or a low-degree algebraic curve. The splitting hyperplanes are defined by faces of the input objects, and so they move continuously, too. The BSP is updated only at discrete *events*, though, when the combinatorial structure of the BSP changes.

Open Problems

- What is the maximum partition complexity of n disjoint $(d-1)$-dimensional simplices in $\mathbb{R}^d$ for $d \geq 3$?
- What is the maximum partition complexity of n disjoint (axis-aligned) boxes in $\mathbb{R}^d$ for $d \geq 3$?
- What is the maximum (axis-aligned) partition complexity of a tiling of n axis-aligned boxes in $\mathbb{R}^d$ for $d \geq 4$?
- Are there families of n disjoint objects in $\mathbb{R}^d$ whose partition complexity is super-quadratic in n?
- How many combinatorial changes can occur in the kinetic BSP of n points moving with constant velocities in the plane?

In all five open problems, the dimension $d \in \mathbb{N}$ of the ambient space $\mathbb{R}^d$ is constant, and asymptotically tight bounds in terms of n are sought.

2013; Yan, Chu

Problem Definition

Floorplanning is an early stage of the very-large-scale integration (VLSI) design process in which a coarse layout of a set of rectangular circuit blocks is determined. A floorplan enables designers to quickly estimate circuit performance, routing congestion, etc., of the circuit. In modern VLSI design flow, a fixed outline of the floorplanning region is given. On the other hand, many circuit blocks do not have a fixed shape during floorplanning as their internal circuitries have not yet been laid out. Those blocks are called soft blocks. Others blocks with predetermined shapes are called hard blocks. Given the geometric (i.e., left-right and above-below) relationship among the blocks, the block shaping problem is to determine the shapes of the soft blocks such that all blocks can be packed without overlap into the fixed-outline region.

To handle the block shaping problem in fixed-outline floorplanning, Yan and Chu [1,2] provide a problem formulation in which the floorplan height is minimized, while the width is upper bounded. The formulation is described below. Let W be the upper bound on the width of the floorplanning region. Given a set of n blocks, each block i has area A_i, width w_i, and height h_i. A_i is fixed, while w_i and h_i may vary as long as they satisfy $w_i \times h_i = A_i$, $W_i^{\min} \le w_i \le W_i^{\max}$, and $H_i^{\min} \le h_i \le H_i^{\max}$. If $W_i^{\min} = W_i^{\max}$ and $H_i^{\min} = H_i^{\max}$, then block i is a hard block. Two constraint graphs G_H and G_V [3, Chapter 10] are given to specify the geometric relationship among the blocks. G_H and G_V consist of $n+2$ vertices. Vertices 1 to n represent the n blocks. In addition, dummy vertices 0 (called source) and $n+1$ (called sink) are added. In G_H, vertices 0 and $n+1$ represent the leftmost and rightmost boundaries of the floorplanning region, respectively. In G_V, vertices 0 and $n+1$ represent the bottommost and topmost boundaries of the floorplanning region, respectively. A_0, w_0, h_0, A_{n+1}, w_{n+1}, and h_{n+1} are all set to 0. If block i is on the left of block j, $(i,j) \in G_H$. If block i is below block j, $(i,j) \in G_V$.

Let x_i and y_i be the x- and y-coordinates of the bottom-left corner of block i in the floorplan. Then, the block shaping problem formulation in [1,2] can be written as the following geometric program:

$$
\begin{aligned}
\text{Minimize } & y_{n+1} \\
\text{subject to } & x_{n+1} \le W \\
& x_i + w_i \le w_j && \forall (i,j) \in G_H \\
& y_i + h_i \le y_j && \forall (i,j) \in G_V \\
& w_i \times h_i = A_i && 1 \le i \le n \\
& W_i^{\min} \le w_i \le W_i^{\max} && 1 \le i \le n \\
& H_i^{\min} \le h_i \le H_i^{\max} && 1 \le i \le n \\
& x_0 = y_0 = 0
\end{aligned}
$$

To solve the original problem of packing all blocks into a fixed-outline region, we can take any feasible solution of the geometric program in which y_{n+1} is less than or equal to the height of the region.

Key Results

Almost all previous works target the classical floorplanning formulation, which minimizes the floorplan area. Such a formulation is not compatible with modern design methodologies [4], but those works may be modified to help fixed-outline floorplanning to various extents. For the special case of slicing floorplan [5], the block shaping problem can be solved by the elegant shape curve idea [6]. For a general floorplan which may not have a slicing structure, various heuristics have been proposed [7–9]. Moh et al. [10] formulated the shaping problem as a geometric program and optimally solved it using standard convex optimization. Young et al. [11] solved the geometric program formulation by Lagrangian relaxation. Lin et al. [12] minimized the floorplan area indirectly by minimizing its perimeter optimally using min-cost flow and trust region method. For previous works which directly tackled the block shaping problem in

fixed-outline floorplanning, Adya and Markov [13] proposed a simple greedy heuristic, and Lin and Hung [14] used second-order cone programming. Previous works are either non-optimal or time-consuming.

Yan and Chu [1, 2] presented a simple and optimal algorithm called slack-driven shaping (SDS). SDS iteratively shapes the soft blocks to reduce the floorplan height while not exceeding the floorplan width bound. We first present a simplified version called basic slack-driven shaping (basic SDS), which almost always produces an optimal solution. Then, we present its extension to the SDS algorithm.

Given some initial block shapes, the blocks can be packed to the four boundaries of the floorplanning region. For block i ($1 \le i \le n$), let Δ_{x_i} be the difference in x_i between the two layouts generated by packing all blocks to $x = W$ and to $x = 0$, respectively. Similarly, let Δ_{y_i} be the difference in y_i between the two layouts generated by packing all blocks to $y = y_{n+1}$ and to $y = 0$, respectively. The horizontal slack s_i^H and vertical slack s_i^V are defined as follows:

$$s_i^H = \max(0, \Delta_{x_i}),\ s_i^V = \max(0, \Delta_{y_i}).$$

Horizontal critical path (HCP) is defined as a path in G_H from source to sink such that all blocks along the path have zero horizontal slack. Vertical critical path (VCP) is similarly defined. We also define two subsets of blocks:

$$\begin{aligned} \text{SH} &= \{i \text{ is soft}\} \cap \{s_i^H > 0, s_i^V = 0\} \\ &\quad \cap \{w_i < W_i^{\max}\} \\ \text{SV} &= \{i \text{ is soft}\} \cap \{s_i^H = 0, s_i^V > 0\} \\ &\quad \cap \{h_i < H_i^{\max}\} \end{aligned}$$

Note that y_{n+1} can be reduced by decreasing the height (i.e., increasing the width) of the blocks in SH, and x_{n+1} can be reduced by decreasing the width (i.e., increasing the height) of the blocks in SV. We call the blocks in the sets SH and SV target soft blocks. In each iteration of basic SDS, we would like to increase the width w_i of each block $i \in$ SH by δ_i^H and the height h_i of each block $i \in$ SV by δ_i^V. The basic SDS algorithm is shown below:

Basic Slack-Driven Shaping Algorithm
Input: A set of n blocks, upper-bound width W, G_H and G_V.
Output: Optimized y_{n+1}, w_i and h_i for all i.
Begin
1. Set w_i to $W_i^{\min}$ for all i.
2. Pack blocks to $x = 0$ and compute x_{n+1}.
3. If $x_{n+1} > W$,
4. Return no feasible solution.
5. Else,
6. Repeat
7. Pack blocks to $y = 0$, $y = y_{n+1}$, $x = 0$, and $x = W$.
8. Calculate s_i^H and s_i^V for all i.
9. Identify target soft blocks in SH and SV.
10. $\forall i \in$ SH, increase w_i by $\delta_i^H = \dfrac{(W_i^{\max} - w_i)}{\text{MAX}_{p \in P_i^H}\left(\sum_{k \in p}(W_k^{\max} - w_k)\right)} s_i^H$,
where P_i^H is the set of paths in G_H passing through block i.
11. $\forall i \in$ SV, increase h_i by $\delta_i^V = \beta \times \dfrac{(H_i^{\max} - h_i)}{\text{MAX}_{p \in P_i^V}\left(\sum_{k \in p}(H_k^{\max} - h_k)\right)} s_i^V$,
where P_i^V is the set of paths in G_V passing through block i.
12. Until there is no target soft block.
End

Note that all δ_i^H and δ_i^V in Lines 10 and 11 can be computed using dynamic programming in linear time. Packing of blocks can also be done in linear time by longest path algorithm on a directed acyclic graph. Hence, each iteration of basic SDS takes linear time. The way δ_i^H and δ_i^V are set in Lines 10 and 11 is the key to the convergence of the algorithm.

Lemma 1 *For any path p from source to sink in G_H, we have $\sum_{i \in p} \delta_i^H \leq s^p_{\max\_H}$, where $s^p_{\max\_H}$ is the maximum horizontal slack over all blocks along p.*

Basically, $s^p_{\max\_H}$ gives us a budget on the total amount of increase in the block width along path p. Hence, Lemma 1 implies that the width of the floorplan will not be more than W after shaping of the blocks in SH at Line 10. The shaping of blocks in SV is done similarly, but a factor β is introduced in Line 11.

Lemma 2 *For any path p from source to sink in G_V, we have $\sum_{i \in p} \delta_i^V \leq \beta \times s^p_{\max\_V}$, where $s^p_{\max\_V}$ is the maximum vertical slack over all blocks along p.*

Lemma 2 guarantees that by setting $\beta \leq 1$, y_{n+1} will not increase after each iteration. In other words, the height of the floorplan will monotonically decrease during the whole shaping process. β is almost always set to 1. However, if $\beta = 1$, it is possible that the floorplan height may remain the same after one iteration even when the solution is not yet optimal. To avoid getting stuck at a local minimum, if the floorplan height does not decrease for two consecutive iterations, β is set to 0.9 for the next iteration.

Consider a shaping solution L generated by basic SDS (i.e., without any target soft block). Blocks at the intersection of some HCP and some VCP are called intersection blocks. The following optimality conditions were derived in [1, 2].

Lemma 3 *If L contains one VCP in which all intersection blocks are hard, then L is optimal.*

Lemma 4 *If L contains at most one HCP in which some intersection blocks are soft, then L is optimal.*

Lemma 5 *If L contains at most one VCP in which some intersection blocks are soft, then L is optimal.*

In practice, it is very rare for a shaping solution generated by basic SDS to satisfy none of the three optimality conditions. According to the experiments in [1, 2], all solutions by basic SDS satisfy at least one of the optimality conditions, i.e., are optimal. However, [1, 2] showed that it is possible for basic SDS to converge to non-optimal solutions. If a non-optimal solution is produced by basic SDS, it can be used as a starting solution to the geometric program above and then be improved by a single step of any descent-based optimization technique (e.g., deepest descent). This perturbed and improved solution can be fed to basic SDS again to be further improved. The resulting SDS algorithm, which is guaranteed optimal, is shown below:

Slack-Driven Shaping Algorithm
Input: A set of n blocks, upper-bound width W, G_H and G_V.
Output: Optimal y_{n+1}, w_i and h_i for all i.
Begin
1. Run basic SDS to generate shaping solution L.
2. If Lemma 3 or Lemma 4 or Lemma 5 is satisfied,
3. L is optimal. Exit.
4. Else,
5. Improve L by a single step of geometric programming.
6. Go to Line 1.
End

Applications

Floorplanning is a very important step in modern VLSI design. It enables designers to explore different alternatives in the design space and make critical decisions early in the design process. Typically, a huge number of alternatives need to be evaluated during the floorplanning stage. Hence, an efficient block shaping algorithm is a crucial component of a floorplanning tool. SDS is tens to hundreds of times faster than previous algorithms in practice. It also directly handles a fixed-outline floorplanning formulation, which is the standard in modern design methodologies. Hence, SDS should be able to improve the quality while also reduce the design time of VLSI circuits.

Open Problems

An interesting open problem is to derive a theoretical bound on the number of iterations for SDS to converge to an optimal solution. Although experimental results have shown that the number of iterations is small in practice, no theoretical bound is known.

Another interesting problem is to design an algorithm to achieve optimal block shaping entirely by simple slack-driven operations without resorting to geometric programming.

Besides, because of the similarity of the concept of slack in floorplanning and in circuit timing analysis, it would be interesting to see if a slack-driven approach similar to that in SDS can be applied to buffer and wire sizing for timing optimization.

Keywords

Context-aware compression; High-order compression models

Years and Authors of Summarized Original Work

2005; Ferragina, Giancarlo, Manzini, Sciortino

Problem Definition

Informally, a boosting technique is a method that, when applied to a particular class of algorithms, yields improved algorithms. The improvement must be provable and well defined in terms of one or more of the parameters characterizing the algorithmic performance. Examples of boosters can be found in the context of randomized algorithms (here, a booster allows one to turn a *BPP* algorithm into an *RP* one [6]) and computational learning theory (here, a booster allows one to improve the prediction accuracy of a weak learning algorithm [10]). The problem of compression boosting consists of designing a technique that improves the compression performance of a wide class of algorithms. In particular, the results of Ferragina et al. provide a general technique for turning a compressor that uses no context information into one that always uses the best possible context.

The classic Huffman and arithmetic coding algorithms [1] are examples of *statistical* compressors which typically encode an input symbol according to its *overall* frequency in the data to be compressed. (In their dynamic versions these algorithms consider the frequency of a symbol in the already scanned portion of the input.) This approach is efficient and easy to implement but achieves poor compression. The compression performance of statistical compressors can be improved by adopting *higher*-order models that obtain better estimates for the frequencies of the input symbols. The PPM compressor [9] implements this idea by collecting (the frequency of) all symbols which follow *any* k-long context and by compressing them via arithmetic coding. The length k of the context is a parameter of the algorithm that depends on the data to be compressed: it is different if one is compressing English text, a DNA sequence, or an XML document. There exist other examples of sophisticated compressors that use context information in an *implicit* way, such as Lempel-Ziv and Burrows-Wheeler compressors [9]. All these context-aware algorithms are effective in terms of compression performance, but are usually rather complex to implement and difficult to analyze.

Applying the boosting technique of Ferragina et al. to Huffman or arithmetic coding yields a new compression algorithm with the following features: (i) the new algorithm uses the boosted compressor as a black box; (ii) the new algorithm compresses in a PPM-like style, automatically choosing the *optimal* value of k; and (iii) the new algorithm has essentially the same time/space asymptotic performance of the boosted compressor. The following sections give a precise and formal treatment of the three properties (i)–(iii) outlined above.

Key Results

Notation: The Empirical Entropy

Let s be a string over the alphabet $\Sigma = \{a_1, \ldots, a_h\}$, and for each $a_i \in \Sigma$, let n_i be the number of occurrences of a_i in s. The *0th order empirical entropy* of the string s is defined as $H_0(s) = -\sum_{i=1}^{h} (n_i/|s|) \log(n_i/|s|)$, where it is assumed that all logarithms are taken to the

base 2 and $0\log 0 = 0$. It is well known that H_0 is the maximum compression one can achieve using a uniquely decodable code in which a fixed codeword is assigned to each alphabet symbol. Greater compression is achievable if the codeword of a symbol depends on the k symbols following it (namely, its *context*). (In data compression it is customary to define the context looking at the symbols *preceding* the one to be encoded. The present entry uses the nonstandard "forward" contexts to simplify the notation of the following sections. Note that working with "forward" contexts is equivalent to working with the traditional "backward" contexts on the string s reversed (see [3] for details).) Let us define w_s as the string of single symbols immediately preceding the occurrences of w in s. For example, for $s = \texttt{bcabcabdca}$, it is $\texttt{ca}_s = \texttt{bbd}$. The value

$$H_k(s) = \frac{1}{|s|} \sum_{w \in \Sigma^k} |w_s| H_0(w_s) \qquad (1)$$

is the k-th order empirical entropy of s and is a lower bound to the compression one can achieve using codewords which only depend on the k symbols immediately following the one to be encoded.

Example 1 Let $s = \texttt{mississippi}$. For $k = 1$, it is $\texttt{i}_s = \texttt{mssp}$, $\texttt{s}_s = \texttt{isis}$, $\texttt{p}_s = \texttt{ip}$. Hence,

$$\begin{aligned} H_1(s) &= \frac{4}{11} H_0(\texttt{mssp}) + \frac{4}{11} H_0(\texttt{isis}) \\ &\quad + \frac{2}{11} H_0(\texttt{ip}) \\ &= \frac{6}{11} + \frac{4}{11} + \frac{2}{11} = \frac{12}{11}. \end{aligned}$$

Note that the empirical entropy is defined for any string and can be used to measure the performance of compression algorithms without any assumption on the input source. Unfortunately, for some (highly compressible) strings, the empirical entropy provides a lower bound that is too conservative. For example, for $s = \texttt{a}^n$, it is $|s| H_k(s) = 0$ for any $k \geq 0$. To better deal with highly compressible strings, [7] introduced the notion of *0th order modified empirical* entropy ${H_0}^*(s)$ whose property is that $|s| {H_0}^*(s)$ is at least equal to the number of bits needed to write down the length of s in binary. The *kth order modified empirical entropy* ${H_k}^*$ is then defined in terms of ${H_0}^*$ as the maximum compression one can achieve by looking at *no more than k* symbols following the one to be encoded.

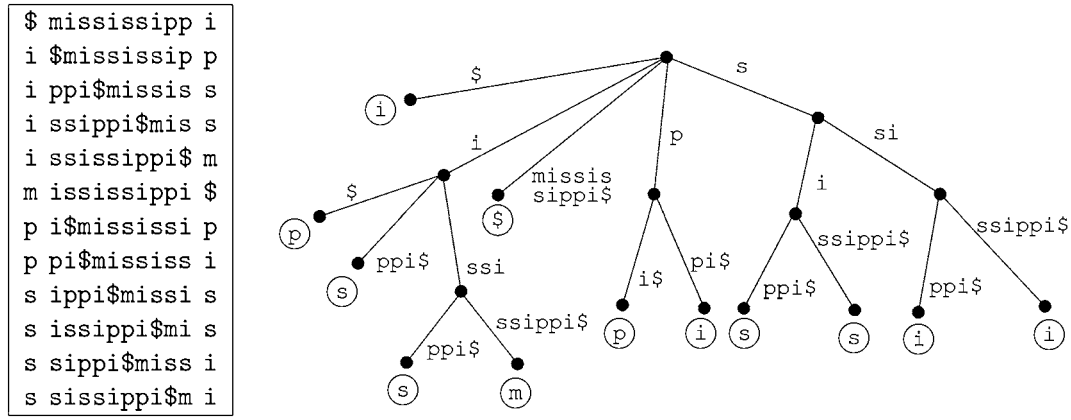
The Burrows-Wheeler Transform

Given a string s, the Burrows-Wheeler transform [2] (*bwt*) consists of three basic steps: (1) append to the end of s a special symbol \$ smaller than any other symbol in Σ; (2) form a *conceptual* matrix $\mathcal{M}$ whose rows are the cyclic shifts of the string $s\$$, sorted in lexicographic order; and (3) construct the transformed text $\hat{s} = \texttt{bwt}(s)$ by taking the last column of $\mathcal{M}$ (see Fig. 1). In [2] Burrows and Wheeler proved that $\hat{s}$ is a permutation of s, and that from $\hat{s}$ it is possible to recover s in $O(|s|)$ time.

To see the power of the *bwt*, the reader should reason in terms of empirical entropy. Fix a positive integer k. The first k columns of the *bwt* matrix contain, lexicographically ordered, all length-k substrings of s (and k substrings containing the symbol \$). For any length-k substring w of s, the symbols immediately preceding every occurrence of w in s are grouped together in a set of consecutive positions of $\hat{s}$ since they are the last symbols of the rows of $\mathcal{M}$ prefixed by w. Using the notation introduced for defining H_k, it is possible to rephrase this property by saying that the symbols of w_s are consecutive within $\hat{s}$ or, equivalently, that $\hat{s}$ contains, as a substring, a permutation $\pi_w(w_s)$ of the string w_s.

Example 2 Let $s = \texttt{mississippi}$ and $k = 1$. Figure 1 shows that $\hat{s}[1,4] = \texttt{pssm}$ is a permutation of $\texttt{i}_s = \texttt{mssp}$. In addition, $\hat{s}[6,7] = \texttt{pi}$ is a permutation of $\texttt{p}_s = \texttt{ip}$, and $\hat{s}[8,11] = \texttt{ssii}$ is a permutation of $\texttt{s}_s = \texttt{isis}$.

Since permuting a string does not change its (modified) 0th order empirical entropy (that is, $H_0(\pi_w(w_s)) = H_0(w_s)$), the Burrows-Wheeler transform can be seen as a tool for reducing the



Boosting Textual Compression, Fig. 1 The *bwt* matrix (*left*) and the suffix tree (*right*) for the string $s =$ `mississippi$`. The output of the *bwt* is the last column of the *bwt* matrix, i.e., $\hat{s} = \texttt{bwt}(s) =$ `ipssm$pissii`

problem of compressing s up to its kth order entropy to the problem of compressing *distinct portions* of $\hat{s}$ up to their 0*th order* entropy. To see this, assume partitioning of $\hat{s}$ into the substrings $\pi_w(w_s)$ by varying w over Σ^k. It follows that $\hat{s} = \bigsqcup_{w \in \Sigma^k} \pi_w(w_s)$ where $\bigsqcup$ denotes the concatenation operator among strings. (In addition to $\bigsqcup_{w \in \Sigma^k} \pi_w(w_s)$, the string $\hat{s}$ also contains the last k symbols of s (which do not belong to any w_s) and the special symbol \$. For simplicity these symbols will be ignored in the following part of the entry.) By (1) it follows that

$$\sum_{w \in \Sigma^k} |\pi_w(w_s)| H_0(\pi_w(w_s)) = \sum_{w \in \Sigma^k} |w_s| \, H_0(w_s) = |s| \, H_k(s).$$

Hence, to compress s up to $|s| \, H_k(s)$, it suffices to compress each substring $\pi_w(w_s)$ up to its 0th order empirical entropy. Note, however, that in the above scheme the parameter k must be chosen in advance. Moreover, a similar scheme cannot be applied to ${H_k}^*$ which is defined in terms of contexts of length *at most* k. As a result, no efficient procedure is known for computing the partition of $\hat{s}$ corresponding to ${H_k}^*(s)$. The compression booster [3] is a natural complement to the *bwt* and allows one to compress any string s up to $H_k(s)$ (or ${H_k}^*(s)$) simultaneously for all $k \geq 0$.

The Compression Boosting Algorithm

A crucial ingredient of compression boosting is the relationship between the *bwt* matrix and the suffix tree data structure. Let $\mathcal{T}$ denote the suffix tree of the string $s\$$. $\mathcal{T}$ has $|s| + 1$ leaves, one per suffix of $s\$$, and edges labeled with substrings of $s\$$ (see Fig. 1). Any node u of $\mathcal{T}$ has *implicitly associated* a substring of $s\$$, given by the concatenation of the edge labels on the downward path from the root of $\mathcal{T}$ to u. In that implicit association, the leaves of $\mathcal{T}$ correspond to the suffixes of $s\$$. Assume that the suffix tree edges are sorted lexicographically. Since each row of the *bwt* matrix is prefixed by one suffix of $s\$$ and rows are lexicographically sorted, the ith leaf (counting from the left) of the suffix tree corresponds to the ith row of the *bwt* matrix. Associate to the ith leaf of $\mathcal{T}$ the ith symbol of $\hat{s} = \texttt{bwt}(s)$. In Fig. 1 these symbols are represented inside circles.

For any suffix tree node u, let $\hat{s}\langle u \rangle$ denote the substring of $\hat{s}$ obtained by concatenating, from left to right, the symbols associated to the leaves descending from node u. Of course $\hat{s}\langle root(\mathcal{T}) \rangle = \hat{s}$. A subset $\mathcal{L}$ of $\mathcal{T}$'s nodes is called a *leaf cover* if every leaf of the suffix tree has a *unique* ancestor in $\mathcal{T}$. Any leaf cover $\mathcal{L} = \{u_1, \ldots, u_p\}$ naturally induces a partition of the leaves of $\mathcal{T}$.

Because of the relationship between $\mathcal{T}$ and the *bwt* matrix, this is also a partition of $\hat{s}$, namely, $\{\hat{s}\langle u_1\rangle, \ldots, \hat{s}\langle u_p\rangle\}$.

Example 3 Consider the suffix tree in Fig. 1. A leaf cover consists of all nodes of depth one. The partition of $\hat{s}$ induced by this leaf cover is {i,pssm,$,pi,ssii}.

Let C denote a function that associates to every string x over $\Sigma \cup \{\$\}$ a positive real value $C(x)$. For any leaf cover $\mathcal{L}$, define its cost as $C(\mathcal{L}) = \sum_{u \in \mathcal{L}} C(\hat{s}\langle u\rangle)$. In other words, the cost of the leaf cover $\mathcal{L}$ is equal to the sum of the costs of the strings in the partition induced by $\mathcal{L}$. A leaf cover $\mathcal{L}_{\min}$ is called *optimal* with respect to C if $C(\mathcal{L}_{\min}) \leq C(\mathcal{L})$, for any leaf cover $\mathcal{L}$.

Let A be a compressor such that, for any string x, its output size is bounded by $|x|H_0(x)+\eta|x|+\mu$ bits, where η and μ are constants. Define the cost function $C_{\mathtt{A}}(x) = |x|H_0(x) + \eta|x| + \mu$. In [3] Ferragina et al. exhibit a linear-time greedy algorithm that computes the optimal leaf cover $\mathcal{L}_{\min}$ with respect to $C_{\mathtt{A}}$. The authors of [3] also show that, for any $k \geq 0$, there exists a leaf cover $\mathcal{L}_k$ of cost $C_{\mathtt{A}}(\mathcal{L}_k) = |s|\, H_k(s)+\eta|s|+O(|\Sigma|^k)$. These two crucial observations show that, if one uses A to compress each substring in the partition induced by the optimal leaf cover $\mathcal{L}_{\min}$, the total output size is bounded in terms of $|s|\, H_k(s)$, for any $k \geq 0$. In fact,

$$\sum_{u \in \mathcal{L}_{\min}} C_{\mathtt{A}}(\hat{s}\langle u\rangle) = C_{\mathtt{A}}(\mathcal{L}_{\min}) \leq C_{\mathtt{A}}(\mathcal{L}_k) = |s|\, H_k(s) + \eta|s| + O(|\Sigma|^k)$$

In summary, boosting the compressor A over the string s consists of three main steps:

1. Compute $\hat{s} = \mathtt{bwt}(s)$.
2. Compute the optimal leaf cover $\mathcal{L}_{\min}$ with respect to $C_{\mathtt{A}}$ and partition $\hat{s}$ according to $\mathcal{L}_{\min}$.
3. Compress each substring of the partition using the algorithm A.

So the boosting paradigm reduces the design of effective compressors that use context information, to the (usually easier) design of 0th order compressors. The performance of this paradigm is summarized by the following theorem.

Theorem 1 ([3]) *Let A be a compressor that squeezes any string x in at most $|x|\, H_0(x) + \eta|x| + \mu$ bits. The compression booster applied to A produces an output whose size is bounded by $|s|\, H_k(s) + \log|s| + \eta|s| + O(|\Sigma|^k)$ bits simultaneously for all $k \geq 0$. With respect to A, the booster introduces a space overhead of $O(|s| \log |s|)$ bits and no asymptotic time overhead in the compression process.* □

A similar result holds for the modified entropy $H_k{}^*$ as well (but it is much harder to prove): given a compressor A that squeezes any string x in at most $\lambda|x|\, H_0^*(x) + \mu$ bits, the compression booster produces an output whose size is bounded by $\lambda|s|\, H_k^*(s) + \log|s| + O(|\Sigma|^k)$ bits, simultaneously for all $k \geq 0$. In [3] the authors also show that no compression algorithm, satisfying some mild assumptions on its inner working, can achieve a similar bound in which both the multiplicative factor λ and the additive logarithmic term are dropped simultaneously. Furthermore [3] proposes an instantiation of the booster which compresses any string s in at most 2.5 $|s|H_k{}^*(s) + \log|s| + O(|\Sigma|^k)$ bits. This bound is analytically superior to the bounds proven for the best existing compressors including Lempel-Ziv, Burrows-Wheeler, and PPM compressors.

Applications

Apart from the natural application in data compression, compressor boosting has been used also to design compressed full-text indexes [8].

Open Problems

The boosting paradigm may be generalized as follows: given a compressor A, find a permutation $\mathcal{P}$ for the symbols of the string s *and* a partitioning strategy such that the boosting approach, applied to them, minimizes the output size. These pages have provided convincing evidence that the Burrows-Wheeler transform is an

elegant and efficient permutation $\mathcal{P}$. Surprisingly enough, other classic data compression problems fall into this framework: shortest common superstring (which is MAX-SNP hard), run length encoding for a set of strings (which is polynomially solvable), *LZ77*, and minimum number of phrases (which is MAX-SNP hard). Therefore, the boosting approach is general enough to deserve further theoretical and practical attention [5].

Experimental Results

An investigation of several compression algorithms based on boosting and a comparison with other state-of-the-art compressors are presented in [4]. The experiments show that the boosting technique is more robust than other *bwt*-based approaches and works well even with less effective 0th order compressors. However, these positive features are achieved using more (time and space) resources.

Data Sets

The data sets used in [4] are available from http://people.unipmn.it/manzini/boosting. Other data sets for compression and indexing are available at the Pizza&Chili site http://pizzachili.di.unipi.it/.

URL to Code

The compression boosting page (http://people.unipmn.it/manzini/boosting) contains the source code of all the algorithms tested in [4]. The code is organized in a highly modular library that can be used to boost any compressor even without knowing the *bwt* or the boosting procedure.

Problem Definition

Branchwidth, along with its better-known counterpart, treewidth, are measures of the "global connectivity" of a graph.

Definition

Let G be a graph on n vertices. A *branch decomposition* of G is a pair (T, τ), where T is a tree with vertices of degree 1 or 3 and τ is a bijection from the set of leaves of T to the edges of G. The *order*, we denote it as $\alpha(e)$, of an edge e in T is the number of vertices v of G such that there are leaves t_1, t_2 in T in different components of $T(V(T), E(T) - e)$ with $\tau(t_1)$ and $\tau(t_2)$ both containing v as an endpoint.

The *width* of (T, τ) is equal to $\max_{e \in E(T)} \{\alpha(e)\}$, i.e., is the maximum order over all edges of T. The *branchwidth* of G is the minimum width over all the branch decompositions of G (in the case where $|E(G)| \leq 1$, then we define the branchwidth to be 0; if $|E(G)| = 0$, then G has no branch decomposition; if $|E(G)| = 1$, then G has a branch decomposition consisting of a tree with one vertex – the width of this branch decomposition is considered to be 0).

The above definition can be directly extended to hypergraphs where τ is a bijection from the leaves of T to the hyperedges of G. The same definition can easily be extended to matroids.

Branchwidth was first defined by Robertson and Seymour in [25] and served as a main tool for their proof of Wagner's Conjecture in their Graph Minors series of papers. There, branchwidth was used as an alternative to the parameter of treewidth as it appeared easier to handle for the purposes of the proof. The relation between branchwidth and treewidth is given by the following result.

Theorem 1 ([25]) *If G is a graph, then* $\text{branchwidth}(G) \leq \text{treewidth}(G) + 1 \leq \lfloor 3/2\ \text{branchwidth}(G) \rfloor$.

The algorithmic problems related to branchwidth are of two kinds: first find fast algorithms computing its value and, second, use it in order to design fast dynamic programming algorithms for other problems.

Key Results

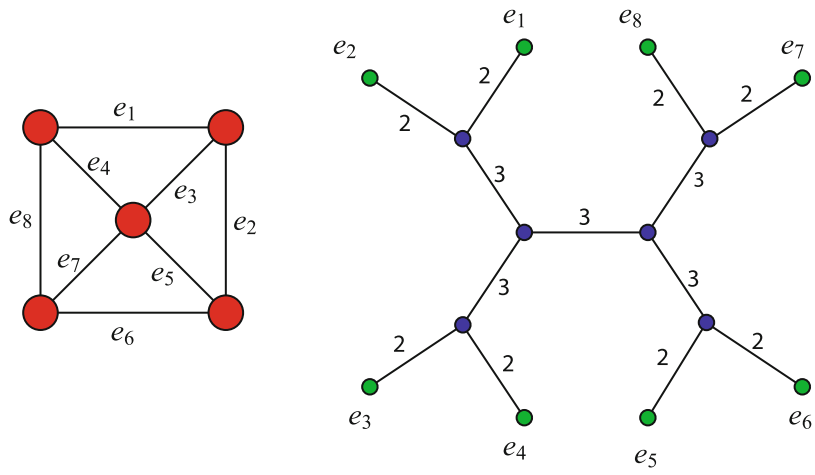
Algorithms for Branchwidth

Computing branchwidth is an NP-hard problem ([29]). Moreover, the problem remains NP-hard even if we restrict its input graphs to the class of split graphs or bipartite graphs [20].

On the positive side, branchwidth is computable in polynomial time on interval graphs [20, 24], and circular arc graphs [21]. Perhaps the most celebrated positive result on branchwidth is an $O(n^2)$ algorithm for the branchwidth of planar graphs, given by Seymour and Thomas in [29]. In the same paper they also give an $O(n^4)$ algorithm to compute an optimal branch decomposition. (The running time of this algorithm has been improved to $O(n^3)$ in [18].) The algorithm in [29] is basically an algorithm for a parameter called carving width, related to telephone routing and the result for branchwidth follows from the fact that the branch width of a planar graph is half of the carving-width of its medial graph.

The algorithm for planar graphs [29] can be used to construct an approximation algorithm for branchwidth of some non-planar graphs. On graph classes excluding a single crossing graph as a minor branchwidth can be approximated within a factor of 2.25 [7] (a graph H is a *minor* of a graph G if H can be obtained by a subgraph of G after applying edge contractions). Finally, it follows from [13] that for every minor closed graph class, branchwidth can be approximated by a constant factor.

Branchwidth cannot increase when applying edge contractions or removals. According to the Graph Minors theory, this implies that, for any fixed k, there is a finite number of minor minimal graphs of branchwidth more than k and we denote this set of graphs by $\mathcal{B}_k$. Checking whether a graph G contains a fixed graph as a minor can be done in polynomial time [27].



Branchwidth of Graphs, Fig. 1 Example of a graph and its branch decomposition of width 3

Therefore, the knowledge of $\mathcal{B}_k$ implies the construction of a polynomial time algorithm for deciding whether branchwidth$(G) \leq k$, for any fixed k. Unfortunately $\mathcal{B}_k$ is known only for small values of k. In particular, $\mathcal{B}_0 = \{P_2\}, B_1 = \{P_4, K_3\}, \mathcal{B}_2 = \{K_4\}$ and $\mathcal{B}_3 = \{K_5, V_8, M_6, Q_3\}$ (here K_r is a clique on r vertices, P_r is a path on r edges, V_8 is the graph obtained by a cycle on 8 vertices if we connect all pairs of vertices with cyclic distance 4, M_6 is the octahedron, and Q_3 is the 3-dimensional cube). However, for any fixed k, one can construct a linear, on $n = |V(G)|$, algorithm that decides whether an input graph G has branchwidth $\leq k$ and, if so, outputs the corresponding branch decomposition (see [3]). In technical terms, this implies that the problem of asking, for a given graph G, whether branchwidth$(G) \leq k$, parameterized by k is fixed parameter tractable (i.e., belongs in the parameterized complexity class FPT). (See [12] for further references on parameterized algorithms and complexity.) The algorithm in [3] is complicated and uses the technique of characteristic sequences, which was also used in order to prove the analogous result for treewidth. For the particular cases where $k \leq 3$, simpler algorithms exist that use the "reduction rule" technique (see [4]). We stress that $\mathcal{B}_4$ remains unknown while several elements of it have been detected so far (including the dodecahedron and the icosahedron graphs). There is a number of algorithms that for a given k in time $2^{O(k)} \cdot n^{O(1)}$ either decide that the branchwidth of a given graph is at least k, or construct a branch decomposition of width $O(k)$ (see [26]). These results can be generalized to compute the branchwidth of matroids and even more general parameters.

An exact algorithm for branchwidth appeared in [14]. Its complexity is $O((2 \cdot \sqrt{3})^n \cdot n^{O(1)})$. The algorithm exploits special properties of branchwidth (see also [24]).

In contrast to treewidth, edge maximal graphs of given branchwidth are not so easy to characterize (for treewidth there are just k-trees, i.e., chordal graphs with all maximal cliques of size $k + 1$). An algorithm for generating such graphs has been given in [23] and reveals several structural issues on this parameter.

It is known that a large number of graph theoretical problems can be solved in linear time when their inputs are restricted to graphs of small (i.e., fixed) treewidth or branchwidth (see [2]).

Branchwidth appeared to be a useful tool in the design of exact subexponential algorithms on planar graphs and their generalizations. The basic idea behind this approach is very simple: Let $\mathcal{P}$ be a problem on graphs and $\mathcal{G}$ be a class of graphs such that

- for every graph $G \in \mathcal{G}$ of branchwidth at most ℓ, the problem $\mathcal{P}$ can be solved in time $2^{c\cdot\ell} \cdot n^{\mathcal{O}(1)}$, where c is a constant, and;
- for every graph $G \in \mathcal{G}$ on n vertices a branch decomposition (not necessarily optimal) of G of width at most $h(n)$ can be constructed in polynomial time, where $h(n)$ is a function.

Then for every graph $G \in \mathcal{G}$, the problem $\mathcal{P}$ can be solved in time $2^{c\cdot h(n)} \cdot n^{\mathcal{O}(1)}$. Thus, everything boils down to computations of constants c and functions $h(n)$. These computations can be quite involved. For example, as was shown in [17], for every planar graph G on n vertices, the branchwidth of G is at most $\sqrt{4.5n} < 2.1214\sqrt{n}$. For extensions of this bound to graphs embeddable on a surface of genus g, see [15].

Dorn [9] used fast matrix multiplication in dynamic programming to estimate the constants c for a number of problems. For example, for the Maximum Independent Set problem, $c \leq \omega/2$, where $\omega < 2.376$ is the matrix product exponent over a ring, which implies that the Independent Set problem on planar graphs is solvable in time $O(2^{2.52\sqrt{n}})$. For the Minimum Dominating Set problem, $c \leq 4$, thus implying that the branch decomposition method runs in time $O(2^{3.99\sqrt{n}})$. It appears that algorithms of running time $2^{O(\sqrt{n})}$ can be designed even for some of the "non-local" problems, such as the Hamiltonian Cycle, Connected Dominating Set, and Steiner Tree, for which no time $2^{O(\ell)} \cdot n^{\mathcal{O}(1)}$ algorithm on general graphs of branchwidth ℓ is known [11]. Here one needs special properties of some optimal planar branch decompositions, roughly speaking that every edge of T corresponds to a disk on a plane such that all edges of G corresponding to one component of $T - e$ are inside the disk and all other edges are outside. Some of the subexponential algorithms on planar graphs can be generalized for graphs embedded on surfaces [10] and, more generally, to graph classes that are closed under taking of minors [8].

A similar approach can be used for parameterized problems on planar graphs. For example, a parameterized algorithm that finds a dominating set of size $\leq k$ (or reports that no such set exists) in time $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$ can be obtained based on the following observations: there is a constant c such that every planar graph of branchwidth at least $c\sqrt{k}$ does not contain a dominating set of size at most k. Then for a given k the algorithm computes an optimal branch decomposition of a palanar graph G and if its width is more than $c\sqrt{k}$ concludes that G has no dominating set of size k. Otherwise, find an optimal dominating set by performing dynamic programming in time $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$. There are several ways of bounding a parameter of a planar graph in terms of its branchwidth or treewidth including techniques similar to Baker's approach from approximation algorithms [1], the use of separators, or by some combinatorial arguments, as shown in [16]. Another general approach of bounding the branchwidth of a planar graph by parameters, is based on the results of Robertson et al. [28] regarding quickly excluding a planar graph. This brings us to the notion of *bidimensionality* [6]. Parameterized algorithms based on branch decompositions can be generalized from planar graphs to graphs embedded on surfaces and to graphs excluding a fixed graph as a minor.

Applications

See [5] for using branchwidth for solving TSP.

Open Problems

1. It is known that any planar graph G has branchwidth at most $\sqrt{4.5}\cdot\sqrt{|V(G)|}$ (or at most $\frac{3}{2}\cdot\sqrt{|E(G)|+2}$) [17]. Is it possible to improver this upper bound? Any possible improvement would accelerate many of the known exact or parameterized algorithms on planar graphs that use dynamic programming on branch decompositions.
2. In contrast to treewidth, very few graph classes are known where branchwidth is computable in polynomial time. Find graphs

classes where branchwidth can be computed or approximated in polynomial time.
3. Find $\mathcal{B}_k$ for values of k bigger than 3. The only structural result on $\mathcal{B}_k$ is that its planar elements will be either self-dual or pairwise-dual. This follows from the fact that dual planar graphs have the same branchwidth [29, 16].
4. Find an exact algorithm for branchwidth of complexity $O^*(2^n)$ (the notation $O^*()$ assumes that we drop the non-exponential terms in the classic $O()$ notation).
5. The dependence on k of the linear time algorithm for branchwidth in [3] is huge. Find an $2^{O(k)} \cdot n^{O(1)}$ step algorithm, deciding whether the branchwidth of an n-vertex input graph is at most k.

Problem Definition

In this entry, we consider the classical broadcast scheduling problem and discuss some recent advances on this problem. The problem is formalized as follows: there is a server which has a collection of unit-sized *pages* $P = \{1, \ldots, n\}$. The server can broadcast pages in integer time slots in response to *requests*, which are given as the following sequence: at time t, the server receives $w_p(t) \in \mathbb{Z}_{\geq 0}$ requests for each page $p \in P$. We say that a request ρ for page p that arrives at time t is satisfied at time $c_p(t)$ if $c_p(t)$ is the first time after t by which the server has completely transmitted page p. The response time of the request ρ is defined to be $c_p(t) - t$, i.e., the time that elapses from its arrival till the time it is satisfied. Notice that by definition, the response time for any request is at least 1. The goal is to find a schedule for broadcasting pages to minimize the average response time, i.e., $(\sum_{t,p} w_p(t)(c_p(t)-t))/\sum_{t,p} w_p(t)$. Recall that the problem we discuss here is an *offline problem*, where the entire request sequence is specified as part of the input. There has also been much research on the online version of the problem, and we briefly discuss this toward the end of the entry.

Key Results

Erlebach and Hall [5] were the first to show complexity theoretic hardness for this problem by showing that it is NP complete. The techniques we describe below were introduced in [1, 3]. By fine-tuning these ideas, [2] shows the following result on the approximability of the offline problem, which will be the main result we will build toward this entry.

Theorem 1 ([2]) *Let $\gamma > 0$ be any arbitrary parameter. There is a polynomial time algorithm that finds a schedule with average response time $(2+\gamma)\cdot OPT + O((\sqrt{\log_{1+\gamma} n \cdot \log\log n})\log n)$, where OPT denotes the value of the average response time in the optimum solution.*

By setting $\gamma = \Theta(\log n)$ above, we can get an approximation guarantee of $O(\log^{1.5} n)$. Also

note that the $O(\log^{1.5} n)$ term in Theorem 1 is additive. As a result, for instance, where OPT is large (say $\Omega(\log^{1.5+\epsilon} n)$ for some $\epsilon > 0$), we can set γ arbitrarily small to get an approximation ratio arbitrarily close to 2.

Linear Programming Formulation

All of the algorithmic results in [1–3] are based on rounding the following natural LP relaxation for the problem. For each page $p \in [n]$ and each time t, there is a variable y_{pt} which indicates whether page p was transmitted at time t. We have another set of variables $x_{ptt'}$ s.t $t' > t$, which indicates whether a request for page p which arrives at time t is satisfied at t'. Let $w_p(t)$ denote the total weight of requests for page p that arrive at time t.

$$\min \sum_{p,t,t'>t} (t'-t) \cdot \omega_p(t) \cdot x_{ptt'} \tag{1}$$

$$\text{s.t.} \sum_{p} y_{pt} \leq 1 \qquad \forall t \tag{2}$$

$$\sum_{t'>t} x_{ptt'} \geq 1 \qquad \forall p, t \tag{3}$$

$$x_{ptt'} \leq y_{pt'} \qquad \forall p, t, t' \geq t \tag{4}$$

$$x_{ptt'}, y_{pt'} \in [0,1] \qquad \forall p, t, t' \tag{5}$$

Constraint (2) ensures that only one page is transmitted in each time, (3) ensures that each request must be satisfied, and (4) ensures that a request for page p can be satisfied at time t only if p is transmitted at time t. Finally, a request arriving at time t that is satisfied at time t' contributes $(t'-t)$ to the objective. Now consider the linear program obtained by relaxing the integrality constraints on $x_{ptt'}$ and y_{pt}.

Rounding Techniques

The following points illustrate the main ideas that form the building blocks of the rounding algorithms in [1–3].

The Half-Integrality Assumption

In what follows, we discuss the techniques in the special case that the LP solution is *half-integral*, i.e., where all the $x_{ptt'} \in \{0, \frac{1}{2}\}$. The general case essentially builds upon this intuition, and all main technical ingredients are contained in this special case.

Viewing the LP Solution as a Convex Combination of Blocks

In half-integral solutions, note that every request is satisfied by the two earliest half broadcasts of the corresponding page. For any page p, let $\tau_p = \{t_{p,1}, t_{p,2}, \ldots\}$ denote the times when the fractional solution broadcasts $\frac{1}{2}$ units of page p. Notice that the fractional solution can be entirely characterized by these sets τ_ρ for all pages p. The main intuition now is to view the fractional broadcast of each page as a *convex combination* of two different solutions, one which broadcasts the page p integrally at the odd times $\{t_{p,1}, t_{p,3}, \ldots\}$ and another which broadcasts the page p integrally at the even times $\{t_{p,2}, t_{p,4}, \ldots\}$. We call these the *odd schedule* and even *schedule* for page p.

Rounding the Solution to Minimize Backlog: Attempt 1 [1]

Our first and most natural rounding idea is to round the convex combination for each page into one of the odd or even schedules, each with probability $1/2$. Let us call this the *tentative schedule*. Note that on average, the tentative schedule broadcasts one page per time slot, and moreover, the expected response time of any request is equal to its fractional response time. The only issue, however, is that different pages may broadcast at the same time slots. Indeed, there could some time interval $[t_1,t_2)$ where the tentative schedule makes many more than $t_2 - t_1$ broadcasts! A natural manner to resolve this issue is to broadcast conflicting pages in a first-come first-serve manner, breaking ties arbitrarily. Now, the typical request waits for at most its fractional cost (on average), plus the *backlog* due to conflicting broadcasts. Formally, the backlog is defined as $\max_{t_1,t_2>t_1} N_A(t_1,t_2) - (t_2 - t_1)$, where $N_A(t_1,t_2)$ is the number of broadcasts made in

the interval $[t_1, t_2)$ by the tentative schedule. For this simple randomized algorithm, note that the backlog of any interval $[t_1, t_2)$ is at most $\tilde{O}(\sqrt{n})$ w.h.p by a standard concentration bound. This can be formalized to give us the $\tilde{O}(\sqrt{n})$ approximation algorithm of [1].

Rounding the Solution to Minimize Backlog: Attempt 2 [3]

Our next attempt involves controlling the backlog by explicitly enforcing constraints which periodically reset the backlog to 0. For this, we write an auxiliary LP as follows: we divide the set τ_p for each page p into blocks of size $B = \Theta(\log n)$ units each and have a variable for choosing the odd schedule or even schedule within each block. (If the first block chooses an odd schedule and the second block chooses an even schedule, then the requests which arrived at the boundary may incur greater costs, but [3] argues that these can be bounded for $B \geq \Omega(\log n)$.) Since each block has $B/2$ units of fractional transmission (recall that the LP is half-integral), the total number of blocks is at most $2T/B$, where T is the time horizon of all broadcasts made by the LP solution. Therefore, the total number of variables is at most $4T/B$ (each block chooses either an odd schedule or even schedule). Now, instead of asking for the LP to choose schedules such that each time has at most one transmission, suppose we *group the time slots into intervals of size B and ask for the LP to choose schedules such that each interval has at most B transmissions.* Now, there are T/B such constraints, and there are $2T/B$ constraints which enforce that we pick one schedule for each block.

Therefore, in this relaxed LP, we start with a solution that has $4T/B$ variables each set to $1/2$ and a total of $3T/B$ constraints. But now, we can convert this into an *optimal basic feasible solution* (where the number of nonzero variables is at most the number of constraints). This implies that at least a constant fraction of the blocks chooses either the odd or even schedules integrally. It is easy to see that the backlog incurred in any time interval $[t_1, t_2)$ is at most $O(B)$ since we explicitly enforce 0 backlog for consecutive intervals of size B. Therefore, by repeating this process $O(\log T)$ time, we get a fully integral schedule with backlog $O(\log TB) = O(\log^2 n)$. This then gives us the $2 \cdot \text{OPT} + O(\log^2 n)$ approximation guarantee of [3].

Rounding the Solution to Minimize Backlog: Attempt 3 [2]

Our final attempt involves combining the ideas of attempts 1 and 2. Indeed, the main issue with approach 2 is that, when we solve for a basic feasible solution, we lose all control over how the solution looks! Therefore, we would ideally like for a rounding which enforces the constraints on time intervals of size B, but still *randomly selects the schedules within each block*. This way, we'll be able to argue that within each time interval of size B, the maximum backlog is $O(\sqrt{B})$. Moreover, if we look at a larger time interval I, we can decompose this into intervals of size B for which we have constraints in the LP, and a prefix and suffix of size at most B. Therefore, the backlog is constrained to be 0 by the LP for all intermediate intervals except the prefix and suffix which can have a backlog of $O(\sqrt{B})$. This will immediately give us the $O(\log^{1.5} n)$ approximation of [2].

Indeed, the main tool which lets us achieve this comes from a recent rounding technique of Lovett and Meka [7]. They prove the following result which they used as a subroutine for minimizing discrepancy of set systems, but it turns out to be a general result applicable in our setting as well [2].

Theorem 2 (Constructive partial coloring theorem [7]) *Let* $\mathbf{y} \in [0,1]^m$ *be any starting point,* $\delta > 0$ *be an arbitrary error parameter,* $v_1, \ldots, v_n \in \mathbf{R}^n$ *vectors, and* $\lambda_1, \ldots, \lambda_n \geq 0$ *parameters with*

$$\sum_{i=1}^{n} e^{-\lambda_i^2/16} \leq \frac{m}{16}. \tag{6}$$

Then, there is a randomized $\tilde{O}((m+n)^3/\delta^2)$*-time algorithm to compute a vector* $\mathbf{z} \in [0,1]^m$ *with*

(i) $z_j \in [0, \delta] \cup [1-\delta, 1]$ *for at least* $m/32$ *of the indices* $j \in [m]$.
(ii) $|v_i, \cdot \mathbf{z} - v_i \cdot \mathbf{y}| \leq \lambda_i \|v_i\|_2$, *for each* $i \in [n]$.

Hardness Results

The authors [2] also complement the above algorithmic result with the following negative results.

Theorem 3 *The natural LP relaxation for the broadcast problem has an integrality gap of* $\Omega(\log n)$.

Interestingly, Theorem 3 is based on establishing a new connection with the problem of minimizing the discrepancy of 3 permutations. In the 3-permutation problem, we are given 3 permutations π_1, π_2, π_3 of $[n]$. The goal of the problem is to find a coloring χ that minimizes the discrepancy. The discrepancy of $\Pi = (\pi_1, \pi_2, \pi_3)$ w.r.t a ± 1 coloring χ is the worst case discrepancy of all prefixes. That is, $\max_{i=1}^{3} \max_{k=1}^{n} \left| \sum_{j=1}^{k} \chi(\pi_{i,j}) \right|$, where $\pi_{i,j}$ is the jth element in π_i. Newman and Nikolov [8] showed a tight $\Omega(\log n)$ lower bound on the discrepancy of 3 permutations, resolving a long-standing conjecture. The authors [2] note that this can be used to give an integrality gap for the broadcast scheduling problem as well. Then, by generalizing the connection to the discrepancy of ℓ permutations, [2] shows the following hardness results (prior to this, only NP hardness was known).

Theorem 4 *There is no* $O(\log^{1/2-\epsilon} n)$ *approximation algorithm for the problem of minimizing average response time, for any* $\epsilon > 0$, *unless* $\mathsf{NP} \subseteq \cup_{t>0} \mathsf{BPTIME}(2^{\log^t n})$. *Moreover, for any sufficiently large* ℓ, *there is no* $O(\ell^{1/2})$ *approximation algorithm for the* ℓ*-permutation problem, unless* $\mathsf{NP} = \mathsf{RP}$.

Online Broadcast Scheduling

The broadcast scheduling problem has also been studied in the *online scheduling model*, where the algorithm is made aware of requests *only when they arrive*, and it has to make the broadcast choices without knowledge of the future requests. Naturally, the performance of our algorithms degrade when compared to the offline model, but remarkably, we can get nontrivial algorithms even in the online model! The only additional assumption we need in the online model is that our scheduling algorithm may broadcast two pages (instead of one) every $1/\epsilon$ time slots, in order to get approximation ratios that depend on $1/\epsilon$. In particular, several $(1+\epsilon)$-speed, $O(\text{poly}(1/\epsilon))$ are now known [4, 6], and it is also known that extra speed is necessary to obtain $n^{o(1)}$ competitive algorithms.

Problem Definition

The Model Overview

Consider a set of stations (nodes) modeled as points in the plane, labeled by natural numbers, and equipped with transmitting and receiving capabilities. Every node u has a *range* r_u depending on the power of its transmitter, and it can reach all nodes at distance at most r_u from it. The collection of nodes equipped with ranges determines a directed graph on the set of nodes, called a *geometric radio network* (GRN), in which a directed edge (uv) exists if node v can be reached from u. In this case u is called a *neighbor* of v. If the power of all transmitters is the same, then all ranges are equal and the corresponding GRN is symmetric.

Research partially supported by NSERC discovery grant and by the Research Chair in Distributed Computing at the Université du Québec en Outaouais.

Nodes send messages in synchronous *rounds*. In every round, every node acts either as a *transmitter* or as a *receiver*. A node gets a message in a given round, if and only if it acts as a receiver and exactly one of its neighbors transmits in this round. The message received in this case is the one that was transmitted. If at least two neighbors of a receiving node u transmit simultaneously in a given round, none of the messages is received by u in this round. In this case, it is said that a *collision* occurred at u.

The Problem

Broadcasting is one of the fundamental network communication primitives. One node of the network, called the *source*, has to transmit a message to all other nodes. Remote nodes are informed via intermediate nodes, along directed paths in the network. One of the basic performance measures of a broadcasting scheme is the total time, i.e., the number of rounds it uses to inform all the nodes of the network.

For a fixed real $s \geq 0$, called the *knowledge radius*, it is assumed that each node knows the part of the network within the circle of radius s centered at it, i.e., it knows the positions, labels, and ranges of all nodes at distance at most s. The following problem is considered:

How does the size of the knowledge radius influence deterministic broadcasting time in GRN?

Terminology and Notation

Fix a finite set $R = \{r_1, \ldots, r_\rho\}$ of positive reals such that $r_1 < \cdots < r_\rho$. Reals r_i are called *ranges*. A *node* v is a triple $[l, (x, y), r_i]$, where l is a binary sequence called the *label* of v; (x, y) are coordinates of a point in the plane, called the *position* of v; and $r_i \in R$ is called the *range* of v. It is assumed that labels are consecutive integers 1 to n, where n is the number of nodes, but all the results hold if labels are integers in the set $\{1, \ldots, M\}$, where $M \in O(n)$. Moreover, it is assumed that all nodes know an upper bound Γ on n, where Γ is polynomial in n. One of the nodes is distinguished and called the *source*. Any set of nodes C with a distinguished source,

such that positions and labels of distinct nodes are different, is called a *configuration*.

With any configuration C, the following directed graph $\mathcal{G}(C)$ is associated. Nodes of the graph are nodes of the configuration and a directed edge (uv) exists in the graph, if and only if the distance between u and v does not exceed the range of u. (The word "distance" always means the geometric distance in the plane and not the distance in a graph.) In this case u is called a neighbor of v. Graphs of the form $\mathcal{G}(C)$ for some configuration C are called *geometric radio networks* (GRN). In what follows, only configurations C such that in $\mathcal{G}(C)$ there exists a directed path from the source to any other node are considered. If the size of the set R of ranges is ρ, a resulting configuration and the corresponding GRN are called a ρ-configuration and ρ-GRN, respectively. Clearly, all 1-GRN are symmetric graphs. D denotes the *eccentricity* of the source in a GRN, i.e., the maximum length of all shortest paths in this graph from the source to all other nodes. D is of order of the diameter if the graph is symmetric but may be much smaller in general. $\Omega(D)$ is an obvious lower bound on broadcasting time.

Given any configuration, fix a nonnegative real s, called the *knowledge radius*, and assume that every node of C has initial input consisting of all nodes whose positions are at distance at most s from its own. Thus, it is assumed that every node knows a priori labels, positions, and ranges of all nodes within a circle of radius s centered at it. All nodes also know the set R of available ranges.

It is not assumed that nodes know any global parameters of the network, such as its size or diameter. The only global information that nodes have about the network is a polynomial upper bound on its size. Consequently, the broadcast process may be finished but no node needs to be aware of this fact. Hence, the adopted definition of broadcasting time is the same as in [3]. An algorithm accomplishes broadcasting in t rounds, if all nodes know the source message after round t, and no messages are sent after round t.

Only deterministic algorithms are considered. Nodes can transmit messages even before getting the source message, which enables preprocessing in some cases. The algorithms are *adaptive*, i.e., nodes can schedule their actions based on their local history. A node can obviously gain knowledge from previously obtained messages. There is, however, another potential way of acquiring information during the communication process. The availability of this method depends on what happens during a collision, i.e., when u acts as a receiver and two or more neighbors of u transmit simultaneously. As mentioned above, u does not get any of the messages in this case. However, two scenarios are possible. Node u may either hear nothing (except for the background noise), or it may receive *interference noise* different from any message received properly but also different from background noise. In the first case, it is said that there is no *collision detection*, and in the second case – that collision detection is available (cf., e.g., [1]). A discussion justifying both scenarios can be found in [1, 7].

Related Work

Broadcasting in geometric radio networks and some of their variations was considered, e.g., in [6, 8, 9, 11, 12]. In [12] the authors proved that scheduling optimal broadcasting is NP hard even when restricted to such graphs and gave an $O(n \log n)$ algorithm to schedule an optimal broadcast when nodes are situated on a line. In [11] broadcasting was considered in networks with nodes randomly placed on a line. In [9] the authors discussed fault-tolerant broadcasting in radio networks arising from regular locations of nodes on the line and in the plane, with reachability regions being squares and hexagons, rather than circles. Finally, in [6] broadcasting with restricted knowledge was considered but the authors studied only the special case of nodes situated on the line.

Key Results

The results summarized below are based on the paper [5], of which [4] is a preliminary version.

Arbitrary GRN in the Model Without Collision Detection

Clearly all upper bounds and algorithms are valid in the model with collision detection as well.

Large Knowledge Radius

Theorem 1 *The minimum time to perform broadcasting in an arbitrary GRN with source eccentricity D and knowledge radius $s > r_\rho$ (or with global knowledge of the network) is $\Theta(D)$.*

This result yields a centralized $O(D)$ broadcasting algorithm when global knowledge of the GRN is available. This is in sharp contrast with broadcasting in arbitrary graphs, as witnessed by the graph from [10] which has bounded diameter but requires time $\Omega(\log n)$ for broadcasting.

Knowledge Radius Zero

Next consider the case when knowledge radius $s = 0$, i.e., when every node knows only its own label, position, and range. In this case, it is possible to broadcast in time $O(n)$ for arbitrary GRN. It should be stressed that this upper bound is valid for arbitrary GRN, not only symmetric, unlike the algorithm from [3] designed for arbitrary symmetric graphs.

Theorem 2 *It is possible to broadcast in arbitrary n-node GRN with knowledge radius zero in time $O(n)$.*

The above upper bound for GRN should be contrasted with the lower bound from [2,3] showing that some graphs require broadcasting time $\Omega(n \log n)$. Indeed, the graphs constructed in [2, 3] and witnessing to this lower bound are not GRN. Surprisingly, this sharper lower bound does not require very unusual graphs. While counterexamples from [2, 3] are not GRN, it turns out that the reason for a longer broadcasting time is really not the topology of the graph but the difference in knowledge available to nodes. Recall that in GRN with knowledge radius 0, it is assumed that each node knows its own position (apart from its label and range): the upper bound $O(n)$ uses this geometric information extensively.

If this knowledge is not available to nodes (i.e., each node knows only its label and range), then there exists a family of GRN requiring broadcasting time $\Omega(n \log n)$. Moreover, it is possible to show such GRN resulting from configurations with only 2 distinct ranges. (Obviously for 1 configurations, this lower bound does not hold, as these configurations yield symmetric GRN, and in [3], the authors showed an $O(n)$ algorithm working for arbitrary symmetric graphs).

Theorem 3 *If every node knows only its own label and range (and does not know its position), then there exist n-node GRN requiring broadcasting time $\Omega(n \log n)$.*

Symmetric GRN

The Model with Collision Detection

In the model with collision detection and knowledge radius zero, optimal broadcast time is established by the following pair of results.

Theorem 4 *In the model with collision detection and knowledge radius zero, it is possible to broadcast in any n-node symmetric GRN of diameter D in time $O(D + \log n)$.*

The next result is the lower bound $\Omega(\log n)$ for broadcasting time, holding for some GRN of diameter 2. Together with the obvious bound, $\Omega(D)$ this matches the upper bound from Theorem 4.

Theorem 5 *For any broadcasting algorithm with collision detection and knowledge radius zero, there exist n-node symmetric GRN of diameter 2 for which this algorithm requires time $\Omega(\log n)$.*

The Model Without Collision Detection

For the model without collision detection, it is possible to maintain complexity $O(D + \log n)$ of broadcasting. However, we need a stronger assumption concerning knowledge radius: it is no longer 0, but positive, although arbitrarily small.

Theorem 6 *In the model without collision detection, it is possible to broadcast in any n-node symmetric GRN of diameter D in time $O(D + \log n)$, for any positive knowledge radius.*

Applications

The radio network model is applicable to wireless networks using a single frequency. The specific model of geometric radio networks described

in section "Problem Definition" is applicable to wireless networks where stations are located in a relatively flat region without large obstacles (natural or human made), e.g., in the sea or a desert, as opposed to a large city or a mountain region. In such a terrain, the signal of a transmitter reaches receivers at the same distance in all directions, i.e., the set of potential receivers of a transmitter is a disc.

Open Problems

1. Is it possible to broadcast in time $o(n)$ in arbitrary n-node GRN with eccentricity D sublinear in n for knowledge radius zero?
   Note: In view of Theorem 2, it is possible to broadcast in time $O(n)$.
2. Is it possible to broadcast in time $O(D+\log n)$ in all symmetric n-node GRN with eccentricity D, without collision detection, when knowledge radius is zero?
   Note: In view of Theorems 4 and 6, the answer is positive if either collision detection or a positive (even arbitrarily small) knowledge radius is assumed.

Problem Definition

This problem is concerned with storing a linearly ordered set of elements such that the DICTIO-

NARY operations FIND, INSERT, and DELETE can be performed efficiently.

In 1972, Bayer and McCreight introduced the class of B-trees as a possible way of implementing an "index for a dynamically changing random access file" [7, p. 173]. B-trees have received considerable attention both in the database and in the algorithms community ever since; a prominent witness to their immediate and widespread acceptance is the fact that the authoritative survey on B-trees authored by Comer [10] appeared as soon as 1979 and, already at that time, referred to the B-tree data structure as the "ubiquitous B-tree."

Notations

A *B-tree* is a multiway search tree defined as follows (the definition of Bayer and McCreight [7] is restated according to Knuth [19, Sec. 6.2.4] and Cormen et al. [11, Ch. 18.1]):

Definition 1 Let $m \geq 3$ be a positive integer. A tree T is a *B-tree* of degree m if it is either empty or fulfills the following properties:

1. All leaves of T appear on the same level of T.
2. Every node of T has at most m children.
3. Every node of T, except for the root and the leaves, has at least $m/2$ children.
4. The root of T is either a leaf or has at least two children.
5. An internal node with k children $c_1[\nu], \ldots, c_k[\nu]$ stores $k-1$ keys, and a leaf stores between $m/2-1$ and $m-1$ keys. The keys $\text{key}_i[\nu]$, $1 \leq i \leq k-1$, of a node $\nu \in T$ are maintained in sorted order, i.e., $\text{key}_1[\nu] \leq \ldots \leq \text{key}_{k-1}[\nu]$.
6. If ν is an internal node of T with k children $c_1[\nu], \ldots, c_k[\nu]$, the $k-1$ keys $\text{key}_1[\nu], \ldots, \text{key}_{k-1}[\nu]$ of ν separate the range of keys stored in the subtrees rooted at the children of ν. If x_i is any key stored in the subtree rooted at $c_i[\nu]$, the following holds:

$$x_1 \leq \text{key}_1[\nu] \leq x_2 \leq \text{key}_2[\nu] \leq \cdots \leq x_{k-1} \leq \text{key}_{k-1}[\nu] \leq x_k$$

To search a B-tree for a given key x, the algorithm starts with the root of the tree being the current node. If x matches one of the current node's keys, the search terminates successfully. Otherwise, if the current node is a leaf, the search terminates unsuccessfully. If the current node's key does not contain x and if the current node is not a leaf, the algorithm identifies the unique subtree rooted at the child of the current node that may contain x and recurses on this subtree. Since the keys of a node guide the search process, they are also referred to as *routing elements*.

Variants and Extensions

Knuth [19] defines a *B^*-tree* to be a B-tree where Property 3 in Definition 1 is modified such that every node (except for the root) contains at least $2m/3$ keys.

A *B^+-tree* is a leaf-oriented B-tree, i.e., a B-tree that stores the keys in the leaves only. Additionally, the leaves are linked in left-to-right order to allow for fast sequential traversal of the keys stored in the tree. In a leaf-oriented tree, the routing elements usually are copies of certain keys stored in the leaves ($\text{key}_i[\nu]$ can be set to be the largest key stored in the subtree rooted at $c_i[\nu]$), but any set of routing elements that fulfills Properties 5 and 6 of Definition 1 can do as well.

Huddleston and Mehlhorn [16] extended Definition 1 to describe a more general class of multiway search trees that includes the class of B-trees as a special case. Their class of so-called (a, b)-trees is parameterized by two integers a and b with $a \geq 2$ and $2a - 1 \leq b$. Property 2 of Definition 1 is modified to allow each node to have up to b children, and Property 3 is modified to require that, except for the root and the leaves, every node of an (a, b)-tree has at least a children. All other properties of Definition 1 remain unchanged for (a, b)-trees. Usually, (a, b)-trees are implemented as leaf-oriented trees.

By the above definitions, a B-tree is a $(b/2, b)$-tree (if b is even) or an $(a, 2a-1)$-tree (if b is odd). The subtle difference between even and odd maximum degree becomes relevant in an important amortization argument of Huddleston and Mehlhorn (see below) where the inequality

$b \geq 2a$ is required to hold. This amortization argument actually caused (a, b)-trees with $b \geq 2a$ to be given a special name: *weak* B-trees [16].

Update Operations

An INSERT operation on an (a, b)-tree first tries to locate the key x to be inserted. After an unsuccessful search that stops at some leaf ℓ, x is inserted into ℓ's set of keys. If ℓ becomes too full, i.e., contains more than b elements, two approaches are possible to resolve this *overflow* situation: (1) the node ℓ can be split around its median key into two nodes with at least a keys each, or (2) the node ℓ can have some of its keys be distributed to its left or right siblings (if this sibling has enough space to accommodate the new keys). In the first case, a new routing element separating the keys in the two new subtrees of ℓ's parent μ has to be inserted into the key set of μ, and in the second case, the routing element in μ separating the keys in the subtree rooted at ℓ from the keys rooted at ℓ's relevant sibling needs to be updated. If ℓ was split, the node μ needs to be checked for a potential overflow due to the insertion of a new routing element, and the split may propagate all the way up to the root.

A DELETE operation also first locates the key x to be deleted. If (in a non-leaf-oriented tree) x resides in an internal node, x is replaced by the largest key in the left subtree of x (or the smallest key in the right subtree of x) which resides in a leaf and is deleted from there. In a leaf-oriented tree, keys are deleted from leaves only (the correctness of a routing element on a higher levels is not affected by this deletion). In any case, a DELETE operation may result in a leaf node ℓ containing less than a elements. Again, there are two approaches to resolve this *underflow* situation: (1) the node ℓ is merged with its left or right sibling node or (2) keys from ℓ's left or right sibling node are moved to ℓ (unless the sibling node would underflow as a result of this). Both underflow handling strategies require updating the routing information stored in the parent of ℓ which (in the case of merging) may underflow itself. As with overflow handling, this process may propagate up to the root of the tree.

Note that the root of the tree can be split as a result of an INSERT operation and that it may disappear if the only two children of the root are merged to form the new root. This implies that B-trees grow and shrink at the top, and thus all leaves are guaranteed to appear on the same level of the tree (Property 1 of Definition 1).

Key Results

Since B-trees are a premier index structure for external storage, the results given in this section are stated not only in the RAM-model of computation but also in the I/O-model of computation introduced by Aggarwal and Vitter [2]. In the I/O-model, not only the number N of elements in the problem instance but also the number M of elements that simultaneously can be kept in main memory and the number B of elements that fit into one disk block are (nonconstant) parameters, and the complexity measure is the number of I/O-operations needed to solve a given problem instance. If B-trees are used in an external memory setting, the degree m of the B-tree is usually chosen such that one node fits into one disk block, i.e., $m \in \Theta(B)$, and this is assumed implicitly whenever the I/O-complexity of B-trees is discussed.

Theorem 1 *The height of an N-key B-tree of degree $m \geq 3$ is bounded by* $\log_{\lceil m/2 \rceil}(N+1)/2$.

Theorem 2 ([22]) *The storage utilization for B-trees of high order under random insertions and deletions is approximately* $\ln 2 \approx 69\,\%$.

Theorem 3 *A B-tree may be used to implement the abstract data type* DICTIONARY *such that the operations* FIND, INSERT, *and* DELETE *on a set of N elements from a linearly ordered domain can be performed in $\mathcal{O}(\log N)$ time (with $\mathcal{O}(\log_B N)$ I/O-operations) in the worst case.*

Remark 1 By threading the nodes of a B-tree, i.e., by linking the nodes according to their in-order traversal number, the operations PREV and

NEXT can be performed in constant time (with a constant number of I/O-operations).

A (one-dimensional) *range query* asks for all keys that fall within a given query range (interval).

Lemma 1 *A B-tree supports (one-dimensional) range queries with $\mathcal{O}(\log N + K)$ time complexity ($\mathcal{O}(\log_B N + K/B)$ I/O-complexity) in the worst case where K is the number of keys reported.*

Under the convention that each update to a B-tree results in a new "version" of the B-tree, a *multiversion* B-tree is a B-tree that allows for updates of the current version but also supports queries in earlier versions.

Theorem 4 ([9]) *A multiversion B-tree can be constructed from a B-tree such that it is optimal with respect to the worst-case complexity of the* FIND, INSERT, *and* DELETE *operations as well as to the worst-case complexity of answering range queries.*

Applications

Databases

One of the main reasons for the success of the B-tree lies in its close connection to databases: any implementation of Codd's relational data model (introduced incidentally in the same year as B-trees were invented) requires an efficient indexing mechanism to search and traverse relations that are kept on secondary storage. If this index is realized as a B^+-tree, all keys are stored in a linked list of leaves which is indexed by the top levels of the B^+-tree, and thus both efficient logarithmic searching and sequential scanning of the set of keys is possible.

Due to the importance of this indexing mechanism, a wide number of results on how to incorporate B-trees and their variants into database systems and how to formulate algorithms using these structures have been published in the database community. Comer [10] and Graefe [14] summarize early and recent results, but due to the bulk of results, even these summaries cannot be fully comprehensive. Also, B-trees have been shown to work well in the presence of concurrent operations [8], and Mehlhorn [20, p. 212] notes that they perform especially well if a top-down splitting approach is used. The details of this splitting approach may be found, e.g., in the textbook of Cormen et al. [11, Ch. 18.2].

Priority Queues

A B-tree may be used to serve as an implementation of the abstract data type PRIORITYQUEUE since the smallest key always resides in the first slot of the leftmost leaf.

Lemma 2 *An implementation of a priority queue that uses a B-tree supports the* MIN *operation in $\mathcal{O}(1)$ time (with $\mathcal{O}(1)$ I/O-operations). All other operations (including* DECREASEKEY*) have a time complexity of $\mathcal{O}(\log N)$ (an I/O-complexity of $\mathcal{O}(\log_B N)$) in the worst case.*

Mehlhorn [20, Sec. III, 5.3.1] examined B-trees (and, more general, (a, b)-trees with $a \geq 2$ and $b \geq 2a - 1$) in the context of *mergeable* priority queues. *Mergeable priority queues* are priority queues that additionally allow for concatenating and splitting priority queues. Concatenating priority queues for a set $S_1 \neq \emptyset$ and a set $S_2 \neq \emptyset$ is only defined if $\max\{x \mid x \in S_1\} < \min\{x \mid x \in S_2\}$ and results in a single priority queue for $S_1 \cup S_2$. Splitting a priority queue for a set $S_3 \neq \emptyset$ according to some $y \in \mathrm{dom}(S_3)$ results in a priority queue for the set $S_4 := \{x \in S_3 \mid x \leq y\}$ and a priority queue for the set $S_5 := \{x \in S_3 \mid x > y\}$ (one of these sets may be empty). Mehlhorn's result restated in the context of B-trees is as follows:

Theorem 5 (Theorem 6 in [20, Sec. III, 5.3.1]) *If sets $S_1 \neq \emptyset$ and $S_2 \neq \emptyset$ are represented by a B-tree each, then operation* CONCATENATE(S_1, S_2) *takes time $\mathcal{O}(\log \max\{|S_1|, |S_2|\})$ (has an I/O-complexity of $\mathcal{O}(\log_B \max\{|S_1|, |S_2|\})$) and operation* SPLIT$(S_1, y)$ *takes time $\mathcal{O}(\log |S_1|)$ (has an I/O-complexity of $\mathcal{O}(\log_B |S_1|)$). All bounds hold in the worst case.*

Buffered Data Structures

Many applications (including sorting) that involve massive data sets allow for batched data processing. A variant of B-trees that exploits this relaxed problem setting is the so-called *buffer tree* proposed by Arge [4]. A *buffer tree* is a B-trees of degree $m \in \Theta(M/B)$ (instead of $m \in \Theta(B)$) where each node is assigned a buffer of size $\Theta(M)$. These buffers are used to collect updates and query requests that are passed further down the tree only if the buffer gets full enough to allow for cost amortization.

Theorem 6 (Theorem 1 in [4]) *The total cost of an arbitrary sequence of N intermixed* INSERT *and* DELETE *operations on an initially empty buffer tree is $\mathcal{O}(N/B \log_{M/B} N/B)$ I/O operations, that is, the amortized I/O-cost of an operation is $\mathcal{O}(1/B \log_{M/B} N/B)$.*

As a consequence, N elements can be sorted spending an optimal number of $\mathcal{O}(N/B \log_{M/B} N/B)$ I/O-operations by inserting them into a (leaf-oriented) buffer tree in a batched manner and then traversing the leaves. By the preceding discussion, buffer trees can also be used to implement (batched) priority queues in the external memory setting. Arge [4] extended his analysis of buffer trees to show that they also support DELETEMIN operations with an amortized I/O-cost of $\mathcal{O}(1/B \log_{M/B} N/B)$.

Since the degree of a buffer tree is too large to allow for efficient Single shot, i.e., non-batched operations, Arge et al. [6] discussed how buffers can be attached to (and later detached from) a multiway tree while at the same time keeping the degree of the base structure in $\Theta(B)$. Their discussion uses the R-tree index structure as a running example; the techniques presented, however, carry over to the B-tree. The resulting data structure is accessed through standard methods and additionally allows for batched update operations, e.g., *bulk loading*, and queries. The amortized I/O-complexity of all operations is analogous to the complexity of the buffer tree operations.

Using this buffering technique along with weight balancing [5], Achakeev and Seeger [1] showed how to efficiently bulk load and bulk update partially persistent data structures such as the multiversion B-tree.

Variants of the B-tree base structure that support modern architectures such as many-core processors and that can be updated efficiently have also been proposed by Sewall et al. [21], Graefe et al. [15], and Erb et al. [12].

B-trees as Base Structures

Several external memory data structures are derived from B-trees or use a B-tree as their base structure – see the survey by Arge [3] for a detailed discussion. One of these structures, the so-called *weight-balanced* B-tree is particularly useful as a base tree for building dynamic external data structures that have secondary structures attached to all (or some) of their nodes. The weight-balanced B-tree, developed by Arge and Vitter [5], is a variant of the B-tree that requires all subtrees of a node to have approximately, i.e., up to a small constant factor, the same number of leaves. Weight-balanced B-trees can be shown to have the following property:

Theorem 7 ([5]) *In a weight-balanced B-tree, rebalancing after an update operation is performed by splitting or merging nodes. When a rebalancing operation involves a node v that is the root of a subtree with $w(v)$ leaves, at least $\Theta(w(v))$ update operations involving leaves below v have to be performed before v itself has to be rebalanced again.*

Using the above theorem, amortized bounds for maintaining secondary data structures attached to nodes of the base tree can be obtained – as long as each such structure can be updated with an I/O-complexity linear in the number of elements stored below the node it is attached to [3,5].

Amortized Analysis

Most of the amortization arguments used for (a,b)-trees, buffer trees, and their relatives are based upon a theorem due to Huddleston and Mehlhorn [16, Theorem 3]. This theorem states that the total number of rebalancing operations in any sequence of N intermixed insert and delete

operations performed on an initially empty *weak* B-tree, i.e., an (a, b)-tree with $b \geq 2a$, is at most linear in N. This result carries over to buffer trees since they are $(M/4B, M/B)$-trees. Since B-trees are (a, b)-trees with $b = 2a - 1$ (if b is odd), the result in its full generality is not valid for B-trees, and Huddleston and Mehlhorn present a simple counterexample for $(2, 3)$-trees.

A crucial fact used in the proof of the above amortization argument is that the sequence of operations to be analyzed is performed on an initially *empty* data structure. Jacobsen et al. [17] proved the existence of *non-extreme* (a, b)-trees, i.e., (a, b)-trees where only few nodes have a degree of a or b. Based upon this, they re-established the above result that the rebalancing cost in a sequence of operations is amortized constant (and thus the related result for buffer trees) also for operations on initially nonempty data structures.

In connection with concurrent operations in database systems, it should be noted that the analysis of Huddleston and Mehlhorn actually requires $b \geq 2a + 2$ if a top-down splitting approach is used. In can be shown, though, that even in the general case, few node splits (in an amortized sense) happen close to the root.

URLs to Code and Data Sets

There is a variety of (commercial and free) implementations of B-trees and (a, b)-trees available for download. Representatives are the `C++`-based implementations that are part of the LEDA-library (http://www.algorithmic-solutions.com), the `STXXL`-library (http://stxxl.sourceforge.net), and the TPIE-library (http://www.madalgo.au.dk/tpie/) as well as the `Java`-based implementation that is part of the `javaxxl`-library (http://xxl.googlecode.com). Furthermore, (pseudo-code) implementations can be found in almost every textbook on database systems or on algorithms and data structures – see, e.g., [11, 13]. Since textbooks almost always leave developing the implementation details of the DELETE operation as an exercise to the reader, the discussion by Jannink [18] is especially helpful.

Problem Definition

The Burrows-Wheeler transform is a technique used for the lossless compression of data. It is the algorithmic core of the tool *bzip2* which has become a standard for the creation and distribution of compressed archives.

Before the introduction of the Burrows-Wheeler transform, the field of lossless data compression was dominated by two approaches (see [2, 21] for comprehensive surveys). The first approach dates back to the pioneering works of Shannon and Huffman, and it is based on the idea of using shorter codewords for the more frequent symbols. This idea has originated the techniques of Huffman and arithmetic coding and, more recently, the PPM (prediction by partial matching) family of compression algorithms. The second approach originated from the works of Lempel and Ziv and is based on the idea of adaptively building a dictionary and representing the input string as a concatenation of dictionary words. The best-known compressors based on this approach form the so-called ZIP-family; they have been the standard for several years and are available on essentially any computing platform (e.g., *gzip*, *zip*, *winzip*, just to cite a few).

The Burrows-Wheeler transform introduced a completely new approach to lossless data compression based on the idea of *transforming* the input to make it easier to compress. In the authors' words: "(this) technique [...] works by applying a reversible transformation to a block of text to make redundancy in the input more accessible to simple coding schemes" [5, Sect. 7]. Not only has this technique produced some state-of-the-art compressors, but it also originated the field of compressed indexes [20] and it has been successfully extended to compress (and index) structured data such as XML files [11] and tables [22].

Key Results

Notation

Let s be a string of length n drawn from an alphabet Σ. For $i = 0,\ldots, n-1$, $s[i]$ denotes the i-th character of s and $s[i, n-1]$ denotes the suffix of s starting at position i (i.e., starting with the character $s[i]$). Given two strings s and t, the notation $s \prec t$ is used to denote that s lexicographically precedes t.

The Burrows-Wheeler Transform

In [5] Burrows and Wheeler introduced a new compression algorithm based on a reversible

transformation, now called the *Burrows-Wheeler transform* (*bwt*). Given a string s, the computation of $bwt(s)$ consists of three basic steps (see Fig. 1):

1. Append to the end of s a special symbol \$ smaller than any other symbol in Σ.
2. Form a *conceptual* matrix $\mathcal{M}$ whose rows are the cyclic shifts of the string $s\$$ sorted in lexicographic order.
3. Construct the transformed text $\hat{s} = bwt(s)$ by taking the last column of $\mathcal{M}$.

Notice that every column of $\mathcal{M}$, hence also the transformed text $\hat{s}$, is a permutation of $s\$$. As an example F, the first column of the *bwt* matrix $\mathcal{M}$ consists of all characters of s alphabetically sorted. In Fig. 1 it is $F = \$iiiimppssss$.

Although it is not obvious from its definition, the *bwt* is an invertible transformation, and both the *bwt* and its inverse can be computed in $O(n)$ optimal time. To be consistent with the more recent literature, the following notation and proof techniques will be slightly different from the ones in [5].

Definition 1 For $1 \leq i \leq n$, let $s[k_i, n-1]$ denote the suffix of s prefixing row i of $\mathcal{M}$, and define $\Psi(i)$ as the index of the row prefixed by $s[k_i + 1, n-1]$.

For example, in Fig. 1 it is $\Psi(2) = 7$ since row 2 of $\mathcal{M}$ is prefixed by *ippi* and row 7 is prefixed by *ppi*. Note that $\Psi(i)$ is not defined for $i = 0$ since row 0 is not prefixed by a proper suffix of s. (In [5] instead of Ψ the authors make use of a map which is essentially the inverse of Ψ. The use of Ψ has been introduced in the literature of compressed indexes where Ψ and its inverse play an important role (see [20]).)

Lemma 1 *For* $i = 1, \ldots, n$, *it is* $F[i] = \hat{s}[\Psi(i)]$.

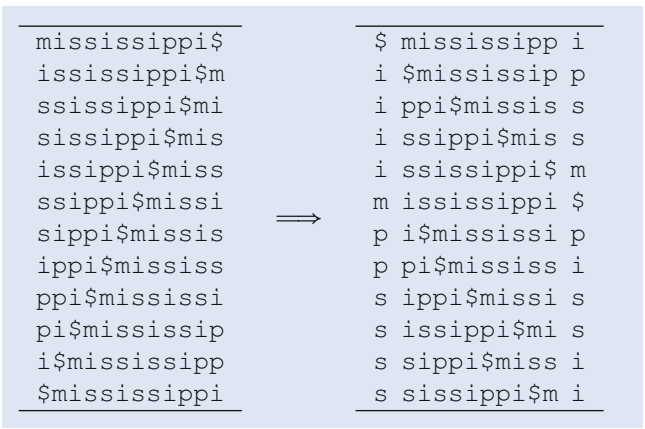
Proof Since each row contains a cyclic shift of $s\$$, the last character of the row prefixed by $s[k_i + 1, n-1]$ is $s[k_i]$. Definition 1 then implies $\hat{s}[\Psi(i)] = s[k_i] = F[i]$ as claimed. □

Lemma 2 *If* $1 \leq i < j \leq n$ *and* $F[i] = F[j]$, *then* $\Psi(i) < \Psi(j)$.

Proof Let $s[k_i, n-1]$ (resp. $s[k_j, n-1]$) denote the suffix of s prefixing row i (resp. row j). The hypothesis $i < j$ implies that $s[k_i, n-1] \prec s[k_j, n-1]$. The hypothesis $F[i] = F[j]$ implies $s[k_i] = s[k_j]$; hence, it must be $s[k_i + 1, n-1] \prec s[k_j + 1, n-1]$. The thesis follows since by construction $\Psi(i)$ (resp. $\Psi(j)$) is the lexicographic position of the row prefixed by $s[k_i + 1, n-1]$ (resp. $s[k_j + 1, n-1]$). □

Lemma 3 *For any character* $c \in \Sigma$, *if* $F[j]$ *is the* ℓ*-th occurrence of* c *in* F, *then* $\hat{s}[\Psi(j)]$ *is the* ℓ*-th occurrence of* c *in* $\hat{s}$.

Proof Take an index h such that $h < j$ and $F[h] = F[j] = c$(the case $h > j$ is symmetric).



Burrows-Wheeler Transform, Fig. 1 Example of Burrows-Wheeler transform for the string $s = mississippi$. The matrix on the right has the rows sorted in lexicographic order. The output of the *bwt* is the last column of the sorted matrix; in this example, the output is $\hat{s} = bwt(s) = ipssm\$pissii$

Lemma 2 implies $\Psi(h) < \Psi(j)$ and Lemma 1 implies $\hat{s}[\Psi(h)] = \hat{s}[\Psi(j)] = c$. Consequently, the number of c's preceding (resp. following) $F[j]$ in F coincides with the number of c's preceding (resp. following) $\hat{s}[\Psi(j)]$ in $\hat{s}$ and the lemma follows. □

In Fig. 1 it is $\Psi(2) = 7$ and both $F[2]$ and $\hat{s}[7]$ are the second i in their respective strings. This property is usually expressed by saying that corresponding characters maintain the *same relative order* in both strings F and $\hat{s}$.

Lemma 4 *For any i, $\Psi(i)$ can be computed from $\hat{s} = bwt(s)$.*

Proof Retrieve F simply by sorting alphabetically the symbols of $\hat{s}$. Then compute $\Psi(i)$ as follows: (1) set $c = F(i)$, (2) compute ℓ such that $F[i]$ is the ℓ-th occurrence of c in F, and (3) return the index of the ℓ-th occurrence of c in $\hat{s}$. □

Referring again to Fig. 1, to compute $\Psi(10)$ it suffices to set $c = F[10] = s$ and observe that $F[10]$ is the second s in F. Then it suffices to locate the index j of the second s in $\hat{s}$, namely, $j = 4$. Hence, $\Psi(10) = 4$, and in fact row 10 is prefixed by *sissippi* and row 4 is prefixed by *issippi*.

Theorem 1 *The original string s can be recovered from bwt(s).*

Proof Lemma 4 implies that the column F and the map Ψ can be retrieved from $bwt(s)$. Let j_0 denote the index of the special character \$ in $\hat{s}$. By construction, the row j_0 of the *bwt* matrix is prefixed by $s[0,n-1]$; hence, $s[0] = F[j_0]$. Let $j_1 = \Psi(j_0)$. By Definition 1 row j_1 is prefixed by $s[1, n-1]$; hence, $s[1] = F[j_1]$. Continuing in this way, it is straightforward to prove by induction that $s[i] = F[\Psi^i(j_0)]$, for $i = 1,\ldots, n-1$. □

Algorithmic Issues

A remarkable property of the *bwt* is that both the direct and the inverse transform admit efficient algorithms that are extremely simple and elegant.

Theorem 2 *Let s[1,n] be a string over a constant size alphabet Σ. String $\hat{s} = bwt(s)$ can be computed in $O(n)$ time using $O(n\log n)$ bits of working space.*

Proof The suffix array of s can be computed in $O(n)$ time and $O(n\log n)$ bits of working space by using, for example, the algorithm in [17]. The suffix array is an array of integers $sa[1, n]$ such that for $i = 1, \ldots, n, s[sa[i], n-1]$ is the i-th suffix of s in the lexicographic order. Since each row of $\mathcal{M}$ is prefixed by a unique suffix of s followed by the special symbol \$, the suffix array provides the ordering of the rows in $\mathcal{M}$. Consequently, $bwt(s)$ can be computed from sa in linear time using the procedure *sa2bwt* of Fig. 2. □

Theorem 3 *Let s[1,n] be a string over a constant size alphabet Σ. Given bwt(s), the string s can be retrieved in $O(n)$ time using $O(n\log n)$ bits of working space.*

Proof The algorithm for retrieving s follows almost verbatim the procedure outlined in the proof of Theorem 1. The only difference is that, for efficiency reasons, all the values of the map Ψ are computed in one shot. This is done by the procedure *bwt2psi* in Fig. 2. In *bwt2psi* instead of working with the column F, it uses the array *count* which is a "compact" representation of F. At the beginning of the procedure, for any character $c \in \Sigma$, $count[c]$ provides the index of the first row of $\mathcal{M}$ prefixed by c. For example, in Fig. 1 $count[i] = 1$, $count[m] = 5$, and so on. In the main *for* loop of *bwt2psi,* the array *bwt* is scanned and *count*[c] is increased every time an occurrence of character c is encountered (line 6). Line 6 also assigns to h the index of the ℓ-th occurrence of c in F. By Lemma 3, line 7 stores correctly in $psi[h]$ the value $i = \Psi(h)$. After the computation of array *psi*, s is retrieved by using the procedure *psi2text* of Fig. 2, whose correctness immediately follows from Theorem 1. Clearly, the procedures *bwt2psi* and *psi2text* in Fig. 2 run in $O(n)$ time. Their working space is dominated by the cost of storing the array *psi* which takes $O(n\log n)$ bits. □

Procedure sa2bwt

```
1. bwt[0]=s[n-1];
2. for(i=1;i<=n;i++)
3. if(sa[i] == 1)
4. bwt[i]='$';
5. else
6. bwt[i]=s[sa[i]-1];
```

Procedure bwt2psi

```
71. for(i=0;i<=n;i++)
2.  c = bwt[i];
3.  if(c == '$')
4.  j0 = i;
5.  else
6.  h = count[c]++;
7.  psi[h]=i;
```

Procedure psi2text

```
891. k = j0; i=0;
2.   do
3.   k = psi[k];
4.   s[i++] = bwt[k];
     while(i<n);
```

Burrows-Wheeler Transform, Fig. 2 Algorithms for computing and inverting the Burrows-Wheeler transform. Procedure *sa2bwt* computes $bwt(s)$ given s and its suffix array *sa*. Procedure *bwt2psi* takes $bwt(s)$ as input and computes the Ψ map storing it in the array *psi*. *bwt2psi* also stores in j_0 the index of the row prefixed by $s[0, n-1]$. *bwt2psi* uses the auxiliary array *count* $[1, |\Sigma|]$ which initially contains in *count[i]* the number of occurrences in $bwt(s)$ of the symbols $1,\ldots,i-1$. Finally, procedure *psi2text* recovers the string s given $bwt(s)$, the array *psi*, and the value j_0

The Burrows-Wheeler Compression Algorithm

The rationale for using the *bwt* for data compression is the following. Consider a string w that appears k times within s. In the *bwt* matrix of s, there will be k consecutive rows prefixed by w, say rows $r_w + 1, r_w + 2, \ldots, r_w + k$. Hence, the positions $r_w + 1, \ldots, r_w + k$ of $\hat{s} = bwt(s)s$ will contain precisely the symbols that immediately precede w in s. If in s certain patterns are more frequent than others, then for many substrings w, the corresponding positions $r_w + 1,\ldots, r_w + k$ of $\hat{s}$ will contain only a few distinct symbols. For example, if s is an English text and w is the string *his*, the corresponding portion of $\hat{s}$ will likely contain many *t*'s and blanks and only a few other symbols. Hence, $\hat{s}$ is a permutation of s that is usually *locally homogeneous*, in that its "short" substrings usually contain only a few distinct symbols. (Obviously this is true only if s has some regularity: if s is a random string $\hat{s}$ will be random as well!)

To take advantage of this property, Burrows and Wheeler proposed to process the string $\hat{s}$ using move-to-front encoding [4] (*mtf*). *mtf* encodes each symbol with the number of distinct symbols encountered since its previous occurrence. To this end, *mtf* maintains a list of the symbols ordered by recency of occurrence; when the next symbol arrives, the encoder outputs its current rank and moves it to the front of the list. Note that *mtf* produces a string which has the same length as $\hat{s}$ and, if $\hat{s}$ is locally homogeneous, the string $mtf(\hat{s})$ will mainly consist of small integers. (If s is an English text, $mtf(\hat{s})$ usually contains more that 50 % zeroes.) Given this skewed distribution, $mtf(\hat{s})$can be easily compressed: Burrows and Wheeler proposed to compress it using Huffman or Arithmetic coding, possibly preceded by the run-length encoding of runs of equal integers.

Burrows and Wheeler were mainly interested in proposing an algorithm with good practical performance. Indeed their simple implementation outperformed, in terms of compression ratio, the tool *gzip* that was the current standard for lossless compression. A few years after the introduction of the *bwt*, [14, 18] have shown that the compression ratio of the Burrows-Wheeler compression algorithm can be bounded in terms of the k-th order empirical entropy of the input string for any $k \geq 0$. For example, Kaplan et al. [14] showed that for any input string s and real $\mu > 1$, the length of the compressed string is bounded by $\mu n H_k(s) + n\log(\zeta(\mu)) + \mu g_k + O(\log n)$ bits, where $\zeta(\mu)$ is the standard Zeta function and g_k is a function depending only on k and the size of Σ. This bound holds *pointwise* for *any* string s, *simultaneously* for any $k \geq 0$ and $\mu > 1$, and it is remarkable since similar bounds have not been proven for any other known compressor. The theoretical study on the performance of *bwt*-based compressors is an active area of research. For more recent results, see [6, 12].

Applications

After the seminal paper of Burrows and Wheeler, many researchers have proposed compression algorithms based on the *bwt* (see [8, 9] and references therein). Of particular theoretical interest are the results in [10] showing that the *bwt* can be used to design a "compression booster," that is, a tool for improving the performance of other compressors in a well-defined and measurable way.

Today the main area of application of the *bwt* is the design of Compressed Full-text Indexes [20]. These indexes take advantage of the relationship between the *bwt* and the suffix array to provide a compressed representation of a string supporting the efficient search and retrieval of the occurrences of an arbitrary pattern.

Open Problems

In addition to the investigation on the performance of *bwt*-based compressors, an open problem of great practical significance is the space-efficient computation of the *bwt*. Given a string s of length n over an alphabet Σ, both s and $\hat{s} = bwt(s)$ take $O(n \log |\Sigma|)$ bits. Unfortunately, the linear time algorithms shown in Fig. 2 make use of auxiliary arrays (i.e., *sa* and Ψ) whose storage takes $\Theta(n \log n)$ bits. This poses a serious limitation to the size of the largest *bwt* that can be computed in main memory. The problem of space- and time-efficient computation of the *bwt* is still open, even if interesting results are reported in [1, 3, 7, 13, 15, 19]. The problem of designing space-efficient algorithms for inverting the *bwt* is also open; see [7, 16, 20] and references therein for further details.

Experimental Results

An experimental study of the performance of several compression algorithms based on the *bwt* and a comparison with other state-of-the-art compressors is presented in [8].

Data Sets

The data sets used in [8] are available from http://people.unipmn.it/manzini/boosting. Other data sets relevant for compression and compressed indexing are available at the Pizza&Chili site http://pizzachili.di.unipi.it/.

URL to Code

The compression boosting page (http://people.unipmn.it/manzini/boosting) contains the source code of the algorithms tested in [8]. An extremely efficient code for the computation of the suffix array and the *bwt* (without compression) is available at http://code.google.com/p/libdivsufsort. The code of *bzip2* is available at http://www.bzip.org.

1980; Pease, Shostak, Lamport

Problem Definition

The study of Pease, Shostak and Lamport was among the first to consider the problem of achieving a coordinated behavior between processors of a distributed system in the presence of failures [21]. Since the paper was published, this subject has grown into an extensive research area. Below is a presentation of the main findings regarding the specific questions addressed in their paper. In some cases this entry uses the currently accepted terminology in this subject, rather than the original terminology used by the authors.

System Model

A distributed system is considered to have n independent processors, p_1, ... ,p_n, each modeled as a (possibly infinite) state machine. The processors are linked by a communication network that supports direct communication between every pair of processors. The processors can communicate only by exchanging messages, where the sender of every message can be identified by the receiver. While the processors may fail, it is assumed that the communication subsystem is fail-safe. It is not known in advance which processors will not fail (remain correct) and which ones will

fail. The types of processor failures are classified according to the following hierarchy.

Crash failure A crash failure means that the processor no longer operates (ad infinitum, starting from the failure point). In particular, other processors will not receive messages from a faulty processor after it crashes.

Omission failure A processor fails to send and receive an arbitrary subset of its messages.

Byzantine failure A faulty processor behaves arbitrarily.

The Byzantine failure is further subdivided into two cases, according to the ability of the processors to create unfalsifiable signatures for their messages. In the *authenticated Byzantine failure* model it is assumed that each message is *signed* by its sender and that no other processor can fake a signature of a correct processor. Thus, even if such a message is forwarded by other processors, its authenticity can be verified. If the processors represent malevolent (human) users of a distributed system, a Public Key Infrastructure (PKI) is typically used to sign the messages (which involves cryptography related issues [17], not discussed here). Practically, in systems where processors are just "processors", a simple signature, such as CRC (cyclic redundancy check), might be sufficient [13]. In the *unauthenticated Byzantine failure* model there are no message signatures.

Definition of the Byzantine Agreement Problem

In the beginning, each processor p_i has an externally provided input value v_i, from some set V (of at least size 2). In the *Byzantine Agreement* (BA) problem, every correct processor p_i is required to decide on an output value $d_i \in V$ such that the following conditions hold:

Termination Eventually, p_i decides, i.e., the algorithm cannot run indefinitely.

Validity If the input value of all the processors is v, then the correct processors decide v.

Agreement All the correct processors decide on the same value.

For crash failures and omission failures there exists a stronger agreement condition:

Uniform Agreement No two processors (either correct or faulty) decide differently.

The termination condition has the following stronger version.

Simultaneous Termination All the correct processors decide in the *same round* (see definition below).

Timing Model

The BA problem was originally defined for *synchronous* distributed systems [18, 21]. In this timing model the processors are assumed to operate in lockstep, which allows to partition the execution of a protocol to rounds. Each round consists of a send phase, during which a processor can send a (different) message to each processor directly connected to it, followed by a receive phase, in which it receives messages sent by these processors in the current round. Unlimited local computations (state transitions) are allowed in both phases, which models the typical situation in real distributed systems, where computation steps are faster than the communication steps by several orders of magnitude.

Overview

This entry deals only with *deterministic* algorithms for the BA problem in the synchronous model. For algorithms involving randomization see the ▸Optimal Probabilistic Synchronous Byzantine Agreement entry in this volume. For results on BA in other models of synchrony, see ▸Asynchronous Consensus Impossibility, ▸Failure Detectors, ▸Consensus with Partial Synchrony entries in this volume.

Key Results

The maximum possible number of faulty processors is assumed to be bounded by an a priori specified number t (e.g., estimated from the failure probability of individual processor and the requirements on the failure probability of the

system as a whole). The number of processors that actually become faulty in a given execution is denoted by f, where $f \leq t$.

The complexity of synchronous distributed algorithms is measured by three complementary parameters. The first is the *round complexity,* which measures the number of rounds required by the algorithm. The second is the *message complexity*, i.e., the total number of messages (and sometimes also their size in bits) sent by all the processors (in case of Byzantine failures, only messages sent by correct processors are counted). The third complexity parameter measures the number of local operations, as in sequential algorithms.

All the algorithms presented bellow are efficient, i.e., the number of rounds, the number of messages and their size, and the local operations performed by each processor are polynomial in n. In most of the algorithms, both the exchanged messages and the local computations involve only the basic data structures (e.g., arrays, lists, queues). Thus, the discussion is restricted only to the round and the message complexities of the algorithms.

The network is assumed to be fully connected, unless explicitly stated otherwise.

Crash Failures

A simple BA algorithm which runs in $t + 1$ rounds and sends $O(n^2)$ messages, together with a proof that this number of rounds is optimal, can be found in textbooks on distributed computing [19]. Algorithms for deciding in $f + 1$ rounds, which is the best possible, are presented in [7, 23] (one additional round is necessary before the processors can stop [11]). Simultaneous termination requires $t + 1$ rounds, even if no failures actually occur [11], however there exists an algorithm that in any given execution stops in the earliest possible round [14]. For uniform agreement, decision can be made in $\min(f + 2, t + 1)$ rounds, which is tight [7].

In case of crash failures it is possible to solve the BA problem with $O(n)$ messages, which is also the lower bound. However, all known message-optimal BA algorithms require a superlinear time. An algorithm that runs in $O(f + 1)$ rounds and uses only $O(n \text{ polylog } n)$ messages, is presented in [8], along with an overview of other results on BA message complexity.

Omission Failures

The basic algorithm used to solve the crash failure BA problem works for omission failures as well, which allows to solve the problem in $t + 1$ rounds [23]. An algorithm which terminates in $\min(f + 2, t + 1)$ rounds was presented in [22]. Uniform agreement is impossible for $t \geq n/2$ [23]. For $t < n/2$, there is an algorithm that achieves uniform agreement in $\min(f + 2, t + 1)$ rounds (and $O(n^2 f)$ message complexity) [20].

Byzantine Failures with Authentication

A $(t + 1)$-round BA algorithm is presented in [12]. An algorithm which terminates in $\min(f + 2, t + 1)$ rounds can be found in [24]. The message complexity of the problem is analyzed in [10], where it is shown that the number of signatures and the number of messages in any authenticated BA algorithm are $\Omega(nt)$ and $\Omega(n + t^2)$, respectively. In addition, it is shown that $\Omega(nt)$ is the bound on the number of messages for the unauthenticated BA.

Byzantine Failures Without Authentication

In the unauthenticated case, the BA problem can be solved if and only if $n > 3t$. The proof can be found in [1, 19]. An algorithm that decides in $\min(f + 3, t + 1)$ rounds (it might require two additional rounds to stop) is presented in [16]. Unfortunately, this algorithm is complicated. Simpler algorithms, that run in $\min(2f + 4, 2t + 1)$ and $3\min(f + 2, t + 1)$ rounds, are presented in [24] and [5], respectively. In these algorithms the number of sent messages is $O(n^3)$, moreover, in the latter algorithm the messages are of constant size (2 bits). Both algorithms assume $V = \{0, 1\}$. To solve the BA problem for a larger V, several instances of a binary algorithm can be run in parallel. Alternatively, there exists a simple 2-round protocol that reduces a BA problem with

arbitrary initial values to the binary case, e.g., see Sect. 6.3.3 in [19]. For algorithms with optimal $O(nt)$ message complexity and $t + o(t)$ round complexity see [4, 9].

Arbitrary Network Topologies

When the network is not fully connected, BA can be solved for crash, omission and authenticated Byzantine failures if and only if it is $(t + 1)$-connected [12]. In case of Byzantine failures without authentication, BA has a solution if and only if the network is $(2t + 1)$-connected and $n > 3t$ [19]. In both cases the BA problem can be solved by simulating the algorithms for the fully connected network, using the fact that the number of disjoint communication paths between any pair of non-adjacent processors exceeds the number of faulty nodes by an amount that is sufficient for reliable communication.

Interactive Consistency and Byzantine Generals

The BA (consensus) problem can be stated in several similar ways. Two widely used variants are the *Byzantine Generals* (BG) problem and the *Interactive Consistency (*IC) problem. In the BG case there is a designated processor, say p_1, which is the only one to have an input value. The termination and agreement requirements of the BG problem are exactly as in BA, while the validity condition requires that if the input value of p_1 is v and p_1 is correct, then the correct processors decide v. The IC problem is an extension of BG, where every processor is "designated", so that each processor has to decide on a vector of n values, where the conditions for the i-th entry are as in BG, with p_i as the designated processor. For deterministic synchronous algorithms BA, BG and IC problems are essentially equivalent, e.g., see the discussion in [15].

Firing Squad

The above algorithms assume that the processors share a "global time", i.e., all the processors start in the same (first) round, so that their round counters are equal throughout the execution of the algorithm. However, there are cases in which the processors run in a synchronous network, yet each processor has its own notion of time (e.g., when each processor starts on its own, the round counter values are distinct among the processors). In these cases, it is desirable to have a protocol that allows the processors to agree on some specific round, thus creating a common round which synchronizes all the correct processors. This synchronization task, known as the *Byzantine firing squad* problem [6], is tightly realted to BA.

General Translation Techniques

One particular direction that was pursued as part of the research on the BA problem is the development of methods that automatically translate any protocol that tolerates a more benign failure type into one which tolerates more severe failures [24]. Efficient translations spanning the entire failure hierarchy, starting from crash failures all the way to unauthenticated Byzantine failures, can be found in [3] and in Ch. 12 of [1].

Applications

Due to the very tight synchronization assumptions made in the algorithms presented above, they are used mainly in real-time, safety-critical systems, e.g., aircraft control [13]. In fact, the original interest of Pease, Shostak and Lamport in this problem was raised by such an application [21]. In addition, BA protocols for the Byzantine failure case serve as a basic building block in many cryptographic protocols, e.g., secure multi-party computation [17], by providing a broadcast channel on top of pairwise communication channels.

Problem Definition

Computers contain a hierarchy of memory levels, with vastly differing access times. Hence, the time for a memory access depends strongly on what is the innermost level containing the data accessed. In analysis of algorithms, the standard RAM (or von Neumann) model cannot capture this effect, and external memory models were introduced to better model the situation. The most widely used of these models is the two-level I/O-model [4], also called the external memory model or the disk access model. The I/O-model approximates the memory hierarchy by modeling two levels, with the inner level having size M, the outer level having infinite size, and transfers between the levels taking place in blocks of B consecutive elements. The cost of an algorithm is the number of such transfers it makes.

The cache-oblivious model, introduced by Frigo et al. [26], elegantly generalizes the I/O-model to a multilevel memory model by a simple measure: the algorithm is not allowed to know the value of B and M. More precisely, a cache-oblivious algorithm is an algorithm formulated in the RAM model, but analyzed in the I/O-model, with an analysis valid for *any* value of B and M. Cache replacement is assumed to take place automatically by an optimal off-line cache replacement strategy. Since the analysis holds for any B and M, it holds for all levels simultaneously (for a detailed version of this statement, see [26]).

The subject of the present chapter is that of efficient dictionary structures for the cache-oblivious model.

Key Results

The first cache-oblivious dictionary was given by Prokop [32], who showed how to lay out a static binary tree in memory such that searches take $O(\log_B n)$ memory transfers. This layout, often called the *van Emde Boas*

Research supported by Danish Council for Independent Research, Natural Sciences.

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

layout because it is reminiscent of the classic van Emde Boas data structure, also ensures that range searches take $O(\log_B n + k/B)$ memory transfers [8], where k is the size of the output. Both bounds are optimal for comparison-based searching.

The first dynamic, cache-oblivious dictionary was given by Bender et al. [13]. Making use of a variant of the van Emde Boas layout, a density maintenance algorithm of the type invented by Itai et al. [28], and weight-balanced B-trees [5], they arrived at the following results:

Theorem 1 ([13]) *There is a cache-oblivious dictionary structure supporting searches in $O(\log_B n)$ memory transfers and insertions and deletions in amortized $O(\log_B n)$ memory transfers.*

Theorem 2 ([13]) *There is a cache-oblivious dictionary structure supporting searches in $O(\log_B n)$ memory transfers, insertions and deletions in amortized $O(\log_B n + (\log^2 n)/B)$ memory transfers, and range searches in $O(\log_B n + k/B)$ memory transfers, where k is the size of the output.*

Later, Bender et al. [10] developed a cache-oblivious structure for maintaining linked lists which supports insertion and deletion of elements in $O(1)$ memory transfers and scanning of k consecutive elements in amortized $O(k/B)$ memory transfers. Combining this structure with the structure of the first theorem above, the following result can be achieved.

Theorem 3 ([10,13]) *There is a cache-oblivious dictionary structure supporting searches in $O(\log_B n)$ memory transfers, insertions and deletions in amortized $O(\log_B n)$ memory transfers, and range searches in amortized $O(\log_B n + k/B)$ memory transfers, where k is the size of the output.*

A long list of extensions of these basic cache-oblivious dictionary results has been given. We now survey these.

Bender et al. [12] and Brodal et al. [20] gave very similar proposals for reproducing the result of Theorem 2 but with simpler structures (avoiding the use of weight-balanced B-trees). Based on exponential trees, Bender et al. [11] gave a proposal with $O(\log_B n)$ worst-case queries and updates. They also gave a solution with partial persistence, where searches (in all versions of the structure) and updates (in latest version of the structure) require amortized $O(\log_B(m+n))$ memory transfers, where m is the number of versions and n is the number of elements in the version operated on. Bender et al. [14] extended the cache-oblivious model to a concurrent setting and gave three proposals for cache-oblivious B-trees in this setting. Bender et al. [16] presented cache-oblivious dictionary structures exploring trade-offs between faster insertion costs and slower search cost, and Brodal et al. [21] later gave improved structures meeting lower bounds. Franceschini and Grossi [25] showed how to achieve $O(\log_B n)$ worst-case queries and updates while using $O(1)$ space besides the space for the n elements stored. Brodal and Kejlberg-Rasmussen [19] extended this to structures adaptive to the working set bound and allowing predecessor queries. Cache-oblivious dictionaries for other data types such as strings [15, 18, 22–24, 27] and geometric data [1, 2, 6, 7, 9] have been given. The expected number of I/Os for hashing was studied in the cache-oblivious model in [31].

It has been shown [17] that the best possible multiplicative constant in the $\Theta(\log_B n)$ search bound for comparison-based searching is different in the I/O-model and in the cache-oblivious model. It has also been shown [1,3] that for three-sided range reporting in 2D, the best possible space bound for structures with worst-case optimal query times is different in the two models. The latter result implies that linear space cache-oblivious persistent B-trees with optimal worst-case bounds for (1D) range reporting are not possible.

Applications

Dictionaries solve a fundamental data structuring problem which is part of solutions for a very high number of computational problems. Dictionaries for external memory are useful in settings

where memory accesses are dominating the running time, and cache-oblivious dictionaries in particular stand out by their ability to optimize the access to all levels of an unknown memory hierarchy. This is an asset, e.g., when developing programs to be run on diverse or unknown architectures (such as software libraries or programs for heterogeneous distributed computing like grid computing and projects such as SETI@home). Even on a single, known architecture, the memory parameters available to a computational process may be nonconstant if several processes compete for the same memory resources. Since cache-oblivious algorithms are optimized for all parameter values, they have the potential to adapt more graceful to these changes and also to varying input sizes forcing different memory levels to be in use.

Open Problems

It is an open problem to find a data structure achieving worst-case versions of all of the bounds in Theorem 3.

Experimental Results

Cache-oblivious dictionaries have been studied empirically in [12, 15, 20, 29, 30, 33]. The overall conclusion of these investigations is that cache-oblivious methods easily can outperform RAM algorithms, although sometimes not as much as algorithms tuned to the specific memory hierarchy and problem size at hand. On the other hand, cache-oblivious algorithms seem to perform well on all levels of the memory hierarchy and to be more robust to changing problem sizes.

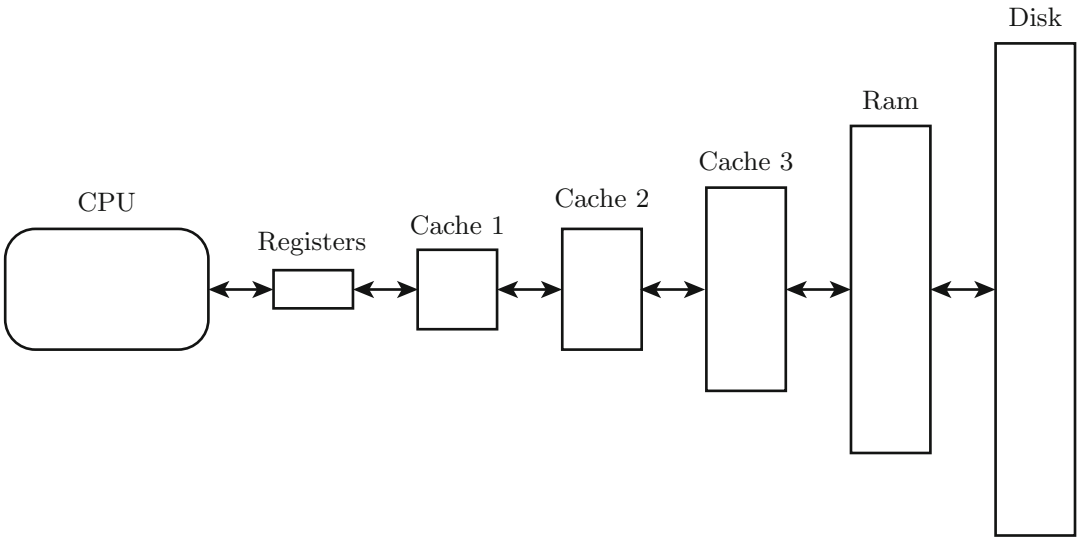
Problem Definition

The memory system of contemporary computers consists of a hierarchy of memory levels, with

Research supported by Danish Council for Independent Research, Natural Sciences.

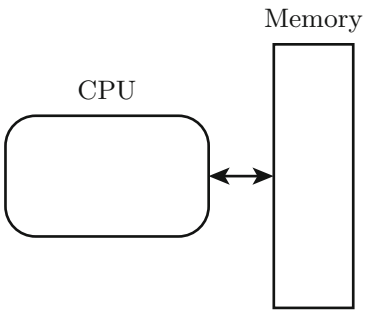


Cache-Oblivious Model, Fig. 1 The memory hierarchy

each level acting as a cache for the next; a typical hierarchy consists of registers, level 1 cache, level 2 cache, level 3 cache, main memory, and disk (Fig. 1). One characteristics of the hierarchy is that the memory levels get larger and slower the further they get from the processor, with the access time increasing most dramatically between RAM memory and disk. Another characteristics is that data is moved between levels in blocks of consecutive elements.

As a consequence of the differences in access time between the levels, the cost of a memory access depends highly on what is the current lowest memory level holding the element accessed. Hence, the memory access pattern of an algorithm has a major influence on its practical running time. Unfortunately, the RAM model (Fig. 2) traditionally used to design and analyze algorithms is not capable of capturing this, as it assumes that all memory accesses take equal time.

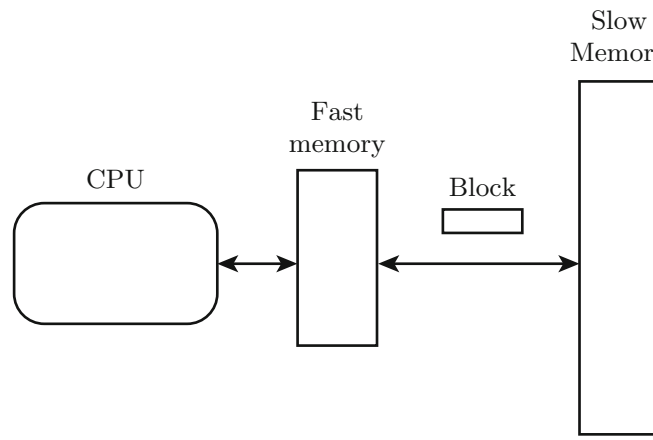
To better account for the effects of the memory hierarchy, a number of computational models have been proposed. The simplest and most successful is the two-level I/O-model introduced by Aggarwal and Vitter [3] (Fig. 3). In this model a two-level memory hierarchy is assumed, consisting of a fast memory of size M and a slower memory of infinite size, with



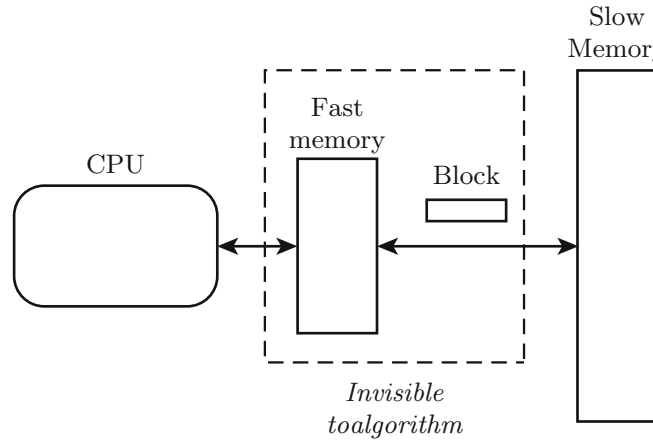
Cache-Oblivious Model, Fig. 2 The RAM model

data transferred between the levels in blocks of B consecutive elements. Computation can only be performed on data in the fast memory, and algorithms are assumed to have complete control over transfers of blocks between the two levels. Such a block transfer is denoted a *memory transfer*. The complexity measure is the number of memory transfers performed. The strength of the I/O-model is that it captures part of the memory hierarchy while being sufficiently simple to make design and analysis of algorithms feasible. Over the last two decades, a large body of results for the I/O-model has been produced, covering most areas of algorithmics. For an overview, see the surveys [5, 32, 34–36].

Cache-Oblivious Model, Fig. 3 The I/O-model



Cache-Oblivious Model, Fig. 4 The cache-oblivious model



More elaborate models of multilevel memory have been proposed (see e.g., [34] for an overview) but these models have been less successful than the I/O-model, mainly because of their complexity which makes analysis of algorithms harder. All these models, including the I/O-model, assume that the characteristics of the memory hierarchy (the level and block sizes) are known.

In 1999 the *cache-oblivious model* (Fig. 4) was introduced by Frigo et al. [30]. In short, a cache-oblivious algorithm is an algorithm formulated in the RAM model but analyzed in the I/O-model, with the analysis required to hold for *any* block size B and memory size M. Memory transfers are assumed to take place automatically by an optimal off-line cache replacement strategy.

The crux of the cache-oblivious model is that because the I/O-model analysis holds for any block and memory size, it holds for all levels of a multilevel memory hierarchy (see [30] for a detailed version of this statement). Put differently, by optimizing an algorithm to one unknown level of the memory hierarchy, it is optimized to all levels simultaneously. Thus, the cache-oblivious model elegantly generalizes the I/O-model to a multilevel memory model by one simple measure: the algorithm is not allowed to know the value of B and M. The challenge, of course, is to develop algorithms having good memory transfer analyses under these conditions.

Besides capturing the entire memory hierarchy in a conceptually simple way, the cache-oblivious model has other benefits: Algorithms developed in the model do not rely on knowing the parameters of the memory hierarchy, which is an asset when developing programs to be run on diverse or unknown architectures

(e.g., software libraries or programs for heterogeneous distributed computing such as grid computing and projects like SETI@home). Even on a single, known architecture, the memory parameters available to a computational process may be nonconstant if several processes compete for the same memory resources. Since cache-oblivious algorithms are optimized for all parameter values, they have the potential to adapt more graceful to these changes. Also, the same code will adapt to varying input sizes forcing different memory levels to be in use. Finally, cache-oblivious algorithms automatically are optimizing the use of translation lookaside buffers (a cache holding recently accessed parts of the page table used for virtual memory) of the CPU, which may be seen as second memory hierarchy parallel to the one mentioned in the introduction.

Possible weak points of the cache-oblivious model are the assumption of optimal off-line cache replacement and the lack of modeling of the limited associativity of many of the levels of the hierarchy. The first point is mitigated by the fact that normally, the provided analysis of a proposed cache-oblivious algorithm will work just as well assuming a least recently used cache replacement policy, which is closer to actual replacement strategies of computers. The second point is also a weak point of most other memory models.

Key Results

This section surveys a number of the known results in the cache-oblivious model. Other surveys available include [6, 15, 26, 32].

First of all, note that scanning an array of N elements takes $O(N/B)$ memory transfers for any values of B and M and hence is an optimal cache-oblivious algorithm. Thus, standard RAM algorithms based on scanning may already posses good analysis in the cache-oblivious model – for instance, the classic deterministic linear time selection algorithm has complexity $O(N/B)$ [26].

For sorting, a fundamental fact in the I/O-model is that comparison-based sorting of N elements takes $\Theta(\mathrm{Sort}(N))$ memory transfers [3], where $\mathrm{Sort}(N) = \frac{N}{B}\log_{M/B}\frac{N}{M}$. Also in the cache-oblivious model, sorting can be carried out in $\Theta(\mathrm{Sort}(N))$ memory transfer, if one makes the so-called *tall cache* assumption $M \geq B^{1+\varepsilon}$ [16, 30]. Such an assumption has been shown to be necessary [18], which proves a separation in power between cache-oblivious algorithms and algorithms in the I/O-model (where this assumption is not needed for the sorting bound).

For searching, B-trees have cost $O(\log_B N)$, which is optimal in the I/O-model for comparison-based searching. This cost is also attainable in the cache-oblivious model, as shown for the static case in [33] and for the dynamic case in [12]. Also for searching, a separation between cache-oblivious algorithms and algorithms in the I/O-model has been shown [13] in the sense that the constants attainable in the $O(\log_B N)$ bound are provably different.

By now, a large number of cache-oblivious algorithms and data structures in many areas have been given. These include priority queues [7, 17]; many dictionaries for standard data, string data, and geometric data (see survey in section on cache-oblivious B-trees); and algorithms for other problems in computational geometry [8, 16, 22], for graph problems [4, 7, 19, 23, 31], for scanning dynamic sets [9], for layout of static trees [11], for search problems on multi-sets [28], for dynamic programming [14, 24], for adaptive sorting [20], for inplace sorting [29], for sorting of strings [27], for partial persistence [10], for matrix operations [30], and for the fast Fourier transform [30].

In the negative direction, a few further separations in power between cache-oblivious algorithms and algorithms in the I/O-model are known. Permuting in the I/O-model has complexity $\Theta(\min\{\mathrm{Sort}(N), N\})$, assuming that elements are indivisible [3]. It has been proven [18] that this asymptotic complexity cannot be attained in the cache-oblivious model. A separation with respect to space complexity has been proven [2] for three-sided range reporting in 2D where the best possible space bound for structures with worst-case optimal query times is different in the two models. This result also implies that linear space cache-oblivious persistent B-trees with optimal

worst-case bounds for (1D) range reporting are not possible.

Applications

The cache-oblivious model is a means for design and analysis of algorithms that use the memory hierarchy of computers efficiently.

Experimental Results

Cache-oblivious algorithms have been evaluated empirically in a number of areas, including sorting [21], searching (see survey in section on cache-oblivious B-trees), matrix algorithms [1, 30, 37], and dynamic programming [24, 25].

The overall conclusion of these investigations is that cache-oblivious methods often outperform RAM algorithms but not always exactly as much as do algorithms tuned to the specific memory hierarchy and problem size. On the other hand, cache-oblivious algorithms seem to perform well on all levels of the memory hierarchy and to be more robust to changing problem sizes than cache-aware algorithms.

Cache-Oblivious Sorting

Gerth Stølting
Department of Computer Science, University of Aarhus, Århus, Denmark

Keywords

Funnelsort

Problem Definition

Sorting a set of elements is one of the most well-studied computational problems. In the cache-oblivious setting, the first study of sorting was presented in 1999 in the seminal paper by Frigo et al. [8] that introduced the cache-oblivious framework for developing algorithms

aimed at machines with (unknown) hierarchical memory.

Model

In the cache-oblivious setting, the computational model is a machine with two levels of memory: a cache of limited capacity and a secondary memory of infinite capacity. The capacity of the cache is assumed to be M elements, and data is moved between the two levels of memory in blocks of B consecutive elements. Computations can only be performed on elements stored in cache, i.e., elements from secondary memory need to be moved to the cache before operations can access the elements. Programs are written as acting directly on one unbounded memory, i.e., programs are like standard RAM programs. The necessary block transfers between cache and secondary memory are handled automatically by the model, assuming an optimal offline cache replacement strategy. The core assumption of the cache-oblivious model is that M and B are *unknown to the algorithm*, whereas in the related I/O model introduced by Aggarwal and Vitter [1], the algorithms know M and B, and the algorithms perform the block transfers explicitly. A thorough discussion of the cache-oblivious model and its relation to multilevel memory hierarchies is given in [8].

Sorting

For the sorting problem, the input is an array of N elements residing in secondary memory, and the output is required to be an array in secondary memory, storing the input elements in sorted order.

Key Results

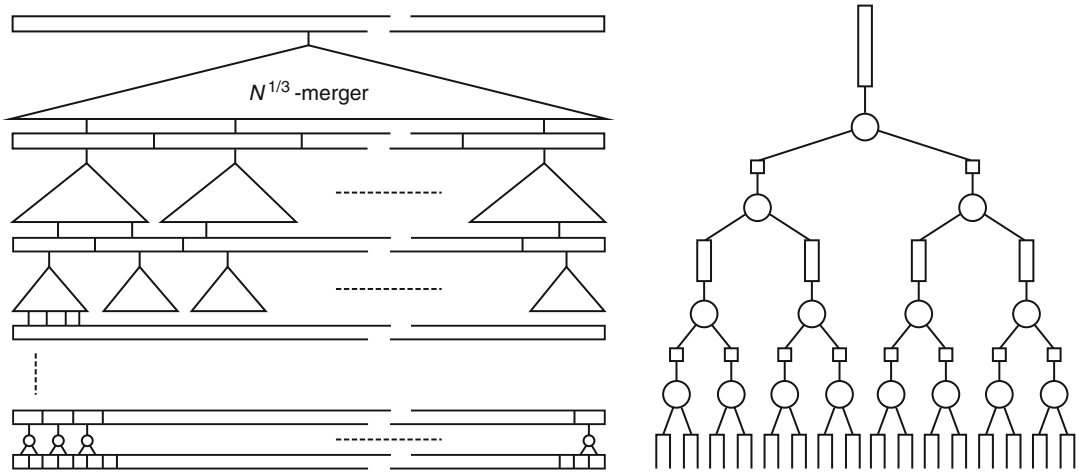
In the I/O model, tight upper and lower bounds were proved for the sorting problem and the problem of permuting an array [1]. In particular it was proved that sorting requires $\Omega\left(\frac{N}{B}\log_{M/B}\frac{N}{B}\right)$ block transfers and permuting an array requires $\Omega\left(\min\left\{N, \frac{N}{B}\log_{M/B}\frac{N}{B}\right\}\right)$ block transfers. Since lower bounds for the I/O model also hold for the cache-oblivious model, the lower bounds from [1] immediately give a lower bound of $\Omega\left(\frac{N}{B}\log_{M/B}\frac{N}{B}\right)$ block transfers for cache-oblivious sorting and $\Omega\left(\min\left\{N, \frac{N}{B}\log_{M/B}\frac{N}{B}\right\}\right)$ block transfers for cache-oblivious permuting. The upper bounds from [1] cannot be applied to the cache-oblivious setting since these algorithms make explicit use of B and M.

Binary mergesort performs $O(N\log_2 N)$ comparisons, but analyzed in the cache-oblivious model, it performs $O\left(\frac{N}{B}\log_2\frac{N}{M}\right)$ block transfers which is a factor $\Theta\left(\log\frac{M}{B}\right)$ from the lower bound (assuming a recursive implementation of binary mergesort, in order to get M in the denominator in the $\log N/M$ part of the bound on the block transfers). Another comparison-based sorting algorithm is the classical quicksort sorting algorithm from 1962 by Hoare [9] that performs expected $O(N\log_2 N)$ comparisons and expected $O\left(\frac{N}{B}\log_2\frac{N}{M}\right)$ block transfers. Both these algorithms achieve their relatively good performance for the number of block transfers from the fact that they are based on repeated scanning of arrays – a property not shared with, e.g., heapsort [10] that has a very poor performance of $\Theta\left(\frac{N}{B}\log_{M/B}\frac{N}{B}\right)$ block transfers. In the I/O model, the optimal performance of $O\left(\frac{M}{B}\log_{M/B}\frac{N}{B}\right)$ is achieved by generalizing binary mergesort to $\Theta\left(\frac{M}{B}\right)$-way mergesort [1].

Frigo et al. in [8] presented two cache-oblivious sorting algorithms (which can also be used to permute an array of elements). The first algorithm [8, Section 4] is denoted as *funnelsort* and is a reminiscent of classical binary mergesort, whereas the second algorithm [8, Section 5] is a distribution-based sorting algorithm. Both algorithms perform *optimal* $O\left(\frac{N}{B}\log_{M/B}\frac{N}{B}\right)$ block transfers – provided a *tall cache assumption* $M = \Omega(B^2)$ is satisfied.

Funnelsort

The basic idea of funnelsort is to rearrange the sorting process performed by binary mergesort, such that the processed data is stored "locally." This is achieved by two basic ideas: (1) a



Cache-Oblivious Sorting, Fig. 1 The overall recursion of funnelsort (*left*) and a 16-merger (*right*)

top-level recursion that partitions the input into $N^{1/3}$ sequences of size $N^{2/3}$ funnelsorts these sequences recursively and merges the resulting sorted subsequences using an $N^{1/3}$-*merger*. (2) A k-merger is recursively defined to perform binary merging of k input sequences in a clever schedule with an appropriate recursive layout of data in memory using buffers to hold suspended merging processes (see Fig. 1). Subsequently two simplifications were made, without sacrificing the asymptotic number of block transfers performed. In [3], it was proved that the binary merging could be performed lazily, simplifying the scheduling of merging. In [5], it was further observed that the recursive layout of k-mergers is not necessary. It is sufficient that a k-merger is stored in a consecutive array, i.e., the buffers can be laid out in an arbitrary order which simplifies the construction algorithm for the k-merger.

Implicit Cache-Oblivious Sorting

Franceschini in [7] showed how to perform optimal cache-oblivious sorting implicitly using only $O(1)$ space, i.e., all data is stored in the input array except for $O(1)$ additional words of information. In particular the output array is just a permutation of the input array.

The Role of the Tall Cache Assumption

The role of the tall cache assumption on cache-oblivious sorting was studied by Brodal and Fagerberg in [4]. If no tall cache assumption is made, they proved the following theorem:

Theorem 1 ([4], Corollary 3) *Let* $B_1 = 1$ *and* $B_2 = M/2$. *For any cache-oblivious comparison-based sorting algorithm, let* t_1 *and* t_2 *be upper bounds on the number of I/Os performed for block sizes* B_1 *and* B_2. *If for a real number* $d \geq 0$, *it is satisfied that* $t_2 = d \cdot \frac{N}{B_2} \log_{M/B_2} \frac{N}{B_2}$ *then* $t_1 > 1/8 \cdot N \log_2 N/M$.

The theorem shows that cache-oblivious comparison-based sorting without a tall cache assumption cannot match the performance of algorithms in the I/O model where M and B are known to the algorithm. It also has the natural interpretation that if a cache-oblivious algorithm is required to be I/O optimal for the case $B = M/2$, then binary mergesort is best possible – any other algorithm will be the same factor of $\Theta(\log M)$ worse than the optimal block transfer bound for the case $M >> D$.

For the related problem of permuting an array, the following theorem states that for all possible tall cache assumptions $B \leq M^{\delta}$, no cache-oblivious permuting algorithm exists with a block transfer bound (even only in the average case sense), matching the worst case bound in the I/O model.

Theorem 2 ([4], Theorem 2) *For all* $\delta > 0$, *there exists no cache-oblivious algorithm for*

permuting that for all $M \geq 2B$ *and* $1 \leq B \leq M^{\delta}$ *achieves* $O\left(\min\left\{N, \frac{N}{B}\log_{M/B}\frac{N}{B}\right\}\right)$ *I/Os averaged over all possible permutations of size* N.

Applications

Many problems can be reduced to cache-oblivious sorting. In particular Arge et al. [2] developed a cache-oblivious priority queue based on a reduction to sorting. They furthermore showed how a cache-oblivious priority queue can be applied to solve a sequence of graph problems, including list ranking, BFS, DFS, and minimum spanning trees.

Brodal and Fagerberg in [3] showed how to modify the cache-oblivious lazy funnelsort algorithm to solve several problems within computational geometry, including orthogonal line segment intersection reporting, all the nearest neighbors, 3D maxima problem, and batched orthogonal range queries. All these problems can be solved by a computation process very similarly to binary mergesort with an additional problem-dependent twist. This general framework to solve computational geometry problems is denoted as *distribution sweeping*.

Open Problems

Since the seminal paper by Frigo et al. [8] introducing the cache-oblivious framework, there has been a lot of work on developing algorithms with a good theoretical performance, but only a limited amount of work has been done on implementing these algorithms. An important issue for future work is to get further experimental results consolidating the cache-oblivious model as a relevant model for dealing efficiently with hierarchical memory.

Experimental Results

A detailed experimental study of the cache-oblivious sorting algorithm funnelsort was performed in [5]. The main result of [5] is that a carefully implemented cache-oblivious sorting algorithm can be faster than a tuned implementation of quicksort already for input sizes well within the limits of RAM. The implementation is also at least as fast as the recent cache-aware implementations included in the test. On disk, the difference is even more pronounced regarding quicksort and the cache-aware algorithms, whereas the algorithm is slower than a careful implementation of multiway mergesort optimized for external memory such as in TPIE [6].

2013; Bader

Background

In scientific computing and related fields, mathematical functions are often approximated on meshes where each mesh cell contains a local approximation (e.g., using polynomials) of the represented quantity (density functions, physical quantities such as temperature or pressure, etc.). The grid cells may adaptively refine within areas of high interest or where the applied numerical algorithms demand improved resolution. The resolution even may dynamically change throughout the computation.

In this context, we consider *tree-structured* adaptive meshes, i.e., meshes that result from a recursive subdivision of grid cells. They can be represented via trees – quadtrees or octrees being the most prominent examples. In typical problem settings, quantities are stored on entities (vertices, edges, faces, cells) of the grid. The computation of these variables is usually characterized by local interaction rules and involves variables of adjacent grid cells only. Hence, efficient algorithms are required for the (parallel) traversal of such tree-structured grids and their associated variables.

Problem Definition

Consider a hierarchical mesh of grid cells (triangles, squares, tetrahedra, cubes, etc.), in which all grid cells result from recursively splitting an existing grid cell into a fixed number k of geometrically similar child cells. The resulting grid is equivalent to a tree with uniform degree k. We refer to it as a *spacetree*. Special cases are quadtrees (based upon squares, i.e., dimension $d = 2$, and $k = 4$) and octrees (cubes, $d = 3$, and $k = 8$). Depending on the problem, only the mesh defined by the leaves of the tree may be of interest, or a *multilevel* grid may be considered. The latter also includes all cells corresponding to interior nodes of the tree. Also, meshes resulting from a collection of spacetrees may be considered. Such a generalized data structure is called a *forest* of spacetrees. A mathematical function shall be defined on such a mesh via coefficients that are associated with entities (vertices, edges, faces, cells) of the grid cells. Each coefficient contributes to the representation of the mathematical function in the grid cells adjacent to its entity. For typical computations, we then require efficient algorithms for *mesh traversals* processing all unknowns on entities.

Mesh traversal (definition): Run through all leaf, i.e., unrefined, grid cells and process all

function coefficients associated to each cell or to entities adjacent to it.

Multiscale traversal (definition): Perform one mesh traversal including all (or a certain subset of the) grid cells (tree-interior and leaf cells), thus processing the coarse-grid cells of the grid hierarchy as well.

Mesh traversals may be used to define a sequential order (linearization) on the mesh cells or coefficients. Sequential orders that preserve locality may be used to define partitions for parallel processing and load balancing. Of special interest are algorithms that minimize the memory accesses during traversals as well as the memory required to store the tree-structured grids.

Key Results

Space-Filling Curve Orders on Tree-Structured Grids

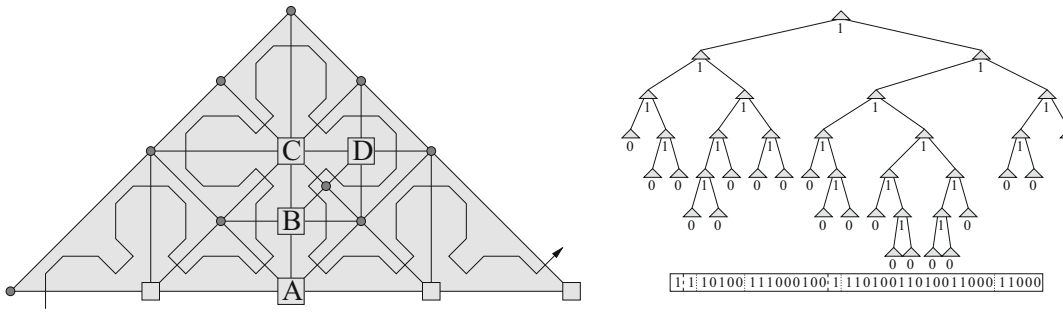
Space-filling curves (SFCs) [1, 5] are continuous surjective mappings from a one-dimensional interval to a higher-dimensional target domain (typically squares, cubes, etc.). They are constructed via an "infinite" recursion process analogous to the generation of tree-structured meshes. Space-filling curves thus induce a sequential order on a corresponding tree-structured grid (an example is given in Fig. 1).

The construction of the curve may be described via a grammar, in which the nonterminals reflect the local orientation of the curve within a grid cell (e.g., Fig. 2). Terminals are used to indicate transfers between grid cells or levels.

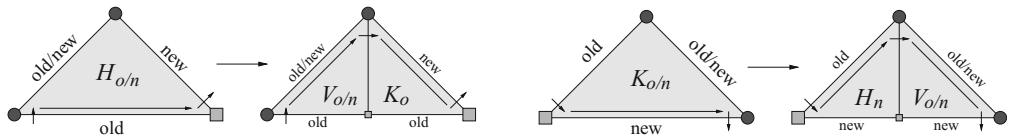
Together with this grammar, a bitstream encoding of the refinement information (as in Fig. 1) provides a minimal-memory data structure to encode a given tree-structured grid. Using Hilbert or Lebesgue (Morton order) SFCs, for example, respective algorithms can be formulated for quadtrees and octrees. Peano curves lead to traversals for (hyper)cube-based spacetrees with 3-refinement along each dimension.

Space-Filling-Curve Traversals

Depth-first traversals of the SFC/bitstream-encoded tree visit all leaf cells of the tree-structured grid in space-filling order (*SFC*



Cache-Oblivious Spacetree Traversals, Fig. 1 Recursively structured triangular mesh and corresponding binary tree with bitstream encoding. The illustrated iteration of a Sierpinski SFC defines a sequential order on the leaf cells (equivalent to a depth-first traversal of the tree) and classifies vertices into groups left (•) and right (□) of the curve. Vertices *A*, *B*, *C*, and *D* are visited in last-in-first-out order during the traversal



Cache-Oblivious Spacetree Traversals, Fig. 2 Replacement rules of a grammar (with six non-terminals $H_{o/n}, K_{o/n}, V_{o/n}$; illustration for $V_{o/n}$ is skipped) to construct the Sierpinski curve. The nonterminals classify for each vertex and edge of a cell, whether it is located left (•) or right (□) of the curve. The *old/new* labels indicate whether the grid cell adjacent to this edge occurs earlier/later in the Sierpinski order

traversal) sequentially. Cell-local data can be held in a stream. All other entities (in 2D: vertices and edges) are to be processed by all adjacent grid cells, i.e., are processed multiple times. For them, a storage scheme for intermediate values or repeated access is required. Figure 1 illustrates that the SFC induces a left/right classification of these entities. During SFC traversals, these entities are accessed in a LIFO fashion, such that intermediate values can be stored on two stacks (left vs. right). Local access rules may be inferred from an augmented grammar (as in Fig. 2). While the left/right classification determines the involved stack, the old/new classification determines whether entities are accessed for the first time during traversal (*first touch*) or have been processed by all adjacent cells (*last touch*). First and last touch trigger loading and storing the respective variables from/onto data streams. These *stack properties* hold for several space-filling curves.

SFC Traversals in the Cache-Oblivious Model

Memory access in SFC traversals is restricted to stack and stream accesses. Random access to memory is entirely avoided. Thus, the number of cache and memory accesses can be accurately described by the I/O or cache-oblivious model (see Cross-References). For the 2D case, assume that for a subtree with K grid cells, the number of edges on the boundary of the respective subgrid is $O(\sqrt{K})$ – which is always satisfied by regularly refined meshes. It can be shown that if we choose K such that all boundary elements fit into cache (size: M words), only boundary edges will cause non-compulsory cache misses [2]. For an entire SFC traversal, the number of cache misses is $O\left(\frac{N}{MB}\right)$, which is asymptotically optimal (B is the number of words per cache line). For adaptively refined meshes, it is an open question what kind of restrictions are posed on the mesh by the $O(\sqrt{K})$ criterion. While it is easy to construct degenerate grids that violate the condition, it is interesting whether grids that result from useful refinement processes (with physically motivated refinement criteria) tend to satisfy the $O(\sqrt{K})$ requirement.

Multiscale Depth-First and Breadth-First Traversals

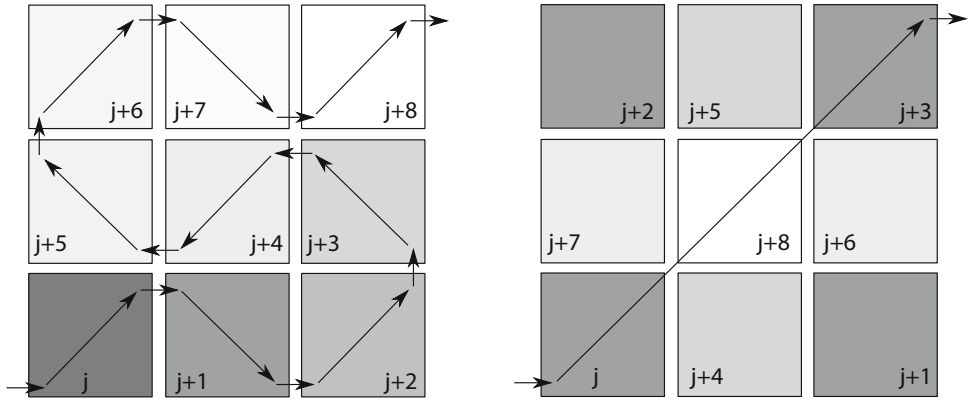
Multiscale traversals find applications in multiphysics simulations, where different physical models are used on the different levels, as well as in (additive) multigrid methods or data analysis, where the different grid levels hold data in different resolutions. If algorithms compute not only results on one level, it is typically sufficient to have two levels available throughout the traversal at one time. Multiscale algorithms then can be constructed recursively.

As variables exist on multiple levels, their (intermediate) access scheme is more elaborate than for a pure SFC traversal. A stack-based management is trivial if we apply one set of stacks per resolution level. Statements on cache obliviousness then have to be weakened, as the maximum number of stacks is not resolution independent anymore. They depend on the number of refinement levels. For depth-first and Peano, $2d + 2$ stacks have been proven to be sufficient (d the spatial dimension). Such a multiscale scheme remains cache oblivious independent of the refinement. It is unknown though doubtful whether schemes for other curves and depth-first traversal exist that allow accesses to unknowns using a resolution-independent number of stacks for arbitrary d.

Toward Parallel Tree Traversals

Data decomposition is the predominant parallelization paradigm in scientific computing: operations are executed on different sets of data in parallel. For distinct sets, the parallelization does not require any synchronization mechanism. For spacetree data structures, distinct pieces of data are given by spacetree cells that do not share a vertex. A parallel data traversal then can be rewritten as a mesh traversal where (in the parallel traversal phases) succeeding cells along the traversal do not share grid entities – a contradiction to connected space-filling curves. For three-partitioning in 2D, such a reordering allows a maximum concurrency level of four (see Fig. 3).

For breadth-first traversals, a reordering is trivial if we drop the space-filling curve ordering and instead reorder all leaves of one level to ob-



Cache-Oblivious Spacetree Traversals, Fig. 3 Peano space-filling curve with numbering on a level $n+1$ (*left*). The ordering then is rearranged to have a concurrency level of four (*right*) illustrated via different shades of gray

tain the highest concurrency level. For depth-first traversals, in contrast, the maximum concurrency level is strictly bounded, even if we drop the SFC paradigm. It remains one for all bipartitioning schemes, is at most 2^d for three-partitioning, and is at most $(\lfloor k/2 \rfloor)^d$ for k-partitioning.

Recursion Unrolling and Parallelism

As concurrency on the cell level is important for many applications, *recursion unrolling* becomes an important technique: (Regular) Subtrees or, more general, fragments along the space-filling curve's depth-first ordering are identified and locally replaced by a breadth-first traversal. This can be done without modifying any data access order on the surfaces of the cut-out curve fragment if the data load and store sequence is preserved along the fragment throughout the unrolling while only computations are reordered. Recursion unrolling then has an impact on the execution overhead as it eliminates recursive function calls and it improves the concurrency of the computations. It can be controlled by an on-the-fly analysis of the tree structure and thus seamlessly integrates into changing grids.

Other Tree-Structured Meshes and Space-Filling Curves

Traversals and stacks can team up only for certain space-filling curves and dimensions:

- In 2D, the stack property is apparently satisfied by all *connected* space-filling curves (for connected SFCs, two contiguous subdomains share an edge). SFC traversals are induced by a grammar that allows a left/right classification. However, no formal proof for this claim has been given yet.
- In 3D and all higher dimensions, the Peano curve is the only connected curve that has been found to satisfy all required properties [6].
- For octree meshes (in 3D), it is an open problem whether SFC traversals exist that can exploit stack properties. Hilbert curves and Lebesgue curves yield data access patterns with spatial and temporal locality but do not provide a stack property.

Applications

Practical applications comprise (parallel) numerical simulations on spacetree meshes that require adaptive refinement and coarsening in each time step or after each iteration [3,4,6]. SFC traversals on spacetrees induce sequential orders that may be exploited to create balanced partitions with favorable quality (due to SFCs being Hölder continuous). Using spacetrees as helper data structures, respective SFC orders can be defined also for entirely unstructured meshes or particle sets.

Space-filling curves are thus a frequently used tool to define parallel partitions.

Canonical Orders and Schnyder Realizers

Stephen Kobourov
Department of Computer Science, University of Arizona, Tucson, AZ, USA

Keywords

Canonical order; Planar graph drawing algorithms; Schnyder realizer

Years and Authors of Summarized Original Work

1990; de Fraysseix, Pach, Pollack
1990; Schnyder

Problem Definition

Every planar graph has a crossings-free drawing in the plane. Formally, a *straight-line drawing* of a planar graph G is one where each vertex is placed at a point in the plane and each edge is represented by a straight-line segment between the two corresponding points such that no two edges cross each other, except possibly at their common end points. A *straight-line grid drawing* of G is a straight-line drawing of G where each vertex of G is placed on an integer grid point. The area for such a drawing is defined by the minimum-area axis-aligned rectangle, or *bounding box*, that contains the drawing.

Wagner in 1936 [12], Fáry in 1948 [5], and Stein in 1951 [10] proved independently that every planar graph has a straight-line drawing. It was not until 1990 that the first algorithms for drawing a planar graph on a grid of polynomial area were developed. The concepts of canonical orders [4] and Schnyder realizers [9] were independently introduced for the purpose of efficiently computing straight-line grid drawings on the $O(n) \times O(n)$ grid. These two seemingly very different combinatorial structures turn out to be closely related and have since been used in many different problems and in many applications.

Key Results

We first describe canonical orders for planar graphs and a linear time procedure to construct them. Then we describe Schnyder realizers and a linear time procedure to compute them. Finally, we show how they can be used to compute straight-line grid drawings for planar graph.

Canonical Order

A planar graph G along with a planar embedding (a cyclic order of the neighbors for each vertex) is

called a *plane graph*. Given a graph G, testing for planarity and computing a planar embedding can be done in linear time [6]. Let G be a maximal plane graph with outer vertices u, v, w in counterclockwise order. Then a *canonical order* or *shelling order* of G is a total order of the vertices $v_1 = u, v_2 = v, v_3, \ldots, v_n = w$ that meets the following criteria for every $4 \leq i \leq n$:

(a) The subgraph $G_{i-1} \subseteq G$ induced by $v_1, v_2, \ldots, v_{i-1}$ is 2-connected, and the boundary of its outerface is a cycle C_{i-1} containing the edge (v_1, v_2).
(b) The vertex v_i is in the outerface of G_{i-1}, and its neighbors in G_{i-1} form a subinterval of the path $C_{i-1} - (u, v)$ with at least two vertices; see Fig. 1a–1b.

Every maximal plane graph G admits a canonical order; see Fig. 1a–1b. Moreover, computing such an order can be done in $O(n)$ time where n is the number of vertices in G. Before proving these claims, we need a simple lemma.

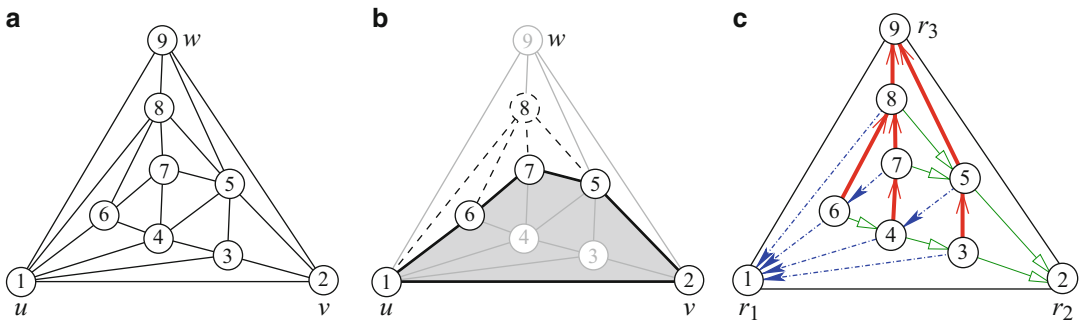
Lemma 1 *Let G be a maximal plane graph with canonical order $v_1, v_2 = v, v_3, \ldots, v_n$. Then for $i \in \{3, \ldots, n-1\}$, any separating pair $\{x, y\}$ of G_i is a chord of C_i.*

The proof of the lemma is simple. Recall that a *chord* of a cycle $\mathcal{C}$ is an edge between nonadjacent vertices of $\mathcal{C}$. Since G is a maximal plane graph and since each vertex $v_j, j \in \{n, \ldots, i+1\}$ is in the outerface of G_j, all the internal faces of G_i are triangles. Adding a dummy vertex d along with edges from d to each vertex on the outerface of G_i yields a maximal plane graph G'. Then G' is 3-connected, and for each separation pair $\{x, y\}$ of G, the set $T = \{x, y, d\}$ is a separating set of G' since $G = G' \setminus d$. The set T is a separating triangle in G' [1], and therefore, the edge (x, y) is a chord on C_i.

Theorem 1 *A canonical order of a maximal plane graph G can be computed in linear time.*

This is also easy to prove. If the number of vertices n in G is 3, then the canonical ordering of G is trivially defined. Let $n > 3$ and choose the vertices $v_n = w, v_{n-1}, \ldots, v_3$ in this order so that conditions (a)–(b) of the definition are satisfied. Since G is a maximal plane graph, G is 3-connected, and hence, $G_{n-1} = G \setminus w$ is 2-connected. Furthermore, the set of vertices adjacent to $v_n = w$ forms a cycle C_{n-1}, which is the boundary of the outerface of G_{n-1}. Thus, conditions (a)–(b) hold for $k = n$.

Assume by induction hypothesis that the vertices $v_n, v_{n-1}, \ldots, v_{i+1}, i \geq 3$ have been appropriately chosen. We now find the next vertex v_i. If we can find a vertex x on C_i, which is not an end vertex of a chord, then we can choose $v_k = x$. Indeed, if deleting x from G_i violated the 2-connectivity, then the cut vertex y of $G_i - x$, together with x, would form a separating pair for G_i, and hence, (x, y) would be a chord in G_i (from the lemma above). We now show that we can find a vertex v_i on C_i which is not an end vertex of a chord.



Canonical Orders and Schnyder Realizers, Fig. 1 (**a**) A canonical order of vertices for a maximal plane graph G, (**b**) insertion of v_8 in G_7, (**c**) a Schnyder realizer for G

If there is no chord of C_i, then we can choose any vertex of C_i other than u and v as v_k. Otherwise, label the vertices of $C_i - \{(u, v)\}$ by $p_1 = u, p_2, \ldots, p_t = v$ consecutively from u to v. By definition, any chord $(p_k, p_l), k < l$ must have $k < l-1$. We say that a chord $(p_k, p_l), k < l$, includes another chord $(p_{k'}, p_{l'}), k' < l'$, if $k \leq k' < l' \leq l$. Then take an inclusion-minimal chord (p_k, p_l) and any vertex p_j for $k < j < l$ can be chosen as v_i. Since v_i is not an end vertex of a chord for $C_{i-1}, G_{i-1} = G_i \setminus v_i$ remains 2-connected. Furthermore, due to the maximal planarity of G, the neighborhood of v_i on C_{i-1} forms a subinterval for $C_{i-1} - (u, v)$.

The algorithm, implicit in the above argument, can be implemented to run in linear time by keeping a variable for each vertex x on C_i, counting the number of chords x is incident to. After each vertex v_i is chosen, the variables for all its neighbors can be updated in $O(\deg(v_i))$ time. Summing over all vertices in the graph leads to an overall linear running time [2], and this concludes the proof of the theorem.

Schnyder Realizer

Let G be a maximal plane graph. A *Schnyder realizer* $\mathcal{S}$ of G is a partition of the internal edges of G into three sets T_1, T_2, and T_3 of directed edges, so that for each interior vertex v, the following conditions hold:

(a) v has outdegree exactly one in each of T_1, T_2, and T_3.
(b) The clockwise order of edges incident to v is outgoing T_1, incoming T_2, outgoing T_3, incoming T_1, outgoing T_2, and incoming T_3; see Fig. 1c.

Since a maximal plane graph has exactly $n - 3$ internal vertices and exactly $3n - 9$ internal edges, the three outgoing edges for each internal vertex imply that all the edges incident to the outer vertices are incoming. In fact, these two conditions imply that for each outer vertex $r_i, i = 1, 2, 3$, the incident edges belong to the same set, say T_i, where r_1, r_2, r_3 are in counterclockwise order around the outerface and each set of edges T_i forms a directed tree, spanning all the internal vertices and one external vertex r_i, oriented towards r_i [3]; see Fig. 1c. Call r_i the root of T_i for $i = 1, 2, 3$.

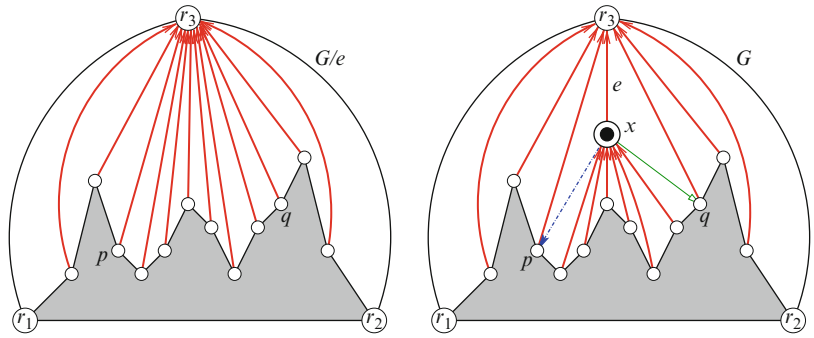
Note that the existence of a decomposition of a maximal planar graph G into three trees was proved earlier by Nash-Williams [8] and by Tutte [11]. Kampen [7] showed that these three trees can be oriented towards any three specified root vertices r_1, r_2, r_3 of G so that each vertex other than these roots has exactly one outgoing edges in each tree. Schnyder [9] proved the existence of the special decomposition defined above, along with a linear time algorithm to compute it. Before we describe the algorithm, we need to define the operation of *edge contraction*. Let G be a graph and $e = (x, y)$ be an edge of G. Then we denote by G/e, the simple graph obtained by deleting x, y and all their incident edges from G, adding a new vertex z and inserting an edge (z, v) for each vertex v that is adjacent to either x or y in G. Note that for a maximal plane graph G, contracting an edge $e = (x, y)$ yields a maximal plane graph if and only if there are exactly two common neighbors of x and y. Two end vertices of an edge $e = (x, y)$ have exactly two common neighbors if and only if the edge e is not on the boundary of a separating triangle.

Lemma 2 *Let G be a maximal plane graph with at least 4 vertices, where u is an outer vertex of G. Then there exists an internal vertex v of G such that (u, v) is an edge in G and vertices u and v have exactly two common neighbors.*

This is easy to prove. If G has exactly 4 vertices, then it is K_4 and the internal vertex of G has exactly two common neighbors. Consider graph G with more than 4 vertices. If u is not on the boundary of any separating triangle, then taking any neighbor of u as v is sufficient. Else, if u is on the boundary of a separating triangle Δ, we can find a desired vertex v by induction on the subgraph of G inside Δ.

Theorem 2 *A Schnyder realizer of a maximal plane graph G can be computed in linear time.*

The proof of the theorem is by induction. If G has exactly 3 vertices, its Schnyder realizer is computed trivially. Consider graph G with



Canonical Orders and Schnyder Realizers, Fig. 2 Computing a Schnyder realizer of a maximal plane graph G from that of G/e

more than 3 vertices. Let r_1, r_2, and r_3 be the three outer vertices in counterclockwise order. Then by the above lemma, there is an internal vertex x in G and edge $e = (r_3, x)$ so that r_3 and x have exactly two common neighbors. Let $G' = G/e$. Then by the induction hypothesis, G' has a Schnyder realizer with the three trees T_1, T_2, and T_3, rooted at r_1, r_2, and r_3. We now modify this to find a Schnyder realizer for G. The orientation and partitioning of all the edges not incident to x remain unchanged from G/e. Among the edges incident to x, we add e to T_3, oriented towards r_3. We add the two edges that are just counterclockwise of e and just clockwise of e in the ordering around x, to T_1 and T_2, respectively, both oriented away from x. Finally we put all the remaining edges in T_3, oriented towards x; see Fig. 2. It is now straightforward to check that these assignment of edges to the trees satisfy the two conditions. The algorithm implicit in the proof can be implemented in linear time, given the edge contraction sequence. The edge contraction sequence itself can be computed in linear time by taking the reverse order of a canonical order of the vertices and in every step contracting the edge between r_3 and the current vertex in this order.

Drawing Planar Graphs

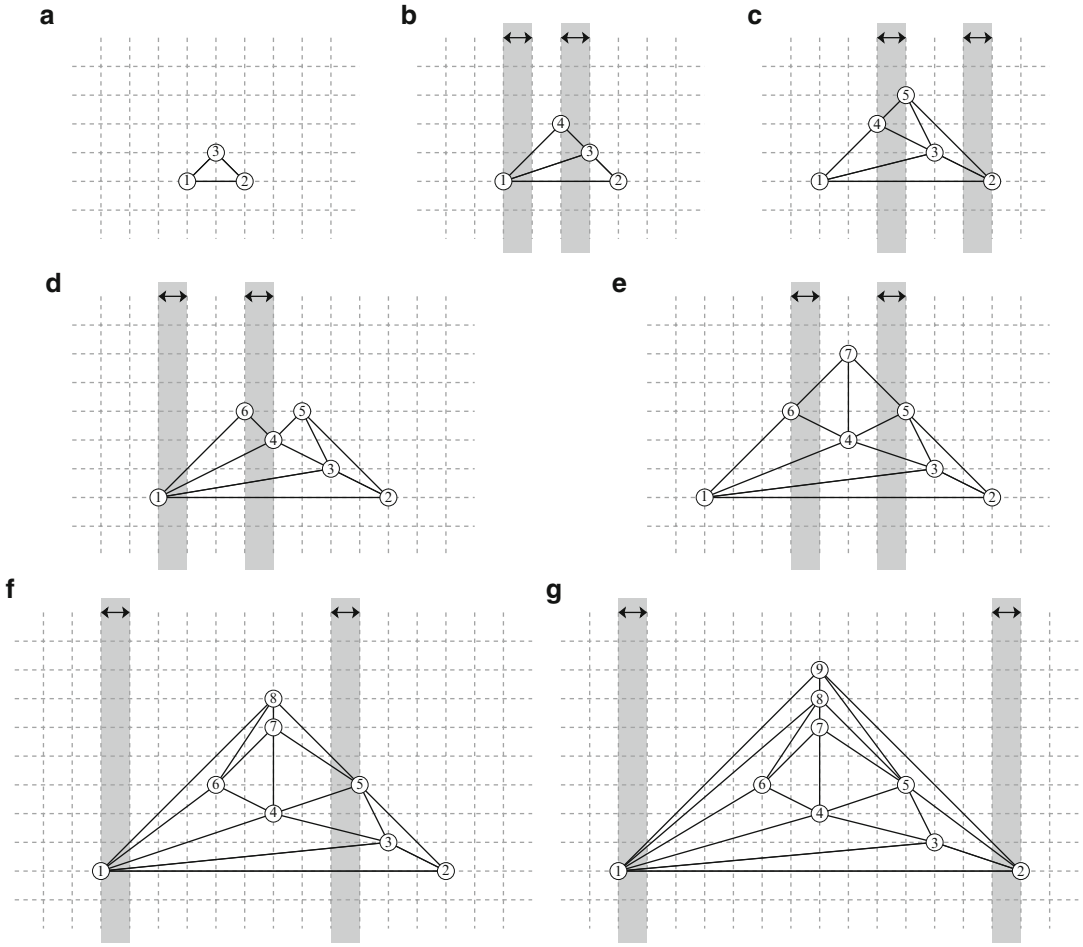
We now show how canonical orders and Schnyder realizers can be used to compute straight-line grid drawings of maximal plane graphs.

Theorem 3 *Let G be a maximal plane graph with n vertices. A straight-line grid drawing of G on the $(2n-4) \times (n-2)$ grid can be computed in linear time.*

This is a constructive proof. Let $\mathcal{O} = v_1, \ldots, v_n$ be a canonical order of G, G_i, the subgraph of G induced by the vertices $v_1, \ldots, v_i$, and C_i the boundary of the outerface of $G_i, i = 3, 4, \ldots, n$. We incrementally obtain straight-line drawing Γ_i of G_i for $i = 3, 4, \ldots, n$. We also maintain the following invariants for Γ_i:

(i) The x-coordinates of the vertices on the path $C_i \setminus \{(v_1, v_2)\}$ are monotonically increasing as we go from v_1 to v_2.
(ii) Each edge of the path $C_i - \{(v_1, v_2)\}$ is drawn with slope 1 or -1.

We begin with G_3, giving v_1, v_2, and v_3 coordinates $(0, 0)$, $(2, 0)$, and $(1, 1)$; the drawing Γ_3 satisfies conditions (i)–(ii); see Fig. 3a. Suppose the drawing for Γ_{i-1} for some $i > 3$ has already been computed; we now show how to obtain Γ_i. We need to add vertex v_i and its incident edges in G_i to Γ_{i-1}. Let $w_1 = v_1, \ldots, w_t = v_2$ be the vertices on $C_{i-1} \setminus \{(v_1, v_2)\}$ in this order from v_1 to v_2. By the property of canonical orders, v_i is adjacent to a subinterval of this path. Let $w_l, \ldots, w_r, 1 \le l < r \le t$, be the vertices adjacent to v_i, in this order. We want to place v_i at the intersection point p between the straight line from w_l with slope 1 and the straight line from w_r with slope -1. Note that by condition (ii),

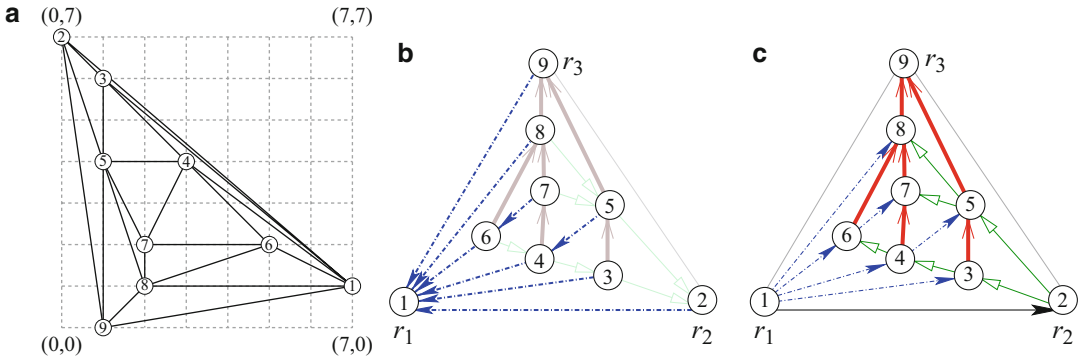


Canonical Orders and Schnyder Realizers, Fig. 3 Illustration for the straight-line drawing algorithm using canonical order

the two vertices w_l and w_r are at even Manhattan distance in Γ, and hence, point p is a grid point. However, if we place v_i at p, then the edges $v_i w_l$ and $v_i w_r$ might overlap with the edges $w_l w_{l+1}$ and $w_{r-1} w_r$, since they are drawn with slopes 1 or -1. We thus shift all the vertices to the left of w_l in Γ_{i-1} (including w_l) one unit to the left at all the vertices to the right of w_r in Γ_{i-1} (including w_r) one unit to the right; see Fig. 3.

Consider a rooted tree T, spanning all the internal vertex of G along with one external vertex v_n, where v_n is the root of T and for each internal vertex x, the parent of x is the highest numbered successor in G. (Later we see that T can be one of the three trees in a Schnyder realizer of G.) For any internal vertex x of G, denote by $U(x)$ the set of vertices that are in the subtree of T rooted at v (including v itself). Then the shifting of the vertices above can be obtained by shifting the vertices in $U(w_i), i = 1, \ldots, l$ one unit to the left and the vertices in $U(w_i), i = r, \ldots, t$ one unit to the right. After these shifts, v_i can be safely placed at the intersection of the line with slope 1 from w_l and the line with slope -1 from w_r. Note that this drawing satisfies conditions (i)–(ii). This algorithm can be implemented in linear time, even though the efficient vertex shifting requires careful relative offset computation [2].

The next theorem shows how Schnyder realizers can be used to compute a straight-line grid



Canonical Orders and Schnyder Realizers, Fig. 4 (**a**) A straight-line drawing for the graph in Fig. 1 using Schnyder realizer, (**b**)–(**c**) computation of a canonical order from a Schnyder realizer

drawing of a plane graph. Let T_1, T_2, and T_3 be the trees in a Schnyder realizer of G, rooted at outer vertices r_1, r_2, and r_3. Since each internal vertex v of G has exactly one outgoing edge in each of the trees, there is a directed path $P_i(v)$ in each of the three trees T_i from v to r_i. These three paths $P_1(v), P_2(v)$, and $P_3(v)$ are vertex disjoint except for v, and they define three regions $R_1(v), R_2(v)$, and $R_3(v)$ for v. Here $R_i(v)$ is the region between the two paths $P_{i-1}(v)$ and $P_{i+1}(v)$, where the addition and subtraction are modulo 3. Let $\eta_i(v)$ denote the number of vertices in $R_i(v) \setminus P_{i-1}(v)$, where $i = 1, 2, 3$ and the subtraction is modulo 3. Extend these definitions to the outer vertices as follows: $\eta_i(r_i) = n - 2, \eta_{i+1}(r_i) = 1, \eta_{i-1}(r_i) = 0$.

Theorem 4 *The coordinates* $((\eta_1(v), \eta_2(v)))$ *for each vertex* v *in* G *give a straight-line drawing* Γ *of* G *on a grid of size* $(n-2) \times (n-2)$.

Place each vertex v at the point with coordinates $(\eta_1(v), \eta_2(v)$, and $\eta_3(v))$. Since $\eta(v) = \eta_1(v) + \eta_2(v) + \eta_3(v)$ counts the number of vertices in all the three regions of v, each vertex of G except v is counted exactly once in $\eta(v)$. Thus, $\eta_1(v) + \eta_2(v) + \eta_3(v) = n - 1$ for each vertex v. Thus, the drawing Γ' obtained by these coordinates $(\eta_1(v), \eta_2(v), \eta_3(v))$ lies on the plane $x + y + z = n - 1$. Furthermore, the drawing does not induce any edge crossings; see [9]. Thus, Γ' is a straight-line drawing of G on the plane $x + y + z = n - 1$. Then Γ is just a projection of Γ' on the plane $z = 0$ and hence is planar. Since each coordinate in the drawing is bounded between 0 and $n - 1$, the area is at most $(n-2) \times (n-2)$; see Fig. 4a.

Equivalency of Canonical Orders and Schnyder Realizers

Here we show that canonical orders and Schnyder realizers are in fact equivalent in the sense that a canonical order of a graph defines a Schnyder realizer and vice versa [3].

Lemma 3 *A canonical order for a maximal plane graph* G *defines a unique Schnyder realizer where the three parents for each vertex* v *of* G *are its leftmost predecessor, its rightmost predecessor, and its highest-labeled successor.*

See Fig. 1a, 1c for a canonical order $\mathcal{O}$ and the corresponding Schnyder realizer $\mathcal{S}$ defined by $\mathcal{O}$ for a maximal plane graph. One can easily verify that this definition of $\mathcal{S}$ satisfies the two conditions for each internal vertex for a maximal plane graph. A canonical order $\mathcal{O}$ and the Schnyder realizer $\mathcal{S}$ obtained from $\mathcal{O}$ for a maximal plane graph are said to be *compatible*.

We now describe two ways to obtain a canonical order from a Schnyder realizer $\mathcal{S}$. In both cases, we obtain a canonical order which is compatible with $\mathcal{S}$.

Lemma 4 *Let* G *be a maximal plane graph with outer vertices* r_1, r_2, *and* r_3 *in counterclockwise order and let* T_1, T_2, *and* T_3 *be the three trees in a Schnyder realizer of* G *rooted at* r_1, r_2, *and* r_3. *Then a compatible canonical order of* G *can be obtained as follows:*

1. *By taking the counterclockwise depth-first traversal order of the vertices in the graph* $T_1 \cup \{(r_2, r_1), (r_3, r_1)\}$*; see Fig. 4b.*
2. *By taking the topological order of the directed acyclic graph* $T_1^{-1} \cup T_2^{-1} \cup T_3$*, where* $T_i^{-1}, i = 1, 2$ *is the Schnyder tree* T_i *with reversed edge directions; see Fig. 4c.*

It is not difficult to show that the directed graph $T_1^{-1} \cup T_2^{-1} \cup T_3$ is in fact acyclic [3, 9]. Then it is easy to verify that the canonical orders obtained from a Schnyder realizer $\mathcal{S}$ are compatible with $\mathcal{S}$; i.e., defining a Schnyder realizer from them by Lemma 3 produces the original Schnyder realizer $\mathcal{S}$.

1978; Lamport

Problem Definition

This entry covers several problems, related with each other. The first problem is concerned with maintaining the causal relationship between events in a distributed system. The motivation is to allow distributed systems to reason about time with no explicit access to a physical clock. Lamport [5] defines a notion of logical clocks that can be used to generate timestamps that are consistent with causal relationships (in a conservative sense). He illustrates logical clocks (also called Lamport clocks) with a distributed mutual exclusion algorithm. The algorithm turns out to be an illustration of state-machine replication. Basically, the algorithm generates a total ordering of the events that is consistent across processes. With all processes starting in the same state, they evolve consistently with no need for further synchronization.

System Model

The system consists of a collection of processes. Each process consists of a sequence of events.

Processes have no shared memory and communicate only by exchanging messages. The exact definition of an event depends on the system actually considered and the abstraction level at which it is considered. One distinguishes between three kinds of events: internal (affects only the process executing it), send, and receive events.

Causal Order

Causal order is concerned with the problem that the occurrence of some events may affect other events in the future, while other events may not influence each other. With processes that do not measure time, the notion of simultaneity must be redefined in such a way that simultaneous events are those that cannot possibly affect each other. For this reason, it is necessary to define what it means for an event to happen before another event.

The following "happened before" relation is defined as an irreflexive partial ordering on the set of all events in the system [5].

Definition 1 The relation "$\rightarrow$" on the set of events of a system is the smallest relation satisfying the following three conditions:

1. If a and b are events in the same process, and a comes before b, then $a \rightarrow b$.
2. If a is the sending of a message by one process and b is the receipt of the same message by another process, then $a \rightarrow b$.
3. If $a \rightarrow b$ and $b \rightarrow c$ then $a \rightarrow c$.

Definition 2 Two distinct events a and b are said to be *concurrent* if $a \not\rightarrow b$ and $b \not\rightarrow a$.

Logical Clocks

Lamport also defines clocks in a generic way, as follows.

Definition 3 A clock C_i for a process p_i is a function which assigns a number $C_i\langle a\rangle$ to any event a on that process. The entire system of clocks is represented by the function C which assigns to any event b the number $C\langle b\rangle$, where $C\langle b\rangle = C_j\langle b\rangle$ if b is an event in process p_j. The system of clocks must meet the following *clock condition*.

- For any events a and b, if $a \rightarrow b$ then $C\langle a\rangle < C\langle b\rangle$.

Assuming that there is some arbitrary total ordering $\prec$ of the processes (e.g., unique names ordered lexicographically), Lamport extends the "happened before" relation and defines a relation "$\Rightarrow$" as a total ordering on the set of all events in the system.

Definition 4 The total order relation $\Rightarrow$ is defined as follows. If a is an event in process p_i and b is an event in process p_j, then $a \Rightarrow b$ if and only if either one of the following conditions is satisfied.

1. $C_i\langle a\rangle < C_j\langle b\rangle$
2. $C_i\langle a\rangle = C_j\langle b\rangle$ and $p_i \prec p_j$.

In fact, Lamport [5] also discusses an adaptation of these conditions to physical clocks, and provides a simple clock synchronization algorithm. This is however not discussed further here.

State Machine Replication

The problem of state-machine replication was originally presented by Lamport [4, 5]. In a later review of the problem, Schneider [8] defines the problem as follows (formulation adapted to the context of the entry).

Problem 1 (State-machine replication)
INPUT: A set of concurrent requests.
OUTPUT: A sequence of the requests processed at each process, such that:

1. *Replica coordination*: all replicas receive and process the same sequence of requests.
2. *Agreement*: every non-faulty state-machine replica receives every request.
3. *Order*: every non-faulty state-machine replica processes the requests it receives in the same relative order.

In his paper on logical time [5] and discussed in this entry, Lamport does not consider failures. He does however consider them in another paper on

state-machine replication for fault-tolerance [4], which he published the same year.

Key Results

Lamport [5] proposed many key results related to the problems described above.

Logical Clocks

Lamport [5] defines an elegant system of logical clocks that meets the clock condition presented in Definition 3. The clock of a process p_i is represented by a register C_i, such that $C_i\langle a\rangle$ is the value held by C_i when a occurs. Each message m carries a timestamp T_m, which equals the time at which m was sent. The clock system can be described in terms of the following rules.

1. Each process p_i increments C_i between any two successive events.
2. If event a is the sending of a message m by process p_i, then the message m contains a timestamp $T_m = C_i\langle a\rangle$.
3. Upon receiving a message m, process p_j sets C_j to $\max(C_j, T_m + 1)$ (before actually executing the receive event).

State Machine Replication

As an illustration for the use of logical clocks, Lamport [5] describes a mutual exclusion algorithm. He also mentions that the approach is more general and discusses the concept of state-machine replication that he refines in a different paper [4].

The mutual exclusion algorithm is based on the idea that every process maintains a copy of a request queue, and the algorithm ensures that the copies remain consistent across the processes. This is done by generating a total ordering of the request messages, according to timestamps obtained from the logical clocks of the sending processes.

The algorithm described works under the following simplifying assumptions:

- Every message that is sent is eventually received.
- For any processes p_i and p_j, messages from p_i to p_j are received in the same order as they are sent.
- A process can send messages directly to every other processes.

The algorithm requires that each process maintains its own request queue, and ensures that the request queues of different processes always remain consistent. Initially, request queues contain a single message $(T_0, p_0, \mathit{request})$, where p_0 is the process that holds the resource and the timestamp T_0 is smaller than the initial value of every clock. Then, the algorithm works as follows.

1. When a process p_i requests the resource, it sends a request message $(T_m, p_i, \mathit{request})$ to all other processes and puts the message in its request queue.
2. When a process p_j receives a message $(T_m, p_i, \mathit{request})$, it puts that message in its request queue and sends an acknowledgment $(T_{m'}, p_j, \mathit{ack})$ to p_i.
3. When a process p_i releases the resource, it removes all instances of messages $(-, p_i, \mathit{request})$ from its queue, and sends a message $(T_{m'}, p_i, \mathit{release})$ to all other processes.
4. When a process p_j receives a release message from process p_i, it removes all instances of messages $(-, p_i, \mathit{request})$ from its queue, and sends a timestamped acknowledgment to p_i.
5. Messages in the queue are sorted according to the total order relation $\Rightarrow$ of Definition 4. A process p_i can use the resource when (a) a message $(T_m, p_i, \mathit{request})$ appears first in the queue, and (b) p_i has received from all other processes a message with a timestamp greater than T_m (or equal from any process p_j where $p_i \prec p_j$).

Applications

A brief overview of some applications of the concepts presented in this entry has been provided.

First of all, the notion of causality in distributed systems (or lack thereof) leads

to a famous problem in which a user may potentially see an answer before she can see the relevant question. The time-independent characterization of causality of Lamport lead to the development of efficient solutions to enforce causal order in communication. In his later work, Lamport [3] gives a more general definition to the "happened before" relation, so that a system can be characterized at various abstraction levels.

About a decade after Lamport's work on logical clock, Fidge [2] and Mattern [6] have developed the notion of vector clocks, with the advantage of a complete characterization of causal order. Indeed, the clock condition enforced by Lamport's logical clocks is only a one-way implication (see Definition 3). In contrast, vector clocks extend Lamport clocks by ensuring that, for any events a and b, if $C\langle a\rangle < C\langle b\rangle$, then $a \rightarrow b$. This is for instance useful for choosing a set of checkpoints after recovery of a distributed system, for distributed debugging, or for deadlock detection. Other extensions of logical time have been proposed, that have been surveyed by Raynal and Singhal [7].

The state-machine replication also has many applications. In particular, it is often used for replicating a distributed service over several processors, so that the service can continue to operate even in spite of the failure of some of the processors. State-machine replication ensures that the different replicas remain consistent.

The mutual exclusion algorithm proposed by Lamport [5] and described in this entry is actually one of the first known solution to the *atomic broadcast* problem (see relevant entry). Briefly, in a system with several processes that broadcast messages concurrently, the problem requires that all processes deliver (and process) all message in the same order. Nowadays, there exist several approaches to solving the problem. Surveying many algorithms, Défago et al. [1] have classified Lamport's algorithm as *communication history* algorithms, because of the way the ordering is generated.

Problem Definition

This problem concerns the query complexity of proper learning in a widely studied learning model: exact learning with membership and equivalence queries. Hellerstein et al. [10] showed that the number of (polynomially sized) queries required to learn a concept class in this model is closely related to the size of certain certificates associated with that class. This relationship gives a combinatorial characterization of the concept classes that can be learned with polynomial query complexity. Similar results were shown by Hegedüs based on the work of Moshkov [8, 13].

The Exact Learning Model

Concepts are functions $f : X \to \{0, 1\}$ where X is an arbitrary domain. In exact learning, there is a hidden concept f from a known class of concepts C, and the problem is to exactly identify the concept f.

Algorithms in the exact learning model obtain information about f, the target concept, by querying two oracles, a membership oracle and an equivalence oracle. A membership oracle for f answers membership queries (i.e., point evaluation queries), which are of the form "What is $f(x)$?" where $x \in X$. The membership oracle responds with the value $f(x)$. An equivalence oracle for f answers equivalence queries, which are of the form "Is $h \equiv f$?" where h is a representation of a concept defined on the domain X. Representation h is called a hypothesis. The equivalence oracle responds "yes" if $h(x) = f(x)$ for all $x \in X$. Otherwise, it returns a counterexample, a value $x \in X$ such that $f(x) \neq h(x)$.

The exact learning model is due to Angluin [2]. Angluin viewed the combination of membership and equivalence oracles as constituting a "minimally adequate teacher." Equivalence queries can be simulated both in Valiant's well-known PAC model, and in the online mistake-bound learning model.

Let R be a set of representations of concepts, and let C_R be the associated set of concepts. For example, if R were a set of DNF formulas, then C_R would be the set of Boolean functions (concepts) represented by those formulas. An exact learning algorithm is said to learn R if, given access to membership and equivalence oracles for any f in C_R, it ends by outputting a hypothesis h that is a representation of f.

Query Complexity of Exact Learning

There are two aspects to the complexity of exact learning: query complexity and computational complexity. The results of Hellerstein et al. concern query complexity.

The query complexity of an exact learning algorithm measures the number of queries it asks and the size of the hypotheses it uses in those queries (and as the final output). We assume that each representation class R has an associated size function that assigns a nonnegative number to each $r \in R$. The size of a concept c with respect to R, denoted by $|c|_R$, is the size of the smallest representation of c in R; if $c \notin C_R$, $|c|_R = \infty$. Ideally, the query complexity of an exact learning algorithm will be polynomial in the size of the target and other relevant parameters of the problem.

Many exact learning results concern learning classes of representations of Boolean functions. Algorithms for learning such classes R are said to have polynomial query complexity if the number of hypotheses used, and the size of those hypotheses, is bounded by some polynomial $p(m, n)$, where n is the number of variables on which the target f is defined, and $m = |f|_R$. We assume that algorithms for learning Boolean representation classes are given the value of n as input.

Since the number and size of queries used by an algorithm are a lower bound on the time taken by that algorithm, query complexity lower bounds imply computational complexity lower bounds.

Improper Learning and the Halving Algorithm

An algorithm for learning a representation class R is said to be proper if all hypotheses used in its equivalence queries are from R, and it outputs a representation from R. Otherwise, the algorithm is said to be improper.

When C_R is a finite concept class, defined on a finite domain X, a simple, generic algorithm called the halving algorithm can be used to exactly learn R using $\log |C_R|$ equivalence queries and no membership queries. The halving algorithm is based on the following idea. For any $V \subseteq C_R$, define the majority hypothesis MAJ_V to be the concept defined on X such that for all $x \in X$, $\mathrm{MAJ}_V(x) = 1$ if $g(x) = 1$ for more than half the concepts g in V, and $\mathrm{MAJ}_V(x) = 0$ otherwise. The halving algorithm begins by setting $V = C_R$. It then repeats the following:

1. Ask an equivalence query with the hypothesis MAJ_V.
2. If the answer is yes, then output MAJ_V.
3. Otherwise, the answer is a counterexample x. Remove from V all g such that $g(x) = \mathrm{MAJ}_V(x)$.

Each counterexample eliminates the majority of the elements currently in V, so the size of V is reduced by a factor of at least 2 with each equivalence query. It follows that the algorithm cannot ask more than $\log_2 |C_R|$ queries.

The halving algorithm cannot necessarily be implemented as a proper algorithm, since the majority of hypotheses may not be representable in C_R. Even when they are representable in C_R, the representations may be exponentially larger than the target concept.

Proper Learning and Certificates

In the exact model, the query complexity of proper learning is closely related to the size of certain certificates.

For any concept f defined on a domain X, a certificate that f has property P is a subset $S \subseteq X$ such that for all concepts g defined on X, if $g(x) = f(x)$ for all $x \in S$, then g has property P. The size of the certificate S is $|S|$, the number of elements in it.

We are interested in properties of the form "g is not a member of the concept class C." To take a simple example, let D be the class of constant-valued n-variable Boolean functions, i.e., D consists of the two functions $f_1(x_1, \ldots, x_n) = 1$ and $f_2(x_1, \ldots, x_n) = 0$. Then if g is an n-variable Boolean function that is not a member of D, a certificate that g is not in C could be just a pair $a \in \{0,1\}^n$ and $b \in \{0,1\}^n$ such that $g(a) = 1$ and $g(b) = 0$.

For C a class of concepts defined on X define the exclusion dimension of C to be the maximum, over all concepts g not in C, of the size of the smallest certificate that g is not in C. Let $XD(C)$ denote the exclusion dimension of C. In the above example, $XD(C) = 2$.

Key Results

Theorem 1 *Let R be a finite class of representations. Then there exists a proper learning algorithm in the exact model that learns C using at most $XD(C) \log |C|$ queries. Further, any such algorithm for C must make at least $XD(C)$ queries.*

Independently, Hegedüs proved a theorem that is essentially identical to the above theorem. The algorithm in the theorem is a variant of the ordinary halving algorithm. As noted by Hegedüs, a similar result to Theorem 1 was proved earlier by Moshkov, and Moshkov's techniques can be used to improve the upper bound by a factor of $\frac{2}{\log_2 XD(C)}$.

An extension of the above result characterizes the representation classes that have polynomial query complexity. The following theorem presents the extended result as it applies to representation classes of Boolean functions.

Theorem 2 *Let R be a class of representations of Boolean functions. Then there exists a proper*

learning algorithm in the exact model that learns R with polynomial query complexity iff there exists a polynomial $p(m,n)$ such that for all $m,n > 0$, and all n-variable Boolean functions g, if $|g|_R > m$, then there exists a certificate of size at most $p(m,n)$ proving that $|g|_R > m$.

A concept class having certificates of the type specified in this theorem is said to have polynomial certificates.

The algorithm in the above theorem does not run in polynomial time. Hellerstein et al. give a more complex algorithm that runs in polynomial time using a $\Sigma_4{}^P$ oracle, provided R satisfies certain technical conditions. Köbler and Lindner subsequently gave an algorithm using a $\Sigma_2{}^P$ oracle [12].

Theorem 2 and its generalization give a technique for proving bounds on proper learning in the exact model. Proving upper bounds on the size of the appropriate certificates yields upper bounds on query complexity. Proving lower bounds on the size of appropriate certificates yields lower bounds on query complexity and hence also on time complexity. Moreover, unlike many computational hardness results in learning, computational hardness results achieved in this way do not rely on any unproven complexity theoretic or cryptographic hardness assumptions.

One of the most widely studied problems in computational learning theory has been the question of whether DNF formulas can be learned in polynomial time in common learning models. The following result on learning DNF formulas was proved using Theorem 2, by bounding the size of the relevant certificates.

Theorem 3 *There is a proper algorithm that learns DNF formulas in the exact model with query complexity bounded above by a polynomial $p(m,r,n)$, where m is the size of the smallest DNF representing the target function f, n is the number of variables on which f is defined, and r is the size of the smallest CNF representing f.*

The size of a DNF is the number of its terms; the size of a CNF is the number of its clauses. The above theorem does not imply polynomial-time learnability of arbitrary DNF formulas, since the running time of the algorithm depends not just on the size of the smallest DNF representing the target but also on the size of the smallest CNF.

Building on results of Alekhnovich et al., Feldman showed that if NP $\neq$ RP, DNF formulas cannot be properly learned in polynomial time in the PAC model augmented with membership queries. The same negative result then follows immediately for the exact model [1, 7]. Hellerstein and Raghavan used certificate size lower bounds and Theorem 1 to prove that DNF formulas cannot be learned by a proper exact algorithm with polynomial query complexity, if the algorithm is restricted to using DNF hypotheses that are only slightly larger than the target [9].

The main results of Hellerstein et al. apply to learning with membership and equivalence queries. Hellerstein et al. also considered the model of exact learning with membership queries alone and showed that in this model, a projection-closed Boolean function class is polynomial query learnable iff it has polynomial teaching dimension. Teaching dimension was previously defined by Goldman and Kearns. Hegedüs defined the extended teaching dimension and showed that all classes are polynomially query learnable with membership queries alone iff they have polynomial extended teaching dimension.

Balcázar et al. introduced the general dimension, which generalizes the combinatorial dimensions discussed above [5]. It can be used to characterize polynomial query learnability for a wide range of different queries. Balcan and Hanneke have investigated related combinatorial dimensions in the active learning setting [4].

Open Problems

It remains open whether DNF formulas can be learned in polynomial time in the exact model, using hypotheses that are not DNF formulas.

Feldman's results show the computational hardness of proper learning of DNF in the exact learning model based on complexity-theoretic assumptions. However, it is unclear whether query complexity is also a barrier to efficient learning of DNF formulas. It is still open whether the class of DNF formulas has

polynomial certificates; showing they do not have polynomial certificates would give a hardness result for proper learning of DNF based only on query complexity, with no complexity-theoretic assumptions (and without the hypothesis-size restrictions used by Hellerstein and Raghavan). DNF formulas do have certain sub-exponential certificates [11].

It is open whether decision trees have polynomial certificates.

Certificate techniques are used to prove lower bounds on learning when we restrict the type of hypotheses used by the learning algorithm. These types of results are called representation dependent, since they depend on the restriction of the representations used as hypotheses. Although there are some techniques for proving representation-independent hardness results, there is a need for more powerful techniques.

Problem Definition

One of the major problems facing wireless networks is the capacity reduction due to interference among multiple simultaneous transmissions. In wireless mesh networks providing mesh

routers with multiple-radios can greatly alleviate this problem. With multiple-radios, nodes can transmit and receive simultaneously or can transmit on multiple channels simultaneously. However, due to the limited number of channels available the interference cannot be completely eliminated and in addition careful channel assignment must be carried out to mitigate the effects of interference. Channel assignment and routing are inter-dependent. This is because channel assignments have an impact on link bandwidths and the extent to which link transmissions interfere. This clearly impacts the routing used to satisfy traffic demands. In the same way traffic routing determines the traffic flows for each link which certainly affects channel assignments. Channel assignments need to be done in a way such that the communication requirements for the links can be met. Thus, the problem of throughput maximization of wireless mesh networks must be solved through channel assignment, routing, and scheduling.

Formally, given a wireless mesh backbone network modeled as a graph (V, E): The node $t \in V$ represents the wired network. An edge $e = (u, v)$ exists in E iff u and v are within *communication range* R_T. The set $V_G \subseteq V$ represents the set of gateway nodes. The system has a total of K channels. Each node $u \in V$ has $I(u)$ network interface cards, and has an aggregated demand $l(u)$ from its associated users. For each edge e the set $I(e) \subset E$ denotes the set of edges that it interferes with. A pair of nodes that use the same channel and are within *interference range* $R_I x$ may interfere with each other's communication, even if they cannot directly communicate. Node pairs using different channels can transmit packets simultaneously without interference. The problem is to maximize λ where at least $\lambda l(u)$ amount of throughput can be routed from each node u to the Internet (represented by a node t). The $\lambda l(u)$ throughput for each node u is achieved by computing $g(1)$ a network flow that associates with each edge $e = (u, v)$ values $f(e(i)), 1 \leq i \leq K$ where $f(e(i))$ is the rate at which traffic is transmitted by node u for node v on channel i; (2) a feasible channel assignment $F(u)$ ($F(u)$ is an ordered set where the ith interface of u operates on the ith channel in $F(u)$) such that, whenever $f(e(i)) > 0, \ i \in F(u) \cap F(v)$; (3) a *feasible* schedule S that decides the set of edge channel pair (e, i) (edge e using channel, i.e., $f(e(i)) > 0$ scheduled at time slot τ, for $\tau = 1, 2, \ldots, T$ where T is the period of the schedule. A schedule is feasible if the edges of no two edge pairs $(e_1, i), (e_2, i)$ scheduled in the same time slot for a common channel i interfere with each other ($e_1 \notin I(e_2)$ and $e_2 \notin I(e_1)$). Thus, a feasible schedule is also referred to as an interference free edge schedule. An indicator variable $X_{e,i,\tau}, e \in E, i \in F(e), \tau \geq 1$ is used. It is assigned 1 if and only if link e is active in slot τ on channel i. Note that $1/T \sum_{1 \leq \tau \leq T} X_{e,i,\tau} c(e) = f(e(i))$. This is because communication at rate $c(e)$ happens in every slot that link e is active on channel i and since $f(e(i))$ is the average rate attained on link e for channel i. This implies $1/T \sum_{1 \leq \tau \leq T} X_{e,i,\tau} = \frac{f(e(i))}{c(e)}$.

Joint Routing, Channel Assignment, and Link Scheduling Algorithm

Even the interference free edge scheduling subproblem given the edge flows is NP-hard [5]. An approximation algorithm called RCL for the joint routing, channel assignment, and link scheduling problem has been developed. The algorithm performs the following steps in the given order:

1. **Solve LP:** First optimally solve a LP relaxation of the problem. This results in a flow on the flow graph along with a not necessarily feasible channel assignment for the node radios. Specifically, a node may be assigned more channels than the number of its radios. However, this channel assignment is "optimal" in terms of ensuring that the interference for each channel is minimum. This step also yields a lower bound on the λ value which is used in establishing the worst case performance guarantee of the overall algorithm.

2. **Channel Assignment:** This step presents a channel assignment algorithm which is used to adjust the flow on the flow graph (routing changes) to ensure a feasible channel assignment. This flow adjustment also strives to keep the increase in interference for each channel to a minimum.
3. **Interference Free Link Scheduling:** This step obtains an interference free link schedule for the edge flows corresponding to the flow on the flow graph.

Each of these steps is described in the following subsections.

A Linear Programming-Based Routing Algorithm

A linear program LP (1) to find a flow that maximizes λ is given below:

$$\max \lambda \tag{1}$$

Subject to

$$\lambda l(v) + \sum_{e=(u,v)\in E} \sum_{i=1}^{K} f(e(i)) = \sum_{e=(v,u)\in E} \sum_{i=1}^{K} f(e(i)) \,, \forall v \in V - V_G \tag{2}$$

$$f(e(i)) \leq c(e) \,, \quad \forall e \in E \tag{3}$$

$$\sum_{1\leq i\leq K} \left(\sum_{e=(u,v)\in E} \frac{f(e(i))}{c(e)} + \sum_{e=(v,u)\in E} \frac{f(e(i))}{c(e)} \right) \leq I(v) \,, v \in V \tag{4}$$

$$\frac{f(e(i))}{c(e)} + \sum_{e'\in I(e)} \frac{f(e'(i))}{c(e')} \leq c(q) \,, \quad \forall e \in E, \; 1 \leq i \leq K. \tag{5}$$

The first two constraints are *flow constraints*. The first one is the flow conservation constraint; the second one ensures no link capacity is violated. The third constraint is the *node radio constraints*. Recall that a IWMN node $v \in V$ has $I(v)$ radios and hence can be assigned at most $I(v)$ channels from $1 \leq i \leq K$. One way to model this constraint is to observe that due to interference constraints v can be involved in at most $I(v)$ simultaneous communications (with different one hop neighbors). In other words this constraint follows from $\sum_{1\leq i\leq K} \sum_{e=(u,v)\in E} X_{e,i,\tau} + \sum_{1\leq i\leq K} \sum_{e=(v,u)\in E} X_{e,i,\tau} \leq I(v)$. The fourth constraint is the *link congestion constraints* which are discussed in detail in section "Link Flow Scheduling". Note that all the constraints listed above are necessary conditions for any feasible solution. However, these constraints are not necessarily sufficient. Hence if a solution is found that satisfies these constraints it may not be a feasible solution. The approach is to start with a "good" but not necessarily feasible solution that satisfies all of these constraints and use it to construct a feasible solution without impacting the quality of the solution.

A solution to this LP can be viewed as a flow on a *flow graph* $H = (V, E^H)$ where $E^H = \{e(i) | \forall e \in E, 1 \leq i \leq K\}$. Although the optimal solution to this LP yields the best possible λ (say λ^*) from a practical point of view more improvements may be possible:

- The flow may have directed cycles. This may be the case since the LP does not try to minimize the amount of interference directly. By removing the flow on the directed cycle (equal amount off each edge) flow conservation is maintained and in addition since there are fewer transmissions the amount of interference is reduced.
- The flow may be using a long path when shorter paths are available. Note that longer paths imply more link transmissions. In this case it is often the case that by moving the flow to shorter paths, system interference may be reduced.

The above arguments suggest that it would be practical to find among all solutions that attain the

optimal λ value of λ^* the one for which the total value of the following quantity is minimized:

$$\sum_{1 \le i \le K} \sum_{e=(v,u) \in E} \frac{f(e(i))}{c(e)}.$$

The LP is then re-solved with this objective function and with λ fixed at λ^*.

Channel Assignment

The solution to the LP (1) is a set of flow values $f(e(i))$ for edge e and channel i that maximize the value λ. Let λ^* denote the optimal value of λ. The flow $f(e(i))$ implies a channel assignment where the two end nodes of edge e are both assigned channel i if and only if $f(e(i)) > 0$. Note that for the flow $f(e(i))$ the implied channel assignment may not be feasible (it may require more than $I(v)$ channels at node v). The channel assignment algorithm transforms the given flow to fix this infeasibility. Below only a sketch of the algorithm is given. More details can be found in [1].

First observe that in an idle scenario, where all nodes v have the same number of interfaces I (i.e., $I = I(v)$) and where the number of available channels K is also I, the channel assignment implied by the LP (1) is feasible. This is because even the trivial channel assignment where all nodes are assigned all the channels 1 to I is feasible. The main idea behind the algorithm is to first transform the LP (1) solution to a new flow in which every edge e has flow $f(e(i)) > 0$ only for the channels $1 \le i \le I$. The basic operation that the algorithm uses for this is to equally distribute, for every edge e, the flow $f(e(i))$, for $I < i \le K$ to the edges $e(j)$, for $1 \le i \le I$. This ensures that all $f(e(i)) = 0$, for $I < i \le K$ after the operation. This operation is called Phase I of the Algorithm. Note that the Phase I operation does not violate the flow conservation constraints or the node radio constraints (5) in the LP (1). It can be shown that in the resulting solution the flow $f(e(i))$ may exceed the capacity of edge e by at most a factor $\phi = K/I$. This is called the "inflation factor" of Phase I. Likewise in the new flow, the *link congestion constraints* (5) may also be violated for edge e and channel i by no more than the inflation factor φ. In other words in the resulting flow

$$\frac{f(e(i))}{c(e)} + \sum_{e' \in I(e)} \frac{f(e'(i))}{c(e')} \le \phi c(q)\,.$$

This implies that if the new flow is scaled by a fraction $1/\phi$ than it is feasible for the LP (1). Note that the implied channel assignment (assign channels 1 to I to every node) is also feasible. Thus, the above algorithm finds a feasible channel assignment with a λ value of at least λ^*/ϕ.

One shortcoming of the channel assignment algorithm (Phase I) described so far is that it only uses I of the K available channels. By using more channels the interference may be further reduced thus allowing for more flow to be pushed in the system. The channel assignment algorithm uses an additional heuristic for this improvement. This is called Phase II of the algorithm.

Now define an operation called "channel switch operation." Let A be a maximal connected component (the vertices in A are not connected to vertices outside A) in the graph formed by the edges e for a given channel i for which $f(e(i)) > 0$. The main observation to use is that for a given channel j, the operation of completely moving flow $f(e(i))$ to flow $f(e(j))$ for every edge e in A, does not impact the feasibility of the implied channel assignment. This is because there is no increase in the number of channels assigned per node after the flow transformation: the end nodes of edges e in A which were earlier assigned channel i are now assigned channel j instead. Thus, the transformation is equivalent to switching the channel assignment of nodes in A so that channel i is discarded and channel j is gained if not already assigned.

The Phase II heuristic attempts to re-transform the unscaled Phase I flows $f(e(i))$ so that there are multiple connected components in the graphs $G(e, i)$ formed by the edges e for each channel $1 \le i \le I$. This re-transformation is done so that the LP constraints are kept satisfied with an inflation factor of at most φ, as is the case for the unscaled flow after Phase I of the algorithm.

Next in Phase III of the algorithm the connected components within each graph $G(e,\ i)$ are grouped such that there are as close to K (but no more than) groups overall and such that the maximum interference within each group is minimized. Next the nodes within the lth group are assigned channel l, by using the channel switch operation to do the corresponding flow transformation. It can be shown that the channel assignment implied by the flow in Phase III is feasible. In addition the underlying flows $f(e(i))$ satisfy the LP (1) constraints with an inflation factor of at most $\phi = K/I$.

Next the algorithm scales the flow by the largest possible fraction (at least $1/\phi$) such that the resulting flow is a feasible solution to the LP (1) and also implies a feasible channel assignment solution to the channel assignment. Thus, the overall algorithm finds a feasible channel assignment (by not necessarily restricting to channels 1 to I only) with a λ value of at least λ^*/ϕ.

Link Flow Scheduling

The results in this section are obtained by extending those of [4] for the single channel case and for the Protocol Model of interference [2]. Recall that the time slotted schedule S is assumed to be periodic (with period T) where the indicator variable $X_{e,i,\tau}, e \in E, i \in F(e), \tau \geq 1$ is 1 if and only if link e is active in slot τ on channel i and i is a channel in common among the set of channels assigned to the end-nodes of edge e.

Directly applying the result (Claim 2) in [4] it follows that a necessary condition for interference free link scheduling is that for every $e \in E, i \in F(e), \tau \geq 1$: $X_{e,i,\tau} + \sum_{e' \in I(e)} X_{e',i,\tau} \leq c(q)$. Here $c(q)$ is a constant that only depends on the interference model. In the interference model this constant is a function of the fixed value q, the ratio of the interference range R_I to the transmission range R_T, and an intuition for its derivation for a particular value $q = 2$ is given below.

Lemma 1 $c(q) = 8$ *for* $q = 2$.

Proof Recall that an edge $e' \in I(e)$ if there exist two nodes $x, y \in V$ which are at most $2R_T$ apart and such that edge e is incident on node x and edge e' is incident on node y. Let $e = (u, v)$. Note that u and v are at most R_T apart. Consider the region C formed by the union of two circles C_u and C_v of radius $2R_T$ each, centered at node u and node v, respectively. Then $e' = (u', v') \in I(e)$ if an only if at least one of the two nodes u', v' is in C; Denote such a node by $C(e')$. Given two edges $e_1, e_2 \in I(e)$ that do not interfere with each other it must be the case that the nodes $C(e_1)$ and $C(e_2)$ are at least $2R_T$ apart. Thus, an upper bound on how many edges in $I(e)$ do not pair-wise interfere with each other can be obtained by computing how may nodes can be put in C that are pair-wise at least $2R_T$ apart. It can be shown [1] that this number is at most 8. Thus, in schedule S in a given slot only one of the two possibilities exist: either edge e is scheduled or an "independent" set of edges in $I(e)$ of size at most 8 is scheduled implying the claimed bound. □

A necessary condition: (*Link Congestion Constraint*) Recall that $\frac{1}{T}\sum_{1\leq\tau\leq T} X_{e,i,\tau} = \frac{f(e(i))}{c(e)}$. Thus: Any valid "interference free" edge flows must satisfy for every link e and every channel i the Link Congestion Constraint:

$$\frac{f(e(i))}{c(e)} + \sum_{e' \in I(e)} \frac{f(e'(i))}{c(e')} \leq c(q). \qquad (6)$$

A matching sufficient condition can also established [1].

A sufficient condition: (*Link Congestion Constraint*) If the edge flows satisfy for every link e and every channel i the following *Link Schedulability Constraint* than an interference free edge communication schedule can be found using an algorithm given in [1].

$$\frac{f(e(i))}{c(e)} + \sum_{e' \in I(e)} \frac{f(e'(i))}{c(e')} \leq 1. \qquad (7)$$

The above implies that if a flow $f(e(i))$ satisfies the *Link Congestion Constraint* then by scaling the flow by a fraction $1/c(q)$ it can be scheduled free of interference.

Key Results

Theorem *The RCL algorithm is a $Kc(q)/I$ approximation algorithm for the Joint Routing and Channel Assignment with Interference Free Edge Scheduling problem.*

Proof Note that the flow $f(e(i))$ returned by the channel assignment algorithm in Sect. "Channel Assignment" satisfies the *Link Congestion Constraint*. Thus, from the result of Sect. "Link Flow Scheduling" it follows that by scaling the flow by an additional factor of $1/c(q)$ the flow can be realized by an interference free link schedule. This implies a feasible solution to the joint routing, channel assignment and scheduling problem with a λ value of at least $\lambda^*/\phi c(q)$. Thus, the RCL algorithm is a $\phi c(q) = Kc(q)/I$ approximation algorithm. □

Applications

Infrastructure mesh networks are increasingly been deployed for commercial use and law enforcement. These deployment settings place stringent requirements on the performance of the underlying IWMNs. Bandwidth guarantee is one of the most important requirements of applications in these settings. For these IWMNs, topology change is infrequent and the variability of aggregate traffic demand from each mesh router (client traffic aggregation point) is small. These characteristics admit periodic optimization of the network which may be done by a system management software based on traffic demand estimation. This work can be directly applied to IWMNs. It can also be used as a benchmark to compare against heuristic algorithms in multi-hop wireless networks.

Open Problems

For future work, it will be interesting to investigate the problem when routing solutions can be enforced by changing link weights of a distributed routing protocol such as OSPF. Also, can the worst case bounds of the algorithm be improved (e.g., a constant factor independent of K and I)?

Problem Definition

Circuit partitioning is a fundamental problem in many areas of VLSI layout and design. *Min-cut balanced bipartition* is the problem of partitioning a circuit into two disjoint components with equal weights such that the number of nets connecting the two components is minimized. The min-cut balanced bipartition problem was shown to be NP-complete [5]. The problem has been solved by heuristic algorithms, e.g., Kernighan and Lin type (K&L) iterative improvement methods [4, 11], simulated annealing approaches [10], and analytical methods for the ratio-cut objective [2, 7, 13, 15]. Although it is a natural method for finding a min-cut, the network max-flow min-cut technique [6, 8] has been overlooked as a viable approach for circuit partitioning. In [16], a method was proposed for exactly modeling a circuit netlist (or, equivalently, a hypergraph) by a flow network, and an algorithm for balanced bipartition based on repeated applications of the max-flow min-cut technique was proposed as well. Our algorithm has the same asymptotic time complexity as one max-flow computation.

A *circuit netlist* is defined as a digraph $N = (V, E)$, where V is a set of nodes representing logic gates and registers and E is a set of edges representing wires between gates and registers. Each node $v \in V$ has a weight $w(v) \in R^+$. The total weight of a subset $U \subseteq V$ is denoted by $w(U) = \Sigma_{v \in U} w(v)$. $W = w(V)$ denotes the total weight of the circuit. A *net* $n = (v; v_1, \ldots, v_l)$ is a set of outgoing edges from node v in N. Given two nodes s and t in N, an $s - t$ *cut* (or *cut* for short) $\left(X, \bar{X}\right)$ of N is a bipartition of the nodes in V such that $s \in X$ and $t \in \bar{X}$. The *net-cut* $net\left(X, \bar{X}\right)$ of the cut is the set of nets in N that are incident to nodes in both X and $\bar{X}$. A cut $\left(X, \bar{X}\right)$ is a *min-net-cut* if $\left|net\left(X, \bar{X}\right)\right|$ is minimum among all $s - t$ cuts of N. In Fig. 1, net $a = [r_1; g_1, g_2)$, net cuts $net\left(X, \bar{X}\right) = \{b, e\}$ and $net\left(Y, \bar{Y}\right) = \{c, a, b, e\}$, and $\left(X, \bar{X}\right)$ is a min-net-cut.

Formally, given an aspect ratio r and a deviation factor ε, *min-cut r-balanced bipartition* is the problem of finding a bipartition $\left(X, \bar{X}\right)$ of the netlist N such that (1) $(1 - \epsilon)rW \leq W(X) \leq (1 + \epsilon)rW$ and (2) the size of the cut $net\left(X, \bar{X}\right)$ is minimum among all bipartitions satisfying (1). When $r = 1/2$, this becomes a min-cut balanced-bipartition problem.

Key Results

Optimal-Network-Flow-Based Min-Net-Cut Bipartition

The problem of finding a min-net-cut in $N = (V, E)$ is reduced to the problem of finding a cut of minimum capacity. Then the latter problem is solved using the max-flow min-cut technique. A flow network $N' = (V', E')$ is constructed from $N = (V, E)$ as follows (see Figs. 2 and 3):

1. V' contains all nodes in V.
2. For each net $n = (v; v_1, \ldots, v_l)$ in N, add two nodes n_1 and n_2 in V' and a *bridging edge* $bridge(n) = (n_1, n_2)$ in E'.
3. For each node $u \in \{v, v_1, \ldots, v_l\}$ incident on net n, add two edges (u, n_1) and (n_2, u) in E'.
4. Let s be the source of N' and t the sink of N'.
5. Assign unit capacity to all bridging edges and infinite capacity to all other edges in E'.
6. For a node $v \in V'$ corresponding to a node in V, $w(v)$ is the weight of v in N. For a node $u \in V'$ split from a net, $w(u) = 0$.

Note that all nodes incident on net n are connected to n_1 and are connected from n_2 in N'. Hence, the flow network construction is symmetric with respect to all nodes incident on a net. This construction also works when the netlist is represented as a hypergraph.

It is clear that N' is a strongly connected digraph. This property is the key to reducing the bidirectional min-net-cut problem to a minimum-capacity cut problem that counts the capacity of the forward edges only.

Theorem 1 *N has a cut of net-cut size at most C if and only if N' has a cut of capacity at most C.*

Corollary 1 *Let $(X', \bar{X}')$ be a cut of minimum capacity C in N'. Let $N_{cut} = \{n \mid bridge(n) \in (X', \bar{X}')\}$. Then $N_{cut} = (X, \bar{X})$ is a min-net-cut in N and $|N_{cut}| = C$.*

Corollary 2 *A min-net-cut in a circuit $N = (V, E)$ can be found in $O(|V||E|)$ time.*

Min-Cut Balanced-Bipartition Heuristic

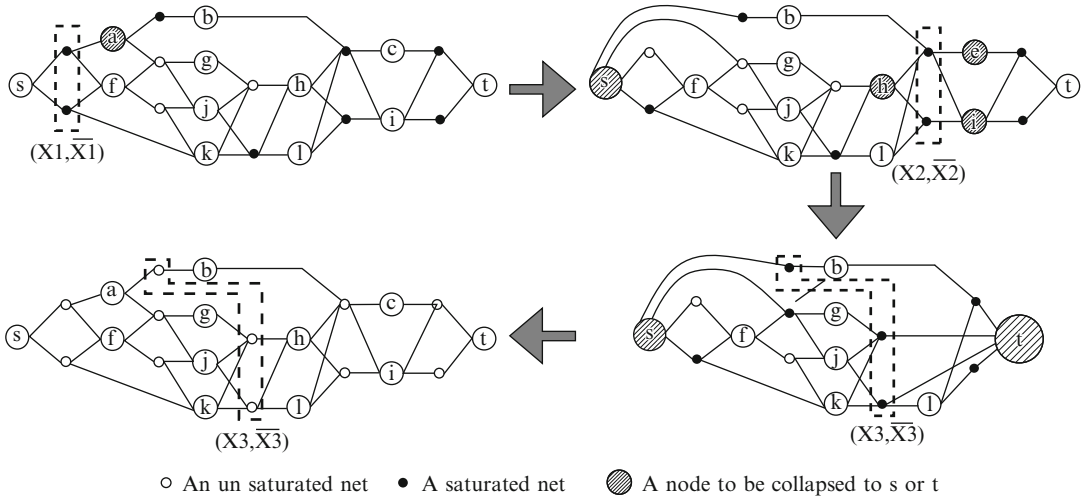
First, a repeated max-flow min-cut heuristic algorithm, flow-balanced bipartition (FBB), is developed for finding an r-balanced bipartition that minimizes the number of crossing nets. Then, an efficient implementation of FBB is developed that has the same asymptotic time complexity as one max-flow computation. For ease of presentation, the FBB algorithm is described on the original circuit rather than the flow network constructed from the circuit. The heuristic algorithm is described in Fig. 4. Figure 5 shows an example.

Table 1 compares the best bipartition net-cut sizes of FBB with those produced by the analytical-method-based partitioners EIG1 [7] and PARABOLI (PB) [13]. The results produced by PARABOLI were the best previously known results reported on the benchmark circuits. The results for FBB were the best of ten runs. On average, FBB outperformed EIG1 and PARABOLI by 58.1 and 11.3 %, respectively. For circuit S38417, the suboptimal result from FBB can be improved by (1) running more times and (2) applying clustering techniques to the circuit based on connectivity before partitioning.

In the FBB algorithm, the node-collapsing method is chosen instead of a more gradual method (e.g., [9]) to ensure that the capacity of a cut always reflects the real net-cut size. To pick a node at steps 4.2 and 5.2, a threshold R is given for the number of nodes in the uncollapsed subcircuit. A node is randomly picked if the number of nodes is larger than R. Otherwise, all nodes adjacent to C are tried and the one whose collapse induces a min-net-cut with the smallest size is picked. A naive implementation of step 2 by computing the max-flow from the zero flow would incur a high time complexity. Instead, the flow value in the flow network is retained, and additional flow is explored to saturate the bridging edges of the min-net-cut from one iteration to the next. The procedure is shown in Fig. 6. Initially, the flow network retains the flow function computed in the previous iteration. Since the max-flow computation using the augmenting-path method is insensitive to the initial flow values in the flow network and the order in which the augmenting paths are found, the above procedure correctly finds a max-flow with the same flow value as a max-flow computed in the collapsed flow network from the zero flow.

Circuit Partitioning: A Network-Flow-Based Balanced Min-Cut Approach, Fig. 4 FBB algorithm

Algorithm: Flow-Balanced-Bipartition (FBB)
1. Pick a pair of nodes s and t in N;
2. Find a min-net-cut C in N;
   Let X be the subcircuit reachable from s through augmenting paths in the flow network, and $\overline{X}$ the rest;
3. **if** $(1-\epsilon)rW \le w(X) \le (1+\epsilon)rW$
   return C as the answer;
4. **if** $w(X) < (1-\epsilon)rW$
4.1. Collapse all nodes in X to s;
4.2. Pick a node $v \in \overline{X}$ adjacent to C and collapse it to s;
4.3. Goto 1;
5. **if** $w(X) > (1+\epsilon)rW$
5.1. Collapse all nodes in $\overline{X}$ to t;
5.2. Pick a node $v \in X$ adjacent to C and collapse it to t;
5.3. Goto 1;



Circuit Partitioning: A Network-Flow-Based Balanced Min-Cut Approach, Fig. 5 FBB on the example in Fig. 3 for $r = 1/2, \epsilon = 0.15$ and unit weight for each node. The algorithm terminates after finding cut $(X_2, \bar{X}_2)$. A small solid node indicates that the bridging edge corresponding to the net is saturated with flow

Circuit Partitioning: A Network-Flow-Based Balanced Min-Cut Approach, Fig. 6 Incremental max-flow computation

Procedure: Incremental Flow Computation

1. **while** ∃ an additional augmenting path from s to t increase flow value along the augmenting path;
2. Mark all nodes u s.t.∃ an augmenting path from s to u;
3. Let C' be the set of bridging edges whose starting nodes are marked and ending nodes are not marked;
4. Return the nets corresponding to the bridging edges in C' as the min-net-cut C, and the marked nodes as X.

Theorem 2 *FBB has time complexity* $O(|V||E|)$ *for a connected circuit* $N = (V, E)$.

Theorem 3 *The number of iterations and the final net-cut size are nonincreasing functions of* $\in$.

In practice, FBB terminates much faster than this worst-case time complexity as shown in the section "Experimental Results." Theorem 3 allows us to improve the efficiency of FBB and the partition quality for a larger $\in$. This is not true for other partitioning approaches such as the K&L heuristics.

Applications

Circuit partitioning is a fundamental problem in many areas of VLSI layout and design automation. The FBB algorithm provides the first efficient predictable solution to the min-cut balanced-circuit-partitioning problem. It directly relates the efficiency and the quality of the solution produced by the algorithm to the deviation factor $\in$. The algorithm can be easily extended to handle nets with different weights by simply assigning the weight of a net to its bridging edge in the flow network. K-way min-cut partitioning for $K > 2$ can be accomplished by recursively applying FBB or by setting $r = 1/K$ and then using FBB to find one partition at a time. A flow-based method for directly solving the problem can be found in [12]. Prepartitioning circuit clustering according to the connectivity or the timing information of the circuit can be easily incorporated into FBB by treating a cluster as a node. Heuristic solutions based on K&L heuristics or simulated annealing with low temperature can be used to further fine-tune the solution.

Experimental Results

The FBB algorithm was implemented in SIS/MISII [1] and tested on a set of large ISCAS and MCNC benchmark circuits on a SPARC 10 workstation with 36-MHz CPU and 32 MB memory.

Table 2 compares the average bipartition results of FBB with those reported by Dasdan and Aykanat in [3]. SN is based on the K&L heuristic algorithm in Sanchis [14]. PFM3 is based on the K&L heuristic with free moves as described in [3]. For each circuit, SN was run 20 times and PFM3 10 times from different randomly generated initial partitions. FBB was run 10 times from different randomly selected s and t. With only one exception, FBB outperformed both SN and PFM3 on the five circuits. On average, FBB found a bipartition with 24.5 and 19.0 % fewer crossing nets than SN and PFM3, respectively. The runtimes of SN, PFM3, and FBB were not compared since they were run on different workstations.

Problem Definition

This problem is concerned with determining constrained positions of objects while minimizing a measure of interconnect between the objects, as in physical layout of integrated circuits, commonly done in 2 dimensions. While most formulations are NP-hard, modern circuits are so large that practical placement algorithms must have near-linear run time and memory requirements, but not necessarily produce optimal solutions. Research in placement algorithms has identified scalable techniques which are now being adopted in the electronic design automation industry.

One models a circuit by a hypergraph $G_h(V_h, E_h)$ with (i) vertices $V_h = \{v_1, \ldots, v_n\}$ representing logic gates, standard cells, larger modules, or fixed I/O pads and (ii) hyperedges $E_h = \{e_1, \ldots, e_m\}$ representing connections between modules. Vertices and hyperedges connect through *pins* for a total of P pins in the hypergraph. Each vertex $v_i \in V_h$ has width w_i, height h_i, and area A_i. Hyperedges may also be weighted. Circuit placement seeks center positions (x_i, y_i) for vertices that optimize a hypergraph-based objective subject to constraints (see below). A placement is captured by $\mathbf{x} = (x_1, \cdots, x_n)$ and $\mathbf{y} = (y_1, \cdots, y_n)$.

Objective: Let C_k be the index set of the hypergraph vertices incident to hyperedge e_k. The total half-perimeter wire length (HPWL) of the circuit hypergraph is given by $\text{HPWL}(G_h) = \sum_{e_k \in E_h} \text{HPWL}(e_k) = \sum_{e_k \in E_h} \left[\max_{i,j \in C_k} |x_i - x_j| + \max_{i,j \in C_k} |y_i - y_j|\right]$. HPWL is piecewise linear, separable in the x and y directions, convex, but not strictly convex. Among many objectives for circuit placement, it is the simplest and most common.

Constraints:

1. **No overlap**. The area occupied by any two vertices cannot overlap; i.e., either $|x_i - x_j| \geq \frac{1}{2}(w_i + w_j)$ or $|y_i - y_j| \geq \frac{1}{2}(h_i + h_j)$, $\forall v_i, v_j \in V_h$.
2. **Fixed outline**. Each vertex $v_i \in V_h$ must be placed entirely within a specified rectangular region bounded by $x_{\min}$ ($y_{\min}$) and $x_{\max}$ ($y_{\max}$) which denote the left (bottom) and right (top) boundaries of the specified region.
3. **Discrete slots**. There is only a finite number of discrete positions, typically on a grid. However, in large-scale circuit layout, slot constraints are often ignored during *global placement* and enforced only during *legalization* and *detail placement*.

Other constraints may include alignment, minimum and maximum spacing, etc. Many placement techniques temporarily relax overlap constraints into density constraints to avoid vertices clustered in small regions. A $m \times n$ regular bin structure B is superimposed over the fixed outline and vertex area is assigned to bins based on the positions of vertices. Let D_{ij} denote the density of bin $B_{ij} \in B$, defined as the total cell area assigned to bin B_{ij} divided by its capacity. Vertex overlap is limited implicitly by satisfying $D_{ij} \leq K$, $\forall B_{ij} \in B$, for some $K \leq 1$ (density target).

Problem 1 (Circuit Placement) INPUT: Circuit hypergraph $G_h(V_h, E_h)$ and a fixed outline for the placement area.
OUTPUT: Positions for each vertex $v_i \in V_h$ such that (1) wire length is minimized and (2) the area-density constraints $D_{ij} \leq K$ are satisfied for all $B_{ij} \in B$.

Key Results

An unconstrained optimal position of a single placeable vertex connected to fixed vertices can be found in linear time as the median of adjacent positions [7]. Unconstrained HPWL minimization for multiple placeable vertices can be formulated as a linear program [6, 11]. For each $e_k \in E_h$, upper and lower bound variables U_k and L_k are added. The cost of e_k (x-direction only) is the difference between U_k and L_k. Each $U_k(L_k)$ comes with p_k inequality constraints that restrict its value to be larger (smaller) than the position of every vertex $i \in C_k$.

Linear programming has poor scalability and integrating constraint-tracking into optimization is difficult. Other approaches include nonlinear optimization and partitioning-based methods.

Combinatorial Techniques for Wire Length Minimization

The no-overlap constraints are not convex and cannot be directly added to the linear program for HPWL minimization. Vertices often cluster in small regions of high density. One can lower bound the distance between closely placed vertices with a single linear constraint that depends on the relative placement of these vertices [11]. The resulting optimization problem is incrementally resolved, and the process repeats until the desired density is achieved.

The *min-cut placement* technique is based on balanced min-cut partitioning of hypergraphs and is more focused on density constraints [12]. Vertices of the initial hypergraph are first partitioned in two similar-sized groups. One of them is assigned to the left half of the placement region, and the other one to the right half. Partitioning is performed by the Multilevel Fiduccia-Mattheyses (MLFM) heuristic [10] to minimize connections between the two groups of vertices (the net-cut objective). Each half is partitioned again but takes into account the connections to the other half [12]. At the large scale, ensuring the similar sizes of bipartitions corresponds to density constraints, and cut minimization corresponds to HPWL minimization. When regions become small and contain <10 vertices, optimal positions can be found with respect to discrete slot constraints by branch-and-bound [2]. Balanced hypergraph partitioning is NP-hard [4], but the MLFM heuristic takes $O((V + E)\log V)$ time. The entire min-cut placement procedure takes $O((V + E)(\log V)^2)$ time and can process hypergraphs with millions of vertices in several hours.

A special case of interest is that of one-dimensional placement. When all vertices have identical width and none of them are fixed, one obtains the NP-hard MINIMUM LINEAR ARRANGEMENT problem [4] which can be approximated in polynomial time within $O(\log V)$ and solved exactly for trees in $O(V^3)$ time as shown by Yannakakis. The min-cut technique described above also works well for the related NP-hard MINIMUM-CUT LINEAR ARRANGEMENT problem [4].

Quadratic and Nonlinear Wire Length Approximations

Quadratic and generic nonlinear optimization may be faster than linear programming while reasonably approximating the original formulation.

Quadratic, Linearized Quadratic, and Bound-to-Bound Placement

The hypergraph is represented by a weighted graph where w_{ij} represents the weight on the 2-pin edge connecting vertices v_i and v_j in the weighted graph. When an edge is absent, $w_{ij} = 0$, and in general $w_{ii} = -\Sigma_{i \neq j} w_{ij}$. A quadratic placement (x-direction only) is given by

$$\Phi(x) = \sum_{i,j} w_{ij} \left[(x_i - x_j)^2\right] = \frac{1}{2}\mathbf{x}^T\mathbf{Q}\mathbf{x} + \mathbf{c}^T\mathbf{x} + \text{const.} \quad (1)$$

The global minimum of $\Phi(x)$ is found by solving $\mathbf{Q}\mathbf{x} + \mathbf{c} = \mathbf{0}$ which is a sparse, symmetric positive definite system of linear equations (assuming $\geq$1 fixed vertex), efficiently solved using any number of iterative solvers. Quadratic placement may have different optima depending on the model (clique or star) used to represent hyperedges. However, for a k-pin hyperedge, if $w_{ij} = W_c$ in a clique model and $w_{ij} = kW_c$ is a star model, then the models are equivalent in quadratic placement [6].

Quadratic placement can produce lower quality placements. To approximate a linear objective, one can iteratively solve Eq. 1 with $w_{ij} = 1/|x_i - x_j|$ computed at every iteration. Alternatively, one can solve a single β-regularized optimization problem given by $\Phi^\beta(\mathbf{x}) = \min_x \sum_{i,j} w_{ij}\sqrt{(x_i - x_j)^2 + \beta}$, $\beta > 0$, e.g., using a Primal-Dual Newton method [1].

In bound-to-bound placement, instead of a clique or star model, hyperedges are decomposed based on the relative placement of vertices. For a k-pin hyperedge, the extreme vertices (min and max) are connected to each other and to each internal vertex with weights $w_{ij} = 1/(k-1)|x_i - x_j|$. With these weights, the quadratic objective captures HPWL exactly, but only for the given placement. As placement changes, updates to the quadratic placement objective are required to reduce discrepancies [8].

Half-perimeter Wire Length Placement:

HPWL can be provably approximated by strictly convex and differentiable functions. For 2-pin hyperedges, β-regularization can be used [1]. For an k-pin hyperedge ($k \geq 3$), one can rewrite HPWL as the maximum (l_∞-norm) of

all $k(k-1)/2$ pairwise distances $|x_i - x_j|$ and approximate the l_∞-norm by the l_p-norm. This removes all non-differentiabilities except at $\mathbf{0}$ which is then removed with β-regularization. The resulting HPWL approximation is given by

$$\mathrm{HPWL}_{\mathrm{REG}}(G_h) = \sum_{e_k \in E_h} \left(\sum_{i,j \in C_k} |x_i - x_j|^p + \beta \right)^{1/p} \tag{2}$$

which overestimates HPWL with arbitrarily small relative error as $p \to \infty$ and $\beta \to 0$ [6]. Alternatively, HPWL can be approximated via the log-sum-exp (LSE) formula given by

$$\mathrm{HPWL}_{\mathrm{LSE}}(G_h) = \alpha \sum_{e_k \in E_h} \left[\ln \left(\sum_{i \in C_k} \exp\left(\frac{x_i}{\alpha}\right) \right) + \ln \left(\sum_{v_i \in C_k} \exp\left(\frac{-x_i}{\alpha}\right) \right) \right] \tag{3}$$

where $\alpha > 0$ is a smoothing parameter [5]. Both approximations can be optimized using conjugate gradient methods. Other convex and differentiable HPWL approximations exist.

Analytic Techniques for Target Density Constraints

The target density constraints are non-differentiable and are typically handled by approximation.

Force-Based Spreading

The key idea is to add constant forces $\mathbf{f}$ that pull vertices always from overlaps, and recompute the forces over multiple iterations to reflect changes in vertex distribution. For quadratic placement, the new optimality conditions are $\mathbf{Qx} + \mathbf{c} + \mathbf{f} = \mathbf{0}$ [7]. The constant force can perturb a placement in any number of ways to satisfy the target density constraints. The force $\mathbf{f}$ is computed using a discrete version of Poisson's equation.

Fixed-Point Spreading

A fixed point f is a pseudo-vertex with zero area, fixed at (x_f, y_f), and connected to one vertex $H(f)$ in the hypergraph through the use of a pseudo-edge with weight $w_{f,H(f)}$. Each fixed point introduces a single quadratic term into the objective function; quadratic placement with fixed points is given by $\Phi(x) = \sum_{i,j} w_{i,j}(x_i - x_j)^2 + \sum_f w_{f,H(f)}(x_{H(f)} - x_f)^2$. By manipulating the positions of fixed points, one can perturb a placement to satisfy the target density constraints. Fixed points improve the controllability and stability of placement iterations, in particular by improving the conditioning number of resulting numerical problem instances. A particularly effective approach to find fixed points is through the use of fast *LookAhead Legalization* (LAL) [8,9]. Given locations found by quadratic placement, LAL gradually modifies them into a relatively overlap-free placement that satisfies density constraints and seeks to preserve the ordering of x and y positions, while avoiding unnecessary movement. The resulting locations are used as fixed target points. LAL can be performed by top-down geometric partitioning with nonlinear scaling between partitions. As described in [8, 9], this approach is particularly effective at handling rectilinear obstacles. Subsequent work developed extensions to account for routing congestion and other considerations arising in global placement. At the most recent (ISPD 2014) placement contest, the contestants ranked in top three used the framework outlined in [8].

Generalized Force-Directed Spreading

The Helmholtz equation models a diffusion process and makes it ideal for spreading vertices [3]. The Helmholtz equation is given by

$$\begin{aligned} \frac{\partial^2 \phi(x,y)}{\partial x^2} + \frac{\partial^2 \phi(x,y)}{\partial y^2} - \epsilon \phi(x,y) &= D(x,y),\ (x,y) \in \mathrm{R} \\ \frac{\partial \phi}{\partial v} &= 0, \qquad (x,y) \text{ on the boundary of } R \end{aligned} \tag{4}$$

where $\epsilon > 0$, v is an outer unit normal, R represents the fixed outline, and $D(x, y)$ represents the continuous density function. The boundary conditions, $\frac{\partial \phi}{\partial v} = 0$, specify that forces pointing outside of the fixed outline be set to zero – this is a key difference with the Poisson method which assumes that forces become zero at infinity. The value ϕ_{ij} at the center of each bin B_{ij} is found by discretization of Eq. 4 using finite differences. The density constraints are replaced by $\phi_{ij} = \hat{K}, \forall B_{ij} \in B$ where $\hat{K}$ is a scaled representative of the density target K. Wire length minimization subject to the smoothed density constraints can be solved via Uzawa's algorithm. For quadratic wire length, this algorithm is a generalization of force-based spreading.

Potential Function Spreading

Target density constraints can also be satisfied via a penalty function. The area assigned to bin B_{ij} by vertex v_i is represented by Potential(v_i, B_{ij}) which is a bell-shaped function. The use of piecewise quadratic functions makes the potential function non-convex but smooth and differentiable [5]. The wire length approximation can be combined together with a penalty term given by Penalty $= \sum_{B_{ij} \in B} \left(\sum_{v_i \in V_h} \text{Potential}(v_i, B_{ij}) - K \right)^2$ to arrive at an unconstrained optimization problem which is solved using a conjugate gradient method [5].

Applications

Practical applications involve more sophisticated interconnect objectives, such as circuit delay, routing congestion, power dissipation, power density, and maximum thermal gradient. The above techniques are adapted to handle multiobjective optimization. Many such extensions are based on heuristic assignment of net weights that encourage the shortening of some (e.g., timing critical and frequently switching) connections at the expense of other connections. To moderate routing congestion, predictive congestion maps are used to decrease the maximal density constraint for placement in congested regions. Another application is in physical synthesis, where incremental placement is used to evaluate changes in circuit topology.

Experimental Results and Data Sets

Circuit placement has been actively studied for the past 30 years, and a wealth of experimental results have been reported. A 2003 result showed that placement tools could produce results as much as 1.41× to 2.09× known optimal wire lengths on average. In a 2006 placement contest, academic software for placement produced results that differed by as much as 1.39× on average when the objective was the simultaneous minimization of wire length, routability, and run time. Placement run times for instances with 2M movable objects ranged into hours. More recently, the gap in wire length between different tools has decreased, and run times have improved, in part due to the use of multicore CPUs and vectorized arithmetics. Over the last 10 years, wire length has improved by 20–25 % and run time by 15–20 times [8, 9]. More recent work in circuit placement has focused on other objectives such as routability in addition to wire length minimization.

Modern benchmark suites include the ISPD05, ISPD06, ISPD11, and ISPD14 suites (http://www.ispd.cc). Additional benchmark suites include the ICCAD12 (http://cad_contest.cs.nctu.edu.tw/CAD-contest-at-ICCAD2012), ICCAD13 (http://cad_contest.cs.nctu.edu.tw/CAD-contest-at-ICCAD2013), and ICCAD14 (http://cad_contest.ee.ncu.edu.tw/CAD-contest-at-ICCAD2014) suites. Instances in these benchmark suites contain between several hundred thousand to several million placeable objects. Additional benchmark suites also exist.

1991; Leiserson, Saxe

Problem Definition

Circuit retiming is one of the most effective structural optimization techniques for sequential circuits. It moves the registers within a circuit without changing its function. Besides clock period, retiming can be used to minimize the number of registers in the circuit. It is also called minimum area retiming problem Leiserson and Saxe [3] started the research on retiming and proposed algorithms for both minimum period and minimum area retiming. Both their algorithms for minimum area and minimum period will be presented here.

The problems can be formally described as follows. Given a directed graph $G = (V, E)$ representing a circuit – each node $v \in V$ represents a gate and each edge $e \in E$ represents a signal passing from one gate to another – with gate delays $d : V \to \mathbb{R}^+$ and register numbers $w : E \to \mathbb{N}$, the minimum area problem asks for a relocation of registers $w' : E \to \mathbb{N}$ such that the number of registers in the circuit is minimum under a given clock period φ. The minimum period problem asks for a solution with the minimum clock period.

Notations

To guarantee that the new registers are actually a relocation of the old ones, a label $r : V \to \mathbb{Z}$ is used to represent how many registers are moved from the outgoing edges to the incoming edges of each node. Using this notation, the new number of registers on an edge (u, v) can be computed as

$$w'[u, v] = w[u, v] + r[v] - r[u].$$

The same notation can be extended from edges to paths. However, between any two nodes u and v, there may be more than one path. Among these

paths, the ones with the minimum number of registers will decide how many registers can be moved outside of u and v. The number is denoted by $W[u, v]$ for any $u, v \in V$, that is,

$$W[u, v] \triangleq \min_{p: u \rightsquigarrow v} \sum_{(x,y) \in p} w[x, y]$$

The maximal delay among all the paths from u to v with the minimum number of registers is also denoted by $D[u, v]$, that is,

$$D[u, v] \triangleq \max_{w[p: u \rightsquigarrow v] = W[u,v]} \sum_{x \in p} d[x]$$

Constraints

Based on the notations, a valid retiming r should not have any negative number of registers on any edge. Such a validity condition is given as

$$P0(r) \triangleq \forall (u, v) \in E : w[u, v] + r[v] - r[u] \geq 0$$

On the other hand, given a retiming r, the minimum number of registers between any two nodes u and v is $W[u, v] - r[u] + r[v]$. This number will not be negative because of the previous constraint. However, when it is zero, there will be a path of delay $D[u, v]$ without any register on it. Therefore, to have a retimed circuit working for clock period φ, the following constraint must be satisfied.

$$P1(r) \triangleq \forall u, v \in V : D[u, v] > \phi \Rightarrow W[u, v] + r[v] - r[u] \geq 1$$

Key Results

The object of the minimum area retiming is to minimize the total number of registers in the circuit, which is given by $\sum_{(u,v) \in E} w'[u, v]$. Expressing $w'[u, v]$ in terms of r, the objective becomes

$$\sum_{v \in V} (\text{in}[v] - \text{out}[v]) * r[v] + \sum_{(u,v) \in E} w[u, v]$$

where $\text{in}[v]$ is the in-degree and $\text{out}[v]$ is the out-degree of node v. Since the second term is a constant, the problem can be formulated as the following integer linear program.

$$\begin{aligned} &\text{Minimize} \sum_{v \in V} (\text{in}[v] - \text{out}[v]) * r[v] \\ &\text{s.t. } w[u, v] + r[v] - r[u] \geq 0 \quad \forall (u, v) \in E \\ &\quad W[u, v] + r[v] - r[u] \geq 1 \quad \forall u, v \in V : D[u, v] > \phi \\ &\quad r[v] \in \mathbb{Z} \quad \forall v \in V \end{aligned}$$

Since the constraints have only difference inequalities with integer-constant terms, solving the relaxed linear program (without the integer constraint) will only give integer solutions. Even better, it can be shown that the problem is the dual of a minimum cost network flow problem and, thus, can be solved efficiently.

Theorem 1 *The integer linear program for the minimum area retiming problem is the dual of the following minimum cost network flow problem.*

$$\begin{aligned} &\text{Minimize} \sum_{(u,v) \in E} w[u, v] * f[u, v] \\ &\quad + \sum_{D[u,v] > \phi} (W[u, v] - 1) * f[u, v] \\ &\text{s.t. } \text{in}[v] + \sum_{(v,w) \in E \vee D[v,w] > \phi} f[v, w] = \text{out}[v] \\ &\quad + \sum_{(u,v) \in ED[u,v] > \phi} f[u, v] \quad \forall v \in V \\ &\quad f[u, v] \geq 0 \quad \forall (u, v) \in ED[u, v] > \phi \end{aligned}$$

From the theorem, it can be seen that the network graph is a dense graph where a new edge (u, v) needs to be introduced for any node pair u, v such that $D[u, v] > \phi$. There may be redundant constraints in the system.

For example, if $W[u, w] = W[u, v] + w[v, w]$ and $D[u, v] > \phi$ then the constraint $W[u, w] + r[w] - r[u] \geq 1$ is redundant, since there are already $W[u, v] + r[v] - r[u] \geq 1$ and $w[v, w] + r[w] - r[v] \geq 0$. However, it may not be easy to check and remove all redundancy in the constraints.

In order to build the minimum cost flow network, it is needed to first compute both matrices W and D. Since $W[u, v]$ is the shortest path from u to v in terms of w, the computation of W can be done by an all-pair shortest paths algorithm such as Floyd-Warshall's algorithm [1]. Furthermore, if the ordered pair $(w[x, y], -d[x])$ is used as the edge weight for each $(x, y) \in E$, an all-pair shortest paths algorithm can also be used to compute both W and D. The algorithm will add weights by component-wise addition and will compare weights by lexicographic ordering.

Leiserson and Saxe's [3] first algorithm for the minimum period retiming was also based on the matrices W and D. The idea was that the constraints in the integer linear program for the minimum area retiming can be checked efficiently by Bellman-Ford's shortest paths algorithm [1], since they are just difference inequalities. This gives a feasibility checking for any given clock period φ. Then the optimal clock period can be found by a binary search on a range of possible periods. The feasibility checking can be done in $O(|V|^3)$ time, thus the runtime of such an algorithm is $O(|V|^3 \log |V|)$.

Their second algorithm got rid of the construction of the matrices W and D. It still used a clock period feasibility checking within a binary search. However, the feasibility checking was done by incremental retiming. It works as follows: Starting with $r = 0$, the algorithm computes the arrival time of each node by the longest paths computation on a DAG (Directed Acyclic Graph). For each node v with an arrival time larger than the given period φ, the $r[v]$ will be increased by one. The process of the arrival time computation and r increasing will be repeated $|V| - 1$ times. After that, if there is still arrival time that is larger than φ, then the period is infeasible. Since the feasibility checking is done in $O(|V||E|)$ time, the runtime for the minimum period retiming is $O(|V|E| \log |V|)$.

Applications

Shenoy and Rudell [7] implemented Leiserson and Saxe's minimum period and minimum area retiming algorithms with some efficiency improvements. For minimum period retiming, they implemented the second algorithm and, in order to find out infeasibility earlier, they introduced a pointer from one node to another where at least one register is required between them. A cycle formed by the pointers indicates the feasibility of the given period. For minimum area retiming, they removed some of the redundancy in the constraints and used the cost-scaling algorithm of Goldberg and Tarjan [2] for the minimum cost flow computation.

As can be seen from the second minimum period retiming algorithm here and Zhou's algorithm [9] in another entry (▸ Circuit Retiming: An Incremental Approach), incremental computation of the longest combinational paths (i.e., those without register on them) is more efficient than constructing the dense graph (via matrices W and D). However, the minimum area retiming algorithm is still based on a minimum cost network flow on the dense graph. A more efficient algorithm based on incremental retiming has recently been designed for the minimum area problem by Wang and Zhou [8].

Experimental Results

Sapatnekar and Deokar [6] and Pan [5] proposed continuous retiming as an efficient approximation for minimum period retiming and reported the experimental results. Maheshwari and Sapatnekar [4] also proposed some efficiency improvements to the minimum area retiming algorithm and reported their experimental results.

Minimum period retiming; Min-period retiming

Years and Authors of Summarized Original Work

2005; Zhou

Problem Definition

Circuit retiming is one of the most effective structural optimization techniques for sequential circuits. It moves the registers within a circuit without changing its function. The minimal period retiming problem needs to minimize the longest delay between any two consecutive registers, which decides the clock period.

The problem can be formally described as follows. Given a directed graph $G = (V, E)$ representing a circuit – each node $v \in V$ represents a gate and each edge $e \in E$ represents a signal passing from one gate to another – with gate delays $d : V \to \mathbb{R}^+$ and register numbers $w : E \to \mathbb{N}$, it asks for a relocation of registers $w' : E \to \mathbb{N}$ such that the maximal delay between two consecutive registers is minimized.

Notations To guarantee that the new registers are actually a relocation of the old ones, a label $r : V \to \mathbb{Z}$ is used to represent how many registers are moved from the outgoing edges to the incoming edges of each node. Using this notation, the new number of registers on an edge (u, v) can be computed as

$$w'[u, v] = w[u, v] + r[v] - r[u].$$

Furthermore, to avoid explicitly enumerating the paths in finding the longest path, another label $t : V \to \mathbb{R}^+$ is introduced to represent the output arrival time of each gate, that is, the maximal delay of a gate from any preceding register. The condition for t to be at least the combinational delays is

$$\forall [u, v] \in E : w'[u, v] = 0 \Rightarrow t[v] \geq t[u] + d[u].$$

Constraints and Objective Based on the notations, a valid retiming r should not have any negative number of registers on any edge. Such a validity condition is given as

$$P0(r) \triangleq \forall (u, v) \in E : w[u, v] + r[v] - r[u] \geq 0.$$

As already stated, the conditions for t to be valid arrival time is given by the following two predicates:

$$P1(t) \triangleq \forall v \in V : t[v] \geq d[v]$$
$$P2(r,t) \triangleq \forall (u,v) \in E : r[u] - r[v] = w[u,v] \Rightarrow t[v] - t[u] \geq d[v].$$

A predicate P is used to denote the conjunction of the above conditions:

$$P(r,t) \triangleq P0(r) \wedge P1(t) \wedge P2(r,t).$$

A minimal period retiming is a solution r, t satisfying the following optimality condition:

$$P3 \triangleq \forall r', t' : P(r', t') \Rightarrow \max(t) \leq \max(t')$$

where

$$\max(t) \triangleq \max_{v \in V}[v].$$

Since only a valid retiming (r', t') will be discussed in the sequel, to simplify the presentation, the range condition $P(r', t')$ will often be omitted; the meaning shall be clear from the context.

Key Results

This section will show how an efficient algorithm is designed for the minimal period retiming problem. Contrary to the usual way of only presenting the final product, i.e., the algorithm, but not the ideas on its design, a step-by-step design process will be shown to finally arrive at the algorithm.

To design an algorithm is to construct a procedure such that it will terminate in finite steps and will satisfy a given predicate when it terminates. In the minimal period retiming problem, the predicate to be satisfied is $P0 \wedge P1 \wedge P2 \wedge P3$. The predicate is also called the *post-condition*. It can be argued that any nontrivial algorithm will have at least one loop; otherwise, the processing length is only proportional to the text length. Therefore, some part of the post-condition will be iteratively satisfied by the loop, while the remaining part will be initially satisfied by an initialization and made invariant during the loop.

The first decision needed to make is to partition the post-condition into possible invariant and loop goal. Among the four conjuncts, the predicate $P3$ gives the optimality condition and is the most complex one. Therefore, it will be used as a loop goal. On the other hand, the predicates $P0$ and $P1$ can be easily satisfied by the following simple initialization:

$$r, t := 0, d.$$

Based on these, the plan is to design an algorithm with the following scheme:

$$\begin{aligned} &r, t := 0, d \\ &\text{do}\{P0 \wedge P1\} \\ &\quad \neg P2 \rightarrow \text{update } t \\ &\quad \neg P3 \rightarrow \text{update } r \\ &\text{od}\{P0 \wedge P1 \wedge P2 \wedge P3\}. \end{aligned}$$

The first command in the loop can be refined as

$$\begin{aligned} \exists (u,v) \in E : r[u] - r[v] = w[u,v] \wedge t[v] &\\ - t[u] < d[v] \rightarrow t[v] &\\ := t[u] + d[v]. & \end{aligned}$$

This is simply the Bellman-Ford relaxations for computing the longest paths.

The second command is more difficult to refine. If $\neg P3$, that is, there exists another valid retiming r', t' such that $\max(t) > \max(t')$, then on any node v such that $t[v] = \max(t)$ it must have $t'[v] < t[v]$. One property known on these nodes is

$$\begin{aligned} &\forall v \in V : t'[v] < t[v] \\ \Rightarrow &(\exists u \in V : r[u] - r[v] > r'[u] - r'[v]), \end{aligned}$$

which means that if the arrival time of v is smaller in another retiming r', t', then there must be a node u such that r' gives more registers between u and v. In fact, one such a u is the starting node of the longest combinational path to v that gives the delay of $t[v]$.

To reduce the clock period, the variable r needs to be updated to make it closer to r'. It should be noted that it is not the absolute values of r but their differences that are relevant in the retiming. If r, t is a solution to a retiming

problem, then $r+c, t$, where $c \in \mathbb{Z}$ is an arbitrary constant, is also a solution. Therefore r can be made "closer" to r' by allocating more registers between u and v, that is, by either decreasing $r[u]$ or increasing $r[v]$. Notice that v can be easily identified by $t[v] = \max(t)$. No matter whether $r[v]$ or $r[u]$ is selected to change, the amount of change should be only one since r should not be overadjusted. Thus, after the adjustment, it is still true that $r[v] - r[u] \leq r'[v] - r'[u]$ or equivalently $r[v] - r'[v] \leq r[u] - r'[u]$. Since v is easy to identify, $r[v]$ is selected to increase. The arrival time $t[v]$ can be immediately reduced to $d[v]$. This gives a refinement of the second command:

$$\neg P3 \wedge P2 \wedge \exists v \in V : t[v] = \max(t) \rightarrow r[v], t[v] := r[v] + 1, d[v].$$

Since registers are moved in the above operation, the predicate $P2$ may be violated. However, the first command will take care of it. That command will increase t on some nodes; some may even become larger than $\max(t)$ before the register move. The same reasoning using r', t' shows that their r values shall be increased, too. Therefore, to implement this as-soon-as-possible (ASAP) increase of r, a snapshot of $\max(t)$ needs to be taken when $P2$ is valid. Physically, such a snapshot records one feasible clock period ϕ and can be implemented by adding one more command in the loop:

$$P2 \wedge \phi > \max(t) \rightarrow \phi := \max(t).$$

However, such an ASAP operation may increase $r[u]$ even when $w[u, v] - r[u] + r[v] = 0$ for an edge (u, v). It means that $P0$ may no longer be an invariant. But moving $P0$ from invariant to loop goal will not cause a problem since one more command can be added in the loop to take care of it:

$$\exists (u, v) \in E : r[u] - r[v] > w[u, v] \rightarrow r[v] := r[u] - w[u, v].$$

Putting all things together, the algorithm now has the following form:

$r, t, \phi := 0, d, \infty;$
do$\{P1\}$
$\exists (u, v) \in E : r[u] - r[v] = w[u, v]$
$\wedge t[v] - t[u] < d[v] \rightarrow t[v] := t[u] + d[v]$
$\neg P3 \wedge \exists v \in V : t[v] \geq \phi$
$\rightarrow r[v], t[v] := r[v] + 1, d[v]$
$P0 \wedge P2 \wedge \phi > \max(t) \rightarrow \phi := \max(t)$
$\exists (u, v) \in E : r[u] - r[v] > w[u, v]$
$\rightarrow r[v] := r[u] - w[u, v]$
od$\{P0 \wedge P1 \wedge P2 \wedge P3\}$.

The remaining task to complete the algorithm is how to check $\neg P3$. From previous discussion, it is already known that $\neg P3$ implies that there is a node u such that $r[u] - r'[u] \geq r'[v] - r'[v]$ every time after $r[v]$ is increased. This means that $\max_{v \in V} r[v] - r'[v]$ will not increase. In other words, there is at least one node v whose $r[v]$ will not change. Before $r[v]$ is increased, it also has $w_{u \rightsquigarrow v} - r[u] + r[v] \leq 0$, where $w_{u \rightsquigarrow v} \geq 0$ is the original number of registers on one path from u to v, which gives $r[v] - r[u] \leq 1$ even after the increase of $r[v]$. This implies that there will be at least $i + 1$ nodes whose r is at most i for $0 \leq i < |V|$. In other words, the algorithm can keep increasing r and when there is any r reaching $|V|$ it shows that $P3$ is satisfied. Therefore, the complete algorithm will have the following form:

$r, t, \phi := 0, d, \infty;$
do$\{P1\}$
$\exists (u, v) \in E : r[u] - r[v] = w[u, v]$
$\wedge t[v] - t[u] < d[v] \rightarrow t[v] := t[u] + d[v]$
$(\forall v \in V : r[v] < |V|)$
$\wedge \exists v \in V : t[v] \geq \phi \rightarrow r[v], t[v] := r[v] + 1, d[v]$
$(\exists v \in V : r[v] \geq |V|)$
$\wedge \exists v \in V : t[v] \geq \phi \rightarrow r[v], t[v] := r[v] + 1, d[v]$
$P0 \wedge P2 \wedge \phi > \max(t) \rightarrow \phi := \max(t)$
$\exists (u, v) \in E : r[u] - r[v] > w[u, v]$
$\rightarrow r[v] := r[u] - w[u, v]$
od$\{P0 \wedge P1 \wedge P2 \wedge P3\}$.

The correctness of the algorithm can be proved easily by showing that the invariant $P1$ is maintained and the negation of the guards implies

$P0 \wedge P2 \wedge P3$. The termination is guaranteed by the monotonic increase of r and an upper bound on it. In fact, the following theorem gives its worst-case runtime.

Theorem 1 *The worst-case running time of the given retiming algorithm is upper bounded by* $O(|V|^2|E|)$.

The runtime bound of the retiming algorithm is got under the worst-case assumption that each increase on r will trigger a timing propagation on the whole circuit ($|E|$ edges). This is only true when the r increase moves all registers in the circuit. However, in such a case, the r is upper bounded by 1, thus the running time is not larger than $O(|V||E|)$. On the other hand, when the r value is large, the circuit is partitioned by the registers into many small parts, thus the timing propagation triggered by one r increase is limited within a small tree.

Applications

In the basic algorithm, the optimality $P3$ is verified by an $r[v] \geq |V|$. However, in most cases, the optimality condition can be discovered much earlier. Since each time $r[v]$ is increased, there must be a "safeguard" node u such that $r[u] - r'[u] \geq r[v] - r'[v]$ after the operation. Therefore, if a pointer is introduced from v to u when $r[v]$ is increased, the pointers cannot form a cycle under $\neg P3$. In fact, the pointers will form a forest where the roots have $r = 0$ and a child can have an r at most one larger than its parent. Using a cycle by the pointers as an indication of $P3$, instead of an $r[v] \geq |V|$, the algorithm can have much better practical performance.

Retiming is usually used to optimize either the clock period or the number of registers in the circuit. The discussed algorithm solves only the minimal period retiming problem. The retiming problem for minimizing the number of registers under a given period has been solved by Leiserson and Saxe [1] and is presented in another entry in this encyclopedia. Their algorithm reduces the problem to the dual of a minimal cost network problem on a denser graph. An efficient iterative algorithm similar to Zhou's algorithm has been designed for the minimal register problem recently [3].

Experimental Results

Experimental results are reported by Zhou [4] which compared the runtime of the algorithm with an efficient heuristic called ASTRA [2]. The results on the ISCAS89 benchmarks are reproduced here in Table 1 from [4], where columns A and B are the running time of the two stages in ASTRA.

Problem Definition

We discuss a simple undirected and connected graph $G = (V, E)$ with a finite set V of vertices and a finite set $E \subseteq V \times V$ of edges. A pair of vertices v and w is said to be adjacent if $(v, w) \in E$. For a subset $R \subseteq V$ of vertices, $G(R) = (R, E \cap (R \times R))$ is an induced subgraph. An induced subgraph $G(Q)$ is said to be a *clique* if $(v, w) \in E$ for all $v, w \in Q \subseteq V$ with $v \neq w$. In this case, we may simply state that Q is a clique. In particular, a clique that is not properly contained in any other clique is called *maximal*. An induced subgraph $G(S)$ is said to be an *independent set* if $(v, w) \notin E$ for all $v, w \in S \subseteq V$. For a vertex $v \in V$, let $\Gamma(v) = \{w \in V | (v, w) \in E\}$. We call $|\Gamma(v)|$ the degree of v.

The problem is to enumerate all maximal cliques of the given graph $G = (V, E)$. It is equivalent to enumerate all maximal independent sets of the *complementary graph* $\bar{G} = \left(V, \bar{E}\right)$, where $\bar{E} = \{(v, w) \in V \times V | (v, w) \notin E, v \neq w\}$.

Key Results

Efficient Algorithms for Clique Enumeration

Efficient algorithms to solve the problem can be found in the following approaches (1) and (2).

(1) Clique Enumeration by Depth-First Search with Pivoting Strategy

The basis of the first approach is a simple depth-first search. It begins with a clique of size 0 and continues with finding all of the progressively larger cliques until they can be verified as maximal. Formally, this approach maintains a global variable $Q = \{p_1, p_2, \ldots, p_d\}$ that consists of vertices of a current clique found so far. Let

$$SUBG = V \cap \Gamma(p_1) \cap \Gamma(p_2) \cap \cdots \cap \Gamma(p_d).$$

We begin the algorithm by letting $Q = \varnothing$ and $SUBG := V$ (the set of all vertices). We select a certain vertex p from $SUBG$ and add p to $Q (Q := Q \cup \{p\})$. Then we compute $SUBG_p := SUBG \cap \Gamma(p)$ as the new set of vertices in question. In particular, the first selected vertex $u \in SUBG$ is called a *pivot*. This procedure (EXPAND()) is applied recursively while $SUBG_p \neq \varnothing$.

When $SUBG_p = \varnothing$ is reached, Q constitutes a *maximal* clique. We then backtrack by removing the lastly inserted vertex from Q and $SUBG$. We select a new vertex p from the resulting $SUBG$ and continue the same procedure until $SUBG = \emptyset$. This process can be represented by a depth-first *search forest*. See Fig. 2b as an

```
procedure CLIQUES(G)
begin                                                        /* Q := ∅ */
 1 : EXPAND(V,V)
end of CLIQUES

      procedure EXPAND(SUBG, CAND)
      begin
 2 :    if SUBG = ∅
 3 :      then print("clique,")                    /* Q is a maximal clique */
 4 :      else u := a vertex u in SUBG that maximizes | CAND ∩ Γ(u) |;   /* pivot */
 5 :           while CAND − Γ(u) ≠ ∅
 6 :             do q := a vertex in (CAND − Γ(u));
 7 :                print (q,",");                          /* Q := Q ∪{ q } */
 8 :                SUBG_q := SUBG ∩ Γ(q);
 9 :                CAND_q := CAND ∩ Γ(q);
10 :                EXPAND(SUBG_q, CAND_q);
11 :                CAND := CAND −{ q};
12 :                print ("back,")                       /* Q := Q −{ q } */
                  od
      fi
      end of EXPAND
```

Clique Enumeration, Fig. 1 Algorithm CLIQUES

example of an essential part of a search forest. It clearly generates all maximal cliques.

The above-generated maximal cliques, however, could contain duplications or nonmaximal ones, so we *prune* unnecessary parts of the search forest as in the Bron-Kerbosch algorithm [3].

First, let *FINI* be a subset of vertices of *SUBG* that have already been processed by the algorithm. (*FINI* is short for *finished*.) Then we denote by *CAND* the set of remaining candidates for expansion: $CAND := SUBG - FINI$, where for two sets X and Y, $X - Y = \{v | v \in X \text{ and } v \notin Y\}$. At the beginning, $FINI := \varnothing$ and $CAND := SUBG$. In the subgraph $G(SUBG_q)$ with $SUBG_q := SUBG \cap \Gamma(q)$, let

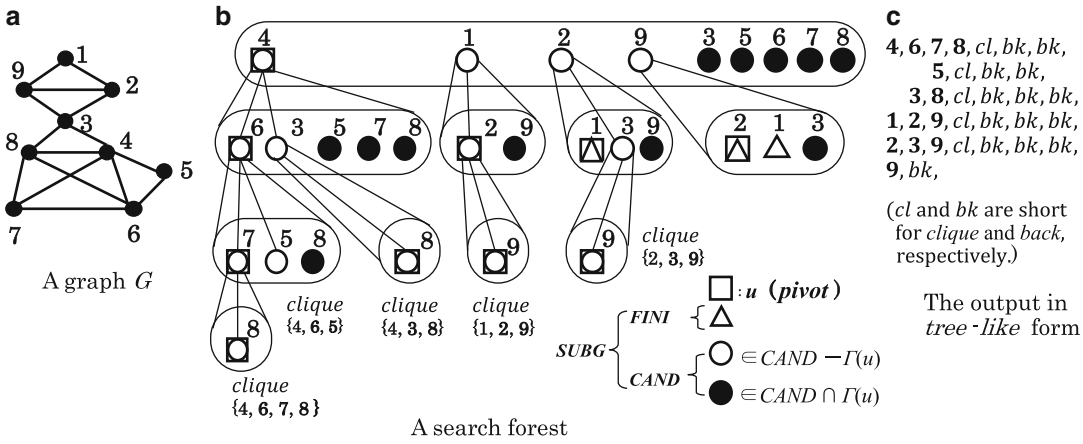
$$FINI_q := SUBG_q \cap FINI,$$
$$CAND_q := SUBG_q - FINI_q.$$

Then only the vertices in $CAND_q$ can be candidates for expanding the clique $Q \cup \{q\}$ to find *new* larger cliques.

Second, for the first selected pivot u in *SUBG*, any maximal clique R in $G(SUBG \cap \Gamma(u))$ is not maximal in $G(SUBG)$, since $R \cup \{u\}$ is a larger clique in $G(SUBG)$. Therefore, searching for maximal cliques from $SUBG \cap \Gamma(u)$ should be excluded.

When the previously described pruning method is also taken into consideration, we find that the only search subtrees to be expanded are from the vertices in $(SUBG - SUBG \cap \Gamma(u)) - FINI = CAND - \Gamma(u)$. Here, in order to minimize $|CAND - \Gamma(u)|$, we choose the pivot $u \in SUBG$ to be the one that *maximizes* $|CAND \cap \Gamma(u)|$. This is *crucial* to establish the *optimality* of the worst-case time complexity of the algorithm. This kind of pivoting strategy was proposed by Tomita et al. [11]. (Recommended Reading [11] was reviewed by Pardalos and Xue [10] and Bomze et al. [2].)

The algorithm CLIQUES by Tomita et al. [12] is shown in Fig. 1. It enumerates all maximal cliques based upon the above approach, but all maximal cliques enumerated are presented in a tree-like form. Here, if Q is a *maximal* clique that is found at statement 2, then the algorithm only prints out a string of characters *clique* instead of Q itself at statement 3. Otherwise, it is impossible to achieve the optimal worst-case running time. Instead, in addition to printing *clique* at statement 3, we print out q followed by a *comma* at statement 7 every time q is picked out as a new element of a larger clique, and we print out a string of characters *back* at statement 12 after q is moved from *CAND* to *FINI* at statement 11. We can easily obtain a tree representation of all



Clique Enumeration, Fig. 2 An example run of CLIQUES [12]. (**a**) A graph G. (**b**) A search forest. (**c**) The output in *tree-like* form

the maximal cliques from the sequence printed by statements 3, 7, and 12. The output in a tree-like format is also important *practically* since it saves space in the output file. An example run of CLIQUES to Fig. 2a is shown in Fig. 2b, c with appropriate indentations.

The worst-case time complexity of CLIQUES was proved to be $O(3^{n/3})$ for an n-vertex graph [11, 12]. This is *optimal* as a function of n since there exist up to $3^{n/3}$ cliques in an n-vertex graph [9].

Eppstein et al. [5] used this approach and proposed an algorithm for enumerating all maximal cliques that runs in time $O(dn3^{d/3})$ for an n-vertex graph G, where d is the *degeneracy* of G that is defined to be the smallest number such that every subgraph of G contains a vertex of degree at most d. If graph G is *sparse*, d can be much smaller than n and hence $O(dn3^{d/3})$ can be much smaller than $O(3^{n/3})$.

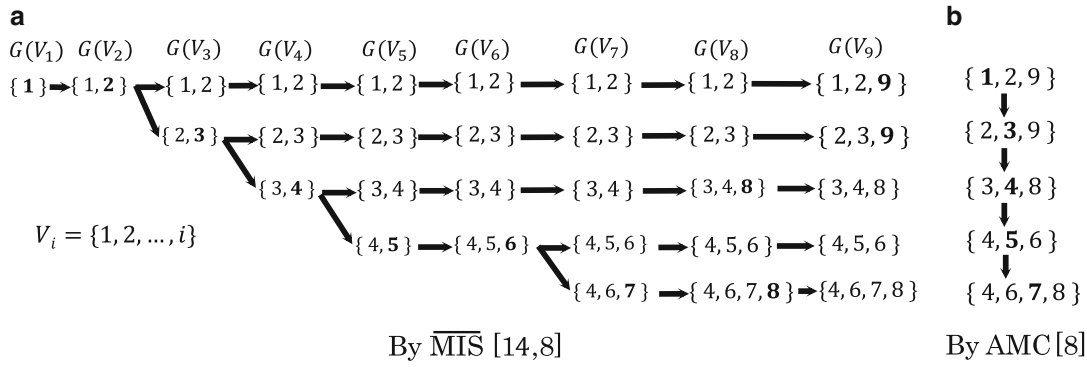
(2) Clique Enumeration by Reverse Search

The second approach is regarded to be based upon the *reverse search* that was introduced by Avis and Fukuda [1] to solve enumeration problems efficiently.

Given the graph $G = (V, E)$ with $V = \{v_1, v_2, \ldots, v_n\}$ where $n = |V|$, let $V_i = \{v_1, v_2, \ldots, v_i\}$. Then $\{v_1\}$ is simply a maximal clique in $G(V_1)$. All the maximal cliques in $G(V_i)$ are enumerated based on those in $G(V_{i-1})$ step by step for $i = 2, 3, \ldots, n$. The process forms an *enumeration tree* whose root is $\{v_1\}$, where the root is considered at depth 1 of the enumeration tree for the sake of simplicity. The children at depth i are all the maximal cliques in $G(V_i)$ for $i = 2, 3, \ldots, n$. For two subsets $X, Y \subseteq V$, we say that X precedes Y in lexicographic order if for $v_i \in (X - Y) \cup (Y - X)$ with the minimum index i it holds that $v_i \in X$.

Let Q be a maximal clique in $G(V_{i-1})$. If v_i is adjacent to all vertices in Q, then $Q \cup \{v_i\}$ is the only child of Q at depth i. Otherwise, Q itself is the first child of Q at depth i. In addition, if $Q \cap \Gamma(v_i) \cup \{v_i\}$ is a *maximal* clique in $G(V_i)$, then it is a candidate for the second child of Q at depth i. The unique parent of $Q \cap \Gamma(v_i) \cup \{v_i\}$ is defined to be the *lexicographically first* maximal clique in $G(V_{i-1})$ that contains $Q \cap \Gamma(v_i)$. (In general, there exist multiple numbers of distinct maximal cliques that contain $Q \cap \Gamma(v_i)$ at depth $i - 1$.)

The algorithm of Tsukiyama et al. [14] traverses the above enumeration tree in a depth-first way. Such a traversal is considered to be reverse search [8]. To be more precise, the algorithm MIS in [14] is to enumerate all maximal independent sets, and we are concerned here with its complementary algorithm in [8] that enumerates all maximal cliques, which we call here $\overline{\text{MIS}}$. An example run of $\overline{\text{MIS}}$ to Fig. 2a is shown in Fig. 3a. Algorithms MIS and $\overline{\text{MIS}}$ run in time $O(m'n)$ and



Clique Enumeration, Fig. 3 Enumeration trees for Fig. 2a in reverse search. (**a**) By $\overline{\text{MIS}}$ [14, 8]. (**b**) By AMC [8]

$O(mn)$ per maximal clique, respectively, where $n = |V|, m = |E|$, and $m' = \left|\bar{E}\right|$ [8, 14].

Chiba and Nishizeki [4] reduced the time complexity of $\overline{\text{MIS}}$ to $O(a(G)m)$ per maximal clique, where $a(G)$ is the *arboricity* of G with $m/(n-1) \leq a(G) \leq O(m^{1/2})$ for a connected graph G. Johnson et al. [7] presented an algorithm that enumerates all maximal cliques in lexicographic order in time $O(mn)$ per maximal clique [7, 8].

Makino and Uno [8] proposed new algorithms that are based on the algorithm of Tsukiyama et al. [14]. Let $C(Q)$ denote the lexicographically first maximal clique containing Q in graph G. The root of their enumeration tree is the lexicographically first maximal clique Q_0 in G. For a maximal clique $Q \neq Q_0$ in the enumeration tree, define the parent of Q to be $C(Q \cap V_i)$ where i is the maximum index such that $C(Q \cap V_i) \neq Q$. Such a parent uniquely exists for every $Q \neq Q_0$. In the enumeration tree, $Q' = C(Q \cap V_j \cap \Gamma(v_j) \cup \{v_j\})$ is a child of Q if and only if Q is a parent of Q'. (In general, a parent has at most $|V|$ children.) This concludes the description of the enumeration tree of AllMaxCliques (AMC for short) in [8]. An example run to Fig. 2a is shown in Fig. 3b, where the bold-faced vertex is the minimum i such that $Q \cap V_i = Q$. Algorithm AMC runs in time $O(M(n))$ per maximal clique, where $M(n)$ denotes the time required to multiply two $n \times n$ matrices. Another algorithm in [8] runs in time $O(\Delta^4)$ per maximal clique, where Δ is the maximum degree of G. Here, if G is sparse, then Δ can be small. In addition, they presented an algorithm that enumerates all *maximal bipartite cliques* in a bipartite graph in time $O(\Delta^3)$ per maximal bipartite clique.

Applications

Clique enumeration has diverse applications in clustering, data mining, information retrieval, bioinformatics, computer vision, wireless networking, computational topology, and many other areas. Here, one of Makino and Uno's algorithms [8] was successfully applied for enumerating *frequent closed itemsets* [16]. See Recommended Reading [2, 5, 6, 8, 10, 12, 13, 16] for details. For practical applications, enumeration of *pseudo cliques* is sometimes more important [15].

Experimental Results

Experimental Results are shown in Recommended Reading [12, 6, 14, 8]. Tomita et al.'s algorithm CLIQUES [12] is fast especially for graphs with high and medium density. Eppstein et al.'s algorithm [5] is effective for very large and sparse graphs [6]. Makino and Uno's algorithms [8] can be fast for sparse graphs especially when they have a small number of maximal cliques.

Problem Definition

Background and Overview

Coordinating processors located in different places is one of the fundamental problems in distributed computing. In his seminal work, Lamport [4, 5] studied the model where the only source of coordination is message exchange between the processors; the time that elapses between successive steps at the same processor, as well as the time spent by a message in transit, may be arbitrarily large or small. Lamport observed that in this model, called the *asynchronous model*, temporal concepts such as "past" and "future" are derivatives of causal dependence, a notion with a simple algorithmic interpretation. The work of Patt-Shamir and Rajsbaum [10] can be viewed as extending Lamport's qualitative treatment with quantitative concepts. For example, a statement like "event a happened before event b" may be refined to a statement like "event a happened at least 2 time units and at most 5 time units before event b". This is in contrast to most previous theoretical work, which focused on the linear-programming aspects of clock synchronization (see below).

The basic idea in [10] is as follows. First, the framework is extended to allow for upper

and lower bounds on the time that elapses between pairs of events, using the system's *real-time specification*. The notion of real-time specification is a very natural one. For example, most processors have local clocks, whose rate of progress is typically bounded with respect to real time (these bounds are usually referred to as the clock's "drift bounds"). Another example is send and receive events of a given message: It is always true that the receive event occurs before the send event, and in many cases, tighter lower and upper bounds are available. Having defined real-time specification, [10] proceeds to show how to combine these local bounds global bounds in the best possible way using simple graph-theoretic concepts. This allows one to derive optimal protocols that say, for example, what is the current reading of a remote clock. If that remote clock is the standard clock, then the result is optimal clock synchronization in the common sense (this concept is called "external synchronization" below).

Formal Model

The system consists of a fixed set of interconnected *processors*. Each processor has a *local clock*. An *execution* of the system is a sequence of events, where each event is either a *send* event, a *receive* event, or an *internal* event. Regarding communication, it is only assumed that each receive event of a message m has a unique corresponding send event of m. This means that messages may be arbitrarily lost, duplicated or reordered, but not corrupted. Each event e occurs at a single specified processor, and has two real numbers associated with it: its *local time*, denoted $\mathrm{LT}(e)$, and its *real time*, denoted $\mathrm{RT}(e)$. The local time of an event models the reading of the local clock when that event occurs, and the local processor may use this value, e.g., for calculations, or by sending it over to another processor. By contrast, the real time of an event is not observable by processors: it is an abstract concept that exists only in the analysis.

Finally, the real-time properties of the system are modeled by a pair of functions that map each pair of events to $\mathbb{R} \cup \{-\infty, \infty\}$: given two events e and e', $L(e, e') = \ell$ means that $\mathrm{RT}(e') - \mathrm{RT}(e) \geq \ell$, and $H(e, e') = h$ means that $\mathrm{RT}(e') - \mathrm{RT}(e) \leq h$, i.e., that the number of (real) time units since the occurrence of event e until the occurrence of e' is at least ℓ and at most h. Without loss of generality, it is assumed that $L(e, e') = -H(e', e)$ for all events e, e' (just use the smaller of them). Henceforth, only the upper bounds function H is used to represent the real-time specification.

Some special cases of real time properties are particularly important. In a completely asynchronous system, $H(e', e) = 0$ if either e occurs before e' in the same processor, or if e and e' are the send and receive events, respectively, of the same message. (For simplicity, it is assumed that two ordered events may have the same real time of occurrence.) In all other cases $H(e, e') = \infty$. On the other extreme of the model spectrum, there is the *drift-free* clocks model, where all local clocks run at exactly the rate of real time. Formally, in this case $H(e, e') = \mathrm{LT}(e') - \mathrm{LT}(e)$ for any two events e and e' occurring at the same processor. Obviously, it may be the case that only some of the clocks in the system are drift-free.

Algorithms

In this work, message generation and delivery is completely decoupled from message information. Formally, messages are assumed to be generated by some "send module", and delivered by the "communication system". The task of algorithms is to add contents in messages and state variables in each node. (The idea of decoupling synchronization information from message generation was introduced in [1].) The algorithm only has local information, i.e., contents of the local state variables and the local clock, as well as the contents of the incoming message, if we are dealing with a receive event. It is also assumed that the real time specification is known to the algorithm. The conjunction of the events, their and their local times (but not their real times) is called as the *view* of the given execution. Algorithms, therefore, can only use as input the view of an execution and its real time specification.

Problem Statement

The simplest variant of clock synchronization is *external synchronization*, where one of the processors, called the source, has a drift-free clock, and the task of all processors is to maintain the tightest possible estimate on the current reading of the source clock. This formulation corresponds to the Newtonian model, where the processors reside in a well-defined time coordinate system, and the source clock is reading the standard time. Formally, in external synchronization each processor v has two output variables Δ_v and ε_v; the estimate of v of the source time at a given state is $LT_v + \Delta_v$, where LT_v is the current local time at v. The algorithm is required to guarantee that the difference between the source time and it estimate is at most ε_v (note that Δ_v, as well as ε_v, may change dynamically during the execution). The performance of the algorithm is judged by the value of the ε_v variables: the smaller, the better.

In another variant of the problem, called *internal synchronization*, there is no distinguished processor, and the requirement is essentially that all clocks will have values which are close to each other. Defining this variant is not as straightforward, because trivial solutions (e.g., "set all clocks to 0 all the time") must be disqualified.

Key Results

The key construct used in [10] is the *synchronization graph* of an execution, defined by combining the concepts of local times and real-time specification as follows.

Definition 1 Let β be a view of an execution of the system, and let H be a real time specification for β. The *synchronization graph* generated by β and H is a directed weighted graph $\Gamma_{\beta H} = (V, E, w)$, where V is the set of events in β, and for each ordered pair of events p q in β such that $H(p,q) < \infty$, there is a directed edge $(p,q) \in E$. The *weight* of an edge (p, q) is $w(p,q) \stackrel{\text{def}}{=} H(p,q) - \mathrm{LT}(p) + \mathrm{LT}(q)$.

The natural concept of *distance* from an event p to an event q in a synchronization graph Γ, denoted $d_\Gamma(p,q)$, is defined by the length of the shortest weight path from p to q, or infinity if q is not reachable from p. Since weights may be negative, one has to prove that the concept is well defined: indeed, it is shown that if $\Gamma_{\beta H}$ is derived from an execution with view β that satisfies real time specification H, then $\Gamma_{\beta H}$ does not contain directed cycles of negative weight.

The main algorithmic result concerning synchronization graphs is summarized in the following theorem.

Theorem 1 *Let α be an execution with view β. Then α satisfies the real time specification H if and only if* $\mathrm{RT}(p) - \mathrm{RT}(q) \leq d_\Gamma(p,q) + \mathrm{LT}(p) - \mathrm{LT}(q)$ *for any two events p and q in $\Gamma_{\beta H}$.*

Note that all quantities in the r.h.s. of the inequality are available to the synchronization algorithm, which can therefore determine upper bounds on the real time that elapses between events. Moreover, these bounds are the best possible, as implied by the next theorem.

Theorem 2 *Let $\Gamma_{\beta H} = (V, E, w)$ be a synchronization graph obtained from a view β satisfying real time specification H. Then for any given event $p_0 \in V$, and for any finite number $N > 0$, there exist executions α_0 and α_1 with view β, both satisfying H, and such that the following real time assignments hold.*

- *In α_0, for all $q \in V$ with $d_\Gamma(q, p_0) < \infty$,$\mathrm{RT}_{\alpha_0}(q) = \mathrm{LT}(q) + d_\Gamma(q, p_0)$, and for all $q \in V$ with $d_\Gamma(q, p_0) = \infty$,$\mathrm{RT}_{\alpha_0}(q) > \mathrm{LT}(q) + N$.*
- *In α_1, for all $q \in V$ with $d_\Gamma(p_0, q) < \infty$,$\mathrm{RT}_{\alpha_1}(q) = \mathrm{LT}(q) - d_\Gamma(p_0, q)$, and for all $q \in V$ with $d_\Gamma(p_0, q) = \infty$,$\mathrm{RT}_{\alpha_1}(q) < \mathrm{LT}(q) - N$.*

From the algorithmic viewpoint, one important drawback of results of Theorems 1 and 2 is that they depend on the view of an execution, which may grow without bound. Is it really necessary?

The last general result in [10] answers this question in the affirmative. Specifically, it is shown that in some variant of the *branching program* computational model, the space complexity of any synchronization algorithm that works with arbitrary real time specifications cannot be bounded by a function of the system size. The result is proved by considering multiple scenarios on a simple system of four processors on a line.

Later Developments

Based on the concept of synchronization graph, Ostrovsky and Patt-Shamir present a refined general optimal algorithm for clock synchronization [9]. The idea in [9] is to discard parts of the synchronization graphs that are no longer relevant. Roughly speaking, the complexity of the algorithm is bounded by a polynomial in the system size and the ratio of processors speeds.

Much theoretical work was invested in the internal synchronization variant of the problem. For example, Lundelius and Lynch [7] proved that in a system of n processors with full connectivity, if message delays can take arbitrary values in [0, 1] and local clocks are drift-free, then the best synchronization that can be guaranteed is $1 - \frac{1}{n}$. Helpern et al. [3] extended their result to general graphs using linear-programming techniques. This work, in turn, was extended by Attiya et al. [1] to analyze any given execution (rather than only the worst case for a given topology), but the analysis is performed off-line and in a centralized fashion. The work of Patt-Shamir and Rajsbaum [10] extended the "per execution" viewpoint to on-line distributed algorithms, and shifted the focus of the problem to external synchronization.

Recently, Fan and Lynch [2] proved that in a line of n processors whose clocks may drift, no algorithm can guarantee that the difference between the clock readings of all pairs of neighbors is $o(\log n / \log \log n)$.

Clock synchronization is very useful in practice. See, for example, Liskov [6] for some motivation. It is worth noting that the Internet provides a protocol for external clock synchronization called NTP [8].

Applications

Theorem 1 immediately gives rise to an algorithm for clock synchronization: every processor maintains a representation of the synchronization graph portion known to it. This can be done using a full information protocol: In each outgoing message this graph is sent, and whenever a message arrives, the graph is extended to include the new information from the graph in the arriving message. By Theorem 2, the synchronization graph obtained this way represents at any point in time all information available required for optimal synchronization. For example, consider external synchronization. Directly from definitions it follows that all events associated with a drift-free clock (such as events in the source node) are at distance 0 from each other in the synchronization graph, and can therefore be considered, for distance computations, as a single node s. Now, assuming that the source clock actually shows real time, it is easy to see that for any event p,

$$\mathrm{RT}(p) \in [\mathrm{LT}(p) - d(s, p), \mathrm{LT}(p) + d(p, s)],$$

and furthermore, no better bounds can be obtained by any correct algorithm.

The general algorithm described above (maintaining the complete synchronization graph) can be used also to obtain optimal results for internal synchronization; details are omitted.

An interesting special case is where all clocks are drift free. In this case, the size of the synchronization graph remains fixed: similarly to a source node in external synchronization, all events occurring at the same processor can be mapped to a single node; parallel edges can be replaced by a single new edge whose weight is minimal among all old edges. This way one can obtain a particularly efficient distributed algorithm solving external clock synchronization, based on the distributed Bellman–Ford algorithm for distance computation.

Finally, note that the asynchronous model may also be viewed as a special case of this general theory, where an event p "happens before" an event q if and only if $d(p, q) \leq 0$.

Open Problems

One central issue in clock synchronization is faulty executions, where the real time specification is violated. Synchronization graphs detect any detectable error: views which do not have an execution that conforms with the real time specification will result in synchronization graphs with negative cycles. However, it is desirable to overcome such faults, say by removing from the synchronization graph some edges so as to break all negative-weight cycles. The natural objective in this case is to remove the least number of edges. This problem is APX-hard as it generalizes the Feedback Arc Set problem. Unfortunately, no non-trivial approximation algorithms for it are known.

Problem Definition

The problem of finding a center string that is "close" to every given string arises and has applications in computational molecular biology [4,5,9–11,18,19] and coding theory [1,6,7].

This problem has two versions: The first problem comes from coding theory when we are looking for a code not too far away from a given set of codes.

Problem 1 (The closest string problem) Input: a set of strings $\mathcal{S} = \{s_1, s_2, \ldots, s_n\}$, each of length m.

Output: the smallest d and a string s of length m which is within Hamming distance d to each $s_i \in \mathcal{S}$.

The second problem is much more elusive than the closest string problem. The problem is formulated from applications in finding conserved regions, genetic drug target identification, and genetic probes in molecular biology.

Problem 2 (The closest substring problem) Input: an integer L and a set of strings $\mathcal{S} = \{s_1, s_2, \ldots, s_n\}$, each of length m.

Output: the smallest d and a string s, of length L, which is within Hamming distance d away from a length L substring t_i of s_i for $i = 1, 2, \ldots, n$.

The following results on approximation algorithms are from [12–15].

Theorem 1 *There is a polynomial time approximation scheme for the closest string problem.*

Theorem 2 *There is a polynomial time approximation scheme for the closest substring problem.*

A faster approximation algorithm for the closest string problem was given in [16].

Lots of results have been obtained in terms of parameterized complexity and fixed-parameter algorithms. In 2005, Marx showed that the closest substring problem is W[1]-hard even if both d and n are parameters [17]. Two algorithms for the closest substring problem have been developed [17] for the cases where d and n are small. The running times for the two algorithms are $f(d) \cdot m^{O(\log d)}$ and $g(d,n) \cdot n^{O(\log \log n)}$ for some functions f and g, respectively. The first fixed-parameter algorithm for closest string problem has a running time complexity $O(nd^{d+1})$ [8]. Ma and Sun designed a fixed-parameter algorithm with running time $O(nm + nd \cdot (16|\Sigma|)^d)$ for the closest string problem [16]. Extending the algorithm for the closest string problem, an $O(nL + nd \times 2^{4d}|\Sigma|^d \times m^{\lceil \log d \rceil + 1})$ time algorithm was given for the closest substring problem [16].

Since then, a series of improved algorithms have been obtained. Wang and Zhu gave an $O(nL + nd \cdot (2^{3.25}(|\Sigma| - 1))^d)$ algorithm for the closest string problem [20]. Chen and Wang gave an algorithm with running times $O(nL + nd \cdot 47.21^d)$ for protein with $|\Sigma| = 20$ and $O(nL + nd \cdot 13.92^d)$ for DNA with $|\Sigma| = 4$, respectively [2]. They also developed a software package for the (L,d) motif model. Currently the fastest fixed-parameter algorithm for the closest string problem was given by Chen, Ma, and Wang. They developed a three-string approach and the running time of the algorithm is $O(nL + nd^3 \cdot d^6.731)$ for binary strings [3].

Results for other measures with applications in computational biology can be found in [5, 9, 18, 19].

Applications

Many problems in molecular biology involve finding similar regions common to each sequence in a given set of DNA, RNA, or protein sequences. These problems find applications in locating binding sites and finding conserved regions in unaligned sequences [5, 9, 18, 19], genetic drug target identification [10], designing genetic probes [10], universal PCR primer design [5, 10], and, outside computational biology, in coding theory [1, 6, 7]. Such problems may be considered to be various generalizations of the common substring problem, allowing errors. Many measures have been proposed for finding such regions common to every given string. A popular and one of the most fundamental

measures is the Hamming distance. Moreover, two popular objective functions are used in these areas. One is the total sum of distances between the center string (common substring) and each of the given strings. The other is the maximum distance between the center string and a given string. For more details, see [10].

A More General Problem

The *distinguishing substring selection* problem has as input two sets of strings, $\mathcal{B}$ and $\mathcal{G}$. It is required to find a substring of unspecified length (denoted by L) such that it is, informally, close to a substring of every string in $\mathcal{B}$ and far away from every length L substring of strings in $\mathcal{G}$. However, we can go through all the possible length L substrings of strings in $\mathcal{G}$, and we may assume that every string in $\mathcal{G}$ has the same length L since $\mathcal{G}$ can be reconstructed to contain all substrings of length L in each of the good strings.

The problem is formally defined as follows: Given a set $\mathcal{B} = \{s_1, s_2, \ldots, s_n\}$ of n_1 (bad) strings of length at least L, and a set $\mathcal{G} = \{g_1, g_2, \ldots g_{n_2}\}$ of n_2 (good) strings of length exactly L, as well as two integers d_b and d_g ($d_b \leq d_g$), the distinguishing substring selection problem (DSSP) is to find a string s such that for each string, there exists a length L substring t_i of s_i with $d(s, t_i) \leq d_b$ and for any string $g_i \in \mathcal{G}$, $d(s, g_i) \geq d_g$. Here $d(,)$ represents the Hamming distance between two strings. If all strings in $\mathcal{B}$ are also of the same length L, the problem is called the distinguishing string problem (DSP).

The distinguishing string problem was first proposed in [10] for generic drug target design. The following results are from [4].

Theorem 3 *There is a polynomial time approximation scheme for the distinguishing substring selection problem. That is, for any constant $\epsilon > 0$, the algorithm finds a string s of length L such that for every $s_i \in \mathcal{B}$, there is a length L substring t_i of s_i with $d(t_i, s) \leq (1 + \epsilon)d_b$ and for every substring u_i of length L of every $g_i \in \mathcal{G}$, $d(u_i, s) \geq (1 - \epsilon)d_g$, if a solution to the original pair ($d_b \leq d_g$) exists. Since there are a polynomial number of such pairs (db,dg), we can exhaust all the possibilities in polynomial time to find a good approximation required by the corresponding application problems.*

Open Problems

The PTASs designed here use linear programming and randomized rounding technique to solve some cases for the problem. Thus, the running time complexity of the algorithms for both the closest string and closest substring is very high. An interesting open problem is to design more efficient PTASs for both problems.

Problem Definition

CLOSEST SUBSTRING is a core problem in the field of consensus string analysis with, in particular, applications in computational biology. Its decision version is defined as follows.

CLOSEST SUBSTRING
Input: k strings $s_1, s_2, \ldots, s_k$ over alphabet Σ and non-negative integers d and L.
Question: Is there a string s of length L and, for all $i = 1, \ldots, k$, a length-L substring s_i' of s_i such that $d_H(s, s_i') \leq d$?
Here $d_H(s, s_i')$ denotes the Hamming distance between s and s_i', i.e., the number of positions in which s and s_i' differ. Following the notation used in [7], m is used to denote the average length of the input strings and n to denote the total size of the problem input.

The optimization version of CLOSEST SUBSTRING asks for the minimum value of the distance parameter d for which the input strings still allow a solution.

Key Results

The classical complexity of CLOSEST SUBSTRING is given by

Theorem 1 ([4, 5]) CLOSEST SUBSTRING *is NP-complete, and remains so for the special case of the* CLOSEST STRING *problem, where the requested solution string s has to be of same length as the input strings.* CLOSEST STRING *is NP-complete even for the further restriction to a binary alphabet.*

The following theorem gives the central statement concerning the problem's approximability:

Theorem 2 ([6]) CLOSEST SUBSTRING *(as well as* CLOSEST STRING*) admit polynomial time approximation schemes (PTAS's), where the objective function is the minimum Hamming distance d.*

In its randomized version, the PTAS cited by Theorem 2 computes, with high probability,

a solution with Hamming distance $(1+\epsilon)d_{\text{opt}}$ for an optimum value d_{opt} in $(k^2m)^{O(\log|\Sigma|/\epsilon^4)}$ running time. With additional overhead, this randomized PTAS can be derandomized. A straightforward and efficient factor-2 approximation for CLOSEST STRING is obtained by trying all length-L substrings of one of the input strings.

The following two statements address the problem's parametrized complexity, with respect to both obvious problem parameters d and k:

Theorem 3 ([3]) CLOSEST SUBSTRING *is W[1]-hard with respect to the parameter k, even for binary alphabet.*

Theorem 4 ([7]) CLOSEST SUBSTRING *is W[1]-hard with respect to the parameter d, even for binary alphabet.*

For non-binary alphabet the statement of Theorem 3 has been shown independently by Evans et al. [2]. Theorem 3 and Theorem 4 show that an exact algorithm for CLOSEST SUBSTRING with polynomial running time is unlikely for a constant value of d as well as for a constant value of k, i.e., such an algorithm does not exist unless 3-SAT can be solved in subexponential time.

Theorem 4 also allows additional insights into the problem's approximability: In the PTAS for CLOSEST SUBSTRING, the exponent of the polynomial bounding the running time depends on the approximation factor. These are not "efficient" PTAS's (EPTAS's), i.e., PTAS's with a $f(\epsilon)\cdot n^c$ running time for some function f and some constant c, and therefore are probably not useful in practice. Theorem 4 implies that most likely the PTAS with the $n^{O(1/\epsilon^4)}$ running time presented in [6] cannot be improved to an EPTAS. More precisely, there is no $f(\epsilon)\cdot n^{o(\log 1/\epsilon)}$ time PTAS for CLOSEST SUBSTRING unless 3-SAT can be solved in subexponential time. Moreover, the proof of Theorem 4 also yields.

Theorem 5 ([7]) *There are no $f(d,k)\cdot n^{o(\log d)}$ time and no $g(d,k)\cdot n^{o(\log\log k)}$ exact algorithms solving* CLOSEST SUBSTRING *for some functions f and g unless 3-SAT can be solved in subexponential time.*

For unbounded alphabet the bounds have been strengthened by showing that Closest Substring has no PTAS with running time $f(\epsilon)\cdot n^{o(1/\epsilon)}$ for any function f unless 3-SAT can be solved in subexponential time [10]. The following statements provide exact algorithms for CLOSEST SUBSTRING with small fixed values of d and k, matching the bounds given in Theorem 5:

Theorem 6 ([7]) CLOSEST SUBSTRING *can be solved in time $f(d)\cdot n^{O(\log d)}$ for some function f, where, more precisely, $f(d)=|\Sigma|^{d(\log d+2)}$.*

Theorem 7 ([7]) CLOSEST SUBSTRING *can be solved in time $g(d,k)\cdot n^{O(\log\log k)}$ for some function g, where, more precisely, $g(d,k)=(|\Sigma|d)^{O(kd)}$.*

With regard to problem parameter L, CLOSEST SUBSTRING can be trivially solved in $O(|\Sigma|^L\cdot n)$ time by trying all possible strings over alphabet Σ.

Applications

An application of CLOSEST SUBSTRING lies in the analysis of biological sequences. In motif discovery, a goal is to search "signals" common to a set of selected strings representing DNA or protein sequences. One way to represent these signals are approximately preserved substrings occurring in each of the input strings. Employing Hamming distance as a biologically meaningful distance measure results in the problem formulation of CLOSEST SUBSTRING.

For example, Sagot [9] studies motif discovery by solving CLOSEST SUBSTRING (and generalizations thereof) using suffix trees; this approach has a worst-case running time of $O(k^2m\cdot L^d\cdot|\Sigma|^d)$. In the context of motif discovery, also heuristics applicable to CLOSEST SUBSTRING were proposed, e.g., Pevzner and Sze [8] present an algorithm called WINNOWER and Buhler and Tompa [1] use a technique called random projections.

Open Problems

It is open [7] whether the $n^{O(1/\epsilon^4)}$ running time of the approximation scheme presented in [6] can be improved to $n^{O(\log 1/\epsilon)}$, matching the bound derived from Theorem 4.

Cross-References

The following problems are close relatives of CLOSEST SUBSTRING:

- ▶ Closest String and Substring Problems is the special case of CLOSEST SUBSTRING, where the requested solution string s has to be of same length as the input strings.
- Distinguishing Substring Selection is the generalization of CLOSEST SUBSTRING, where a second set of input strings and an additional integer d' are given and where the requested solution string s has – in addition to the requirements posed by CLOSEST SUBSTRING – Hamming distance at least d' with every length-L substring from the second set of strings.
- Consensus Patterns is the problem obtained by replacing, in the definition of CLOSEST SUBSTRING, the maximum of Hamming distances by the sum of Hamming distances. The resulting modified question of CONSENSUS PATTERNS is: Is there a string s of length L with

$$\sum_{i=1,\ldots,m} d_H(s, s_i') \leq d?$$

CONSENSUS PATTERNS is the special case of SUBSTRING PARSIMONY in which the phylogenetic tree provided in the definition of SUBSTRING PARSIMONY is a star phylogeny.

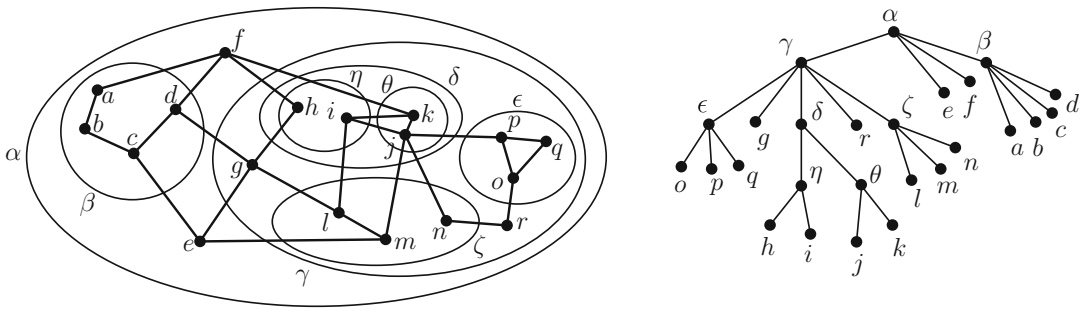
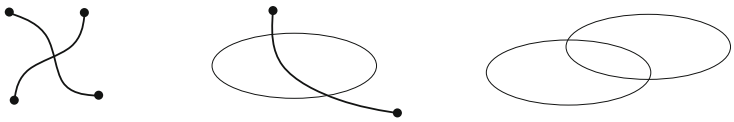
Problem Definition

A *clustered graph* $C(G, T)$ consists of a graph G, called *underlying graph*, and of a rooted tree T, called *inclusion tree*. The leaves of T are the vertices of G; each internal node μ of T



Clustered Graph Drawing, Fig. 1 A clustered graph $C(G, T)$ (*left*) and its inclusion tree (*right*)

Clustered Graph Drawing, Fig. 2 Types of crossings in a drawing of a clustered graph



represents a *cluster*, that is, the set of vertices of G that are the leaves of the subtree of T rooted at μ. Figure 1 shows a clustered graph and its inclusion tree.

Clustered graphs are widely used in applications where it is needed at the same time to represent relationships between entities and to group entities with semantic affinities. For example, in the Internet network, the routers and the links between them are the vertices and edges of a graph, respectively; geographically close routers are grouped into areas that are hence associated with clusters of vertices. In turn, areas are grouped into autonomous systems that are hence associated with clusters of vertices.

Visualizing clustered graphs is a difficult problem, due to the simultaneous need for a readable drawing of the underlying structure and of the clustering relationship. As for the visualization of graphs, the most important aesthetic criterion for the readability of a drawing of a clustered graph is the *planarity*, whose definition needs a refinement in the context of clustered graphs, in order to deal with the clustering structure.

In a *drawing* of a clustered graph $C(G, T)$, vertices and edges of G are drawn as points and open curves, respectively, and each cluster μ is represented by a simple closed region R_μ containing all and only the vertices of μ. A drawing of C can have three types of crossings. *Edge-edge crossings* are crossings between edges of G (see Fig. 2, left). Consider an edge e of G and a cluster μ in T. If e intersects the boundary of R_μ more than once, we have an *edge-region crossing* (see Fig. 2, middle). Finally, consider two clusters μ and ν in T; if the boundary of R_μ intersects the boundary of R_ν, we have a *region-region crossing* (see Fig. 2, right). A drawing of a clustered graph is *c-planar* (short for *clustered planar*) if it does not have any edge-edge, edge-region, or region-region crossing. A clustered graph is *c-planar* if it admits a c-planar drawing. A drawing of a clustered graph is *straight line* if each edge is represented by a straight-line segment; also, it is *convex* if each cluster is represented by a convex region.

The notion of c-planarity was first introduced by Feng, Cohen, and Eades in 1995 [10, 11]. The graph drawing community has subsequently adopted this definition as a standard, and the topological and geometric properties of c-planar drawings of clustered graphs have been investigated in tens of papers. The two main questions raised by Feng, Cohen, and Eades were the following.

Problem 1 (C-Planarity Testing)

QUESTION: What's the time complexity of testing the c-planarity of a clustered graph?

Problem 2 (Straight-Line Convex C-Planar Drawability)

QUESTION: Does every c-planar-clustered graph admit a straight-line convex c-planar drawing?

Key Results

Almost 20 years after the publication of the seminal papers by Feng et al. [10, 11], a solution for Problem 1 remains an elusive goal, arguably the most intriguing and well-studied algorithmic problem in the graph drawing research area (see, e.g., [3, 4, 7, 12, 13, 15–17]).

Polynomial-time algorithms have been presented to test the c-planarity of a large number of classes of clustered graphs. A particular attention has been devoted to *c-connected* clustered graphs that are clustered graphs $C(G, T)$ such that each cluster $\mu \in T$ induces a connected component G_μ of G. The following theorem reveals the importance of c-connected clustered graphs.

Theorem 1 (Feng, Cohen, and Eades [11]) *A clustered graph is c-planar if and only if it is a subgraph of a c-planar c-connected clustered graph.*

Feng, Cohen, and Eades provided in [11] a nice and simple quadratic-time testing algorithm, which is described in the following.

Theorem 2 (Feng, Cohen, and Eades [11]) *The c-planarity of an n-vertex c-connected clustered graph can be tested in $O(n^2)$ time.*

The starting point of Feng et al. result is a characterization of c-planar drawings.

Theorem 3 (Feng, Cohen, and Eades [11]) *A drawing of a c-connected clustered graph $C(G, T)$ is c-planar if and only if it is planar, and, for each cluster μ, all the vertices and edges of $G - G_\mu$ are in the outer face of the drawing of G_μ.*

The algorithm of Feng et al. [11] performs a bottom-up traversal of T.

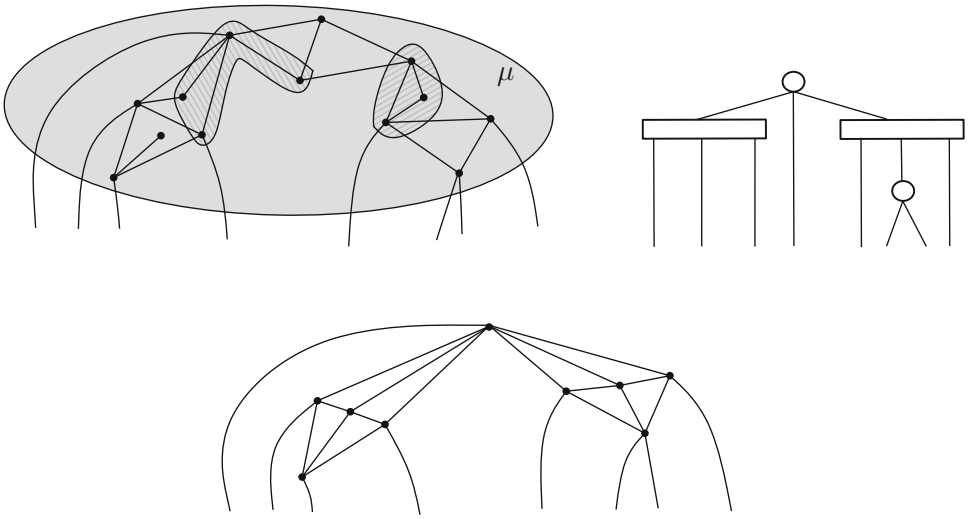
When a node $\mu \in T$ is considered, the algorithm tests whether a drawing of G_μ exists such that (P1) for each descendant ν of μ, all the vertices and edges of $G_\mu - G_\nu$ are in the outer face of the drawing of G_ν in Γ_μ and (P2) all the vertices of G_μ having neighbors in $G - G_\mu$ are incident to the outer face of G_μ in Γ_μ. Feng et al. show how a PQ-tree P_μ [2] can be used to efficiently represent all the (possibly exponentially many) orderings in which the edges incident to μ can cross the boundary of R_μ in any planar drawing Γ_μ of G_μ satisfying properties P1 and P2 (see Fig. 3, left and middle).

PQ-tree P_μ can be easily computed for each leaf $\mu \in T$. Consider an internal node $\mu \in T$ and assume that PQ-trees $P_{\mu_1}, \ldots, P_{\mu_k}$ have been associated to the children $\mu_1, \ldots, \mu_k$ of μ. *Representative graphs* $H_{\mu_1}, \ldots, H_{\mu_k}$ are constructed from $P_{\mu_1}, \ldots, P_{\mu_k}$; the embeddings of H_{μ_i} are in bijection with the embeddings of G_{μ_i} satisfying properties P1 and P2 (see Fig. 3, left and right). Then, a graph G'_μ is constructed composed of $H_{\mu_1}, \ldots, H_{\mu_k}$, of a dummy vertex v_μ, and of length-2 paths connecting v_μ with every vertex of $H_{\mu_1}, \ldots, H_{\mu_k}$ that has a neighbor in $G - G_\mu$. Feng et al. argue that the embeddings of G_μ satisfying properties P1 and P2 are in bijection with the embeddings of G'_μ in which v_μ is incident to the outer face. Hence, a planarity testing for G'_μ is performed. This allows to determine P_μ, thus allowing the visit of T to go on.

If no planarity test fails, the algorithm completes the visit of T. Top-down traversing T and fixing an embedding for the PQ-tree associated to each node of T determines a c-planar drawing of $C(G, T)$.

Involved linear-time algorithms to test the c-planarity of c-connected clustered graphs are known nowadays [5, 6]. The algorithm in [5] relies on a structural characterization of the c-planarity of a c-connected clustered graph $C(G, T)$ based on the decomposition of G into triconnected components. The characterization allows one to test in linear time the c-planarity of $C(G, T)$ via a bottom-up visit of the SPQR-tree [8] of G, which is a data structure efficiently representing the planar embeddings of G.

Problem 1 is fundamental for the graph drawing research area. However, no less importance has to be attributed to the task of designing



Clustered Graph Drawing, Fig. 3 *Left*: Graph G_μ and the edges incident to μ. *Middle*: The PQ-tree representing the possible orderings in which the edges incident to μ can cross the boundary of R_μ in a planar drawing of G_μ satisfying properties P1 and P2. *Right*: The representative graph H_μ for G_μ

algorithms for constructing *geometric representations* of clustered graphs. The milestones in this research direction have been established by Feng et al., who provided in [10] a full answer to Problem 2.

Theorem 4 (Feng, Cohen, and Eades [10]) *Every c-planar clustered graph admits a straight-line convex c-planar drawing.*

The proof of Theorem 4 relies on a positive answer for the following question: Does every *planar hierarchical graph* admit a *planar straight-line hierarchical drawing*? A *hierarchical graph* is a graph with an assignment of its vertices to k layers $l_1, \ldots, l_k$. A hierarchical drawing maps each vertex assigned to layer l_i to a point on the horizontal line $y = i$ and each edge to a y-monotone curve between the corresponding endpoints. A hierarchical graph is *planar* if it admits a planar hierarchical drawing. Feng et al. [10] showed an algorithm to construct a planar straight-line hierarchical drawing of any planar hierarchical graph H. Their algorithm splits H into some subgraphs, inductively constructs planar straight-line hierarchical drawings of such subgraphs, and glues these drawings together to obtain a planar straight-line hierarchical drawing of H.

Feng et al. also showed how the result on hierarchical graphs leads to a proof of Theorem 4, namely:

1. Starting from any c-planar clustered graph $C(G, T)$, construct a hierarchical graph H by assigning the vertices of G to n layers, in the same order as in an st-numbering of G in which vertices of the same cluster are numbered consecutively.
2. Construct a planar straight-line hierarchical drawing Γ_H of H.
3. Construct a straight-line convex c-planar drawing of $C(G, T)$ starting from Γ_H by drawing each cluster as a convex region slightly surrounding the convex hull of its vertices.

Angelini, Frati, and Kaufmann [1] recently strengthened Theorem 4 by proving that every c-planar clustered graph admits a straight-line c-planar drawing in which each cluster is represented by a scaled copy of an arbitrary convex shape.

Hong and Nagamochi [14] studied straight-line convex c-planar drawings in which the faces of the underlying graph are delimited by convex polygons. They proved that a c-connected

clustered graph admits such a drawing if and only if it is c-planar, completely connected (i.e., for every cluster μ, both G_μ and $G - G_\mu$ are connected), and internally triconnected (i.e., for every separation pair $\{u, v\}$, vertices u and v are incident to the outer face of G and each connected component of $G - \{u, v\}$ contains vertices incident to the outer face of G).

The drawings constructed by the algorithm in [10] use real coordinates. Hence, when displaying these drawings on a screen with a finite resolution rule, exponential area might be required for the visualization. This drawback is however unavoidable. Namely, Feng et al. proved in [10] that there exist clustered graphs requiring exponential area in *any* straight-line convex c-planar drawing with a finite resolution rule. This harshly differentiates c-planar clustered graphs from planar graphs, as straight-line convex planar drawings of planar graphs can be constructed in polynomial area.

Theorem 5 (Feng, Cohen, and Eades [10]) *There exist n-vertex c-planar clustered graphs requiring $2^{\Omega(n)}$ area in any straight-line convex c-planar drawing.*

The proof of Theorem 5 adapts techniques introduced by Di Battista et al. [9] to prove area lower bounds for *straight-line upward planar drawings* of *directed graphs*.

Open Problems

After almost 20 years since it was first posed by Feng, Cohen, and Eades, Problem 1 still represents a terrific challenge for researchers working in graph drawing.

A key result of Feng, Cohen, and Eades [11] shows that testing the c-planarity of a clustered graph $C(G, T)$ is a polynomial-time solvable problem if $C(G, T)$ is c-connected – see Theorem 2. Moreover, a clustered graph is c-planar if and only if it is a subgraph of a c-planar c-connected clustered graph – see Theorem 1. Hence, the core of testing the c-planarity of a non-c-connected clustered graph $C(G, T)$ is an augmentation problem, asking whether $C(G, T)$ can be augmented to a c-connected c-planar clustered graph $C'(G', T)$ by inserting edges in G.

This augmentation problem seems far from being solved. A particular attention [3,4,7,15,16] has been devoted to the case in which a planar embedding for G is prescribed as part of the input. In this case, edges might only be inserted inside faces of G, in order to guarantee the planarity of G'. Thus, the problem becomes equivalent to the one selecting a set S of edges into a set M of topological embedded multigraphs, where each cluster μ defines a multigraph M_μ in M consisting of all the edges that can be inserted inside faces of G in order to connect distinct connected components of G_μ. Then the edges in S are those that are selected to augment G to G' – hence no two edges in S are allowed to cross. Even in this prescribed-embedding version, only partial results are known. For example, polynomial-time algorithms to test the c-planarity of $C(G, T)$ are known if the faces of G have at most five incident vertices [7], or if each cluster induces at most two connected components [15], or if each cluster has at most two incident vertices on each face of G [3].

Problem Definition

The problem of clustering consists of partitioning a set of objects such as images, text documents, etc. into groups of related items. The information available to the clustering algorithm consists of pairwise similarity information between objects. One of the most popular approaches to clustering is to map the objects into data points in a metric space, define an objective function over the data points, and find a partitioning which achieves the optimal solution, or an approximately optimal solution to the given objective function. In this entry, we will focus on two of the most widely studied objective functions for clustering: the k-median objective and the k-means objective.

In k-median clustering, the input is a set P of n points in a metric space (X, d), where $d(\cdot)$ is

the distance function. The objective is to find k center points $c_1, c_2, \cdots c_k$. The clustering is then formed by assigning each data point to the closest center point. If a point x is assigned to center $c(x)$, then the cost incurred is $d(x, c(x))$. The goal is to find center points and a partitioning of the data so as to minimize the total cost $\Phi = \min_{c_1,c_2,\ldots c_k} \sum_x \min_i d(x, c_i)$. This objective is closely related to the well-studied facility location problem [1, 9] in theoretical computer science.

Similarly, for the k-means objective, the goal is to find k center points. However, the cost incurred by a point x is the distance squared to its center. Hence, the goal is to minimize $\Phi = \min_{c_1,c_2,\ldots c_k} \sum_x \min_i d^2(x, c_i)$. A special case of the k-means objective which is of particular interest is the Euclidean k-means problem where the points are in $\Re^m$ and the distance function is the squared Euclidean distance. Again, the goal is to choose k center points and assign each point to the closest center while minimizing the total cost. However, unlike k-median and k-means in metric spaces, the center points do not necessarily have to belong to the data set P and can be arbitrarily chosen from $\Re^m$. Unfortunately, optimizing both these objectives turns out to be NP-hard. Hence, a lot of the work in the theoretical computer science community focuses on designing good approximation algorithms for these problems[1, 8–10, 12] with formal guarantees on worst-case instances.

However, in most practical scenarios, the clustering instances which one encounters are not worst case but instead have additional structure/stability associated with them. In such cases, it is natural to ask if one can abstract out this structure in the form of a stability notion, formally study it, and exploit this additional structure in order to obtain optimal or nearly optimal solutions and bypass NP-hardness which only applies to worst-case instances. This modern take on clustering research has, in recent years, produced new insights and deeper understanding of what we know about clustering. In this entry, we will survey some key results on clustering under stability assumptions.

Key Results

ϵ-separability:

This notion of stability was proposed by Ostrovsky et al. [15]. The motivation comes from the fact that in practice, when solving a clustering instance, one typically has to decide how many clusters to partition the data into, i.e., the value of k. If the k-means objective is the underlying criteria being used to judge the quality of a clustering, and the optimal $(k-1)$-means clustering is comparable to the optimal k-means clustering; then, one can in principle also use $(k-1)$ clusters to describe the data set. Hence, the particular clustering instance is not well behaved or not stable. In fact this particular method is a very popular heuristic to find out the number of hidden clusters in the data set suggesting that real-world instances have this property.

Definition 1 (ϵ-Separability) Given an instance of Euclidean k-means clustering, let $\mathrm{OPT}(k)$ denote the cost of the optimal k-means solution. We can also decompose $\mathrm{OPT}(k)$ as $\mathrm{OPT} = \sum_{i=1}^{k} \mathrm{OPT}_i$, where OPT_i denotes the 1-means cost of cluster C_i, i.e., $\sum_{x \in C_i} d(x, c_i)^2$. Such an instance is called *ϵ-separable* if it satisfies $\mathrm{OPT}(k-1) > \frac{1}{\epsilon^2}\mathrm{OPT}(k)$.

It was shown by Ostrovsky et al. [15] that one can design much better approximation algorithms for such instances. The algorithm is based on over sampling $O(k)$ candidate centers using a distance weighted sampling scheme, followed by a greedy deletion strategy to reduce the k centers without incurring too much increase in the k-means cost.

Theorem 1 ([15]) *There is a polynomial time algorithm which given any ϵ-separable Euclidean k-means instance, outputs a clustering of cost at most $\frac{\mathrm{OPT}}{1-\rho}$ with probability $1 - O((\rho)^{1/4})$ where $\rho = \Theta(\epsilon^2)$.*

$(1+\alpha, \epsilon)$-Approximation-Stability:

Balcan et al. [5] introduced and analyzed a class of approximation stable instances for which one can find near optimal clusterings in polynomial time. The motivation comes from the fact that for many problems of interest to machine learning, there is an unknown underlying correct "target"

clustering. In such cases, the implicit hope when pursuing an objective-based clustering approach (k-means or k-median) is that approximately optimizing the objective function will in fact produce a clustering of low clustering error, i.e., a clustering that is point wise close to the target clustering. Balcan et al. showed that by making this implicit assumption explicit, one can efficiently compute a low-error clustering even in cases when the approximation problem of the objective function is NP-hard!

Definition 2 (**$(1+\alpha,\epsilon)$-approximation-stability**) Let P be a set of n points residing in a metric space (M,d). Given an objective function Φ (such as k-median, k-means), we say that instance (M,P) *satisfies* $(1+\alpha,\epsilon)$-*approximation-stability for* Φ if all clusterings $\mathcal{C}$ with $\Phi(\mathcal{C}) \leq (1+\alpha)\cdot \mathrm{OPT}(k)$ are point-wise ϵ-close to the target clustering $\mathcal{T}$ for (M,P).

Here, the term "target" clustering refers to the ground truth clustering of P which one is trying to approximate. The distance between any two k clusterings $\mathcal{C}$ and $\mathcal{C}^*$ of n points is measured as $\mathrm{dist}(\mathcal{C},\mathcal{C}^*) = \min_{\sigma\in S_k}\frac{1}{n}\sum_{i=1}^{k}|C_i \setminus C^*_{\sigma(i)}|$. Interestingly, this approximation stability condition implies a lot of structure about the problem instance which could be exploited algorithmically. For example, one can show the following:

Theorem 2 (**[5]**) *If the given instance* (M,P) *satisfies* $(1+\alpha,\epsilon)$*-approximation-stability for the* k*-median or the* k*-means objective, then we can efficiently produce a clustering that is* $O(\epsilon+\epsilon/\alpha)$*-close to the target clustering* $\mathcal{T}$.

As mentioned above, this theorem is valid even for values of α for which getting a $(1+\alpha)$-approximation to k-median and k-means is NP-hard! The algorithm first creates a graph over data points by connecting points which are within a certain distance threshold. The next step involves iteratively peeling off connected components in the graph and simultaneously de-noising the instance.

Related Notions

The notion of ϵ-separability and $(1+\alpha,\epsilon)$-approximation-stability are related to each other. For example, Theorem 5.1 in [15] shows that ϵ-separability implies that any near-optimal solution to k-means is $O(\epsilon^2)$-close to the k-means optimal clustering. However, the converse is not necessarily the case; an instance could satisfy approximation-stability without being ϵ-separated. In [6], Balcan et al. present a specific example of points in Euclidean space with $\alpha = 1$. In fact, when k is much larger than $1/\epsilon$, the difference between the two properties can be more substantial.

The notion of separability and approximation stability was generalized in [2] where the authors study a notion of stability called α-*weak deletion* stability. A clustering instance is stable under this notion if in the optimal clustering merging any two clusters into one increases the cost by a multiplicative factor of $(1+\alpha)$. This definition captures both ϵ-separability and approximation stability in the case of large cluster sizes. Remarkably, [2] show that for such instances of k-median and Euclidean k-means, one can design a $(1+\epsilon)$ approximation algorithm for any constant $\epsilon > 0$. This leads to immediate improvements over the works of [5] (for the case of large clusters) and of [15]. However, the run time of the resulting algorithm depends polynomially in n and k and exponentially in the parameters $1/\alpha$ and $1/\epsilon$, so the simpler algorithms of [2] and [5] are more suitable for scenarios where one expects the stronger properties to hold.

Kumar and Kannan [11] study a separation condition motivated by the k-means objective and the kind of instances produced by Gaussian and related mixture models. They consider the setting of points in Euclidean space and show that if the projection of any data point onto the line joining the mean of its cluster in the target clustering to the mean of any other cluster of the target is $\Omega(k)$ standard deviations closer to its own mean than the other mean, then they can recover the target clusters in polynomial time. This condition was further analyzed and reduced by work of [3].

Bilu and Linial [7] study clustering instances which are perturbation resilient. An instance is c-perturbation resilient if it has the property that the optimal solution to the objective remains optimal even after bounded perturbations (up to factor c) to the input weight matrix. They give an algorithm for maxcut (which can be viewed

as a 2-clustering problem) under the assumption that the optimal solution is stable to (roughly) $O(n^{2/3})$-factor multiplicative perturbations to the edge weights. This was improved by [14]. Awasthi et al. [3] study perturbation resilience for center-based clustering objectives such as k-median and k-means and give an algorithm that finds the optimal solution when the input is stable to only factor-3 perturbations. This factor is improved to $1 + \sqrt{2}$ by [4], who also design algorithms under a relaxed (c, ϵ)-stability to perturbation condition in which the optimal solution need not be identical on the c-perturbed instance, but may change on an ϵ fraction of the points (in this case, the algorithms require $c = 2 + \sqrt{3}$).

For the k-median objective, (c, ϵ)-approximation-stability with respect to $\mathcal{C}^*$ implies (c, ϵ)-stability to perturbations because an optimal solution in a c-perturbed instance is guaranteed to be a c-approximation on the original instance. Similarly, for k-means, (c, ϵ)-stability to perturbations is implied by (c^2, ϵ)-approximation-stability. However, as noted above, the values of c known to lead to efficient clustering in the case of stability to perturbations are larger than for approximation-stability, where any constant $c > 1$ suffices.

Open Problems

The algorithm proposed in [15] for ϵ-separability is a variant of the popular Lloyd's heuristic for k-means [13]. Hence, the result can also be viewed as a characterization of when such heuristics work in practice. It would be interesting to establish weaker sufficient conditions for such heuristics. For instance, is it possible that weak-deletion stability is sufficient for a version of the Lloyd's heuristic to converge to the optimal clustering? Another open direction concerns the notion of perturbation resilience. Can one reduce the perturbation factor c needed for efficient clustering? Alternatively, if one cannot find the *optimal* clustering for small values of c, can one still find a near-optimal clustering, of approximation ratio better than what is possible on worst-case instances?

In a different direction, one can also consider relaxations of the perturbation-resilience condition. For example, Balcan et al. [4] also consider instances that are "mostly resilient" to c-perturbations; under any c-perturbation of the underlying metric, no more than an ϵ-fraction of the points gets mislabeled under the optimal solution. For sufficiently large constant c and sufficiently small constant ϵ, they present algorithms that get good approximations to the objective under this condition. A different kind of relaxation would be to consider a notion of *resilience to perturbations on average*: a clustering instance whose optimal clustering is likely not to change, assuming the perturbation is *random* from a suitable distribution. Can this weaker notion be used to still achieve positive guarantees?

Finally, the notion of stability can also shed light on practically interesting instances of many other important problems. Can stability assumptions, preferably ones of a mild nature, allow us to bypass NP-hardness results of other problems? One particularly intriguing direction is the problem of Sparsest-Cut, for which no PTAS or constant-approximation algorithm is known, yet a powerful heuristics based on spectral techniques work remarkably well in practice.

Problem Definition

Color coding [2] is a novel method used for solving, in polynomial time, various subcases of the generally NP-Hard *subgraph isomorphism* problem. The input for the subgraph isomorphism problem is an ordered pair of (possibly directed) graphs (G, H). The output is either a mapping showing that H is isomorphic to a (possibly induced) subgraph of G, or **false** if no such subgraph exists. The subgraph isomorphism problem includes, as special cases, the HAMILTON-PATH, CLIQUE, and INDEPENDENT SET problems, as well as many others. The problem is also interesting when H is *fixed*. The goal, in this case, is to design algorithms whose running times are significantly better than the running time of the naïve algorithm.

Method Description

The color coding method is a randomized method. The vertices of the graph $G = (V, E)$ in which a subgraph isomorphic to $H = (V_H, E_H)$ is sought are randomly colored by $k = |V_H|$ colors. If $|V_H| = O(\log |V|)$, then with a small probability, but only polynomially small (i.e., one over a polynomial), all the vertices of a subgraph of G which is isomorphic to H, if there is such a subgraph, will be colored by distinct colors. Such a subgraph is called *color coded*. The color coding method exploits the fact that, in many cases, it is easier to detect color coded subgraphs than uncolored ones.

Perhaps the simplest interesting subcases of the subgraph isomorphism problem are the following: Given a directed or undirected graph $G = (V, E)$ and a number k, does G contain a simple (directed) path of length k? Does G contain a simple (directed) cycle of length *exactly* k? The following describes a $2^{O(k)} \cdot |E|$

time algorithm that receives as input the graph $G = (V, E)$, a coloring $c: V \to \{1, \ldots, k\}$ and a vertex $s \in V$, and finds a colorful path of length $k-1$ that starts at s, if one exists. To find a colorful path of length $k-1$ in G that starts somewhere, just add a new vertex s' to V, color it with a new color 0 and connect it with edges to all the vertices of V. Now look for a colorful path of length k that starts at s'.

A colorful path of length $k-1$ that starts at some specified vertex s is found using a dynamic programming approach. Suppose one is already given, for each vertex $v \in V$, the possible sets of colors on colorful paths of length i that connect s and v. Note that there is no need to record all colorful paths connecting s and v. Instead, record the color sets appearing on such paths. For each vertex v there is a collection of at most $\binom{k}{i}$ color sets. Now, inspect every subset C that belongs to the collection of v, and every edge $(v, u) \in E$. If $c(u) \notin C$, add the set $C \cup \{c(u)\}$ to the collection of u that corresponds to colorful paths of length $i+1$. The graph G contains a colorful path of length $k-1$ with respect to the coloring c if and only if the final collection, that corresponding to paths of length $k-1$, of at least one vertex is non-empty. The number of operations performed by the algorithm outlined is at most $O(\sum_{i=0}^{k} i\binom{k}{i} \cdot |E|)$ which is clearly $O(k2^k \cdot |E|)$.

Derandomization

The randomized algorithms obtained using the color coding method are derandomized with only a small loss in efficiency. All that is needed to derandomize them is a family of colorings of $G = (V, E)$ so that every subset of k vertices of G is assigned distinct colors by at least one of these colorings. Such a family is also called a family of *perfect hash functions* from $\{1, 2, \ldots, |V|\}$ to $\{1, 2, \ldots, k\}$. Such a family is explicitly constructed by combining the methods of [1, 9, 12, 16]. For a derandomization technique yielding a constant factor improvement see [5].

Key Results

Lemma 1 *Let $G = (V, E)$ be a directed or undirected graph and let $c: V \to \{1, \ldots, k\}$ be a coloring of its vertices with k colors. A colorful path of length $k-1$ in G, if one exists, can be found in $2^{O(k)} \cdot |E|$ worst-case time.*

Lemma 2 *Let $G = (V, E)$ be a directed or undirected graph and let $c: V \to \{1, \ldots, k\}$ be a coloring of its vertices with k colors. All pairs of vertices connected by colorful paths of length $k-1$ in G can be found in either $2^{O(k)} \cdot |V||E|$ or $2^{O(k)} \cdot |V|^{\omega}$ worst-case time (here $\omega < 2.376$ denotes the matrix multiplication exponent).*

Using the above lemmata the following results are obtained.

Theorem 3 *A simple directed or undirected path of length $k-1$ in a (directed or undirected) graph $G = (V, E)$ that contains such a path can be found in $2^{O(k)} \cdot |V|$ expected time in the undirected case and in $2^{O(k)} \cdot |E|$ expected time in the directed case.*

Theorem 4 *A simple directed or undirected cycle of size k in a (directed or undirected) graph $G = (V, E)$ that contains such a cycle can be found in either $2^{O(k)} \cdot |V||E|$ or $2^{O(k)} \cdot |V|^{\omega}$ expected time.*

A cycle of length k in minor-closed families of graphs can be found, using color coding, even faster (for planar graphs, a slightly faster algorithm appears in [6]).

Theorem 5 *Let* C *be a non-trivial minor-closed family of graphs and let $k \geq 3$ be a fixed integer. Then, there exists a randomized algorithm that given a graph$G = (V, E)$ from* C*, finds a C_k (a simple cycle of size k) in G, if one exists, in $O(|V|)$ expected time.*

As mentioned above, all these theorems can be derandomized at the price of a $\log |V|$ factor. The algorithms are also easily to parallelize.

Applications

The initial goal was to obtain efficient algorithms for finding simple paths and cycles in graphs. The color coding method turned out, however, to have a much wider range of applicability. The linear time (i.e., $2^{O(k)} \cdot |E|$ for directed graphs and $2^{O(k)} \cdot |V|$ for undirected graphs) bounds for simple paths apply in fact to any *forest* on k vertices. The $2^{O(k)} \cdot |V|^{\omega}$ bound for simple cycles applies in fact to any *series-parallel* graph on k vertices. More generally, if $G = (V, E)$ contains a subgraph isomorphic to a graph $H = (V_H, E_H)$ whose *tree-width* is at most t, then such a subgraph can be found in $2^{O(k)} \cdot |V|^{t+1}$ expected time, where $k = |V_H|$. This improves an algorithm of Plehn and Voigt [14] that has a running time of $k^{O(k)} \cdot |V|^{t+1}$. As a very special case, it follows that the LOG PATH problem is in P. This resolves in the affirmative a conjecture of Papadimitriou and Yannakakis [13]. The exponential dependence on k in the above bounds is probably unavoidable as the problem is NP-complete if k is part of the input.

The color coding method has been a fruitful method in the study of parametrized algorithms and parametrized complexity [7, 8]. Recently, the method has found interesting applications in computational biology, specifically in detecting signaling pathways within protein interaction networks, see [10, 17, 18, 19].

Open Problems

Several problems, listed below, remain open.

- Is there a polynomial time (deterministic or randomized) algorithm for deciding if a given graph $G = (V, E)$ contains a path of length, say, $\log^2 |V|$? (This is unlikely, as it will imply the existence of an algorithm that decides in time $2^{O(\sqrt{n})}$ whether a given graph on n vertices is Hamiltonian.)
- Can the $\log |V|$ factor appearing in the derandomization be omitted?
- Is the problem of deciding whether a given graph $G = (V, E)$ contains a triangle as difficult as the Boolean multiplication of two $|V| \times |V|$ matrices?

Experimental Results

Results of running the basic algorithm on biological data have been reported in [17, 19].

Problem Definition

A *proper coloring* of a graph $G = (V, E)$ is an assignment of colors to all vertices in V in such a way that no two adjacent vertices have the same color. A *k-coloring* of G is a coloring that uses k colors. The minimum number of colors that can be used to properly color G is the (*vertex*) *chromatic number* of G and is denoted by $\chi(G)$.

Deciding whether a given graph admits a k-coloring for a given $k \geq 3$ is well known to be NP complete. In particular, it is NP hard to compute the chromatic number [5]. The best known approximation algorithm computes a coloring of size at most within a factor $O\left(\frac{n(\log\log n)^2}{(\log n)^3}\right)$ of the chromatic number [6]. Furthermore, for any constant $\epsilon > 0$, it is NP hard to approximate the chromatic number within a factor $n^{1-\epsilon}$ [14].

The intractability of the vertex coloring problem for arbitrary graphs leads researchers to the study of the problem for appropriately generated random graphs. In the current entry, we consider coloring random instances of the *random intersection graphs model*, which is defined as follows:

Definition 1 (Random Intersection Graph – $\mathcal{G}_{n,m,p}$ [9, 13]) Consider a universe $\mathcal{M} = \{1, 2, \ldots, m\}$ of elements and a set of n vertices V. Assign independently to each vertex $v \in V$ a subset S_v of $\mathcal{M}$, choosing each element $i \in \mathcal{M}$ independently with probability p, and draw an edge between two vertices $v \neq u$ if and only if $S_v \cap S_u \neq \emptyset$. The resulting graph is an instance $G_{n,m,p}$ of the random intersection graphs model.

We will say that a property holds in $\mathcal{G}_{n,m,p}$ *with high probability (whp)* if the probability that a random instance of the $\mathcal{G}_{n,m,p}$ model has the property is at least $1 - o(1)$.

In this model, we will refer to the elements in the universe $\mathcal{M}$ as *labels*. We also denote by L_i the set of vertices that have chosen label $i \in M$.

Given $G_{n,m,p}$, we will refer to $\{L_i, i \in \mathcal{M}\}$ as its *label representation*. Consider the bipartite graph with vertex set $V \cup \mathcal{M}$ and edge set $\{(v,i) : i \in S_v\} = \{(v,i) : v \in L_i\}$. We will refer to this graph as the *bipartite random graph* $B_{n,m,p}$ *associated to* $G_{n,m,p}$. Notice that the associated bipartite graph is uniquely defined by the label representation.

It follows from the definition of the model that the edges in $G_{n,m,p}$ are not independent. This dependence becomes stronger as the number of labels decreases. In fact, the authors in [3] prove the equivalence (measured in terms of total variation distance) of the random intersection graphs model $\mathcal{G}_{n,m,p}$ and the Erdős-Rényi random graphs model $\mathcal{G}_{n,\hat{p}}$, for $\hat{p} = 1 - (1 - p^2)^m$, when $m = n^\alpha, \alpha > 6$. This bound on the number of labels was improved in [12], by showing equivalence of sharp threshold functions among the two models for $\alpha \geq 3$. We note that $1 - (1 - p^2)^m$ is in fact the (unconditioned) probability that a specific edge exists in $G_{n,m,p}$. In view of this equivalence, in this entry, we consider the interesting range of values $m = n^\alpha, \alpha < 1$, where random intersection graphs seem to differ the most from Erdős-Rényi random graphs.

In [1] the authors propose algorithms that whp probability color sparse instances of $G_{n,m,p}$. In particular, for $m = n^\alpha, \alpha > 0$ and $p = o\left(\sqrt{\frac{1}{nm}}\right)$, they show that $G_{n,m,p}$ can be colored optimally. Also, in the case where $m = n^\alpha, \alpha < 1$ and $p = o\left(\frac{1}{m \ln n}\right)$, they show that $\chi(G_{n,m,p}) \sim np$ whp. To do this, they prove that $G_{n,m,p}$ is chordal whp (or equivalently, the associated bipartite graph does not contain cycles), and so a perfect elimination scheme can be used to find a coloring in polynomial time. The range of values we consider here is different than the one needed for the algorithms in [1] to work. In particular, we study coloring $G_{n,m,p}$ for the wider range $mp \leq (1-\alpha)\ln n$, as well as the denser range $mp \geq \ln^2 n$. We have to note also that the proof techniques used in [1] cannot be used in the range we consider, since the properties that they examine do not hold in our case. Therefore, a completely different approach is required.

Key Results

In this entry, we initially considered the problem of properly coloring almost all vertices in $G_{n,m,p}$. In particular, we proved the following:

Theorem 1 *Let $m = n^\alpha, \alpha < 1$ and $mp \leq \beta \ln n$, for any constant $\beta < 1-\alpha$. Then a random instance of the random intersection graphs model $G_{n,m,p}$ contains a subset of at least $n - o(n)$ vertices that can be colored using np colors, with probability at least $1 - e^{-n^{0.99}}$.*

Note that the range of values of m, p considered in the above Theorem is quite wider than the one studied in [1]. For the proof, we combine ideas from [4] (see also [7]) and [10]. In particular, we define a Doob martingale as follows: Let $v_1, v_2, \ldots, v_n$ be an arbitrary ordering of the vertices of $G_{n,m,p}$. For $i = 1, 2, \ldots, n$, let B_i be the subgraph of the associated bipartite graph for $G_{n,m,p}$ (namely, $B_{n,m,p}$) induced by $\cup_{j=1}^{i} v_j \bigcup \mathcal{M}$. We denote by H_i the intersection graph whose bipartite graph has vertex set $V \bigcup \mathcal{M}$ and edge set that is exactly as B_i between $\cup_{j=1}^{i} v_j$ and $\mathcal{M}$, whereas every other edge (i.e., the ones between $\cup_{j=i+1}^{n} v_j$ and $\mathcal{M}$) appears independently with probability p.

Let also X denote the size of the largest np-colorable subset of vertices in $G_{n,m,p}$, and let X_i denote the expectation of the largest np-colorable subset in H_i. Notice that X_i is a random variable depending on the overlap between $G_{n,m,p}$ and H_i. Obviously, $X = X_n$ and setting $X_0 = E[X]$, we have $|X_i - X_{i+1}| \leq 1$, for all $i = 1, 2, \ldots, n$. It is straightforward to verify that the sequence $X_0, X_1, \ldots, X_n$ is a Doob martingale, and thus we can use Azuma's inequality to prove concentration of X_n around its mean value. However, the exact value of $E[X]$ is unknown. Nevertheless, we could prove a lower bound on $E[X]$ by providing a lower bound on the probability that X takes sufficiently large values. In particular, we showed that, for any positive constant $\epsilon > 0$, the probability that X takes values at least $(1-\epsilon)n$ is larger than the upper bound given by Azuma's inequality, implying that $E[X] \geq n - o(n)$.

It is worth noting here that the proof of Theorem 1 can also be used to prove that $\Theta(np)$

colors are enough to color $n - o(n)$ vertices, even in the case where $mp = \beta \ln n$, for any constant $\beta > 0$. However, finding the exact constant multiplying np is technically more difficult. Finally, note that Theorem 1 does not provide any direct information for the chromatic number of $G_{n,m,p}$, because the vertices that remain uncolored could induce a clique in $G_{n,m,p}$ in the worst case.

An Efficient Algorithm

Following our existential result of Theorem 1, we also proposed and analyzed an algorithm `CliqueColor` for finding a proper coloring of a random instance of $\mathcal{G}_{n,m,p}$, for any $mp \geq \ln^2 n$, where $m = n^\alpha, \alpha < 1$. The algorithm uses information of the label sets assigned to the vertices of $G_{n,m,p}$, and it runs in $O\left(\frac{n^2mp^2}{\ln n}\right)$ time whp (i.e., polynomial in n and m). In the algorithm, every vertex initially chooses independently uniformly at random a preference in colors from a set $\mathcal{C}$, denoted by $shade(\cdot)$, and every label l chooses a preference in the colors of the vertices in L_l, denoted by $c_l(\cdot)$. Subsequently, the algorithm visits every label clique and fixes the color (according to preference lists) for as many vertices as possible without causing collisions with already-colored vertices. Finally, it finds a proper coloring to the remaining uncolored vertices, using a new set of colors $\mathcal{C}'$. Algorithm `CliqueColor` is described below:

It is evident that algorithm `CliqueColor` always finds a proper coloring of $G_{n,m,p}$, but its efficiency depends on the number of colors included in $\mathcal{C}$ and $\mathcal{C}'$. The main idea is that if we have enough colors in the initial color set $\mathcal{C}$, then the subgraph $\mathcal{H}$ containing uncolored vertices will have sufficiently small maximum degree $\Delta(\mathcal{H})$, so that we can easily color it using $\Delta(\mathcal{H})$ extra colors. More specifically, we prove the following:

Theorem 2 (Efficiency) *Let $m = n^\alpha, \alpha < 1$ and $mp \geq \ln^2 n, p = o\left(\frac{1}{\sqrt{m}}\right)$. Then algorithm `CliqueColor` succeeds in finding a proper $\Theta\left(\frac{nmp^2}{\ln n}\right)$-coloring using for $G_{n,m,p}$ in polynomial time whp.*

Algorithm `CliqueColor`:

Input: An instance $G_{n,m,p}$ of $\mathcal{G}_{n,m,p}$ and its associated bipartite $B_{n,m,p}$.
Output: A proper coloring of $G_{n,m,p}$.

1. for every $v \in V$ choose a color denoted by $shade(v)$ independently, uniformly at random among those in $\mathcal{C}$;
2. for every $l \in \mathcal{M}$, choose a coloring of the vertices in L_l such that, for every color in $\{c \in \mathcal{C} : \exists v \in L_l$ with $shade(v) = c\}$, there is exactly one vertex in the set $\{u \in L_l : shade(u) = c\}$ having $c_l(u) = c$, while the rest remain uncolored;
3. set $U = \emptyset$ and $C = \emptyset$;
4. **for** $l = 1$ **to** m **do** {
5. color every vertex in $L_l \setminus (U \cup C)$ according to $c_l(\cdot)$ iff there is no collision with the color of a vertex in $L_l \cap C$;
6. include every vertex in L_l colored that way in C and the rest in U; } **enddo**
7. let $\mathcal{H}$ denote the (intersection) subgraph of $G_{n,m,p}$ induced by the vertices in U and let $\Delta(\mathcal{H})$ be its maximum degree;
8. give a proper $\Delta(\mathcal{H})$-coloring of $\mathcal{H}$ using a new set of colors $\mathcal{C}'$ of cardinality $\Delta(\mathcal{H})$;
9. **output** a coloring of $G_{n,m,p}$ using $|\mathcal{C} \cup \mathcal{C}'|$ colors;

It is worth noting that the number of colors used by algorithm `CliqueColor` in the case $mp \geq \ln^2 n, p = O\left(\frac{1}{\sqrt[4]{m}}\right)$ and $m = n^\alpha, \alpha < 1$ is of the correct order of magnitude (i.e., it is optimal up to constant factors). Indeed, by the concentration of the values of $|S_v|$ around mp for any vertex v with high probability, we can use the results of [11] on the independence number of the *uniform random intersection graphs model* $\mathcal{G}_{n,m,\lambda}$, with $\lambda \sim mp$, to provide a lower bound on the chromatic number. Indeed, it can be easily verified that the independence number of $G_{n,m,\lambda}$ for $\lambda = mp \geq \ln^2 n$ is at most $\Theta\left(\frac{\ln n}{mp^2}\right)$, which implies that the chromatic number of $G_{n,m,\lambda}$ (hence also of the $G_{n,m,p}$ because of the concentration of the values of $|S_v|$) is at least $\Omega\left(\frac{nmp^2}{\ln n}\right)$.

Coloring Random Hypergraphs

The model of random intersection graphs $\mathcal{G}_{n,m,p}$ could also be thought of as generating random hypergraphs. The hypergraphs generated have vertex set V and edge set $\mathcal{M}$. There is a huge amount of literature concerning coloring hypergraphs. However, the question about coloring

there seems to be different from the one we considered here. More specifically, a proper coloring of a hypergraph is any assignment of colors to the vertices, so that no monochromatic edge exists. This of course implies that fewer colors than the chromatic number (studied in this entry) are needed in order to achieve this goal.

In $\mathcal{G}_{n,m,p}$, the problem of finding a coloring such that no label is monochromatic seems to be quite easier when p is not too small. The proof of the following Theorem is based on the method of conditional expectations (see [2, 8]).

Theorem 3 *Let $G_{n,m,p}$ be a random instance of the model $\mathcal{G}_{n,m,p}$, for $p = \omega\left(\frac{\ln m}{n}\right)$ and $m = n^{\alpha}$, for any fixed $\alpha > 0$. Then with high probability, there is a polynomial time algorithm that finds a k-coloring of the vertices such that no label is monochromatic, for any fixed integer $k \geq 2$.*

Applications

Graph coloring enjoys many practical applications as well as theoretical challenges. Beside the classical types of problems, different limitations can also be set on the graph, or on the way a color is assigned, or even on the color itself. Some of the many applications of graph coloring include modeling scheduling problems, register allocation, pattern matching, etc.

Random intersection graphs are relevant to and capture quite nicely social networking. Indeed, a social network is a structure made of nodes (individuals or organizations) tied by one or more specific types of interdependency, such as values, visions, financial exchange, friends, conflicts, web links, etc. Social network analysis views social relationships in terms of nodes and ties. Nodes are the individual actors within the networks and ties are the relationships between the actors. Other applications include oblivious resource sharing in a (general) distributed setting, efficient and secure communication in sensor networks, interactions of mobile agents traversing the web, etc. Even epidemiological phenomena (like spread of disease) tend to be more accurately captured by this "interaction-sensitive" random graphs model.

Open Problems

In [1], the authors present (among other results) an algorithm for coloring $G_{n,m,p}$ in the case where $m = n^{\alpha}, \alpha < 1$ and $mp = o\left(\frac{1}{\log n}\right)$. In contrast, we presented algorithm `CliqueColor`, which finds a proper coloring of $G_{n,m,p}$ using $\Theta(\chi(G_{n,m,p}))$ whp, in the case $m = n^{\alpha}, \alpha < 1$ and $mp \geq \ln^2 n$. It remains open whether we can construct efficient algorithms (both in terms of the running time and the number of colors used) for finding proper colorings of $G_{n,m,p}$ for the range of values $\Omega\left(\frac{1}{\log n}\right) \leq mp \leq \ln^2 n$.

Problem Definition

In the field of *combinatorial generation*, the goal is to have fast elegant algorithms and code for exhaustively listing the elements of various combinatorial classes such as permutations, combinations, partitions, trees, graphs, and so on. Often it is desirable that successive objects in the listing satisfy some closeness condition, particularly conditions where successive objects differ only by a constant amount. Such listings are called *combinatorial Gray codes*; thus the study of combinatorial Gray codes is an important subfield of combinatorial generation.

There are a variety of applications of combinatorial objects where there is an inherent *closeness operation* that takes one object to another object and vice versa. There is a natural *closeness graph* $G = (V, E)$ that is associated with this setting. The vertices, V, of this graph are the combinatorial objects and edges, E, are between objects that are close. A combinatorial Gray code then becomes a Hamilton path in G and a *Gray cycle* is a Hamilton cycle in G.

The term *Combinatorial Gray Code* seems to have first appeared in print in Joichi, White, and Williamson [4]. An excellent survey up to 1997 was provided by Savage [10], and many examples of combinatorial Gray codes may be found in Knuth [5]. There are literally thousands of papers and patents on Gray codes in general, and although fewer about combinatorial Gray codes, this article can only scratch the surface and will focus on fundamental concepts, generalized settings, and recent results.

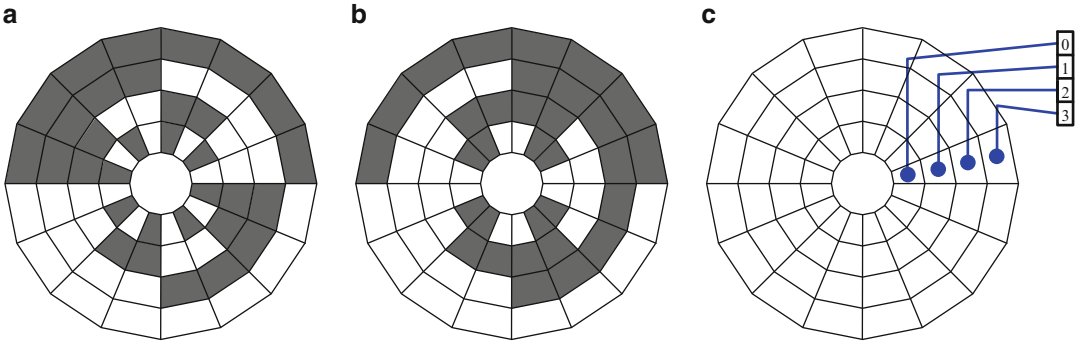
The Binary Reflected Gray Codes

The binary reflected Gray code (BRGC) is a well-known circular listing of the bit strings of a fixed length in which successive bit strings differ by a single bit. (The word *bit string* is used in this article instead of "binary string.") Let B_n be the Gray code list of all bit strings of length n. The list is defined by the following simple recursion:

$$B_0 = \varepsilon, \quad \text{and for } n > 0 \quad B_{n+1} = 0B_n, 1B_n^R. \tag{1}$$

In this definition, ε is the empty string, the comma represents concatenation of lists, the symbol x preceding a list indicates that an x is to be prepended to every string in list, and the superscript R indicates that the list is reversed. For example, $B_1 = 0, 1$, $B_1 = 00, 01, 11, 10$, and $B_3 = 000, 001, 011, 010, 110, 111, 101, 100$.

Figure 1 illustrates one of the most useful applications of the BRGC. Imagine a rotating "shaft," like a photocopier drum or a shutoff valve



Combinatorial Gray Code, Fig. 1 Applications of the binary reflected Gray code (**a**, **b**, **c**: see explanation in the text)

on a pipeline, in which the amount of rotation is to be determined by reading n "bits" from a sensor (c). If the sensor position is between two adjacent binary strings, then the result is indeterminate; so, for example, if the sensor fell between 0110 and 1100, then it could return either of these, but also 0100 or 1110 could be returned. If the bits are encoded around the shaft as a sequence of bit strings in lexicographic order, as shown in (a), and the sensor falls between 0000 and 1111, then any bit string might be returned! This problem is entirely mitigated by using a Gray code, such as the BRGC (b), since then only one of the two bit strings that lay under the sensor will be returned.

The term "Gray" comes from Frank Gray and engineer at Bell Labs who was issued a patent that uses the BRGC (Pulse code communication, March 17, 1953. U.S. patent no. 2,632,058). However, the BRGC was known much earlier; in particular it occurs in solutions to the Chinese rings puzzle and was used to list diagrams in the I Ching. See Knuth [5] for further historical background.

Surprisingly, new things are yet being proved about the BRGC; e.g., Williams [15] shows that the BRGC is generated by the following iterative "greedy" rule: Starting with the all 0s bit string, flip the rightmost bit that yields a bit string that has not already been generated. There are many other useful Gray code listings of bit strings known, for example, where the bit flips are equally distributed over the indexing positions or where all bit strings of density k (i.e., having k 1s) are listed before any of those of density $k+2$.

Combinations as Represented by Bit Strings

Many other simple Gray codes can be described using rules in the style of (1). For example, $B_{n,k} = 0B_{n-1,k}, 1B^R_{n-1,k-1}$ gives a Gray code of all bit strings of length n with exactly k 1s. It has the property that successive bit strings differ by the transposition of two (possibly nonadjacent) bits. Observe also that this is the list obtained from the BRGC by deleting all bit strings that do not contain k 1s.

A more restrictive Gray code for combinations is that of Eades and McKay [1]. Here the recursive construction ($1 < k < n$) is $E_{n,k} = 0E_{n-1,k-1}, 10E^R_{n-2,k-1}, 11E_{n-2,k-2}$. This Gray code has the nice property that successive bit strings differ by a transposition of two bits *and* only 0s lie between the two transposed bits. It is worth noting that there is no Gray code for combinations by transpositions in which the transposed bits are always adjacent (unless n is even and k is odd).

Generating Permutations via Plain Changes

The second most well-known combinatorial Gray code lists all $n!$ permutations of $\{1, 2, \ldots, n\}$ in one-line notation in such a way that successive permutations differ by the transposition of two adjacent elements. In its algorithmic form it is usually attributed to Johnson [3] and Trotter [13] although it has been used for centuries by campanologists [5], who refer to it as *plain changes*. Given such a list L_{n-1} for $\{1, 2, \ldots, n-1\}$, the list L_n can be created by successively sweeping

the n back-and-forth through each permutation in L_{n-1}. For example, if L_3 is 123, 132, 312, 321, 231, 213, then the first 8 permutations of L_4 are 1234, 1243, 1423, 4123, 4132, 1432, 1342, 1324. The "weave" below illustrates plane changes for $n = 5$, where the permutations occur as columns and the leftmost column corresponds to the permutation 12345, read top to bottom.

Hamiltonicity

In our BRGC example above, the closeness operation is the flipping of a bit, and the closeness graph is the hypercube. In a Gray code for permutations, a natural closeness operation is the transposing of two adjacent elements; in this case the closeness graph is sometimes called the permutohedron.

Sometimes it happens that the closeness graph G has no Hamilton path. If it is not connected, then there is no hope of finding a Gray code, but if it is connected, then there are several approaches that have proved successful in finding a Gray code in a related graph; the result is a weaker Gray code that permits 2 or 3 applications of the closeness operation. One approach is to consider the prism $G \times e$ [7]. If G is bipartite and Hamiltonian, then the Gray code consists of every other vertex along the Hamilton cycle. As a last resort the result of Sekanina below [12] can be used. An implementation of Sekanina's proof, called prepostorder, is given by Knuth [5].

Theorem 1 (Sekanina) *If G is connected, then G^3 is Hamiltonian.*

At this point the reader may be wondering: "What distinguishes the study of Gray codes from the study of Hamiltonicity of graphs?" The underlying motivation for most combinatorial Gray codes is algorithmic; proving the existence of the Hamilton cycle is only the first step; one then tries to get an efficient implementation according to the criteria discussed in the next section (e.g., the recent "middle-level" result gives an existence proof via a complex construction – but it lacks the nice construction that one would strive for when thinking about a Gray code). Another difference is that the graphs studied usually have a very specific underlying structure; often this structure is recursive and is exploited in the development of efficient algorithms.

The Representation Issue

Many combinatorial structures exhibit a chameleonic nature. The canonical example of this is the objects counted by the Catalan numbers, C_n, of which there are hundreds. For example, they count the well-formed parentheses strings with n left and n right parentheses but also count the binary trees with n nodes. The most natural ways of representing these are very different; well-formed parentheses are naturally represented by bit strings of length $2n$, whereas binary trees are naturally represented using a linked structure with two pointers per cell. Furthermore, the natural closeness conditions are also different; for parentheses, a swap of two parentheses is natural, and for binary trees, the class rotation operation is most natural. When discussing Gray codes it is imperative to know precisely what representation is being used (and then what closeness operation is being used).

Algorithmic Issues

For the vast majority of combinatorial Gray codes, *space* is the main enemy. The first task of the algorithm designer is to make sure that their algorithm uses an amount of space that is a small polynomial of the input size; algorithms that rely on sublists of the objects being listed are doomed even though many Hamiltonicity proofs naïvely lead to such algorithms. For example, an efficient algorithm for generating the BRGC cannot directly use (1) since that would require exponential space.

CAT Algorithms, Loopless Algorithms

From the global point of view, the best possible algorithms are those that output the objects (V)

in time that is proportional to the number of objects ($|V|$). Such algorithms are said to be CAT, standing for constant amortized time.

From a more local point of view, the best possible algorithms are those that output successive objects so that the amount of work between successive objects is constant. Such algorithms are said to be *loopless*, a term introduced by Ehrlich [2]. Both the BRGC and the plain changes algorithm for permutations mentioned above can be implemented as loopless algorithms.

Note that in both of these definitions we ignore the time that it would take to actually output the objects; what is being measured is the amount of data structure change that is occurring. This measure is the correct one to use because in many applications it is only the part of the data structure that changes that is really needed by the application (e.g., to update an objective function).

Key Results

Below are listed some combinatorial Gray codes, focusing on those that are representative, are very general, or are recent breakthroughs.

Numerical Partitions [5, 9]

Objects: All numerical partitions of an integer n.

Representation: Sequence of positive integers $a_1 \geq a_2 \geq \cdots$ such that $a_1 + a_2 \cdots = n$.

Closeness operation: Two partitions a and a' are close if there are two indices i and j such that $a'_i = a_i + 1$ and $a'_j = a_j - 1$.

Efficiency: CAT.

Comments: Results have been extended to the case where all parts are distinct and where the number of parts or the largest part is fixed.

Spanning Trees

Objects: Spanning trees of connected unlabeled graphs.

Representation: List of edges in the graph.

Closeness operation: Successive trees differ by a single edge replacement.

Efficiency: CAT.

References: University of Victoria MSc thesis of Malcolm Smith. Knuth 4A, [5], pages 468–469. Knuth has an implementation of the Smith algorithm on his website mentioned below; see the programs *SPAN.

Basic Words of Antimatroids [7]

Objects: Let $\mathcal{A}$ be a set system over $[n] := \{1, 2, \ldots, n\}$ that (a) is closed under union ($S \cup T \in \mathcal{A}$ for all $S, T \in \mathcal{A}$) and (b) is accessible (for all $S \in \mathcal{A}$ with $S \neq \emptyset$, there is an $x \in S$ such that $S \setminus \{x\} \in \mathcal{A}$). Such a set system $\mathcal{A}$ is an *antimatroid*. Repeated application of (b) starting with the set $[n]$ and ending with $\emptyset$ gives a permutation of $[n]$ called a *basic word*.

Representation: A permutation of $[n]$ in one-line notation.

Closeness operation: Successive permutations differ by the transposition of one or two adjacent elements.

Efficiency: CAT if there is an $O(1)$ "oracle" for determining whether the closeness operation applied to a basic word gives another basic word of $\mathcal{A}$; loopless if the antimatroid is the set of ideals of a poset.

Important special cases: Linear extensions of posets (partially ordered sets), convex shellings of finite point sets, and perfect elimination orderings of chordal graphs. Linear extensions have as special cases permutations (of a multiset), k-ary trees, standard young tableau, alternating permutations, etc.

Additional notes: If G is the cover graph of an antimatroid $\mathcal{A}$ where the sets are ordered by set inclusion, then the prism of G is Hamiltonian. Thus there is a Gray code for the elements of $\mathcal{A}$. No CAT algorithm is known for this Gray code, even in the case where the antimatroid consists of the ideals of a poset.

Words in a Bubble Language [8, 11]

Objects: A language L over alphabet $\{0, 1\}$ is a *bubble language* if it is closed under the operation of changing the rightmost 01 to a 10.

Representation: Bit strings of length n (i.e., elements of $\{0, 1\}^n$).

Closeness operation: Two $01 \leftrightarrow 10$ swaps, or (equivalently) one rotation of a prefix.

Important special cases: Combinations, well-formed parentheses, necklaces, and prefix normal words.
Efficiency: CAT if there is an $O(1)$ oracle for determining membership under the operation.

Permutations via σ and τ [16]

Objects: Permutations of $[n]$.
Representation: One-line notation.
Closeness operation: Successive permutations differ by the rotation $\sigma = (1\ 2\ \cdots\ n)$ or the transposition $\tau = (1\ 2)$ as applied to the indices of the representation.
Efficiency: CAT, but has a loopless implementation if only the successive σ or τ generators are output or if the permutation is represented using linked lists.
Comments: This is known as Wilf's (directed) $\sigma - \tau$ problem.

Middle Two Levels of the Boolean Lattice [6]

Objects: All subsets S of $\mathcal{B}_{2n+1}$ of density n or $n+1$.
Representation: Characteristic bit strings ($b_i = 1$ if and only if $i \in S$).
Closeness operation: Bit strings differ by a transposition of adjacent bits.
Efficiency: Unknown. A good open problem.
Comments: This is famously known as the "middle two-level problem."

URLs to Code and Data Sets

Don Knuth maintains a web page which contains some implementations of combinatorial Gray codes at http://www-cs-faculty.stanford.edu/~uno/programs.html. See, in particular, the programs GRAYSPAN, SPSPAN, GRAYSPSPAN, KODA-RUSKEY, and SPIDERS.

Jeorg Arndt maintains a website (http://www.jjj.de/fxt/) and book with many C programs for generating combinatorial objects, some of which are combinatorial Gray codes. The book may be freely downloaded. Chapter 14, entitled "Gray codes for strings with restrictions", is devoted to combinatorial Gray codes, but they can also be found in other chapters; e.g., 15.2 and 15.3 both contain Gray codes for well-formed parentheses strings.

The "Combinatorial Object Server" at http://www.theory.cs.uvic.ca/~cos/ allows you to produce small lists of combinatorial objects, often in various Gray code orders.

Problem Definition

Tile Assembly Models

Two of the most studied tile self-assembly models in the literature are the abstract Tile Assembly Model (aTAM) [7] and the Two-Handed Tile Assembly Model (2HAM) [4]. Both models constitute a mathematical model of self-assembly in which system components are four-sided Wang tiles with glue types assigned to each tile edge. Any pair of glue types are assigned some nonnegative interaction strength denoting how strongly the pair of glues bind. The models differ in their rules for growth in that the aTAM allows singleton tiles to attach one at a time to a growing seed, whereas the 2HAM permits any two previously built assemblies to combine given enough affinity for attachment.

In more detail, an aTAM system is an ordered triplet (T, τ, σ) consisting of a set of tiles T, a positive integer threshold parameter τ called the system's *temperature*, and a special tile $\sigma \in T$ denoted as the *seed* tile. Assembly proceeds by attaching copies of tiles from T to a growing seed assembly whenever the placement of a tile on the 2D grid achieves a total strength of attachment from abutting edges, determined by the sum of pairwise glue interactions, that meets or exceeds the temperature parameter τ. An additional twist that is often considered is the ability to specify a relative concentration distribution on the tiles in T. The growth from the initial seed then proceeds randomly with higher concentrated tile types attaching more quickly than lower concentrated types. Even when the final assembly is deterministic, adjusting concentration profiles may substantially alter the expected time to reach the unique terminal state.

The Two-Handed Tile Assembly Model (2HAM) [4] is similar to the aTAM, but removes the concept of a seed tile. Instead, a 2HAM system (T, τ) *produces* a new assembly whenever any two previously built (and potentially large) assemblies may translate together into a new stable assembly based on glue interactions and temperature. The distinction between the 2HAM and the aTAM is that the 2HAM allows large assemblies to grow independently and attach as large, pre-built assemblies, while the aTAM grows through the step-by-step attachment of singleton tiles to a growing seed.

A typical goal in tile self-assembly is to design an *efficient* tile system that uniquely assembles a target shape. Two primary efficiency metrics are (1) the number of distinct tile types used to self-assemble the target shape and (2) the expected time the system takes to self-assemble the target shape. Toward minimizing the number of tiles used to build a shape, the Minimum Tile Set

Problem is considered. Toward the goal of minimizing assembly time, the problem of selecting an optimal concentration distribution over the tiles of a given set is considered in the Tile Concentration Problem. Finally, the computational problem of simply verifying whether a given system correctly and uniquely self-assembles a target shape is considered in the Unique Assembly Verification Problem. Formally, the problems are as follows:

Problem 1 (The Minimum Tile Set Problem [2]) Given a shape, find the tile system with the minimum number of tile types that uniquely self-assembles into this shape.

Problem 2 (The Tile Concentration Problem [2]) Given a shape and a tile system that uniquely produces the given shape, assign concentrations to each tile type so that the expected assembly time for the shape is minimized.

Problem 3 (The Unique Assembly Verification Problem [2, 4]) Given a tile system and an assembly, determine if the tile system uniquely self-assembles into the assembly.

Key Results

Minimum Tile Set Problem

The NP-completeness of the Minimum Tile Set Problem within the aTAM is proven in [2] by a reduction from 3CNF-SAT. The proof is notable in that the polynomial time reduction relies on the polynomial time solution of the Minimum Tile Set Problem for tree shapes, which the authors show is polynomial time solvable. The authors also show that the Minimum Tile Set Problem is polynomial time solvable for $n \times n$ squares by noting that since the optimal solution has at most $O(\log n)$ tile types [7], a brute force search of candidate tile sets finishes in polynomial time as long as the temperatures of the systems under consideration are all a fixed constant. Extending the polynomial time solution to find the minimum tile system over any temperature is achieved in [5].

Theorem 1 *The Minimum Tile Set Problem is NP-complete within the aTAM. For the restricted classes of shapes consisting of squares and trees, the Minimum Tile Set Problem is polynomial time solvable.*

Concentration Optimization

The next result provides an approximation algorithm for the Tile Concentration Problem for a restricted class of aTAM tile system called *partial order* systems. Partial order systems are systems in which a unique assembly is constructed, and for any pair of adjacent tiles in the final assembly which have positive bonding strength, there is a strict order in which the two tiles are placed with respect to each other for all possible assembly sequences. For such systems, a $O(\log n)$-approximation algorithm is presented [2].

Theorem 2 *For any partial order aTAM system (T, τ, σ) that uniquely self-assembles a size-n assembly, there exists a polynomial time $O(\log n)$-approximation algorithm for the Tile Concentration Problem.*

Assembly Verification

The next result provides an important distinction in verification complexity between the aTAM and the 2HAM. In [2] a straightforward quadratic time algorithm for assembly verification is presented. In contrast, the problem is shown to be co-NP-complete in [4] through a reduction from 3CNF-SAT. The hardness holds for a 3D generalization of the 2HAM, but requires only 1 step into the third dimension. To achieve this reduction, the exponentially many candidate 3CNF-SAT solutions are engineered into the order in which the system might grow while maintaining that these candidate paths all collapse into a single polynomial-sized final assembly in the case that no satisfying solution exists. This reduction fundamentally relies on the third dimension and thus leaves open the complexity of 2D verification in the 2HAM.

Theorem 3 *The Unique Assembly Verification Problem is co-NP-complete for the 3D 2HAM and solvable in polynomial time $O(|A|^2+|A||T|)$ in the aTAM.*

Open Problems

A few open problems in this area are as follows. The Minimum Tile Set Problem has an efficient solution for squares which stems from a logarithmic upper bound on the complexity of assembling such shapes. This holds more generally for thick rectangles, but this ceases to be true when the width of the rectangle becomes sufficiently thin [3]. The complexity of the Minimum Tile Set Problem is open for this class of simple geometric shapes. For the Tile Concentration Problem, an exact solution is conjectured to be #P-hard for partial order systems [2], but this has not been proven. More generally, little is known about the Tile Concentration Problem for non-partial order systems. Another direction within the scope of minimizing assembly time is to consider optimizing over the tiles used, as well as the concentration distribution over the tile set. Some work along these lines has been done with respect to the fast assembly of $n \times n$ squares [1] and the fast implementation of basic arithmetic primitives in self-assembly [6]. In the case of the Unique Assembly Verification Problem, the complexity of the problem for the 2HAM in 2D is still unknown. For the aTAM, it is an open question as to whether the quadratic run time of verification can be improved.

Problem Definition

Two players – Alice and Bob – are playing a game in which their shared goal is to compute a function $f : \mathcal{X} \times \mathcal{Y} \to \mathcal{Z}$ efficiently. The game starts with Alice holding a value $x \in \mathcal{X}$ and Bob holding $y \in \mathcal{Y}$. They then communicate by sending each other messages according to a predetermined *protocol*, at the end of which they must both arrive at some output $z \in \mathcal{Z}$. The protocol is deemed *correct* if $z = f(x, y)$ for all inputs (x, y). Each message from Alice (resp. Bob) is an arbitrary binary-string-valued function of x (resp. y) and all previous messages received during the protocol's execution. The *cost* of the protocol is the maximum total length of all such messages, over all possible inputs, and is the basic measure of efficiency of the protocol. The central goals in communication complexity [23] are (i) to design protocols with low cost for given problems of interest, and (ii) to prove lower bounds on the cost that must be paid to solve a given problem. The minimum possible such cost is a natural measure of complexity of the function f and is denoted $\mathrm{D}(f)$.

Notably, the "message functions" in the above definition are not required to be efficiently computable. Thus, communication complexity focuses on certain basic information theoretic aspects of computation, abstracting away messier and potentially unmanageable lower-level details. Arguably, it is this aspect of communication complexity that has made it such a successful paradigm for proving lower bounds in a wide range of areas in computer science.

Most work in communication complexity focuses on *randomized* protocols, wherein random coin tosses (equivalently, a single random binary string) may be used to determine the messages sent. These coin tosses may be performed either in private by each player or in public: the resulting protocols are called private coin and public coin, respectively. A randomized protocol is said to compute f with error bounded by $\varepsilon \geq 0$ if, for all inputs (x, y), its output on (x, y) differs from $f(x, y)$ with probability at most ε. With this notion in place, one can then define the ε-error randomized communication complexity of f, denoted $\mathrm{R}_\varepsilon(f)$, analogously to the deterministic one. By convention, this notation assumes private coins; the analogous public-coin variant is denoted $\mathrm{R}^{\mathrm{pub}}_\varepsilon(f)$. Further, when f has Boolean output, it is convenient to put $\mathrm{R}(f) = \mathrm{R}_{1/3}(f)$. Clearly, one always has $\mathrm{R}^{\mathrm{pub}}(f) \leq \mathrm{R}(f) \leq \mathrm{D}(f)$.

Consider a probability distribution μ on the input domain $\mathcal{X} \times \mathcal{Y}$. A protocol's error under μ is the probability that it errs when given a random input $(X, Y) \sim \mu$. The ε-error μ-*distributional complexity* of f, denoted $\mathrm{D}^\mu_\varepsilon(f)$, is then the minimum cost of a deterministic protocol for f whose error, under μ, is at most ε; an easy averaging argument shows that the restriction of determinism incurs no loss of generality. The fundamental minimax principle of Yao [22] says that $\mathrm{R}_\varepsilon(f) = \max_\mu \mathrm{D}^\mu_\varepsilon(f)$. In particular, exhibiting a lower bound on $\mathrm{D}^\mu_\varepsilon(f)$ for a wisely chosen μ lower bounds $\mathrm{R}_\varepsilon(f)$; this is a key lower-bounding technique in the area.

Let Π be a protocol that uses a public random string R as well as private random strings: R_A for Alice, R_B for Bob. Let $\Pi(x, y, R, R_A, R_B)$ denote the *transcript* of conversation between Alice and Bob, on input (x, y). The internal and external information costs of Π with respect to the distribution μ are then defined as follows:

$$\begin{aligned}\mathrm{icost}(\Pi) &= \mathrm{I}(\Pi(X, Y, R, R_A, R_B) : X \mid Y, R) \\ &\quad + \mathrm{I}(\Pi(X, Y, R, R_A, R_B) : Y \mid X, R), \\ \mathrm{icost}^{\mathrm{ext}}(\Pi) &= \mathrm{I}(\Pi(X, Y, R, R_A, R_B) : X, Y \mid R),\end{aligned}$$

where $(X, Y) \sim \mu$ and I denotes mutual information. These definitions capture the amount of *information* learned by each player about the other's input (in the internal case) and by an external observer about the total input (in the external case) when Π is run on a random μ-distributed input. It is elementary to show that these quantities lower bound the actual communication cost of the protocol. Therefore, the corresponding *information complexity* [3,9] measures – denoted $\mathrm{IC}^{\mu}_{\varepsilon}(f)$ and $\mathrm{IC}^{\mu,\mathrm{ext}}_{\varepsilon}(f)$ – defined as the infima of these costs over all worst-case ε-error protocols for f, naturally lower bound $\mathrm{R}_{\varepsilon}(f)$. This is another important lower-bounding technique.

Key Results

In a number of basic communication problems, Alice's and Bob's inputs are n-bit strings, denoted x and y, respectively, and the goal is to compute a Boolean function $f(x, y)$. We shall denote the ith bit of x as x_i. The bound $\mathrm{D}(f) \leq n+1$ is then trivial, because Alice can always just sent Bob her input, for a cost of n.

The textbook by Kushilevitz and Nisan [14] gives a thorough introduction to the subject and contains detailed proofs of several of the results summarized below. We first present results about specific communication problems, then move on to more abstract results about general problems, and close with a few applications of these results and ideas.

Problem-Specific Results

Equality Testing

This problem is defined by the *equality* function, given by $\mathrm{EQ}_n(x, y) = 1$ if $x = y$ and $\mathrm{EQ}_n(x, y) = 0$ otherwise. This can be solved nontrivially by a randomized protocol wherein Alice sends Bob a *fingerprint* of x, which Bob can compare with the corresponding fingerprint of y generated using the same random seed. Using public coins, a random n-bit string r can be used as a seed to generate the fingerprint $\langle x, r\rangle = \sum_{i=1}^{n} x_i r_i \bmod 2$. One can readily check that this yields $\mathrm{R}^{\mathrm{pub}}(\mathrm{EQ}_n) = O(1)$ and, more generally, $\mathrm{R}^{\mathrm{pub}}_{\varepsilon}(\mathrm{EQ}_n) = O(\log(1/\varepsilon))$. In the private coin setting, one can use a different kind of fingerprinting, e.g., by treating the bits of x as the coefficients of a degree-n polynomial and evaluating it at a random element of $\mathbb{F}_q$ (for a large enough prime q) to obtain a fingerprint. This idea leads to the bound $\mathrm{R}(\mathrm{EQ}_n) = O(\log n)$.

Randomization is essential for the above results: it can be shown that $\mathrm{D}(\mathrm{EQ}_n) \geq n$. The argument relies on the fundamental *rectangle property* of deterministic protocols, which states that the set of inputs (x, y) that lead to the same transcript must form a combinatorial rectangle inside the input space $\mathcal{X} \times \mathcal{Y}$. This can be proved by induction on the length of the transcript. This rectangle property then implies that if $u \neq v \in \{0, 1\}^n$, then a correct protocol for EQ_n cannot have the same transcript on inputs (u, u) and (v, v); otherwise, it would have the same transcript of (u, v) as well, and therefore err, because $\mathrm{EQ}_n(u, u) \neq \mathrm{EQ}_n(u, v)$. It follows that the protocol must have at least 2^n distinct transcripts, whence one of them must have length at least n.

It can also be shown that the upper bounds above are optimal [14]. The lower bound $\mathrm{R}(\mathrm{EQ}_n) = \Omega(\log n)$ is a consequence of the more general result that $\mathrm{D}(f) = 2^{O(\mathrm{R}(f))}$ for every Boolean function f. The lower bound $\mathrm{R}^{\mathrm{pub}}_{\varepsilon}(\mathrm{EQ}_n) = \Omega(\log(1/\varepsilon))$ follows from Yao's minimax principle and a version of the above rectangle-property argument.

More refined results can be obtained by considering the expected (rather than worst case) cost

of an r-round protocol, i.e., a protocol in which a total of r are sent: in this case, $\mathrm{R}_{\varepsilon}^{\mathrm{pub},(r)}(\mathrm{EQ}_n) = \Theta(\log\log\cdots\log(\min\{n, \log(1/\varepsilon)\}))$ with the outer chain of logarithms iterated $(r-1)$ times. This is tight [7]. Another, incomparable, result is that EQ_n has a zero-error randomized protocol with information cost only $O(1)$, regardless of the joint distribution from which the inputs are drawn [5].

Comparison

This problem is defined by the *greater-than* function, given by $\mathrm{GT}_n(x, y) = 1$ if $x > y$ and $\mathrm{GT}_n(x, y) = 0$ otherwise, where we treat x and y as integers written in binary. Like EQ_n, it has no nontrivial deterministic protocol, for much the same reason. As before, this implies $\mathrm{R}(\mathrm{GT}_n) = \Omega(\log n)$.

In fact the tight bound $\mathrm{R}(\mathrm{GT}_n) = \Theta(\log n)$ holds, but the proof requires a subtle argument. Binary search based on equality testing on substrings of x and y allows one to zoom in, in $O(\log n)$ rounds, on the most significant bit position where x differs from y. If each equality test is allowed $O(1/\log n)$ probability of error, a straightforward union bound gives an $O(1)$ overall error rate, but this uses $\Theta(\log\log n)$ communication per round. The improvement to an overall $O(\log n)$ bound is obtained by preceding each binary search step with an extra "sanity check" equality test on prefixes of x and y and backtracking to the previous level of the binary search if the check fails: this allows one to use only $O(1)$ communication per round.

The bounded-round complexity of GT_n is also fairly well understood. Replacing the binary search above with an $n^{1/r}$-ary search leads to the r-round bound $\mathrm{R}_{\varepsilon}^{(r)}(\mathrm{GT}_n) = O(n^{1/r}\log n)$. A lower bound of $\Omega(n^{1/r}/r^2)$ can be proven by carefully analyzing information cost.

Indexing and Bipartite Pointer Jumping

The *indexing* or *index* problem is defined by the Boolean function $\mathrm{INDEX}_n(x, k) = x_k$, where $x \in \{0,1\}^n$ as usual, but Bob's input $k \in [n]$, where $[n] = \{1, 2, \ldots, n\}$. Straightforward information-theoretic arguments show that the one-round complexity $\mathrm{R}^{(1)}(\mathrm{INDEX}_n) = \Omega(n)$, where the single message must go from Alice to Bob. Without this restriction, clearly $\mathrm{R}(\mathrm{INDEX}_n) = O(\log n)$. A more delicate result [17] is that in a $(1/3)$-error protocol for INDEX_n, for any $b \in [1, \log n]$, either Bob must send b bits or Alice must send $n/2^{O(b)}$ bits; an easy 2-round protocol shows that this trade-off is optimal. Even more delicate results, involving information cost, are known, and these are useful in certain applications (see below).

The indexing problem illustrates that interaction can improve communication cost exponentially. This can be generalized to show that $r+1$ rounds can be exponentially more powerful than r rounds. For this, one considers the *bipartite pointer jumping* problem, where Alice and Bob receive functions $f, g : [n] \to [n]$, respectively, and Bob also receives $y \in [n]$. Their goal is to compute $\mathrm{PJ}_{r,n}(f, g, y) = h_r(\cdots h_2(h_1(y))\cdots) \bmod 2$, where $h_i = f$ for odd i and $h_i = g$ for even i. Notice that $\mathrm{PJ}_{1,n}$ is essentially the same as INDEX_n and that $\mathrm{R}^{(r+1)}(\mathrm{PJ}_{r,n}) = O(r\log n)$. Suitably generalizing the information-theoretic arguments for INDEX_n shows that $\mathrm{R}^{(r)}(\mathrm{PJ}_{r,n}) = \Omega(n/r^2)$.

Inner Product Parity

The Boolean function $\mathrm{IP}_n(x, y) = \langle x, y\rangle$, which is the parity of the inner product $\sum_{i=1}^{n} x_i y_i$, is the most basic *very* hard communication problem: solving it to error $\frac{1}{2} - \delta$ (for constant δ) requires $n - O(\log(1/\delta))$ communication. This is proved by considering the distributional complexity $\mathrm{D}_{\varepsilon}^{\mu}(\mathrm{IP}_n)$, where μ is the uniform distribution and lower bounding it using the *discrepancy method*. Observe that a deterministic protocol Π with cost C induces a partition of the input domain into 2^C combinatorial rectangles, on each of which Π has the same transcript, hence the same output. If Π has error at most $\frac{1}{2} - \delta$ under μ, then the μ-discrepancies of these rectangles – i.e., the differences between the μ-measures of the 0s and 1s within them – must sum up to at least 2δ. Letting $\mathrm{disc}^{\mu}(f)$ denote the maximum over all rectangles R in $\mathcal{X}\times\mathcal{Y}$ of the μ- discrepancy of R, we then obtain $2^C\,\mathrm{disc}^{\mu}(f) \geq 2\delta$, which allows us to lower bound C if we can upper bound the discrepancy $\mathrm{disc}^{\mu}(f)$.

For the function IP, the matrix $(\text{IP}(x, y))_{x\in\{0,1\}^n, y\in\{0,1\}^n}$ is easily seen to be a Hadamard matrix, whose spectrum is well understood. With a bit of matrix analysis, this enables the discrepancy of IP under a uniform μ to be computed very accurately. This in turn yields the claimed communication complexity lower bound.

Set Disjointness

The problem of determining whether Alice's set $x \subseteq [n]$ is disjoint from Bob's set $y \subseteq [n]$, denoted $\text{DISJ}_n(x, y)$, is, along with its natural generalizations, the most studied and widely useful problem in communication complexity. It is easy to prove, from first principles, the strong lower bound $\text{D}(\text{DISJ}_n(x, y)) = n - o(n)$. Obtaining a similarly strong lower bound for randomized complexity turns out to be quite a challenge, one that has driven a number of theoretical innovations.

The discrepancy method outlined above is provably very weak at lower bounding $\text{R}(\text{DISJ}_n)$. Instead, one considers a refinement called the *corruption* technique: it consists of showing that "large" rectangles in the matrix for DISJ_n cannot come close to consisting purely of 1-inputs (i.e., disjoint pairs (x, y)) but must be corrupted by a "significant" fraction of 0-inputs. On the other hand, a sufficiently low-cost communication protocol for DISJ_n would imply that at least one such large rectangle must exist. The tension between these two facts gives rise to a lower bound on $\text{D}^{\mu}_{\varepsilon}(\text{DISJ}_n)$, where μ and ε figure in the quantification of "large" and "significant" above. Following this outline, Babai et al. [2] proved an $\Omega(\sqrt{n})$ lower bound using the uniform distribution. This was then improved by using a certain non-product input distribution, i.e., one where the inputs x and y are correlated – a provably necessary complication – to the optimal $\Omega(n)$, initially via a complicated Kolmogorov complexity technique, but eventually via elementary (though ingenious) combinatorics by Razborov [20]. Subsequently, Bar-Yossef et al. [4] re-proved the $\Omega(n)$ bound via a novel notion of *conditional information complexity*, a proof that has since been reworked to use the more natural internal information complexity [5].

Disjointness is also interesting and natural as a multiparty problem, where each of t players holds a subset of $[n]$ and they wish to determine if these are disjoint. An important result with many applications (see below) is that under a promise that the sets are pairwise disjoint except perhaps at one element, this requires $\Omega(n/t)$ communication, even if the players communicate via broadcast; this bound is essentially tight. Without this promise, and with only private message channels between the t players, disjointness requires $\Omega(tn)$ communication.

Gap Hamming Distance

This problem is defined by the partial Boolean function on $\{0,1\}^n \times \{0,1\}^n$ given by $\text{GHD}_n(x, y) = 0$ if $\|x - y\|_1 \leq \frac{1}{2}n - \sqrt{n}$; $\text{GHD}_n(x, y) = 1$ if $\|x - y\| \geq \frac{1}{2}n + \sqrt{n}$; and $\text{GHD}_n(x, y) = \star$ otherwise. Correctness and error probability for protocols for GHD_n are based only on inputs not mapped to $\star$. After several efforts giving special-case lower bounds, it was eventually proved [8] that $\text{R}(\text{GHD}_n) = \Omega(n)$ and in particular $\text{D}^{\mu}_{\varepsilon}(\text{GHD}_n) = \Omega(n)$ with μ being uniform and $\varepsilon = \Theta(1)$ being sufficiently small. This bound provably does not follow from the corruption method because of the presence of large barely-corrupted rectangles in the matrix for GHD_n; instead it was proved using the so-called *smooth corruption* technique [12].

General Complexity-Theoretic Results

There is a vast literature on general results connecting various notions of complexity for communication problems. As before, we survey some highlights. Throughout, we consider a general function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$.

Determinism vs. Public vs. Private Randomness

A private-coin protocol can be deterministically simulated by direct estimation of the probability of generating each possible transcript. This leads to the relation $\text{R}(f) = \Omega(\log \text{D}(f))$. This separation is the best possible, as witnessed by EQ_n. Further, a public-coin protocol can be restricted to draw its random string – no matter

how long – from a fixed set S consisting of $O(n)$ strings, for a constant additive increase in error probability [18]. This implies that it can be simulated using a private coin (which is used only to draw a random element of S) at an additional communication cost of $\log n + O(1)$. Therefore, $\mathrm{R}(f) \leq \mathrm{R}^{\mathrm{pub}}(f) + \log n + O(1)$. Again the EQ_n function shows that this separation is the best possible.

The Log-Rank Conjecture and Further Matrix Analysis

The rectangle property of communication protocols readily implies that $\mathrm{D}(f) \geq \log_2 \mathrm{rk}\, f$, where $\mathrm{rk}\, f$ is the rank of the matrix $(f(x,y))_{\{0,1\}^n \times \{0,1\}^n}$. It has long been conjectured that $\mathrm{D}(f) = \mathrm{poly}(\log \mathrm{rk}\, f)$. This famous conjecture remains wide open; the best-known relevant upper bound is $\mathrm{D}(f) \leq O(\sqrt{\mathrm{rk}\, f} \log \mathrm{rk}\, f)$ [16].

Other, more sophisticated, matrix analysis techniques can be used to establish lower bounds on $\mathrm{R}(f)$ by going through the approximate rank and factorization norms. The survey by Lee and Shraibman [15] has a strong focus on such techniques and provides a comprehensive coverage of results.

Direct Sum, Direct Product, and Amortization

Does the complexity of f grow n-fold, or even $\Omega(n)$-fold, if we have to compute f on n independent instances? This is called a direct sum question. Attempts to answer it and its variants, for general, as well as specific functions f have spurred a number of developments. Let f^k denote the (non-Boolean) function that, on input $((x^{(1)}, \ldots, x^{(k)}), (y^{(1)}, \ldots, y^{(k)}))$, outputs $(f(x^{(1)}, y^{(1)}), \ldots, f(x^{(k)}, y^{(k)}))$. Let $\mathrm{R}^k_\varepsilon(f^k)$ denote the cost of the best randomized protocol that computes each entry of the k-tuple of of values of f^k up to error ε. This is in contrast to the usual $\mathrm{R}_\varepsilon(f^k)$, which is concerned with getting the entire k-tuple correct except with probability ε. An alternate way of posing the direct sum question is to ask how the *amortized* randomized complexity $\overline{\mathrm{R}}_\varepsilon(f) = \lim_{k\to\infty} \mathrm{R}^k_\varepsilon(f^k)/k$ compares with $\mathrm{R}_\varepsilon(f)$.

An early result along these lines shows that $\overline{\mathrm{R}}(\mathrm{EQ}_n) = O(1)$ [10]. Recalling that $\mathrm{R}(\mathrm{EQ}_n) = \Omega(\log n)$, this shows that (in the private-coin setting) EQ_n exhibits economy of scale; we say that it does not satisfy the direct sum property. It had long been conjectured that no such economy of scale is possible in a public-coin setting; in fact information complexity rose to prominence as a technique precisely because in the *informational* setting, the direct sum property is easy to prove [9]. Thus, $\mathrm{IC}^\mu(f)$, for every distribution μ, lower bounds not just $\mathrm{R}(f)$ but also $\overline{\mathrm{R}}(f)$. More interestingly, the opposite inequality also holds, so that information and amortized randomized complexities are in fact equal; the proof uses a sophisticated *interactive protocol compression* technique [6] that should be seen as an analog of classical information theoretic results about single-message compression, e.g., via Huffman coding.

Thus, proving a general direct sum theorem for randomized communication is equivalent to compressing a protocol with information cost I down to $O(I)$ bits of communication. However, the best-known compression uses $2^{O(I)}$ bits [5], and this is optimal [11]. The proof of optimality – despite showing that a fully general direct sum theorem is impossible – is such that a slightly weakened direct sum result, such as $\mathrm{R}^k(f^k) = \Omega(k)\,\mathrm{R}(f) - O(\log n)$, remains possible and open. Meanwhile, fully general and strong direct sum theorems can be proven by restricting the model to bounded-round communication, or restricting the function to those whose complexity is captured by the smooth corruption bound.

Round Elimination

For problems that are hard only under a limitation on the number of rounds – e.g., GT_n, discussed above – strong bounded-round lower bounds are proved using the round elimination technique. Here, one shows that if an r-round protocol for f starts with a short enough first message, then this message can be eliminated altogether, and the resulting $(r-1)$-round protocol will solve a "subproblem" of f. Repeating this operation r times results in a 0-round protocol that, hopefully,

solves a nontrivial subproblem, giving a contradiction.

To make this useful, one then has to identify a reasonable notion of subproblem. It is especially useful to have this subproblem be a smaller instance of f itself. This does happen in several cases and can be illustrated by looking at GT_n: restricting n-length strings to indices in $[\ell, h]$ and forcing agreement at indices in $[1, \ell - 1]$ shows that GT_n contains $\mathrm{GT}_{h-\ell}$ as a subproblem. The proof of the aforementioned lower bound $\mathrm{R}^{(r)}(\mathrm{GT}_n) = \Omega(n^{1/r}/r^2)$ uses exactly this observation. The pointer jumping lower bound, also mentioned before, proceeds along similar lines.

Applications

Data Stream Algorithms

Consider a data stream algorithm using s bits of working memory and p passes over its input. Splitting the stream into two pieces, giving the first to Alice and the second to Bob, creates a communication problem and a $(2p - 1)$-round protocol for it, using s bits of communication per round. A generalization to multiplayer communication is immediate. These observations [1] allow us to infer several space (or pass/space trade-off) lower bounds for data stream algorithms from suitable communication lower bounds, often after a suitable reduction.

For instance, the problem of approximating the number of distinct items in a stream and its generalization to the problem of approximating frequency moments are almost fully understood, based on lower bounds for EQ_n, GHD_n, DISJ_n, and its generalization to multiple players, under the unique intersection restriction noted above. A large number of graph-theoretic problems can be shown to require $\Omega(n)$ space, n being the number of vertices, based on lower bounds for INDEX_n, PJ_n and variants, and again DISJ_n. For several other data streaming problems – e.g., approximating ℓ_∞ and cascaded norms and approximating a maximum cut or maximum matching – a reduction using an off-the-shelf communication lower bound is not known, but one can still obtain strong space lower bounds by considering a tailor-made communication problem in each case and applying the familiar lower-bounding techniques outlined above.

Data Structures

The cell-probe model of Yao is designed to capture all conceivable data structures on a modern computer: it models the query/update process as a sequence of probes into the entries (memory words) of a table containing the data structure. Focusing on static data structures for the moment, note that a t-probe algorithm using an s-word table with w-bit words directly leads to a $2t$-round communication protocol in which Alice (the querier) sends $(\log_2 s)$-bit messages and Bob (the table holder) sends w-bit messages. Lower bounds trading off t against w and s are therefore implied by suitable *asymmetric* communication lower bounds, where Alice's messages need to be much shorter than Bob's and Alice also has a correspondingly smaller input.

The study of these kinds of lower bounds was systematized by Miltersen et al. [17], who used round elimination as well as corruption-style techniques to obtain cell-probe lower bounds for set membership, predecessor search, range query, and further static data structure problems. Pătraşcu [19] derived an impressive number of cell-probe lower bounds – for problems ranging from union-find to dynamic stabbing and range reporting (in low dimension) to approximate near neighbor searching – by a tree of reductions starting from the *lopsided set disjointness* problem. This latter problem, denoted $\mathrm{LSD}_{k,n}$, gives Alice a set $x \subseteq [kn]$ with $|x| \leq k$ and Bob a set $y \subseteq [kn]$. Using information complexity techniques and a direct sum result for the basic INDEX problem, one can use the Alice/Bob trade-off result for INDEX discussed earlier to establish the nearly optimal trade-off that, for each $\delta > 0$, solving $\mathrm{LSD}_{k,n}$ to $\frac{1}{3}$ error (say) requires either Alice to send at least $\delta n \log k$ bits or Bob to send $nk^{1-O(\delta)}$ bits.

Circuit Complexity

Early work in circuit complexity had identified certain conjectured communication complexity lower bounds as a route towards strong lower bounds for circuit size and depth and related complexity measures for Boolean formulas and branching programs. Several of these conjectures remain unproven, especially ones involving the *number-on-the-forehead* (NOF) communication model, where the input is "written on the foreheads" of a large number, t, of players. The resulting high degree of input sharing allows for some rather novel nontrivial protocols, making lower bounds very hard to prove. Nevertheless, the discrepancy technique has been extended to NOF communication, and some of the technically hardest work in communication complexity has gone towards using it effectively for concrete problems, such as set disjointness [21]. While NOF lower bounds strong enough to imply circuit lower bounds remain elusive, certain other communication lower bounds, such as two-party bounds for computing *relations*, have had more success. In particular, monotone circuits for directed and undirected graph connectivity have been shown to require super-logarithmic depth, via the influential idea of Karchmer-Wigderson games [13].

Further Applications

We note in passing that there are plenty more applications of communication complexity than are possible to even outline in this short article. These touch upon such diverse areas as proof complexity; extension complexity for linear and semidefinite programming; AT^2 lower bounds in VLSI design; query complexity in the classical and quantum models; and time complexity on classical Turing machines. Kushilevitz and Nisan [14] remains the best starting point for further reading about these and more applications.

Problem Definition

A mobile ad hoc network is a temporary dynamic interconnection network of wireless mobile nodes without any established infrastructure or centralized administration. A *basic communication problem*, in ad hoc mobile networks, is to send information from a *sender* node, A, to another designated *receiver* node, B. If mobile nodes A and B come within wireless range of each other, then they are able to communicate. However, if they do not, they can communicate if other network nodes of the network are willing to forward their packets. One way to solve this problem is the protocol of notifying every node that the sender A meets and provide it with *all the information* hoping that some of them will eventually meet the receiver B.

> Is there a more efficient technique (other than notifying every node that the sender meets, in the hope that some of them will then eventually meet the receiver) that will effectively solve the communication establishment problem without flooding the network and exhausting the battery and computational power of the nodes?

The problem of communication among mobile nodes is one of the most fundamental problems in ad hoc mobile networks and is at the core of many algorithms, such as for counting the number of nodes, electing a leader, data processing etc. For an exposition of several important problems in ad hoc mobile networks see [13]. The work of Chatzigiannakis, Nikoletseas and Spirakis [5] focuses on wireless mobile networks that are subject to highly dynamic structural changes created by mobility, channel fluctuations and device failures. These changes affect topological connectivity, occur with high frequency and may not be predictable in advance. Therefore, the environment where the nodes move (in three-dimensional space with possible obstacles) as

well as the motion that the nodes perform are *input* to any distributed algorithm.

The Motion Space

The space of possible motions of the mobile nodes is combinatorially abstracted by a *motion-graph*, i.e., the detailed geometric characteristics of the motion are neglected. Each mobile node is assumed to have a transmission range represented by a sphere *tr* centered by itself. Any other node inside *tr* can receive any message broadcast by this node. This sphere is approximated by a cube *tc* with volume $\mathrm{V}(tc)$, where $\mathrm{V}(tc) < \mathrm{V}(tr)$. The size of *tc* can be chosen in such a way that its volume $\mathrm{V}(tc)$ is the maximum that preserves $\mathrm{V}(tc) < \mathrm{V}(tr)$, and if a mobile node inside *tc* broadcasts a message, this message is received by any other node in *tc*. Given that the mobile nodes are moving in the space S, S is divided into consecutive cubes of volume $\mathrm{V}(tc)$.

Definition 1 The motion graph $G(V, E)$, $(|V| = n, |E| = m)$, which corresponds to a quantization of S is constructed in the following way: a vertex $u \in G$ represents a cube of volume $\mathrm{V}(tc)$ and an edge $(u, v) \in G$ exists if the corresponding cubes are adjacent.

The number of vertices n, actually approximates the ratio between the volume V(S) of space S, and the space occupied by the transmission range of a mobile node $\mathrm{V}(tr)$. In the extreme case where $\mathrm{V(S)} \approx \mathrm{V}(tr)$, the transmission range of the nodes approximates the space where they are moving and $n = 1$. Given the transmission range *tr*, n depends linearly on the volume of space S regardless of the choice of *tc*, and $n = O(V(\mathrm{S})/V(tr))$. The ratio $V(\mathrm{S})/V(tr)$ is the *relative motion space size* and is denoted by ρ. Since the edges of G represent neighboring polyhedra each vertex is connected with a constant number of neighbors, which yields that $m = \Theta(n)$. In this example where *tc* is a cube, G has maximum degree of six and $m \leq 6n$. Thus *motion graph* G is (usually) a *bounded degree graph* as it is derived from a regular graph of small degree by deleting parts of it corresponding to motion or communication obstacles. Let Δ be the maximum vertex degree of G.

The Motion of the Nodes-Adversaries

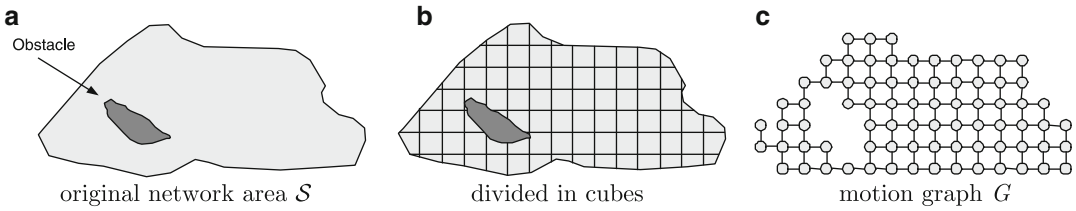
In the general case, the motions of the nodes are decided by an *oblivious adversary*: The adversary determines motion patterns in any possible way but independently of the distributed algorithm. In other words, the case where some of the nodes are deliberately trying to *maliciously affect* the protocol, e.g., avoid certain nodes, are excluded. This is a pragmatic assumption usually followed by applications. Such kind of motion adversaries are called *restricted motion adversaries*.

For purposes of studying efficiency of distributed algorithms for ad hoc networks *on the average*, the motions of the nodes are modeled by *concurrent and independent random walks*. The assumption that the mobile nodes move randomly, either according to uniformly distributed changes in their directions and velocities or according to the random waypoint mobility model by picking random destinations, has been used extensively by other research.

Key Results

The key idea is to take advantage of the mobile nodes natural movement by exchanging information whenever mobile nodes meet incidentally. It is evident, however, that if the nodes are spread in remote areas and they do not move beyond these areas, there is no way for information to reach them, unless the protocol takes special care of such situations. The work of Chatzigiannakis, Nikoletseas and Spirakis [5] proposes the idea of forcing only a small subset of the deployed nodes to move as per the needs of the protocol; they call this subset of nodes the *support* of the network. Assuming the availability of such nodes, they are used to provide a simple, correct and efficient strategy for communication between any pair of nodes of the network that avoids message flooding.

Let k nodes be a predefined set of nodes that become the nodes of the support. These



Communication in Ad Hoc Mobile Networks Using Random Walks, Fig. 1 The original network area S (**a**), how it is divided in consecutive cubes of volume $V(tc)$ (**b**) and the resulting motion graph G (**c**)

nodes move randomly and fast enough so that they visit in sufficiently short time the entire motion graph. When some node of the support is within transmission range of a sender, it notifies the sender that it may send its message(s). The messages are then stored "somewhere within the support structure". When a receiver comes within transmission range of a node of the support, the receiver is notified that a message is "waiting" for him and the message is then forwarded to the receiver.

Protocol 1 (The "Snake" Support Motion Coordination Protocol) Let $S_0, S_1, \ldots, S_{k-1}$ be the members of the support and let S_0 denote the leader node (possibly elected). The protocol forces S_0 to perform a random walk on the motion graph and each of the other nodes S_i execute the simple protocol "move where S_{i-1} was before". When S_0 is about to move, it sends a message to S_1 that states the new direction of movement. S_1 will change its direction as per instructions of S_0 and will propagate the message to S_2. In analogy, S_i will follow the orders of S_{i-1} after transmitting the new directions to S_{i+1}. Movement orders received by S_i are positioned in a queue Q_i for sequential processing. The very first move of S_i, $\forall i \in \{1, 2, \ldots, k-1\}$ is delayed by a δ period of time.

The purpose of the random walk of the head S_0 is to ensure a *cover*, within some finite time, of the whole graph G without knowledge and memory, other than local, of topology details. This memoryless motion also ensures fairness, low-overhead and inherent robustness to structural changes.

Consider the case where any sender or receiver is allowed a general, unknown motion strategy, but its strategy is provided by a restricted motion adversary. This means that each node not in the support either (a) executes a deterministic motion which either stops at a vertex or cycles forever after some initial part or (b) it executes a stochastic strategy which however is *independent* of the motion of the support. The authors in [5] prove the following correctness and efficiency results. The reader can refer to the excellent book by Aldous and Fill [1] for a nice introduction on Makrov Chains and Random Walks.

Theorem 1 *The support and the "snake" motion coordination protocol guarantee reliable communication between any sender-receiver (A, B) pair in finite time, whose expected value is bounded only by a function of the relative motion space size ρ and does not depend on the number of nodes, and is also independent of how MH_S, MH_R move, provided that the mobile nodes not in the support do not deliberately try to avoid the support.*

Theorem 2 *The expected communication time of the support and the "snake" motion coordination protocol is bounded above by $\Theta(\sqrt{mc})$ when the (optimal) support size $k = \sqrt{2mc}$ and c is $e/(e-1)u$, u being the "separation threshold time" of the random walk on G.*

Theorem 3 *By having the support's head move on a regular spanning subgraph of G, there is an absolute constant $\gamma > 0$ such that the expected meeting time of A (or B) and the support is bounded above by $\gamma n^2/k$. Thus the protocol*

guarantees a total expected communication time of $\Theta(\rho)$, independent of the total number of mobile nodes, and their movement.

The analysis assumes that the head S_0 moves according to a continuous time random walk of total rate 1 (rate of exit out of a node of G). If S_0 moves ψ *times faster* than the rest of the nodes, all the estimated times, except the inter-support time, will be divided by ψ. Thus the expected total communication time can be made to be as small as $\Theta(\gamma\rho/\sqrt{\psi})$ where γ is an absolute constant. In cases where S_0 can take advantage of the network topology, all the estimated times, except the inter-support time are improved:

Theorem 4 *When the support's head moves on a regular spanning subgraph of G the expected meeting time of A (or B) and the support cannot be less than $(n-1)^2/2m$. Since $m = \Theta(n)$, the lower bound for the expected communication time is $\Theta(n)$. In this sense, the "snake" protocol's expected communication time is optimal, for a support size which is $\Theta(n)$.*

The "on-the-average" analysis of the time-efficiency of the protocol assumes that the motion of the mobile nodes not in the support *is a random walk on the motion graph G*. The random walk of each mobile node is performed independently of the other nodes.

Theorem 5 *The expected communication time of the support and the "snake" motion coordination protocol is bounded above by the formula*

$$E(T) \leq \frac{2}{\lambda_2(G)}\Theta\left(\frac{n}{k}\right) + \Theta(k)\,.$$

The upper bound is minimized when $k = \sqrt{2n/\lambda_2(G)}$, where λ_2 is the second eigenvalue of the motion graph's adjacency matrix.

The way the support nodes move and communicate is robust, in the sense that it can tolerate failures of the support nodes. The types of failures of nodes considered are permanent, i.e., stop failures. Once such a fault happens, the support node of the fault does not participate in the ad hoc mobile network anymore. A communication protocol is β-*faults tolerant*, if it still allows the members of the network to communicate correctly, under the presence of at most β permanent faults of the nodes in the support ($\beta \geq 1$). [5] shows that:

Theorem 6 *The support and the "snake" motion coordination protocol is 1-fault tolerant.*

Applications

Ad hoc mobile networks are rapidly deployable and self-configuring networks that have important applications in many critical areas such as disaster relief, ambient intelligence, wide area sensing and surveillance. The ability to network *anywhere*, *anytime* enables teleconferencing, home networking, sensor networks, personal area networks, and embedded computing applications [13].

Related Work

The most common way to establish communication is to form paths of intermediate nodes that lie within one another's transmission range and can directly communicate with each other. The mobile nodes act as hosts and routers at the same time in order to propagate packets along these paths. This approach of maintaining a global structure with respect to the temporary network is a difficult problem. Since nodes are moving, the underlying communication graph is changing, and the nodes have to adapt quickly to such changes and reestablish their routes. Busch and Tirthapura [2] provide the first analysis of the performance of some characteristic protocols [8, 13] and show that in some cases they require $\Omega(u^2)$ time, where u is the number of nodes, to stabilize, i.e., be able to provide communication.

The work of Chatzigiannakis, Nikoletseas and Spirakis [5] focuses on networks where topological connectivity is subject to frequent, unpredictable change and studies the problem of efficient data delivery in sparse networks where network partitions can last for a significant period of time. In such cases, it is possible to

have a small team of fast moving and versatile vehicles, to implement the support. These vehicles can be cars, motorcycles, helicopters or a collection of independently controlled mobile modules, i.e., robots. This specific approach is inspired by the work of Walter, Welch and Amato [14] that study the problem of motion coordination in distributed systems consisting of such robots, which can connect, disconnect and move around.

The use of mobility to improve performance in ad hoc mobile networks has been considered in different contexts in [6, 9, 11, 15]. The primary objective has been to provide intermittent connectivity in a disconnected ad hoc network. Each solution achieves certain properties of end-to-end connectivity, such as delay and message loss among the nodes of the network. Some of them require long-range wireless transmission, other require that all nodes move pro-actively under the control of the protocol and collaborate so that they meet more often. The *key idea* of forcing only a subset of the nodes to facilitate communication is used in a similar way in [10, 15]. However, [15] focuses in cases where only one node is available. Recently, the application of mobility to the domain of wireless sensor networks has been addressed in [3, 10, 12].

Open Problems

A number of problems related to the work of Chatzigiannakis, Nikoletseas and Spirakis [5] remain open. It is clear that the size of the support, k, the shape and the way the support moves affects the performance of end-to-end connectivity. An open issue is to investigate alternative structures for the support, different motion coordination strategies and comparatively study the corresponding effects on communication times. To this end, the support idea is extended to hierarchical and highly changing motion graphs in [4]. The idea of cooperative routing based on the existence of support nodes may also improve security and trust.

An important issue for the case where the network is sparsely populated or where the rate of motion is too high is to study the performance of path construction and maintenance protocols. Some work has be done in this direction in [2] that can be also used to investigate the end-to-end communication in wireless sensor networks. It is still unknown if there exist impossibility results for distributed algorithms that attempt to maintain structural information of the implied fragile network of virtual links.

Another open research area is to analyze the properties of end-to-end communication given certain support motion strategies. There are cases where the mobile nodes interactions may behave in a similar way to the Physics paradigm of *interacting particles* and their modeling. Studies of interaction times and propagation times in various graphs are reported in [7] and are still important to further research in this direction.

Experimental Results

In [5] an experimental evaluation is conducted via simulation in order to model the different possible situations regarding the geographical area covered by an ad-hoc mobile network. A number of experiments were carried out for grid-graphs (2D, 3D), random graphs ($G_{n,p}$ model), bipartite multi-stage graphs and two-level motion graphs. All results verify the theoretical analysis and provide useful insight on how to further exploit the support idea. In [4] the model of hierarchical and highly changing ad-hoc networks is investigated. The experiments indicate that, the pattern of the "snake" algorithm's performance remains the same even in such type of networks.

Approximate shortest paths; Compact routing; Stretch factor

Years and Authors of Summarized Original Work

2013; Chechik

Problem Definition

Routing is a distributed mechanism that allows sending messages between any pair of nodes of the network. As in all distributed algorithms, a routing scheme runs locally on every processor/node of the network. Each node/processor of the network has a routing daemon running on it whose responsibility is to forward arriving messages while utilizing local information that is stored at the node itself. This local information is usually referred to as the routing table of the node.

A routing scheme involves two phases, a preprocessing phase and a routing phase. In the preprocessing phase, the algorithm assigns every node of the network a routing table and a small-size label. The label is used as the address of the node and therefore is usually expected to be of

small size – poly-logarithmic in the size of the network.

In the routing phase, some node of the networks wishes to send a message to some other nodes of the network in a distributed manner. During the routing phase, each node of the network may receive this message, and it has to decide whether this message reached its final destination, and if not, the node needs to decide to which of its neighbors this message should be forwarded next. In order to make these decisions, the node may use its own routing table and the header of the message that usually contains the label of the final destination and perhaps some additional information.

The stretch of a routing scheme is defined as the worst case ratio between the length of the path obtained by the routing scheme and the length of the shortest path between the source and the destination. There are two main objectives in designing the routing scheme. The first is to minimize the stretch of the routing scheme, and the second is to minimize the size of the routing tables. Much of the work on designing routing schemes focuses on the trade-off between these two objectives.

One extreme case is when it is allowed to use linear-size routing tables. In this case, one can store a complete routing table at all nodes, i.e., for every source node s and every potential destination node t, store at s the port number of the neighbor of s on the shortest path from s to t. In this case, the stretch is 1, i.e., the algorithm can route on exact shortest paths. However, a clear drawback is that the size of the routing tables is large, linear in the size of the network.

One may wish to use smaller routing tables at the price of a larger stretch. A routing scheme is considered to be compact if the size of the routing tables is sublinear in the number of nodes.

Key Results

This section presents a survey on compact routing schemes and a highlight of some recent new developments.

Many papers focus on the trade-off between the size of the routing tables and the stretch (e.g., [1, 2, 4, 5, 7–9]). The first trade-off was obtained by Peleg and Upfal [9]. Their scheme considered unweighted graph and achieved a bound on the total size of the routing tables.

Later, Awerbuch et al. [1] considered weighted graphs and achieved a routing scheme with a guarantee on the maximum table size. Their routing scheme uses table size of $\tilde{O}(n^{1/k})$ and was with $O(k^2 9^k)$ stretch. A better trade-off was later achieved by Awerbuch and Peleg [2].

Until very recently, the best-known trade-off was due to Thorup and Zwick [10]. They presented a routing scheme that uses routing tables of size $\tilde{O}(n^{1/k})$, a stretch of $4k - 5$, and label size of $O(k \log^2 n)$. Moreover, they showed that if a handshaking is allowed, namely, if the source node and the destination are allowed to exchange an information of size $O(\log^2 n)$ bits, then the stretch can be improved to $2k - 1$. Clearly, in many cases, it would be desirable to avoid the use of handshaking, as the overhead of establishing a handshake can be as high as sending the original message itself.

A natural question is, what is the best trade-off between routing table size and stretch one can hope for with or without a handshake? In fact, assuming the girth conjecture of Erdős [6], one can show that with table size of $O(n^{1/k})$, the best stretch possible is $2k - 1$ with or without a handshake. Hence, in the case of a handshake, Thorup and Zwick's scheme [10] is essentially optimal. However, in the case of no handshake, there is still a gap between the lower and upper bound. A main open problem in the area of compact routing schemes is on the gap between the stretch $4k - 5$ and $2k - 1$.

Recently, Chechik [3] gave the first evidence that the asymptotically optimal stretch is less than $4k$. Chechik [3] presented the first improvement to the stretch-space trade-off of compact routing scheme since the result of Thorup and Zwick [10]. More specifically, [3] presented a compact routing scheme for weighted general undirected graphs that uses tables of size $\tilde{O}(n^{1/k})$ and has stretch $c \cdot k$ for some absolute constant $c < 4$.

Open Problems

The main question that still remains unresolved is to prove or disprove the existence of a compact routing scheme that utilizes tables of size $\tilde{O}\left(n^{1/k}\right)$ and has stretch of $2k$ without the use of a handshake.

2001; Goldberg, Hartline, Wright
2002; Fiat, Goldberg, Hartline, Karlin

Problem Definition

This problem studies the *one round*, *sealed-bid* auction model where an auctioneer would like to sell an idiosyncratic commodity with unlimited copies to n bidders and each bidder $i \in \{1, \ldots, n\}$ will get at most one item.

First, for any i, bidder i bids a value b_i representing the price he is willing to pay for the item. They submit the bids simultaneously. After receiving the bidding vector $\mathbf{b} = (b_1, \ldots, b_n)$, the auctioneer computes and outputs the allocation vector $\mathbf{x} = (x_1, \ldots, x_n) \in \{0, 1\}^n$ and the price vector $\mathbf{p} = (p_1, \ldots, p_n)$. If for any i, $x_i = 1$, then bidder i gets the item and pays p_i for it. Otherwise, bidder i loses and pays nothing. In the auction, the auctioneer's revenue is $\sum_{i=1}^{n} \mathbf{x}\mathbf{p}^T$.

Definition 1 (Optimal Single Price Omniscient Auction $\mathcal{F}$) Given a bidding vector $\mathbf{b}$ sorted in decreasing order,

$$\mathcal{F}(\mathbf{b}) = \max_{1 \le i \le n} i \cdot b_i$$

Further,

$$\mathcal{F}^{(m)}(\mathbf{b}) = \max_{m \le i \le n} i \cdot b_i$$

Obviously, $\mathcal{F}$ maximizes the auctioneer's revenue if only uniform price is allowed.

However, in this problem, each bidder i is associated with a private value v_i representing the item's value in his opinion. So if bidder i gets the item, his payoff should be $v_i - p_i$. Otherwise, his payoff is 0. So for any bidder i, his payoff function can be formulated as $(v_i - p_i)x_i$. Furthermore, free will is allowed in the model. In other words, each bidder would bid some b_i different from his true value v_i, to maximize his payoff.

The objective of the problem is to design a *truthful* auction which could still maximize the auctioneer's revenue. An auction is *truthful* if for every bidder i, bidding his true value would maximize his payoff, regardless of the bids submitted by the other bidders [12, 13].

Definition 2 (Competitive Auctions)

INPUT: the submitted bidding vector $\mathbf{b}$.
OUTPUT: the allocation vector $\mathbf{x}$ and the price vector $\mathbf{p}$.
CONSTRAINTS:

(a) Truthful;
(b) The auctioneer's revenue is within a constant factor of the optimal single pricing for all inputs.

Key Results

Let $\mathbf{b}_{-i} = (b_1, \ldots, b_{i-1}, b_{i+1}, \ldots, b_n)$. f is any function from $\mathbf{b}_{-i}$ to the price.

Algorithm 1 Bid-independent auction: $\mathcal{A}_f(\mathbf{b})$

2: **if** $f(\mathbf{b}_{-i}) \le b_i$ **then**
3: $x_i = 1$ and $p_i = f(\mathbf{b}_i)$
4: **else**
5: $x_i = 0$
6: **end if**
7: **end for**

Theorem 1 ([6]) *An auction is truthful if and only if it is equivalent to a bid-independent auction.*

Definition 3 A truthful auction $\mathcal{A}$ is β-competitive against $\mathcal{F}^{(m)}$ if for all bidding vectors $\mathbf{b}$, the expected profit of $\mathcal{A}$ on $\mathbf{b}$ satisfies

$$\mathbf{E}(\mathcal{A}(\mathbf{b})) \ge \frac{\mathcal{F}^{(m)}(\mathbf{b})}{\beta}$$

Definition 4 (CostShare$_C$ [11]) Given bids $\mathbf{b}$, this mechanism finds the largest k such that the highest k bidders' biddings are at least $\frac{C}{k}$. Charge each of such k bidders $\frac{C}{k}$.

Algorithm 2 Sampling cost-sharing auction (SCS)

1: Partition bidding vector $\mathbf{b}$ uniformly at random into two sets $\mathbf{b}'$ and $\mathbf{b}''$.
2: Computer $\mathcal{F}' = \mathcal{F}(\mathbf{b}')$ and $\mathcal{F}'' = \mathcal{F}(\mathbf{b}'')$.
3: Running CostShare$_{\mathcal{F}''}$ on $\mathbf{b}'$ and CostShare$_{\mathcal{F}'}$ on $\mathbf{b}''$.

Theorem 2 ([6]) *SCS is 4-competitive against $\mathcal{F}^{(2)}$, and the bound is tight.*

SCS could be extended for partitioning into k parts for any k. In fact, $k = 3$ is the optimal partition.

Theorem 3 ([10]) *The random three partitioning cost sharing auction is 3.25-competitive.*

Theorem 4 ([9]) *Let $\mathcal{A}$ be any truthful randomized auction. There exists an input bidding vector $\mathbf{b}$ on which $\boldsymbol{E}(\mathcal{A}(\mathbf{b})) \le \frac{\mathcal{F}^{(2)}(\mathbf{b})}{2.42}$.*

Applications

As the Internet becomes more popular, more and more auctions are beginning to appear. Further, the items on sale in the auctions vary from antiques, paintings, and digital goods, for example, mp3, licenses, network resources, and so on. Truthful auctions can reduce the bidders' cost of investigating the competitors' strategies, since truthful auctions encourage bidders to bid their true values. On the other hand, competitive auctions can also guarantee the auctioneer's profit. So this problem is very practical and significant. These years, designing and analyzing competitive auctions under various auction models has become a hot topic [1–5, 7, 8].

Problem Definition

It is well known that if NP $\neq$ P, there is an infinite hierarchy of complexity classes between them [10]. However, for some broad classes of problems, a *complexity dichotomy* exists: every problem in the class is either in polynomial time or NP-hard. Such results include Schaefer's theorem [13], the dichotomy of Hell and Nešetřil for H-coloring [9], and some subclasses of the general constraint satisfaction problem [4]. These developments lead to the following questions: How far can we push the envelope and show dichotomies for even broader classes of problems? Given a class of problems, what is the criterion that distinguishes the tractable problems from the intractable ones? How does it help in solving the tractable problems efficiently? Now replacing NP

with #P [15], all the questions above can be asked for *counting* problems.

One family of counting problem concerns graph homomorphisms. Given two undirected graphs G and H, a graph homomorphism from G to H is a map ξ from the vertex set $V(G)$ to $V(H)$ such that (u, v) is an edge in G if and only if $(\xi(u), \xi(v))$ is an edge in H. The counting problem for graph homomorphism is to compute the number of homomorphisms from G to H. For a fixed graph H, this problem is also known as the $\#H$-coloring problem. In addition to $\#H$-coloring, a more general family of problems that has been studied intensively over the years is to count graph homomorphisms with weights. Formally, we use $\mathbf{A}$ to denote an $m \times m$ symmetric matrix with entries $(A_{i,j})$, $i, j \in [m] = \{1, \ldots, m\}$. Given any undirected graph $G = (V, E)$, we define the graph homomorphism function $Z_{\mathbf{A}}(G)$ as follows:

$$Z_{\mathbf{A}}(G) = \sum_{\xi: V \to [m]} \prod_{(u,v) \in E} A_{\xi(u),\xi(v)}. \quad (1)$$

This is also called the *partition function* from statistical physics. It is clear from the definition that $Z_{\mathbf{A}}(G)$ is exactly the number of homomorphisms from G to H, when $\mathbf{A}$ is the $\{0, 1\}$ adjacency matrix of H.

Graph homomorphism can express many natural graph properties. For example, if one takes H to be the graph over two vertices $\{0, 1\}$ with an edge $(0, 1)$ and a self-loop at 1, then the set of vertices mapped to 1 in a graph homomorphism from G to H corresponds to a VERTEX COVER of G, and the counting problem simply counts the number of vertex covers. As another example, if H is the complete graph over k vertices (without self-loops), then the problem is exactly the k-COLORING problem for G. Many additional graph invariants can be expressed as $Z_{\mathbf{A}}(G)$ for appropriate $\mathbf{A}$. Consider the Hadamard matrix

$$\mathbf{H} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \quad (2)$$

where we index the rows and columns by $\{0, 1\}$. In $Z_{\mathbf{H}}(G)$, every product

$$\prod_{(u,v) \in E} H_{\xi(u),\xi(v)} \in \{1, -1\}$$

and is -1 precisely when the induced subgraph of G on $\xi^{-1}(1)$ has an odd number of edges. Thus, $(2^n - Z_{\mathbf{H}}(G))/2$ is the number of induced subgraphs of G with an odd number of edges. Also expressible as $Z_{\mathbf{A}}(\cdot)$ are S-flows where S is a subset of a finite Abelian group closed under inversion [6], and a scaled version of the Tutte polynomial $\hat{T}(x, y)$ where $(x - 1)(y - 1)$ is a positive integer. In [6], Freedman, Lovász, and Schrijver characterized the graph functions that can be expressed as $Z_{\mathbf{A}}(\cdot)$.

Key Results

In [5], Dyer and Greenhill first prove a complexity dichotomy theorem for all undirected graphs H. To state it formally, we give the following definition of *block-rank*-1 matrices:

Definition 1 (Block-rank-1 matrices) A nonnegative (but not necessarily symmetric) matrix $\mathbf{A} \in \mathbb{C}^{m \times n}$ is said to be *block-rank*-1 if after separate appropriate permutations of its rows and columns, $\mathbf{A}$ becomes a block diagonal matrix and every block is of rank 1.

It is clear that a nonnegative matrix $\mathbf{A}$ is block-rank-1 iff every 2×2 submatrix of $\mathbf{A}$ with at least three positive entries is of rank 1. Here is the dichotomy theorem of Dyer and Greenhill [5]:

Theorem 1 ([5]) *Given any undirected graph H, the $\#H$-coloring problem is in polynomial time if its adjacency matrix is block-rank-1 and is #P-hard otherwise.*

For the special case when H has two vertices, the dichotomy above states that $\#H$-coloring is in polynomial time if the number of 1s in its adjacency matrix is 0, 1, 2, or 4 and is #P-hard otherwise. For the latter case, one of the diagonal entries is 0 (as H is undirected), and $\#H$-coloring

is indeed the problem of counting independent sets [16]. However, proving a dichotomy theorem for H of arbitrary size is much more challenging. Besides counting independent sets, the other starting point used in [5] is the problem of counting proper q-colorings [12]. To show that there is a reduction from one of these two problems whenever H violates the block-rank-1 criterion, Dyer and Greenhill need to define a more general counting problem with vertex weights and employ the technique of interpolation [14,16], as well as two tools often used with interpolation, stretching, and thickening.

Later in [1], Bulatov and Grohe give a sweeping complexity dichotomy theorem that generalizes the result of Dyer and Greenhill to nonnegative symmetric matrices:

Theorem 2 ([1]) *Given any symmetric and nonnegative algebraic matrix* $\mathbf{A}$*, computing* $Z_{\mathbf{A}}(\cdot)$ *is in polynomial time if* $\mathbf{A}$ *is block-rank-*1 *and is #P-hard otherwise.*

This dichotomy theorem has since played an important role in many of the new developments in the study of counting graph homomorphisms as well as counting constraint satisfaction problem because of its enormous applicability. Many #P-hardness results are built on top of this dichotomy. A proof of the dichotomy theorem with a few shortcuts can also be found in [8].

Recently in a paper with both exceptional depth and conceptual vision, Goldberg, Jerrum, Grohe, and Thurley [7] proved a complexity dichotomy for all real-valued symmetric matrices:

Theorem 3 ([7]) *Given any symmetric and real algebraic matrix* $\mathbf{A}$*, the problem of computing* $Z_{\mathbf{A}}(\cdot)$ *is either in polynomial time or #P-hard.*

The exact tractability criterion in the dichotomy above, however, is much more technical and involved. Roughly speaking, the proof of the theorem proceeds by establishing a sequence of successively more stringent properties that a tractable $\mathbf{A}$ must satisfy. Ultimately, it arrives at a point where the satisfaction of these properties together implies that the computation of $Z_{\mathbf{A}}(G)$ can be reduced to the following sum:

$$\sum_{x_1,\ldots,x_n\in\mathbb{Z}_2} (-1)^{f_G(x_1,\ldots,x_n)} \tag{3}$$

where f_G is a quadratic polynomial over $\mathbb{Z}_2$ constructed from the input graph G efficiently. This sum is known to be computable in polynomial time in n, the number of variables (e.g., see [3] and [11, Theorem 6.30]). In particular, the latter immediately implies that the following two Hadamard matrices

$$\mathbf{H}_2 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \quad \text{and} \quad \mathbf{H}_4 = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}$$

are both tractable. This can be seen from the following polynomial view of these two matrices. If we index the rows and columns of $\mathbf{H}_2$ by $\mathbb{Z}_2$ and index the rows and columns of $\mathbf{H}_4$ by $(\mathbb{Z}_2)^2$, then their (x, y)th entry and $((x_1, x_2), (y_1, y_2))$th entry are

$$(-1)^{xy} \quad \text{and} \quad (-1)^{x_1y_2+x_2y_1},$$

respectively. From here, it is easy to reduce $Z_{\mathbf{H}_2}(\cdot)$ and $Z_{\mathbf{H}_4}(\cdot)$ to (3).

Compared with the nonnegative domain [1,5], there are a lot more interesting tractable cases over the real numbers, e.g., the two Hadamard matrices above as well as their arbitrary tensor products. It is not surprising that the potential cancelations in the sum $Z_{\mathbf{A}}(\cdot)$ may in fact be the source of efficient algorithms for computing $Z_{\mathbf{A}}(\cdot)$ itself. This motivates Cai, Chen, and Lu to continue to investigate the computational complexity of $Z_{\mathbf{A}}(\cdot)$ with $\mathbf{A}$ being a symmetric complex matrix [2], because over the complex domain, there is a significantly richer variety of possible cancelations with the roots of unit, and more interesting tractable cases are expected. This turns out to be the case, and they prove the following complexity dichotomy:

Theorem 4 ([2]) *given any symmetric and algebraic complex matrix* $\mathbf{A} \in \mathbb{C}^{m\times m}$*, the problem of*

computing $Z_{\mathbf{A}}(\cdot)$ is either in polynomial time or #P-hard.

Applications

None is reported.

Open Problems

The efficient approximation of $Z_{\mathbf{A}}(\cdot)$ remains widely open even for small nonnegative matrices. See the entry "Approximating the Partition Function of Two-Spin Systems" for the current state of the art on this. Two families of counting problems that generalize $Z_{\mathbf{A}}(\cdot)$ are counting constraint satisfaction and Holant problems. Open problems in these two areas can be found in the two entries "Complexity Dichotomies for the Counting Constraint Satisfaction Problem" and "Holant Problems."

Complexity of Bimatrix Nash Equilibria

Xi Chen
Computer Science Department, Columbia University, New York, NY, USA
Computer Science and Technology, Tsinghua University, Beijing, China

Keywords

Bimatrix games; Nash Equilibria; Two-player games

Years and Authors of Summarized Original Work

2006; Chen, Deng

Problem Definition

In the middle of the last century, Nash [8] studied general noncooperative games and proved that there exists a set of mixed strategies, now commonly referred to as a Nash equilibrium, one for each player, such that no player can benefit if he/she changes his/her own strategy unilaterally. Since the development of Nash's theorem, researchers have worked on how to compute Nash equilibria efficiently. Despite much effort in the last half century, no significant progress has been made on characterizing its algorithmic complexity, though both hardness results and algorithms have been developed for various modified versions.

An exciting breakthrough, which shows that computing Nash equilibria is possibly hard, was made by Daskalakis, Goldberg, and Papadimitriou [5], for games among four players or more. The problem was proven to be complete in **PPAD** (polynomial parity argument, directed version), a complexity class introduced by Papadimitriou in [9]. The work of [5] is based on the techniques developed in [6]. This hardness result was then improved to the three-player case by Chen and Deng [1] and Daskalakis and Papadimitriou [4], independently and with different proofs. Finally, Chen and Deng [2] proved that NASH, the problem of finding a Nash equilibrium in a bimatrix game (or two-player game), is **PPAD**-complete.

A bimatrix game is a noncooperative game between two players in which the players have m and n choices of actions (or pure strategies), respectively. Such a game can be specified by two $m \times n$ matrices $\mathbf{A} = (a_{i,j})$ and $\mathbf{B} = (b_{i,j})$. If the first player chooses action i and the second player chooses action j, then their payoffs are $a_{i,j}$ and $b_{i,j}$, respectively. A mixed strategy of a player is a probability distribution over his/her choices. Let $\mathbb{P}^n$ denote the set of all probability vectors in $\mathbb{R}^n$, i.e., nonnegative vectors whose entries sum to 1. The Nash equilibrium theorem on noncooperative games, when specialized to bimatrix games, states that for every bimatrix game $\mathcal{G} = (\mathbf{A}, \mathbf{B})$, there exists a pair of mixed strategies $(\mathbf{x}^* \in \mathbb{P}^m, \mathbf{y}^* \in \mathbb{P}^n)$, called a Nash equilibrium, such that for all $\mathbf{x} \in \mathbb{P}^m$ and $\mathbf{y} \in \mathbb{P}^n$, $(\mathbf{x}^*)^{\mathrm{T}}\mathbf{A}\mathbf{y}^* \geq \mathrm{x}^T\mathbf{A}\mathbf{y}^*$ and $(\mathbf{X}^*)^{\mathrm{T}}\mathbf{B}\mathbf{y}^* \geq (\mathbf{x}^*)^{\mathrm{T}}\mathbf{B}\mathbf{y}$.

Computationally, one might settle with an approximate Nash equilibrium. Let $\mathbf{A}_i$ denote the ith row vector of $\mathbf{A}$ and $\mathbf{B}_i$ denote the ith column vector of $\mathbf{B}$. An ε-well-supported Nash equilibrium of game $(\mathbf{A},\mathbf{B})$ is a pair of mixed strategies $(\mathbf{x}^*, \mathbf{y}^*)$ such that

$$\mathbf{A}_i\mathbf{y}^* > \mathbf{A}_j\mathbf{y}^* + \epsilon \Rightarrow x_j^* = 0, \forall\, i, j : 1 \leq i, j \leq m;$$

$$(\mathbf{x}^*)^{\mathrm{T}}\mathbf{B}_i > (\mathbf{x}^*)^{\mathrm{T}}\mathbf{B}_j + \epsilon \Rightarrow y_j^* = 0, \forall\, i, j : 1 \leq i, j \leq n.$$

Definition 1 (2-NASH and NASH) The input instance of problem 2-NASH is a pair $(\mathcal{G}, 0^k)$ where $\mathcal{G}$ is a bimatrix game and the output is a 2^{-k}-well-supported Nash equilibrium of $\mathcal{G}$. The input of problem NASH is a bimatrix game $\mathcal{G}$ and the output is an exact Nash equilibrium of $\mathcal{G}$.

Key Results

A binary relation $R \subset \{0,1\}^* \times \{0,1\}^*$ is *polynomially balanced* if there exists a polynomial p such that for all pairs $(x, y) \in R$, $|y| \leq p(|x|)$. It is a *polynomial-time computable relation* if for each pair (x, y), one can decide whether or not $(x, y) \in R$ in polynomial time in $|x| + |y|$. The **NP** search problem Q_R specified by R is defined as follows: given $x \in \{0,1\}^*$, if there exists y such that $(x, y) \in R$, return y; otherwise, return a special string "no."

Relation R is *total* if for every $x \in \{0,1\}^*$, there exists a y such that $(x, y) \in R$. Following [7], let **TFNP** denote the class of all **NP** search problems specified by total relations. A search problem $Q_{R_1} \in$ **TFNP** is *polynomial-time reducible* to problem $Q_{R_2} \in$ **TFNP** if there exists a pair of polynomial-time computable functions (f, g) such that for every x of R_1, if y satisfies that $(f(x), y) \in R_2$, then $(x, g(y)) \in R_1$.

Furthermore, Q_{R1} and Q_{R2} are polynomial-time equivalent if Q_{R2} is also reducible to Q_{R1}.

The complexity class **PPAD** is a subclass of **TFNP**, containing all the search problems which are polynomial-time reducible to:

Definition 2 (Problem LEAFD) The input instance of LEAFD is a pair $(M, 0^n)$, where M defines a polynomial-time Turing machine satisfying:

1. For every $v \in \{0,1\}^n$, $M(v)$ is an ordered pair (u_1, u_2) with $u_1, u_2 \in \{0,1\}^n \cup \{\text{“no”}\}$.
2. $M(0^n) = (\text{“no,”}\ 1^n)$ and the first component of $M(1^n)$ is 0^n.

This instance defines a directed graph $G = (V, E)$ with $V = \{0,1\}^n$. Edge $(u, v) \in E$ iff v is the second component of $M(u)$ and u is the first component of $M(v)$.

The output of problem LEAFD is a directed leaf of G other than 0^n. Here a vertex is called a *directed leaf* if its out-degree plus in-degree equals one.

A search problem in **PPAD** is said to be *complete* in **PPAD** (or **PPAD**-complete) if there exists a polynomial-time reduction from LEAFD to it.

Theorem ([2]) *2-Nash and Nash are* **PPAD***-complete.*

Applications

The concept of Nash equilibria has traditionally been one of the most influential tools in the study of many disciplines involved with strategies, such as political science and economic theory. The rise of the Internet and the study of its anarchical environment have made the Nash equilibrium an indispensable part of computer science. Over the past decades, the computer science community has contributed a lot to the design of efficient algorithms for related problems. This sequence of results [1–6], for the first time, provides *some evidence* that the problem of finding a Nash equilibrium is possibly hard for **P**. These results are very important to the emerging discipline, algorithmic game theory.

Open Problems

This sequence of works shows that $(r+1)$-player games are polynomial-time reducible to r-player games for every $r \geq 2$, but the reduction is carried out by first reducing $(r+1)$-player games to a fixed-point problem and then further to r-player games. Is there a natural reduction that goes directly from $(r+1)$-player games to r-player games? Such a reduction could provide a better understanding for the behavior of multiplayer games. Although many people believe that **PPAD** is hard for **P**, there is no strong evidence for this belief or intuition. The natural open problem is: can one rigorously prove that class **PPAD** is hard, under one of those generally believed assumptions in theoretical computer science, like “**NP** is not in **P**” or “one-way function exists”? Such a result would be extremely important to both computational complexity theory and algorithmic game theory.

Complexity of Core

Qizhi Fang
School of Mathematical Sciences, Ocean University of China, Qingdao, Shandong Province, China

Keywords

Balanced; Least core

Years and Authors of Summarized Original Work

2001; Fang, Zhu, Cai, Deng

Problem Definition

The core is one of the most important solution concepts in cooperative game, which is based on the coalition rationality condition: no subgroup of the players will do better if they break away from the joint decision of all players to form their own coalition. The principle behind this condition can be seen as an extension to that of the Nash Equilibrium in noncooperative games. The work of Fang, Zhu, Cai, and Deng [4] discusses the computational complexity problems related to the cores of some cooperative game models arising from combinatorial optimization problems, such as flow games and Steiner tree games.

A cooperative game with side payments is given by the pair (N, v), where $N = \{1, 2, \ldots, n\}$ is the player set and $v : 2^N \to R$ is the characteristic function. For each coalition $S \subseteq N$, the value $v(S)$ is interpreted as the profit or cost achieved by the collective action of players in S without any assistance of players in $N \backslash S$. A game is called a profit (cost) game if the characteristic function values measure the profit (cost) achieved by the coalitions. Here, the definitions are only given for profit games, symmetric statements hold for cost games.

A vector $x = \{x_1, x_2, \ldots, x_n\}$ is called an imputation if it satisfies $\sum_{i \in N} x_i = v(N)$ and $\forall i \in N : x_i \geq v(\{i\})$. The core of the game (N, v) is defined as:

$$\mathcal{C}(v) = \{x \in R^n : x(N) = v(N) \text{ and } x(S) \geq v(S),\ \forall S \subseteq N\},$$

where $x(S) = \sum_{i \in S} x_i$ for $S \subseteq N$. A game is called *balanced*, if its core is nonempty, and *totally balanced*, if every subgame (i.e., the game obtained by restricting the player set to a coalition and the characteristic function to the power set of that coalition) is balanced.

It is a challenge for the algorithmic study of the core, since there are an exponential number of constraints imposed on its definition. The following computational complexity questions have attracted much attention from researchers:

1. *Testing balancedness:* Can it be tested in polynomial time whether a given instance of the game has a nonempty core?
2. *Checking membership:* Can it be checked in polynomial time whether a given imputation belongs to the core?
3. *Finding a core member:* Is it possible to find an imputation in the core in polynomial time?

In reality, however, there is an important case in which the characteristic function value of a coalition can be evaluated via a combinatorial optimization problem, subject to constraints of resources controlled by the players of this coalition. In such circumstances, the input size of a game is the same as that of the related optimization problem, which is usually polynomial

in the number of players. Therefore, this class of games, called combinatorial optimization games, fits well into the framework of algorithm and complexity analysis. Flow games and Steiner tree games discussed in Fang et al. [4] fall within this scope.

Flow Game Let $D = (V, E; \omega; s, t)$ be a directed flow network, where V is the vertex set, E is the arc set, $\omega: E \to R^+$ is the arc capacity function, and s and t are the source and the sink of the network, respectively. Assume that each player controls one arc in the network. The value of a maximum flow can be viewed as the profit achieved by the players in cooperation. The flow game $\Gamma_f = (E, v)$ associated with the network D is defined as follows:

(i) The player set is E.
(ii) $\forall S \subseteq E$, $v(S)$ is the value of a maximum flow from s to t in the subnetwork of D consisting only of arcs belonging to S.

In Kailai and Zemel [6] and Deng et al. [1], it was shown that the flow game is totally balanced and finding a core member can be done in polynomial time.

Problem 1 (Checking membership for flow game) INSTANCE: A flow network $D = (V, E; \omega; s, t)$ and $x : E \to R^+$.

QUESTION: Is it true that $x(E) = v(E)$ and $x(S) \geq v(S)$ for all subsets $S \subset E$?

Steiner Tree Game Let $G = (V, E; \omega)$ be an edge-weighted graph with $V = \{v_0\} \cup N \cup M$, where $N, M \subseteq V \backslash \{v_0\}$ are disjoint. v_0 represents a central supplier, N represents the consumer set, M represents the switch set, and $\omega(e)$ denotes the cost of connecting the two endpoints of edge e directly. It is required to connect all the consumers in N to the central supplier v_0. The connection is not limited to using direct links between two consumers or a consumer and the central supplier; it may pass through some switches in M. The aim is to construct the cheapest connection and distribute the connection cost among the consumers fairly. Then, the associated Steiner tree game $\Gamma_s = (N, \gamma)$ is defined as follows:

(i) The player set is N.
(ii) $\forall S \subseteq N$, $\gamma(S)$ is the weight of a minimum Steiner tree on G w.r.t. the set $S \cup \{v_0\}$, that is, $\gamma(S) = \min\{\sum_{e \in E_S} \omega(e) : T_S = (V_S, E_S)$ is a subtree of G with $V_S \supseteq S \cup \{v_0\}\}$.

Different from flow games, the core of a Steiner tree game may be empty. An example with an empty core was given in Megiddo [9].

Problem 2 (Testing balancedness for a Steiner tree game) INSTANCE: An edge-weighted graph $G = (V, E; \omega)$ with $V = \{v_0\} \cup N \cup M$.

QUESTION: Does there exist a vector $x : N \to R^+$ such that $x(N) = \gamma(N)$ and $x(S) \leq \gamma(S)$ for all subsets $S \subset N$?

Problem 3 (Checking membership for a Steiner tree game) INSTANCE: An edge-weighted graph $G = (V, E; \omega)$ with $V = \{v_0\} \cup N \cup M$ and $x : N \to R^+$.

QUESTION: Is it true that $x(N) = \gamma(N)$ and $x(S) \leq \gamma(S)$ for all subsets $S \subset N$?

Key Results

Theorem 1 *It is $\mathcal{NP}$-complete to show that given a flow game $\Gamma_f = (E, v)$ defined on network $D = (V, E; \omega; s, t)$ and a vector $x : E \to R^+$ with $x(E) = v(E)$, whether there exists a coalition $S \subset N$ such that $x(S) < v(S)$. That is, checking membership of the core for flow games is co-$\mathcal{NP}$-complete.*

The proof of Theorem 1 yields directly the same conclusion for linear production games. In Owen's linear production game [10], each player j ($j \in N$) is in possession of an individual resource vector b^j. For a coalition S of players, the profit obtained by S is the optimum value of the following linear program:

$$\max \left\{ c^t y : Ay \leq \sum_{j \in S} b^j,\ y \geq 0 \right\}.$$

That is, the characteristic function value is what the coalition can achieve in the linear production

model with the resources under the control of its players. Owen showed that one imputation in the core can also be constructed through an optimal dual solution to the linear program which determines the value of N. However, in general, there exist some imputations in the core which cannot be obtained in this way.

Theorem 2 *Checking membership of the core for linear production games is co-$\mathcal{NP}$-complete.*

The problem of finding a minimum Steiner tree in a network is $\mathcal{NP}$-hard; therefore, in a Steiner tree game, the value $\gamma(S)$ of each coalition S may not be obtained in polynomial time. It implies that the complement problem of checking membership of the core for Steiner tree games may not be in $\mathcal{NP}$.

Theorem 3 *It is $\mathcal{NP}$-hard to show that given a Steiner tree game $\Gamma_s = (N, \gamma)$ defined on network $G = (V, E; \omega)$ and a vector $x : N \to R^+$ with $x(N) = \gamma(N)$, whether there exists a coalition $S \subset N$ such that $x(S) > \gamma(S)$. That is, checking membership of the core for Steiner tree games is $\mathcal{NP}$-hard.*

Theorem 4 *Testing balancedness for Steiner tree games is $\mathcal{NP}$-hard.*

Given a Steiner tree game $\Gamma_s = (N, \gamma)$ defined on network $G = (V, E; \omega)$ and a subset $S \subseteq N$, in the subgame (S, γ_S), the value $\gamma(S')$ $(S' \subseteq S)$ is the weight of a minimum Steiner tree of G w.r.t. the subset $S' \cup \{v_0\}$, where all the vertices in $N \setminus S$ are treated as switches but not consumers. It is further proved in Fang et al. [4] that determining whether a Steiner tree game is totally balanced is also $\mathcal{NP}$-hard. This is the first example of $\mathcal{NP}$-hardness for the totally balanced condition.

Theorem 5 *Testing total balancedness for Steiner tree games is $\mathcal{NP}$-hard.*

Applications

The computational complexity results on the cores of combinatorial optimization games have been as diverse as the corresponding combinatorial optimization problems. For example:

1. In matching games [2], testing balancedness, checking membership, and finding a core member can all be done in polynomial time.
2. In both flow games and minimum-cost spanning tree games [3, 4], although their cores are always nonempty and a core member can be found in polynomial time, the problem of checking membership is *co-$\mathcal{NP}$*-complete.
3. In facility location games [5], the problem of testing balancedness is in general $\mathcal{NP}$-hard; however, given the information that the core is nonempty, both finding a core member and checking membership can be solved efficiently.
4. In a game of sum of edge weight defined on a graph [1], all the problems of testing balancedness, checking membership, and finding a core member are $\mathcal{NP}$-hard.

Based on the concept of bounded rationality [3, 8], it is suggested that computational complexity be taken as an important factor in considering rationality and fairness of a solution concept. That is, the players are not willing to spend super-polynomial time to search for the most suitable solution. In the case when the solutions of a game do not exist or are difficult to compute or to check, it may not be simple to dismiss the problem as hopeless, especially when the game arises from important applications. Hence, various conceptual approaches are proposed to resolve this problem.

When the core of a game is empty, it motivates conditions ensuring nonemptiness of approximate cores. A natural way to approximate the core is the *least core*. Let (N, v) be a profit cooperative game. Given a real number ε, the ε-core is defined to contain the imputations such that $x(S) \geq v(S) - \varepsilon$ for each nonempty proper subset S of N. The *least core* is the intersection of all nonempty ε-cores. Let ε^* be the minimum value of ε such that the ε-core is empty and then the least core is the same as the ε^*-core.

The concept of the least core poses new challenges in regard to algorithmic issues. The most natural problem is how to efficiently compute the value ε^* for a given cooperative game. The catch is that the computation of ε^* requires solving

of a linear program with an exponential number of constrains. Though there are cases where this value can be computed in polynomial time [7], it is in general very hard. If the value of ε^* is considered to represent some subsidies given by the central authority to ensure the existence of the cooperation, then it is significant to give the approximate value of it even when its computation is $\mathcal{NP}$-hard.

Another possible approach is to interpret approximation as bounded rationality. For example, it would be interesting to know if there is any game with a property that for any $\varepsilon > 0$, checking membership in the ε-core can be done in polynomial time, but it is $\mathcal{NP}$-hard to tell if an imputation is in the core. In such cases, the restoration of cooperation would be a result of bounded rationality. That is to say, the players would not care an extra gain or loss of ε as the expense of another order of degree of computational resources. This methodology may be further applied to other solution concepts.

Problem Definition

We face the following problem.

Problem 1 (Top-k document retrieval) *Let $\mathcal{D} = \{\mathsf{T}_1, \mathsf{T}_2, \ldots, \mathsf{T}_D\}$ be a collection of D documents of n characters in total, drawn from an alphabet set $\Sigma = [\sigma]$. The relevance of a document T_d with respect to a pattern P, denoted by $w(P, d)$ is a function of the set of occurrences of P in T_d. Our task is to index $\mathcal{D}$, such that whenever a pattern $P[1, p]$ and a parameter k comes as a query, the k documents with the highest $w(P, \cdot)$ values can be reported efficiently.*

Source	Report time per document
Hon et al. [3]	$O(t_{\mathsf{SA}} \log^{3+\epsilon} n)$
Gagie et al. [2]	$O(t_{\mathsf{SA}} \log D \log(D/k) \log^{1+\epsilon} n)$
Belazzougui et al. [1]	$O(t_{\mathsf{SA}} \log k \log(D/k) \log^{\epsilon} n)$
Hon et al. [4]	$O(t_{\mathsf{SA}} \log k \log^{\epsilon} n)$

Compressed Document Retrieval on String Collections, Table 2 Indexes of space $|\mathsf{CSA}| + D\log(n/D) + O(D) + o(n)$ bits

Source	Report time per document
Tsur [12]	$O(t_{\mathsf{SA}} \log k \log^{1+\epsilon} n)$
Navarro and Thankachan [8]	$O(t_{\mathsf{SA}} \log^2 k \log^{\epsilon} n)$

Traditionally, inverted indexes are employed for this task in Information Retrieval. However, they are not powerful enough to handle scenarios where the documents need to be treated as general strings over an arbitrary alphabet set (e.g., genome sequences in bioinformatics, text in many East-Asian languages) [5]. Hon et al. [3] proposed the first solution for Problem 1, requiring $O(n \log n)$ bits of space and $O(p + k \log k)$ query time. Later, optimal $O(p + k)$ query time indexes were proposed by Navarro and Nekrich [7], and also by Shah et al. [11]. There also exist compressed/compact space solutions, tailored to specific relevance functions (mostly term-frequency or PageRank). In this article, we briefly survey the compressed space indexes for Problem 1 for the case where the relevance function is term-frequency (i.e., $w(P, d)$ is the number of occurrences of P in T_d), which we call the *Compressed Top-k Frequent Document Retrieval* (CTFDR) problem.

Key Results

First we introduce some notations. For convenience, we append a special character \$ to every document. Then, $\mathsf{T} = \mathsf{T}_1 \circ \mathsf{T}_2 \circ \cdots \circ \mathsf{T}_D$ is the concatenation of all documents. GST, SA, and CSA are the suffix tree, suffix array, and a compressed suffix array of T, respectively. Notice that both GST and SA take $O(n \log n)$ bits of space, whereas the space of CSA ($|\mathsf{CSA}|$ bits) can be made as close as the minimum space for maintaining $\mathcal{D}$ (which is not more than $n \log \sigma$ bits) by choosing an appropriate version of CSA [6]. Using CSA, the suffix range $[sp, ep]$ of $P[1, p]$, as well as any $\mathsf{SA}[\cdot]$, can be computed in times $\mathsf{search}(p)$ and t_{SA}, respectively. Hon et al. [3] gave the first solution for the CTFDR Problem, requiring roughly $2|\mathsf{CSA}|$ bits of space, whereas the first space-optimal index was given by Tsur [12]. Various improvements on both results have been proposed and are summarized in Tables 1 and 2. Notice that the total query time is $\mathsf{search}(p)$ plus k times per reported document.

Notations and Basic Framework

The suffix tree GST of T can be considered as a generalized suffix tree of $\mathcal{D}$, where

- ℓ_i is the ith leftmost leaf in GST
- $\mathrm{doc}(\ell_i)$ is the document to which the suffix corresponding to ℓ_i belongs
- $\mathsf{Leaf}(u)$ is the set of leaves in the subtree of node u
- $\mathsf{tf}(u, d)$ is the number of leaves in $\mathsf{Leaf}(u)$ with $\mathrm{doc}(\cdot) = d$
- $\mathsf{Top}(u, k)$ is the set k of document identifiers with the highest $\mathsf{tf}(u, \cdot)$ value

From now onwards, we assume all solutions consists of a fully compressed representation of GST in $|\mathsf{CSA}| + o(n)$ bits [10], and a bitmap

$B[1,n]$, where $B[i] = 1$ iff $\mathsf{T}[i] = \$$. We use a $D\log(n/D) + O(D) + o(n)$ bits representation of B with constant time rank/select query support [9]. Therefore, $\mathrm{doc}(\ell_i)$ can be computed as 1 plus the number of 1's in $B[1, \mathsf{SA}[i]-1]$ in time $t_{\mathsf{SA}} + O(1)$. Observe that a CTFDL query (P,k) essentially asks to return the set $\mathsf{Top}(u_P, k)$, where u_P is the *locus node* of P in GST. Any superset of $\mathsf{Top}(u_P,k)$ be called as a candidate set of (P,k). The following lemma is crucial.

Lemma 1 *The set* $\mathsf{Top}(w,k) \cup \{\mathrm{doc}(\ell_i) | \ell_i \in \mathsf{Leaf}(u_P) \backslash \mathsf{Leaf}(w)\}$ *is a candidate set of* (P,k)*, where* w *is any node in the subtree of* u_P*.*

All query processing algorithms consist of the following two steps: (i) Generate a candidate set $\mathcal{C}$ of size as close to k as possible. (ii) Compute $\mathsf{tf}(u_P, d)$ of all $d \in \mathcal{C}$ and report those k document identifiers with the highest $\mathsf{tf}(u_P, \cdot)$ values as output.

An Index of Size $\approx 2|\mathsf{CSA}|$ Bits

Queries are categorized into $O(\log D)$ different types.

Definition 1 A query (P,k) is of type x if $\lceil \log k \rceil = x$.

We start with the description of a structure DS_x (of size $|\mathsf{DS}_x|$ bits) that along with GST and B can generate a candidate set of size proportional to k for any type-x query. The first step is to identify a set Mark_g of nodes in GST using the scheme described in Lemma 2 (parameter g will be fixed later). Then maintain $\mathsf{Top}(u', 2^x)$ for all $u' \in \mathsf{Mark}_g$.

Lemma 2 ([3]) *There exists a scheme to identify a set* Mark_g *of nodes in* GST *(called marked nodes) based on a grouping factor* g*, where the following conditions are satisfied: (i)* $|\mathsf{Mark}_g| = O(n/g)$*, (ii) if it exists, the highest marked node* $u' \in \mathsf{Mark}_g$ *in the subtree of any node* u *is unique, and* $\mathsf{Leaf}(u) \backslash \mathsf{Leaf}(u') \leq 2g$*. For example,* Mark_g *can be the set of all lowest common ancestor (LCA) nodes of* ℓ_i *and* ℓ_{i+g}*, where* i *is an integer multiple of* g*.*

Using DS_x, any type-x query (P,k) can be processed as follows: find the highest node u'_P in the subtree of u_P and generate the following candidate set.

$$\mathsf{Top}(u'_P, 2^x) \cup \{\mathrm{doc}(\ell_i) | \ell_i \in \mathsf{Leaf}(u_P) \backslash \mathsf{Leaf}(u'_P)\}$$

From the properties described in Lemma 2, the cardinality of this set is $O(2^x + g) = O(k+g)$ and the size of DS_x is $O((n/g)2^x \log D)$ bits. By fixing $g = 2^x \log^{2+\epsilon} n$ [3], we can bound the set cardinality by $O(k \log^{2+\epsilon} n)$ and $|\mathsf{DS}_x|$ by $O(n/\log^{1+\epsilon} n)$ bits. Therefore, we maintain DS_x for $x = 1, 2, 3, \ldots, \log D$ in $o(n)$ bits overall, and whenever a query comes, generate a candidate set of size $O(k \log^{2+\epsilon} n)$ using appropriate structures. The observation by Belazzougui et al. [1] is that $g = x2^x \log^{1+\epsilon} n$ in the above analysis yields a candidate set of even lower cardinality $O(k \log k \log^{1+\epsilon} n)$, without blowing up the space.

Later, Hon et al. [4] came up with another strategy for generating a candidate set of even smaller size, $O(k \log k \log^{\epsilon} n)$. They associate another structure DS^*_x (of space $|\mathsf{DS}^*_x|$ bits) with each DS_x. Essentially, DS^*_x maintains $\mathsf{Top}(u'', 2^x)$ of every $u'' \in \mathsf{Mark}_h$ with $h = x2^x \log^{\epsilon} n$ in an *encoded* form. Now, whenever a type-x query (P,k) comes, we first find the highest node u''_P in the subtree of u_P that belongs to Mark_h and generate the candidate set $\mathsf{Top}(u''_P, 2^x) \cup \{\mathrm{doc}(\ell_i) | \ell_i \in \mathsf{Leaf}(u_P) \backslash \mathsf{Leaf}(u''_P)\}$, whose cardinality is $O(2^x + h) = O(k \log k \log^{\epsilon} n)$.

We now describe the scheme for encoding a particular $\mathsf{Top}(u'', 2^x)$. Let u' be the highest node in the subtree of u'', that belongs to Mark_g. Then, $\mathsf{Top}(u'', 2^x) \subseteq \mathsf{Top}(u', 2^x) \cup \{\mathrm{doc}(\ell_i) | \ell_i \in \mathsf{Leaf}(u'') \backslash \mathsf{Leaf}(u')\}$. Notice that $\mathsf{Top}(u'', 2^x)$ is stored in DS_x and any $\mathrm{doc}(\ell_i)$ can be decoded in $O(t_{\mathsf{SA}})$ time. Therefore, instead of explicitly storing an entry d within $\mathsf{Top}(u'', 2^x)$ in $\log D$ bits, we can refer to the position of d in $\mathsf{Top}(u', 2^x)$ if $d \in \mathsf{Top}(u', 2^x)$, else refer to the relative position of a leaf node ℓ_i in $\mathsf{Leaf}(u'') \backslash \mathsf{Leaf}(u')$ with $\mathrm{doc}(\ell_i) = d$. Therefore, maintaining the following two bitmaps is sufficient.

- $\mathsf{F}[1, 2^x]$, where $\mathsf{F}[i] = 1$ iff ith entry in $\mathsf{Top}(u', 2^x)$ is present in $\mathsf{Top}(u'', 2^x)$
- $\mathsf{F}'[1, |\mathsf{Leaf}(u'')\backslash\mathsf{Leaf}(u')|]$, $\mathsf{F}'[i] = 1$ iff $\mathsf{doc}(\cdot)$ of ith leaf node in $\mathsf{Leaf}(u'')\backslash\mathsf{Leaf}(u')$ is present in $\mathsf{Top}(u'', 2^x)$, but not in $\mathsf{Top}(u', 2^x)$.

As the total length and the number of 1's over F and F' is $O(g + 2^x)$ and $O(2^x)$, respectively, we can encode them in $O(2^x \log(g/2^x)) = O(2^x \log\log n)$ bits. Therefore, $|\mathsf{DS}^*_x| = O((n/(x2^x \log^\epsilon n))2^x \log\log n)$ bits and $\sum_{x=1}^{\log D} |\mathsf{DS}_x| = o(n)$ bits.

Lemma 3 *By maintaining a $|\mathsf{CSA}| + o(n) + D\log(n/D) + O(D)$ bits space structure (which includes the space of CSA and B), a candidate set of size $O(k \log k \log^\epsilon n)$ can be generated for any query (P, k) in time $O(t_{\mathsf{SA}} \cdot k \log k \log^\epsilon n)$.*

We now turn our attention to Step 2 of the query algorithm. Let $[sp, ep]$ be the suffix range of P in CSA and $[sp_d, ep_d]$ be the suffix range of P in CSA_d, the compressed suffix array of T_d. Hon et al. [3] showed that by additionally maintaining all CSA_d's (in space roughly $\approx |\mathsf{CSA}|$ bits), any $[sp_d, ep_d]$ can be computed in time $O(t_{\mathsf{SA}} \log n)$ (and thus $\mathsf{tf}(P, d) = ep_d - sp_d + 1$). Belazzougui et al. [1] improved this time to $O(t_{\mathsf{SA}} \log\log n)$ using $o(n)$ extra bits. Combined with Lemma 3, this gives the following.

Theorem 1 ([4]) *Using a $2|\mathsf{CSA}| + o(n) + D\log(n/D) + O(D)$ bits space index, top-k frequent document retrieval queries can be answered in $O(\mathsf{search}(p) + k \cdot t_{\mathsf{SA}} \log k \log^\epsilon n)$ time.*

Space-Optimal Index

Space-optimal indexes essentially circumvent the need of CSA_d's. We first present a simplified version of Tsur's index (with slightly worse query time). To handle type-x queries, first identify the set of nodes Mark_g based on a grouping factor g (to be fixed later). Tsur proved that each node $u' \in \mathsf{Mark}_g$ can be associated with a set $\mathsf{Set}(u')$ of $O(2^x + \sqrt{2^x g})$ document identifiers, such that $\mathsf{Set}(u'_P)$ represents a candidate set, where u'_P is the highest node in the subtree of u_P that belongs to Mark_g. Therefore, we can store $S(u')$ for every $u' \in \mathsf{Mark}_g$ along with $\mathsf{tf}(u', d)$ of every $d \in S(u')$ in $O((n/g)(2^x + \sqrt{2^x g}) \log n)$ bits. Now a type-x query can be processed as follows:

1. Find u'_P, the highest node in the subtree of u_P that belongs to Mark_g.
2. Extract $\mathsf{Set}(u'_P)$ and $\mathsf{tf}(u'_P, d)$ of all $d \in \mathsf{Set}(u'_P)$.
3. Scan the leaves in $\mathsf{Leaf}(u_P)\backslash\mathsf{Leaf}(u'_P)$, decode the corresponding $\mathsf{doc}(\cdot)$ values and compute $\mathsf{tf}(u_P, d) - \mathsf{tf}(u'_P, d)$ for all $d \in \mathsf{Set}(u'_P)$.
4. Then obtain $\mathsf{tf}(u_P, d) = \mathsf{tf}(u'_P, d) + (\mathsf{tf}(u_P, d) - \mathsf{tf}(u'_P, d))$ for all $d \in \mathsf{Set}(u'_P)$.
5. Report k documents within $\mathsf{Set}(u'_P)$ with highest $\mathsf{tf}(u_P, \cdot)$ values as output.

In summary, an $O((n/g)(2^x + \sqrt{2^x g}) \log n)$-bit structure (along with GST and B) can answer any type-x query in $O(\mathsf{search}(p) + (|\mathsf{Set}(u'_P)| + |\mathsf{Leaf}(u_P)\backslash\mathsf{Leaf}(u'_P)|) \cdot t_{\mathsf{SA}}) = O(\mathsf{search}(p) + (2^x + \sqrt{2^x g} + g) \cdot t_{\mathsf{SA}}) = O(\mathsf{search}(p) + (g + 2^x) \cdot t_{\mathsf{SA}})$ time. By fixing $g = x^2 2^x \log^{2+\epsilon} n$, the query time can be bounded by $O(\mathsf{search}(p) + k \cdot t_{\mathsf{SA}} \log^2 k \log^{2+\epsilon} n)$ and the overall space corresponding to $x = 1, 2, 3, \ldots, \log D$ is $o(n)$ bits. We remark that the index originally proposed by Tsur is even faster.

Navarro and Thankachan [8] observed that each document identifier and the associated $\mathsf{tf}(\cdot,\cdot)$ value can be compressed into $O(\log\log n)$ bits. For compressing document identifiers, ideas from Hon et al. [4] were borrowed. For compressing $\mathsf{tf}(\cdot,\cdot)$ values, they introduced an $o(n)$-bit structure, called *sampled document array* that can compute an approximate value of any $\mathsf{tf}(\cdot,\cdot)$ (denoted by $\mathsf{tf}^*(\cdot,\cdot)$) in time $O(\log\log n)$ within an additive error of at most $\log^2 n$. This means that, instead of storing $\mathsf{tf}(\cdot,\cdot)$, storing $\mathsf{tf}(\cdot,\cdot) - \mathsf{tf}^*(\cdot,\cdot)$ (in just $O(\log\log n)$ bits) is sufficient. In summary, by maintaining an $O((n/g)(2^x + \sqrt{2^x g}) \log\log n)$-bit structure (along with GST, B and the sampled document array), any type-x query can be answered in $O((g + 2^x) \cdot t_{\mathsf{SA}})$ time.

A similar analysis with $g = x^2 2^x \log^\epsilon n$ gives the following result.

Theorem 2 ([8]) *Top-k frequent document retrieval queries can be answered in* $O(\mathsf{search}(p) + k \cdot t_{\mathsf{SA}} \log^2 k \log^\epsilon n)$ *time using a* $|\mathsf{CSA}| + o(n) + D \log(n/D) + O(D)$*-bit index.*

Problem Definition

Given a static array A of n totally ordered objects, the range minimum query problem (RMQ problem) is to build a data structure $\mathcal{D}$ on A that allows us to answer efficiently subsequent online queries of the form "what is the position of a minimum element in the subarray ranging from i to j?" (We consider the *minimum*; all results hold for *maximum* as well.) Such queries are denoted by $\mathrm{RMQ}_A(i, j)$ and are formally defined by $\mathrm{RMQ}_A(i, j) = \mathrm{argmin}_{i \le k \le j}\{A[k]\}$ for an array $A[1, n]$ and indices $1 \le i \le j \le n$. In the succinct or compressed setting, the goal is to use as few *bits* as possible for $\mathcal{D}$, hopefully sublinear in the space needed for storing A itself. The space for A is denoted by $|A|$ and is $|A| = \Theta(n \log n)$ bits if A stores numbers from a universe of size $n^{\Theta(1)}$.

Indexing Versus Encoding Model

There are two variations of the problem, depending on whether the input array A is available at query time (*indexing model*) or not (*encoding model*). In the indexing model, some space for the data structure $\mathcal{D}$ can in principle be saved, as the query algorithm can substitute the "missing information" by consulting A when answering the

queries, and this is indeed what all indexing data structures make heavy use of. However, due to the need to access A at query time, the *total* space (which is $|A| + |\mathcal{D}|$ bits) will never be sublinear in the space needed for storing the array A itself.

This is different in the *encoding model*, where the data structure $\mathcal{D}$ must be built in a way such that the query algorithm can derive its answers *without* consulting A. Such encoding data structures are important when only the *positions* of the minima matter (and not the actual *values*) or when the access to A itself is slow.

Any encoding data structure $\mathcal{D}_\mathrm{E}$ is automatically also an indexing data structure; conversely, an indexing data structure $\mathcal{D}_\mathrm{I}$ can always be "converted" to an encoding data structure by storing $\mathcal{D}_\mathrm{I}$ plus (a copy of) A. Hence, differentiating between the two concepts only makes sense if there are indexing data structures that use less space than the best encoding data structures and if there exist encoding data structures which use space sublinear in $|A|$. Interestingly, for range minimum queries, exactly this is the case.

Model of Computation

All results assume the usual word RAM model of computation with word size $\Omega(\log n)$ bits.

Key Results

Table 1 summarizes the key results from [12] by showing the sizes of data structures for range minimum queries (left column). The first data structure is in the indexing model, and the last two are encoding data structures. The leading terms $(2n/c(n)$ bits with $O(c(n))$ query time in the indexing model and $2n$ bits for arbitrary query time in the encoding model) are optimal: in the encoding model, this is rather easy to see by establishing a bijection between the class of binary trees and the class of arrays with different answers for at least one RMQ [12], and in the indexing model, Brodal et al. [4] prove the lower bound. Particular emphasis is placed on the additional space needed for constructing the data structure (middle column), where it is important to use asymptotically less space than the final data structure.

Compressed Range Minimum Queries, Table 1 Data structures [12] for range minimum queries, where $|A|$ denotes the space of the (read-only) input array A. Construction space is *in addition* to the final space of the data structure. All data structures can be constructed in $O(n)$ time, and query time is $O(1)$ unless noted otherwise

Final space (bits)	Construction space	Comment
$\lvert A\rvert + \frac{2n}{c(n)} - \Theta\left(\frac{n \log\log n}{c(n) \log n}\right)$	$O(\log^3 n)$	Query time $O(c(n))$ for $c(n) = O(n^\varepsilon)$, $0 < \varepsilon < 1$
$2n + O(n \log\log n / \log n)$	$\lvert A\rvert + n + O\left(\frac{n \log\log n}{\log n}\right)$	Construction space improved to $\lvert A\rvert + o(n)$ [8]
$2n + O(n/\mathrm{polylog}\, n)$	$\lvert A\rvert + O(n)$	Using succinct data structures from [23] and [21]

Extensions

Surpassing the Lower Bound

Attempts have been made to break the lower bound for special cases. If A is compressible under the order-k empirical entropy measure $H_k(A)$, then also the leading term $2n/c(n)$ of the indexing data structure can be compressed to $nH_k(A)$ [12]. Other results (in both the indexing and the encoding model) exist for compressibility measures based on the number of *runs* in A [2]. Davoodi et al. [8] show that *random* input arrays can be encoded in expected $1.919n + o(n)$ bits for RMQs. All of the above results retain constant query times.

Top-k Queries

A natural generalization of RMQs is listing the k smallest (or largest) values in a query range (k needs only be specified at query time). In the indexing model, any RMQ structure with constant query time can be used to answer top-k queries in $O(k)$ time [16].

Recently, an increased interest in encoding data structures for top-k queries can be observed. For general k, Grossi et al. [15] show that $\Omega(n \log k)$ bits are needed for answering top-k queries. Therefore, interesting encodings can only exist if an upper limit κ on k is given at construction time. This lower bound is matched

asymptotically by an encoding data structure using $O(n \log \kappa)$ bits and $O(k)$ query time by Navarro et al. [22]. For the specific case $\kappa = 2$, Davoodi et al. [8] provide a lower bound of $2.656n - O(\log n)$ bits (using computer-assisted search) and also give an encoding data structure using at most $3.272n + o(n)$ bits supporting top-2 queries in $O(1)$ time.

Range Selection

Another generalization are queries asking for the k-th smallest (or largest) value in the query range (k is again part of the query). This problem is harder for nonconstant k, as Jørgensen and Larsen prove a lower bound of $\Omega(\log k / \log \log n)$ on the query time when using $O(n\text{polylog}n)$ words of space [17]. Also, the abovementioned space lower bounds on encoding top-k queries also apply to range selection. Again, Navarro et al. [22] give a matching upper bound: $O(n \log \kappa)$ bits suffice to answer queries asking for the k-largest element in a query range ($k \leq \kappa$) in $O(\log k / \log \log n)$ time. Note that this includes queries asking for the *median* in a query range.

Higher Dimensions

Indexing and encoding data structures for range minima also exist for higher-dimensional arrays (matrices) of total size N. Atallah and Yuan [25] show an (uncompressed) indexing data structure of size $O(2^d d! N)$ words with $O(3^d)$ query time, where d is the dimension of the underlying matrix A.

Tighter results exist in the two-dimensional case [1], where A is an $(m \times n)$ matrix consisting of $N = m \cdot n$ elements (w.l.o.g. assume $m \leq n$). In the indexing model, the currently best solution is a data structure of size $|A| + O(N/c)$ bits ($1 \leq c \leq n$) that answers queries in $O(c \log c \log^2 \log c)$ time [3], still leaving a gap between the highest lower bounds of $\Omega(c)$ query time for $O(N/c)$ bits of space [4].

In the encoding model, a lower bound of $\Omega(N \log m)$ bits exists [4], but the best data structure with constant query time achieves only $O(N \min\{m, \log n\})$ bits of space [4], which still leaves a gap unless $m = n^{\Omega(1)}$. However, Brodal et al. [5] *do* show an encoding using only $O(N \log m)$ bits, but nothing better than the trivial $O(N)$ can be said about its query time. Special cases for small (constant) values of m (e.g., optimal $5n + o(n)$ bits for $m = 2$) and also for random input arrays are considered by Golin et al. [14].

Further Extensions

The indexing technique [12] has been generalized such that a specific minimum (e.g., the position of the median of the minima) can be returned if the minimum in the query range is not unique [11]. Further generalizations include functions other than the "minimum" on the query range, e.g., median [17], mode [6], etc. RMQs have also been generalized to edge-weighted trees [9], where now a query specifies two nodes v and w, and a minimum-weight edge on the path from v to w is sought.

Applications

Data structures for RMQs have many applications. Most notably, the problem of preprocessing a tree for *lowest common ancestor* (LCA) queries is equivalent to the RMQ problem. In succinctly encoded trees (using balanced parentheses), RMQs can also be used to answer LCA queries in constant time; in this case, the RMQ structure is built on the virtual excess sequence of the parentheses and uses only $o(n)$ bits in addition to the parenthesis sequence [24]. Other applications of RMQs include document retrieval [20], succinct trees [21], compressed suffix trees [13], text-index construction [10], Lempel-Ziv text compression [e.g., 18], orthogonal range searching [19], and other kinds of range queries [7].

Problem Definition

The problem is to represent a graph of a given *size* and *type* (e.g., an n node planar graph) in a compressed form while still supporting efficient navigation operations. More formally, if $G = (V, E)$ is a graph of a given type χ, with n nodes and m edges, then represent G using $\lg|\chi| + o(\lg|\chi|)$ bits of space, and support a set of appropriate operations on the graph in constant time (assuming we can access $\Theta(\lg n)$ consecutive bits in one operation). This may not be possible; if not, then explore what trade-offs are possible. Data structures that achieve this space bound are called *succinct* [13]. To simplify the statement of results, we assume the graph G in question contains no self-loops, and we also restrict ourselves to the static case.

Key Results

Outerplanar, Planar, and k-Page Graphs

The area of succinct data structures was initiated by Jacobson [13], who presented a succinct representation of planar graphs. His approach was to decompose the planar graph into at most *four* one-page (or outerplanar) graphs by applying a theorem of Yannikakis [20]. Each one-page graph is then represented as a sequence of *balanced parentheses*: this representation extends naturally to k-pages for $k \geq 1$. Using this representation, it is straightforward to support the following operations efficiently:

- `Adjacent`(x, y): report whether there is an edge $(x, y) \in E$.
- `Neighbors`(x): report all vertices that are adjacent to vertex x.
- `Degree`(x): report the degree of vertex x.

Munro and Raman [16] improved Jacobson's balanced parenthesis representation, thereby improving the constant factor in the space bound for representing both k-page and planar graphs. We present Table 1 which compares a representative selection of the various succinct data structures for representing planar graphs. Subsequent simplifications to the representation of balanced parentheses have been presented; cf., [11, 17]. Barbay et al. [1] present results for larger values of k, as well as the case where the edges or vertices of the graph have labels.

The decomposition into four one-page graphs is not the only approach to representing static planar graphs. Chuang et al. [7] presented another encoding based on *canonical orderings* of a planar graph and represented the graph using a *multiple parentheses sequence* (a sequence of balanced parentheses of more than one type). Later, Chiang et al. [6] generalized the notion of canonical orderings to *orderly spanning trees*, yielding improved constant factors in terms of n and m. Gavoille and Hanusse [10] presented an alternate encoding scheme for k-page graphs that yields a trade-off based on the number of isolated nodes (connected components with one vertex). Further improvements have been presented by Chuang et al. [7], as well as Castelli Aleardi et al. [5], for the special case of planar triangulations.

Blandford et al. [2] considered unlabelled *separable graphs*. A separable graph is one that admits an $O(n^c)$ separator for $c < 1$. Their structure occupies $O(n)$ bits and performs all three query types optimally. Subsequently, Blelloch and Farzan [3] made the construction of Blandford et al. [2] succinct in the sense that, given a graph G from a separable class of graphs χ (e.g., the class of arbitrary planar graphs), their data structure represents G using $\lg|\chi| + o(n)$ bits. Interestingly, we need not even *know* the value of $\lg|\chi|$ in order to use this representation.

Arbitrary Directed Graphs, DAGs, Undirected Graphs, and Posets

We consider the problem of designing succinct data structures for *arbitrary* digraphs. In a directed graph, we refer to the set of vertices $\{y : (x, y) \in E\}$ as the *successors* of x and

Compressed Representations of Graphs, Table 1 Comparison of various succinct planar graph representations. The second column indicates whether the representation supports multigraphs. For the entries marked with a †, the query cost is measured in *bit* accesses. Notation: n is the number of vertices in G, m is the number of edges in G, i is the number of isolated vertices in G, ε is an arbitrary positive constant, $\tau = \min\{\lg k/\lg\lg m, \lg\lg k\}$, and H is the information theoretic lower space bound for storing a graph G drawn from a class of separable graphs

the set of vertices $\{y : (y, x) \in E\}$ as the *predecessors* of x.

It is well known that an arbitrary directed graph can be represented using $n \times n$ bits by storing its adjacency matrix. This representation supports the `Adjacency`(x, y) operation by probing a single bit in the table in constant time. On the other hand, we can represent the graph using $\Theta(m \lg n)$ bits using an adjacency list representation, such that the following operations can be supporting in constant time:

- `Successor`(x, i): list the ith successor of vertex x
- `Predecessor`(x, i): list the ith predecessor of vertex x

The information theoretic lower bound dictates that essentially $\lg \binom{n^2}{m}$ bits are necessary for representing an arbitrary digraph. By representing each row (resp. column) of the adjacency matrix using an *indexable dictionary* [19], we get a data structure that supports `Adjacency` and `Successor` (resp. `Predecessor`) queries in constant time and occupies $\lg \binom{n^2}{m} + o\left(\lg \binom{n^2}{m}\right)$ bits of space. Note that we can only support two of the three operations with this approach. Farzan and Munro [9] showed that if $\Theta(n^\varepsilon) \le m \le \Theta\left(n^{2-\varepsilon}\right)$ for some constant $\varepsilon > 0$, then $(1+\varepsilon')\binom{n^2}{m}$ bits are sufficient and required to support all three operations. In a more general setting, Golynski [12] had proven that the difficulty in supporting both `Successor` and `Predecessor` queries simultaneously using succinct space relates to the fact that they have the so-called *reciprocal property*. In other words, if the graph is not extremely sparse or dense, then it is impossible to support all three operations succinctly. On the other hand, if $m = o(n^\varepsilon)$ or $m = \Omega(n^2/\lg^{1-\varepsilon} n)$, for some constant $\varepsilon > 0$, then Farzan and Munro [9] showed that succinctness can be achieved while supporting the three operations.

Suppose G is a directed acyclic graph instead of an arbitrary digraph. In this case, one can exploit the fact that the graph is acyclic by ordering the vertices topologically. This ordering induces an adjacency matrix which is upper triangular. Exploiting this fact, when $\Theta(n^\varepsilon) \le$

$m \leq \Theta(n^{2-\varepsilon})$, the data structure of Farzan and Munro can support all three operations using $(1+\varepsilon)\lg\binom{\binom{n}{2}}{m}$ bits, for an arbitrary positive constant ε, which is optimal. If $m = o(n^{\epsilon})$ or $m = \Omega(n^2/\lg^{1-\varepsilon} n)$, for some constant $\varepsilon > 0$, then they achieve $\lg\binom{\binom{n}{2}}{m}(1+o(1))$ bits. By orienting the edges in an *undirected* graph so that they are directed toward the vertex with the with the larger label, this representation can also be used to support the operations `Adjacency` and `Neighbors` on an arbitrary undirected graph.

A partial order or *poset* is a directed acyclic graph with the additional transitivity constraint on the set of edges E: if (x, y) and (y, z) are present in E, then it is implied that $(x, z) \in E$. Farzan and Fischer [8] showed that a poset can be stored using $2nw(1+o(1)) + (1+\varepsilon)n\lg n$ bits of space, where w is the *width* of the poset – i.e., the length of the maximum antichain – and ε is an arbitrary positive constant. Their data structure supports `Adjacency` queries in constant time, as well as many other operations in time proportional to w. This matches a lower bound of Brightwell and Goodall [4] up to the additive $\varepsilon n \lg n$ term when n is sufficiently large relative to w. For an arbitrary poset, Kleitman and Rothschild showed that $n^2/4 + O(n)$ bits are sufficient and necessary by a constructive counting argument [14]. Munro and Nicholson [15,18] showed that there is a data structure that occupies $n^2/4 + o(n^2)$ bits, such that `Adjacency`, `Predecessor`, and `Successor` queries can be supported in constant time.

Problem Definition

Given a *text string* $T = t_1 t_2 \dots t_n$ over an alphabet Σ of size σ, the suffix array $A[1,n]$ is a permutation of the interval $[1,n]$ that sorts the suffixes of T. More precisely, it satisfies $T[A[i],n] < T[A[i+1],n]$ for all $1 \leq i < n$, where "<" between strings is the lexicographical order. The *suffix array* is the canonical full-text index that allows to efficiently compute basic string matching queries on T.

The *compressed suffix array (CSA)* problem asks to replace A with a space-efficient data structure that is capable of efficiently computing $A[i]$.

If a CSA does not require T to operate, and is capable of efficiently answering substring queries on T, it is called a *self-index*, as it can be seen as a replacement of T itself. Typical queries required from such an index are the following:

- count(P): count how many times a given *pattern string* $P = p_1 p_2 \dots p_m$ occurs in T.
- locate(P): return the locations where P occurs in T.
- display(i, j): return $T[i, j]$.

Key Results

Ψ-Based CSAs

The first solution to the problem is by Grossi and Vitter [8], who exploit the regularities of the suffix array via the Ψ-function:

Definition 1 Given suffix array $A[1,n]$, *function* $\Psi : [1,n] \to [1,n]$ is defined so that, for all $1 \leq i \leq n$, $A[\Psi(i)] = A[i] + 1$. The exception is $A[1] = n$, in which case the requirement is that $A[\Psi(1)] = 1$ so that Ψ is a permutation.

The following lemma shows that Ψ is appealing to compression:

Lemma 1 *Given a text $T[1,n]$, its suffix array $A[1,n]$, and the corresponding function Ψ, it holds $\Psi(i) < \Psi(i+1)$ whenever $T_{A[i]} = T_{A[i+1]}$.*

Grossi and Vitter used a hierarchical decomposition of Ψ into $h = \lceil \log \log n \rceil$ levels. The piecewise increasing property of Ψ can be used to represent each level of Ψ in $\frac{1}{2} n \log \sigma$ bits [8]. By storing some sampled values of A in the bottom level, any $A[i]$ can be computed by traversing the hierarchical structure. Other tradeoffs are possible using different amount of levels. The following one involves the use of a constant number of levels:

Theorem 1 (inspired from [8]) *The* Compressed Suffix Array *of Grossi and Vitter supports retrieving $A[i]$ in $O(\log^{\epsilon} n)$ time using $(\frac{1}{\epsilon} n) \log \sigma + O(n \log \log \sigma)$ bits of space, for any $0 < \epsilon < 1$.*

As a consequence, simulating the classical binary searches [13] to find the range of suffix array containing all the occurrences of a pattern $P[1,m]$ in $T[1,n]$, can then be done in $O(m \log^{1+\epsilon} n)$ time.

Sadakane [16] shows how the above compressed suffix array can be converted into a self-index, and at the same time optimized it in several ways.

Sadakane represents both A and T using the full function Ψ, and a few extra structures. Imagine one wishes to compare P against $T[A[i],n]$. For the binary search, one needs to extract enough characters from $T[A[i],n]$ so that its lexicographical relation to P is clear. Retrieving character $T[A[i]]$, given i, is easy. Use a bit vector $F[1,n]$ marking the suffixes of $A[i]$ where the first character changes from that of $A[i-1]$. After preprocessing F for $rank$-queries, computing $j = \text{rank}_1(F,i)$ tells us that $T[A[i]] = c_j$, where c_j is the j-th smallest alphabet character. Once $T[A[i]] = c_j$ is determined this way, one needs to obtain the next character, $T[A[i]+1]$. But $T[A[i]+1] = T[A[\Psi(i)]]$, so one can simply move to $i' = \Psi(i)$ and keep extracting characters with the same method, as long as necessary. Note that at most $|P| = m$ characters suffice to decide a comparison with P. Thus the binary search is simulated in $O(m \log n)$ time.

Up to now, the space used is $n + o(n) + \sigma \log \sigma$ bits for F and Σ. Sadakane [16] gives an improved representation for Ψ using $O(nH_0 + n \log\log \sigma)$ bits, where H_0 is the *zeroth order entropy* of T.

Sadakane also shows how $A[i]$ can be retrieved, by plugging in the hierarchical scheme of Grossi and Vitter. He adds to the scheme the retrieval of the inverse $A^{-1}[j]$. This is used in order to retrieve arbitrary text substrings $T[p,r]$, by first applying $i = A^{-1}[p]$ and then continuing as before to retrieve $r-p+1$ first characters of suffix $T[A[i],n]$. This capability turns the compressed suffix array into self-index. The following bound is a modified version of Sadakane's CSA taken from [15]:

Theorem 2 *The* Compressed Suffix Array *of Sadakane is a self-index occupying* $\frac{1}{\epsilon} nH_0 + O(n \log\log \sigma)$ *bits, and supporting retrieval of values* $A[i]$ *and* $A^{-1}[j]$ *in* $O(\log^{\epsilon} n)$ *time, counting of pattern occurrences in* $O(m \log n)$ *time, and displaying any substring of* T *of length* ℓ *in* $O(\ell + \log^{\epsilon} n)$ *time. Here* $0 < \epsilon \leq 1$ *is an arbitrary constant.*

Grossi, Gupta, Vitter, and Foschini [6, 9] have improved the space requirement of compressed suffix arrays to depend on the *k-th order entropy* H_k of T. The idea behind this improvement is a more careful analysis of regularities captured by the Ψ-function when combined with the indexing capabilities of their new elegant data structure, *wavelet tree*. They obtain, among other results, the following tradeoff:

Theorem 3 (Grossi, Gupta, and Vitter [9]) *The* Compressed Suffix Array *of Grossi, Gupta, and Vitter is a self-index of size* $\frac{1}{\epsilon} nH_k + o(n \log \sigma)$ *bits, that supports* $A[i]$ *and* $A^{-1}[j]$ *in* $O(\log^{1+\epsilon} n/\epsilon)$ *time,* count(P) *in* $O(m \log \sigma + \log^{2+\epsilon} n/\epsilon)$ *time, and* display(i,j) *in* $O((j-i)/\log_\sigma n + \log^{1+\epsilon} n/\epsilon)$ *time. Here* $0 < \epsilon \leq 1$ *is an arbitrary constant,* $k \leq \alpha \log_\sigma n$ *for some constant* $0 < \alpha < 1$.

They also obtain an interesting special case:

Theorem 4 (Grossi, Gupta, and Vitter [9]) *The space optimized* Compressed Suffix Array *of Grossi, Gupta, and Vitter is a self-index of size* $nH_k + o(n \log \sigma)$ *bits, that supports* $A[i]$ *and* $A^{-1}[j]$ *in* $O(\log^2 n/\log\log n)$ *time,* count(P) *in* $O(m \log n \log \sigma + \log^3 n/\log\log n)$ *time, and* display(i,j) *in* $O((j-i)/\log \sigma + \log^2 n/\log\log n)$ *time. Here* $k \leq \alpha \log_\sigma n$ *for some constant* $0 < \alpha < 1$.

In the above results, value k must be fixed before building the indexes. Later, they notice that a simple coding of Ψ-values yields an nH_k-dependent bound without the need of fixing k beforehand [6].

FM-Index

A different solution to the problem (at least on the surface) is obtained by exploiting the connection of *Burrows-Wheeler Transform (BWT)* [2] and *Suffix Array* data structure

[13]. The BWT is formed by a permutation T^{bwt} of T defined as $T^{\text{bwt}}[i] = T[A[i] - 1]$ for $A[i] > 1$ and $T^{\text{bwt}}[i] = T[n]$ for $A[i] = 1$. Without lack of generality, one can assume that T ends with $T[n] = \$$ with \$ being distinct symbol smaller than other symbols in T. Then $T^{\text{bwt}}[1] = T[n-1]$.

A property of the BWT is that symbols having the same context (i.e., string following them in T) are consecutive in T^{bwt}. This makes it easy to compress T^{bwt} achieving space close to high-order empirical entropies [14].

Ferragina and Manzini [3] discovered a way to combine the compressibility of the BWT and the indexing properties of the suffix array. The structure is essentially a compressed representation of the BWT plus some small additional structures to make it searchable.

To retrieve the whole text from the structure (that is, to support display$(1, n)$), it is enough to invert the BWT. For this purpose, let us consider a table $LF[1, n]$ defined such that if $T[i]$ is permuted to $T^{\text{bwt}}[j]$ and $T[i-1]$ to $T^{\text{bwt}}[j']$ then $LF[j] = j'$. It is then immediate that T can be retrieved *backwards* by printing $\$ \cdot T^{\text{bwt}}[1] \cdot T^{\text{bwt}}[LF[1]] \cdot T^{\text{bwt}}[LF[LF[1]]] \ldots$.

To represent array LF space-efficiently, Ferragina and Manzini noticed that each $LF[i]$ can be expressed as follows:

Lemma 2 (Ferragina and Manzini [3]) *$LF[i] = C(c) + \text{rank}_c(i)$, where $c = T^{\text{bwt}}[i]$, $C(c)$ tells how many times symbols smaller than c appear in T^{bwt} and $\text{rank}_c(i)$ tells how many times symbol c appears in $T^{\text{bwt}}[1, i]$.*

It was later observed that LF is in fact the inverse of Ψ.

It also happens that the very same two-part expression of $LF[i]$ enables efficient count(P) queries. The idea is that if one knows the range of the suffix array, say $A[sp_i, ep_i]$, such that the suffixes $T[A[sp_i], n], T[A[sp_i + 1], n], \ldots, T[A[ep_i], n]$ are the only ones containing $P[i, m]$ as a prefix, then one can compute the new range $A[sp_{i-1}, ep_{i-1}]$ where the suffixes contain $P[i-1, m]$ as a prefix, as follows: $sp_{i-1} = C(P[i-1]) + \text{rank}_{P[i-1]}(sp_i - 1) + 1$ and $ep_{i-1} = C(P[i-1]) + \text{rank}_{P[i-1]}(ep_i)$. It is then enough to scan the pattern *backwards* and compute values $C()$ and $\text{rank}_c()$ $2m$ times to find out the (possibly empty) range of the suffix array where all the suffixes start with the complete P. Returning $ep_1 - sp_1 + 1$ solves the count(P) query without the need of having the suffix array available at all.

For locating each such occurrence $A[i]$, $sp_1 \leq i \leq ep_1$, one can compute the sequence i, $LF[i]$, $LF[LF[i]]$, ..., until $LF^k[i]$ is a *sampled suffix array position*; sampled positions can be marked in a bit vector B such that $B[LF^k[i]] = 1$ indicates that $\texttt{samples}[\text{rank}_1(B, LF^k[i])] = A[LF^k[i]]$, where `samples` is a compact array storing the sampled suffix array values. Then $A[i] = A[LF^k[i]] + k = \texttt{samples}[\text{rank}_1(B, LF^k[i])] + k$. A similar structure can be used to support display(i, j).

Values $C()$ can be stored trivially in a table of $\sigma \log_2 n$ bits. $T^{\text{bwt}}[i]$ can be computed in $O(\sigma)$ time by checking for which c is $\text{rank}_c(i) \neq \text{rank}_c(i-1)$. The suffix array sampling rate can be chosen as $s = \Theta(\log^{1+\epsilon} n)$ so that the samples require $o(n)$ bits. The real challenge is to preprocess the text for $\text{rank}_c()$ queries. The original proposal builds several small partial sum data structures on top of the compressed BWT, and achieves the following result:

Theorem 5 (Ferragina and Manzini [3]) *The* FM-Index (FMI) *is a* self-index *of size $5nH_k + o(n \log \sigma)$ bits that supports* count(P) *in $O(m)$ time,* locate(P) *in $O(\sigma \log^{1+\epsilon} n)$ time per occurrence, and* display(i, j) *in $O(\sigma(j - i + \log^{1+\epsilon} n))$ time. Here $\sigma = o(\log n / \log \log n)$, $k \leq \log_\sigma(n / \log n) - \omega(1)$, and $\epsilon > 0$ is an arbitrary constant.*

The original FM-Index has a severe restriction on the alphabet size. This has been removed in follow-up works. Conceptually, the easiest way to achieve a more alphabet-friendly instance of the FM-index is to build a wavelet tree [9] on T^{bwt}. It allows one to simulate a single $\text{rank}_c()$ query or to obtain $T^{\text{bwt}}[i]$ in $O(\log \sigma)$ time. Some later enhancements have improved the time

requirement, so as to obtain, for example, the following result:

Theorem 6 (Mäkinen and Navarro [11]) *The CSA problem can be solved using a so-called* Succinct Suffix Array (SSA)*, of size* $nH_0 + o(n \log \sigma)$ *bits that supports* count(P) *in* $O(m(1 + \log \sigma / \log\log n))$ *time,* locate(P) *in* $O(\log^{1+\epsilon} n\ (1 + \log \sigma / \log\log n))$ *time per occurrence, and* display(i, j) *in* $O((j - i + \log^{1+\epsilon} n)(1 + \log \sigma / \log\log n))$ *time. Here* $\sigma = o(n)$ *and* $\epsilon > 0$ *is an arbitrary constant.*

Ferragina et al. [4] developed a technique called *compression boosting* that finds an optimal partitioning of T^{bwt} such that, when one compresses each piece separately using its zero-order model, the result is proportional to the k-th order entropy. It was observed in [10] that a fixed block partitioning achieves the same result.

Compression boosting can be combined with the idea of SSA by building a wavelet tree separately for each piece and some additional structures in order to solve global $\text{rank}_c()$ queries from the individual wavelet trees:

Theorem 7 (Ferragina et al. [5]) *The CSA problem can be solved using a so-called* Alphabet-Friendly FM-Index (AF-FMI)*, of size* $nH_k + o(n \log \sigma)$ *bits, with the same time complexities and restrictions of SSA with* $k \leq \alpha \log_\sigma n$*, for any constant* $0 < \alpha < 1$.

A careful analysis [12] reveals that the space of the plain SSA is bounded by the same $nH_k + o(n \log \sigma)$ bits, making the boosting approach to achieve the same result unnecessary in theory. By plugging a better wavelet tree implementation [7], the space of Theorem 7 can be improved to $nH_k + o(n)$ bits.

The wavelet tree is space-efficient, but it cannot operate in time better than $O(1 + \frac{\log \sigma}{\log\log n})$. To achieve better performance, some other techniques must be used. One example, is the following fastest FM-index with dominant term nH_k in the space.

Theorem 8 (Belazzougui and Navarro [1]) *The CSA problem can be solved using an index of size* $nH_k + o(n \log \sigma)$*, that supports* count(P) *in* $O(m)$ *time,* locate(P) *in* $O(\log_\sigma n \log\log n)$ *time per occurrence, and* display(i, j) *in* $O((j - i) + \log_\sigma n \log\log n)$ *with* $k \leq \alpha \log_\sigma n$*,* $\sigma = O(n)$*, and* α *is any constant such that* $0 < \alpha < 1$.

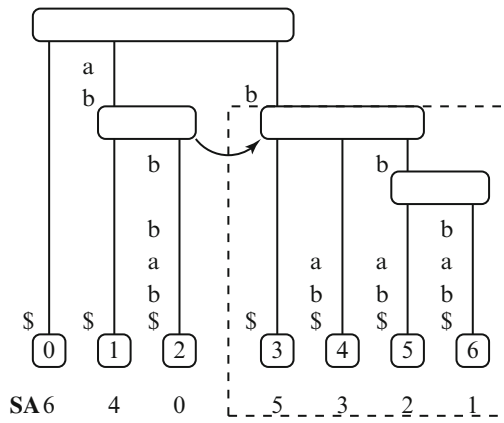
Problem Definition

The problem consists in representing suffix trees in main memory. The representation needs to support operations efficiently, using a reasonable amount of space.

Suffix trees were proposed by Weiner in 1973 [16]. Donald Knuth called them the "Algorithm of the Year." Their ubiquitous nature was quickly perceived and used to solve a myriad of string processing problems. The downside of this flexibility was the notorious amount of space necessary to keep it in main memory. A direct implementation is several times larger than the file it is indexing. Initial research into this matter discovered smaller data structures, sometimes by sacrificing functionality, namely, suffix arrays [6], directed acyclic word graphs [5], or engineered solutions.

A suffix tree is obtained from a sequence of characters T by considering all its suffixes. The suffixes are collated together by their common prefixes into a labeled tree. This means that suffixes that share a common prefix are united by that prefix and split only when the common prefix ends, i.e., in the first letter where they mismatch. A special terminator character \$ is placed at the end to force these mismatches for the small suffixes of T. The string depth of a node is the number of letters between the node and the root. Figure 1 shows the suffix tree of the string *abbbab*.

A viable representation needs to support several operations: tree navigation, such as finding a parent node, a child node, or a sibling node; labeling, such as reading the letters along a branch or using a letter to choose a child node; and indexing operations, such as determining a leaf's index or a node's string depth.



Compressed Suffix Trees, Fig. 1 Suffix tree of string *abbbab*, with the leaves numbered. The *arrow* shows the SLINK between nodes ab and b. Below we show the suffix array. The portion of the tree corresponding to node b and respective leaves interval is within a *dashed box*

Besides the usual tree topology, suffix trees contain suffix links. For a given node, the suffix link points to a second node. The string from the root to the second node can be obtained by removing the first letter of the string from the root to the first node. For example, the suffix link of node ab is node b. See Fig. 1.

An acceptable lower bound to represent a DNA sequence is $2n$ bits, i.e., $n \log \sigma$ bits (we use logarithms in base 2) for a text of size n with an alphabet of size σ. The size of the suffix array for such a sequence, on a 32-bit machine, is 16 times bigger than this bound. A space-engineered suffix tree would be 40 times larger. Succinct data structures are functional representations whose space requirements are close to the space needed to represent the data (i.e., close to $2n$ bits, in our example). If we consider the order-k statistical compressibility of the text, then the information-theory lower bound is even smaller, $nH_k + o(n)$ bits, where H_k is the empirical entropy of the text. Such representations require data compression techniques, which need to be made functional. The prospect of representing suffix trees within this space was significant.

Objective

Obtain a representation of a suffix tree that requires $n \log \sigma + o(n)$ bits, or even $nH_k + o(n)$ bits, or close, and that supports all operations efficiently.

Key Results

Classical Results

Suffix arrays [6] are a common alternative to suffix trees. They do not provide the same set of operations or the same time bounds, and still they require only 5 bytes per text character as opposed to the >10 bytes of suffix trees.

The suffix array stores the lexicographical order of the suffixes of T. Figure 1 shows the suffix array SA of our running example, i.e., the suffixes in the suffix tree are lexicographically ordered. Suffix arrays lack node information. Still they can represent nodes as an interval of suffixes, for example, node b corresponds to the interval $[3, 6]$. This mapping is injective, i.e., no two nodes can map to the same interval. Hence, a given interval corresponds to no more than one node. Some intervals do not correspond to any node, for example, $[4, 6]$ does not correspond to a node on the suffix tree. To determine which intervals are invalid and speed up navigation operations, the suffix array can be augmented with longest common prefix (LCP) information. It is enough to store the length of the LCP between consecutive suffixes. For an arbitrary pair of suffixes, the LCP value can be computed as a range minimum query (RMQ) on the corresponding leaf interval. For example, $\mathrm{LCP}(3, 5)$ can be computed as the minimum of $1, 1, 2$. The suffix array enhanced with LCP information [2] can now be used to emulate several algorithms that required suffix tree navigation.

Another approach is to reduce suffix tree redundancy, by factoring repeated structures. The following lemma is used to build directed acyclic word graphs.

Lemma 1 *If the sub-trees rooted at nodes v and v', of the suffix tree of T, have the same number of leaves and v' is the suffix link of v, then the sub-trees are isomorphic.*

Succinct Results

A fundamental component of compressed suffix trees is the underlying compressed index, which provides the suffix array information. Additionally these indexes provide support for ψ and LF, which are used to compute suffix links and backward search. In fact, ψ is the equivalent to suffix links over the suffix array, i.e., $\mathrm{SA}[\psi(i)] = \mathrm{SA}[i] + 1$. Moreover, LF is the inverse of ψ, i.e., $\mathrm{LF}(\psi(i)) = \psi(\mathrm{LF}(i)) = i$. There is a wide variety of these indexes, depending on the underlying data compression technique, namely, the Burrows-Wheeler transform, δ-coding, or Lempel-Ziv. For a complete survey on these indexes, consult the survey by Navarro and Mäkinen [7]. For our purposes, we consider the following index.

Theorem 1 *For a string T, over an alphabet of size* polylog n, *there exists a suffix array*

representation that requires $nH_k + o(n)$ *bits and computes* ψ, LF *and retrieves letters* $T[\text{SA}[i]]$ *in* $O(1)$ *time, while it obtains values* $\text{SA}[i]$ *in* $O(\log n \log\log n)$ *time.*

Sadakane was the first to combine a compressed suffix array with a succinct tree and a succinct representation of string depth information. The combination of these three ingredients leads to the first succinct representation of suffix trees, which set the basic structure for later developments.

Theorem 2 ([14]) *There is a compressed suffix tree representation that requires* $nH_k + 6n + o(n)$ *bits and supports child in* $O(\log^2 n \log\log n)$, *string depth and edge letters in* $O(\log n \log\log n)$ *time, and the remaining operations in* $O(1)$ *time.*

The $6n$ term is composed of $4n$ for the succinct tree and $2n$ to store LCP values. A tree can be represented succinctly as a sequence of balanced parentheses. A suffix tree contains at most $2n - 1$ nodes; since each node requires exactly 2 parentheses, this accounts for the $4n$ parcel. For example, the parentheses representation of the tree in Fig. 1 is `((0)((1)(2))((3)(4)((5)(6))));` the numbers correspond to the leaf indexes and are not part of the representation; only the parentheses are necessary. These parentheses are encoded with bits, set to 0 or 1, respectively.

We refer to the position of T in the suffix array as t, i.e., $\text{SA}[t] = 0$, in our running example $t = 2$. A technique used to store the SA values is to use the relation $\text{SA}[\psi(i)] = \text{SA}[i] + 1$. This means that, if ψ is supported, we can store the $\text{SA}[\psi^{il}(t)]$ values, with $l = \log n \log\log n$, and obtain the missing values in at most l steps. The resulting SA values require only $n/\log\log n$ bits to store. To encode the LCP of internal nodes, Sadakane used that $\text{LCP}(\psi(i), \psi(i)+1) \geq \text{LCP}(i, i+1) - 1$. Hence $\text{LCP}(\psi^k(i), \psi^k(i)+1) + k$ forms an increasing sequence of numbers, which can be encoded in at most $2n$ bits such that any element can be accessed with a "select" operation on the bits (find the position of the jth 1, which can be solved in constant time with an $o(n)$-bit extra index). Hence computing LCP requires determining k and subtracting it from the number in the sequence; this can be achieved with SA. Subsequent research focused on eliminating the $6n$ term. Fischer, Mäkinen, and Navarro obtained a smaller representation.

Theorem 3 ([4]) *There is a compressed suffix tree representation which, for any constant* $\epsilon > 0$, *requires* $nH_k(2\log(1/H_k) + (1/\epsilon) + O(1)) + o(n\log\sigma)$ *bits and supports all operations in* $O(\log^{\epsilon} n)$ *time, except level ancestor queries (LAQ) which need* $O(\log^{1+\epsilon} n)$ *time.*

This bound is obtained by compressing the differential LCP values in Sadakane's representation and discarding the parentheses representation. Instead it relies exclusively on range minimum queries over the LCP values. The next smaller value (NSV) and previous smaller value (PSV) operations are presented to replace the need to find matching closing or opening parentheses. Later, Fischer [3] further improved the speed at which ϵ vanishes.

Russo, Navarro, and Oliveira [13] obtained the smallest representation by showing that $\text{LCA}(\text{SLINK}(v), \text{SLINK}(v')) = \text{SLINK}(\text{LCA}(v, v'))$ holds for any nodes v and v'. $\text{LCA}(v, v')$ means the lowest common ancestor of nodes v and v', and $\text{SLINK}(v)$ means the suffix link of node v. This relation generalizes Lemma 1.

Theorem 4 ([13]) *There is a compressed suffix tree representation that requires* $nH_k + o(n)$ *bits and supports child in* $O(\log n(\log\log n)^2)$ *and the other operations in time* $O(\log n \log\log n)$.

The reduced space requirements are obtained by storing information about a few sampled nodes. Information for the remaining nodes is computed with the property above. Only the sampled nodes are stored in a parentheses representation and moreover string depth is stored only for these nodes. Although Theorem 4 obtains optimal space, the logarithmic time is significant, in theory and in practice. This limitation was

recently improved by Navarro and Russo [9] with a new approach to compare sampled nodes. They obtain $O(\text{polyloglog } n)$ time for all operations within the same space, except for child, which retains the previous time bound.

Applications

There is a myriad of practical applications for suffix trees. An extensive description can be found in the book by Gusfield [5]. Nowadays, most applications are related to bioinformatics, due to the string-like nature of DNA sequences. Most of these problems can be solved with compressed suffix trees and in fact can only be computed in reasonable time if the ever-increasing DNA database can be kept in main memory with suffix tree functionality.

Experimental Results

The results we have described provided a firm ground for representing suffix trees efficiently in compressed space. Still the goal was not a theoretical endeavor, since these data structures play a center role in the analysis of genomic data, among others. In practice, several aspects of computer architecture come into play, which can significantly impact the resulting performance. Different approaches can sacrifice space optimality to be orders of magnitude faster than the smaller variants.

Abeliuk, Cánovas, and Navarro [1] presented an exhaustive experimental analysis of existing CSTs. They obtained practical CSTs by implementing the PSV and NSV operations of Fischer, Mäkinen, and Navarro [4], with a range min-max tree [10]. Their CSTs covered a wide range in the space and time spectrum. Roughly, they need 8–12 bits per character (bpc) and perform the operations in microseconds. Further, practical variants considered reducing the $6n$ term of Sadakane's representation by using a single data structure that simultaneously provides RMQ/PSV/NSV. Ohlebusch and Gog [11] used only $2n + o(n)$ bits, obtaining around 10–12 bpc and operations in microseconds. Ohlebusch, Fischer, and Gog [12] also used this approach to obtain the same time performance of Theorem 2, within $3n$ extra bits instead of $6n$. This yields around 16 bpc and operations running in micro- to nanoseconds. An implementation of Theorem 4 [13] needed around 4 bpc but queries required milliseconds, although better performance is expected for the new version [9].

The proposal in [1] is also designed to adapt efficiently to highly repetitive sequence collections, obtaining 1–2 bpc and operations in milliseconds. Also for repetitive texts, Navarro and Ordóñez [8] obtained a speedup to microsecond operations, with a slight space increase, 1–3 bpc, by representing the parenthesis topology explicitly but in grammar-compressed form.

URLs to Code and Data Sets

An implementation of Sadakane's compressed suffix tree [14] is available from the SuDS group at http://www.cs.helsinki.fi/group/suds/cst/. Implementation details and engineering decisions are described by Välimäki, Gerlach, Dixit, and Mäkinen [15]. The compressed suffix tree of Abeliuk, Cánovas, and Navarro [1] is available in the libcds library at https://github.com/fclaude/libcds.

An alternative implementation of Sadakane's CST is available in the Succinct Data Structure Library at https://github.com/simongog/sdsl-lite. The SDSL also contains an implementation of the CST++ [12].

The Pizza and Chili site contains a large and varied dataset to test compressed indexes, http://pizzachili.dcc.uchile.cl.

Problem Definition

Given a *text string* $T = t_1 t_2 \ldots t_n$ over an alphabet Σ of size σ, the *compressed text indexing (CTI)* problem asks to *replace* T with a space-efficient data structure capable of efficiently answering basic string matching and substring queries on T. Typical queries required from such an index are the following:

- *count*(P): count how many times a given *pattern string* $P = p_1 p_2 \ldots p_m$ occurs in T.
- *locate*(P): return the locations where P occurs in T.
- *display*(i, j): return $T[i, j]$.

Key Results

An elegant solution to the problem is obtained by exploiting the connection of *Burrows-Wheeler Transform (BWT)* [1] and *Suffix Array* data structure [9]. The suffix array $SA[1, n]$ of T is the permutation of text positions $(1 \ldots n)$ listing the *suffixes* $T[i, n]$ in lexicographic order. That is, $T[SA[i], n]$ is the ith smallest suffix. The BWT

is formed by (1) a permutation T^{bwt} of T defined as $T^{\text{bwt}}[i] = T[SA[i]-1]$, where $T[0] = T[n]$, and (2) the number $i^* = SA^{-1}[1]$.

A property of the BWT is that symbols having the same context (i.e., string following them in T) are consecutive in T^{bwt}. This makes it easy to compress T^{bwt} achieving space close to high-order empirical entropies [10]. On the other hand, the suffix array is a versatile text index, allowing for example $O(m \log n)$ time counting queries (using two binary searches on SA) after which one can locate the occurrences in optimal time.

Ferragina and Manzini [3] discovered a way to combine the compressibility of the BWT and the indexing properties of the suffix array. The structure is essentially a compressed representation of the BWT plus some small additional structures to make it searchable.

We first focus on retrieving arbitrary substrings from this compressed text representation, and later consider searching capabilities. To retrieve the whole text from the structure (that is, to support *display*$(1, n)$), it is enough to invert the BWT. For this purpose, let us consider a table $LF[1, n]$ defined such that if $T[i]$ is permuted to $T^{\text{bwt}}[j]$ and $T[i-1]$ to $T^{\text{bwt}}[j']$ then $LF[j] = j'$. It is then immediate that T can be retrieved *backwards* by printing $T^{\text{bwt}}[i^*] \cdot T^{\text{bwt}}[LF[i^*]] \cdot T^{\text{bwt}}[LF[LF[i^*]]] \ldots$ (by definition $T^{\text{bwt}}[i^*]$ corresponds to $T[n]$).

To represent array LF space-efficiently, Ferragina and Manzini noticed that each $LF[i]$ can be expressed as follows:

Lemma 1 (Ferragina and Manzini [3]) *$LF[i] = C(c) + rank_c(i)$, where $c = T^{\text{bwt}}[i]$, $C(c)$ tells how many times symbols smaller than c appear in T^{bwt} and $rank_c(i)$ tells how many times symbol c appears in $T^{\text{bwt}}[1, i]$.*

General *display*(i, j) queries rely on a regular sampling of the text. Every text position of the form $j' \cdot s$, being s the sampling rate, is stored together with $SA^{-1}[j' \cdot s]$, the suffix array position pointing to it. To solve *display*(i, j) we start from the smallest sampled text position $j' \cdot s > j$ and apply the BWT inversion procedure starting with $SA^{-1}[j' \cdot s]$ instead of i^*. This gives the characters in reverse order from $j' \cdot s - 1$ to i, requiring at most $j - i + s$ steps.

It also happens that the very same two-part expression of $LF[i]$ enables efficient $count(P)$ queries. The idea is that if one knows the range of the suffix array, say $SA[sp_i, ep_i]$, such that the suffixes $T[SA[sp_i], n], T[SA[sp_i + 1], n], \ldots, T[SA[ep_i], n]$ are the only ones containing $P[i, m]$ as a prefix, then one can compute the new range $SA[sp_{i-1}, ep_{i-1}]$ where the suffixes contain $P[i-1, m]$ as a prefix, as follows: $sp_{i-1} = C(P[i-1]) + rank_{P[i-1]}(sp_i - 1) + 1$ and $ep_{i-1} = C(P[i-1]) + rank_{P[i-1]}(ep_i)$. It is then enough to scan the pattern *backwards* and compute values $C()$ and $rank_c()$ $2m$ times to find out the (possibly empty) range of the suffix array where all the suffixes start with the complete P. Returning $ep_1 - sp_1 + 1$ solves the $count(P)$ query without the need of having the suffix array available at all.

For locating each such occurrence $SA[i]$, $sp_1 \leq i \leq ep_1$, one can compute the sequence i, $LF[i]$, $LF[LF[i]]$, ..., until $LF^k[i]$ is a sampled suffix array position and thus it is explicitly stored in the sampling structure designed for *display*(i, j) queries. Then $SA[i] = SA[LF^k[i]] + k$. As we are virtually moving sequentially on the text, we cannot do more than s steps in this process.

Now consider the space requirement. Values $C()$ can be stored trivially in a table of $\sigma \log_2 n$ bits. $T^{\text{bwt}}[i]$ can be computed in $O(\sigma)$ time by checking for which c is $rank_c(i) \neq rank_c(i-1)$. The sampling rate can be chosen as $s = \Theta(\log^{1+\epsilon} n)$ so that the samples require $o(n)$ bits. The only real challenge is to preprocess the text for $rank_c()$ queries. This has been a subject of intensive research in recent years and many solutions have been proposed. The original proposal builds several small partial sum data structures on top of the compressed BWT, and achieves the following result:

Theorem 2 (Ferragina and Manzini [3]) *The CTI problem can be solved using a so-called FM-Index (FMI), of size $5nH_k + o(n \log \sigma)$ bits, that supports $count(P)$ in $O(m)$ time, $locate(P)$ in $O(\sigma \log^{1+\epsilon} n)$ time per occurrence, and*

display(i, j) in $O(\sigma(j-i+\log^{1+\epsilon} n))$ *time. Here* H_k *is the k th order empirical entropy of T,* $\sigma = o(\log n/\log\log n)$, $k \leq \log_\sigma(n/\log n)$, $-\omega(1)$, *and* $\epsilon > 0$ *is an arbitrary constant.*

The original FM-Index has a severe restriction on the alphabet size. This has been removed in follow-up works. Conceptually, the easiest way to achieve a more alphabet-friendly instance of the FM-index is to build a *wavelet tree* [5] on T^{bwt}. This is a binary tree on Σ such that each node v handles a subset $S(v)$ of the alphabet, which is split among its children. The root handles Σ and each leaf handles a single symbol. Each node v encodes those positions i so that $T^{\text{bwt}}[i] \in S(v)$. For those positions, node v only stores a bit vector telling which go to the left, which to the right. The node bit vectors are preprocessed for constant time $rank_1()$ queries using $o(n)$-bit data structures [6, 12]. Grossi et al. [4] show that the wavelet tree built using the encoding of [12] occupies $nH_0 + o(n\log\sigma)$ bits. It is then easy to simulate a single $rank_c()$ query by $\log_2\sigma$ $rank_1()$ queries. With the same cost one can obtain $T^{\text{bwt}}[i]$. Some later enhancements have improved the time requirement, so as to obtain, for example, the following result:

Theorem 3 (Mäkinen and Navarro [7]) *The CTI problem can be solved using a so-called Succinct Suffix Array (SSA), of size* $nH_0 + o(n\log\sigma)$ *bits, that supports* $count(P)$ *in* $O(m(1+\log\sigma/\log\log n))$ *time,* $locate(P)$ *in* $O(\log^{1+\epsilon} n\log\sigma/\log\log n)$ *time per occurrence, and display(i, j) in* $O((j-i+\log^{1+\epsilon} n)\log\sigma/\log\log n)$ *time. Here* H_0 *is the zero-order entropy of T,* $\sigma = o(n)$, *and* $\epsilon > 0$ *is an arbitrary constant.*

Ferragina et al. [2] developed a technique called *compression boosting* that finds an optimal partitioning of T^{bwt} such that, when one compresses each piece separately using its zero-order model, the result is proportional to the kth order entropy. This can be combined with the idea of SSA by building a wavelet tree separately for each piece and some additional structures in order to solve global $rank_c()$ queries from the individual wavelet trees:

Theorem 4 (Ferragina et al. [4]) *The CTI problem can be solved using a so-called Alphabet-Friendly FM-Index (AF-FMI), of size* $nH_k + o(n\log\sigma)$ *bits, with the same time complexities and restrictions of SSA with* $k \leq \alpha\log_\sigma n$, *for any constant* $0 < \alpha < 1$.

A very recent analysis [8] reveals that the space of the plain SSA is bounded by the same $nH_k + o(n\log\sigma)$ bits, making the boosting approach to achieve the same result unnecessary in theory. In practice, implementations of [4, 7] are superior by far to those building directly on this simplifying idea.

Applications

Sequence analysis in Bioinformatics, search and retrieval on oriental and agglutinating languages, multimedia streams, and even structured and traditional database scenarios.

Problem Definition

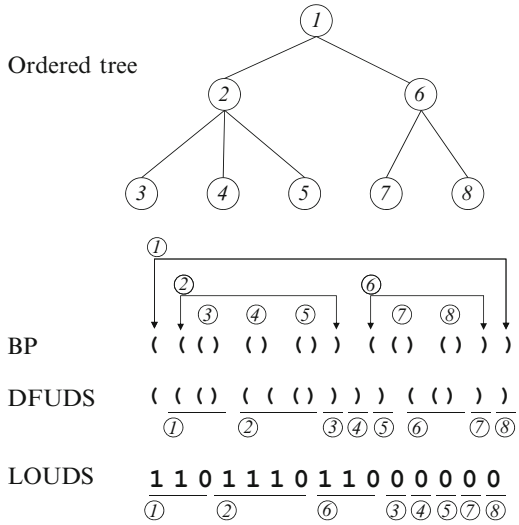
The problem is, given a tree, to encode it compactly so that basic operations on the tree are done quickly, preferably in constant time for static trees. Here, we consider the most basic class of trees: rooted ordered unlabeled trees. The information-theoretic lower bound for representing an n-node ordered tree is $2n - o(n)$ bits because there are $\binom{2n-2}{n-1}/n$ different trees. Therefore, the aim is to encode an ordered tree in $2n + o(n)$ bits including auxiliary data structures so that basic operations are done quickly. We assume that the computation model is the $\Theta(\log n)$-bit word RAM, that is, memory access for consecutive $\Theta(\log n)$ bits and arithmetic and logical operations on two $\Theta(\log n)$-bit integers are done in constant time.

Preliminaries

Let X be a string on alphabet $\mathcal{A}$. The number of occurrences of $c \in \mathcal{A}$ in $X[1 \ldots i]$ is denoted by $rank_c(X, i)$, and the position of j-th c from the left is denoted by $select_c(j)$ (with $select_c(0) = 0$). For binary strings ($|\mathcal{A}| = 2$) of length n, *rank* and *select* are computed in constant time using an $n + o(n)$-bit data structure [4]. Let us define for simplicity $prev_c(i) = select_c(rank_c(i-1))$ and $next_c(i) = select_c(rank_c(i)+1)$ the position of the c preceding and following, respectively, position i in X.

Key Results

Basically, there are three representations of ordered trees: LOUDS (Level-Order Unary Degree Sequence) [11], DFUDS (Depth-First Unary Degree Sequence) [2], and BP (Balanced Parenthesis sequence) [16]. An example is shown in Fig. 1. All these representations are succinct, that is, of $2n + o(n)$ bits. However, their functionality is slightly different.



Compressed Tree Representations, Fig. 1 Succinct representations of trees

LOUDS

In LOUDS representation, the degree of each node is encoded by a unary representation, that is, a node with d children is encoded in d ones, followed by a zero. Codes for the nodes are stored in level order: the root node is encoded first, then its children are encoded from left to right, all the nodes at depth 2 are encoded next, and so on. Let L be the LOUDS representation of a tree. Then L is a 0,1-string of length $2n-1$. Tree navigation operations are expressed by *rank* and *select* operations. The i-th node in level order is represented by $select_0(i-1)+1$. The operations $isleaf(i)$, $parent(i)$, $first\_child(i)$, $last\_child(i)$, $next\_sibling(i)$, $prev\_sibling(i)$, $degree(i)$, $child(i,q)$, and $child\_rank(i)$ (see Table 1) are computed in constant time using *rank* and *select* operations, for example, $degree(i) = next_0(i-1)-i$, $child(i,q) = select_0(rank_1(i-1+q))+1$, and $parent(i) = prev_0(select_1(rank_0(i-1)))+1$. However, because nodes are stored in level order, other operations cannot be done efficiently, such as $depth(i)$, $subtree\_size(i)$, $lca(i,j)$, etc. A merit of the LOUDS representation is that in practice it is fast and simple to implement because all the operations are done by only *rank* and *select* operations.

BP Representation

In BP representation, the tree is traversed in depth-first order, appending an open parenthesis "(" to the sequence when we reach a node and a closing parenthesis ")" when we leave it. These parentheses are represented with the bits 1 and 0, respectively. The result is a sequence of $2n$ parentheses that is balanced: for any open (resp. close) parenthesis, there is a matching close (resp. open) parenthesis to the right (resp. left), so that the areas between two pairs of matching parentheses either nest or are disjoint. Each node is identified with the position of its open parenthesis.

Munro and Raman [16] showed how to implement operations $findclose(i)$, $findopen(i)$, and $enclose(i)$ in constant time and $2n+o(n)$ bits in total. Later, Geary et al. [8] considerably simplified the solutions. With those operations and *rank* and *select* support, many operations in Table 1 are possible. For example, $pre\_rank(i) = rank_1(i)$, $pre\_select(j) = select_1(j)$, $isleaf(i)$ iff there is a 0 at position $i+1$, $isancestor(i,j)$ if $i \le j \le findclose(i)$, $depth(i) = rank_1(i) - rank_0(i)$, $parent(i) = enclose(i)$, $first\_child(i) = i+1$, $next\_sibling(i) = findclose(i)+1$, $subtree\_size(i) = (findclose(i)-i+1)/2$, etc. Operations lca, $height(i)$, and $deepest\_node(i)$ could be added with additional structures for range minimum queries, $rmqi(i,j)$, in $o(n)$ further bits [20]. Some other operations can be also supported in constant time by adding different additional structures. Lu and Yeh [14] gave $o(n)$-bit data structures for $degree(i)$, $child(i,q)$, and $child\_rank(i)$. Geary et al. [9] gave $o(n)$-bit data structures for $LA(i,d)$. However, these extra structures are complicated and add considerably extra space in practice.

DFUDS

In DFUDS representation, nodes are also encoded by a unary representation of their degrees, but stored in depth-first order. The bits 1 and 0 are interpreted as open parenthesis "(" and close parenthesis ")", respectively. By adding a dummy open parenthesis at the beginning, the DFUDS sequence becomes balanced. Each node is identified with the first position of its unary description.

Compressed Tree Representations, Table 1 Operations supported by the data structure of [19]. The time complexities are for the dynamic case; in the static case, all operations take $\mathcal{O}(1)$ time. The first group, of basic operations, is used to implement the others, but could have other uses

Operation	Description	Time complexity	
		Variant 1	Variant 2
inspect(i)	$P[i]$	$\mathcal{O}(\frac{\log n}{\log\log n})$	
findclose(i) / *findopen*(i)	Position of parenthesis matching $P[i]$		
enclose(i)	Position of tightest open parent. enclosing i		
rmqi(i,j) / *RMQi*(i,j)	Position of min/max excess value in range $[i,j]$		
pre_rank(i) / *post_rank*(i)	Preorder/postorder rank of node i	$\mathcal{O}(\frac{\log n}{\log\log n})$	
pre_select(i) / *post_select*(i)	The node with preorder/postorder i		
isleaf(i)	Whether $P[i]$ is a leaf		
isancestor(i,j)	Whether i is an ancestor of j		
depth(i)	Depth of node i		
parent(i)	Parent of node i		
first_child(i) / *last_child*(i)	First/last child of node i		
next_sibling(i) / *prev_sibling*(i)	Next/previous sibling of node i		
subtree_size(i)	Number of nodes in the subtree of node i		
lca(i,j)	The lowest common ancestor of two nodes i,j		
deepest_node(i)	The (first) deepest node in the subtree of i		
height(i)	The height of i (distance to its deepest node)		
in_rank(i)	Inorder of node i		
in_select(i)	Node with inorder i		
leaf_rank(i)	Number of leaves to the left of leaf i		
leaf_select(i)	i-th leaf		
lmost_leaf(i) / *rmost_leaf*(i)	Leftmost/rightmost leaf of node i		
LA(i,d)	Ancestor j of i s.t. *depth*$(j) =$ *depth*$(i) - d$	$\mathcal{O}(\log n)$	
level_next(i) / *level_prev*(i)	Next/previous node of i in BFS order		
level_lmost(d) / *level_rmost*(d)	Leftmost/rightmost node with depth d		
degree(i)	$q =$ number of children of node i	$\mathcal{O}(\frac{q\log n}{\log\log n})$	$\mathcal{O}(\log n)$
child(i,q)	q-th child of node i		
child_rank(i)	$q =$ number of siblings to the left of node i		
insert(i,j)	Insert node given by matching parent at i and j	$\mathcal{O}(\frac{\log n}{\log\log n})$	$\mathcal{O}(\log n)$
delete(i)	Delete node i		

A merit of using DFUDS is that it retains many operations supported in BP, but *degree*(i), *child*(i,q), and *child_rank*(i) are done in constant time by using only the basic operations supported by Munro and Raman [16]. For example, *degree*$(i) =$ *next*$_0(i-1) - i$, *child*$(i,q) =$ *findclose*$(i +$ *degree*$(i) - q) + 1$, and *parent*$(i) =$ *prev*$_0($*findopen*$(i-1)) + 1$. Operation *lca*(i,j) can also be computed using *rmqi*(i,j) [12].

Another important feature of DFUDS is that some trees can be represented in less than $2n$ bits. The number of ordered trees having n_i nodes with degree i ($i = 0,1,\ldots,n-1$) is $\frac{1}{n}\binom{n}{n_0 n_1 \cdots n_{n-1}}$ if $\sum_{i\geq 0} n_i(i-1) = -1$ and 0 otherwise (i.e., there are no trees satisfying the condition). Jansson et al. [12] proposed a compression algorithm for DFUDS sequences that achieves the lower bound $\lg\left(\frac{1}{n}\binom{n}{n_0 n_1 \cdots n_{n-1}}\right) +$

$o(n)$ bits. For example, a full binary tree, that is, a tree in which all internal nodes have exactly two children, is encoded in n bits.

A demerit of DUFDS is that computing $depth(i)$ and $LA(i,d)$ is complicated, though it is possible in constant time [12].

Fully Functional BP Representation

Navarro and Sadakane [19] proposed a data structure for ordered trees using the BP representation [16]. The data structure is called *range min-max tree*. Let P be the BP sequence. For each entry $P[i]$ of the sequence, we define its *excess value* as the number of open parentheses minus the number of close parentheses in $P[1,i]$. If $P[i]$ is an open parenthesis, its excess value is equal to $depth(i)$. Let $E[i]$ denote the excess value for $P[i]$. With the range min-max tree and small additional data structures, they support in constant time the operations $fwd\_search(i,d) = \min\{\{j > i | E[j] = E[i] + d\} \cup \{n+1\}\}$, $bwd\_search(i,d) = \max\{\{j < i | E[j] = E[i] + d\} \cup \{0\}\}$, and $rmqi(i,j) = \mathrm{argmin}_{i \le k \le j} E[k]$. Then, the basic operations can be expressed as $findclose(i) = fwd\_search(i,-1)$, $findopen(i) = bwd\_search(i,0) + 1$, and $enclose(i) = bwd\_search(i,-2) + 1$. In addition to those operations and *rank*/*select*, other operations can be computed, such as $LA(i,d) = bwd\_search(i,-d-1)+1$. Operation $child(i,q)$ and related ones are also done in constant time using small additional structures. The results are summarized as follows:

Theorem 1 ([19]) *For any ordinal tree with n nodes, all operations in Table 1 except insert and delete are carried out in constant time $\mathcal{O}(c)$ with a data structure using $2n + \mathcal{O}(n/\log^c n)$ bits of space on a $\Theta(\log n)$-bit word RAM, for any constant $c > 0$. The data structure can be constructed from the balanced parenthesis sequence of the tree, in $\mathcal{O}(n)$ time using $\mathcal{O}(n)$ bits of space.*

Another merit of using the range min-max tree is that it is easy to dynamize. By using a balanced tree, we obtain the following:

Theorem 2 ([19]) *On a $\Theta(\log n)$-bit word RAM, all operations on a dynamic ordinal tree with n nodes can be carried out within the worst-case complexities given in Table 1, using a data structure that requires $2n + \mathcal{O}(n \log\log n / \log n)$ bits. Alternatively, all the operations of the table can be carried out in $\mathcal{O}(\log n)$ time using $2n + \mathcal{O}(n/\log n)$ bits of space.*

The time complexity $\mathcal{O}(\log n / \log\log n)$ is optimal [3].

Other Representations

There are other representations of ordered trees and other types of trees [6, 7, 10]. The idea is that the entire tree is partitioned into mini-trees using the tree cover technique [10], and mini-trees are again partitioned into micro-trees.

Applications

There are many applications of succinct ordered trees because trees are fundamental data structures. A typical application is compressed suffix trees [20]. Balanced parentheses have also been used to represent planar and k-page graphs [16]. We also have other applications to encoding permutations and functions [17], grammar compression [15], compressing BDDs/ZDDs (binary decision diagrams/zero-suppressed BDDs) [5], etc.

Open Problems

An open problem is to give a dynamic data structure supporting all operations in the optimal $\mathcal{O}(\log n / \log\log n)$ time.

Experimental Results

Arroyuelo et al. [1] implemented LOUDS and the static version of the fully functional BP representation. LOUDS uses little space (as little as $2.1n$ bits) and solves its operations in half a microsecond or less, but its functionality is limited. The range min-max tree [19] requires about $2.4n$ bits and can be used to represent both BP and DFUDS. It solves all the operations within 1–2 microseconds. Previous implementations [8, 18] require more space and are generally slower.

Joannou and Raman [13] proposed an efficient implementation of the dynamic version using splay trees to represent the range min-max tree.

URLs to Code and Data Sets

An implementation of the BP representation using the range min-max tree by the original authors is available at https://github.com/fclaude/libcds. Another implementation by Simon Gog is at https://github.com/simongog/sdsl-lite.

Problem Definition

Trees are a fundamental structure in computing. They are used in almost every aspect of modeling and representation for computations like searching for keys, maintaining directories, and representations of parsing or execution traces, to name just a few. One of the latest uses of trees is *XML*, the de facto format for data storage, integration, and exchange over the Internet (see http://www.w3.org/XML/). Explicit storage of trees, with one pointer per child as well as other auxiliary information (e.g., label), is often taken as given but can account for the dominant storage cost. Just to have an idea, a simple tree encoding needs at least 16 bytes per tree node: one pointer to the auxiliary information (e.g., node label) plus three node pointers to the parent, the first child, and the next sibling. This large space occupancy may even prevent the processing of medium-sized trees, e.g., *XML* documents. This entry surveys the best-known storage solutions for unlabeled and labeled trees that are space efficient and support fast navigational and search operations over the tree structure. In the literature, they are referred to as *succinct/compressed tree-indexing* solutions.

Notation and Basic Facts

The information-theoretic storage cost for any item of a universe U can be derived via a simple *counting argument*: at least $\log |U|$ bits are needed to distinguish any two items of U. (Throughout the entry, all logarithms are taken to the base 2, and it is assumed $0 \log 0 = 0$.) Now, let $\mathcal{T}$ be a rooted tree of arbitrary degree and shape, and consider the following three main classes of trees:

Ordinal trees $\mathcal{T}$ is unlabeled and its children are left-to-right *ordered*. The number of ordinal trees on t nodes is $C_t = \binom{2t}{t} / (t+1)$ which induces a lower bound of $2t - \Theta(\log t)$ bits

Cardinal k-ary Trees $\mathcal{T}$ is labeled on its *edges* with symbols drawn from the alphabet $\Sigma = \{1, \ldots, k\}$. Any node has degree at most k because the edges outgoing from each node have *distinct* labels. Typical examples of cardinal trees are the binary tree ($k = 2$), the (uncompacted) trie, and the *Patricia tree*. The number of k-ary cardinal trees on t nodes is $C_t^k = \binom{kt+1}{t} / (kt+1)$ which induces a lower bound of $t(\log k + \log e) - \Theta(\log kt)$ bits, when k is a slowly growing function of t

(Multi-)labeled trees $\mathcal{T}$ is an ordinal tree, labeled on its *nodes* with symbols drawn from the alphabet Σ. In the case of multi-labeled trees, every node has *at least* one symbol as its label. The *same* symbols may repeat among sibling nodes, so that the degree of each node is *unbounded*, and the same labeled subpath may occur many times in $\mathcal{T}$, anchored anywhere. The information-theoretic lower bound on the storage complexity of this class of trees on t nodes comes easily from the decoupling of the tree structure and the storage of tree labels. For labeled trees, it is $\log C_t + t \log |\Sigma| = t(\log |\Sigma| + 2) - \Theta(\log t)$ bits

The following query operations should be supported over $\mathcal{T}$:

Basic navigational queries They ask for the parent of a given node u, the ith child of u, and the degree of u. These operations may be restricted to some label $c \in \Sigma$, if $\mathcal{T}$ is labeled

Sophisticated navigational queries They ask for the jth level-ancestor of u, the depth of u, the subtree size of u, the lowest common ancestor of a pair of nodes, and the ith node according to some node ordering over $\mathcal{T}$, possibly restricted to some label $c \in \Sigma$ (if $\mathcal{T}$ is labeled). For even more operations, see [2, 14]

Subpath query Given a labeled subpath Π, it asks for the (number *occ* of) nodes of $\mathcal{T}$ that immediately descend from every occurrence of

Π in $\mathcal{T}$. Each subpath occurrence may be anchored anywhere in the tree (i.e., not necessarily in its root)

The elementary solution to the tree-indexing problem consists of encoding the tree $\mathcal{T}$ via a mixture of pointers and arrays, thus taking a total of $\Theta(t \log t)$ bits. This supports basic navigational queries in constant time, but it is not space efficient and requires visiting the whole tree to implement the subpath query or the more sophisticated navigational queries. Here, the goal is to design tree storage schemes that are either *succinct*, namely, "close to the information-theoretic lower bound" mentioned before or *compressed* in that they achieve "entropy-bounded storage." Furthermore, these storage schemes do *not* require the whole visit of the tree for most navigational operations. Thus, succinct/compressed tree-indexing solutions are distinct from simply compressing the input and then uncompressing it at query time.

In this entry, it is assumed that $t \geq |\Sigma|$. The model of computation used is the random access machine (RAM) with word size $\Theta(\log t)$, where one can perform various arithmetic and bit-wise Boolean operations on single words in constant time.

Key Results

The notion of *succinct* data structures was introduced by Jacobson [13] in a seminal work over 25 years ago. He presented a storage scheme for ordinal trees using $2t + o(t)$ bits that supports basic navigational queries in $O(\log \log t)$ time (i.e., parent, first child, and next sibling of a node). Later, Munro and Raman [16] closed the issue for ordinal trees on basic navigational queries and the subtree-size query by achieving constant query time and $2t + o(t)$ bits of storage. Their storage scheme is called *balanced parenthesis* (*BP*) representation (some papers [Chiang et al., ACM-SIAM SODA '01; Sadakane, ISAAC '01; Munro et al., J.ALG '01; Munro and Rao, ICALP '04] have extended *BP* to support in constant time other sophisticated navigational queries like *LCA*, node degree, rank/select on leaves and number of leaves in a subtree, level-ancestor and level-successor) representation. Subsequently, Benoit et al. [3] proposed a storage scheme called *depth-first unary degree sequence* (shortly, *DFUDS*) that still uses $2t + o(t)$ bits but performs more navigational queries like ith child, child rank, and node degree in constant time. Geary et al. [10] gave another representation still taking optimal space that extends *DFUDS*'s operations with the level-ancestor query.

Although these three representations achieve the optimal space occupancy, none of them supports every existing operation in constant time: e.g., *BP* does not support ith child and child rank and *DFUDS* and Geary et al.'s representation do not support *LCA*. Later, Jansson et al. [14] extended the *DFUDS* storage scheme in two directions: (1) they showed how to implement in constant time all navigational queries above and (the *BP* representation and the one of Geary et al. [10] have been recently extended to support further operations-like depth/height of a node, next node in the same level, rank/select over various node orders-still in constant time and $2t + o(t)$ bits see [11] and references therein) (2) they showed how to compress the new tree storage scheme up to $H^*(\mathcal{T})$, which denotes the entropy of the distribution of node degrees in $\mathcal{T}$.

Theorem 1 (Jansson et al. [14]) *For any rooted (unlabeled) tree $\mathcal{T}$ with t nodes, there exists a tree-indexing scheme that uses $tH^*(\mathcal{T}) + O(t(\log \log t)^2/\log t)$ bits and supports all navigational queries in constant time.*

This improves the standard tree pointer-based representation, since it needs no more than $H^*(\mathcal{T})$ bits per node and does not compromise the performance of sophisticated navigational queries. Since it is $H^*(\mathcal{T}) \leq 2$, this solution is also never worse than BP or DFUDS, but its improvement may be significant! This result can be extended to achieve the kth-order entropy of the *DFUDS* sequence, by adopting any compressed-storage scheme for strings (see, e.g., [7] and references therein).

Further work in the area of succinct ordinal tree representations came in the form of (i) a

uniform approach to succinct tree representations [5] that simplified and extended the representation of Geary et al., (ii) a *universal representation* [6] that emulates all three representations mentioned above, and (iii) a *fully functional representation* [18] that obtains a simplified ordinal tree encoding with reduced space occupancy.

Benoit et al. [3] extended the use of *DFUDS* to cardinal trees and proposed a tree-indexing scheme whose space occupancy is close to the information-theoretic lower bound and supports various navigational queries in constant time. Raman et al. [19] improved the space by using a different approach (based on storing the tree as a set of edges), thus proving the following:

Theorem 2 (Raman et al. [19]) *For any k-ary cardinal tree $\mathcal{T}$ with t nodes, there exists a tree-indexing scheme that uses $\log C_t^k + o(t) + O(\log\log k)$ bits and supports in constant time the following operations: finding the parent, the degree, the ordinal position among its siblings, the child with label c, and the ith child of a node.*

The subtree-size operation cannot be supported efficiently using this representation, so [3] should be resorted to in case this operation is a primary concern.

Despite this flurry of activity, the fundamental problem of indexing *labeled* trees succinctly has remained mostly unsolved. In fact, the succinct encoding for ordered trees mentioned above might be replicated $|\Sigma|$ times (once for each symbol of Σ), and then the divide-and-conquer approach of [10] might be applied to reduce the final space occupancy. However, the final space bound would be $2t + t\log|\Sigma| + O(t|\Sigma|(\log\log\log t)/(\log\log t))$ bits, which is nonetheless far from the information-theoretic storage bound even for moderately large Σ. On the other hand, if subpath queries are of primary concern (e.g., *XML*), one can use the approach of [15] which consists of a variant of the suffix-tree data structure properly designed to index all $\mathcal{T}$'s labeled paths. Subpath queries can be supported in $O(|\Pi|\log|\Sigma| + occ)$ time, but the required space would still be $\Theta(t\log t)$ bits (with large hidden constants, due to the use of suffix trees). Subsequently, some papers [1, 2, 8, 12] addressed this problem in its whole generality by either dealing simultaneously with subpath and basic navigational queries [8] or by considering *multi*-labeled trees and a larger set of navigational operations [1, 2, 12].

In particular, [8] introduced a *transform* of the labeled tree $\mathcal{T}$, denoted $xbw[\mathcal{T}]$, which linearizes it into *two* coordinated arrays $\langle \mathcal{S}_{\text{last}}, \mathcal{S}_\alpha \rangle$: the former capturing the tree structure and the latter keeping a permutation of the labels of $\mathcal{T}$. $xbw[\mathcal{T}]$ has the optimal (up to lower-order terms) size of $2t + t\log|\Sigma|$ bits and can be built and inverted in optimal linear time. In designing the *XBW*-transform, the authors were inspired by the elegant Burrows-Wheeler transform for strings [4]. The power of $xbw[\mathcal{T}]$ relies on the fact that it allows one to transform compression and indexing problems on labeled trees into easier problems over strings. Namely, the following two string-search primitives are key tools for indexing $xbw[\mathcal{T}]$:$\text{rank}_c(S, i)$ returns the number of occurrences of the symbol c in the string prefix $S[1,i]$, and $\text{select}_c(S, j)$ returns the position of the jth occurrence of the symbol c in string S. The literature offers many time-/space-efficient solutions for these primitives that could be used as a *black box* for the compressed indexing of $xbw[\mathcal{T}]$ (see, e.g., [2, 17] and references therein).

Theorem 3 (Ferragina et al. [8]) *Consider a tree $\mathcal{T}$ consisting of t nodes labeled with symbols drawn from alphabet Σ. There exists a compressed tree-indexing scheme that achieves the following performance:*

- *If $|\Sigma| = O(\text{polylog}(t))$, the index takes at most $tH_0(\mathcal{S}_\alpha) + 2t + o(t)$ bits and supports basic navigational queries in constant time and (counting) subpath queries in $O(|\Pi|)$ time.*
- *For any alphabet Σ, the index takes less than $tH_k(\mathcal{S}_\alpha) + 2t + o(t\log|\sum|))$ bits, but label-based navigational queries and (counting) subpath queries are slowed down by a factor $o((\log\log|\Sigma|)3)$.*

Here, $H_k(s)$ is the kth-order empirical entropy of string s, with $H_k(s) \le H_{k-1}(s)$ for any $k > 0$.

Since $H_k(\mathcal{S}_\alpha) \leq H_0(\mathcal{S}_\alpha) \log |\sum|$, the indexing of $xbw[\mathcal{T}]$ takes at most as much space as its plain representation, up to lower-order terms, but with the additional feature of being able to navigate and search $\mathcal{T}$ efficiently. This is indeed a sort of *pointerless representation* of the labeled tree $\mathcal{T}$ with additional search functionalities (see [8] for details).

If sophisticated navigational queries over labeled trees are a primary concern, and subpath queries are not necessary, then the approach of Barbay et al. [1, 2] should be followed. They proposed the novel concept of *succinct index*, which is different from the concept of *succinct/compressed encoding* implemented by all the above solutions. A succinct index does not *touch* the data to be indexed; it just accesses the data via basic operations offered by the underlying abstract data type (ADT) and requires asymptotically less space than the information-theoretic lower bound on the storage of the data itself. The authors reduce the problem of indexing labeled trees to the one of indexing ordinal trees and strings and the problem of indexing multi-labeled trees to the one of indexing ordinal trees and binary relations. Then, they provide succinct indexes for strings and binary relations. In order to present their result, the following definitions are needed. Let m be the total number of symbols in $\mathcal{T}$, let t_c be the number of nodes labeled c in $\mathcal{T}$, and let ρ_c be the maximum number of labels c in any rooted path of $\mathcal{T}$ (called the *recursivity* of c). Define ρ as the average recursivity of $\mathcal{T}$, namely, $\rho = (1/m) \sum_{c \in \sum} (t_c \rho_c)$.

Theorem 4 (Barbay et al. [1]) *Consider a tree $\mathcal{T}$ consisting of t nodes (multi-)labeled with possibly many symbols drawn from alphabet Σ. Let m be the total number of symbols in $\mathcal{T}$, and assume that the underlying ADT for $\mathcal{T}$ offers basic navigational queries in constant time and retrieves the ith label of a node in time f. There is a succinct index for $\mathcal{T}$ using $m(\log \rho + o(\log(|\Sigma|\rho)))$ bits that supports for a given node u the following operations (where $L = \log\log|\sum| \log\log\log|\sum|$):*

- *Every c-descendant or c-child of u can be retrieved in $O(L(f + \log\log|\sum|))$ time.*
- *The set A of c-ancestors of u can be retrieved in $O(L(f + \log\log|\sum|)) + |A|(\log\log\rho_c + \log\log\log|\sum|(f + \log\log|\sum|)))$ time.*

More recently, He et al. [12] obtained new representations that support a much broader collection of operations than the ones mentioned above.

Applications

As trees are ubiquitous in many applications, this section concentrates just on two examples that, in their simplicity, highlight the flexibility and power of succinct/compressed tree indexes.

The first example regards suffix trees, which are a crucial algorithmic block of many string processing applications – ranging from bioinformatics to data mining, from data compression to search engines. Standard implementations of suffix trees take at least 80 bits per node. The compressed suffix tree of a string $S[1,s]$ consists of three components: the tree topology, the string depths stored into the internal suffix-tree nodes, and the suffix pointers stored in the suffix-tree leaves (also called *suffix array* of S). The succinct tree representation of [14] can be used to encode the suffix-tree topology and the string depths taking $4s + o(s)$ bits (assuming w.l.o.g. that $|\Sigma| = 2$). The suffix array can be compressed up to the kth-order entropy of S via any solution surveyed in [17]. The overall result is never worse than 80 bits per node, but can be significantly better for highly compressible strings.

The second example refers to the *XML* format which is often modeled as a labeled tree. The succinct/compressed indexes in [1, 2, 8] are theoretical in flavor but turn out to be relevant for practical *XML* processing systems. As an example, [9] has published some encouraging experimental results that highlight the impact of the *XBW*-transform on real *XML* datasets. The authors show that a proper adaptation of the *XBW*-transform allows one to compress *XML* data up to state-of-the-art XML-conscious compressors

and to provide access to its content, navigate up and down the *XML* tree structure, and search for simple path expressions and substrings in a few milliseconds over MBs of *XML* data, by uncompressing only a tiny fraction of them at each operation. Previous solutions took several seconds per operation!

Open Problems

For recent results, open problems, and further directions of research in the general area of succinct tree representation, the interested reader is referred to [2, 11, 14, 18] and references therein. Here, we describe two main problems, which naturally derive from the discussion above.

Motivated by *XML* applications, one may like to extend the subpath search operation to the *efficient* search for all leaves of $\mathcal{T}$ whose labels *contain* a substring β and that *descend from* a given subpath Π. The term "efficient" here means in time proportional to $|\Pi|$ and to the number of retrieved occurrences, but independent as much as possible of $\mathcal{T}$'s size in the worst case. Currently, this search operation is possible only for the leaves which are immediate descendants of Π, and even for this setting, the solution proposed in [9] is not optimal.

There are two main encodings for trees which lead to the results above: ordinal tree representation (*BP*, *DFUDS* or the representation of Geary et al. [10]) and *XBW*. The former is at the base of solutions for sophisticated navigational operations, and the latter is at the base of solutions for sophisticated subpath searches. Is it possible to devise *one unique* transform for the labeled tree $\mathcal{T}$ which combines the best of the two worlds and is still compressible?

Experimental Results

Problem Definition

An n-symbol message $M = \langle s_0, s_1, \ldots, s_{n-1} \rangle$ is given, where each symbol s_i is an integer in the range $0 \le s_i < U$. If the s_is are strictly increasing, then M identifies an n-subset of $\{0, 1, \ldots, U-1\}$.

Objective To economically encode M as a binary string over $\{0, 1\}$.

Constraints

1. **Short messages.** The message length n may be small relative to U.
2. **Monotonic equivalence.** Message M is converted to a strictly increasing message M' over the alphabet $U' \le Un$ by taking prefix sums, $s'_i = i + \sum_{j=0}^{i} s_j$ and $U' = s'_{n-1} + 1$. The inverse is to "take gaps," $g_i = s_i - s_{i-1} - 1$, with $g_0 = s_0$.
3. **Combinatorial Limit.** If M is monotonic then $\left\lceil \log_2 \binom{U}{n} \right\rceil \le U$ bits are required in the worst case. When $n \ll U$, $\log_2 \binom{U}{n} \approx n(\log_2(U/n) + \log_2 e)$.

Key Results

Monotonic sequences can be coded in $\min\{U, n(\log_2(U/n) + 2)\}$ bits. Non-monotonic sequences can be coded in $\min\{\sum_{i=0}^{n-1}(\log_2(1 + s_i) + o(\log s_i)), n(\log_2(U'/n) + 2)\}$ bits.

Unary and Binary Codes

The *unary code* represents symbol x as x `1`-bits followed by a single `0`-bit. The unary code for x is $1 + x$ bits long; hence, the corresponding ideal symbol probability distribution (for which this

pattern of codeword lengths yields the minimal message length) is given by $p_x = 2^{-(1+x)}$. Unary is an *infinite code*, for which knowledge of U is not required. But unless M is dominated by small integers, unary is expensive – the representation of a message $M = \langle s_0 \dots s_{n-1} \rangle$ requires $n + \sum_i s_i = U' + 1$ bits.

If $U \leq 2^k$ for integer k, then s_i can be represented in k bits using the *binary code*. Binary is *finite*, with an ideal probability distribution given by $p_x = 2^{-k}$. When $U = 2^k$, the ideal probability $p_x = 2^{-\log_2 U} = 1/U$. When $2^{k-1} < U < 2^k$, then $2^k - U$ of the codewords can be shortened to $k-1$ bits, in a *minimal binary code*. It is usual (but not necessary) to assign the short codewords to $0 \dots 2^k - U - 1$, leaving the codewords for $2^k - U \dots U - 1$ as k bits.

Elias Codes

Peter Elias described a suite of hybrids between unary and binary in work published in 1975 [7]. This family of codes are defined recursively, with unary being the base method. To code a value x, the "predecessor" Elias code is used to specify $x' = \lfloor \log_2(1 + x) \rfloor$, followed by an x'-bit binary code for $x - (2^{x'} - 1)$. The second member of the Elias family is C_γ and is a unary-binary code: unary for the prefix part and then binary to indicate the value of x within the range it specifies. The first few C_γ codewords are `0`, `10 0`, `10 1`, `110 00`, and so on, where spaces are used to illustrate the split between the components. The C_γ codeword for a value x requires $1 + \lfloor \log_2(1 + x) \rfloor$ bits for the unary part and a further $\lfloor \log_2(1+x) \rfloor$ bits for the binary part. The ideal probability distribution is thus given by $p_x \approx 1/(2(1 + x)^2)$. After C_γ, the next member of the Elias family is C_δ, in which C_γ is used to store x'. The first few codewords are `0`, `100 0`, `100 1`, and `101 00`; like unary and C_γ, C_δ is infinite, but now the codeword for x requires $1+2\lfloor \log_2(1+x') \rfloor + x'$ bits, where $x' = \lfloor \log_2(1 + x) \rfloor$. Further members of the family can be generated, but for most practical purposes, C_δ is the last useful one. To see why, note that $|C_\gamma(x')| \leq |C_\delta(x')|$ whenever $x' \leq 30$, meaning that the next Elias code is shorter than C_δ only for values $x' \geq 31$, that is, for $x \geq 2^{31} - 1$.

Fibonacci-Based Codes

Another infinite code arises from the Fibonacci sequence described (for this purpose) as $F_0 = 1$, $F_1 = 2$, $F_2 = 3$, $F_3 = 5$, $F_4 = 8$, and in general $F_i = F_{i-1} + F_{i-2}$. The *Zeckendorf* representation of a natural number is a list of Fibonacci values that add up to it, such that no two adjacent Fibonacci numbers are used. For example, 9 is the sum of $1 + 8 = F_0 + F_4$. The *Fibonacci code* for $x \geq 0$ is derived from the Zeckendorf representation of $x + 1$ and consists of a `1` bit in the ith position (counting from the left) if F_i appears in the sum and a `0` bit if not. Because it is not possible for both F_i and F_{i+1} to be part of the sum, the last 2 bits must be `01`; hence, appending a further `1` bit provides a unique sentinel for the codeword. The code for $x = 0$ is `11`, and the next few codewords are `011`, `0011`, `1011`, `00011`, and `10011`. Because (for large i) $F_i \approx \phi^{i+2}/\sqrt{5}$, where $\phi = (1 + \sqrt{5})/2 \approx 1.62$, the codeword for x requires approximately $\lfloor \log_\phi \sqrt{5} + \log_\phi(1 + x)\sqrt{5} \rfloor \approx \lfloor 1.67 + 1.44 \log_2(1 + x) \rfloor$ bits and is longer than C_γ only for $x = 0$ and $x = 2$. The Fibonacci code is also as good as, or better than, C_δ between $x = 1$ and $F_{18} - 2 = 6{,}763$. Higher-order variants are also possible, with increased minimum codeword lengths and decreased coefficients on the logarithmic term. Fenwick [8] provides coverage of Fibonacci codes.

Byte-Aligned Codes

Extracting bits from bitstrings can slow down decoding rates, especially if each bit is then tested in a loop guard. Operations on larger units tend to be faster. The simplest *byte-aligned code* is an interleaved 8-bit analog of the Elias C_γ mechanism. The top bit in each byte is reserved for a flag that indicates (when `0`) that this is the last byte of the codeword and (when `1`) that the codeword continues; the other 7 bits in each byte are for data. A total of $8\lceil (\log_2 x)/7 \rceil$ bits are used, which makes it more effective asymptotically than the Elias C_γ code or the Fibonacci code. However, the minimum 8 bits means that byte-aligned codes are expensive on messages dominated by small values. A further advantage of byte codes is that

compressed sequences can be searched, using a search pattern converted using the same code [5]. The zero top bit in all final bytes means that false matches can be easily eliminated.

An improvement to the simple byte-aligned coding mechanism arises from the observation that different values for the separating value between the *stopper* and *continuer* bytes lead to different trade-offs in overall codeword lengths [3]. In the (S, C)-*byte-aligned code*, values for $S + C = 256$ are chosen, and each codeword consists of a sequence of zero or more continuer bytes with values greater than or equal to S, followed by a stopper byte with a value less than S. Other variants include methods that use bytes as the coding units to form Huffman codes, either using 8-bit coding symbols or tagged 7-bit units [5] and methods that partially permute the alphabet, but avoid the need for a complete mapping [4]. Culpepper and Moffat [4] also describe a byte-aligned coding method that creates a set of byte-based codewords with the property that the first byte uniquely identifies the length of the codeword. Similarly, *nibble* codes can be designed as a 4-bit analog of the byte-aligned approach, with 1 bit reserved for a stopper-continuer flag, and 3 bits used for data.

Golomb Codes

In 1966 Solomon Golomb observed that the intervals between consecutive members of a random n-subset of the items $0 \ldots U-1$ could be modeled by a geometric probability distribution $p_x = p(1-p)^{x-1}$, where $p = n/U$ [10]. This probability distribution implies that in a *Golomb code*, the representation for $x+b$ should be 1 bit longer than the representation for x when $(1-p)^b \approx 0.5$, that is, when $b = \log 0.5 / \log(1-p) \approx (\ln 2)/p \approx 0.69U/n$. Assuming a monotonic message, each s_i is converted to a gap; then g_i div b is coded in unary; and finally g_i mod b is coded in minimal binary with respect to b. Like unary, the Golomb code is infinite. If the sequence is non-monotonic, then the values s_i are coded directly using parameter $b = 0.69U'/n$. Each `1`-bit that is part of a unary part spans b elements of U, meaning that there are at most $\lfloor U/b \rfloor$ of them in total; and there are exactly n `0`-bits in the unary parts. The minimal binary parts, one per symbol, take fewer than $n\lceil \log_2 b \rceil$ bits in total. Summing these components, and maximizing the cost over different values of n and U by assuming an adversary that forces the use of the first long minimal binary codeword whenever possible, yields a total Golomb code length for a monotonic sequence of at most $n(\log_2(U/n) + 2)$ bits. The variant in which $b = 2^k$ is used, $k = \lfloor \log_2(U/n) \rfloor$, is called a *Rice code*. Note that Golomb and Rice codes are infinite, but require that a parameter be set and that one way of estimating the parameter is based on knowing a value for U.

Other Static Codes

Elias codes and Golomb codes are examples of methods specified by a set of *buckets*, with symbol x coded in two parts: a bucket identifier, followed by an offset within the bucket, the latter usually using minimal binary. For example, the Elias C_γ code employs a vector of bucket sizes $\langle 2^0, 2^1, 2^2, 2^3, 2^4, \ldots \rangle$. Teuhola (see Moffat and Turpin [14]) proposed a hybrid in which a parameter k is chosen, and the vector of bucket sizes is given by $\langle 2^k, 2^{k+1}, 2^{k+2}, 2^{k+3}, \ldots \rangle$. One way of setting the parameter k is the length in bits of the median sequence value, so that the first bit of each codeword approximately halves the range of observed symbol values. Another variant is described by Boldi and Vigna [2], using vector $\langle 2^k-1, (2^k-1)2^k, (2^k-1)2^{2k}, (2^k-1)2^{3k}, \ldots \rangle$ to obtain a family of codes that are analytically and empirically well suited to power-law probability distributions, especially (taking k in the range 2–4) those associated with web-graph compression. Fraenkel and Klein [9] observed that the sequence of symbol *magnitudes* (i.e., the sequence of values $\lfloor \log_2(1 + s_i) \rfloor$) provides a denser range than the message itself and that it can be effective to use a principled code for them. For example, rather than using unary for the prefix part, a Huffman code can be used. Moffat and Anh [12] consider other ways in which the prefix part of each codeword can be reduced; and Fenwick [8] provides general coverage of other static coding methods.

Elias-Fano Codes

In 1974 Elias [6] presented another coding method, noting that it was described independently in 1971 by Robert Fano. The approach is now known as *Elias-Fano coding*. For monotonic sequence M, parameter $k = \lfloor \log_2(U/n) \rfloor$ is used to again break each codeword into quotient and remainder, *without* first taking gaps, with codewords formed relative to a sequence of buckets each of width $b = 2^k$. The number of symbols in the buckets is stored in a bitstring of $\lceil U/b \rceil < 2n$ unary codes. The n remainder parts $r_i = s_i \bmod b$ are stored as a sequence of k-bit binary codes. Each symbol contributes k bits as a binary part and adds 1 bit to one of the unary parts; plus there are at most $\lceil U/b \rceil$ 0-bits terminating the unary parts. Based on these relationships, the total length of an Elias-Fano code can be shown to be at most $n(\log_2(U/n) + 2)$ bits. Vigna [15] has deployed Elias-Fano codes to good effect.

Packed Codes

If each n-subset of $0 \ldots U-1$ is equally likely, the Golomb code is effective in the average case; and the Elias-Fano code is effective in the worst case. But if the elements in the subset are *clustered*, then it is possible to obtain smaller representations, provided that groups of elements themselves can be employed as part of the process of determining the code. The *word-aligned* codes of Anh and Moffat [1] fit as many binary values into each output word as possible. For example, in their Simple-9 method, 32-bit output words are used, and the first 4 bits of each word contain a *selector* which specifies how to decode the next 28 bits: one 28-bit binary number, or two 14-bit binary numbers, or three 9-bit numbers, and so on. Other variants use 64-bit words [1]. In these codes, clusters of low s_i (or g_i) values can be represented more compactly than would occur with the Golomb code and an all-of-message b parameter; and decoding is fast because whole words are expanded without any need for conditionals or branching.

Zukowski et al. [16] describe a different approach, in which blocks of z values from M are coded in binary using k bits each, where k is chosen such that 2^k is larger than most, but not necessarily all, of the z elements in the block. Any s_i's in the block that are larger than $2^k - 1$ are noted as *exceptions* and handled separately; a variety of methods for coding the exceptions have been used in different forms of the *pfordelta code*. This mechanism is again fast when decoding, due to the absence of conditional bit evaluations, and, for typical values such as $z = 128$, also yields effective compression. Lemire and Boytsov have carried out detailed experimentation with packed codes [11].

Context-Sensitive Codes

If the objective is to create the smallest representation, rather than provide a balance between compression effectiveness and decoding speed, the nonsequential *binary interpolative code* of Moffat and Stuiver [13] can be used. As an example, consider message M, shown in Table 1, and suppose that the decoder is aware that $U' = 29$, that is, that $s'_i < 29$. Every item in M is greater than or equal to $lo = 0$ and less than $hi = 29$, and the mid-value in M, in this example $s_4 = 6$ (it doesn't matter which mid-value is chosen), can be transmitted to the decoder using $\lceil \log_2 29 \rceil = 5$ bits. Once that middle number is pinned, the remaining values can be coded recursively within more precise ranges and might require fewer than 5 bits each.

In fact, there are four distinct values in M that precede s'_4 and another five that follow it, so a more restricted range for s'_4 can be inferred: it must be greater than or equal to $lo' = lo + 4 = 4$ and less than $hi' = hi - 5 = 24$. That is, $s'_4 = 6$ can be minimal binary coded as the value $6 - lo' = 2$ within the range $[0, 20)$ using just 4 bits.

It remains to transmit the left part, $\langle 0, 3, 4, 5 \rangle$, against the knowledge that every value is greater than or equal to $lo = 0$ and less than $hi = 6$, and the right part, $\langle 16, 24, 26, 27, 28 \rangle$, against the knowledge that every value is greater than or equal to $lo = 7$ and less than $hi = 29$. These two sublists are processed recursively in the order shown in the remainder of Table 1, with the tighter ranges $[lo', hi')$ also shown at

Compressing Integer Sequences, Table 1 Example encodings of message $M = \langle 0, 3, 4, 5, 6, 16, 24, 26, 27, 28 \rangle$ using the interpolative code. When a minimal binary code is applied to each value in its corresponding range, a total of **20** bits are required. No bits are output if $lo' = hi' - \mathbf{1}$

i	s_i	s'_i	lo	hi	lo'	hi'	$s_i - lo'$	$hi' - lo'$	Binary	MinBin
4	0	6	0	29	4	24	2	20	`00010`	`0010`
1	2	3	0	6	1	4	2	3	`10`	`11`
0	0	0	0	3	0	3	0	3	`00`	`0`
2	0	4	4	6	4	5	0	1	`--`	`--`
3	0	5	5	6	5	6	0	1	`--`	`--`
7	1	26	7	29	9	27	17	18	`10001`	`11111`
5	9	16	7	26	7	25	9	18	`01001`	`1001`
6	7	24	17	26	17	26	7	9	`0111`	`1110`
8	1	27	27	29	27	28	0	1	`--`	`--`
9	0	28	28	29	28	29	0	1	`--`	`--`

each step. One key feature of the interpolative code is that the when the range is just one, codewords of length zero are used. Four of the symbols in M benefit in this way. The interpolative code is particularly effective when the subset contains runs of consecutive items, or localized regions where there is a high density.

The final column of Table 1 uses minimal binary for each value within its bounded range. A refinement is to use a *centered minimal binary code*, so that the short codewords are assigned in the middle of the range rather than at the beginning, recognizing that the midpoint of a set is more likely to be near the middle of the range spanned by the set than it is to be near the ends of the range. Adding this enhancement tends to be beneficial. But improvement is not guaranteed, and on M it adds 1 bit to the compressed representation compared to what is shown in Table 1.

Applications

Messages in this form are often the output of a modeling step in a data compression system. Other examples include recording the hyperlinks in the graph representation of the World Wide Web and storing inverted indexes for large document collections.

Problem Definition

Recall that a simple digraph T is a tournament if for every two vertices $u, v \in V(T)$, exactly one of the arcs (u, v) and (v, u) exists in T. If we relax this condition by allowing both these arcs to exist at the same time, then we obtain the definition of a *semi-complete* digraph. We say that a digraph T contains a digraph H as a *topological minor* if one can map vertices of H to different vertices of T, and arcs of H to directed paths connecting respective images of the endpoints that are internally vertex disjoint. By relaxing vertex disjointness to arc disjointness, we obtain the definition of an *immersion*. (For simplicity, we neglect here the difference between weak immersions and strong immersions, and we work with weak immersions only.) Finally, we say that T contains H as a *minor* if vertices of H can be mapped to vertex disjoint strongly connected subgraphs of T in such a manner that for every arc (u, v) of H, there exists a corresponding arc of T going from a vertex belonging to the image of u to a vertex belonging to the image of v.

The topological minor, immersion, and minor relations form fundamental containment orderings on the class of digraphs. Mirroring the achievements of the graph minors program of Robertson and Seymour, it is natural to ask what is the complexity of testing these relations when the pattern graph H is assumed to be small. For general digraphs, even very basic problems of this nature are NP-complete [5]; however, the structure of semi-complete digraphs allow us to design efficient algorithms.

On semi-complete digraphs, the considered containment relations are tightly connected to digraph parameters *cutwidth* and *pathwidth*. For a digraph T and an ordering $(v_1, v_2, \ldots, v_n)$ of $V(T)$, by *width* of this ordering, we mean the maximum over $1 \leq t \leq n-1$ of the number of arcs going from $\{v_1, v_2, \ldots, v_t\}$ to $\{v_{t+1}, v_{t+2}, \ldots, v_n\}$ in T. The cutwidth of a digraph T, denoted by $\mathbf{ctw}(T)$, is the minimum width of an ordering of $V(T)$. A *path decomposition* of a digraph T is a sequence $\mathcal{P} = (W_1, W_2, \ldots, W_r)$ of subsets of vertices, called bags, such that (i) $\bigcup_{i=1}^{r} W_i = V(T)$, (ii) $W_j \supseteq W_i \cap W_k$ for all $1 \leq i < j < k \leq r$, and (iii) whenever (u, v) is an edge of T, then u and v appear together in some bag of $\mathcal{P}$ or all

the bags in which u appears are placed after all the bags in which v appears. The *width* of $\mathcal{P}$ is equal to $\max_{1 \leq i \leq r} |W_i| - 1$. The pathwidth of T, denoted by $\mathbf{pw}(T)$, is the minimum width of a path decomposition of T.

It appears that if a semi-complete digraph T excludes some digraph H as an immersion, then its cutwidth is bounded by a constant c_H depending on H only. Similarly, if T excludes H as a minor or as a topological minor, then its pathwidth is bounded by a constant p_H depending on H only. These Erdős-Pósa-style results were proven by Chudnovsky et al. [2] and Fradkin and Seymour [7], respectively. Based on this understanding of the links between containment relations and width parameters, it has been shown that immersion and minor relations are well-quasi-orderings of the class of semi-complete digraphs [1,6].

The aforementioned theorems give also raise to natural algorithms for testing the containment relations. We try to approximate the appropriate width measure: If we obtain a guarantee that it is larger than the respective constant c_H or p_H, then we can conclude that H is contained in T for sure. Otherwise, we can construct a decomposition of T of small width on which a dynamic programming algorithm can be employed. In fact, the proofs of Chudnovsky et al. [2] and Fradkin and Seymour [7] can be turned into (some) approximation algorithms for cutwidth and pathwidth on semi-complete digraphs. Therefore, it is natural to look for more efficient such algorithms, both in terms of the running time and the approximation ratio. The efficiency of an approximation subroutine is, namely, the crucial ingredient of the overall running time for testing containment relations.

Key Results

As a by-product of their proof, Chudnovsky et al. [2] obtained an algorithm that, given an n-vertex semi-complete digraph T and an integer k, either finds an ordering of $V(T)$ of width $\mathcal{O}(k^2)$ or concludes that $\mathbf{ctw}(T) > k$ by finding an appropriate combinatorial obstacle embedded in T. The running time is $\mathcal{O}(n^3)$. Similarly, a by-product of the proof of Fradkin and Seymour [7] is an algorithm that, for the same input, either finds a path decomposition of T of width $\mathcal{O}(k^2)$ or concludes that $\mathbf{pw}(T) > k$, again certifying this by providing an appropriate obstacle. Unfortunately, here the running time is $\mathcal{O}(n^{\mathcal{O}(k)})$; in other words, the exponent of the polynomial grows with k.

The proofs of the Erdős-Pósa statements proceed as follows: One shows that if the found combinatorial obstacle is large enough, i.e., it certifies that $\mathbf{ctw}(T) > k$ or $\mathbf{pw}(T) > k$ for large enough k, then already inside this obstacle one can find an embedding of every digraph H of a fixed size. Of course, the final values of constants c_H and p_H depend on how efficiently we can extract a model of H from an obstacle and, more precisely, how large k must be in terms of $|H|$ in order to guarantee that an embedding of H can be found. (We denote $|H| = |V(H)| + |E(H)|$.) Unfortunately, in the proofs of Chudnovsky et al. [2] and Fradkin and Seymour [7], this dependency is exponential (even multiple exponential in the case of p_H) and so is the overall dependency of constants c_H and p_H on $|H|$. Using the framework presented before, one can obtain an $f(|H|) \cdot n^3$-time algorithm for testing whether H can be immersed into an n-vertex semi-complete digraph T, as well as similar tests for the (topological) minor relations with running time $n^{g(|H|)}$. Here, f and g are some multiple-exponential functions.

The running time of the immersion testing algorithm is fixed-parameter tractable (FPT), while the running time for (topological) minor testing is only XP. It is natural to ask for an FPT algorithm also for the latter problem. Fomin and the current author [3,4,8] approached the issue from a different angle, which resulted in reproving the previous results with better constants, refined running times, and also in giving FPT algorithms for all the containment tests. Notably, the framework seems to be simpler and more uniform compared to the previous work. We now state the results of [3,4,8] formally, since they constitute the best known so far algorithms for topological problems in semi-complete digraphs.

Theorem 1 ([8]) *There exists an algorithm that, given an n-vertex semi-complete digraph T, runs in time $\mathcal{O}(n^2)$ and returns an ordering of $V(T)$ of width at most $\mathcal{O}(\mathbf{ctw}(T)^2)$.*

Theorem 2 ([8, 9]) *There exists an algorithm that, given an n-vertex semi-complete digraph T and an integer k, runs in time $\mathcal{O}(kn^2)$ and either returns a path decomposition of $V(T)$ of width at most $6k$ or correctly concludes that $\mathbf{pw}(T) > k$.*

Theorem 3 ([4, 8, 9]) *There exist algorithms that, given an n-vertex semi-complete digraph T and an integer k, determine whether:*

- $\mathbf{ctw}(T) \leq k$ *in time* $2^{\mathcal{O}(\sqrt{k \log k})} \cdot n^2$.
- $\mathbf{pw}(T) \leq k$ *in time* $2^{\mathcal{O}(k \log k)} \cdot n^2$.

Theorem 4 ([8]) *There exist algorithms that, given a digraph H and an n-vertex semi-complete digraph T, determine whether:*

- *H can be immersed in T in time* $2^{\mathcal{O}(|H|^2 \log |H|)} \cdot n^2$.
- *H is a topological minor of T in time* $2^{\mathcal{O}(|H| \log |H|)} \cdot n^2$.
- *H is a minor of T in time* $2^{\mathcal{O}(|H| \log |H|)} \cdot n^2$.

Thus, Theorems 1 and 2 provide approximation algorithms for cutwidth and pathwidth, Theorem 3 provides FPT algorithms for computing the exact values of these parameters, and Theorem 4 utilizes the approximation algorithms to give efficient algorithms for containment testing. We remark that the exact algorithm for cutwidth (the first bullet of Theorem 3) is a combination of the results of [8] (which gives a $2^{\mathcal{O}(k)} \cdot n^2$-time algorithm) and of [4] (which gives a $2^{\mathcal{O}(\sqrt{k \log k})} \cdot n^{\mathcal{O}(1)}$-time algorithm). A full exposition of this algorithm can be found in the PhD thesis of the current author [9], which contains a compilation of [3, 4, 8]. Moreover, for Theorem 2 work [8] claims only a 7-approximation, which has been consequently improved to a 6-approximation in the aforementioned PhD thesis [9]. Finally, it also follows that in the Erdős-Pósa results, one can take $c_H = \mathcal{O}(|H|^2)$ and $p_H = \mathcal{O}(|H|)$; this claim is not mentioned explicitly in [8], but follows easily from the results proven there.

To conclude, let us shortly deliberate on the approach that led to these results. The key to the understanding is the work [8]. The main observation there is that a large cluster of vertices with very similar outdegrees is already an obstacle for admitting a path decomposition of small width. More precisely, if one finds $4k + 2$ vertices whose outdegrees pairwise differ by at most k (a so-called $(4k + 2, k)$-*degree tangle*), then this certifies that $\mathbf{pw}(T) > k$; see Lemma 46 of [9]. As it always holds that $\mathbf{pw}(T) \leq 2\mathbf{ctw}(T)$, this conclusion also implies that $\mathbf{ctw}(T) > k/2$. Therefore, in semi-complete digraphs of small pathwidth or cutwidth, the outdegrees of vertices must be spread evenly; there is no "knot" with a larger density of vertices around some value of the outdegree. If we then order the vertices of T by their outdegrees, then this ordering should crudely resemble an ordering with the optimal width, as well as the order in which the vertices appear on an optimal path decomposition of T. Indeed, it can be shown that any ordering of $V(T)$ w.r.t. nondecreasing outdegrees has width at most $\mathcal{O}(\mathbf{ctw}(T)^2)$ [8]. Hence, the algorithm of Theorem 1 is, in fact, trivial: We just sort the vertices by their outdegrees. The pathwidth approximation algorithm (Theorem 2) is obtained by performing a left-to-right scan through the outdegree ordering that constructs a path decomposition in a greedy manner. For the exact algorithms (Theorem 3), in the scan we maintain a dynamic programming table of size exponential in k, whose entries correspond to possible endings of partial decompositions for prefixes of the ordering. The key to improving the running time for cutwidth to subexponential in terms of k (shown in [4]) is relating the states of the dynamic programming algorithm to *partition numbers*, a sequence whose subexponential asymptotics is well understood. Finally, the obstacles yielded by the approximation algorithms of Theorems 1 and 2 are more useful for finding embeddings of small digraphs H than the ones used in the previous works. This leads to a better dependence on $|H|$ of constants

c_H, p_H in the Erdős-Pósa results, as well as of the running times of the containment tests (Theorem 4).

Problem Definition

This problem concerns the construction of pure Nash equilibria (PNE) in a special class of atomic congestion games, known as the Parallel Links Game (PLG). The purpose of this note is to gather recent advances in the *existence and tractability of PNE in PLG*.

THE PURE PARALLEL LINKS GAME. Let $N \equiv [n]$ ($\forall k \in \mathbb{N}$, $[k] \equiv \{1, 2, \ldots, k\}$.) be a set of (selfish) players, each of them willing to have her good served by a *unique* shared resource (link) of a system. Let $E = [m]$ be the set of all these links. For each link $e \in E$, and each player $i \in N$,let $D_{i,e}(\cdot) : \mathbb{R}_{\geq 0} \mapsto \mathbb{R}_{\geq 0}$ be the **charging mechanism** according to which link e charges player i for using it. Each player $i \in [n]$ comes with a service requirement (e.g., traffic demand, or processing time) $W[i, e] > 0$, if she is to be served by link $e \in E$. A service requirement $W[i, e]$ is allowed to get the value ∞, to denote the fact that player i would never want to be assigned to link e. The charging mechanisms are functions of each link's cumulative congestion.

Any element $\sigma \in E$ is called a **pure strategy** for a player. Then, this player is assumed to assign her own good to link e. A collection of pure strategies for all the players is called a **pure strategies profile**, or a **configuration** of the players, or a **state** of the game.

The **individual cost** of player i wrt the profile σ is: $\mathtt{IC}_i(\sigma) = D_{i,\sigma_i}(\sum_{j \in [n]:\sigma_j = \sigma_i} W[j, \sigma_j])$. Thus, the **Pure Parallel Links Game** (PLG) is the game in strategic form defined as $\Gamma = \langle N, (\Sigma_i = E)_{i \in N}, (\mathtt{IC}_i)_{i \in N} \rangle$, whose acceptable solutions are only PNE. Clearly, an arbi-

trary instance of PLG can be described by the tuple $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$.

DEALING WITH SELFISH BEHAVIOR. The dominant solution concept for finite games in strategic form, is the Nash Equlibrium [14]. The definition of pure Nash Equilibria for PLG is the following:

Definition 1 (Pure Nash Equilibrium) For any instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG, a pure strategies profile $\sigma \in E^n$ is a **Pure Nash Equilibrium** (PNE in short), iff: $\forall i \in N, \forall e \in E, \mathtt{IC}_i(\sigma) = D_{i,\sigma_i}\left(\sum_{j\in[n]:\sigma_j=\sigma_i} W[j,\sigma_i]\right) \leq D_{i,e}\left(W[i,e] + \sum_{j\in[n]\setminus\{i\}:\sigma_j=e} W[j,e]\right)$.

A refinement of PNE are the ***k*- robust PNE**, for $n \geq k \geq 1$ [9]. These are pure profiles for which no subset of at most k players may concurrently change their strategies in such a way that the worst possible individual cost among the movers is *strictly decreased*.

QUALITY OF PURE EQUILIBRIA. In order to determine the quality of a PNE, a social cost function that measures it must be specified. The typical assumption in the literature of PLG, is that the social cost function is the worst individual cost paid by the players: $\forall \sigma \in E^n$, $\mathtt{SC}(\sigma) = \max_{i\in N}\{\mathtt{IC}_i(\sigma)\}$ and $\forall \mathbf{p} \in (\Delta_m)^n$, $\mathtt{SC}(\mathbf{p}) = \sum_{\sigma\in E^n}(\prod_{i\in N} p_i(\sigma_i)) \cdot \max_{i\in N}\{\mathtt{IC}_i(\sigma)\}$. Observe that, for mixed profiles, the social cost is the *expectation* of the maximum individual cost among the players.

The measure of the quality of an instance of PLG wrt PNE, is measured by the **Pure Price of Anarchy** (PPoA in short) [12]: $\mathtt{PPoA} = \max\{(\mathtt{SC}(\sigma))/\mathtt{OPT} : \sigma \in E^n \text{ is PNE}\}$ where $\mathtt{OPT} \equiv \min_{\sigma\in E^n}\{\mathtt{SC}(\sigma)\}$.

DISCRETE DYNAMICS. Crucial concepts of strategic games are the best and better responses. Given a configuration $\sigma \in E^n$, an **improvement step**, or **selfish step**, or **better response** of player $i \in N$ is the choice by i of a pure strategy $\alpha \in E \setminus \{\sigma_i\}$, so that player i would have a positive gain by this *unilateral* change (i.?e., provided that the other players maintain the same strategies). That is, $\mathtt{IC}_i(\sigma) > \mathtt{IC}_i(\sigma \oplus_i \alpha)$ where, $\sigma \oplus_i \alpha \equiv (\sigma_1, \ldots, \sigma_{i-1}, \alpha, \sigma_{i+1}, \ldots, \sigma_n)$. A **best response**, or **greedy selfish step** of player i, is any change from the current link σ_i to an element $\alpha^* \in \arg\max_{a\in E}\{\mathtt{IC}_i(\sigma \oplus_i \alpha)\}$. An **improvement path** (aka a **sequence of selfish steps** [6], or an **elementary step system** [3]) is a sequence of configurations $\pi = \langle\sigma(1), \ldots, \sigma(k)\rangle$ such that

$$\forall 2 \leq r \leq k, \exists i_r \in N, \exists \alpha_r \in E:$$
$$[\sigma(r) = \sigma(r-1) \oplus_{i_r} \alpha_r] \wedge [\mathtt{IC}_{i_r}(\sigma(r)) < \mathtt{IC}_{i_r}(\sigma(r-1))] .$$

A game has the **Finite Improvement Property** (FIP) iff any improvement path has *finite* length. A game has the **Finite Best Response Property** (FBRP) iff any improvement path, each step of whose is a best response of some player, has *finite* length.

An alternative trend is to, rather than consider *sequential* improvement paths, let the players conduct selfish improvement steps *concurrently*. Nevertheless, the selfish decisions are no longer deterministic, but rather distributions over the links, in order to have some notion of a priori Nash property that justifies these moves. The selfish players try to minimize their *expected* individual costs this time. Rounds of concurrent moves occur until a posteriori Nash Property is achieved. This is called a **selfish rerouting** policy [4].

Subclasses of PLG

[$\mathbf{PLG}_1$] Monotone PLG: The charging mechanism of each pair of a link and a player, is a *non–decreasing function* of the resource's cumulative congestion.

[$\mathbf{PLG}_2$] Resource Specific Weights PLG (RSPLG): Each player may have a different service demand from every link.

[$\mathbf{PLG}_3$] Player Specific Delays PLG (PSPLG): Each link may have a different charging mechanism for each player. Some special cases of PSPLG are the following:

[PLG$_{3.1}$] Linear Delays PSPLG: Every link has a (player specific) *affine* charging mechanism: $\forall i \in N, \forall e \in E, D_{i,e}(x) = a_{i,e}x + b_{i,e}$ for some $a_{i,e} > 0$ and $b_{i,e} \geq 0$.

[PLG$_{3.1.1}$] Related Delays PSPLG: Every link has a (player specific) *non–uniformly related* charging mechanism: $\forall i \in N, \forall e \in E, W[i,e] = w_i$ and $D_{i,e}(x) = a_{i,e}x$ for some $a_{i,e} > 0$.

[PLG$_4$] Resource Uniform Weights PLG (RUPLG): Each player has a unique service demand from all the resources. Ie, $\forall i \in N, \forall e \in E, W[i,e] = w_e > 0$. A special case of RUPLG is:

[PLG$_{4.1}$] Unweighted PLG: All the players have identical demands from all the links: $\forall i \in N, \forall e \in E, W[i,e] = 1$.

[PLG$_5$] Player Uniform Delays PLG (PUPLG): Each resource adopts a unique charging mechanism, for all the players. That is, $\forall i \in N, \forall e \in E, D_{i,e}(x) = d_e(x)$.

[PLG$_{5.1}$] Unrelated Parallel Machines, or **Load Balancing PLG (LBPLG)**: The links behave as parallel machines. That is, they charge each of the players for the cumulative load assigned to their hosts. One may think (wlog) that all the machines have as charging mechanisms the identity function. That is, $\forall i \in N, \forall e \in E, D_{i,e}(x) = x$.

[PLG$_{5.1.1}$] Uniformly Related Machines LBPLG: Each player has the same demand at every link, and each link serves players at a fixed rate. That is: $\forall i \in N, \forall e \in E, W[i,e] = w_i$ and $D_{i,e}(x) = \frac{x}{s_e}$. Equivalently, service demands proportional to the capacities of the machines are allowed, but the identity function is required as the charging mechanism: $\forall i \in N, \forall e \in E, W[i,e] = \frac{w_i}{s_e}$ and $D_{i,e}(x) = x$.

[PLG$_{5.1.1.1}$] Identical Machines LBPLG: Each player has the same demand at every link, and all the delay mechanisms are the identity function: $\forall i \in N, \forall e \in E, W[i,e] = w_i$ and $D_{i,e}(x) = x$.

[PLG$_{5.1.2}$] Restricted Assignment LBPLG: Each traffic demand is either of unit or infinite size. The machines are identical. Ie, $\forall i \in N, \forall e \in E, W[i,e] \in \{1, \infty\}$ and $D_{i,e}(x) = x$.

Algorithmic Questions Concerning PLG

The following algorithmic questions are considered:

Problem 1 (PNEExistsInPLG(E, N, W, D))
INPUT: An instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG
OUTPUT: Is there a configuration $\sigma \in E^n$ of the players to the links, which is a PNE?

Problem 2 (PNEConstructionInPLG(E,N,W,D))
INPUT: An instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG
OUTPUT: An assignment $\sigma \in E^n$ of the players to the links, which is a PNE.

Problem 3 (BestPNEInPLG(E, N, W, D))
INPUT: An instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG. A **social cost** function $\mathtt{SC} : (\mathbb{R}_{\geq 0})^m \mapsto \mathbb{R}_{\geq 0}$ that characterizes the quality of any configuration $\sigma \in E^N$.
OUTPUT: An assignment $\sigma \in E^n$ of the players to the links, which is a PNE and minimizes the value of the social cost, compared to other PNE of PLG.

Problem 4 (WorstPNEInPLG(E, N, W, D))
INPUT: An instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG. A **social cost** function $\mathtt{SC} : (\mathbb{R}_{\geq 0})^m \mapsto \mathbb{R}_{\geq 0}$ that characterizes the quality of any configuration $\sigma \in E^N$.
OUTPUT: An assignment $\sigma \in E^n$ of the players to the links, which is a PNE and *maximizes* the value of the social cost, compared to other PNE of PLG.

Problem 5 (DynamicsConvergeInPLG(E, N, W, D))
INPUT: An instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG
OUTPUT: Does FIP (or FBRP) hold? How long does it take then to reach a PNE?

Problem 6 (ReroutingConvergeInPLG(E, N, W, D))
INPUT: An instance $\langle N, E, (W[i,e])_{i\in N, e\in E}, (D_{i,e}(\cdot))_{i\in N, e\in E}\rangle$ of PLG

OUTPUT: Compute (if any) a selfish rerouting policy that converges to a PNE.

Status of Problem 1

Player uniform, unweighted atomic congestion games always possess a PNE [15], with no assumption on monotonicity of the charging mechanisms. Thus, Problem 1 is already answered for all unweighted PUPLG. Nevertheless, this is not necessarily the case for weighted versions of PLG:

Theorem 1 ([13]) *There is an instance of (monotone) PSPLG with only three players and three strategies per player, possessing no PNE. On the other hand, any unweighted instance of monotone PSPLG possesses at least one PNE.*

Similar (positive) results were given for LBPLG. The key observation that lead to these results, is the fact that the lexicographically minimum vector of machine loads is always a PNE of the game.

Theorem 2 *There is always a PNE for any instance of Uniformly Related LBPLG* [7]*, and actually for any instance of LBPLG* [3]*. Indeed, there is a $k-$robust PNE for any instance of LBPLG, and any $1 \leq k \leq n$* [9].

Status of Problem 2, 5 and 6

Milchtaich [13] gave a constructive proof of existence for PNE in unweighted, monotone PSPLG, and thus implies a path of length at most n that leads to a PNE. Although this is a very efficient construction of PNE, it is not necessarily an improvement path, when all players are considered to coexist all the time, and therefore there is no justification for the adoption of such a path by the players. Milchtaich [13] proved that from an arbitrary initial configuration and allowing only best reply defections, there is a best reply improvement path of length at most $m \cdot \binom{n+1}{2}$. Finally, [11] proved for unweighted, Related PSPLG that it possesses FIP. Nevertheless, the convergence time is poor.

For LBPLG, the implicit connection of PNE construction to classical scheduling problems, has lead to quite interesting results.

Theorem 3 ([7]) *The LPT algorithm of Graham, yields a PNE for the case of Uniformly Related LBPLG, in time $\mathcal{O}(m \log m)$.*

The drawback of the LPT algorithm is that it is centralized and not selfishly motivated. An alternative approach, called **Nashification**, is to start from an arbitrary initial configuration $\sigma \in E^n$ and then try to construct a PNE of at most the same maximum individual cost among the players.

Theorem 4 ([6]) *There is an $\mathcal{O}(nm^2)$ time Nashification algorithm for any instance of Uniformly Related PLG.*

An alternative style of Nashification, is to let the players follow an arbitrary improvement path. Nevertheless, it is not always the case that this leads to a polynomial time construction of a PNE, as the following theorem states:

Theorem 5 *For Identical Machines LBPLG:*

- *There exist best response improvement paths of length $\Omega\left(\max\left\{2^{\sqrt{n}}, \left(\frac{n}{m^2}\right)^m\right\}\right)$* [3,6].
- *Any best response improvement path is of length $\mathcal{O}(2^n)$* [6].
- *Any best response improvement path, which gives priority to players of maximum weight among those willing to defect in each improvement step, is of length at most n* [3].
- *If all the service demands are integers, then any improvement path which gives priority to unilateral improvement steps, and otherwise allows only selfish 2-flips (ie, swapping of hosting machines between two goods) converges to a 2-robust PNE in at most $\frac{1}{2}(\sum_{i \in N} w_i)^2$ steps* [9].

The following result concerns selfish rerouting policies:

Theorem 6 ([4])

- *For unweighted Identical Machines LBPLG, a simple policy (BALANCE) forcing all the*

players of overloaded links to migrate to a new (random) link with probability proportional to the load of the link, converges to a PNE in $\mathcal{O}(\log\log n + \log m)$ rounds of concurrent moves. The same convergence time holds also for a simple Nash Rerouting Policy, in which each mover actually has an incentive to move.

- *For unweighted Uniformly Related LBPLG, BALANCE has the same convergence time, but the Nash Rerouting Policy may converge in $\Omega(\sqrt{n})$ rounds.*

Finally, a generic result of [5] is mentioned, that computes a PNE for arbitrary *unweighted, player uniform* symmetric network congestion games in polynomial time, by a nice exploitation of Rosenthal's potential and the solution of a proper minimum cost flow problem. Therefore, for PLG the following result is implied:

Theorem 7 ([5]) *For unweighted, monotone PUPLG, a PNE can be constructed in polynomial time.*

Of course, this result provides no answer, e.g., for Restricted Assignment LBPLG, for which it is still not known how to efficiently compute PNE.

Status of Problem 3 and 4

The proposed LPT algorithm of [7] for constructing PNE in Uniformly Related LBPLG, actually provides a solution which is at most $1.52 < \texttt{PPoA}(LPT) < 1.67$ times worse than the optimum PNE (which is indeed the allocation of the goods to the links that minimizes the make-span). The construction of the optimum, as well as the worst PNE are hard problems, which nevertheless admits a PTAS (in some cases):

Theorem 8 *For LBPLG with a social cost function as defined in the Quality of Pure Equilibria paragraph:*

- *For Identical Machines, constructing the optimum or the worst PNE is* **NP***–hard* [7].
- *For Uniformly Related Machines, there is a PTAS for the optimum PNE* [6].
- *For Uniformly Related Machines, it holds that* $\texttt{PPoA} = \Theta\left(\min\left\{(\log m)/(\log\log m), \log(s_{\max})/(s_{\min})\right\}\right)$ [2].
- *For the Restricted Assignments,* $\texttt{PPoA} = \Omega((\log m)/(\log\log m))$ [10].
- *For a generalization of the Restricted Assignments, where the players have goods of any positive, otherwise infinite service demands from the links (and not only elements of $\{1, \infty\}$), it holds that $m - 1 \leq \texttt{PPoA} < m$* [10].

It is finally mentioned that a recent result [1] for unweighted, single commodity network congestion games with linear delays, is translated to the following result for PLG:

Theorem 9 ([1]) *For unweighted PUPLG with linear charging mechanisms for the links, the worst case PNE may be a factor of* $\texttt{PPoA} = 5/2$ *away from the optimum solution, wrt the social cost defined in the Quality of Pure Equilibria paragraph.*

Key Results

None

Applications

Congestion games in general have attracted much attention from many disciplines, partly because they capture a large class of routing and resource allocation scenarios.

PLG in particular, is the most elementary (non–trivial) atomic congestion game among a large number of players. Despite its simplicity, it was proved ([8] that it is asymptotically the worst case instance wrt the maximum individual cost measure, for a large class atomic congestion games involving the so called *layered networks*. Therefore, PLG is considered an excellent starting point for studying congestion games in large scale networks.

The importance of seeking for PNE, rather than arbitrary (mixed in general) NE, is quite obvious in sciences like the economics, ecology,

and biology. It is also important for computer scientists, since it enforces deterministic costs to the players, and both the players and the network designer may feel safer in this case about what they will actually have to pay.

The question whether the Nash Dynamics converge to a PNE in a reasonable amount of time, is also quite important, since (in case of a positive answer) it justifies the selfish, decentralized, local dynamics that appear in large scale communications systems. Additionally, the selfish rerouting schemes are of great importance, since this is what should actually be expected from selfish, decentralized computing environments.

Open Problems

Open Question 1 *Determine the (in)existence of PNE for all the instances of PLG that do not belong in LBPLG, or in monotone PSPLG.*

Open Question 2 *Determine the (in)existence of $k-$robust PNE for all the instances of PLG that do not belong in LBPLG.*

Open Question 3 *Is there a polynomial time algorithm for constructing $k-$robust PNE, even for the Identical Machines LBPLG and $k \geq 1$ being a constant?*

Open Question 4 *Do the improvement paths of instances of PLG other than PSPLG and LBPLG converge to a PNE?*

Open Question 5 *Are there selfish rerouting policies of instances of PLG other than Identical Machines LBPLG converge to a PNE? How long much time would they need, in case of a positive answer?*

Problem Definition

Concurrency, Synchronization and Resource Allocation

A *concurrent* system is a collection of processors that communicate by reading and writing from a shared memory. A distributed system is a collection of processors that communicate by sending messages over a communication network. Such systems are used for various reasons: to allow a large number of processors to solve a problem together much faster than any processor can do alone, to allow the distribution of data in several locations, to allow different processors to share resources such as data items, printers or discs, or simply to enable users to send electronic mail.

A *process* corresponds to a given computation. That is, given some program, its execution is a process. Sometimes, it is convenient to refer to the program code itself as a process. A process runs on a *processor*, which is the physical hardware. Several processes can run on the same processor although in such a case only one of them may be active at any given time. Real concurrency is achieved when several processes are running simultaneously on several processors.

Processes in a concurrent system often need to synchronize their actions. *Synchronization* between processes is classified as either cooperation or contention. A typical example for cooperation is the case in which there are two sets of processes, called the producers and the consumers, where the producers produce data items which the consumers then consume.

Contention arises when several processes compete for exclusive use of shared resources, such as data items, files, discs, printers, etc. For example, the integrity of the data may be destroyed if two processes update a common file at the same time, and as a result, deposits and withdrawals could be lost, confirmed reservations might have disappeared, etc. In such cases it is sometimes essential to allow at most one process to use a given resource at any given time.

Resource allocation is about interactions between processes that involve contention. The problem is, how to resolve conflicts resulting when several processes are trying to use shared resources. Put another way, how to allocate shared resources to competing processes. A special case of a general resource allocation problem is the *mutual exclusion* problem where only a single resource is available.

The Mutual Exclusion Problem

The *mutual exclusion* problem, which was first introduced by Edsger W. Dijkstra in 1965, is the guarantee of mutually exclusive access to a single shared resource when there are several competing processes [6]. The problem arises in operating systems, database systems, parallel supercomputers, and computer networks, where it is necessary to resolve conflicts resulting when several processes are trying to use shared resources. The problem is of great significance, since it lies at the heart of many interprocess synchronization problems.

The problem is formally defined as follows: it is assumed that each process is executing a sequence of instructions in an infinite loop. The instructions are divided into four continuous sections of code: the *remainder, entry, critical section* and *exit*. Thus, the structure of a mutual exclusion solution looks as follows:

loop forever
remainder code;
entry code;
critical section;
exit code
end loop

A process starts by executing the remainder code. At some point the process might need to execute some code in its critical section. In order to access its critical section a process has to go through an entry code which guarantees that while it is executing its critical section, no other process is allowed to execute its critical section. In addition, once a process finishes its critical section, the process executes its exit code in which it notifies other processes that it is no longer in its critical section. After executing the exit code the process returns to the remainder.

The Mutual exclusion problem is to write the code for the *entry code* and the *exit code* in such a way that the following two basic requirements are satisfied.

Mutual exclusion: *No two processes are in their critical sections at the same time.*

Deadlock-freedom: *If a process is trying to enter its critical section, then some process, not necessarily the same one, eventually enters its critical section.*

The deadlock-freedom property guarantees that the system as a whole can always continue to make progress. However deadlock-freedom may still allow "starvation" of individual processes. That is, a process that is trying to enter its critical section, may never get to enter its critical section, and wait forever in its entry code. A stronger requirement, which does not allow starvation, is defined as follows.

Starvation-freedom: *If a process is trying to enter its critical section, then this process must eventually enter its critical section.*

Although starvation-freedom is strictly stronger than deadlock-freedom, it still allows processes to execute their critical sections arbitrarily many times before some trying process can execute its critical section. Such a behavior is prevented by the following fairness requirement.

First-in-first-out (FIFO): *No beginning process can enter its critical section before a process that is already waiting for its turn to enter its critical section.*

The first two properties, mutual exclusion and deadlock freedom, were required in the original statement of the problem by Dijkstra. They are the minimal requirements that one might want to impose. In solving the problem, it is assumed that once a process starts executing its critical section the process always finishes it regardless of the activity of the other processes. Of all the problems in interprocess synchronization, the mutual exclusion problem is the one studied most extensively. This is a deceptive problem, and at first glance it seems very simple to solve.

Key Results

Numerous solutions for the problem have been proposed since it was first introduced by Edsger W. Dijkstra in 1965 [6]. Because of its importance and as a result of new hardware and software developments, new solutions to the problem are still being designed. Before the results are discussed, few models for interprocess communication are mentioned.

Atomic Operations

Most concurrent solutions to the problem assumes an architecture in which n processes communicate asynchronously via a shared objects. All architectures support *atomic registers*, which are shared objects that support atomic reads and writes operations. A weaker notion than an atomic register, called a *safe* register, is also considered in the literature. In a safe register, a read not concurrent with any writes must obtain the correct value, however, a read that is concurrent with some write, may return an arbitrary value. Most modern

architectures support also some form of atomicity which is stronger than simple reads and writes. Common atomic operations have special names. Few examples are,

- *Test-and-set*: takes a shared registers r and a value *val*. The value *val* is assigned to r, and the old value of r is returned.
- *Swap*: takes a shared registers r and a local register ℓ, and atomically exchange their values.
- *Fetch-and-increment*: takes a register r. The value of r is incremented by 1, and the old value of r is returned.
- *Compare-and-swap*: takes a register r, and two values: *new* and *old*. If the current value of the register r is equal to *old*, then the value of r is set to *new* and the value *true* is returned; otherwise r is left unchanged and the value *false* is returned.

Modern operating systems (such as Unix and Windows) implement synchronization mechanisms, such as semaphores, that simplify the implementation of mutual exclusion locks and hence the design of concurrent applications. Also, modern programming languages (such as Modula and Java) implement the monitor concept which is a program module that is used to ensure exclusive access to resources.

Algorithms and Lower Bounds

There are hundreds of beautiful algorithms for solving the problem some of which are also very efficient. Only few are mentioned below. First algorithms that use only atomic registers, or even safe registers, are discussed.

The Bakery Algorithm. The Bakery algorithm is one of the most known and elegant mutual exclusion algorithms using only safe registers [9]. The algorithm satisfies the FIFO requirement, however it uses unbounded size registers. A modified version, called the Black-White Bakery algorithm, satisfies FIFO and uses bounded number of bounded size atomic registers [14].

Lower bounds. A space lower bound for solving mutual exclusion using only atomic registers is that: any deadlock-free mutual exclusion algorithm for n processes must use at least n shared registers [5]. It was also shown in [5] that this bound is tight. A time lower bound for any mutual exclusion algorithm using atomic registers is that: there is no a priori bound on the number of steps taken by a process in its entry code until it enters its critical section (counting steps only when no other process is in its critical section or exit code) [2]. Many other interesting lower bounds exist for solving mutual exclusion.

A Fast Algorithm. A *fast* mutual exclusion algorithm, is an algorithm in which in the absence of contention only a constant number of shared memory accesses to the shared registers are needed in order to enter and exit a critical section. In [10], a fast algorithm using atomic registers is described, however, in the presence of contention, the winning process may have to check the status of all other n processes before it is allowed to enter its critical section. A natural question to ask is whether this algorithm can be improved for the case where there is contention.

Adaptive Algorithms. Since the other contending processes are waiting for the winner, it is particularly important to speed their entry to the critical section, by the design of an *adaptive* mutual exclusion algorithm in which the time complexity is independent of the total number of processes and is governed only by the current degree of contention. Several (rather complex) adaptive algorithms using atomic registers are known [1, 3, 14]. (Notice that, the time lower bound mention earlier implies that no adaptive algorithm using only atomic registers exists when time is measured by counting *all* steps.)

Local-spinning Algorithms. Many algorithms include busy-waiting loops. The idea is that in order to wait, a process *spins* on a flag register, until some other process terminates the spin with a single write operation. Unfortunately, under contention, such spinning may generate lots of traffic on the interconnection network between the process and the memory. An algorithm satisfies local spinning if the only type of spinning required is local spinning. Local Spinning is the situation where a process is spinning on locally-accessible registers. Shared registers may

be locally-accessible as a result of either coherent caching or when using distributed shared memory where shared memory is physically distributed among the processors.

Three local-spinning algorithms are presented in [4, 8, 11]. These algorithms use strong atomic operations (i.e., fetch-and-increment, swap, compare-and-swap), and are also called *scalable* algorithms since they are both local-spinning and adaptive. Performance studies done, have shown that these algorithms scale very well as contention increases. Local spinning algorithms using only atomic registers are presented in [1, 3, 14].

Only few representative results have been mentioned. There are dozens of other very interesting algorithms and lower bounds. All the results discussed above, and many more, are described details in [15]. There are also many results for solving mutual exclusion in distributed message passing systems [13].

Applications

Synchronization is a fundamental challenge in computer science. It is fast becoming a major performance and design issue for concurrent programming on modern architectures, and for the design of distributed and concurrent systems.

Concurrent access to resources shared among several processes must be synchronized in order to avoid interference between conflicting operations. Mutual exclusion *locks* (i.e., algorithms) are the de facto mechanism for concurrency control on concurrent applications: a process accesses the resource only inside a critical section code, within which the process is guaranteed exclusive access. The popularity of this approach is largely due the apparently simple programming model of such locks and the availability of implementations which are efficient and scalable. Essentially all concurrent programs (including operating systems) use various types of mutual exclusion locks for synchronization.

When using locks to protect access to a resource which is a large data structure (or a database), the *granularity* of synchronization is important. Using a single lock to protect the whole data structure, allowing only one process at a time to access it, is an example of *coarse-grained* synchronization. In contrast, *fine-grained* synchronization enables to lock "small pieces" of a data structure, allowing several processes with non-interfering operations to access it concurrently. Coarse-grained synchronization is easier to program but is less efficient and is not fault-tolerant compared to fine-grained synchronization. Using locks may degrade performance as it enforces processes to wait for a lock to be released. In few cases of simple data structures, such as queues, stacks and counters, locking may be avoided by using lock-free data structures.

In 1968, Edsger Wybe Dijkstra has published his famous paper "Co-operating sequential processes" [7], that originated the field of concurrent programming. The mutual exclusion problem was first stated and solved by Dijkstra in [6], where the first solution for two processes, due to Dekker, and the first solution for n processes, due to Dijkstra, have appeared. In [12], a collection of some early algorithms for mutual exclusion are described. In [15], dozens of algorithms for solving the mutual exclusion problems and wide variety of other synchronization problems are presented, and their performance is analyzed according to precise complexity measures.

Problem Definition

Consider a graph $G = (V, E)$. A subset C of V is called a *dominating set* if every vertex is either in C or adjacent to a vertex in C. If, furthermore, the subgraph induced by C is connected, then C is called a *connected dominating set*. A connected dominating set with a minimum cardinality is called a *minimum connected dominating set (MCDS)*. Computing an MCDS is an NP-hard problem and there is no polynomial-time approximation with performance ratio $\rho H(\Delta)$ for $\rho < 1$ unless $NP \subseteq DTIME(n^{O(\ln \ln n)})$ where H is the harmonic function and Δ is the maximum degree of the input graph [11].

A unit disk is a disk with radius one. A *unit disk graph (UDG)* is associated with a set of unit disks in the Euclidean plane. Each node is at the center of a unit disk. An edge exists between two nodes u and v if and only if $|uv| \leq 1$ where $|uv|$ is the Euclidean distance between u and v. This means that two nodes u and v are connected with an edge if and only if u's disk covers v and v's disk covers u.

Computing an MCDS in a unit disk graph is still NP-hard. How hard is it to construct a good approximation for MCDS in unit disk graphs? Cheng et al. [5] answered this question by presenting a polynomial-time approximation scheme.

Historical Background

The connected dominating set problem has been studied in graph theory for many years [23]. However, recently it becomes a hot topic due to its application in wireless networks for virtual backbone construction [4]. Guha and Khuller [11] gave a two-stage greedy approximation for the minimum connected dominating set in general graphs and showed that its performance ratio is $3 + \ln \Delta$ where Δ is the maximum node degree in the graph. To design a one-step greedy approximation to reach a similar performance

ratio, the difficulty is to find a submodular potential function. In [22], Ruan et al. successfully designed a one-step greedy approximation that reaches a better performance ratio $c + \ln \Delta$ for any $c > 2$. Du et al. [7] showed that there exists a polynomial-time approximation with a performance ratio $a(1 + \ln \Delta)$ for any $a > 1$. The importance of those works is that the potential functions used in their greedy algorithm are non-submodular and they managed to complete its theoretical performance evaluation with fresh ideas.

Guha and Khuller [11] also gave a negative result that there is no polynomial-time approximation with a performance ratio $\rho \ln \Delta$ for $\rho < 1$ unless $NP \subseteq DTIME(n^{O(\ln \ln n)})$. As indicated by [9], dominating sets cannot be approximated arbitrarily well, unless P almost equal to NP. These results move ones' attention from general graphs to unit disk graphs because the unit disk graph is the model for wireless sensor networks, and in unit disk graphs, MCDS has a polynomial-time approximation with a constant performance ratio. While this constant ratio is getting improved step-by-step [1, 2, 20, 25], Cheng et al. [5] closed this story by showing the existence of a polynomial-time approximation scheme (PTAS) for the MCDS in unit disk graphs. This means that theoretically, the performance ratio for polynomial-time approximation can be as small as $1+\varepsilon$ for any positive number ε.

Dubhashi et al. [8] showed that once a dominating set is constructed, a connected dominating set can be easily computed in a distributed fashion. Most centralized results for dominating sets are available at [19]. In particular, a simple constant approximation for dominating sets in unit disk graphs was presented in [19]. Constant-factor approximation for minimum-weight (connected) dominating sets in UDGs was studied in [3]. A PTAS for the minimum dominating set problem in UDGs was proposed in [21]. Kuhn et al. [16] proved that a maximal independent set (MIS) (and hence also a dominating set) can be computed in asymptotically optimal time $O(\log n)$ in UDGs and a large class of bounded independence graphs. Luby [18] reported an elegant local $O(\log n)$ algorithm for MIS on general graphs. Jia et al. [12] proposed a fast $O(\log n)$ distributed approximation for dominating set in general graphs. The first constant-time distributed algorithm for dominating sets that achieves a nontrivial approximation ratio for general graphs was reported in [13]. The matching $\Omega(\log n)$ lower bound is considered to be a classic result in distributed computing [17]. For UDGs a PTAS is achievable in a distributed fashion [15]. The fastest deterministic distributed algorithm for dominating sets in UDGs was reported in [14], and the fastest randomized distributed algorithm for dominating sets in UDGs was presented in [10].

Key Results

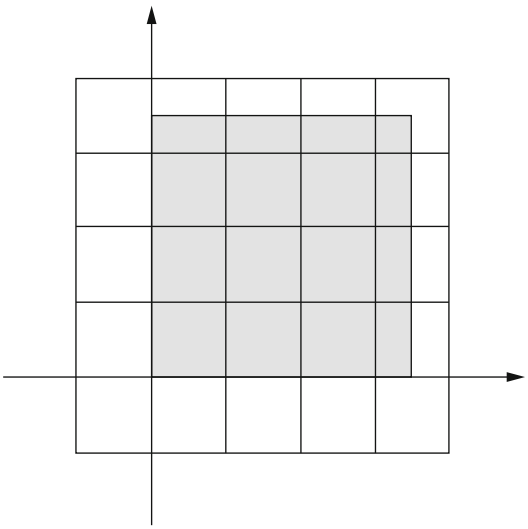
The construction of PTAS for MCDS is based on the fact that there is a polynomial-time approximation with a constant performance ratio. Actually, this fact is quite easy to see. First, note that a unit disk contains at most five independent vertices [2]. This implies that every maximal independent set has a size at most $1 + 4opt$ where opt is the size of an MCDS. Moreover, every maximal independent set is a dominating set and it is easy to construct a maximal independent set with a spanning tree of all edges with length two. All vertices in this spanning tree form a connected dominating set of a size at most $1 + 8opt$. By improving the upper bound for the size of a maximal independent set [26] and the way to interconnecting a maximal independent set [20], the constant ratio has been improved to 6.8 with a distributed implementation.

The basic techniques in this construction are nonadaptive partition and shifting. Its general picture is as follows: First, the square containing all vertices of the input unit disk graph is divided into a grid of small cells. Each small cell is further divided into two areas, the central area and the boundary area. The central area consists of points h distance away from the cell boundary. The boundary area consists of points within distance $h + 1$ from the boundary. Therefore, two areas are overlapping. Then a minimum union of connected dominating sets is computed in each cell

for connected components of the central area of the cell. The key lemma is to prove that the union of all such minimum unions is no more than the minimum connected dominating set for the whole graph. For vertices not in central areas, just use the part of an 8-approximation lying in boundary areas to dominate them. This part together with the above union forms a connected dominating set for the whole input unit disk graph. By shifting the grid around to get partitions at different coordinates, a partition having the boundary part with a very small upper bound can be obtained.

The following details the construction.

Given an input connected unit disk graph $G = (V, E)$ residing in a square $Q = \{(x, y)|0 \le x \le q, 0 \le y \le q\}$ where $q \le |V|$. To construct an approximation with a performance ratio $1 + \varepsilon$ for $\varepsilon > 0$, choose an integer $m = O((1/\varepsilon)\ln(1/\varepsilon))$. Let $p = \lfloor q/m \rfloor + 1$. Consider the square Q''. Partition $\bar{Q}$ into $(p + 1) \times (p + 1)$ grids so that each cell is an $m \times m$ square excluding the top and the right boundaries, and hence, no two cells are overlapping each other. This partition of $\bar{Q}$s is denoted by $P(0)$ (Fig. 1). In general, the partition $P(a)$ is obtained from $P(0)$ by shifting the bottom-left corner of $\bar{Q}$ from $(-m, -m)$ to $(-m + a, -m + a)$. Note that shifting from $P(0)$ to $P(a)$ for $0 \le a \le m$ keeps Q covered by the partition.



Connected Dominating Set, Fig. 1 Squares Q and $\bar{Q}$

For each cell e (an $m \times m$ square), $C_e(d)$ denotes the set of points in e away from the boundary by distance at least d, e.g., $C_e(0)$ is the cell e itself. Denote $B_e(d) = C_e(0) - C_e(d)$. Fix a positive integer $h = 7 + 3\lfloor \log_2(4m^2/\pi) \rfloor$. Call $C_e(h)$ the *central area* of e and $B_e(h + 1)$ the *boundary area* of e. Hence, the boundary area and the central area of each cell are overlapping with width one.

C

Central Area

Let $G_e(d)$ denote the part of input graph G lying in area $C_e(d)$. In particular, $G_e(h)$ is the part of graph G lying in the central area of e. $G_e(h)$ may consist of several connected components. Let K_e be a subset of vertices in $G_e(0)$ with a minimum cardinality such that for each connected component H of $G_e(h)$, K_e contains a connected component dominating H. In other words, K_e is a minimum union of connected dominating sets in $G(0)$ for the connected components of $G_e(h)$.

Now, denote by $K(a)$ the union of K_e for e over all cells in partition $P(a)$. $K(a)$ has two important properties:

Lemma 1 *$K(a)$ can be computed in time $n^{O(m2)}$.*

Lemma 2 *$|K^a| \le opt$ for $0 \le a \le m - 1$.*

Lemma 1 is not hard to see. Note that in a square with edge length $\sqrt{2}/2$, all vertices induce a complete subgraph in which any vertex must dominate all other vertices. It follows that the minimum dominating set for the vertices of $G_e(0)$ has size at most $\left(\left\lfloor \sqrt{2}m \right\rfloor\right)^2$. Hence, the size of K_e is at most $3\left(\left\lfloor \sqrt{2}m \right\rfloor\right)^2$ because any dominating set in a connected graph has a spanning tree with an edge length at most three. Suppose cell $G_e(0)$ has n_e vertices. Then the number of candidates for K_e is at most

$$\sum_{k=0}^{3(\lceil \sqrt{2}m \rceil)^2} \binom{n_e}{k} = n_e^{O(m^2)}.$$

Hence, computing $K(a)$ can be done in time

$$\sum_e n_e^{O(m^2)} \le \left(\sum_e n_e\right)^{O(m^2)} = n^{O(m^2)}.$$

However, the proof of Lemma 2 is quite tedious. The reader who is interested in it may find it in [5].

Boundary Area

Let F be a connected dominating set of G satisfying $|F| \le 8opt + 1$. Denote by $F(a)$ the subset of F lying in the boundary area $B_a(h+1)$. Since F is constructed in polynomial time, only the size of $F(a)$ needs to be studied.

Lemma 3 *Suppose* $h = 7 + 3\lfloor \log_2(4m^2/\pi)\rfloor$ *and* $\lfloor m/(h+1)\rfloor \ge 32/\varepsilon$. *Then there is at least half of* $i = 0, 1, \ldots, \lfloor m/(h+1)\rfloor - 1$ *such that* $|F(i(h+1))| \le \varepsilon \cdot opt$.

Proof Let $F_H(a)$ ($F_V(a)$) denote the subset of vertices in $F(a)$ each with distance $< h+1$ from the horizontal (vertical) boundary of some cell in $P(a)$. Then $F(a) = F_H(a) \cup F_V(a)$. Moreover, all $F_H(i(h+1))$ for $i = 0, 1, \ldots, \lfloor m/(h+1)\rfloor - 1$ are disjoint. Hence,

$$\sum_{i=0}^{\lfloor m/(h+1)\rfloor - 1} |F_H(i(h+1))| \le |F| \le 8opt.$$

Similarly, all $F_V(i(h+1))$ for $i = 0, 1, \ldots, \lfloor m/(h+1)\rfloor - 1$ are disjoint and

$$\sum_{i=0}^{\lfloor m/(h+1)\rfloor - 1} |F_V(i(h+1))| \le |F| \le 8opt.$$

Thus,

$$\sum_{i=0}^{\lfloor m/(h+1)\rfloor - 1} |F(i(h+1))| \le \sum_{i=0}^{\lfloor m/(h+1)\rfloor - 1} (|F_H(i(h+1))| + |F_V(i(h+1))|) \le 16opt.$$

That is,

$$\frac{1}{\lfloor m/(h+1)\rfloor} \sum_{i=0}^{\lfloor m/(h+1)\rfloor - 1} |F(i(h+1))| \le (\varepsilon/2)opt.$$

This means that there are at least half of $F(i(h+1))$ for $i = 0, 1, \lfloor m/(h+1)\rfloor - 1$ satisfying

$$|F(i(h+1))| \le \varepsilon \cdot opt.$$

□

Putting Together

Now put $K(a)$ and $F(a)$. By Lemmas 2 and 3, there exists $a \in \{0, h+1, \ldots, (\lfloor m/(h+1)\rfloor - 1)(h+1)\}$ such that

$$|K(a) \cup F(a)| \le (1+\varepsilon)opt.$$

Lemma 4 *For* $0 \le a \le m-1$, $K(a) \cup F(a)$ *is a connected dominating for input connected graph* G.

Proof $K(a) \cup F(a)$ is clearly a dominating set for input graph G. Its connectivity can be shown as follows. Note that the central area and the boundary area are overlapping with an area of width one. Thus, for any connected component H of the subgraph $G_e(h)$, $F(a)$ has a vertex in H. Hence, $F(a)$ must connect to any connected dominating set for H, especially, the one D_H in $K(a)$. This means that D_H is making up the connections of F lost from cutting a part in H. Therefore, the connectivity of $K(a) \cup F(a)$ follows from the connectivity of F. □

By summarizing the above results, the following result is obtained:

Theorem 1 *There is a* $(1+\varepsilon)$*-approximation for MCDS in connected unit disk graphs, running in time* $n^{O((1/\varepsilon)log(1/\varepsilon)2)}$.

Applications

An important application of connected dominating sets is to construct virtual backbones for wireless networks, especially, wireless sensor net-

works [4]. The topology of a wireless sensor network is often a unit disk graph.

Open Problems

In general, the topology of a wireless network is a disk graph, that is, each vertex is associated with a disk. Different disks may have different sizes. There is an edge from vertex u to vertex v if and only if the disk at u covers v. A virtual backbone in disk graphs is a subset of vertices, which induces a strongly connected subgraph, such that every vertex not in the subset has an in-edge coming from a vertex in the subset and also has an out-edge going into a vertex in the subset. Such a virtual backbone can be considered as a *connected dominating set* in disk graph. Is there a polynomial-time approximation with a constant performance ratio? It is still open right now [6]. Thai et al. [24] has made some effort towards this direction.

Problem Definition

Given a collection C of subsets of a finite set X, find a minimum subcollection C′ of C such that every element of X appears in some subset in C′. This problem is called the *minimum set-cover* problem. Every feasible solution, i.e., a subcollection C′ satisfying the required condition, is called a *set-cover*. The minimum set-cover problem is NP-hard, and the complexity of approximation for it is well solved. It is well known that (1) the minimum set-cover problem has a polynomial-time $(1 + \ln n)$-approximation where $n = |X|$ [2, 7, 8], and moreover (2) if the minimum set-cover problem has a polynomial-time $(\rho \ln n)$-approximation for any $0 < \rho < 1$, then $NP \subseteq DTIME(n^{O(\log \log n)})$ [4].

The *minimum connected set-cover* problem is closely related to the minimum set-cover problem, which can be described as follows: Given a collection C of subsets of a finite set X and a graph G with vertex set C, find a minimum set-cover C′ $\subseteq$ C such that the subgraph induced by C′ is connected. An issue of whether the minimum connected set-cover problem has a polynomial-time $O(\log n)$-approximation or not [1, 9, 11] was open for several years.

Key Results

Zhang et al. [12] solved this problem by discovering a relationship between the minimum connected set-cover problem and the group Steiner tree problem.

Given a graph $G = (V, E)$ with edge nonnegative weight $c : E \to N$ and k subsets (called groups) of vertices, $V_1, \ldots, V_k$, find the minimum edge-weight tree interconnecting those k vertex subsets, i.e., containing at least one vertex from each subset. This is called the *group Steiner tree* problem. It has another formulation as follows: Given a graph $G = (V, E)$ with edge nonnegative weight $c : E \to R^+$, a special vertex r, and k subsets of vertices, $V_1, \ldots, V_k$, find the minimum edge-weight tree with root r, interconnecting those k vertex subsets.

These two formulations are equivalent in the sense that one has a polynomial-time ρ-approximation and so does the other one. Actually, consider vertex r as a group with only one member. Then it is immediately known that if the first formulation has a polynomial-time ρ-

approximation, so does the second formulation. Next, assume the second formulation has a polynomial-time ρ-approximation. In the first formulation, fix a group V_1, for each vertex $v \in V_1$, and apply the polynomial-time ρ-approximation algorithm for the second formulation to the root $r = v$ and $k - 1$ groups $V_2, \ldots, V_k$. Choose the shortest one from $|V_1|$ obtained trees, which would be a polynomial-time ρ-approximation for the first formulation.

The following are well-known results for the group Steiner tree problem

Theorem 1 (Halperin and Krauthgamer [6]) *The group Steiner tree problem has no polynomial-time $O(\log^{2-\varepsilon} n)$-approximation for any $\varepsilon > 0$ unless NP has quasi-polynomial Las-Vega algorithm.*

Theorem 2 (Garg, Konjevod, Ravi [5]) *The group Steiner tree problem has a polynomial-time random $O(\log^2 n \log k)$-approximation where n is the number of nodes in the input graph and k is the number of groups.*

Zhang et al. [12] showed that if the minimum connected set-cover problem has a polynomial-time ρ-approximation, then for any $\varepsilon > 0$, there is a polynomial-time $(\rho + \varepsilon)$-approximation for the group Steiner tree problem. Therefore, by Theorem 1 they obtained the following result.

Theorem 3 (Zhang et al. [12]) *The connected set-cover problem has no polynomial-time $O(\log^{2-\varepsilon} n)$-approximation for any $\varepsilon > 0$ unless NP has quasi-polynomial Las-Vega algorithm.*

To obtain a good approximation for the minimum connected set-cover problem, Wu et al. [10] showed that if the group Steiner tree problem has a polynomial-time ρ-approximation, so does the minimum connected set-cover problem. Therefore, they obtained the following theorem.

Theorem 4 (Wu et al. [10]) *The connected set-cover problem has a polynomial-time random $O(\log^2 n \log k)$-approximation where $n = |\mathrm{C}|$ and $k = |X|$.*

Combining what have been proved by Zhang et al. [12] and by Wu et al. [10], it is easy to know the following relation.

Theorem 5 *The connected set-cover problem has a polynomial-time $(\rho + \varepsilon)$-approximation for any $\varepsilon > 0$ if and only if the group Steiner tree problem has a polynomial-time $(\rho + \varepsilon)$-approximation.*

This equivalence is also independently discovered by [3]. Actually, this equivalence is similar to the one between the minimum set-cover problem and the *minimum hitting set* problem.

For each element $x \in X$, define a collection of subsets:

$$\mathrm{C}_x = \{S \mid x \in S \in \mathrm{C}\}.$$

Then, the minimum set-cover problem becomes the minimum hitting set problem as follows: Given a finite set C and a collection of subsets of C, $\{\mathrm{C}_x \mid x \in\}$, find the minimum hitting set, i.e., a subset C' of C such that for every $x \in X$, $\mathrm{C}' \cap \mathrm{C}_x \neq \emptyset$.

Similarly, the minimum connected set-cover problem becomes the equivalent *connected hitting set* problem as follows: Given a finite set C, a graph G with vertex set C, and a collection of subsets of C, $\{\mathrm{C}_x \mid x \in\}$, find the minimum connected hitting set where a connected hitting set is a hitting set C' such that C' induces a connected subgraph of G.

To see the equivalence between the minimum connected hitting set problem and the group Steiner tree problem, it is sufficient to note the following two facts.

First, the existence of a connected hitting set C' is equivalent to the existence of a tree with weight $|\mathrm{C}'| - 1$, interconnecting groups C_x for all $x \in X$ when the graph G is given unit weight for each edge. This is because in the subgraph induced by C', we can construct a spanning tree with weight $|\mathrm{C}'| - 1$.

Second, a graph with nonnegative integer edge weight can be turned into an equivalent graph with unit edge weight by adding some new vertices to cut each edge with weight bigger than one into several edges with unit weight.

Open Problems

It is an open problem whether there exists or not a polynomial-time approximation for the minimum connected set-cover problem with performance ratio $O(\log^{\alpha} n)$ for $2 < \alpha < 3$.

Problem Definition

A new model of random graphs was introduced in [10], that of random regular graphs with edge faults (denoted hereafter by $G^r_{n,p}$), obtained by selecting the edges of a random member of the set of all regular graphs of degree r independently and with probability p. Such graphs can represent a communication network in which the links fail independently and with probability $f = 1 - p$. A formal definition of the probability space $G^r_{n,p}$ follows.

Definition 1 (The $G^r_{n,p}$ Probability Space) Let G^r_n be the probability space of all random regular graphs with n vertices where the degree of each vertex is r. The probability space $G^r_{n,p}$ of random regular graphs with edge faults is constructed by the following two subsequent random experiments: first, a random regular graph is chosen from the space G^r_n and, second, each edge is randomly and independently deleted from this graph with probability $f = 1 - p$.

Important connectivity properties of $G^r_{n,p}$ are investigated in this entry by estimating the ranges of r, f for which, with high probability, $G^r_{n,p}$

graphs (a) are highly connected (b) become disconnected and (c) admit a giant (i.e., of $\Theta(n)$ size) connected component of small diameter.

Notation. The terms "almost certainly" (a.c.) and "with high probability" (w.h.p.) will be frequently used with their standard meaning for random graph properties. A property defined in a random graph holds almost certainly when its probability tends to 1 as the independent variable (usually the number of vertices in the graph) tends to infinity. "With high probability" means that the probability of a property of the random graph (or the success probability of a randomized algorithm) is at least $1 - n^{-\alpha}$, where $\alpha > 0$ is a constant and n is the number of vertices in the graph.

The interested reader can further study [1] for an excellent exposition of the probabilistic method and its applications, [3] for a classic book on random graphs, as well as [6] for an excellent book on the design and analysis of randomized algorithms.

Key Results

Summary. This entry studies several important connectivity properties of random regular graphs with edge faults. In order to deal with the $G^r_{n,p}$ model, [10] first extends the notion of configurations and the translation lemma between configurations and random regular graphs provided by B. Bollobás [2, 3], by introducing the concept of *random configurations* to account for edge faults and by also providing an *extended translation lemma* between random configurations and random regular graphs with edge faults.

For this new model of random regular graphs with edge faults [10] shows that:

1. For all failure probabilities $f = 1 - p \leq n^{-\epsilon}$ ($\epsilon \geq \frac{3}{2r}$ fixed) and any $r \geq 3$ the biggest part of $G^r_{n,p}$ (i.e., the whole graph except of $O(1)$ vertices) remains connected and this connected part cannot be separated, almost certainly, unless more than r vertices are removed. Note interestingly that the situation for this range of f and r is very similar, despite the faults, to the properties of G^r_n which is r-connected for $r \geq 3$.
2. $G^r_{n,p}$ is *disconnected* a.c. for constant f and any $r = o(\log n)$ but is *highly connected*, almost certainly, when $r \geq \alpha \log n$, where $\alpha > 0$ an appropriate constant.
3. Even when $G^r_{n,p}$ becomes disconnected, it still has *a giant component of small diameter*, even when $r = O(1)$. An $O(n \log n)$-time algorithm to construct a giant component is provided.

Configurations and Translation Lemmata

Note that it is not as easy (from the technical point of view) as in the $G_{n,p}$ case to argue about random regular graphs, because of the stochastic dependencies on the existence of the edges due to regularity. The following notion of *configurations* was introduced by B. Bollobás [2, 3] to translate statements for random regular graphs to statements for the corresponding configurations which avoid the edge dependencies due to regularity and thus are much easier to deal with:

Definition 2 (Bollobás [2]) Let $w = \cup_{j=1}^{n} w_j$ be a fixed set of $2m = \sum_{j=1}^{n} d_j$ labeled vertices where $|w_j| = d_j$. A configuration F is a partition of w into m pairs of vertices, called edges of F.

Given a configuration F, let $\theta(F)$ be the (multi)graph with vertex set V in which (i, j) is an edge if and only if F has a pair (edge) with one element in w_i and the other in w_j. Note that every regular graph $G \in G^r_n$ is of the form $\theta(F)$ for exactly $(r!)^n$ configurations. However not every configuration F with $d_j = r$ for all j corresponds to a $G \in G^r_n$ since F may have an edge entirely in some w_j or parallel edges joining w_i and w_j.

Let ϕ be the set of all configurations F and let G^r_n be the set of all regular graphs. Given a property (set) $Q \subseteq G^r_n$ let $Q^* \subseteq \phi$ such that $Q^* \cap \theta^{-1}(G^r_n) = \theta^{-1}(Q)$. By estimating the probability of possible cycles of length one (self-loops) and two (loops) among pairs w_i, w_j in $\theta(F)$, the following important lemma follows:

Lemma 1 (Bollobás [3]) *If $r \geq 2$ is fixed and property Q^* holds for a.e. configuration, then property Q holds for a.e. $r-$regular graph.*

The main importance of the above lemma is that when studying random regular graphs, instead of considering the set of all random regular graphs, one can study the (much more easier to deal with) set of configurations.

In order to deal with edge failures, [10] introduces here the following extension of the notion of configurations:

Definition 3 (Random Configurations) Let $w = \cup_{j=1}^{n} w_j$ be a fixed set of $2m = \sum_{j=1}^{n} d_j$ labeled "vertices" where $|w_j| = d_j$. Let F be any configuration of the set ϕ. For each edge of F, remove it with probability $1 - p$, independently. Let $\hat{\phi}$ be the new set of objects and $\hat{F}$ the outcome of the experiment. $\hat{F}$ is called a *random configuration*.

By introducing probability p in every edge, an extension of the proof of Lemma 1 leads (since in both $\bar{Q}$ and $\hat{Q}$ each edge has the same probability and independence to be deleted, thus the modified spaces follow the properties of Q and Q^*) to the following extension to random configurations.

Lemma 2 (Extended Translation Lemma) *Let $r \geq 2$ fixed and $\bar{Q}$ be a property for $G_{n,p}^r$ graphs. If $\hat{Q}$ holds for a.e. random configuration, then the corresponding property $\bar{Q}$ holds for a.e. graph in $G_{n,p}^r$.*

Multiconnectivity Properties of $G_{n,p}^r$

The case of constant link failure probability f is studied, which represents a worst case for connectivity preservation. Still, [10] shows that logarithmic degrees suffice to guarantee that $G_{n,p}^r$ remains w.h.p. highly connected, despite these constant edge failures. More specifically:

Theorem 1 *Let G be an instance of $G_{n,p}^r$ where $p = \Theta(1)$ and $r \geq \alpha \log n$, where $\alpha > 0$ an appropriate constant. Then G is almost certainly k-connected, where*

$$k = O\left(\frac{\log n}{\log \log n}\right)$$

The proof of the above theorem uses Chernoff bounds to estimate the vertex degrees in $G_{n,p}^r$ and "similarity" of $G_{n,p}^r$ and $G_{n,p'}$ (whose properties are known) for a suitably chosen p'.

Now the (more practical) case in which $f = 1 - p = o(1)$ is considered and it is proved that the desired connectivity properties of random regular graphs are almost preserved despite the link failures. More specifically:

Theorem 2 *Let $r \geq 3$ and $f = 1 - p = O(n^{-\epsilon})$ for $\epsilon \geq \frac{3}{2r}$. Then the biggest part of $G_{n,p}^r$ (i.e., the whole graph except of $O(1)$ vertices) remains connected and this connected part (excluding the vertices that were originally neighbors of the $O(1)$-sized disconnected set) cannot be separated unless more than r vertices are removed, with probability tending to 1 as n tends to $+\infty$.*

The proof is carefully extending, in the case of faults, a known technique for random regular graphs about not admitting small separators.

$G_{n,p}^r$ Becomes Disconnected

Next remark that a constant link failure probability dramatically alters the connectivity structure of the regular graph in the case of low degrees. In particular, by using the notion of random configurations, [10] proves the following theorem:

Theorem 3 *When $2 \leq r \leq \frac{\sqrt{\log n}}{2}$ and $p = \Theta(1)$ then $G_{n,p}^r$ has at least one isolated node with probability at least $1 - n^{-k}, k \geq 2$.*

The regime for disconnection is in fact larger, since [10] shows that $G_{n,p}^r$ is a.c. disconnected even for any $r = o(\log n)$ and constant f. The proof of this last claim is complicated by the fact that due to the range for r one has to avoid using the extended translation lemma.

Existence of a Giant Component in $G_{n,p}^r$

Since $G_{n,p}^r$ is a.c. disconnected for $r = o(\log n)$ and $1 - p = f = \Theta(1)$, it would be interesting to know whether at least a large part

of the network represented by $G^r_{n,p}$ is still connected, i.e., whether the biggest connected component of $G^r_{n,p}$ is large. In particular, [10] shows that:

Theorem 4 *When $f < 1 - \frac{32}{r}$ then $G^r_{n,p}$ admits a giant (i.e., $\Theta(n)$-sized) connected component for any $r \geq 64$ with probability at least $1 - O\left(\frac{\log^2 n}{n^{\alpha/3}}\right)$, where $\alpha > 0$ a constant that can be selected.*

In fact, the proof of the existence of the component includes first proving the existence (w.h.p.) of a sufficiently long (of logarithmic size) path as a basis for a BFS process starting from the vertices of that path that creates the component. The proof is quite complex: occupancy arguments are used (bins correspond to the vertices of the graphs while balls correspond to its edges); however, the random variables involved are not independent, and in order to use Chernoff-Hoeffding bounds for concentration one must prove that these random variables, although not independent, are negatively associated. Furthermore, the evaluation of the success of the BFS process uses a careful, detailed average case analysis.

The path construction and the BFS process can be viewed as an algorithm that (in case of no failures) actually reveals a giant connected component. This algorithm is very efficient, as shown by the following result:

Theorem 5 *A giant component of $G^r_{n,p}$ can be constructed in $O(n \log n)$ time, with probability at least $1 - O\left(\frac{\log^2 n}{n^{\alpha/3}}\right)$, where $\alpha > 0$ a constant that can be selected.*

Applications

In recent years the development and use of distributed systems and communication networks has increased dramatically. In addition, state-of-the-art multiprocessor architectures compute over structured, regular interconnection networks. In such environments, several applications may share the same network while executing concurrently. This may lead to unavailability of certain network resources (e.g., links) for certain applications. Similarly, faults may cause unavailability of links or nodes. The aspect of *reliable distributed computing* (which means computing with the available resources and resisting faults) adds value to applications developed in such environments.

When computing in the presence of faults, one cannot assume that the actual structure of the computing environment is known. Faults may happen even in execution time. In addition, what is a "faulty" or "unavailable" link for one application may in fact be the de-allocation of that link because it is assigned (e.g., by the network operation system) to another application. The problem of analyzing allocated computation or communication in a network over a *randomly assigned subnetwork* and *in the presence of faults* has a nature different from fault analysis of special, well-structured networks (e.g., hypercube), which does not deal with network aspects. The work presented in this entry addresses this interesting issue, i.e., analyzing the average case taken over a set of possible topologies and focuses on multiconnectivity and existence of giant component properties required for reliable distributed computing in such randomly allocated unreliable environments.

The following important application of this work should be noted: multitasking in distributed memory multiprocessors is usually performed by assigning an arbitrary subnetwork (of the interconnection network) to each task (called the *computation graph*). Each parallel program may then be expressed as communicating processors over the computation graph. Note that a multiconnectivity value k of the computation graph means also that the execution of the application can tolerate up to $k - 1$ *online additional faults*.

Open Problems

The ideas presented in [10] inspired already further interesting research. Andreas Goerdt [4] continued the work presented in a preliminary version [8] of [10] and showed the following results: if the degree r is fixed then $p = \frac{1}{r-1}$ is a

threshold probability for the existence of a linear-sized component in the faulty version of almost all random regular graphs. In fact, he further shows that if each edge of an *arbitrary* graph G with maximum degree bounded above by r is present with probability $p = \frac{\lambda}{r-1}$, when $\lambda < 1$, then the faulty version of G has only components whose size is at most logarithmic in the number of nodes, with high probability. His result implies some kind of optimality of random regular graphs with edge faults. Furthermore, [5, 7] investigates important expansion properties of random regular graphs with edge faults, as well as [9] does in the case of fat trees, a common type of interconnection networks. It would be also interesting to further pursue this line of research, by also investigating other combinatorial properties (and also provide efficient algorithms) for random regular graphs with edge faults.

Consensus with Partial Synchrony

Bernadette Charron-Bost[1] and André Schiper[2]
[1]Laboratory for Informatics, The Polytechnic School, Palaiseau, France
[2]EPFL, Lausanne, Switzerland

Keywords

Agreement problem

Years and Authors of Summarized Original Work

1988; Dwork, Lynch, Stockmeyer

Problem Definition

Reaching agreement is one of the central issues in fault tolerant distributed computing. One version of this problem, called *Consensus*, is defined over a fixed set $\Pi = \{p_1, \ldots, p_n\}$ of n processes that communicate by exchanging messages along channels. Messages are correctly transmitted (no duplication, no corruption), but some of them may be lost. Processes may fail by prematurely stopping (crash), may omit to send or receive some messages (omission), or may compute erroneous values (Byzantine faults). Such processes are said to be *faulty*. Every process $p \in \Pi$ has an initial value v_p and non-faulty processes must decide irrevocably on a common value v. Moreover, if the initial values are all equal to the same value v, then the common decision value is v. The properties that define Consensus can be split into safety properties (processes decide on the same value; the decision value must be consistent with initial values) and a liveness property (processes must eventually decide).

Various Consensus algorithms have been described [6, 12] to cope with any type of process

failures if there is a known (Intuitively, "known bound" means that the bound can be "built into" the algorithm. A formal definition is given in the next section.) bound on the transmission delay of messages (*communication is synchronous*) and a known bound on process relative speeds (*processes are synchronous*). In completely asynchronous systems, where there exists no bound on transmission delays and no bound on process relative speeds, Fischer, Lynch, and Paterson [8] have proved that there is no Consensus algorithm resilient to even one crash failure. The paper by Dwork, Lynch, and Stockmeyer [7] introduces the concept of *partial synchrony*, in the sense it lies between the completely synchronous and completely asynchronous cases, and shows that partial synchrony makes it possible to solve Consensus in the presence of process failures, whatever the type of failure is.

For this purpose, the paper examines the quite realistic case of asynchronous systems that behave synchronously during some "good" periods of time. Consensus algorithms designed for synchronous systems do not work in such systems since they may violate the safety properties of Consensus during a bad period, that is when the system behaves asynchronously. This leads to the following question: is it possible to design a Consensus algorithm that never violates safety conditions in an asynchronous system, while ensuring the liveness condition when some additional conditions are met?

Key Results

The paper has been the first to provide a positive and comprehensive answer to the above question. More precisely, the paper (1) defines various types of partial synchrony and introduces a new round based computational model for partially synchronous systems, (2) gives various Consensus algorithms according to the severity of failures (crash, omission, Byzantine faults with or without authentication), and (3) shows how to implement the round based computational model in each type of partial synchrony.

Partial Synchrony

Partial synchrony applies both to communications and to processes. Two definitions for *partially synchronous communications* are given: (1) for each run, there exists an upper bound Δ on communication delays, but Δ is *unknown* in the sense it depends on the run; (2) there exists an upper bound Δ on communication delays that is common for all runs (Δ is *known*), but holds only after some time T, called the *Global Stabilization Time* (*GST*) that may depend on the run (*GST* is *unknown*). Similarly, *partially synchronous processes* are defined by replacing "transmission delay of messages" by "relative process speeds" in (1) and (2) above. That is, the upper bound on relative process speed Φ is unknown, or Φ is known but holds only after some unknown time.

Basic Round Model

The paper considers a round based model: computation is divided into *rounds* of message exchange. Each round consists of a *send step*, a *receive step*, and then a *computation step*. In a send step, each process sends messages to any subset of processes. In a receive step, some subset of the messages sent to the process during the send step at the *same* round is received. In a computation step, each process executes a state transition based on its current state and the set of messages just received.

Some of the messages that are sent may not be received, i.e., some can be lost. However, the *basic round model* assumes that there is some round GSR, such that all messages sent from non faulty processes to non faulty processes at round GSR or afterward are received.

Consensus Algorithm for Benign Faults (Requires $f < n/2$)

In the paper, the algorithm is only described informally (textual form). A formal expression is given by Algorithm 1: the code of each process is given round by round, and each round is specified by the send and the computation steps (the receive step is implicit). The constant f denotes the maximum number of processes that may be faulty (crash or omission). The algorithm requires $f < n/2$.

Algorithm 1 Consensus algorithm in the basic round model for benign faults ($f < n/2$)

```
 1: Initialization:
 2:     Acceptable_p := {v_p}                                   {v_p is the initial value of p}
 3:     Proper_p := {v_p}          {All the lines for maintaining Proper_p are trivial to write, and so are omitted}
 4:     vote_p := ⊥
 5:     Lock_p := ∅

 6: Round r = 4k − 3:
 7:     Send:
 8:         send ⟨Acceptable_p⟩ to coord_k

 9:     Compute:
10:         if p = coord_k and p receives at least ≥ n − f messages containing a common value then
11:             vote_p := select one of these common acceptable values

12: Round r = 4k − 2:
13:     Send:
14:         if p = coord_k and vote_p ≠ ⊥ then
15:             send ⟨vote_p⟩ to all processes

16:     Compute:
17:         if received ⟨v⟩ from coord_k then
18:             Lock_p := Lock_p ∖ {v, −}; Lock_p := Lock_p ∪ {(v, k)};

19: Round r = 4k − 1:
20:     Send:
21:         if ∃v s.t. (v, k) ∈ Lock_p then
22:             send ⟨ack⟩ to coord_k

23:     Compute:
24:         if p = coord_k then
25:             if received at least ≥ f + 1 ack messages then
26:                 DECIDE(vote_p);
27:             vote_p := ⊥

28: Round r = 4k:
29:     Send:
30:         send ⟨Lock_p⟩ to all processes

31:     Compute:
32:         for all (v, θ) ∈ Lock_p do
33:             if received (w, θ̄) s.t. w ≠ v and θ̄ ≥ θ then                {release lock on v}
34:                 Lock_p := Lock_p ∪ {(w, θ̄)} ∖ {(v, θ)};
35:         if |Lock_p| = 1 then
36:             Acceptable_p := v where (v, −) ∈ Lock_p
37:         else
38:             if Lock_p = ∅ then Acceptable_p := Proper_p else Acceptable_p := ∅
```

Rounds are grouped into phases, where each phase consists in four consecutive rounds. The algorithm includes the rotating coordinator strategy: each phase k is led by a unique coordinator – denoted by $coord_k$ – defined as process p_i for phase $k = i\,(mod\ n)$. Each process p maintains a set $Proper_p$ of values that p has heard of (*proper* values), initialized to $\{v_p\}$ where v_p is p's initial value. Process p attaches $Proper_p$ to each message it sends.

Process p may *lock* value v when p thinks that some process might decide v. Thus value v is an *acceptable* value to p if (1) v is a proper value to p, and (2) p does not have a lock on any value except possibly v (lines 35–38).

At the first round of phase k (round $4k-3$), each process sends the list of its acceptable values to $coord_k$. If $coord_k$ receives at least $n-f$ sets of acceptable values that all contain some value v, then $coord_k$ votes for v (line 11), and sends its vote to all at second round $4k-2$. Upon receiving a vote for v, any process locks v in the current phase (line 18), releases any earlier lock on v, and sends an acknowledgment to $coord_k$ at the next round $4k-1$. If the latter process receives acknowledgments from at least $f+1$ processes, then it decides (line 26). Finally locks are released at round $4k$ – for any value v, only the lock from the most recent phase is kept, see line 34 – and the set of values *acceptable* to p is updated (lines 35–38).

Consensus Algorithm for Byzantine Faults (Requires $f < n/3$)

Two algorithms for Byzantine faults are given. The first algorithm assumes *signed messages*, which means that any process can verify the origin of all messages. This fault model is

called *Byzantine faults with authentication*. The algorithm has the same phase structure as Algorithm 1. The difference is that (1) messages are signed, and (2) "proofs" are carried by some messages. A proof carried by message m sent by some process p_i in phase k consists of a set of signed messages $sgn_j(m', k)$, proving that p_i received message (m', k) in phase k from p_j before sending m. A proof is carried by the message send at line 16 and line 30 (Algorithm 1). Any process receiving a message carrying a proof accepts the message and behaves accordingly if – and only if the proof is found valid. The algorithm requires $f < n/3$ (less than a third of the processes are faulty).

The second algorithm does not assume a mechanism for signing messages. Compared to Algorithm 1, the structure of a phase is slightly changed. The problem is related to the vote sent by the coordinator (line 15). Can a Byzantine coordinator fool other processes by not sending the right vote? With signed messages, such a behavior can be detected thanks to the "proofs" carried by messages. A different mechanism is needed in the absence of signature.

The mechanism is a small variation of the *Consistent Broadcast* primitive introduced by Srikanth and Toueg [15]. The broadcast primitive ensures that (1) if a non faulty process broadcasts m, then every non faulty process delivers m, and (2) if some non faulty process delivers m, then all non faulty processes also eventually deliver m. The implementation of this broadcast primitive requires two rounds, which define a *superround*. A phase of the algorithm consists now of three superrounds. The superrounds $3k-2$, $3k-1$, $3k$ mimic rounds $4k-3$, $4k-2$, and $4k-1$ of Algorithm 1, respectively. Lock-release of phase k occurs at the end of superround $3k$, i.e., does not require an additional round, as it does in the two previous algorithms. The algorithm also requires $f < n/3$.

The Special Case of Synchronous Communication

By strengthening the round based computational model, the authors show that synchronous communication allow higher resiliency. More precisely, the paper introduces the model called the *basic round model with signals*, in which upon receiving a signal at round r, every process knows that all the non faulty processes have received the messages that it has sent during round r. At each round after *GSR*, each non faulty process is guaranteed to receive a signal. In this computational model, the authors present three new algorithms tolerating less than n benign faults, $n/2$ Byzantine faults with authentication, and $n/3$ Byzantine faults respectively.

Implementation of the Basic Round Model

The last part of the paper consists of algorithms that simulate the basic round model under various synchrony assumption, for crash faults and Byzantine faults: first with partially synchronous communication and synchronous processes (case 1), second with partially synchronous communication and processes (case 2), and finally with partially synchronous processes and synchronous communication (case 3).

In case 1, the paper first assumes the basic case $\Phi = 1$, i.e., all non faulty process progress exactly at the same speed, which means that they have a common notion of time. Simulating the basic round model is simple in this case. In case 2 processes do not have a common notion of time. The authors handle this case by designing an algorithm for clock synchronization. Then each process uses its private clock to determine its current round. So processes alternate between steps of the clock synchronization algorithm and steps simulating rounds of the basic round model. With synchronous communication (case 3), the authors show that for any type of faults, the so-called basic round model with signals is implementable.

Note that, from the very definition of partial synchrony, the six algorithms share the fundamental property of tolerating message losses, provided they occur during a finite period of time.

Upper Bound for Resiliency

In parallel, the authors exhibit upper bounds for the resiliency degree of Consensus algorithms in each partially synchronous model, according to the type of faults. They show that their Consensus

Consensus with Partial Synchrony, Table 1 Tight resiliency upper bounds (P stands for "process", C for "communication"; 0 means "asynchronous", 1/2 means "partially synchronous", and 1 means "synchronous")

	$P = 0 \quad C = 0$	$P = 1/2 \quad C = 1/2$	$P = 1 \quad C = 1/2$	$P = 1/2 \quad C = 1$	$P = 1 \quad C = 1$
Benign	0	$\lceil (n-1)/2 \rceil$	$\lceil (n-1)/2 \rceil$	$n-1$	$n-1$
Authenticated Byzantine	0	$\lceil (n-1)/3 \rceil$	$\lceil (n-1)/3 \rceil$	$\lceil (n-1)/2 \rceil$	$n-1$
Byzantine	0	$\lceil (n-1)/3 \rceil$	$\lceil (n-1)/3 \rceil$	$\lceil (n-1)/3 \rceil$	$\lceil (n-1)/3 \rceil$

algorithms achieve these upper bounds, and so are optimal with respect to their resiliency degree. These results are summarized in Table 1.

Applications

Availability is one of the key features of critical systems, and is defined as the ratio of the time the system is operational over the total elapsed time. Availability of a system can be increased by replicating its critical components. Two main classes of replication techniques have been considered: *active* replication and *passive* replication. The Consensus problem is at the heart of the implementation of these replication techniques. For example, active replication, also called *state machine replication* [10, 14], can be implemented using the group communication primitive called *Atomic Broadcast*, which can be reduced to Consensus [3].

Agreement needs also to be reached in the context of distributed transactions. Indeed, all participants of a distributed transaction need to agree on the output *commit* or *abort* of the transaction. This agreement problem, called *Atomic Commitment*, differs from Consensus in the validity property that connects decision values (*commit* or *abort*) to the initial values (favorable to commit, or demanding abort) [9]. In the case decisions are required in all executions, the problem can be reduced to Consensus if the abort decision is acceptable although all processes were favorable to commit, in some restricted failure cases.

Open Problems

A slight modification to each of the algorithms given in the paper is to force a process repeatedly to broadcast the message "Decide v" after it decides v. Then the resulting algorithms share the property that all non faulty processes definitely make a decision within $O(f)$ rounds after GSR, and the constant factor varies between 4 (benign faults) and 12 (Byzantine faults). A question raised by the authors at the end of the paper is whether this constant can be reduced. Interestingly, a positive answer has been given later, in the case of benign faults and $f < n/3$, with a constant factor of 2 instead of 4. This can be achieved with deterministic algorithms, see [4], based on the communication schema of the Rabin randomized Consensus algorithm [13].

The second problem left open is the generalization of this algorithmic approach – namely, the design of algorithms that are always safe and that terminate when a sufficiently long good period occurs – to other fault tolerant distributed problems in partially synchronous systems. The latter point has been addressed for the Atomic Commitment and Atomic Broadcast problems (see section "Applications").

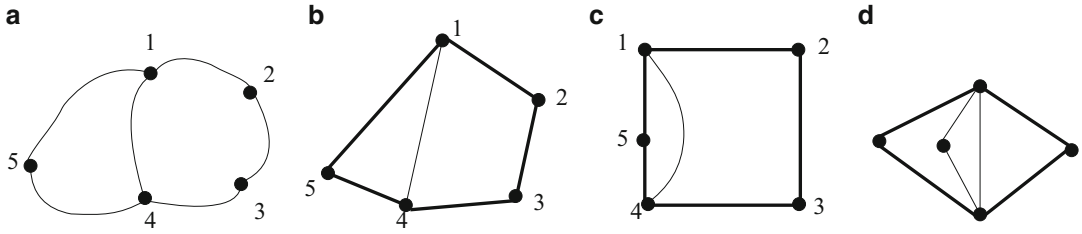
1984; Chiba, Yamanouchi, Nishizeki

Problem Definition

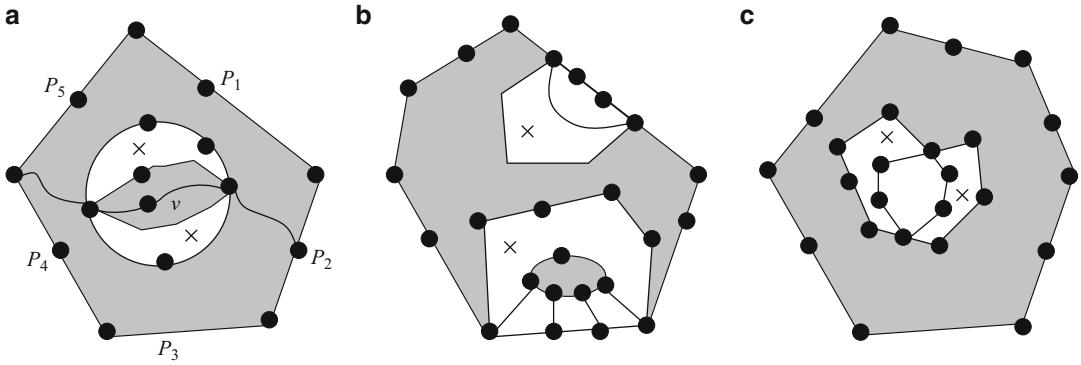
A convex drawing of a planar graph G is a planar drawing of G where every vertex is drawn as a point, every edge is drawn as a straight line segment, and every face is drawn as a convex polygon. Not every planar graph has a convex drawing. The planar graph in Fig. 1a has a convex drawing as shown in Fig. 1b whereas the planar graph in Fig. 1d has no convex drawing. Tutte [11] showed that every 3-connected planar graph has a convex drawing, and obtained a necessary and sufficient condition for a planar graph to have a convex drawing with a prescribed outer polygon. Furthermore, he gave a "barycentric mapping" method for finding a convex drawing, which requires solving a system of $O(n)$ linear equations [12] and leads to an $O(n^{1.5})$ time convex drawing algorithm for a planar graph with a fixed embedding. Development of faster algorithms for determining whether a planar graph (where the embedding is not fixed) has a convex drawing and finding such a drawing if it exits is addressed in the paper of Chiba, Yamanouchi, and Nishizeki [2].

A Characterization for Convex Drawing A plane graph is a planar graph with a fixed embedding. In a convex drawing of a plane graph G, the outer cycle $C_o(G)$ is also drawn as a convex polygon. The polygonal drawing C_o^* of $C_o(G)$, called an *outer convex polygon*, plays a crucial role in finding a convex drawing of G. The plane graph G in Fig. 1a admits a convex drawing if an outer convex polygon C_o^* has all vertices 1, 2, 3, 4, and 5 of $C_o(G)$ as the *apices* (i.e., geometric vertices) of C_o^*, as illustrated in Fig. 1b. However, if C_o^* has only apices 1, 2, 3, and 4, then G does not admit a convex drawing as depicted in Fig. 1c. We say that an outer convex polygon C_o^* is *extendible* if there exists a convex drawing of G in which $C_o(G)$ is drawn as C_o^*. Thus, the outer convex polygon drawn by thick lines in Fig. 1b is extendible, while that in Fig. 1c is not. If the outer facial cycle C_o has an extendible outer convex polygon, we say that the facial cycle C_o is *extendible.*

Tutte established a necessary and sufficient condition for an outer convex polygon to be



Convex Graph Drawing, Fig. 1 Plane graphs and drawings



Convex Graph Drawing, Fig. 2 G and C_o^* violating Conditions (i)–(iii) in Theorem 1

extendible [11]. The following theorem obtained by Thomassen [9] is slightly more general than the result of Tutte.

Theorem 1 *Let G be a 2-connected plane graph, and let C_o^* be an outer convex polygon of G. Let C_o^* be a k-gon, $k \geq 3$, and let $P_1, P_2, \ldots, P_k$ be the paths in $C_o(G)$, each corresponding to a side of the polygon C_o^*, as illustrated in Fig. 2a. Then, C_o^* is extendible if and only if the following Conditions (i)–(iii) hold.*

(i) For each inner vertex v with $d(v) \geq 3$, there exist three paths disjoint except v, each joining v and an outer vertex.
(ii) $G - V(C_o(G))$ has no connected component H such that all the outer vertices adjacent to vertices in H lie on a single path P_i, and no two outer vertices in each path P_i are joined by an inner edge.
(iii) Any cycle containing no outer edge has at least three vertices of degree ≥ 3.

Figure 2a–c violate Conditions (i)–(iii) of Theorem 1, respectively, where each of the faces marked by $\times$ cannot be drawn as a convex polygon.

Key Results

Two linear algorithms for convex drawings are the key contribution of the paper of Chiba, Yamanouchi, and Nishizeki [2]. One algorithm is for finding a convex drawing of a plane graph if it exists, and the other algorithm is for testing whether there is a planar embedding of a given planar graph which has a convex drawing. Thus, the main result of the paper can be stated as in the following theorem.

Theorem 2 *Let G be a 2-connected planar graph. Then, one can determine whether G has a convex drawing in linear time and find such a drawing in linear time if it exists.*

Convex Drawing Algorithm

In this section, we describe the drawing algorithm of Chiba, Yamanouchi, and Nishizeki [2] which is

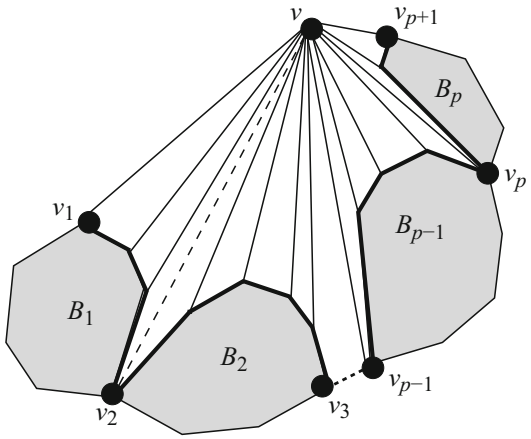
based on Thomassen's short proof of Theorem 1. Suppose that a 2-connected plane graph G and an outer convex polygon C_o^* satisfy conditions in Theorem 1. The convex drawing algorithm extends C_o^* into a convex drawing of G in linear time. For simplicity, it is assumed that every inner vertex has degree three or more in G. Otherwise, replace each maximal induced path not on $C_o(G)$ by a single edge joining its ends (the resulting simple graph G' satisfies Conditions (i)–(iii) of Theorem 1); then, find a convex drawing of G'; and finally, subdivide each edge substituting a maximal induced path.

They reduce the convex drawing of G to those of several subgraphs of G as follows: delete from G an arbitrary apex v of the outer convex polygon C_o^* together with the edges incident to v; divide the resulting graph $G' = G - v$ into blocks $B_1, B_2, \ldots, B_p$, $p \geq 1$ as illustrated in Fig. 3; determine an outer convex polygon C_i^* of each block B_i so that B_i with C_i^* satisfies Conditions (i)–(iii) of Theorem 1; and recursively apply the algorithm to each block B_i with C_i^* to determine the position of inner vertices of B_i.

The recursive algorithm described above can be implemented in linear time by ensuring that only the edges which newly appear on the outer face are traversed in each recursive step.

Convex Testing Algorithm

In this section, we describe the convex testing algorithm of Chiba, Yamanouchi, and Nishizeki [2] which implies a constructive proof of Theorem 2. They have modified the conditions in Theorem 1 into a form suitable for the convex testing, which is represented in terms of 3-connected components. Using the form, they have shown that the convex testing of a planar graph G can be reduced to the planarity testing of a certain graph obtained from G.



Convex Graph Drawing, Fig. 3 Reduction of the convex drawing of G into subproblems

To describe the convex testing algorithm, we need some definitions. A pair $\{x, y\}$ of vertices of a 2-connected graph $G = (V, E)$ is called a *separation pair* if there exists two subgraphs $G_1' = (V_1, E_1')$ and $G_2' = (V_2, E_2')$ satisfying the following conditions (a) and (b): (a) $V = V_1 \cup V_2, V_1 \cap V_2 = \{x, y\}$; and (b) $E = E_1' \cup E_2', E_1' \cap E_2' = \emptyset, |E_1'| \geq 2, |E_2'| \geq 2$. For a separation pair $\{x, y\}$ of G, $G_1 = (V_1, E_1' + (x, y))$ and $G_2 = (V_2, E_2' + (x, y))$ are called the *split graphs* of G. The new edges (x, y) added to G_1 and G_2 are called the *virtual edges*. Dividing a graph G into two split graphs G_1 and G_2 is called *splitting*. Reassembling the two split graphs G_1 and G_2 into G is called *merging*. Suppose that a graph G is split, the split graphs are split, and so on, until no more splits are possible. The graphs constructed in this way are called the *split components* of G. The split components are of three types: triple bonds (i.e., a set of three multiple edges), triangles, and 3-connected graphs. The *3-connected components* of G are obtained from the split components of G by merging triple bonds into a bond and triangles into a ring, as far as possible, where a *bond* is a set of multiple edges and a *ring* is a cycle. Note that the split components of G are not necessarily unique, but the 3-connected components of G are unique [5].

A separation pair $\{x, y\}$ is *prime* if x and y are the end vertices of a virtual edge contained in a 3-connected component. Suppose that $\{x, y\}$ is a prime separation pair of a graph G and that G is split at $\{x, y\}$, the split graphs are split, and so on, until no more splits are possible at $\{x, y\}$. A graph constructed in this way is called an $\{x, y\}$-*split component* of G if it has at least one real (i.e., non-virtual) edge.

In some cases, it can be easily known only from the $\{x, y\}$-split components for a single

separation pair $\{x, y\}$ that a graph G has no convex drawing. A prime separation pair $\{x, y\}$ of G is called a *forbidden separation pair* if there are either (a) at least four $\{x, y\}$-split components or (b) exactly three $\{x, y\}$-split components, each of which is neither a ring nor a bond. Note that an $\{x, y\}$-split component corresponds to an edge (x, y) if it is a bond and to a subdivision of an edge (x, y) if it is a ring. One can easily know that if a planar graph G has a forbidden separation pair, then any plane embedding of G has no convex drawing, that is, G has no extendible facial cycle. On the other hand, the converse of the fact above is not true. A prime separation pair $\{x, y\}$ is called a *critical separation pair* if there are either (i) exactly three $\{x, y\}$-split components including a bond or a ring or (ii) exactly two $\{x, y\}$-split components each of which is neither a bond nor a ring. When a planar graph G has no forbidden separation pair, two cases occur: if G has no critical separation pair either, then G is a subdivision of a 3-connected graph, and so every facial cycle of G is extendible; otherwise, that is, if G has critical separation pairs, then a facial cycle F of G may or may not be extendible, depending on the interaction of F and critical separation pairs.

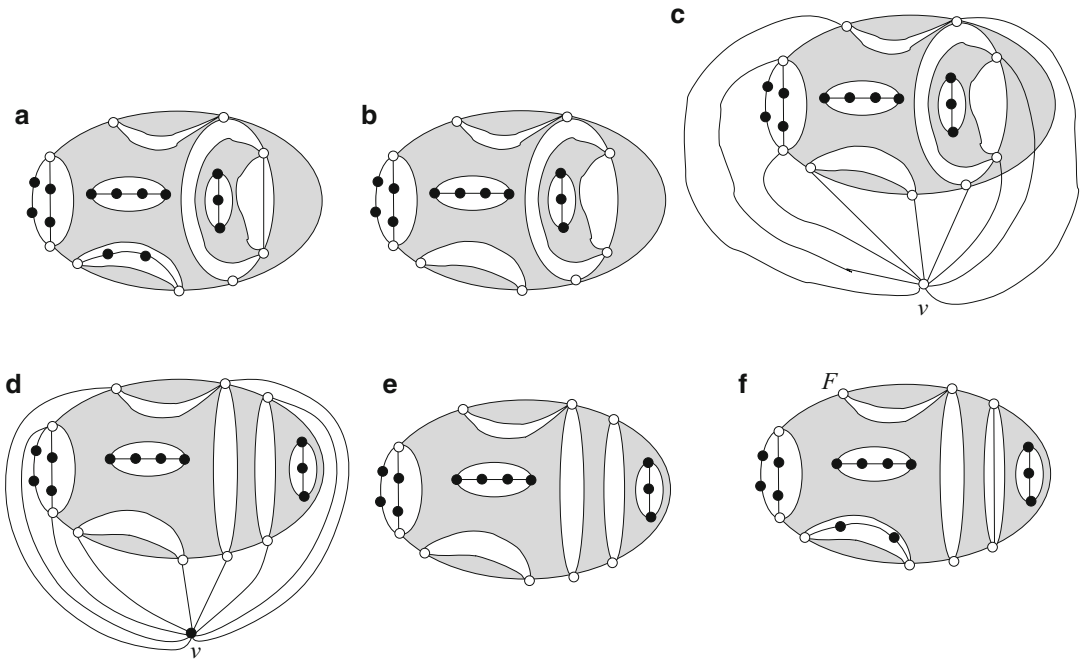
Using the concepts of forbidden separation pairs and critical separation pairs, Chiba et al. gave the following condition in Theorem 3 which is suitable for the testing algorithm. They proved that the condition in Theorem 3 is equivalent to the condition in Theorem 1 under a restriction that the outer convex polygon C_o^* is strict, that is, every vertex of $C_o(G)$ is an apex of C_o^* [2].

Theorem 3 *Let $G = (V, E)$ be a 2-connected plane graph with the outer facial cycle $F = C_o(G)$, and let C_o^* be an outer strict convex polygon of G. Then, C_o^* is extendible if and only if G and F satisfy the following conditions.*

(a) G has no forbidden separation pair.
(b) For each critical separation pair $\{x, y\}$ of G, there is at most one $\{x, y\}$-split component having no edge of F, and, if any, it is either a bond if $(x, y) \in E$ or a ring, otherwise.

The convex testing condition in Theorem 3 is given for a plane graph. Note that Condition (a) does not depend on a plane embedding. Thus, to test whether a planar graph G has a convex drawing, it is needed to test whether G satisfies Condition (a) or not and if G satisfies Condition (a) then test whether G has a plane embedding such that its outer face F satisfies Condition (b) in Theorem 3. With some simple observation, it is shown that every graph G having no forbidden separation pair has an embedding such that the outer face satisfies Condition (b) if G has at most one critical separation pair. Hence, every planar graph with no forbidden separation pair and at most one critical separation pair has a convex drawing.

The convex testing problem of G for the case where G has no forbidden separation pair and has two or more critical separation pairs is reduced to the planarity testing problem of a certain graph obtained from G. If G has a plane embedding which has a convex drawing, the outer face F of the embedding must satisfy Condition (b) of Theorem 3. Then, F contains every vertex of critical separation pairs and any split component which is neither a bond nor a ring must have an edge on the outer face. Observe that if a critical separation pair $\{x, y\}$ has exactly three $\{x, y\}$-split components, then two of them can have edges on F and one cannot have an edge on F; the $\{x, y\}$-split component which will not have an edge on F must be either a bond or a ring. Thus, to test whether G has such an embedding or not, a new graph from G is constructed as follows. For each critical separation pair $\{x, y\}$, if (x, y) is an edge of G, then delete the edge $\{x, y\}$ from G. If (x, y) is not an edge of G and exactly one $\{x, y\}$-split component is a ring, then delete the x-y path in the component from G. Let G_1 be the resulting graph, as illustrated in Fig. 4b. Let G_2 be the graph obtained from G_1 by adding a new vertex v and joining v to all vertices of critical separation pairs of G, as illustrated in Fig. 4c. If G_2 has a planar embedding Γ_2 such that v is embedded on the outer face of Γ_2 as illustrated in Fig. 4d, we get a planar embedding Γ_1 of G_1 from Γ_2 by deleting v from the embedding as illustrated in Fig. 4e. The outer facial cycle of Γ_1 will be the outer facial cycle F of a planar embedding of G as illustrated in Fig. 4f which satisfies the Condition (b) of Theorem 3. Thus,



Convex Graph Drawing, Fig. 4 Illustration for convex testing; (**a**) G, (**b**) G_1, (**c**) G_2, (**d**) Γ_2, (**e**) Γ_1, and (**f**) Γ

the strict convex polygon F^* of F is extendible. Hence, G has a convex drawing if G_2 has a planar embedding with v on the outer face. It is not difficult to show the converse implication. Hence, Theorem 2 holds.

Observe that F may not be the only extendible facial cycle of G, that is, Γ may not be the only planar embedding of G which has a convex drawing. Chiba et al. [2] also gave a linear algorithm which finds all extendible facial cycles of G.

Applications

Thomassen [10] showed applications of convex representations in proving a conjecture of Grünbaum and Shephard on convex deformation of convex graphs and for giving a short proof of the result of Mani-Levistka, Guigas, and Klee on convex representation of infinite doubly periodic 3-connected planar graphs. The research on convex drawing of planar graphs was motivated by the desire of finding aesthetic drawings of graphs [3]. Arkin et al. [1] showed that there is a monotone path in some direction between every pair of vertices in any strictly convex drawing of a planar graph.

Open Problems

A convex drawing is called a *convex grid drawing* if each vertex is drawn at a grid point of an integer grid. Using canonical ordering and shift method, Chrobak and Kant [4] showed that every 3-connected plane graph has a convex grid drawing on an $(n-2) \times (n-2)$ grid and such a grid drawing can be found in linear time. However, the question of whether every planar graph which has a convex drawing admits a convex grid drawing on a grid of polynomial size remained as an open problem. Several research works are concentrated in this direction [6, 7, 13]. For example, Zhou and Nishizeki showed that every internally triconnected plane graph G whose decomposition tree $T(G)$ has exactly four leaves has a convex grid drawing on a $2n \times 4n = O(n^2)$ grid and presented a linear algorithm to find such a drawing [13].

Problem Definition

The *convex hull* of a set P of n points in $\mathbb{R}^d$ is the intersection of all convex regions that contain P. While convex hulls are defined for arbitrary d, the focus here is on $d = 2$ (and $d = 3$). For a more general overview, we recommend reading [7, 9] as well as [3].

A frequently used visual description for a convex hull in 2D is a rubber band: when we imagine the points in the plane to be nails and put a rubber band around them, the convex hull is exactly the structure we obtain by a tight rubber band; see Fig. 1.

The above definition, though intuitive, is hard to use for algorithms to compute the convex hull – one would have to intersect all convex supersets of P. However, one can show that there is an alternative definition of the convex hull of P: it is the set of all convex combinations of P.

Notation

For a point set $P = \{p_1, \ldots, p_n\}$, a *convex combination* is of the form

$$\lambda_1 p_1 + \lambda_2 p_2 + \ldots \lambda_n p_n \quad \text{with} \quad \lambda_i \geq 0, \sum \lambda_i = 1. \tag{1}$$

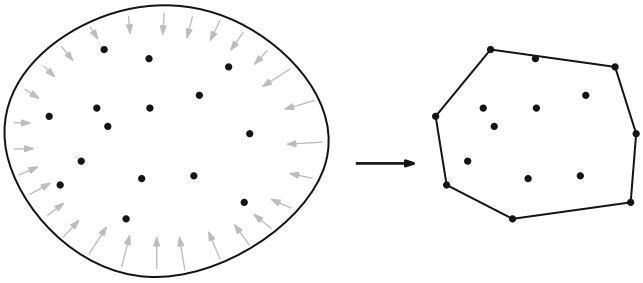
The convex hull, $CH(P)$, of P is the polygon that consists of all convex combinations of P. The *ordered* convex hull gives the ordered sequence of vertices on the boundary of $CH(P)$, instead of only the set of vertices that constitute the hull.

Key Results

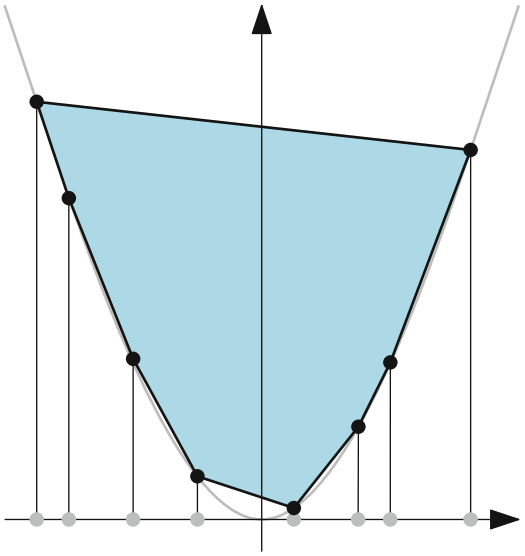
In the following, we present algorithms that compute the ordered convex hull of a given point set P in the plane. We start with a short proof for a lower bound of $\Omega(n \log n)$.

Lower Bound

Theorem 1 *Let P be a set of n points in the plane. An algorithm that computes the ordered convex hull is in $\Omega(n \log n)$.*



Convex Hulls, Fig. 1 The convex hull of a set of points in $\mathbb{R}^2$



Convex Hulls, Fig. 2 Set of numbers X in *gray*, the point set P in *black* and the convex hull $CH(P)$ in *blue*

Proof Given an unsorted list of numbers $X = \{x_1, x_2, \ldots, x_n\}$, we can lift these to a parabola as depicted in Fig. 2. Computing the convex hull $CH(P)$ of the resulting set $P = \{(x_i, x_i^2) \mid x_i \in X\}$ allows to output the sorted numbers by reading off the x-values of the vertices on the lower chain of $CH(P)$ in $O(n)$ time. Thus, a computation of $CH(P)$ in $o(n \log n)$ time would contradict the lower bound $\Omega(n \log n)$ for sorting.

Divide and Conquer by Preparata and Hong [8]

In the first step, the elements of P are sorted, and then the algorithm recursively divides P into subsets A and B of similar size. This is done until at most three points are left in each set, for which the convex hull is trivially computed. The sorting assures that the computed convex hulls are disjoint. Thus, in each step of the merge phase, the algorithm is given two ordered convex hulls $\mathrm{CH}(A)$ and $\mathrm{CH}(B)$, which are separated by a vertical line. To compute $\mathrm{CH}(A \cup B)$, it needs to find the two tangents supporting $\mathrm{CH}(A)$ and $\mathrm{CH}(B)$ from above and below, respectively. The procedure, which is often referred to as a "wobbly stick", is exemplified in Fig. 3.

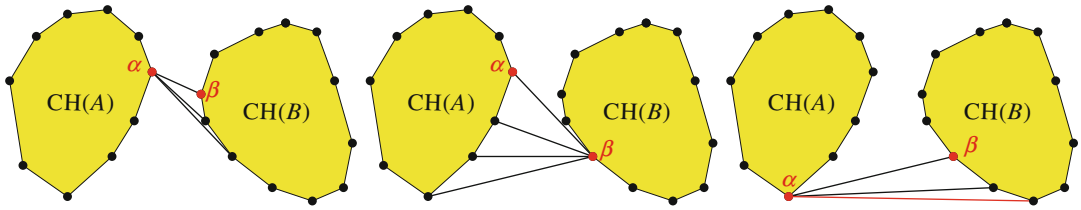
It is easy to see that each level of the merge phase requires $O(n)$ time, resulting in a total running time of $O(n \log n)$. A similar idea is also applicable in 3D.

Graham Scan [4]

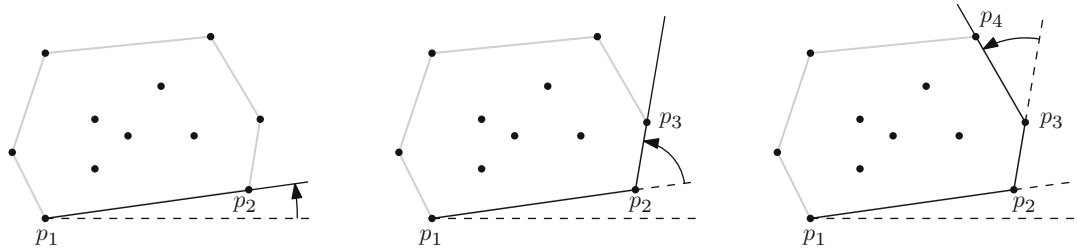
The Graham Scan starts with a known point on the hull as an anchor, the bottommost (rightmost) point p_1. The remaining $n - 1$ points are sorted according to the angles they form with the negative x-axis through p_1, from the largest angle to the smallest angle. The points p_i are processed using this angular order. For the next point p_i, the algorithm determines whether the last constructed hull edge xy and p_i form a left or a right turn. In case of a right turn, y is not part of the hull and is discarded. The discarding is continued as long as the last three points form a right turn. Once xy and p_i form a left turn, the next point in the angular order is considered. Because of the initial sorting step, the total running time of the Graham Scan is $O(n \log n)$.

Jarvis's March or Gift Wrapping [5]

Jarvis's March is an output-sensitive algorithm, i.e., the running time does depend on the size of the output. Its total running time is $O(nh)$, where h is the number of points on $\mathrm{CH}(P)$.



Convex Hulls, Fig. 3 Finding the tangent supporting CH(A) and CH(B) from below: considering CH(A) and CH(B) as obstacles, the algorithm iteratively tries to increment either α or β in clockwise (cw) and counterclockwise (ccw) order, respectively, while maintaining visibility of α and β. That is, it stops as soon as α does not see the ccw neighbor of β and β does not see the cw neighbor of α



Convex Hulls, Fig. 4 The first three steps of the gift wrapping algorithm. Starting at p_1, the algorithm acts as if it was wrapping a string around the point set

The algorithm starts with a known point on the hull, i.e., the bottommost (rightmost) point p_1. Just like wrapping a string around the point set, it then computes the next point on CH(P) in counterclockwise order: compare angles to all other points and choose the point with the largest angle to the negative x-axis. In general, the wrapping step is as follows: let p_{k-1} and p_k be the two previously computed hull vertices, then p_{k+1} is set to the point $p \in P$, $p \neq p_k$, that maximizes the angle $\angle p_{k-1} p_k p_{k+1}$; see Fig. 4. Each steps takes $O(n)$ time and finds one point on CH(P). Thus, the total running time is $O(nh)$.

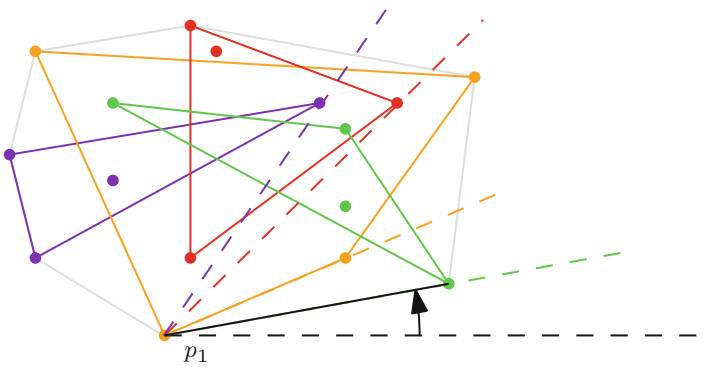
Chan's Algorithm [2]

In 1996, Chan presented an output-sensitive algorithm, with a worst-case optimal running time of $O(n \log h)$. This does not contradict the lower bound presented above, as it features n points on the hull. Let us for now assume that h is known, the number of points on the final convex hull. The algorithm runs in two phases.

Phase 1 splits P into $\lceil n/h \rceil$ groups of size at most h. Computing the convex hull for each set using, e.g., Graham Scan takes $O(h \log h)$. This results in $\lceil n/h \rceil$ (potentially overlapping) convex hulls and takes $O(\lceil n/h \rceil \cdot h \log h) = O(n \log h)$; see Fig. 5.

Phase 2 essentially applies Jarvis's March. Starting at the lowest leftmost point, it wraps a string around the set of convex hulls, i.e., for each hull it computes the proper tangent to the current point and chooses the tangent with the best angle in order to obtain the next point on the final convex hull. Computing the tangent for a hull of size h takes $O(\log h)$, which must be done for each of the $\lceil n/h \rceil$ hulls in each of the h rounds. Thus, the running time is $O(h \cdot \lceil n/h \rceil \log h) = O(n \log h)$.

Because h is not known, the algorithm does several such rounds for increasing values of h, until h is determined. In the initial round, it starts with a very small $h_0 = 4 = 2^{2^0}$ and continues with $h_i = 2^{2^i}$ in round i. As long as $h_i < h$, phase 1 is very quick. The second phase stops with an incomplete hull, knowing that h_i is still too small. That is, round i costs at most $n \log(h_i) = n2^i$. The algorithm terminates as soon as $h_i > h$. Thus, in total we obtain $\lceil \log \log h \rceil$ rounds. Therefore, the total



Convex Hulls, Fig. 5 Initial step of Jarvis's March in the first round of Chan's algorithm ($h_0 = 4$). Starting at p_1, the algorithm computes tangents to each convex hull (indicated in different colors) and selects the first tangent in counterclockwise order

cost is:

$$O\left(\sum_{t=1}^{\lceil \log\log h\rceil} n2^t\right) = O(n2^{\lceil \log\log h\rceil+1}) = O(n\log h). \quad (2)$$

Implementation

Like many geometric algorithms, the computation of the convex hull can be very sensitive to inconsistencies, due to rounding errors [6]. A well-maintained collection of exact implementations that eliminates problems due to rounding errors can be found in CGAL, the Computational Geometry Algorithms Library [1].

Problem Definition

Data is often sampled as a means of addressing resource constraints on storage, bandwidth, or processing – even when we have the resources to store the full data set, processing queries exactly over the data can be very expensive, and we therefore may opt for approximate fast answers obtained from the much smaller sample.

Our focus here is on data sets that have the form of a set of *keys* from some universe and multiple *instances*, which are assignments of nonnegative values to keys. We denote by v_{hi} the value of key h in instance i. Examples of data sets with this form include measurements of a set of parameters; snapshots of a state of a system; logs of requests, transactions, or activity; IP flow records in different time periods; and occurrences of terms in a set of documents. Typically, this matrix is very sparse – the vast majority of entries are $v_{ih} = 0$.

The sampling algorithms we apply can scan the full data set but retain the values v_{hi} of only a subset of the entries (h, i). From the sample, we would like to estimate functions (or statistics) specified over the original data. In particular, many common queries can be expressed as (or as a function of) the sum $\sum_{h\in H} f(v_{h\cdot})$ over selected keys $h \in H$ of a basic function f applied to the values of the key h in one or more instances. These include domain (subset) queries $\sum_{h\in H} v_{hi}$ which are the total weight of keys H in instance i, L_p distances between instances i, j which use $f(v_{h\cdot}) \equiv |v_{hi} - v_{hj}|^p$, one-sided distances which use $f(v_{h\cdot}) \equiv \max\{0, v_{hi} - v_{hj}\}^p$, and sums of quantiles (say maximum or median) of the tuple $(v_{h1}, \ldots, v_{hr})$.

The objective is to design a family of sampling scheme that is suitable for one or more query types. When the sampling scheme is specified, we are interested in designing estimators that use the information in the sample in the "best" way. The estimators are functions $\hat{f}$ that are applied to the sample and return an approximate answer to the query.

When sampling a single-instance i and aiming for approximation quality on domain queries and on sparse or skewed data, we use a *weighted sample*, meaning that the inclusion probability of an entry (h, i) in the sample depends (usually is increasing) with its weight v_{hi}. In particular, zero entries are never sampled. Two popular weighted sampling schemes are Poisson sampling, where entries are sampled independently, and bottom-k (order) sampling [12, 35, 36]. It is convenient for our purposes to specify these sampling schemes through a *rank function*, $r : [0, 1] \times V \to \mathbb{R}$, which maps seed-value pairs to a number $r(u, v)$ that is nonincreasing with u and nondecreasing with v. For each item h, we draw a *seed* $u(h) \sim U[0, 1]$ uniformly at random and compute the rank value $r(u(h), v_{hi})$. A Poisson sample includes a key $h \iff r(u(h), v_{hi}) \geq T_{hi}$, where T_{hi} are fixed thresholds. A bottom-k sample includes the k items with the highest ranks. (The term bottom-k is due to equivalently using the inverse rank function and lowest k ranks [12–14, 35, 36].)

Specifically, Poisson probability proportional to size (PPS) [28] samples include each key with probability proportion to its value. They are specified using the rank function $r(u, v) = v/u$ and a fixed $T_i \equiv T_{hi}$ across all keys in the instance. Priority (sequential Poisson) samples [22, 33, 38] are bottom-k samples utilizing the PPS ranks $r(u, v) = v/u$, and successive weighted samplings without replacement [12, 23, 35] are bottom-k samples with the rank function $r(u, v) = -v/\ln(1 - u)$. All these sampling algorithms can be easily implemented when the data is streamed or distributed.

Queries over a single instance can be estimated using inverse probabilities [29]. For each sampled key h, we can compute the probability $q(h)$ that it is included in the sample. With Poisson sampling, this probability is that of $u \sim U[0, 1]$ satisfying $r(u(h), v_{hi}) \geq T_{hi}$. With bottom-$k$ sampling, we use a conditioned version [13, 22, 38]: The probability $q(h)$ is that of $r(u(h), v_{hi})$ being larger than the kth largest value among $r(u(y), v_{yi})$, where y are all keys other than h and $u(y)$ is fixed to be as in the current sample. Note that this threshold value is available to us from the sample, and hence

keys:	1	2	3	4	5	6	7	8

Instance2:	0.00	0.25	0.75	0.50	0.00	0.25	0.50	0.75

Coordinated Sampling, Fig. 1 Two instances with 8 keys and respective PPS sampling probabilities for threshold value 4, so a key with value v is sampled with probability $\min\{1, v/4\}$. To obtain two coordinated PPS samples of the instances, we associate an independent $u(i) \sim U[0,1]$ with each key $i \in [8]$. We then sample $i \in [8]$ in instance $h \in [2]$ if and only if $u(i) \leq v_{hi}/4$, where v_{hi} is the value of i in instance h. When coordinating the samples this way, we make them as similar as possible. In the example, key 8 will always (for any drawing of seeds) be sampled in instance 2 if it is sampled in instance 1 and vice versa for key 2

$q(h)$ can be computed for each sampled key. We then estimate $\sum_{h\in H} f(v_{hi})$ using the sum over sampled keys that are in H of $f(v_{hi})/q(h)$. This estimator is a *sum* estimator in that it is applied separately for each key: $\hat{f}(h) = 0$ when the key is not sampled and is $\hat{f}(h) = f(v_{hi})/q(h)$ otherwise. When the sampling scheme is such that $q(h) > 0$ whenever $f(v_{hi}) > 0$, this estimator is unbiased. Moreover, this is also the optimal sum estimator, in terms of minimizing variance. We note that tighter estimators can be obtained when the total weight of the instance is available to the estimator [13].

What Is Sample Coordination?

When the data has multiple instances, we distinguish between a data source that is *dispersed*, meaning that different entries of each key occur in different times or locations and *co-located* if all entries occur together. These scenarios [17] impose different constraints on the sampling algorithm. In particular, with co-located data, it is easy to include the complete tuple $v_{h\cdot}$ of each key h that is sampled in at least one instance, whereas with dispersed data, we would want the sampling of one entry v_{hi} not to depend on the values v_{hj} in other instances j.

When sampling, we can redraw a fresh set of random seed values $u(h)$ for each instance, which results in the samples being independent. Samples of different instances are *coordinated* when the set of seeds $u(h)$ is common in all instances. Scalable sharing of seeds when data is dispersed is facilitated through random hash functions $u(h)$, where the only requirement for our purposes is uniformity and pairwise independence.

Coordinated sampling has the property that the samples of different instances are more similar when the instances are more similar, a property also known as Locality Sensitive Hashing (LSH) [26, 30, 31]. Figure 1 contains an example data set of two instances and the PPS sampling probabilities of each item in each instance. When the samples are coordinated, a key sampled in one instance is always sampled in the instance with a higher inclusion probability.

Why Use Coordination?

Co-located Data

With co-located data, coordination allows us to minimize the sample size, which is the (expected) total number of included keys, while ensuring that the sample "contains" a desired Poisson or bottom-k sample of each instance.

For a key h, we can consider its respective inclusion probabilities in each of the instances (for bottom-k, inclusion may be conditioned on seeds of other keys). With coordination, the inclusion probability in the combined sample, $q(h)$, is always the maximum of these probabilities. Estimation with these samples is easy: We estimate $\sum_{h\in H} f(v_{h\cdot})$ using the Horvitz-Thompson estimator (inverse probabilities) [29]. The estimate is the sum $f(v_{h\cdot})/q(h)$ over sampled keys that are in H. Since the complete tuple $v_{h\cdot}$ is available for

each sampled key, we can compute $f(v_h.)$, $q(h)$, and thus the estimate.

When the query involves entries from a single-instance i, the variance of this estimate is at most that obtained from a respective sample of i. This is because the inclusion probability $q(h)$ of each key is at least as high as in the respective single-instance sample. Therefore, by coordinating the samples, we minimize the total number of keys included while ensuring estimation quality with respect to each instance.

Dispersed Data

With dispersed data, coordination is useful when we are interested in both domain queries over a single instance at a time and some queries that involve complex relation, such as similarity queries between multiple instances. Estimation of more complex relations, however, can be much more involved. Intuitively, this is because the sample can provide us with partial information on $f(v_h.)$ that is short of the exact value but still lower bounds it by a positive amount. Therefore, in this case, inverse probability estimators may not be optimal or even well defined – there could be zero probability of knowing the exact value, but the function f can have a nonnegative unbiased estimator. In the sequel, we overview estimators that are able to optimally use the available information.

Implicit Data

Another setting where coordination arises is when the input is not explicit, for example, expressed as relations in a graph, and coordinated samples can be obtained much more efficiently than independent samples. In this case, we work with coordinated samples even when we are interested in queries that are approximated well with independent samples.

Key Results

We now overview results on estimators that are applied to coordinated samples of dispersed data.

We first observe that coordinated PPS and bottom-k samples are mergeable, meaning that a respective sample of the union, or more generally, of a new instance whose weight of each key is the coordinate-wise maxima of several instances can be computed from the individual samples of each instance. This makes some estimation problems very simple. Even in these cases, however, better estimators of cardinalities of unions and intersections (key-wise maxima or minima) can be computed when we consider all sampled keys in the two sets rather than just the sample of the union. Such estimators for the 0/1 case are presented in [14] and for general nonnegative weights in [17].

The general question is to derive estimators for an arbitrary function $f \geq 0$ with respect to a coordinated sampling scheme. This problem can be formalized as a Monotone Estimation Problem (MEP) [9]: The smaller the seed $u(h) \in U[0, 1]$ is, the more information we have on the values $v_h.$ and therefore on $f(v_h.)$. We are interested in deriving estimators $\hat{f}$ that are nonnegative; this is because we are interested in nonnegative functions and estimates should be from the same range. We also seek unbiasedness, because we are ultimately estimating a sum over many keys, and bias accumulates even when sampling of different keys are independent. Other desirable properties are finite variance (for any $v_h.$ in the domain) or bounded estimates. A complete characterization of functions f for which estimators with subsets of these properties exist is given in [15].

We are also interested in deriving estimators that are *admissible*. Admissibility is Pareto optimality, meaning that any other estimator with lower variance on some data would have higher variance on another. Derivations of admissible estimators (for any MEP for which an unbiased nonnegative estimator exists) are provided in [9]. Of particular interest is the L* estimator, which is the unique admissible monotone estimator. By monotone, we mean that when there is more information, that is, when $u(h)$ is higher, the estimate $\hat{f}$ is at least as high.

A definition of *variance competitiveness* of MEP estimators is provided in [15]. The competitive ratio of an estimator $\hat{f}$ is the maximum, over all possible inputs (data values) $v_h.$, of the ratio of the integral of the square of $\hat{f}$ to the minimum possible by a nonnegative unbiased estimator. It turns out that the L* has ratio of at most 4 on any

MEP for which a nonnegative unbiased estimator with finite variances exists [9]. Two interesting remaining open problems, partially addressed in [10], are to design an estimator with minimum ratio for a given MEP and also to bound the maximum minimum ratio over all MEPs that admit an unbiased nonnegative estimator with finite variance.

Applications

We briefly discuss the history and some applications of coordinated sampling.

Sample coordination was proposed in 1972 by Brewer, Early, and Joice [2], as a method to maximize overlap and therefore minimize overhead in repeated surveys [34, 36, 37]: The values of keys change, and therefore, there is a new set of PPS sampling probabilities. With coordination, the sample of the new instance is as similar as possible to the previous sample, and therefore, the number of keys that need to be surveyed again is minimized. The term permanent random numbers (PRN) is used in the statistics literature for sample coordination.

Coordination was subsequently used by computer scientists to facilitate efficient processing of large data sets, as estimates obtained over coordinated samples are much more accurate than possible with independent samples [1, 3–6, 8, 13, 14, 16, 17, 21, 24, 25, 27, 32].

In some applications, the representation of the data is not explicit, and coordinated samples are much easier to compute than independent samples. One such example is computing all-distance sketches, which are coordinated samples of (all) d-neighborhoods of all nodes in a graph [6,7,11–13,32]. These sketches support centrality and similarity and influence queries useful in the analysis of massive graph data sets such as social networks or Web graphs [18–20].

Problem Definition

We consider a framework of the problems to enumerate all the subsets of a given graph, each

subset of which satisfies a given constraint. For example, enumerating all Hamilton cycles, all spanning trees, all paths between two vertices, all independent sets of vertices, etc. When we assume a graph $G = (V, E)$ with the vertex set $V = \{v_1, v_2, \ldots, v_n\}$ and the edge set $E = \{e_1, e_2, \ldots, e_m\}$, a graph enumeration problem is to compute a subset of the power set 2^E (or 2^V), each element of which satisfies a given constraint. In this model, we can consider that each solution is a combination of edges (or vertices), and the problem is how to represent the set of solutions and how to generate it efficiently.

Constraints

Any kind of constraint for the graph edges and vertices can be considered. For example, we consider to enumerate all the simple (self-avoiding) paths connecting the two vertices s and t on the graph shown in Fig. 1. The constraint is described as:

1. At a terminal vertex (s and t), only one edge is selected and connected to the vertex.
2. At the other vertices, none or just two edges are selected and connected to the vertex, respectively.
3. The set of selected edges forms a connected component.

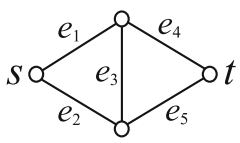
In this example, the set of solutions can be represented as a combination of the edges, $\{e_1e_3e_5,\ e_1e_4,\ e_2e_3e_4,\ e_2e_5\}$.

Key Results

A binary decision diagram (BDD) is a representation of a Boolean function, one of the most basic models of discrete structures. After the epoch-making paper [1] by Bryant in 1986, BDD-based methods have attracted a great deal of attention. BDD was originally invented for the efficient Boolean function manipulation required in VLSI logic design, but Boolean functions are also used for modeling many kinds of combinatorial problems. Zero-suppressed BDD (ZDD) [8] is a variant of BDD, customized for manipulating "sets of combinations." ZDDs have been successfully applied not only for VLSI design but also for solving various combinatorial problems, such as constraint satisfaction, frequent pattern mining, and graph enumeration.

Recently, D. E. Knuth presented a surprisingly fast algorithm "Simpath" [7] to construct a ZDD which represents all the paths connecting two points in a given graph structure. This work is important because many kinds of practical problems are efficiently solved by some variations of this algorithm. We generically call such ZDD construction method "frontier-based methods."

Counting by ZDD, Fig. 1
Example of a graph



BDDs/ZDDs for Graph Enumeration

A binary decision diagram (BDD) is a graph representation for a Boolean function, developed for VLSI design. A BDD is derived by reducing a binary decision tree, which represents a decision-making process by the input variables. If we fix the order of input variables and apply the following two reduction rules, then we have a compact canonical form for a given Boolean function:

1. Delete all redundant nodes whose two edges have the same destination.
2. Share all equivalent nodes having the same child nodes and the same variable.

The compression ratio achieved by using a BDD instead of a decision tree depends on the property of Boolean function to be represented, but it can be 10–100 times in some practical cases.

A zero-suppressed BDD (ZDD) is a variant of BDD, customized for manipulating sets of combinations. This data structure was first introduced by Minato [8]. ZDDs are based on the special reduction rules different from ordinary ones, as follows:

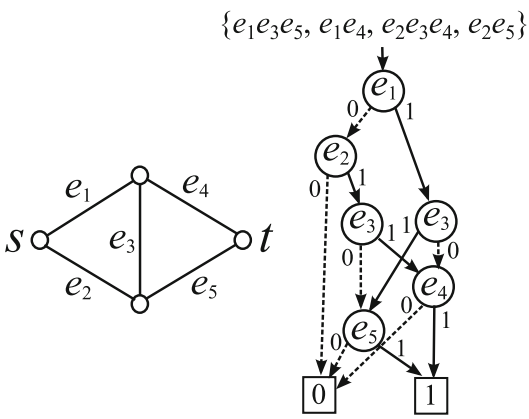
1. Delete all nodes whose 1-edge directly points to the 0-terminal node, but do not delete the nodes which were deleted in ordinary BDDs.

This new reduction rule is extremely effective, when it is applied to a set of sparse combinations. If each item appears in 1 % of combinations in average, ZDDs are possibly more compact than ordinary BDDs, by up to 100 times. Such situations often appear in real-life problems, for example, in a supermarket, the number of items in a customer's basket is usually much less than all the items displayed there. Because of such an advantage, ZDDs are now widely recognized as the most important variant of BDD.

ZDDs can be utilized for enumerating and indexing the solutions of a graph problem. For example, Fig. 2 shows the ZDD enumerating all the simple paths of the graph the same as Fig. 1. The ZDD has four paths from the root node to the 1-terminal node, and each path corresponds to the solution of the problem, where $e_i = 1$ means to use the edge e_i and $e_i = 0$ means not to use e_i.

Frontier-Based Method

In 2009, Knuth published the surprisingly fast algorithm "Simpath" [7] (Vol. 4, Fascicle 1, p. 121, or p. 254 of Vol. 4A) to construct a ZDD which represents all the simple (or self-avoiding) paths connecting two points s and t in a given graph (not necessarily the shortest ones but ones not passing through the same point twice). This work is important because many kinds of practical problems can be efficiently solved by some variations of this algorithm. Knuth provides his own C source codes on his web page for public access, and the program is surprisingly fast. For example, in a 14×14 grid graph (420 edges in total), the number of self-avoiding paths between opposite corners is exactly 227449714676812739631826459327989863387613323440 ($\approx 2.27 \times 10^{47}$) ways. By applying the Simpath algorithm, the set of paths can be compressed into a ZDD with only 144759636 nodes, and the computation time is only a few minutes.



Counting by ZDD, Fig. 2 ZDD representing the paths from s to t

The Simpath algorithm is minutely written in Knuth's book, and his source codes are also provided, but it is not easy to read. The survey paper [9] will be helpful for understanding the basic mechanism of the Simpath algorithm.

The Simpath algorithm belongs to the method of dynamic programming, by scanning the given graph from left to right like a moving frontier line. If the frontier grows larger in the computation process, more intermediate states appear and more computation time is required. Thus, it is important to keep the frontier small. The maximum size of the frontier depends on the given graph structures and the order of the edges. Planar and narrow graphs tend to have small frontier.

Knuth described in his book [7] that the Simpath algorithm can easily be modified to generate not only $s - t$ paths but also Hamilton paths, directed paths, some kinds of cycles, and many other problems by slightly changing the mate data structure. We generically call such ZDD construction method "frontier-based methods."

Applications

Here we list graph problems which can be enumerated and indexed by a ZDD using a frontier-based method.

All $s - t$ paths, $s - t$ paths with length k, k-pairs of $s - t$ paths, all cycles, cycles with length k, Hamilton paths/cycles, directed

paths/cycles, all connected components, spanning trees/forests, Steiner trees, all cutsets, k-partitioning, calculating probability of connectivity, all cliques, all independent sets, graph colorings, tilings, and perfect/imperfect matching.

These problems are strongly related to many kinds of real-life problems. For example, path enumeration is of course important in geographic information systems and is also used for dependency analysis of a process flow chart, fault analysis of industrial systems, etc. Recently, Inoue et al. [5] discussed the design of electric power distribution systems. Such civil engineering systems are usually near to planar graphs, so the frontier-based method is very effective in many cases. They succeeded in generating a ZDD to enumerate all the possible switching patterns in a realistic benchmark of an electric power distribution system with 468 switches. The obtained ZDD represents as many as 10^{60} of the valid switching patterns, but the actual ZDD size is less than 100 MB, and computation time is around 30 min. After generating the ZDD, all valid switching patterns are compactly represented, and we can efficiently discover the switching patterns with maximum, minimum, and average cost. We can also efficiently apply additional constraints to the current solutions. In this way, frontier-based methods can be utilized for many kinds of real-life problems.

Open Problems

Frontier-based method is a general framework of the algorithm, and we have to develop particular algorithm for enumerating graphs to satisfy a given constraint. It is sometimes time consuming, and it is not clearly understood which kind of graphs can be generated easily and which are hard or impossible.

Experimental Results

It is an interesting problem how large n is possible to count the number of simple paths included in an $n \times n$ grid graph with s and t at the opposite corners. We have worked for this problems and succeeded in counting the total number of self-avoiding $s - t$ paths for the 26×26 grid graph. The number is exactly:

908108906396.

This is the current world record and is officially registered in the On-Line Encyclopedia of Integer Sequences [10] in November 2013. The detailed techniques for solving larger problems are presented in the report by Iwashita et al. [6]

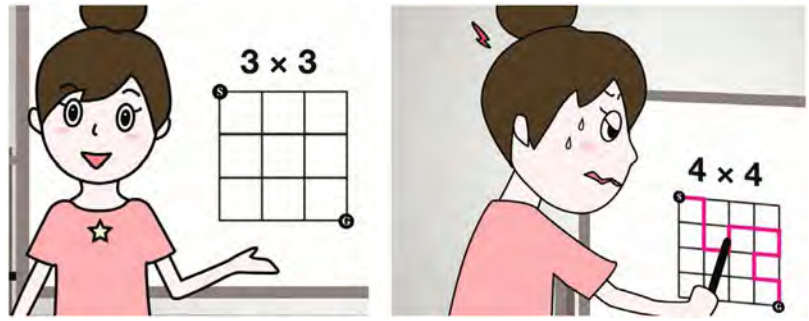
A Related YouTube Video

In 2012, Minato supervised a short educational animation video (Fig. 3). The video is mainly designed for junior high school to college students, to show the power of combinatorial explosion and the state-of-the-art techniques for solving such hard problems. This video uses the simple path enumeration problem for $n \times n$ grid graphs. The story is that the teacher counts the total number of paths for children starting from $n = 1$, but she will be faced with a difficult situation, since the number grows unbelievably fast. She would spend 250,000 years to count the paths for the 10×10 grid graph by using a supercomputer if she used a naive method. The story ends by telling that a state-of-the-art algorithm can finish the same problem in a few seconds. The video is now shown in YouTube [2] and received more than 1.5 million views, which is an extraordinary case in the scientific educational contents. We hear that Knuth also enjoyed this video and shared it to several of his friends.

Graphillion: Open Software Library

The above techniques of data structures and algorithms have been implemented and published as an open software library, named “Graphillion”

Counting by ZDD, Fig. 3 Screenshots of the animation video [2]



[3, 4]. Graphillion is a library for manipulating very large sets of graphs, based on ZDDs and frontier-based method. Traditional graph libraries maintain each graph individually, which causes poor scalability, while Graphillion handles a set of graphs collectively without considering individual graph. Graphillion is implemented as a Python extension in C++, to encourage easy development of its applications without introducing significant performance overhead.

Counting Triangles in Graph Streams

Madhav Jha
Sandia National Laboratories, Livermore, CA, USA
Zenefits, San Francisco, CA, USA

Keywords

Counting triangles; Streaming algorithms

Years and Authors of Summarized Original Work

2013; Jha, Seshadhri, Pinar

Problem Definition

A *graph stream* is a sequence of unordered pairs of elements from a set V implicitly describing an underlying graph G on vertex set. The unordered pairs represent edges of the graph. A *triangle* is a triple of vertices $u, v, w \in V$ which form a 3-clique, that is, every unordered pair of vertices of the set $\{u, v, w\}$ is connected by an edge. In this article, we investigate the problem of counting the number of triangles in an input graph G given as a graph stream. Furthermore, we restrict our attention to algorithms which are severely limited in total space (in particular, they cannot store the entire stream) and are allowed only a single scan over the stream of edges.

Next we describe the streaming setting more formally. Consider a sequence of *distinct* unordered pairs or, equivalently, edges $e_1, e_2, \ldots, e_m$ on the set V. Let G_t be the graph formed by the first t edges of the stream where $t \in \{1, \ldots, m\}$. Denoting the empty graph by G_0, we see that graph G_t is obtained from G_{t-1} by *inserting* edge e_t for all $t \in \{1, \ldots, m\}$. An edge $\{u, v\}$ of the stream implicitly introduces vertex labels u and v. New vertices are therefore implicitly added as new labels. In this article, we do not consider edge or vertex deletions, nor do we allow repeated edges. The problem of counting triangles even in this simple setting has received a lot of attention [1, 2, 6, 12–15, 17].

A streaming algorithm has a small working memory M and gets to scan the input stream in a sequential fashion at most a few times. In this article, we only consider algorithms which make a single pass over the input stream. Thus, the algorithm proceeds by sequentially reading each edge e_t from the input graph stream and updating its data structures in M using e_t. The algorithm cannot read an edge that has already passed again. (It may remember it in M.) Since the size of M is much smaller than m, the algorithm must work with only a "sketch" of the input graph stored in M. The streaming algorithm has access to random coins and typically maintains a random sketch of the input graph (e.g., a random subsample of the input edge stream).

The aim is to output an accurate estimate of the number of triangles in graph G_m. In fact, we require that the algorithm output a running estimate of the number of triangles T_t in graph G_t seen so far as it is reading the edge stream. It is also of interest to output an estimate of another quantity, related to the number of triangles, called *transitivity*. The transitivity of a graph, denoted κ, is the fraction of length-2 paths which form triangles. A path of length 2 is also called a *wedge*. A wedge $\{\{u, v\}, \{u, w\}\}$ is *open* (respectively, *closed*) if the edge $\{v, w\}$ is absent (respectively, present) in the graph. Every closed wedge is part of a triangle, and every triangle has exactly three closed wedges. This immediately gives a formula for transitivity: $\kappa = 3T/W$, where T and W are the total number of triangles and wedges in the graph, respectively. We use the subscript t, as in T_t, W_t, and κ_t, to denote corresponding quantities for graph G_t. The key result described in this article is a small space single-pass streaming algorithm for maintaining a running estimate for each of T_t, W_t, and κ_t.

Outline of the Rest of the Article

The bulk of this article is devoted to the description of results and algorithms of [12]. This is complemented by a section on related work where we briefly describe some of the other algorithms for triangle counting. This is followed by applications of triangle counting, an open problem, a section describing experimental results, and, finally, references used in this article.

Key Results

The main result (from [12]) presented in this article is a single pass, $O(m/\sqrt{T})$-space streaming algorithm to estimate the transitivity and the number of triangles of the input graph with small additive error.

The Algorithm of [12] and Its Analysis

The starting point of the algorithm is the wedge sampling idea from [19]. The transitivity of a

graph is precisely the probability that a uniformly random wedge from the graph is closed. Thus, estimating transitivity amounts to approximating the bias of a coin flip simulated by the following probabilistic experiment: sample a wedge $\{\{u, v\}, \{u, w\}\}$ uniformly from the set of wedges and output "Heads" if it is closed and "Tails" otherwise. One can check whether a wedge is closed by checking if $\{v, w\}$ is an edge in the graph. If, in addition, we have an accurate estimate of W, the triangle count can be estimated using $T = \kappa/3 \cdot W$.

If we adopt the described strategy, we need a way to sample a wedge uniformly from the *graph stream*. While this task by itself appears rather challenging, we note that sampling an edge uniformly from the graph stream can be done easily via an adaptation of reservoir sampling. (See below for details.) Can we use an edge sampling primitive to sample wedges uniformly from a graph stream? This is exactly what [12] achieves. Before we describe the algorithm of [12], we present a key primitive which is also used in other works on counting triangles in graph streams.

A key Algorithmic Tool: A Reservoir of Uniform Edges

This algorithmic tool allows one to maintain a set R_t of k edges while reading the edge stream with the following guarantee for every t: each of the k edges in R_t is selected uniformly from the edges of G_t and all edges are mutually independent. The idea is to adapt the classic reservoir sampling [21]. More precisely, at the beginning of the stream, R_0 consists of k empty slots. While reading the edge stream, on observing edge e_t, do the following probabilistic experiment independently for each of the k slots of R_{t-1} to yield R_t: (i) sample a random number x uniformly from [0, 1], and (ii) if $x \leq 1/t$, replace the slot with e_t. Otherwise, keep the slot unchanged.

How does a reservoir of edges R_t help in sampling wedges from the graph stream? When the edge reservoir R_t is large enough, there are many pairs of edges in R_t sharing a common vertex, yielding many wedges. Further, if the transitivity of the input graph is high, many of these wedges will in fact be closed wedges, aka, triangles. This is the idea behind the algorithm of [12]. The key theoretical insight is that there is a *birthday paradox*-like situation here: many uniform edges result in sufficiently many "collisions" to form wedges. Recall (e.g., from Chap.II.3 of [10]) that the classic birthday paradox states that if we choose 23 random people, the probability that 2 of them share a birthday is at least 1/2. In our setting, edges correspond to people and "sharing a birthday" corresponds to sharing a common vertex.

A Key Analytical Tool: The Birthday Paradox

Suppose $R_1, \ldots, R_k$ are i.i.d. samples from the uniform distribution on the edges of G. Then for distinct $i, j \in [k]$, $\Pr(\{R_i, R_j\}$ forms a wedge$) = 2W/m^2$. By linearity of expectation, the expected number of expected wedges is $\binom{k}{2}(2W/m^2)$. In particular, setting k to be c times a large constant multiple of $m/\sqrt{W}$ results in expectation of at least c^2 wedges. Even better is the fact that these wedges are uniformly (but not independently) distributed in the set of all wedges. Similarly, one can show that when k is $\Omega(m/\sqrt{T})$, one obtains many closed wedges. This is the heart of the argument in the analysis of the algorithm of [12].

While we do not wish to present all the technical details of the algorithm of [12] here, we do provide some high-level ideas from [12]. The algorithm maintains a reservoir of edges R_t as explained above. Further, it maintains a set C_t of wedges $\{e_a, e_b\}$ with $e_a, e_b \in \mathrm{R}_t$ such that (i) $\{e_a, e_b\}$ is a closed wedge in G_t and (ii) the closing edge appears after edges e_a and e_b in the stream. In other words, C_t are the wedges in R_t which can be *detected to be closed*. The algorithm outputs a random bit b_t whose expectation is close to κ_t.

For each edge e_t of the graph stream:

(a) Update reservoir R_t of k edges as described above.
(b) Let W_t be the set of wedges in R_t. Let N_t be the set of wedges in R_t which have e_t as their closing edge.

(c) Update C_t to $C_{t-1} \cap W_t \cup N_t$.
(d) If there are no wedges in R_t, output $b_t = 0$. Otherwise, sample a uniform wedge in R_t and output $b_t = 1$ if this wedge is in C_t and $b_t = 0$ otherwise.

The next theorem shows that the expectation of b_m is close to $\kappa/3$. Moreover, it shows that $|W_m|$ can be used to estimate W. Getting a good estimate on $\mathbf{E}[b_m]$ and W allows one to estimate T by multiplying the two estimates together. We note that while the theorem is stated for the final index $t = m$, it holds for any large enough t.

Theorem 1 ([12]) *Assume $W \geq m$ and fix $\beta \in (0,1)$. Suppose $k = |R_m|$ is $\Omega(m/(\beta^3\sqrt{T}))$. Set $\hat{W} = m^2|W_m|/(k(k-1))$. Then $|\kappa/3 - \mathbf{E}[b_m]| < \beta$ and $\Pr[|W - \hat{W}| < \beta W]$ are at least $1-\beta$.*

Related Work

The problem of counting triangles in graphs has been studied extensively in a variety of different settings: exact, sampling, streaming, and MapReduce. We refer the reader to references in [12] for a comprehensive list of these works. Here we focus on a narrow topic: single-pass streaming algorithms for estimating triangle counts. In particular, we do not discuss streaming algorithms that make multiple passes (e.g., [11,13]) or algorithms that compute triangles incident on every vertex (e.g., Becchetti et al. [4]).

Bar-Yossef et al. [3] were the first to study the problem of triangle counting in the streaming setting. Since then there have been a long line of work improving the guarantees of the algorithm in various ways [1, 2, 6, 12–15, 17]. Specifically, Buriol et al. [6] gave an $O(mn/T)$ space algorithm. The algorithm maintains samples of the form $((u,v),w)$ where (u,v) is a uniform edge in the stream and w is a uniform node label other than u and v. The algorithm checks for presence of edges (u,w) and (v,w) to detect triangle. They also give an implementation of their algorithm which is practical but relative error in triangle estimates can be high. The $O(m/\sqrt{T})$ algorithm described in this algorithm is from Jha et al. [12]. In parallel with [12], Pavan et al. [17] independently gave an $O(m\Delta/T)$ space algorithm where Δ is the maximum degree of the graph. Their algorithm is based on a sampling technique they introduced called *neighborhood sampling*. Neighborhood sampling maintains edge pair samples of the form (r_1, r_2). In each pair, edge r_1 is sampled uniformly from the edges observed so far. Edge r_2 is sampled uniformly from the set $N(r_1)$ where $N(r_1)$ consists of the edges adjacent to edge r_1 that appear after edge r_1 in the stream. When r_2 is nonempty, the pair (r_1, r_2) forms a wedge which can be monitored to see if it forms a triangle. Observe that a triangle formed by edges e_{t_1}, e_{t_2}, and e_{t_3} appearing in this order is detected as a closed triangle with probability $1/|N(e_{t_1})| \cdot m$. Accounting for this bias by keeping track of the quantity $N(r_1)$ for each sample (r_1, r_2), one gets an unbiased estimator for triangle counts. In a recent work, Ahmed et al. [1] give practical algorithms for triangle counting which seem to empirically improve on some of the previous results. In this work, the authors present a generic technique called *graph sample and hold* and use it for estimating triangle counts. At a high level, graph sample and hold associates a nonzero probability p_{e_t} to each edge e_t which corresponds to the probability with which edge e_t is independently sampled. Importantly, the probability p_{e_t} may depend on the graph sampled so far. But the actual probability with which the edge is sampled is *recorded*. Now estimates about the original graph can be obtained from the sampled graph using the selection estimator. For example, the number of triangles is estimated by summing $1/(p_{e_{t_1}} \cdot p_{e_{t_2}} \cdot p_{e_{t_3}})$ over all sampled triangles $\{e_{t_1}, e_{t_2}, e_{t_3}\}$. This can be seen as a generalization of neighborhood sampling.

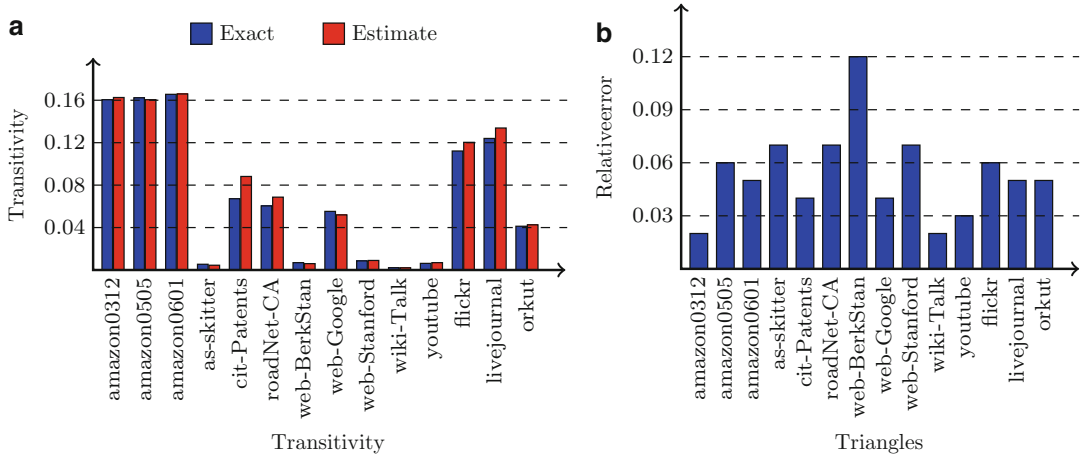
On the lower bound side, Braverman et al. [5] show that any single-pass streaming algorithm which gives a good *multiplicative* approximation of triangle counts must use $\Omega(m)$ bits of storage even if the input graph has $\Omega(n)$ triangles. This improves lower bounds from [3, 13]. For algorithms making a constant c number of passes, for every constant c, the lower bound is shown to be $\Omega(m/T)$ in the same work.

Applications

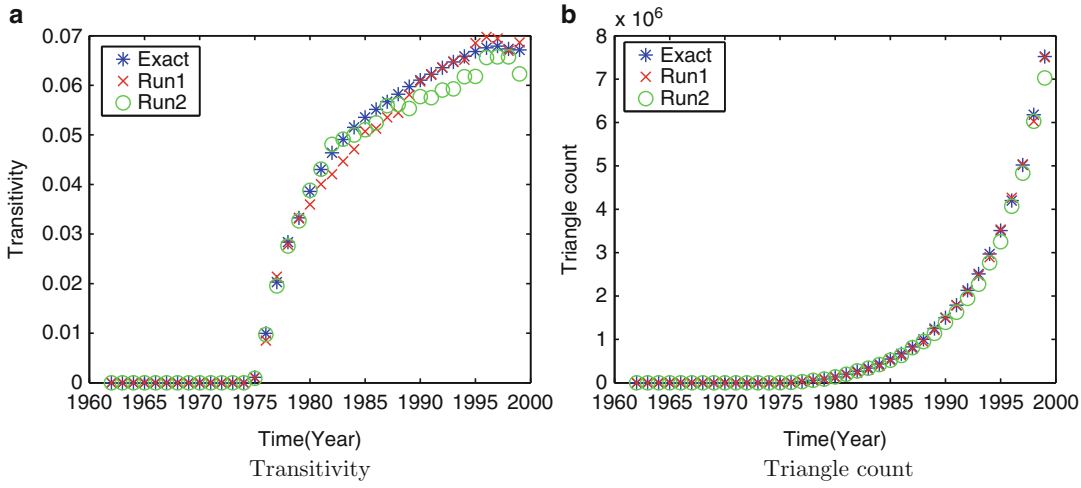
The number of triangles in a graph and the transitivity of a graph are important measures used widely in the study of networks across many different domains. For example, these measures appear in social science research [7, 8, 18, 22], in data mining applications such as spam detection and finding common topics on the World Wide Web [4, 9], and in bioinformatics for motif counting [16]. For a more detailed list of applications, we point the reader to introductory sections of references in the related work.

Open Problems

Give a tight lower bound on the space required by a single-pass streaming algorithm for estimating the number of triangles in graph stream with additive error. The lower bound for multiplicative approximation is known to be $\Omega(m)$ [3, 5].



Counting Triangles in Graph Streams, Fig. 1 Output of STREAMING-TRIANGLES algorithm of [12] on a variety of real datasets while storing at most 40 K edges. (**a**) Gives the estimated transitivity values alongside their exact values. (**b**) Gives the relative error of STREAMING-TRIANGLES's estimates of triangles T. Observe that the relative error for T is mostly below 8 % and often below 4 %



Counting Triangles in Graph Streams, Fig. 2 Real-time tracking of number of triangles and transitivities on cit-Patents (16 M edges), storing only 200 K edges (**a**) Transitivity. (**b**) Triangle count

Experimental Results

Figures 1 and 2 give a glimpse of experimental results from [12] on performance of algorithm STREAMING-TRIANGLES. Specifically, Fig. 1 shows the result of running the algorithm on a variety of graph datasets obtained from [20]. This includes run on graph datasets such as Orkut social network consisting of 200 M edges. The relative errors on κ and T are mostly less than 5 % (except for graphs with tiny κ). The storage used by the algorithm stated in terms of number of edges is at most 40 K. (The storage roughly corresponds to the size of edge reservoir used in the algorithm of [12] described in this article.)

An important aspect of the algorithm presented in [12] is that it can track the quantities κ_t and T_t for all values of t in real time. This is exhibited in Fig. 2.

Years and Authors of Summarized Original Work

2004; Cormode, Muthukrishnan

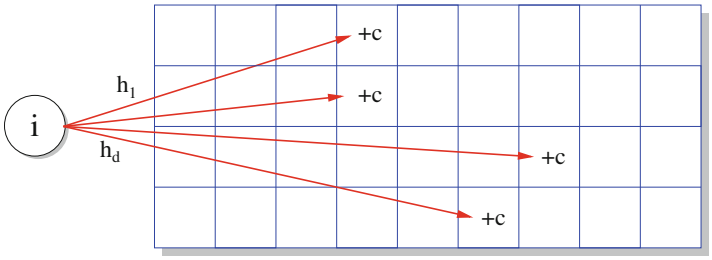
Problem Definition

The problem of *sketching* a large mathematical object is to produce a compact data structure that approximately represents it. The Count-Min (CM) sketch is an example of a sketch that allows a number of related quantities to be estimated with accuracy guarantees, including point queries and dot product queries. Such queries are at the core of many computations, so the structure can be used in order to answer a variety of other queries, such as frequent items (heavy hitters), quantile finding, join size estimation, and more. Since the sketch can process updates in the form of additions or subtractions to dimensions of the vector (which may correspond to insertions or deletions or other transactions), it is capable of working over streams of updates, at high rates.

The data structure maintains the linear projection of the vector with a number of other random vectors. These vectors are defined implicitly by simple hash functions. Increasing the range of the hash functions increases the accuracy of the summary, and increasing the number of hash functions decreases the probability of a bad estimate. These trade-offs are quantified precisely below. Because of this linearity, CM sketches can be scaled, added, and subtracted, to produce summaries of the corresponding scaled and combined vectors.

Key Results

The Count-Min sketch was first proposed in 2003 [4], following several other sketch techniques, such as the Count sketch [2] and the AMS sketch [1]. The sketch is similar to a counting Bloom filter or multistage filter [7].



Count-Min Sketch, Fig. 1 Each item i is mapped to one cell in each row of the array of counts: when an update of c to item i_t arrives, c_t is added to each of these cells

Data Structure Description

The CM sketch is simply an array of counters of width w and depth d, $CM[1,1] \ldots CM[d,w]$. Each entry of the array is initially zero. Additionally, d hash functions

$$h_1 \ldots h_d : \{1 \ldots n\} \rightarrow \{1 \ldots w\}$$

are chosen uniformly at random from a pairwise-independent family. Once w and d are chosen, the space required is fixed: the data structure is represented by wd counters and d hash functions (which can each be represented in $O(1)$ machine words [12]).

Update Procedure

A vector $\boldsymbol{a}$ of dimension n is described incrementally. Initially, $\boldsymbol{a}(0)$ is the zero vector, $\mathbf{0}$, so $a_i(0)$ is 0 for all i. Its state at time t is denoted $\boldsymbol{a}(t) = [a_1(t), \ldots a_i(t), \ldots a_n(t)]$. Updates to individual entries of the vector are presented as a stream of pairs. The tth update is (i_t, c_t), meaning that

$$\begin{aligned} a_{i_t}(t) &= a_{i_t}(t-1) + c_t \\ a_{i'}(t) &= a_{i'}(t-1) \qquad i' \neq i_t. \end{aligned}$$

For convenience, the subscript t is dropped, and the current state of the vector simply referred to as $\boldsymbol{a}$. For simplicity of description, it is assumed here that although values of a_i increase and decrease with updates, each $a_i \geq 0$. However, the sketch can also be applied to the case where a_is can be less than zero with some increase in costs [4].

When an update (i_t, c_t) arrives, c_t is added to one count in each row of the Count-Min sketch; the counter is determined by h_j. Formally, given (i_t, c_t), the following modifications are performed:

$$\forall 1 \leq j \leq d : CM[j, h_j(i_t)] \leftarrow CM[j, h_j(i_t)] + c_t.$$

This procedure is illustrated in Fig. 1. Because computing each hash function takes constant time, the total time to perform an update is $O(d)$, independent of w. Since d is typically small in practice (often less than 10), updates can be processed at high speed.

Point Queries

A *point query* is to estimate the value of an entry in the vector a_i. Given a query point i, an estimate is found from the sketch as $\hat{a}_i = \min_{1 \leq j \leq d} CM[j, h_j(i)]$. The approximation guarantee is that if $w = \lceil \frac{e}{\varepsilon} \rceil$ and $d = \lceil \ln \frac{1}{\delta} \rceil$, the estimate $\hat{a}_i$ obeys $a_i \leq \hat{a}_i$; and, with probability at least $1 - \delta$,

$$\hat{a}_i \leq a_i + \varepsilon \|\boldsymbol{a}\|_1.$$

Here, $\|\boldsymbol{a}\|_1$ is the L_1 norm of $\boldsymbol{a}$, i.e., the sum of the (absolute) values. The proof follows by using the Markov inequality to limit the error in each row and then using the independence of the hash functions to amplify the success probability.

This analysis makes no assumption about the distribution of values in $\boldsymbol{a}$. In many applications, there are Zipfian, or power law, distributions of item frequencies. Here, the (relative) frequency of the ith most frequent item is proportional to i^{-z}, for some parameter z, where z is typically in the range 1–3. Here, the skew in the distribution can be used to show a stronger space/accuracy trade-off: for a Zipf distribution with parameter z, the space required to answer point queries with

error $\varepsilon\|\boldsymbol{a}\|_1$ with probability at least $1-\delta$ is given by $O(\varepsilon^{-\min\{1,1/z\}} \ln 1/\delta)$ [5].

Range, Heavy Hitter, and Quantile Queries

A *range query* is to estimate $\sum_{i=l}^{r} a_i$ for a range $[l \ldots r]$. For small ranges, the range sum can be estimated as a sum of point queries; however, as the range grows, the error in this approach also grows linearly. Instead, $\log n$ sketches can be kept, each of which summarizes a derived vector a^k where

$$a^k[j] = \sum_{i=j2^k}^{(j+1)2^k-1} a_i$$

for $k = 1 \ldots \log n$. A range of the form $j2^k \ldots (j+1)2^k - 1$ is called a *dyadic range*, and any arbitrary range $[l \ldots r]$ can be partitioned into at most $2 \log n$ dyadic ranges. With appropriate rescaling of accuracy bounds, it follows that Count-Min sketches can be used to find an estimate $\hat{r}$ for a range query on $l \ldots r$ such that

$$\hat{r} - \varepsilon\|\boldsymbol{a}\|_1 \leq \sum_{i=l}^{r} a_i \leq \hat{r}.$$

The right inequality holds with certainty, and the left inequality holds with probability at least $1-\delta$. The total space required is $O(\frac{\log^2 n}{\varepsilon} \log \frac{1}{\delta})$ [4]. The closely related *ϕ-quantile query* is to find a point j such that

$$\sum_{i=1}^{j} a_i \leq \phi\|\boldsymbol{a}\|_1 \leq \sum_{i=1}^{j+1} a_i.$$

Range queries can be used to (binary) search for a j which satisfies this requirement approximately (i.e., tolerates up to $\varepsilon\|\boldsymbol{a}\|_1$ error in the above expression) given ϕ. The overall cost is space that depends on $1/\varepsilon$, with further log factors for the rescaling necessary to give the overall guarantee [4]. The time for each insert or delete operation and the time to find any quantile are logarithmic in n, the size of the domain.

Heavy hitters are those points i such that $a_i \geq \phi\|\boldsymbol{a}\|_1$ for some specified ϕ. The range query primitive based on Count-Min sketches can again be used to find heavy hitters, by recursively splitting dyadic ranges into two and querying each half to see if the range is still heavy, until a range of a single, heavy item is found. The cost of this is similar to that for quantiles, with space dependent on $1/\varepsilon$ and $\log n$. The time to update the data structure and to find approximate heavy hitters is also logarithmic in n. The guarantee is that every item with frequency at least $(\phi+\varepsilon)\|\boldsymbol{a}\|_1$ is output, and with probability $1-\delta$ no item whose frequency is less than $\phi\|\boldsymbol{a}\|_1$ is output.

Inner Product Queries

The Count-Min sketch can also be used to estimate the inner product between two vectors. The inner product $\boldsymbol{a}\cdot\boldsymbol{b}$ can be estimated by treating the Count-Min sketch as a collection of d vectors of length w and finding the minimum inner product between corresponding rows of sketches of the two vectors. With probability $1-\delta$, this estimate is at most an additive quantity $\varepsilon\|\boldsymbol{a}\|_1\|\boldsymbol{b}\|_1$ above the true value of $\boldsymbol{a}\cdot\boldsymbol{b}$. This is to be compared with AMS sketches which guarantee $\varepsilon\|\boldsymbol{a}\|_2\|\boldsymbol{b}\|_2$ additive error but require space proportional to $\frac{1}{\varepsilon^2}$ to make this guarantee.

Conservative Update

If only positive updates arrive, then the "conservative update" process (due to Estan and Varghese [7]) can be used. For an update (i,c), $\hat{a}_i$ is computed, and the counts are modified according to $\forall 1 \leq j \leq d : CM[j,h_j(i)] \leftarrow \max(CM[j,h_j(i)], \hat{a}_i + c)$. This procedure still ensures for point queries that $a_i \leq \hat{a}_i$, and that the error is no worse than in the normal update procedure; it has been observed that conservative update can improve accuracy "up to an order of magnitude" [7]. However, deletions or negative updates can no longer be processed, and the new update procedure is slower than the original one.

Applications

The Count-Min sketch has found a number of applications.

- Indyk [9] used the Count-Min sketch to estimate the residual mass after removing a set of items, that is, given a (small) set of indices I, to estimate $\sum_{i \notin I} a_i$. This supports clustering over streaming data.
- The *entropy* of a data stream is a function of the relative frequencies of each item or character within the stream. Using Count-Min sketches within a larger data structure based on additional hashing techniques, B. Lakshminath and Ganguly [8] showed how to estimate this entropy to within relative error.
- Sarlós et al. [14] gave approximate algorithms for personalized page rank computations which make use of Count-Min sketches to compactly represent web-sized graphs.
- In describing a system for building selectivity estimates for complex queries, Spiegel and Polyzotis [15] use Count-Min sketches in order to allow clustering over a high-dimensional space.
- Sketches that reduce the amount of information stored seem like a natural candidate to preserve privacy of information. However, proving privacy requires more care. Roughan and Zhang use the Count-Min sketch to allow private computation of a sketch of a vector [13]. Dwork et al. show that the Count-Min sketch can be made *pan-private*, meaning that information about individuals contributing to the data structure is held private.

Experimental Results

There have been a number of experimental studies of COUNT-MIN and related algorithms for a variety of computing models. These have shown that the algorithm is accurate and fast to execute [3, 11]. Implementations on desktop machines achieve many millions of updates per second, primarily limited by IO throughput. Other implementations have incorporated Count-Min sketch into high-speed streaming systems such as Gigascope [6] and tuned it to process packet streams of multi-gigabit speeds. Lai and Byrd report on an implementation of Count-Min sketches on a low-power stream processor [10] capable of processing 40 byte packets at a throughput rate of up to 13 Gbps. This is equivalent to about 44 million updates per second.

URLs to Code and Data Sets

Sample implementations are widely available in a variety of languages.

C code is given by the MassDal code bank: http://www.cs.rutgers.edu/~muthu/massdal-code-index.html.

C++ code by Marios Hadjieleftheriou is available from http://hadjieleftheriou.com/sketches/index.html.

The MADlib project has SQL implementations for Postgres/Greenplum http://madlib.net/.

OCaml implementation is available via https://github.com/ezyang/ocaml-cminsketch.

CPU Time Pricing

Li-Sha Huang
Department of Compurter Science and Technology, Tsinghua University, Beijing, China

Keywords

Competitive auction; Market equilibrium; Resource scheduling

Years and Authors of Summarized Original Work

2005; Deng, Huang, Li

Problem Definition

This problem is concerned with a Walrasian equilibrium model to determine the prices of CPU time. In a market model of a CPU job scheduling problem, the owner of the CPU processing time sells time slots to customers and the prices of each time slot depends on the seller's strategy and the customers' bids (valuation functions). In a Walrasian equilibrium, the market is clear and each customer is most satisfied according to its valuation function and current prices. The work of Deng, Huang, and Li [1] establishes the existence conditions of Walrasion equilibrium, and obtains complexity results to determine the existence of equilibrium. It also discusses the issues of excessive supply of CPU time and price dynamics.

Notations

Consider a combinatorial auction (Ω, I, V):

- Commodities: The seller sells m kinds of indivisible commodities. Let $\Omega = \{\omega_1 \times \delta_1, \ldots, \omega_m \times \delta_m\}$ denote the set of commodities, where δ_j is the available quantity of the item ω_j.
- Agents: There are n agents in the market acting as buyers, denoted by $I = \{1, 2, \ldots, n\}$.
- Valuation functions: Each buyer $i \in I$ has a valuation function $v_i : 2^{\Omega} \to \mathbb{R}^+$ to submit the maximum amount of money he is willing to pay for a certain bundle of items. Let $V = \{v_1, v_2, \ldots, v_n\}$.

An XOR combination of two valuation functions v_1 and v_2 is defined by:

$$(v_1 \text{ XOR } v_2)(S) = \max\{v_1(S), v_2(S)\}$$

An *atomic bid* is a valuation function v denoted by a pair (S, q), where $S \subset \Omega$ and $q \in \mathbb{R}^+$:

$$v(T) = \begin{cases} q\,, & \text{if } S \subset T \\ 0\,, & \text{otherwise} \end{cases}$$

Any valuation function v_i can be expressed by an XOR combination of atomic bids,

$$v_i = (S_{i1}, q_{i1}) \text{XOR } (S_{i2}, q_{i2}) \ldots \text{ XOR } (S_{in}, q_{in})$$

Given (Ω, I, V) as the input, the seller will determine an *allocation* and a *price vector* as the output:

- An *allocation* $X = \{X_0, X_1, X_2, \ldots, X_n\}$ is a partition of Ω, in which X_i is the bundle of commodities assigned to buyer i and X_0 is the set of unallocated commodities.
- A *price* vector p is a non-negative vector in $\mathbb{R}^m$, whose jth entry is the price of good $\omega_j \in \Omega$.

For any subset $T = \{\omega_1 \times \sigma_1, \ldots, \omega_m \times \sigma_m\} \subset \Omega$, define $p(T)$ by $p(T) = \sum_{j=1}^{m} \sigma_j p_j$. If buyer i is assigned to a bundle X_i, his *utility* is $u_i(X_i, p) = v_i(X_i) - p(X_i)$.

Definition A *Walrasian equilibrium* for a combinatorial auction (Ω, I, V) is a tuple (X, p), where $X = \{X_0, X_1, \ldots, X_n\}$ is an allocation and p is a price vector, satisfying that:

(1) $p(X_0) = 0$;

(2) $u_i(X_i, p) \geq u_i(B, p), \quad \forall B \subset \Omega, \quad \forall 1 \leq i \leq n$

Such a price vector is also called a market clearing price, or Walrasian price, or equilibrium price.

The CPU Job-Scheduling Problem

There are two types of players in a market-driven CPU resource allocation model: a resource provider and n consumers. The provider sells to the consumers CPU time slots and the consumers each have a job that requires a fixed number of CPU time, and its valuation function depends on the time slots assigned to the job, usually the last assigned CPU time slot. Assume that all jobs are released at time $t = 0$ and the ith job needs s_i time units. The jobs are interruptible without preemption cost, as is often modeled for CPU jobs.

Translating into the language of combinatorial auctions, there are m commodities (time units), $\Omega = \{\omega_1, \ldots, \omega_m\}$, and n buyers (jobs), $I = \{1, 2, \ldots, n\}$, in the market. Each buyer has a valuation function v_i, which only depends on the completion time. Moreover, if not explicitly mentioned, every job's valuation function is non-increasing w.r.t. the completion time.

Key Results

Consider the following linear programming problem:

$$\max \sum_{i=1}^{n} \sum_{j=1}^{k_i} q_{ij} x_{ij}$$

$$\text{s.t.} \sum_{i,j \mid \omega_k \in S_{ij}} x_{ij} \leq \delta_k \,, \quad \forall \omega_k \in \Omega$$

$$\sum_{j=1}^{r_i} x_{ij} \leq 1 \,, \quad \forall 1 \leq i \leq n$$

$$0 \leq x_{ij} \leq 1 \,, \quad \forall i, j$$

Denote the problem by **LPR** and its integer restriction by **IP**. The following theorem shows that a non-zero gap between the integer programming problem **IP** and its linear relaxation implies the non-existence of the Walrasian equilibrium.

Theorem 1 *In a combinatorial auction, the Walrasian equilibrium exists if and only if the optimum of **IP** equals the optimum of **LPR**. The size of the LP problem is linear to the total number of XOR bids.*

Theorem 2 *Determination of the existence of Walrasian equilibrium in a CPU job scheduling problem is strong NP-hard.*

Now consider a job scheduling problem in which the customers' valuation functions are all linear. Assume n jobs are released at the time $t = 0$ for a single machine, the jth job's time span is $s_j \in \mathbb{N}^+$ and weight $w_j \geq 0$. The goal of the scheduling is to minimize the weighted completion time: $\sum_{i=1}^{n} w_i t_i$, where t_i is the completion time of job i. Such a problem is called an MWCT (Minimal Weighted Completion Time) problem.

Theorem 3 *In a single-machine MWCT job scheduling problem, Walrasian equilibrium always exists when $m \geq EM + \Delta$, where m is the total number of processor time, $EM = \sum_{i=1}^{n} s_i$ and $\Delta = \max_k \{s_k\}$. The equilibrium can be computed in polynomial time.*

The following theorem shows the existence of a non-increasing price sequence if Walrasian equilibrium exists.

Theorem 4 *If there exists a Walrasian equilibrium in a job scheduling problem, it can be adjusted to an equilibrium with consecutive allocation and a non-increasing equilibrium price vector.*

Applications

Information technology has changed people's lifestyles with the creation of many digital goods, such as word processing software, computer games, search engines, and online communities. Such a new economy has already demanded many theoretical tools (new and old, of economics and other related disciplines) be applied to their development and production, marketing, and pricing. The lack of a full understanding of the new economy is mainly due to the fact that digital goods can often be re-produced at no additional cost, though multi-fold other factors could also be part of the difficulty. The work of Deng, Huang, and Li [1] focuses on CPU time as a product for sale in the market, through the Walrasian pricing model in economics. CPU time as a commercial product is extensively studied in grid computing. Singling out CPU time pricing will help us to set aside other complicated issues caused by secondary factors, and a complete understanding of this special digital product (or service) may shed some light on the study of other goods in the digital economy.

The utilization of CPU time by multiple customers has been a crucial issue in the development of operating system concept. The rise of grid computing proposes to fully utilize computational resources, e.g., CPU time, disk space, bandwidth. Market-oriented schemes have been proposed for efficient allocation of computational grid recourses, by [2, 5]. Later, various practical and simulation systems have emerged in grid resource management. Besides the resource allocation in grids, an economic mechanism has also been introduced to TCP congestion control problems, see Kelly [4].

Problem Definition

Given a point set V, a graph of the vertex set V in which two vertices have an edge if and only if the distance between them is at most r for some positive real number r is called a r-disk graph over the vertex set V and denoted by $G_r(V)$. If $r_1 \leq r_2$, obviously $G_{r_1}(V) \subseteq G_{r_2}(V)$. A graph property is monotonic (increasing) if a graph is with the property, then every supergraph with the same vertex set also has the property. The critical-range problem (or critical-radius problem) is concerned with the minimal range r such that $G_r(V)$ is with some monotonic property. For example, graph connectivity is monotonic and crucial to many applications. It is interesting to know whether $G_r(V)$ is connected or not. Let $\rho_{\text{con}}(V)$ denote the minimal range r such that $G_r(V)$ is connected. Then, $G_r(V)$ is connected if $r \geq \rho_{\text{con}}(V)$, and otherwise not connected. Here $\rho_{\text{con}}(V)$ is called the critical range for connectivity of V. Formally, the critical-range problem is defined as follows.

Definition 1 The critical range for a monotonic graph property π over a point set V, denoted by $\rho_\pi(V)$, is the smallest range r such that $G_r(V)$ has property π.

From another aspect, for a given geometric property, a corresponding geometric structure is usually embedded. In many cases, the critical-range problem for graph properties is related or equivalent to the longest-edge problem of corresponding geometric structures. For example, if $G_r(V)$ is connected, it contains a Euclidean minimal spanning tree (EMST), and $\rho_{\text{con}}(V)$ is equal to the largest edge length of the EMST. So the critical range for connectivity problem is equivalent to the longest edge of the EMST problem, and the critical range for connectivity is the smallest r such that $G_r(V)$ contains the EMST.

In most cases, given an instance, the critical range can be calculated by polynomial time algorithms. So it is not a hard problem to decide the critical range. Researchers are interested in the probabilistic analysis of the critical range, especially asymptotic behaviors of r-disk graphs over random point sets. Random geometric graphs [8] is a general term for the theory about r-disk graphs over random point sets.

Key Results

In the following, problems are discussed in a 2D plane. Let $X_1, X_2, \cdots$ be independent and uniformly distributed random points on a bounded region A. Given a positive integer n, the point process $\{X_1, X_2, \ldots, X_n\}$ is referred to as the uniform n-point process on A, and is denoted by $\mathrm{X}_n(A)$. Given a positive number λ, let $Po(\lambda)$ be a Poisson random variable with parameter λ, independent of $\{X_1, X_2, \ldots\}$. Then the point process $\{X_1, X_2, \ldots, X_{Po(n)}\}$ is referred to as the Poisson point process with mean n on A, and is denoted by $\mathrm{P}_n(A)$. A is called a deployment region. An event is said to be asymptotic almost sure if it occurs with a probability that converges to 1 as $n \to \infty$.

In a graph, a node is "isolated" if it has no neighbor. If a graph is connected, there exists no isolated node in the graph. The asymptotic

distribution of the number of isolated nodes is given by the following theorem [2, 6, 14].

Theorem 1 *Let* $r_n = \sqrt{\frac{\ln n + \xi}{\pi n}}$ *and* Ω *be a unit-area disk or square. The number of isolated nodes in* $G_r(\mathrm{X}_n(\Omega))$ *or* $G_r(\mathrm{P}_n(\Omega))$ *is asymptotically Poisson with mean* $\mathrm{e}^{-\xi}$.

According to the theorem, the probability of the event that there is no isolated node is asymptotically equal to $\exp\left(-\mathrm{e}^{-\xi}\right)$. In the theory of random geometric graphs, if a graph has no isolated node, it is almost surely connected. Thus, the next theorem follows [6, 8, 9].

Theorem 2 *Let* $r_n = \sqrt{\frac{\ln n + \xi}{\pi n}}$ *and* Ω *be a unit-area disk or square. Then,*
$\Pr[G_r(\mathrm{X}_n(\Omega)) \text{ is connected}] \to \exp\left(-\mathrm{e}^{-\xi}\right)$, and

$$\Pr[G_r(\mathrm{P}_n(\Omega)) \text{ is connected}] \to \exp\left(-\mathrm{e}^{-\xi}\right).$$

In wireless sensor networks, the deployment region is k-covered if every point in the deployment region is within the coverage ranges of at least k sensors (vertices). Assume the coverage ranges are disks of radius r centered at the vertices. Let k be a fixed non-negative integer, and Ω be the unit-area square or disk centered at the origin $\mathbf{o}$. For any real number t, let $t\Omega$ denote the set $\{tx : x \in \Omega\}$, i. e., the square or disk of area t^2 centered at the origin. Let $C_{n,r}$ (respectively, $C'_{n,r}$) denote the event that Ω is $(k+1)$-covered by the (open or closed) disks of radius r centered at the points in $\mathrm{P}_n(\Omega)$ (respectively, $\mathrm{X}_n(\Omega)$). Let $K_{s,n}$ (respectively, $K'_{s,n}$) denote the event that $\sqrt{s}\Omega$ is $(k+1)$-covered by the unit-area (closed or open) disks centered at the points in $\mathrm{P}_n(\sqrt{s}\Omega)$ (respectively, $\mathrm{X}_n(\sqrt{s}\Omega)$). To simplify the presentation, let η denote the peripheral of Ω, which is equal to 4 (respectively, $2\sqrt{\pi}$) if Ω is a square (respectively, disk). For any $\xi \in \mathbb{R}$, let

$$\alpha(\xi) = \begin{cases} \dfrac{\left(\frac{\sqrt{\pi}\eta}{2} + \mathrm{e}^{-\frac{\xi}{2}}\right)^2}{16\left(2\sqrt{\pi}\eta + \mathrm{e}^{-\frac{\xi}{2}}\right)} \mathrm{e}^{-\frac{\xi}{2}}, & \text{if } k = 0; \\ \dfrac{\sqrt{\pi}\eta}{2^{k+6}(k+2)!} \mathrm{e}^{-\frac{\xi}{2}}, & \text{if } k \geq 1. \end{cases}$$

and

$$\beta(\xi) = \begin{cases} 4\mathrm{e}^{-\xi} + 2\left(\sqrt{\pi} + \frac{1}{\sqrt{\pi}}\right)\eta \mathrm{e}^{-\frac{\xi}{2}}, & \text{if } k = 0; \\ \dfrac{\sqrt{\pi} + \frac{1}{\sqrt{\pi}}}{2^{k-1}k!}\eta \mathrm{e}^{-\frac{\xi}{2}}, & \text{if } k \geq 1. \end{cases}$$

The asymptotics of $\Pr[C_{n,r}]$ and $\Pr\left[C'_{n,r}\right]$ as n approaches infinity, and the asymptotics of $\Pr[K_{s,n}]$ and $\Pr\left[K'_{s,n}\right]$ as s approaches infinity are given in the following two theorems [4, 10, 16].

Theorem 3 *Let* $r_n = \sqrt{\frac{\ln n + (2k+1)\ln\ln n + \xi_n}{\pi n}}$. *If* $\lim_{n\to\infty} \xi_n = \xi$ *for some* $\xi \in \mathbb{R}$, *then*

$$1 - \beta(\xi) \leq \lim_{n\to\infty} \Pr[C_{n,r_n}] \leq \frac{1}{1 + \alpha(\xi)}, \text{ and}$$

$$1 - \beta(\xi) \leq \lim_{n\to\infty} \Pr\left[C'_{n,r_n}\right] \leq \frac{1}{1 + \alpha(\xi)}.$$

If $\lim_{n\to\infty} \xi_n = \infty$, *then*

$$\lim_{n\to\infty} \Pr[C_{n,r_n}] = \lim_{n\to\infty} \Pr\left[C'_{n,r_n}\right] = 1.$$

If $\lim_{n\to\infty} \xi_n = -\infty$, *then*

$$\lim_{n\to\infty} \Pr[C_{n,r_n}] = \lim_{n\to\infty} \Pr\left[C'_{n,r_n}\right] = 0.$$

Theorem 4 *Let* $\mu(s) = \ln s + 2(k+1)\ln\ln s + \xi(s)$. *If* $\lim_{s\to\infty} \xi(s) = \xi$ *for some* $\xi \in \mathbb{R}$, *then*

$$1 - \beta(\xi) \leq \lim_{s\to\infty} \Pr\left[K_{s,\mu(s)s}\right] \leq \frac{1}{1 + \alpha(\xi)}, \text{ and}$$

$$1 - \beta(\xi) \leq \lim_{s\to\infty} \Pr\left[K'_{s,\mu(s)s}\right] \leq \frac{1}{1 + \alpha(\xi)}.$$

If $\lim_{s\to\infty} \xi(s) = \infty$, *then*

$$\lim_{s\to\infty} \Pr\left[K_{s,\mu(s)s}\right] = \lim_{s\to\infty} \Pr\left[K'_{s,\mu(s)s}\right] = 1.$$

If $\lim_{s\to\infty} \xi(s) = -\infty$, *then*

$$\lim_{s\to\infty} \Pr\left[K_{s,\mu(s)s}\right] = \lim_{s\to\infty} \Pr\left[K'_{s,\mu(s)s}\right] = 0.$$

In Gabriel graphs (GG), two nodes have an edge if and only if there is no other node in the

disk using the segment of these two nodes as its diameter. If V is a point set and l is a positive real number, we use $\rho_{\mathrm{GG}}(V)$ to denote the largest edge length of the GG over V, and $N(V,l)$ denotes the number of GG edges over V whose length is at least l. Wan and Yi (2007) [11] gave the following theorem.

Theorem 5 *Let Ω be a unit-area disk. For any constant ξ, $N\left(\mathrm{P}_n(\Omega), 2\sqrt{\frac{\ln n+\xi}{\pi n}}\right)$ is asymptotically Poisson with mean $2\mathrm{e}^{-\xi}$, and*

$$\lim_{n\to\infty}\Pr\left[\rho_{\mathrm{GG}}\left(\mathrm{P}_n(\Omega)\right) < 2\sqrt{\frac{\ln n+\xi}{\pi n}}\right] = \exp\left(-2\mathrm{e}^{-\xi}\right).$$

Let $\rho_{\mathrm{Del}}(V)$ denote the largest edge length of the Delaunay triangulation over a point set V. The following theorem is given by Kozma et al. [3].

Theorem 6 *Let Ω be a unit-area disk. Then,*

$$\rho_{\mathrm{Del}}\left(\mathrm{X}_n(\Omega)\right) = O\left(\sqrt[3]{\frac{\ln n}{n}}\right).$$

In wireless networks with greedy forward routing (GFR), each node discards a packet if none of its neighbors is closer to the destination of the packet than itself, or otherwise forwards the packet to the neighbor that is the closest to the destination. Since each node only needs to maintain the locations of its one-hop neighbors and each packet should contain the location of the destination node, GFR can be implemented in a localized and memoryless manner. Because of the existence of local minima where none of the neighbors is closer to the destination than the current node, a packet may be discarded before it reaches its destination. To ensure that every packet can reach its destination, all nodes should have sufficiently large transmission radii to avoid the existence of local minima. Applying the r-disk model, we assume every node has the same transmission radius r, and each pair of nodes with distance at most r has a link. For a point set V, the *critical transmission radius* for GFR is given by

$$\rho_{\mathrm{GFR}}(V) = \max_{(u,v)\in V^2, u\neq v}\left(\min_{\|w-v\|<\|u-v\|}\|w-u\|\right).$$

In the definition, (u,v) is a source–destination pair and w is a node that is closer to v than u. If every node is with a transmission radius not less than $\rho_{\mathrm{GFR}}(V)$, GFR can guarantee the deliverability between any source–destination pair [12].

Theorem 7 *Let Ω be a unit-area convex compact region with bounded curvature, and $\beta_0 = 1/\left(2/3-\sqrt{3}/2\pi\right) \approx 1.6^2$. Suppose that $n\pi r_n^2 = (\beta + o(1))\ln n$ for some $\beta > 0$. Then,*

1. *If $\beta > \beta_0$, then $\rho_{\mathrm{GFR}}\left(\mathrm{P}_n(\Omega)\right) \le r_n$ is asymptotically almost sure.*
2. *If $\beta < \beta_0$, then $\rho_{\mathrm{GFR}}\left(\mathrm{P}_n(\Omega)\right) > r_n$ is asymptotically almost sure.*

Applications

In the literature, r-disk graphs (or unit disk graphs by proper scaling) are widely used to model homogeneous wireless networks in which each node is equipped with an omnidirectional antenna. According to the path loss of radio frequency, the transmission ranges (radii) of wireless devices depend on transmission powers. For simplicity, the power assignment problem usually is modeled by a corresponding transmission range assignment problem. Recently, wireless ad-hoc networks have attracted attention from a lot of researchers because of various possible applications. In many of the possible applications, since wireless devices are powered by batteries, transmission range assignment has become one of the most important tools for prolonging system lifetime. By applying the theory of critical ranges, a randomly deployed wireless ad-hoc network may have good properties in high probability if the transmission range is larger than some critical value.

One application of critical ranges is to connectivity of networks. A network is k-vertex-

connected if there exist k node-disjoint paths between any pair of nodes. With such a property, at least k distinct communication paths exist between any pair of nodes, and the network is connected even if $k-1$ nodes fail. Thus, with a higher degree of connectivity, a network may have larger bandwidth and higher fault tolerance capacity. In addition, in [9, 14], and [15], networks with node or link failures were considered.

Another application is in topology control. To efficiently operate wireless ad-hoc networks, subsets of network topology will be constructed and maintained. The related topics are called topology control. A spanner is a subset of the network topology in which the minimal total cost of a path between any pair of nodes, e.g., distance or energy consumption, is only a constant fact larger than the minimal total cost in the original network topology. Hence spanners are good candidates for virtual backbones. Geometric structures, including Euclidean minimal spanning trees, relative neighbor graphs, Gabriel graphs, Delaunay triangulations, Yao's graphs, etc., are widely used ingredients to construct spanners [1, 5, 13]. By applying the knowledge of critical ranges, the complexity of algorithm design can be reduced, e.g., [3, 11].

Open Problems

A number of problems related to critical ranges remain open. Most problems discussed here apply 2-D plane geometry. In other words, the point set is in the plane. The first direction for future work is to study those problems in high-dimension spaces. Another open research area is on the longest-edge problems for other geometric structures, e.g., relative neighbor graphs and Yao's graphs. A third direction for future work involves considering relations between graph properties. A well-known result in random geometric graphs is that vanishment of isolated nodes asymptotically implies connectivity of networks. But for the wireless networks with unreliable links, this property is still open. In addition, in wireless sensor networks, the relations between connectivity and coverage are also interesting.

Cryptographic Hardness of Learning

Adam Klivans
Department of Computer Science, University of Texas, Austin, TX, USA

Keywords

Representation-independent hardness for learning

Years and Authors of Summarized Original Work

1994; Kearns, Valiant

Problem Definition

This entry deals with proving negative results for distribution-free PAC learning. The crux of the problem is proving that a polynomial-time algorithm for learning various concept classes in the PAC model implies that several well-known cryptosystems are insecure. Thus, if we assume a particular cryptosystem is secure, we can conclude that it is impossible to efficiently learn a corresponding set of concept classes.

PAC Learning

We recall here the PAC learning model. Let C be a concept class (a set of functions over n variables), and let D be a distribution over the input space $\{0,1\}^n$. With C we associate a size function *size* that measures the complexity of each $c \in C$. For example, if C is a class of Boolean circuits, then $size(c)$ is equal to the number of gates in c. Let A be a randomized algorithm that has access to an oracle which returns labeled examples $(x, c(x))$ for some unknown $c \in C$; the examples x are drawn according to D. Algorithm A PAC learns concept class C by hypothesis class H if for any $c \in C$, for any distribution D over the input space, and any $\epsilon, \delta > 0$, A runs in time $poly(n, 1/\epsilon, 1/\delta, size(c))$ and produces a hypothesis $h \in H$ such that with probability at least $(1 - \delta)$, $Pr_D[c(x) \neq h(x)] < \epsilon$. This probability is taken over the random coin tosses of A as well as over the random labeled examples seen from distribution D. When $H = C$ (the hypothesis must be some concept in C), then A is a *proper* PAC learning algorithm. In this entry it is not assumed $H = C$, i.e., hardness results for *representation-independent* learning algorithms are discussed. The only assumption made on H is that for each $h \in H$, h can be evaluated in polynomial time for every input of length n.

Cryptographic Primitives

Also required is knowledge of various cryptographic primitives such as public-key cryptosystems, one-way functions, and one-way trapdoor functions. For a formal treatment of these primitives, refer to Goldreich [3].

Informally, a function f is *one way* if, after choosing a random x of length n and giving an adversary A only $f(x)$, it is computationally intractable for A to find y such that $f(y) = f(x)$. Furthermore, given x, $f(x)$ can be evaluated in polynomial time. That is, f is easy to compute one way, but there is no polynomial-time algorithm for finding pre-images of f on randomly chosen inputs. Say a function f is *trapdoor* if f is one way, but if an adversary A is given access to a secret "trapdoor" d, then A *can* efficiently find random pre-images of f.

Trapdoor functions that are permutations are closely related to *public-key cryptosystems*: imagine a person Alice who wants to allow others to secretly communicate with her. She publishes a one-way trapdoor permutation f so that it is publicly available to everyone, but keeps the "trapdoor" d to herself. Then Bob can send Alice a secret message x by sending her $f(x)$. Only Alice is able to invert f (recall f is a permutation) and recover x because only she knows d.

Key Results

The main insight in Kearns and Valiant's work is the following: if f is a trapdoor one-way function, and C is a circuit class containing the set of functions capable of inverting f given access to the trapdoor, then C is not efficiently PAC learnable, i. e., assuming the difficulty of inverting trap-door function f, there is a distribution on $\{0,1\}^n$ where no learning algorithm can succeed in learning f's associated decryption function.

The following theorem is stated in the (closely related) language of public-key cryptosystems:

Theorem 1 (Cryptography and learning; cf. Kearns and Valiant [4]) *Consider a public-key cryptosystem for encrypting individual bits into n-bit strings. Let C be a concept class that contains all the decryption functions $\{0,1\}^n \to \{0,1\}$ of the cryptosystem. If C is PAC learnable in polynomial time, then there is a polynomial-time distinguisher between the encryptions of 0 and 1.*

The intuition behind the proof is as follows: fix an encryption function f, associated secret key d, and let C be a class of functions such that the problem of inverting $f(x)$ given d can be computed by an element c of C; notice that knowledge of d is not necessary to generate a polynomial-size sample of $(x, f(x))$ pairs.

If C is PAC learnable, then given a relatively small number of encrypted messages $(x, f(x))$, a learning algorithm A can find a hypothesis h that will approximate c and thus have a non-negligible advantage for decrypting future *randomly* encrypted messages. This violates the security properties of the cryptosystem.

A natural question follows: "what is the simplest concept class that can compute the decryption function for secure public-key cryptosystems?" For example, if a public-key cryptosystem is proven to be secure, and encrypted messages can be decrypted (given the secret key) by polynomial-size DNF formulas, then, by Theorem 1, one could conclude that polynomial-size DNF formulas cannot be learned in the PAC model.

Kearns and Valiant do not obtain such a hardness result for learning DNF formulas (it is still an outstanding open problem), but they do obtain a variety of hardness results assuming the security of various well-known public-key cryptosystems based on the hardness of number-theoretic problems such as factoring.

The following list summarizes their main results:

- Let C be the class of polynomial-size Boolean formulas (not necessarily DNF formulas) or polynomial-size circuits of logarithmic depth. Assuming that the RSA cryptosystem is secure, or recognizing quadratic residues is intractable, or factoring Blum integers is intractable, C is not PAC learnable.
- Let C be the class of polynomial-size deterministic finite automata. Under the same assumptions as above, C is not PAC learnable.
- Let C be the class of constant depth threshold circuits of polynomial size. Under the same assumptions as above, C is not PAC learnable.

The depth of the circuit class is not specified but it can be seen to be at most 4.

Kearns and Valiant also prove the intractability of finding optimal solutions related to coloring problems assuming the security of the above cryptographic primitives (e.g., breaking RSA).

Relationship to Hardness Results for Proper Learning

The key results above should not be confused with the extensive literature regarding hardness results for *properly* PAC learning concept classes. For example, it is known [1] that, unless RP = NP, it is impossible to properly PAC learn polynomial-size DNF formulas (i.e., require the learner to learn DNF formulas by outputting a DNF formula as its hypothesis). Such results are *incomparable* to the work of Kearns and Valiant, as they require something much stronger from the learner but take a much weaker assumption (RP $\neq$ NP is a weaker assumption than the assumption that RSA is secure).

Applications and Related Work

Valiant [10] was the first to observe that the existence of a particular cryptographic primitive (pseudorandom functions) implies hardness results for PAC learning concept classes. The work of Kearns and Valiant has subsequently found many applications. Klivans and Sherstov have recently shown [7] that the problem of PAC learning intersections of halfspaces (a very simple depth-2 threshold circuit) is intractable unless certain lattice-based cryptosystems due to Regev [9] are not secure. Their result makes use of the Kearns and Valiant approach. Angluin and Kharitonov [2] have extended the Kearns and Valiant paradigm to give cryptographic hardness results for learning concept classes even if the learner has *query access* to the unknown concept. Kharitonov [6] has given hardness results for learning polynomial-size, constant depth circuits that assumes the existence of secure pseudorandom generators rather than the existence of public-key cryptosystems.

Open Problems

The major open problem in this line of research is to prove a cryptographic hardness result for PAC learning polynomial-size DNF formulas. Currently, polynomial-size DNF formulas seem far too weak to compute cryptographic primitives such as the decryption function for a well-known cryptosystem. The fastest known algorithm for PAC learning DNF formulas runs in time $2^{\tilde{O}(n^{1/3})}$ [8].

Cuckoo Hashing

Rasmus Pagh
Theoretical Computer Science, IT University of Copenhagen, Copenhagen, Denmark

Keywords

Dictionary; Hash table; Key-value store; Open addressing

Years and Authors of Summarized Original Work

2001; Pagh, Rodler

Problem Definition

A *dictionary* (also known as an *associative array*) is an abstract data structure capable of storing a set S of elements, referred to as *keys*, and information associated with each key. The operations supported by a dictionary are insertion of a key (and associated information), deletion of a key, and lookup of a key (retrieving the associated information). In case a lookup is made on a key that is not in S, this must be reported by the data structure.

The *hash table* is a class of data structures use to implement dictionaries in the RAM model of computation. *Open addressing* hash tables are a particularly simple type of hash table, where the data structure is an array such that each entry either contains a key of S or is marked "empty." *Cuckoo hashing* addresses the problem of implementing an open addressing hash table with *worst-case* constant lookup time. Specifically, a constant number of entries in the hash table should be associated with each key x, such that x is present in one of these entries if $x \in S$.

In the following it is assumed that a key and the information associated with a key are single machine words. This is essentially without loss of generality: If more associated data is wanted, it can be referred to using a pointer. If keys are longer than one machine word, they can be mapped down to a single (or a few) machine words using universal hashing [4] and the described method used on the hash values (which are unique to each key with high probability). The original key must then be stored as associated data. Let n denote an upper bound on the size of S. To allow the size of the set to grow beyond n, *global rebuilding* can be used.

Key Results

Prehistory

It has been known since the advent of universal hashing [4] that if the hash table has $r \geq n^2$ entries, a lookup can be implemented by retrieving just a single entry in the hash table. This is done by storing a key x in entry $h(x)$ of the hash table, where h is a function from the set of machine words to $\{1, \ldots, n^2\}$. If h is chosen at random from a *universal family* of hash functions [4], then with probability at least 1/2 every key in S is assigned a unique entry. The same behavior would be seen if h was a random function, but in contrast to random functions, there are universal families that allow efficient storage and evaluation of h (constant number of machine words and constant evaluation time).

This overview concentrates on the case where the space used by the open- addressing hash table is linear, $r = O(n)$. It was shown by Azar et al. [1] that it is possible to combine linear space with worst-case constant lookup time. It was not considered how to construct the data structure. Since randomization is used, all schemes discussed have a probability of error. However, this probability is small, $O(1/n)$ or less for all schemes, and an error can be handled by *rehashing* (changing the hash functions and rebuilding the hash table). The result of [1] was shown under the assumption that the algorithm is given free access to a number of truly random hash functions. In many of the subsequent papers, it is shown how to achieve the bounds using explicitly defined hash functions. However, no attempt is made here to cover these constructions.

In the following, let ε denote an arbitrary positive constant. Pagh [11] showed that retrieving two entries from the hash table suffices when

$r \geq (2+\varepsilon)n$. Specifically, lookup of a key x can be done by retrieving entries $h_1(x)$ and $h_2(x)$ of the hash table, where h_1 and h_2 are random hash functions mapping machine words to $\{1,\ldots,r\}$. The same result holds if h_1 has range $\{1,\ldots,r/2\}$ and h_2 has range $\{r/2+1,\ldots,r\}$, that is, if the two lookups are done in disjoint parts of memory.

It follows from [11] that it is not possible to perform lookup by retrieving a *single* entry in the worst case unless the hash table is of size $n^{2-o(1)}$.

Cuckoo Hashing

Pagh and Rodler [12] showed how to maintain the data structure of Pagh [11] under insertions. They considered the variant in which the lookups are done in disjoint parts of the hash table. It will be convenient to think of these as separate arrays, T_1 and T_2. Let $\perp$ denote the contents of an empty hash table entry, and let $x \leftrightarrow y$ express that the values of variables x and y are swapped. The proposed dynamic algorithm, called *cuckoo hashing*, performs insertions by the following procedure:

```
procedure insert(x)
  i := 1;
  repeat
    x ↔ T_i[h_i(x)]; i := 3 − i;
  until x = ⊥
  end
```

At any time the variable x holds a key that needs to be inserted in the table, or $\perp$. The value of i changes between 1 and 2 in each iteration, so the algorithm is alternately exchanging the contents of x with a key from Table 1 and Table 2. Conceptually, what happens is that the algorithm moves a sequence of zero or more keys from one table to the other to make room for the new key. This is done in a greedy fashion, by kicking out any key that may be present in the location where a key is being moved. The similarity of the insertion procedure and the nesting habits of the European cuckoo is the reason for the name of the algorithm.

The pseudocode above is slightly simplified. In general the algorithm needs to make sure not to insert the same key twice and handle the possibility that the insertion may not succeed (by rehashing if the loop takes too long).

Theorem 1 *Assuming that* $r \geq (2+\varepsilon)n$, *the expected time for the cuckoo hashing insertion procedure is O(1).*

Generalizations of Cuckoo Hashing

Cuckoo hashing has been generalized in several directions. Kirsh et al. [8] showed that keeping a small *stash* of memory locations that are inspected at every lookup can significantly reduce the error probability of cuckoo hashing.

More generally the case of $k > 2$ hash functions has been considered. Also, the hash table may be divided into "buckets" of size b, such that the lookup procedure searches an entire bucket for each hash function. Let (k, b)-cuckoo denote a scheme with k hash functions and buckets of size b. What was described above is a (2,1)-*cuckoo* scheme. Already in 1999, (4,1)-cuckoo was described in a patent application by David A. Brown (US patent 6,775,281). Fotakis et al. described and analyzed a $(k, 1)$-cuckoo scheme in [7], and a (2,b)-cuckoo scheme was described and analyzed by Dietzfelbinger and Weidling [5]. In both cases, it was shown that space utilization arbitrarily close to 100 % is possible and that the necessary fraction of unused space decreases exponentially with k and b. The insertion procedure considered in [5, 7] is a breadth-first search for the shortest sequence of key moves that can be made to accommodate the new key. Panigrahy [13] studied (2,2)-cuckoo schemes in detail, showing that a space utilization of 83 % can be achieved dynamically, still supporting constant time insertions using breadth-first search. In a *static* setting with no updates, thresholds for general (k, b)-cuckoo hashing have been established (see LeLarge [10] and its references).

Applications

Dictionaries (sometimes referred to as key-value stores) have a wide range of uses in computer science and engineering. For example, dictionaries arise in many applications in string algorithms

and data structures, database systems, data compression, and various information retrieval applications. Also, cuckoo hashing has been used in oblivious RAM simulations and other cryptographic constructions [2, 14].

Open Problems

The results above provide a good understanding of the properties of open-addressing schemes with worst-case constant lookup time. However, several aspects are still not understood satisfactorily.

First of all, there is no practical class of hash functions for which the above results can be shown. The only explicit classes of hash functions that are known to make the methods work either have evaluation time $\Theta(\log n)$ or use space $n^{\Omega(1)}$. It is an intriguing open problem to construct a class having constant evaluation time and space usage.

For the generalizations of cuckoo hashing, the use of breadth-first search is not so attractive in practice, due to the associated overhead in storage. A simpler approach that does not require any storage is to perform a random walk where keys are moved to a random, alternative position. (This generalizes the cuckoo hashing insertion procedure, where there is only one alternative position to choose.) Panigrahy [13] showed that this works for (2,2)-cuckoo when the space utilization is low. However, it is unknown whether this approach works well as the space utilization approaches 100 %.

Finally, many of the analyses that have been given are not tight. In contrast, most classical open addressing schemes have been analyzed very precisely. It seems likely that precise analysis of cuckoo hashing and its generalizations is possible using techniques from analysis of algorithms and tools from the theory of random graphs. In particular, the relationship between space utilization and insertion time is not well understood. A precise analysis of the probability that cuckoo hashing fails has been given by Kutzelnigg [9].

Experimental Results

All experiments on cuckoo hashing and its generalizations so far presented in the literature have been done using simple, heuristic hash functions. Pagh and Rodler [12] presented experiments showing that, for space utilization 1/3, cuckoo hashing is competitive with open addressing schemes that do not give a worst-case guarantee. Zukowski et al. [15] showed how to implement cuckoo hashing such that it runs very efficiently on pipelined processors with the capability of processing several instructions in parallel. For hash tables that are small enough to fit in cache, cuckoo hashing was 2 to 4 times faster than chained hashing in their experiments. Erlingsson et al. [6] considered (k, b)-cuckoo schemes for various combinations of small values of k and b, showing that very high space utilization is possible even for modestly small values of k and b. For example, a space utilization of 99.9 % is possible for $k = b = 4$. It was further found that the resulting algorithms were very robust. Experiments in [7] indicate that the random walk insertion procedure performs as well as one could hope for.

Current Champion for Online Bin Packing

Rob van Stee
University of Leicester, Leicester, UK

Keywords

Bin packing; Champion; Competitive analysis; Online algorithms

Years and Authors of Summarized Original Work

2002; Seiden

Problem Definition

In the online bin packing problem, a sequence of *items* with sizes in the interval $(0, 1]$ arrive one by one and need to be packed into *bins*, so that each bin contains items of total size at most 1. Each item must be irrevocably assigned to a bin before the next item becomes available. The algorithm has no knowledge about future items. There is an unlimited supply of bins available, and the goal is to minimize the total number of used bins (bins that receive at least one item).

The most common performance measure for online bin packing algorithms is the asymptotic performance ratio, or asymptotic competitive ratio, which is defined as

$$R_{\mathrm{ASY}}(A) := \limsup_{n\to\infty} \left\{ \max_{L} \left\{ \frac{A(L)}{n} \middle| \mathrm{OPT}(L)=n \right\} \right\}. \tag{1}$$

Hence, for any input L, the number of bins used by an online algorithm A is compared to the optimal number of bins needed to pack the same input. Note that calculating the optimal number of bins might take exponential time; moreover, it requires that the entire input is known in advance.

Key Results

This paper presents a new framework for analyzing online bin packing algorithms. It can be used to analyze all known versions of the well-known Harmonic algorithm, including a new version introduced in this paper.

The Harmonic algorithm [4] partitions the input into types depending on its size and packs each type separately. Harmonic-k has k types, and type i consists of items of size in the interval $(1/(i+1), 1/i]$. Harmonic has k open bins at

all times, one for each type, and packs i items of type i in one bin. Thus it achieves an asymptotic performance ratio of 1.691.

For some inputs, this algorithm wastes a lot of space in some bins, for instance, if many items of size $1/2 + \varepsilon$ arrive for some small $\varepsilon > 0$. Several authors improved on the basic Harmonic algorithm by combining some items of different types together into bins. Typically this is done by partitioning the intervals $(1/2, 1]$ and $(1/3, 1/2]$ further, guaranteeing that items can be combined. As a simple example, by introducing intervals $(1/2, 0.6]$ and $(1/3, 0.4]$, we can guarantee that items of these two new types can always be packed together in a single bin. Furthermore, the remaining intervals $(0.6, 1]$ and $(0.4, 0.5]$ now give better area guarantees than before: bins with items of these types will be at least 0.6 and at least 0.8 full, respectively.

Seiden builds on this idea and gives a new algorithm, Harmonic++, which beats all previously known algorithms and is still the best algorithm known. He used a computer-assisted search to set the many parameters of this algorithm. The algorithm partitions the intervals $(1/2, 1]$ and $(1/3, 1/2]$ in ten matching subintervals (in the sense described above) and also partitions intervals of several smaller types, using no less than 70 intervals in total. Also using a computer search, he proves that the asymptotic performance ratio of this algorithm is at most 1.58889.

Seiden also showed that the asymptotic performance ratio of a similar algorithm presented earlier, Harmonic+1, is at least 1.5972, disproving a claim by Richey [6] that Harmonic+1 is 1.58872-competitive.

The framework introduced by Seiden was used later in other contexts, for instance, for two-dimensional bin packing, where a set of rectangles needs to be packed into square bins. Han et al. [3] presented an algorithm with asymptotic performance ratio 2.5545. For the special case of packing squares, Han et al. [2] presented an algorithm with asymptotic performance ratio 2.1187.

Open Problems

The algorithm is very close to optimal for Harmonic-type algorithms, for which Ramanan et al. [5] showed a lower bound of 1.58333.... However, the general lower bound for this problem is only 1.54037 [1]. It is very difficult to see how either result can be improved, and this remains a challenging open problem which will require new ideas. There has been essentially no improvement in this area in over a decade.

Curve Reconstruction

Stefan Funke
Department of Computer Science, Universität Stuttgart, Stuttgart, Germany

Keywords

Computational geometry; Curve reconstruction

Years and Authors of Summarized Original Work

1998; Amenta, Bern, Eppstein
1999; Dey, Kumar
1999; Dey, Mehlhorn, Ramos
1999; Giesen
2001; Funke, Ramos
2003; Cheng, Funke, Golin, Kumar, Poon, Ramos

Problem Definition

Given a set S of sample points from a collection Γ of simple (nonintersecting) curves in the Euclidean plane, *curve reconstruction* is the problem of computing the graph $G(S, \Gamma)$, called the *correct reconstruction*, whose vertex set is S and that has an edge between two vertices if and only if the respective samples are adjacent on a curve in Γ; see Fig. 1.

Obviously, it is not possible to correctly reconstruct a given collection of curves from an arbitrary sample set from it. Therefore, some restriction on the sample set S – a so-called sampling condition – is required which specifies how dense a sampling has to be to guarantee a correct output of an algorithm. The difficulty for an algorithm to solve the curve reconstruction problem (and to come up with a suitable sampling condition) varies with the classes of allowed curves in Γ and whether the set S is actually sampled from the curves or noisy.

Key Results

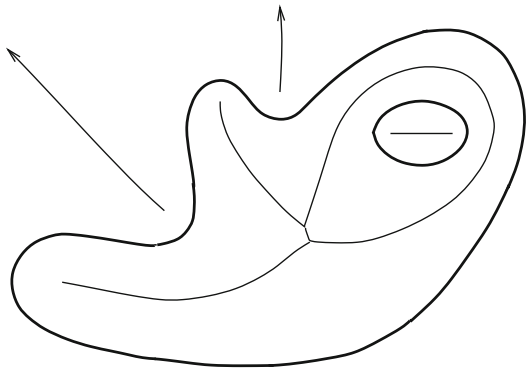
If the curves are closed, smooth, and uniformly sampled – that is, with a uniform maximum distance between adjacent sample points – several methods for the curve reconstruction problem are known to work ranging over minimum spanning trees,α-shapes, β-skeletons [KR85], and r-regular shapes; see the survey by Edelsbrunner [7]. The focus of this section are approaches which can deal with *nonuniform sampling conditions*, that is, conditions which allow sparser sampling in areas of low detail and require higher sampling only in areas of high detail.

Closed Smooth Curves

Amenta, Bern, and Epstein [2] introduced the concept of the *local feature size* $\mathrm{lfs}(p)$ of a point $p \in \Gamma$ which is defined as the distance to the *medial axis* of Γ. The medial axis of a collection of curves Γ is defined as the set of points in the plane which have more than one closest point on a curve in Γ; see Fig. 2. Roughly speaking, a neighborhood of a point of size equal to its local feature size is intersected by the curves in a single piece that winds up only a small angle.

The introduction of the local feature size allowed for a very elegant sampling condition: A sample set S is called an ϵ-sampling for a collection of curves Γ, if for all $p \in \Gamma$, $\exists s \in S$ with $|ps| \leq \epsilon \mathrm{lfs}(p)$. This condition naturally captures the intuition that "complicated" areas of the curve require higher sampling density than areas of low detail.

Curve Reconstruction, Fig. 1 A collection of curves Γ, a sample S from Γ, and the correct reconstruction G(S,Γ)



Curve Reconstruction, Fig. 2 The light curves are the medial axis of the heavy curves (Courtesy of N. Amenta, M. Bern, and D. Eppstein)

For small enough ϵ, the Voronoi nodes in the Voronoi diagram $VD(S)$ of an ϵ-sampling S for Γ approximate the medial axis of Γ. Based on that intuition, the *CRUST* algorithm in [1] outputs as correct reconstruction the edges of the Delaunay triangulation of S having a ball empty of Voronoi vertices in the Voronoi diagram $VD(S)$. For $\epsilon < 0.252$ CRUST provably outputs the correct reconstruction of an ϵ-sampling S with respect to a collection of closed smooth curves Γ.

In the same paper, the authors could also show that a known algorithm – the β-skeleton – for suitable choice of β also correctly reconstructs a collection of closed smooth curves for $\epsilon < 0.297$.

Later, Dey and Kumar [4] presented an extremely simple and straightforward algorithm connecting essentially the nearest neighbors on opposite sides. They could prove this algorithm to be correct under the local feature size sampling condition for $\epsilon \leq 1/3$. What is particularly interesting about this algorithm is the fact that decisions which points to connect are made based on a very local neighborhood of the respective points. This idea later nicely translated to algorithms for the 3- and higher-dimensional manifold reconstruction problem.

Open Smooth Curves

When considering the larger class of *open* and closed smooth curves, there is a little caveat. While one can guarantee for sufficiently dense samplings, i.e., small enough values of ϵ, that all edges of the correct reconstruction are present in the output of a reconstruction algorithm, one cannot always avoid the inclusion of additional edges in the output of an algorithm. Essentially, the problem is that a sample set, S set, might be an ϵ-sampling for two collections of curves Γ and Γ' with different correct reconstructions $G(S, \Gamma)$ and $G(S, \Gamma')$ irrespectively how small ϵ is chosen.

Dey, Mehlhorn, and Ramos in [5] introduced the concept of a *witness curve* Γ^*, proving the following guarantee for their *CONSERVATIVE CRUST* algorithm: If S is an ϵ-sampling for a collection of open and closed smooth curves Γ, their algorithm returns a reconstruction H such that $H \supseteq G(S, \Gamma)$, that is, H contains all edges of the correct reconstruction. Furthermore, the algorithm outputs a curve Γ^* such that S is an $\epsilon' \approx \epsilon$-sampling for Γ^* and $H = G(S, \Gamma^*)$. Their algorithm is similar to the CRUST algorithm in that it identifies a subcomplex of the Delaunay triangulation.

Closed Curves with Corners

Another natural extension of the allowed classes of curves in Γ is the inclusion of curves with corners, that is, points where left and right tangent do not coincide. Unfortunately, in this case, one cannot use the sampling condition based on the local feature size since the medial axis actually touches the corners, requiring an infinitely dense sampling near corners. The first algorithms to deal with a *single* closed curve possibly with corners were by Giesen [9] and Althaus/Mehlhorn [2] based on the construction of a travelling salesman tour. In their sampling condition, areas of the curve nearby a corner were exempt from the ϵ-sampling condition. [2] could even prove that the respective TSP instance can be solved in polynomial time for sufficiently dense sample sets. Dey and Wenger [6] proposed a non-TSP-based approach for collections of closed curves with corners.

Open and Closed Curves with Corners

Finally Funke/Ramos [8] considered the case of collections of open and closed curves. While their algorithm also comes with a guarantee for

some variant of an ϵ-sampling condition (with special condition near corners like [9] and [2]), they also propose a sampling condition which is expressed with respect to the correct reconstruction $G(S, \Gamma)$. Not being based on a travelling salesman tour computation, their algorithm can also handle collections containing several open curves. As [5] the algorithm also produces a collection of witness curves Γ'.

Noisy Sample Sets

A generalization in a different direction is the consideration of sample sets S which do not consist of points exactly *on* the curves in Γ but – e.g., due to measurement errors – lie only "nearby." In [3] the authors considered such noisy sample sets from a collection of disjoint smooth closed curves and could prove for a perturbed locally uniform sample set that their algorithm computes as output a set of polygonal curves converging to Γ as the sampling density increases.

Problem Definition

The problem is motivated by the need to manage data on a set of storage devices to handle dynamically changing demand. To maximize utilization, the data layout (i.e., a mapping that specifies the subset of data items stored on each disk) needs to be computed based on disk capacities as well as the demand for data. Over time as the demand for data changes, the system needs to create new data layout. The data migration problem is to compute an efficient schedule for the set of disks to convert an initial layout to a target layout.

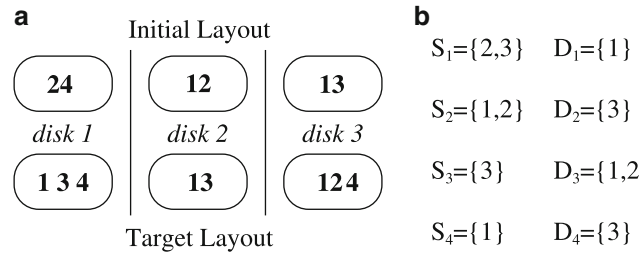
The problem is defined as follows. Suppose that there are N disks and Δ data items, and an initial layout and a target layout are given (see Fig. 1a for an example). For each item i, source disks S_i is defined to be a subset of disks which have item i in the initial layout. Destination disks D_i is a subset of disks that want to receive item i. In other words, disks in D_i have to store item i in the target layout but do not have to store it in the initial layout. Figure 1b shows the corresponding S_i and D_i. It is assumed that $S_i \neq \emptyset$ and $D_i \neq \emptyset$ for each item i. Data migration is the transfer of data to have all D_i receive data item i residing in S_i initially, and the goal is to minimize the total amount of time required for the transfers.

Assume that the underlying network is fully connected and the data items are all the same size. In other words, it takes the same amount of time to migrate an item from one disk to another. Therefore, migrations are performed in rounds. Consider the half-duplex model, where each disk can participate in the transfer of only one item – either as a sender or as a receiver. The objective is to find a migration schedule using the minimum number of rounds. No bypass nodes (A bypass node is a node that is not the target of a move operation, but is used as an intermediate holding point for a data item.) can be used and therefore all data items are sent only to disks that desire them.

Key Results

Khuller et al. [11] developed a 9.5-approximation for the data migration problem, which was later improved to $6.5 + o(1)$. In the next subsection,

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4



Data Migration, Fig. 1
Left An example of initial and target layout and *right* their corresponding S_i's and D_i's

the lower bounds of the problem are first examined.

Notations and Lower Bounds

1. **Maximum in-degree (β):** Let β_j be the number of data items that a disk j has to receive. In other words, $\beta_j = |\{i \,|\, j \in D_i\}|$. Then $\beta = \max_j \beta_j$ is a lower bound on the optimal as a disk can receive only one data item in one round.
2. **Maximum number of items that a disk may be a source or destination for (α):** For each item i, at least one disk in S_i should be used as a source for the item, and this disk is called a *primary source*. A unique primary source $s_i \in S_i$ for each item i that minimizes $\alpha = \max_{j=1,\ldots,N}(|\{i \,|\, j = s_i\}| + \beta_j)$ can be found using a network flow. Note that $\alpha \geq \beta$, and α is also a lower bound on the optimal solution.
3. **Minimum time required for cloning (M):** Let a disk j make a copy of item i at the kth round. At the end of the mth round, the number of copies that can be created from the copy is at most 2^{m-k} as in each round the number of copies can only be doubled. Also note that each disk can make a copy of only one item in one round. Since at least $|D_i|$ copies of item i need to be created, the minimum m that satisfies the following linear program gives a lower bound on the optimal solution: **L(m):**

$$\sum_j \sum_{k=1}^{m} 2^{m-k} x_{ijk} \geq |D_i| \quad \text{for all } i \qquad (1)$$

$$\sum_i x_{ijk} \leq 1 \quad \text{for all } j,k \qquad (2)$$

$$0 \leq x_{ijk} \leq 1 \qquad (3)$$

Data Migration Algorithm

A 9.5-approximation can be obtained as follows. The algorithm first computes representative sets for each item and sends the item to the representative sets first, which in turn send the item to the remaining set. Representative sets are computed differently depending on the size of D_i.

Representatives for Big Sets

For sets with size at least β, a *disjoint* collection of *representative sets* $R_i, i = 1 \ldots \Delta$ has to satisfy the following properties: Each R_i should be a subset of D_i and $|R_i| = \lfloor |D_i|/\beta \rfloor$. The representative sets can be found using a network flow.

Representatives for Small Sets

For each item i, let $\gamma_i = |D_i| \bmod k$. A *secondary representative*$_i$ in D_i for the items with $\gamma_i \neq 0$ needs to be computed. A disk j can be a secondary representative r_i for several items as long as $\sum_{i \in I_j} \gamma_i \leq 2\beta - 1$, where I_j is a set of items for which j is a secondary representative. This can be done by applying the Shmoys–Tardos algorithm [17] for the generalized assignment problem.

Scheduling Migrations

Given representatives for all data items, migrations can be done in three steps as follows:

1. **Migration to R_i:** Each item i is first sent to the set R_i. By converting a fractional solution given in $L(M)$, one can find a migration schedule from s_i to R_i and it requires at most $2M + \alpha$ rounds.
2. **Migration to r_i:** Item i is sent from primary source s_i to r_i. The migrations can be done in 1.5α rounds, using an algorithm for edge coloring [16].

3. **Migration to the remaining disks:** A transfer graph from representatives to the remaining disks can now be created as follows. For each item i, add directed edges from disks in R_i to $(\beta - 1)\lfloor \frac{|D_i|}{\beta} \rfloor$ disks in $D_i \setminus R_i$ such that the out-degree of each node in R_i is at most $\beta - 1$ and the in-degree of each node in $D_i \setminus R_i$ from R_i is 1. A directed edge is also added from the secondary representative r_i of item i to the remaining disks in D_i which do not have an edge coming from R_i. It has been shown that the maximum degree of the transfer graph is at most $4\beta - 5$ and the multiplicity is $\beta + 2$. Therefore, migration for the transfer graph can be done in $5\beta - 3$ rounds using an algorithm for multigraph edge coloring [18].

Analysis

Note that the total number of rounds required in the algorithm described in "Data Migration Algorithm" is at most $2M + 2.5\alpha + 5\beta - 3$. As α, β and M are lower bounds on the optimal number of rounds, the abovementioned algorithm gives a 9.5-approximation.

Theorem 1 ([11]) *There is a 9.5-approximation algorithm for the data migration problem.*

Khuller et al. [10] later improved the algorithm and obtained a $(6.5 + o(1))$-approximation.

Theorem 2 ([10]) *There is a (6.5 + o(1))-approximation algorithm for the data migration problem.*

Applications

Data Migration in Storage Systems

Typically, a large storage server consists of several disks connected using a dedicated network, called a *storage area network*. To handle high demand, especially for multimedia data, a common approach is to replicate data objects within the storage system. Disks typically have constraints on storage as well as the number of clients that can access data from a single disk simultaneously. Approximation algorithms have been developed to map known demand for data to a specific data layout pattern to maximize utilization (The utilization is the total number of clients that can be assigned to a disk that contains the data they want.) [4, 8, 14, 15]. In the layout, they compute not only how many copies of each item need to be created, but also a layout pattern that specifies the precise subset of items on each disk. The problem is NP-hard, but there are polynomial-time approximation schemes [4, 8, 14]. Given the relative demand for data, the algorithm computes an almost optimal layout.

Over time as the demand for data changes, the system needs to create new data layouts. To handle high demand for popular objects, new copies may have to be dynamically created and stored on different disks. The data migration problem is to compute a specific schedule for the set of disks to convert an initial layout to a target layout. Migration should be done as quickly as possible since the performance of the system will be suboptimal during migration.

Gossiping and Broadcasting

The data migration problem can be considered as a generalization of gossiping and broadcasting. The problems of gossiping and broadcasting play an important role in the design of communication protocols in various kinds of networks and have been extensively studied (see for example [6, 7] and the references therein). The gossip problem is defined as follows. There are n individuals and each individual has an item of gossip that he/she wish to communicate to everyone else. Communication is typically done in rounds, where in each round an individual may communicate with at most one other individual. Some communication models allow for the full exchange of all items of gossip known to each individual in a single round. In addition, there may be a communication graph whose edge indicates which pairs of individuals are allowed to communicate directly in each round. In the broadcast problem, one individual needs to convey an item of gossip to every other individual. The data migration problem generalizes the gossiping and broadcasting in three ways: (1) each item of gossip needs to be communicated to only a subset of individuals; (2) several items of gossip may be known to an

individual; (3) a single item of gossip can initially be shared by several individuals.

Open Problems

The data migration problem is NP-hard by reduction from the edge coloring problem. However, no inapproximability results are known for the problem. As the current best approximation factor is relatively high $(6.5 + o(1))$, it is an interesting open problem to narrow the gap between the approximation guarantee and the inapproximability.

Another open problem is to combine data placement and migration problems. This question was studied by Khuller et al. [9]. Given the initial layout and the new demand pattern, their goal was to find a set of data migrations that can be performed in a specific number of rounds and gives the best possible layout to the current demand pattern. They showed that even one-round migration is NP-hard and presented a heuristic algorithm for the one-round migration problem. The experiments showed that performing a few rounds of one-round migration consecutively works well in practice. Obtaining nontrivial approximation algorithms for this problem would be interesting future work.

Data migration in a heterogeneous storage system is another interesting direction for future research. Most research on data migration has focused mainly on homogeneous storage systems, assuming that disks have the same fixed capabilities and the network connections are of the same fixed bandwidth. In practice, however, large-scale storage systems may be heterogenous. For instance, disks tend to have heterogeneous capabilities as they are added over time owing to increasing demand for storage capacity. Lu et al. [13] studied the case when disks have variable bandwidth owing to the loads on different disks. They used a control-theoretic approach to generate adaptive rates of data migrations which minimize the degradation of the quality of the service. The algorithm reduces the latency experienced by clients significantly compared with the previous schemes. However, no theoretical bounds on the efficiency of data migrations were provided. Coffman et al. [2] studied the case when each disk i can handle p_i transfers simultaneously and provided approximation algorithms. Some papers [2, 12] considered the case when the lengths of data items are heterogenous (but the system is homogeneous), and present approximation algorithms for the problem.

Experimental Results

Golubchik et al. [3] conducted an extensive study of the performance of data migration algorithms under different changes in user-access patterns. They compared the 9.5-approximation [11] and several other heuristic algorithms. Some of these heuristic algorithms cannot provide constant approximation guarantees, while for some of the algorithms no approximation guarantees are known. Although the worst-case performance of the algorithm by Khuller et al. [11] is 9.5, in the experiments the number of rounds required was less than 3.25 times the lower bound.

They also introduced the *correspondence problem*, in which a matching between disks in the initial layout with disks in the target layout is computed so as to minimize changes. A good solution to the correspondence problem can improve the performance of the data migration algorithms by a factor of 4.4 in their experiments, relative to a bad solution.

Recommended Reading

A special case of the data migration problem was studied by Anderson et al. [1] and Hallet al. [5].

They assumed that a data transfer graph is given, in which a node corresponds to each disk and a directed edge corresponds to each move operation that is specified (the creation of new copies of data items is not allowed). Computing a data movement schedule is exactly the problem of edge-coloring the transfer graph. Algorithms for edge-coloring multigraphs can now be applied to produce a migration schedule since each color class represents a matching in the graph that can be scheduled simultaneously. Computing a solution with the minimum number of rounds is NP-hard, but several good approximation algorithms are available for edge coloring. With space constraints on the disk, the problem becomes more challenging. Hall et al. [5] showed that with the assumption that each disk has one spare unit of storage, very good constant factor approximations can be developed. The algorithms use at most $4\lceil\Delta/4\rceil$ colors with at most $n/3$ bypass nodes, or at most $6\lceil\Delta/4\rceil$ colors without bypass nodes.

Most of the results on the data migration problem deal with the half-duplex model. Another interesting communication model is the full-duplex model where each disk can act as a sender and a receiver in each round for a single item. There is a $(4 + o(1))$-approximation algorithm for the full-duplex model [10].

Problem Definition

The NP-complete DOMINATING SET problem is a notoriously hard problem:

Problem 1 (Dominating Set)
INPUT: An undirected graph $G = (V, E)$ and an integer $k \geq 0$.
QUESTION: Is there an $S \subseteq V$ with $|S| \leq k$ such that every vertex $v \in V$ is contained in S or has at least one neighbor in S?

For instance, for an n-vertex graph its optimization version is known to be polynomial-time approximable only up to a factor of $\Theta(\log n)$ unless some standard complexity-theoretic assumptions fail [9]. In terms of parametrized complexity, the problem is shown to be W[2]-complete [8]. Although still NP-complete when restricted to planar graphs, the situation much improves here. In her seminal work, Baker showed that there is an efficient polynomial-time approximation scheme (PTAS) [6], and the problem also becomes fixed-parameter tractable [2, 4] when restricted to planar graphs. In particular, the problem becomes accessible to fairly effective data reduction rules and a kernelization result (see [16] for a general description of data reduction and kernelization) can be proven. This is the subject of this entry.

Key Results

The key idea behind the data reduction is preprocessing based on locally acting simplification rules. Exemplary, here we describe a rule where the local neighborhood of each graph vertex is considered. To this end, we need the following definitions.

We partition the neighborhood $N(v)$ of an arbitrary vertex $v \in V$ in the input graph into three disjoint sets $N_1(v)$, $N_2(v)$, and $N_3(v)$ depending on local neighborhood structure. More specifically, we define

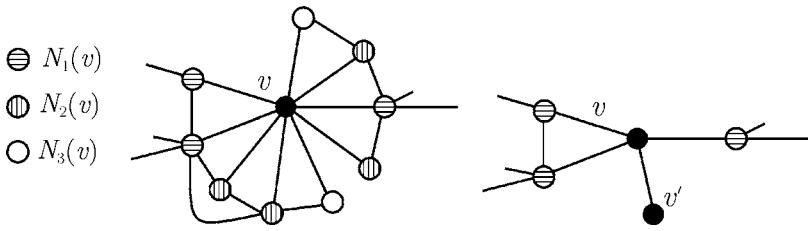
- $N_1(v)$ to contain all neighbors of v that have edges to vertices that are not neighbors of v;
- $N_2(v)$ to contain all vertices from $N(v) \setminus N_1(v)$ that have edges to at least one vertex from $N_1(v)$;
- $N_3(v)$ to contain all neighbors of v that are neither in $N_1(v)$ nor in $N_2(v)$.

An example which illustrates such a partitioning is given in Fig. 1 (left-hand side). A helpful and intuitive interpretation of the partition is to see vertices in $N_1(v)$ as *exits* because they have direct connections to the world outside the closed neighborhood of v, vertices in $N_2(v)$ as *guards* because they have direct connections to exits, and vertices in $N_3(v)$ as *prisoners* because they do not see the world outside $\{v\} \cup N(v)$.

Now consider a vertex $w \in N_3(v)$. Such a vertex only has neighbors in $\{v\} \cup N_2(v) \cup N_3(v)$. Hence, to dominate w, at least one vertex of $\{v\} \cup N_2(v) \cup N_3(v)$ *must* be contained in a dominating set for the input graph. Since v can dominate all vertices that would be dominated by choosing a vertex from $N_2(v) \cup N_3(v)$ into the dominating set, we obtain the following data reduction rule.

If $N_3(v) \neq \emptyset$ for some vertex v, then remove
$N_2(v)$ and $N_3(v)$ from G
and add a new vertex v'
with the edge $\{v, v'\}$ to G.

Note that the new vertex v' can be considered as a "gadget vertex" that "enforces" v to be chosen into the dominating set. It is not hard to verify the correctness of this rule, that is, the original graph has a dominating set of size k iff the reduced graph has a dominating set of size k. Clearly, the data reduction can be executed in polynomial time [5]. Note, however, that there are particular "diamond" structures that are not amenable to this reduction rule. Hence, a second, somewhat more complicated rule based on considering the joint neighborhood of *two* vertices has been introduced [5].



Data Reduction for Domination in Graphs, Fig. 1 The *left-hand side* shows the partitioning of the neighborhood of a single vertex v. The *right-hand side* shows the result of applying the presented data reduction rule to this particular (sub)graph

Altogether, the following core result could be shown [5].

Theorem 1 *A planar graph $G = (V, E)$ can be reduced in polynomial time to a planar graph $G' = (V', E')$ such that G has a dominating set of size k iff G' has a dominating set of size k and $|V'| = O(k)$.*

In other words, the theorem states that the DOMINATING SET in planar graphs has a linear-size problem kernel. The upper bound on $|V'|$ was first shown to be $335k$ [5] and was then further improved to $67k$ [7]. Moreover, the results can be extended to graphs of bounded genus [10]. In addition, similar results (linear kernelization) have been recently obtained for the FULL-DEGREE SPANNING TREE problem in planar graphs [13]. Very recently, these results have been generalized into a methodological framework [12].

Applications

DOMINATING SET is considered to be one of the most central graph problems [14, 15]. Its applications range from facility location to bioinformatics.

Open Problems

The best lower bound for the size of a problem kernel for DOMINATING SET in planar graphs is $2k$ [7]. Thus, there is quite a gap between known upper and lower bounds. In addition, there have been some considerations concerning a generalization of the above-discussed data reduction rules [3]. To what extent such extensions are of practical use remains to be explored. Finally, a study of deeper connections between Baker's PTAS results [6] and linear kernelization results for DOMINATING SET in planar graphs seems to be worthwhile for future research. Links concerning the class of problems amenable to both approaches have been detected recently [12]. The research field of data reduction and problem kernelization as a whole together with its challenges is discussed in a recent survey [11].

Experimental Results

The above-described theoretical work has been accompanied by experimental investigations on synthetic as well as real-world data [1]. The results have been encouraging in general. However, note that grid structures seem to be a hard case where the data reduction rules remained largely ineffective.

Problem Definition

The problem is concerned with the following setting. A computationally limited client wants to compute some property of a massive input, but lacks the resources to store even a small fraction of the input, and hence cannot perform the desired computation locally. The client therefore accesses a powerful but untrusted service provider (e.g., a commercial cloud computing service), who not only performs the requested computation but also proves that the answer is correct. An array of closely related models have been introduced to capture this scenario. The following section provides a unified presentation of these models, emphasizing their common features before delineating their differences.

Streaming Verification Model

Let $\sigma = \langle a_1, a_2, \ldots, a_m \rangle$ be a data stream, where each a_i comes from a data universe $\mathcal{U}$ of size n, and let F be a function mapping data streams to a finite range $\mathcal{R}$. A stream verification protocol for F involves two parties: a *prover* $\mathcal{P}$ and a (randomized) *verifier* $\mathcal{V}$. The protocol consists of two stages: a stream observation stage and a proof verification stage.

In the stream observation stage, $\mathcal{V}$ processes the stream σ, subject to the standard constraints of the data-stream model, i.e., sequential access to σ and limited memory. In the proof verification stage, $\mathcal{V}$ and $\mathcal{P}$ exchange a sequence of one or more messages, and afterward $\mathcal{V}$ outputs a value b. $\mathcal{V}$ is allowed to output a special symbol $\perp$ indicating a rejection of $\mathcal{P}$'s claims. Formally, $\mathcal{V}$ constitutes a stream verification protocol if the following two properties are satisfied:

- **Completeness**: There is some prover strategy $\mathcal{P}$ such that, for all streams σ, the probability that $\mathcal{V}$ outputs $F(\sigma)$ after interacting with $\mathcal{P}$ is at least $2/3$.
- **Soundness**: For all streams σ and all prover strategies $\mathcal{P}$, the probability that $\mathcal{V}$ outputs a value not in $\{F(x), \perp\}$ after interacting with $\mathcal{P}$ is at most $\epsilon \leq 1/3$.

Here, the probabilities are taken over $\mathcal{V}$'s internal randomness. The constants $2/3$ and $1/3$ are not essential and are chosen by convention. The parameter ϵ is referred to as the *soundness error* of the protocol.

Costs

There are five primary costs in any stream verification protocol: (1) $\mathcal{V}$'s space usage, (2) the total communication cost, (3) $\mathcal{V}$'s runtime, (4) $\mathcal{P}$'s runtime, and (5) the number of messages exchanged.

Differences Between Models

There are three primary differences between the various models of stream verification that have been put forth in the literature. The first is whether the soundness condition is required to hold against all cheating provers (such protocols are called *information-theoretically* or *statistically* sound), or only against cheating provers that run in polynomial time (such protocols are called *computationally* sound). The second is the amount and format of the interaction allowed between $\mathcal{P}$ and $\mathcal{V}$. The third is the temporal relationship between the stream observation and proof verification stage – in particular, several models permit $\mathcal{P}$ and $\mathcal{V}$ to exchange messages before and during the stream observation stage and sometimes permit the prover's messages to depend on parts of the data stream that $\mathcal{V}$ has not yet seen. In general, more permissive models allow a larger class of problems to be solved efficiently, but may yield protocols that are less realistic.

Summary of Models

The *annotated data streaming* (ADS) model [3] is noninteractive: $\mathcal{P}$ is permitted to send a single message to $\mathcal{V}$, with no communication allowed in the reverse direction. Technically, this model permits the contents of $\mathcal{P}$'s message to be interleaved with the stream, in which case each bit of $\mathcal{P}$'s message may be viewed as an "annotation" associated with a particular stream update. However, for most ADS protocols that have been developed, $\mathcal{P}$'s message can be sent after the stream observation phase. There are two kinds of ADS protocols: *prescient* protocols, in which the annotation sent at any given time can depend on parts of the data stream that $\mathcal{V}$ has not yet seen, and *online* protocols, which disallow this kind of dependence.

Streaming interactive proofs (SIPs) extend the ADS model to allow the prover and verifier to exchange many messages [6]. The *Arthur–Merlin streaming model* [10] is equivalent to a restricted class of SIPs, in which $\mathcal{V}$ is only allowed to send a single message to $\mathcal{P}$ (which must consist entirely of random coin tosses, in analogy with the classical complexity class AM), before receiving $\mathcal{P}$'s reply. The *streaming delegation model* [5] corresponds to SIPs that only satisfy computational, rather than information-theoretic, soundness.

Key Results

Obtaining exact answers even for basic problems in the standard data streaming model is impossible using $o(n)$ space. In contrast, stream verification protocols with $o(n)$ space and communication costs have been developed for (exactly solving) a wide variety of problems. Many of these protocols have adapted powerful algebraic techniques originally developed in the classical literature on interactive proofs, particularly the *sum-check* protocol of Lund et al. [14]. All of the protocols described here apply even to streams in the strict turnstile update model, where universe items can be deleted as well as inserted.

Annotated Data Streams

Chakrabarti et al. [3] showed that prescient ADS protocols can be exponentially more powerful than online ones for some problems. For example,

there is a prescient ADS protocol with logarithmic space and communication costs for computing the median of a sequence of numbers: $\mathcal{P}$ sends $\mathcal{V}$ the claimed median τ at the start of the stream, and while observing the stream, $\mathcal{V}$ checks that $|\{j : a_j < \tau\}| \leq m/2$, and $|\{j : a_j > \tau\}| \leq m/2$, which can be done using an $O(\log m)$-bit counter. Meanwhile, [3] proved that any online protocol for MEDIAN with communication cost h and space cost v requires $h \cdot v = \Omega(n)$ and gave an online ADS protocol achieving these communication–space trade-offs up to logarithmic factors.

Chakrabarti et al. [3] also gave online ADS protocols achieving identical trade-offs between space and communication costs for problems including FREQUENCY MOMENTS and FREQUENT ITEMS and used a lower bound due to Klauck [11] on the *Merlin–Arthur communication complexity* of the SET-DISJOINTNESS function to show that these trade-offs are optimal for these problems even among prescient protocols. Subsequent work gave similarly optimal online ADS protocols for several more problems, including maximum matching and counting triangles in graphs and matrix-vector multiplication [8, 18]. Chakrabarti et al. [2] gave optimized protocols for streams whose length m is much smaller than the universe size n.

Streaming Interactive Proofs

Cormode, Thaler, and Yi [6] showed that several general protocols from the classical literature on interactive proofs can be simulated in the SIP model. In particular, this includes a powerful, general-purpose protocol due to Goldwasser, Kalai, and Rothblum [9] (henceforth, the GKR protocol). Given any problem computed by an arithmetic or Boolean circuit of polynomial size and polylogarithmic depth, the GKR protocol requires only polylogarithmic space and communication while using polylogarithmic rounds of verifier–prover interaction. This yields SIPs for exactly solving many basic streaming problems with polylogarithmic space and communication costs, including FREQUENCY MOMENTS, FREQUENT ITEMS, and GRAPH CONNECTIVITY. Optimized protocols for specific problems, including FREQUENCY MOMENTS (see the detailed example below), were also presented.

Chakrabarti et al. [4] give *constant-round* SIPs with logarithmic space and communication costs for many problems, including INDEX, RANGE-COUNTING, and NEAREST-NEIGHBOR SEARCH. Gur and Raz [10] gave an Arthur–Merlin streaming protocol for the DISTINCT ELEMENTS problem with communication cost $\tilde{O}(h)$ space cost $\tilde{O}(v)$ for any h, v satisfying $h \cdot v \geq n$. Klauck and Prakash [13] extended this protocol to give an SIP for Distinct Elements with polylogarithmic space and communication costs and logarithmically many rounds of prover–verifier interaction.

Computationally Sound Protocols

Computationally sound protocols may achieve properties that are unattainable in the information-theoretic setting. For example, they typically achieve reusability, allowing the verifier to use the same randomness to answer many queries. In contrast, most SIPs only support "one-shot" queries, because they require the verifier to reveal secret randomness to the prover over the course of the protocol. Chung et al. [5] combined the GKR protocol with fully homomorphic encryption (FHE) to give reusable two-message protocols with polylogarithmic space and communication costs for any problem in the complexity class NC. They also gave reusable four-message protocols with polylogarithimic space and communication costs for any problem in the complexity class P. Papamanthou et al. [15] gave improved protocols for a class of low-complexity queries including point queries and range search: these protocols avoid the use of FHE and allow the prover to answer such queries in polylogarithmic time. (In contrast, protocols based on the GKR protocol [5, 6] require the prover to spend time quasilinear in the size of the data stream after receiving a query, even if the answer itself can be computed in sublinear time.)

Implementations

Implementations of the GKR protocol were provided in [7, 17]. Cormode, Mitzenmacher, and Thaler [7] also provided optimized

implementations of several ADS protocols from [3, 8]. Thaler et al. [19] provided parallelized implementations using Graphics Processing Units.

Detailed Example

The sum-check protocol can be directly applied to give an SIP for the kth frequency moment problem with $\log n$ rounds of prover–verifier iteration and $O(\log^2(n))$ space and communication costs. The sum-check protocol is described in Fig. 1.

Properties and Costs of the Sum-Check Protocol

The sum-check protocol satisfies perfect completeness and has soundness error $\epsilon \leq \deg(g)/|\mathbb{F}|$, where $\deg(g)$ denotes the total degree of g [14]. There is one round of prover–verifier interaction in the sum-check protocol for each of the v variables of g, and the total communication is $O(\deg(g))$ field elements.

Note that as described in Fig. 1, the sum-check protocol assumes that the verifier has oracle access to g. However, this will not be the case in applications, as g will ultimately be a polynomial that depends on the input data stream.

The SIP for Frequency Moments

In the kth frequency moment problem, the goal is to output $\sum_{i \in \mathcal{U}} f_i^k$, where f_i is the number of times item i appears in the data stream σ. For a vector $\mathbf{i} = (i_1, \ldots, i_{\log n}) \in \{0,1\}^{\log n}$, let $\chi_{\mathbf{i}}(x_1, \ldots, x_{\log n}) = \prod_{k=1}^{\log n} \chi_{i_k}(x_k)$, where $\chi_0(x_k) = 1 - x_k$ and $\chi_1(x_k) = x_k$. $\chi_{\mathbf{i}}$ is the unique multilinear polynomial that maps $\mathbf{i} \in \{0,1\}^{\log n}$ to 1 and all other values in $\{0,1\}^{\log n}$ to 0, and it is referred to as the *multilinear extension* of $\mathbf{i}$.

For each $i \in \mathcal{U}$, associate i with a vector $\mathbf{i} \in \{0,1\}^{\log n}$ in the natural way, and let $\mathbb{F}$ be a finite field with $n^k \leq |\mathbb{F}| \leq 4 \cdot n^k$. Define the polynomial $\hat{f}: \mathbb{F}^{\log n} \to \mathbb{F}$ via

Input: $\mathcal{V}$ is given oracle access to a v-variate polynomial g over finite field $\mathbb{F}$ and an $H \in \mathbb{F}$.
Goal: Determine whether $H = \sum_{(x_1,\ldots,x_v) \in \{0,1\}^v} g(x_1,\ldots,x_v)$.

- In the first round, $\mathcal{P}$ computes the univariate polynomial

$$g_1(X_1) := \sum_{x_2,\ldots,x_v \in \{0,1\}^{v-1}} g(X_1, x_2, \ldots, x_v),$$

  and sends g_1 to $\mathcal{V}$. $\mathcal{V}$ checks that g_1 is a univariate polynomial of degree at most $\deg_1(g)$, and that $H = g_1(0) + g_1(1)$, rejecting if not.
- $\mathcal{V}$ chooses a random element $r_1 \in \mathbb{F}$, and sends r_1 to $\mathcal{P}$.
- In the jth round, for $1 < j < v$, $\mathcal{P}$ sends to $\mathcal{V}$ the univariate polynomial

$$g_j(X_j) = \sum_{(x_{j+1},\ldots,x_v) \in \{0,1\}^{v-j}} g(r_1, \ldots, r_{j-1}, X_j, x_{j+1}, \ldots, x_v).$$

  $\mathcal{V}$ checks that g_j is a univariate polynomial of degree at most $\deg_j(g)$, and that $g_{j-1}(r_{j-1}) = g_j(0) + g_j(1)$, rejecting if not.
- $\mathcal{V}$ chooses a random element $r_j \in \mathbb{F}$, and sends r_j to $\mathcal{P}$.
- In round v, $\mathcal{P}$ sends to $\mathcal{V}$ the univariate polynomial

$$g_v(X_v) = g(r_1, \ldots, r_{v-1}, X_v).$$

  $\mathcal{V}$ checks that g_v is a univariate polynomial of degree at most $\deg_v(g)$, rejecting if not.
- $\mathcal{V}$ chooses a random element $r_v \in \mathbb{F}$ and evaluates $g(r_1, \ldots, r_v)$ with a single oracle query to g. $\mathcal{V}$ checks that $g_v(r_v) = g(r_1, \ldots, r_v)$, rejecting if not.
- If $\mathcal{V}$ has not yet rejected, $\mathcal{V}$ halts and accepts.

Data Stream Verification, Fig. 1 Description of the sum-check protocol. $\deg_i(g)$ denotes the degree of g in the ith variable

$$\hat{f} = \sum_{\mathbf{i} \in \{0,1\}^{\log n}} f_i \cdot \chi_{\mathbf{i}}. \qquad (1)$$

Note that $\hat{f}$ is the unique multilinear polynomial satisfying the property that $\hat{f}(\mathbf{i}) = f_i$ for all $\mathbf{i} \in \{0,1\}^{\log n}$.

The kth frequency moment of σ is equal to

$$\sum_{\mathbf{i} \in \{0,1\}^{\log n}} f_i^k = \sum_{\mathbf{i} \in \{0,1\}^{\log n}} (\hat{f}^k)(\mathbf{i}) \,.$$

Hence, in order to compute the kth frequency moment of σ, it suffices to apply the sum-check protocol to the polynomial $g = \hat{f}^k$. This requires $\log n$ rounds of prover–verifier interaction, and since the total degree of $\hat{f}^k$ is $k \cdot \log n$, the total communication cost is $O(k \log n)$ field elements, which require $O(k^2 \log^2 n)$ total bits to specify.

At the end of the sum-check protocol, $\mathcal{V}$ must compute

$$g(r_1, \ldots, r_{\log n}) = (\hat{f}^k)(r_1, \ldots, r_{\log n})$$

for randomly chosen $(r_1, \ldots, r_{\log n}) \in \mathbb{F}^{\log n}$. It suffices for $\mathcal{V}$ to evaluate $z := \hat{f}(r_1, \ldots, r_{\log n})$, since $(\hat{f}^k)(r_1, \ldots, r_{\log n}) = z^k$. The following lemma establishes that $\mathcal{V}$ can evaluate z with a single pass over σ, while storing $O(\log n)$ field elements.

Lemma 1 *$\mathcal{V}$ can compute $z = \hat{f}(r_1, \ldots, r_{\log n})$ with a single streaming pass over σ, while storing $O(\log n)$ field elements.*

Proof Given any stream update $a_j \in \mathcal{U}$, let $\mathbf{a_j}$ denote the binary vector associated with a_j. It follows from Eq. (1) that $\hat{f}(r_1, \ldots, r_{\log n}) = \sum_{j=1}^{m} \chi_{\mathbf{a_j}}(r_1, \ldots, r_{\log n})$. Thus, $\mathcal{V}$ can compute $\hat{f}(r_1, \ldots, r_{\log n})$ incrementally from the raw stream by initializing $\hat{f}(r_1, \ldots, r_{\log n}) \leftarrow 0$ and processing each update a_j via

$$\hat{f}(r_1, \ldots, r_{\log n}) \leftarrow \hat{f}(r_1, \ldots, r_{\log n}) + \chi_{\mathbf{a_j}}(r_1, \ldots, r_{\log n}).$$

$\mathcal{V}$ only needs to store $(r_1, \ldots, r_{\log n})$ and $\hat{f}(r_1, \ldots, r_{\log n})$, which is $O(\log n)$ field elements in total.

Open Problems

- For several functions $F: \{0,1\}^n \to \{0,1\}$, it is known that any online ADS protocol for F with communication cost h and space cost v requires $h \cdot v = \Omega(n)$. This lower bound is tight in many cases, such as for the INDEX function [3]. However, it is open to exhibit a function that cannot be computed by any online ADS protocol with communication and space costs both bounded above by h, for some $h = \omega(n^{1/2})$.
- Two-message online SIP protocols with logarithmic space and communication costs are known for several functions, including the INDEX function [4]. It is also known that *existing techniques* cannot yield 2- or 3-message online SIPs of polylogarithmic cost for the MEDIAN or FREQUENCY MOMENT problems. However, it is open to exhibit a function $F: \{0,1\}^n \to \{0,1\}$ that cannot be computed by any online two-message SIP with communication and space costs both bounded above by h, for some $h = \omega(\log n)$.

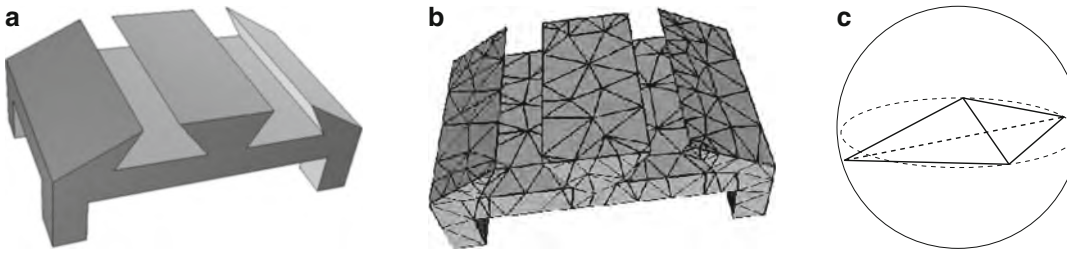
Problem Definition

A three-dimensional domain with piecewise linear boundary elements can be represented as a *piecewise linear complex* (PLC) of *linear cells* – vertices, edges, polygons, and polyhedra – that satisfy the following properties [4]. First, no vertex lies in the interior of an edge and every two edges are interior-disjoint. Second, the boundary of a polygon or polyhedra are union of cells in the PLC. Third, if two cells f and g intersect, the intersection is a union of cells in the PLC with dimensions lower than f or g. A triangulation of an input PLC is *conforming* if every edge and polygon appear as a union of segments and triangles in the triangulation. Additional Steiner vertices are often necessary. The 3D conforming Delaunay triangulation problem is to construct a triangulation of an input PLC that is both conforming and Delaunay. Figure 1a, b shows an input PLC and its conforming Delaunay triangulation. In many applications, it is often desired that the triangulation is not unnecessarily dense and the resulting tetrahedra are of *bounded*



3D Conforming Delaunay Triangulation, Fig. 1 A PLC and its conforming Delaunay triangulation in (**a**) and (**b**). A sliver with negligible volume and edge lengths similar to its circumradius in (**c**).

aspect ratio. Another popular shape measure is the *radius-edge ratio*, which is the ratio of the circumradius of the tetrahedron to its shortest edge length. Tetrahedra with bounded radius-edge ratio may still have negligible volume, and they are known as *slivers*. Figure 1c shows a sliver.

Key Results

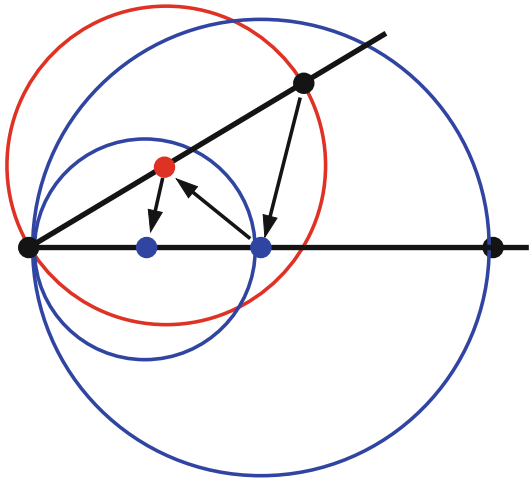
Since the Delaunayhood of edges and triangles are guaranteed by the emptiness of their circumspheres, one would imagine that a conforming Delaunay triangulation can be obtained by sprinkling Steiner vertices on the input edges and polygons. Indeed, Murphy, Mount, and Gable [6] showed a way to do this, but the resulting triangulation is very dense, and no shape guarantee is offered.

Shewchuk [9] gave the first algorithm that offers shape guarantee for PLCs in which two adjoining elements do not make an acute angle. (The exact requirement is more general and is called the projection condition [4, 9].) The algorithm is a generalization of Ruppert's Delaunay refinement algorithm in the plane [8]. An initial Delaunay triangulation is formed using the input vertices, and then Steiner vertices are added incrementally. Boundary conformity takes precedence. Therefore, whenever a segment on an edge or a triangle on a polygon has a nonempty diametric ball (the ball enclosed by the smallest circumsphere), that segment or triangle is split by inserting the center of its diametric ball. A Delaunay tetrahedron with radius-edge ratio larger than a prescribed constant $\rho > 2$ is split by inserting its circumcenter. However, if this circumcenter lies inside the diametric ball of a segment or a triangle, then the insertion is aborted and that segment or triangle is split instead. Similarly, the insertion of a triangle's diametric ball center is aborted if it lies in the diametric ball of a segment, and that segment is split instead. The following theorem states the main result.

Theorem 1 ([4, 9]) *Let ρ be a constant greater than 2. Let P be a PLC with no acute input angle. A conforming Delaunay triangulation of P can be obtained by Delaunay refinement and all tetrahedra obtained have radius-edge ratio at most ρ.*

In the presence of acute angles, the splitting of segments and triangles may lead to an infinite loop as illustrated in Fig. 2. Notice that the Steiner vertices inserted are approaching the input vertex in Fig. 2. In the plane, Ruppert [8] proposed a fix: place some protecting circles centered at the input vertices, disallow the insertion of Steiner vertices inside these protecting circles, and triangulate the inside of these protecting circles using a separate mechanism. A key change is that if a Steiner vertex to be inserted is too close to an arc on a protecting circle, then the insertion of the Steiner vertex is aborted and the circular arc is split by inserting its midpoint. This is analogous to the splitting of segments.

Cohen-Steiner, de Verdière, and Yvinec [5] generalized this idea partly to three dimensions. They proposed to place protecting balls centered at the input vertices as well as at some appropriate points in the interior of input edges. These protecting balls cover all input vertices and edges. The intersection between a protecting ball



3D Conforming Delaunay Triangulation, Fig. 2 The midpoint of the segment with the largest diametric ball triggers the splitting of the segment with the second largest diametric ball, which in turn triggers the splitting of the segment with the smallest diametric ball. This may go on indefinitely

boundary and an input polygon is analogous to a protecting circle in 2D. Therefore, when we want to insert Steiner vertices in a polygon f to recover the Delaunay triangles on f, if such a Steiner vertex v is too close to an arc α at the intersection of f and some protecting ball boundary, the insertion of v is aborted and α is split instead. The portions of polygons inside the protecting balls are triangulated using a separate mechanism. If a tetrahedron τ has large radius-edge ratio but its circumcenter lies inside some protecting ball, then τ is just kept in the triangulation. As a result, no shape guarantee is offered.

Theorem 2 ([5]) *There is a Delaunay refinement algorithm that constructs a conforming Delaunay triangulation of any input PLC.*

Cheng and Poon [2] extended Delaunay refinement by observing that segments, circular arcs, triangles, and spherical triangles can all be handled in a uniform way.

Let $\mathcal{B}$ be the union of protecting balls with centers at the input vertices and interior of input edges. Let B be a protecting ball. Let ∂ denote the boundary operator. For every input polygon f, the Steiner vertices on $f \cap B \cap \partial\mathcal{B}$ divide $f \cap B \cap \partial\mathcal{B}$ into circular arcs. For every protecting B, the projection of the convex hull of the Steiner vertices on B onto ∂B divides ∂B into some spherical triangles. The diametric ball of a segment or triangle can be viewed as the circumscribing ball whose boundary intersects the affine hull of the segment or triangle at right angle. Analogously, the "diametric ball" of a circular arc in ∂B or a spherical triangle with vertices in ∂B can be defined as the circumscribing ball whose boundary intersects B at right angle. If a Steiner vertex to be inserted lies inside this "diametric ball," the insertion is aborted and the circular arc or spherical triangle is split instead. A circular arc is split by inserting its midpoint. A spherical triangle is split by inserting the intersection point between ∂B and the line segment joining the centers of B and the "diametric ball." The last ingredient is that for every pair of protecting balls whose centers are adjacent on an input edge, their boundaries should intersect at right angle. That is, the protecting ball B' adjacent to B serves as the "diametric ball" of the spherical triangles that have vertices on the circle $\partial B \cap \partial B'$.

Theorem 3 ([2]) *There exist a constant $\rho > 2$ and a Delaunay refinement algorithm that constructs a conforming Delaunay triangulation of any input PLC such that all resulting tetrahedra have radius-edge ratio at most ρ.*

In fact, all tetrahedra inside the union of protecting balls have aspect ratios that depend only on the smallest angle in the input PLC. Subsequently, different simplifications and algorithms with less expensive primitives have been proposed [3, 7].

Placing Steiner vertices on the protecting balls and constructing the convex hull of the Steiner vertices on a protecting ball are fairly expensive. Even checking whether a Steiner vertex to be inserted lies inside any protecting ball is a burden. These expensive computations can be bypassed by switching to the *weighted Delaunay triangulation* – a more general variant of Delaunay triangulation.

Let B_x and B_y be two balls with centers x and y and radii $r_x \geq 0$ and $r_y \geq 0$. The *power distance* between B_x and B_y is defined to be

$$\pi(B_x, B_y) = d(x, y)^2 - r_x^2 - r_y^2.$$

This definition allows B_x or B_y to degenerate to a single point. As in the Euclidean case, the bisector between B_x and B_y is also a plane perpendicular to the line through x and y; however, the bisector plane may not pass through the midpoint of xy. Using the power distance, one can define a weighted version of the Voronoi diagram called the *power diagram*. The dual of the power diagram is known as the *weighted Delaunay triangulation*. For each segment, triangle or tetrahedron σ in the triangulation, there is a point z at equal and minimum power distances D from the vertices of σ. This point z is known as the *orthocenter* of σ. The ball centered at z with radius $\sqrt{D}$ is called the *orthoball* of σ, which is at zero power distances from the vertices of σ.

The key idea is to use a weighted Delaunay triangulation after placing the protecting balls. The Delaunay refinement strategy is then modified to insert orthocenters instead of centers of diametric balls. If the protecting balls are not too large, every triangle or tetrahedron σ in the initial weighted Delaunay triangulation involve a pair of nonoverlapping protecting ball, which must be a positive power distance apart. It follows that the orthocenter of σ lies outside all protecting balls. As the refinement progresses, an edge, triangle, or tetrahedron σ may involve Steiner vertices which can be viewed as balls of zero radii. Such a Steiner vertex must be at positive power distances from the other vertices of σ, so the orthocenter of σ also lies outside all protecting balls. In summary, the indefinite insertions of Steiner vertices at decreasing distances from the input vertices and edges as shown in Fig. 2 cannot happen. The following theorem summarizes the result.

Theorem 4 ([4]) *Let P be a PLC. Let ρ be any constant at least 2. There is an algorithm that constructs a conforming weighted Delaunay triangulation of P in which no tetrahedron has an orthoradius-edge ratio greater than ρ. Therefore, tetrahedra with no weighted vertices have circumradius-edge ratio at most ρ.*

There are known methods for eliminating slivers from a conforming weighted Delaunay triangulation of a PLC [1, 4].

Decoding Reed–Solomon Codes

Venkatesan Guruswami
Department of Computer Science and Engineering, University of Washington, Seattle, WA, USA

Keywords

Decoding; Error correction

Years and Authors of Summarized Original Work

1999; Guruswami, Sudan

Problem Definition

In order to ensure the integrity of data in the presence of errors, an *error-correcting code* is used to *encode* data into a redundant form (called a *codeword*). It is natural to view both the original data (or *message*) as well as the associated codeword as strings over a finite alphabet. Therefore, an error-correcting code C is defined by an injective encoding map $E: \Sigma^k \rightarrow \Sigma^n$, where k is called the *message length*, and n the *block length*. The codeword, being a redundant form of the message, will be longer than the message. The *rate* of an error-correcting code is defined as the ratio k/n of the length of the message to the length of the codeword. The rate is a quantity in the interval $(0, 1]$, and is a measure of the redundancy introduced by the code. Let $R(C)$ denote the rate of a code C.

The redundancy built into a codeword enables detection and hopefully also correction of any errors introduced, since only a small fraction of all possible strings will be legitimate codewords. Ideally, the codewords encoding different messages should be "far-off" from each other, so that one can recover the original codeword even when it is distorted by moderate levels of noise. A natural measure of distance between strings is the Hamming distance. The Hamming distance between strings $x, y \in \Sigma^*$ of the same length, denoted $\mathsf{dist}(x, y)$, is defined to be the number of positions i for which $x_i \neq y_i$.

The *minimum distance*, or simply *distance*, of an error-correcting code C, denoted $d(C)$, is defined to be the smallest Hamming distance between the encodings of two distinct messages. The *relative distance* of a code C of block length n, denoted $\delta(C)$, is the ratio between its distance and n. Note that arbitrary corruption of any $\lfloor (d(C) - 1)/2 \rfloor$ of locations of a codeword of C cannot take it closer (in Hamming distance) to any other codeword of C. Thus in principle (i.e., efficiency considerations apart) error patterns of at most $\lfloor (d(C) - 1)/2 \rfloor$ errors can be corrected. This task is called *unique decoding* or *decoding up to half-the-distance*. Of course, it is also possible, and will often be the case, that error patterns with more than $d(C)/2$ errors can also be corrected by decoding the string to the closest codeword in Hamming distance. The latter task is called *Nearest-Codeword decoding* or *Maximum Likelihood Decoding (MLD)*.

One of the fundamental trade-offs in the theory of error-correcting codes, and in fact one could say all of combinatorics, is the one between rate $R(C)$ and distance $d(C)$ of a code. Naturally, as one increases the rate and thus number of codewords in a code, some two codewords must come closer together thereby lowering the distance. More qualitatively, this represents the tension between the redundancy of a code and its error-resilience. To correct more errors requires greater redundancy, and thus lower rate.

A code defined by encoding map $E : \Sigma^k \rightarrow \Sigma^n$ with minimum distance d is said to be an (n, k, d) code. Since there are $|\Sigma|^k$ codewords and only $|\Sigma^{k-1}|$ possible projections onto the first $k = 1$ coordinates, some two codewords must agree on the first $k - 1$ positions, implying that the distance d of the code must obey $d \leq n - k + 1$ (this is called the *Singleton bound*). Quite surprisingly, over large alphabets Σ there are well-known codes called Reed–Solomon codes which meet this bound exactly and have the optimal distance $d = n - k + 1$ for any given rate k/n. (In contrast, for small alphabets, such as $\Sigma = \{0, 1\}$, the optimal trade-off between rate and relative distance for an asymptotic family of codes is unknown and is a major open question in combinatorics.)

This article will describe the best known algorithmic results for error-correction of Reed–Solomon codes. These are of central theoretical and practical interest given the above-mentioned optimal trade-off achieved by Reed–Solomon codes, and their ubiquitous use in our everyday lives ranging from compact disc players to deep-space communication.

Reed–Solomon Codes

Definition 1 A *Reed–Solomon code* (or RS code), $\mathsf{RS}_{\mathbb{F},S}[n,k]$, is parametrized by integers n,k satisfying $1 \le k \le n$, a finite field $\mathbb{F}$ of size at least n, and a tuple $S = (\alpha_1, \alpha_2, \ldots, \alpha_n)$ of n *distinct* elements from $\mathbb{F}$. The code is described as a subset of $\mathbb{F}^n$ as:

$$\mathsf{RS}_{\mathbb{F},S}[n,k] = \{(p(\alpha_1), p(\alpha_2), \ldots, p(\alpha_n)) \mid p(X) \in \mathbb{F}[X] \text{ is a polynomial of degree} \le k-1\}.$$

In other words, the message is viewed as a polynomial, and it is encoded by evaluating the polynomial at n distinct field elements $\alpha_1, \ldots, \alpha_n$. The resulting code is linear of dimension k, and its minimum distance equals $n - k + 1$, which matches the Singleton bound.

The distance property of RS codes follows from the fact that the evaluations of two distinct polynomials of degree less than k can agree on at most $k-1$ field elements. Note that in the absence of errors, given a codeword $\mathbf{y} \in \mathbb{F}^n$, one can recover its corresponding message by polynomial interpolation on any k out of the n codeword positions. In fact, this also gives an *erasure decoding* algorithm when all but the information-theoretically bare minimum necessary k symbols are erased from the codeword (but the receiver *knows* which symbols have been erased and the correct values of the rest of the symbols). The RS decoding problem, therefore, amounts to a noisy polynomial interpolation problem when some of the evaluation values are incorrect.

The holy grail in decoding RS codes would be to find the polynomial $p(X)$ whose RS encoding is closest in Hamming distance to a noisy string $\mathbf{y} \in \mathbb{F}^n$. One could then decode $\mathbf{y}$ to this message $p(X)$ as the maximum likelihood choice. No efficient algorithm for such nearest-codeword decoding is known for RS codes (or for that matter any family of "good" or non-trivial codes), and it is believed that the problem is NP-hard. Guruswami and Vardy [6] proved the problem to NP-hard over exponentially large fields, but this is a weak negative result since normally one considers Reed–Solomon codes over fields of size at most $O(n)$.

Given the intractability of nearest-codeword decoding in its extreme generality, lot of attention has been devoted to the *bounded distance decoding* problem, where one assumes that the string $\mathbf{y} \in \mathbb{F}^n$ to be decoded has at most e errors, and the goal is to find the Reed–Solomon codeword(s) within Hamming distance e from $\mathbf{y}$.

When $e < (n-k)/2$, this corresponds to decoding up to half the distance. This is a classical problem for which a polynomial time algorithm was first given by Peterson [8]. (It is notable that this even before the notion of polynomial time was put forth as the metric of theoretical efficiency.) The focus of this article is on a *list decoding* algorithm for Reed–Solomon codes due to Guruswami and Sudan [5] that decode beyond half the minimum distance. The formal problem and the key results are stated next.

Key Results

In this section, the main result of focus concerning decoding Reed–Solomon codes is stated. Given the target of decoding errors beyond half-the-minimum distance, one needs to deal with inputs where there may be more than one codeword within the radius e specified in the bounded distance decoding problem. This is achieved by a relaxation of decoding called *list decoding* where the decoder outputs a list of all codewords (or the corresponding messages) within Hamming distance e from the received word. If one wishes, one can choose the closest codeword among the list as the "most likely" answer, but there are many applications of Reed–Solomon decoding, for example to decoding concatenated codes and several applications in complexity theory and cryptography, where having the entire list of codewords adds to the power of the decoding primitive. The main result of Guruswami and Sudan [5], building upon the work of Sudan [9], is the following:

Theorem 1 ([5]) *Let $C = \mathsf{RS}_{\mathbb{F},S}[n,k]$ be a Reed–Solomon code over a field $\mathbb{F}$ of size $q \ge n$ with $S = (\alpha_1, \alpha_2, \ldots, \alpha_n)$. There is a deterministic algorithm running in time polynomial in q that on input $y \in \mathbb{F}_q^n$ outputs*

a list of all polynomials $p(X) \in \mathbb{F}[X]$ *of degree less than* k *for which* $p(\alpha_i) \neq y_i$ *for less than* $n - \sqrt{(k-1)n}$ *positions* $i \in \{1, 2, \ldots, n\}$. *Further, at most* $O(n^2)$ *polynomials will be output by the algorithm in the worst-case.*

Alternatively, one can correct a RS code of block length n and rate $R = k/n$ up to $n - \sqrt{(k-1)}$ errors, or equivalently a fraction $1 - \sqrt{R}$ of errors.

The Reed–Solomon decoding algorithm is based on the solution to the following more general polynomial reconstruction problem which seems like a natural algebraic question in itself. (The problem is more general than RS decoding since the α_i's need not be distinct.)

Problem 1 (Polynomial Reconstruction)
Input: Integers $k, t \leq n$ and n distinct pairs $\{(\alpha_i, y_i)\}_{i=1}^{n}$ where $\alpha_i, y_i \in \mathbb{F}$.
Output: A list of all polynomials $p(X) \in \mathbb{F}[X]$ of degree less than k which satisfy $p(\alpha_i) = y_i$ for at least t values of $i \in [n]$.

Theorem 2 *The polynomial reconstruction problem can be solved in time polynomial in* $n, |\mathbb{F}|$, *provided* $t > \sqrt{(k-1)n}$.

The reader is referred to the original papers [5, 9], or a recent survey [1], for details on the above algorithm. A quick, high level peek into the main ideas is given below. The first step in the algorithm consists of an interpolation step where a nonzero bivariate polynomial $Q(X,Y)$ is "fit" through the n pairs (α_i, y_i), so that $Q(\alpha_i, y_i) = 0$ for every i. The key is to do this with relatively low degree; in particular one can find such a $Q(X,Y)$ with so-called $(1, k-1)$-weighted degree at most $D \approx \sqrt{2(k-1)n}$. This degree budget on Q implies that for any polynomial $p(X)$ of degree less than k, $Q(X, p(X))$ will have degree at most D. Now whenever $p(\alpha_i) = y_i$, $Q(\alpha_i, p(\alpha)i)) = Q(\alpha_i, y_i) = 0$. Therefore, if a polynomial $p(X)$ satisfies $p(\alpha_i) = y_i$ for at least t values of i, then $Q(X, p(X))$ has at least t roots. On the other hand the polynomial $Q(X, p(X))$ has degree at most D. Therefore, if $t > D$, one must have $Q(X, p(X)) = 0$, or in other words $Y - p(X)$ is a factor of $Q(X,Y)$. The second step of the algorithm factorized the polynomial $Q(X,Y)$, and all polynomials $p(X)$ that must be output will be found as factors $Y - p(X)$ of $Q(X,Y)$.

Note that since $D \approx \sqrt{2(k-1)n}$ this gives an algorithm for polynomial reconstruction provided the agreement parameter t satisfies $t > \sqrt{2(k-1)n}$ [9]. To get an algorithm for $t > \sqrt{(k-1)n}$, and thus decode beyond half the minimum distance $(n-k)/2$ for all parameter choices for k, n, Guruswami and Sudan [5] use the crucial idea of allowing "multiple roots" in the interpolation step. Specifically, the polynomial Q is required to have $r \geq 1$ roots at each pair (α_i, y_i) for some integer multiplicity parameter r (the notion needs to be formalized properly, see [5] for details). This necessitates an increase in the $(1, k-1)$-weighted degree of a factor of about $r/\sqrt{2}$, but the gain is that one gets a factor r more roots for the polynomial $Q(X, p(X))$. These facts together lead to an algorithm that works as long as $t > \sqrt{(k-1)n}$.

There is an additional significant benefit offered by the multiplicity based decoder. The multiplicities of the interpolation points need not all be equal and they can picked in proportion to the reliability of different received symbols. This gives a powerful way to exploit "soft" information in the decoding stage, leading to impressive coding gains in practice. The reader is referred to the paper by Koetter and Vardy [7] for further details on using multiplicities to encode symbol level reliability information from the channel.

Applications

Reed–Solomon codes have been extensively studied and are widely used in practice. The above decoding algorithm corrects more errors beyond the traditional half the distance limit and therefore directly advances the state of the art on this important algorithmic task. The RS list decoding algorithm has also been the backbone for many further developments in algorithmic coding theory. In particular, using this algorithm in concatenation schemes leads to good binary list-decodable codes. A variant of

RS codes called folded RS codes have been used to achieve the optimal trade-off between error-correction radius and rate [3] (see the companion encyclopedia entry by Rudra on folded RS codes).

The RS list decoding algorithm has also found many surprising applications beyond coding theory. In particular, it plays a key role in several results in cryptography and complexity theory (such as constructions of randomness extractors and pseudorandom generators, hardness amplification, constructions to hardcore predicates, traitor tracing, reductions connecting worst-case hardness to average-case hardness, etc.); more information can be found, for instance, in [10] or Chap. 12 in [2].

Open Problems

The most natural open question is whether one can improve the algorithm further and correct more than a fraction $1 - \sqrt{R}$ of errors for RS codes of rate R. It is important to note that there is a combinatorial limitation to the number of errors one can list decode from. One can only list decode in polynomial time from a fraction ρ of errors if for every received word $\mathbf{y}$ the number of RS codewords within distance $e = \rho n$ of $\mathbf{y}$ is bounded by a polynomial function of the block length n. The largest ρ for which this holds as a function of the rate R is called the list decoding radius $\rho_{\mathsf{LD}} = \rho_{\mathsf{LD}}(R)$ of RS codes. The RS list decoding algorithm discussed here implies that $\rho_{\mathsf{LD}}(R) \geq 1 - \sqrt{R}$, and it is trivial to see than $\rho_{\mathsf{LD}}(R) \leq 1 - R$. Are there RS codes (perhaps based on specially structured evaluation points) for which $\rho_{\mathsf{LD}}(R) > 1 - \sqrt{R}$? Are there RS codes for which the $1 - \sqrt{R}$ radius (the so-called "Johnson bound") is actually tight for list decoding? For the more general polynomial reconstruction problem the $\sqrt{(k-1)n}$ agreement cannot be improved upon [4], but this is not known for RS list decoding.

Improving the NP-hardness result of [6] to hold for RS codes over polynomial sized fields and for smaller decoding radii remains an important challenge.

Problem Definition

A dynamic graph algorithm maintains a given property P on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property P quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. An algorithm is *fully dynamic* if it can handle both edge insertions and edge deletions. A *partially dynamic* algorithm can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only.

This entry addressed the *decremental* version of the all-pairs shortest paths problem (APSP), which consists of maintaining a directed graph with real-valued edge weights under an intermixed sequence of the following operations:

`delete`(u, v): delete edge (u, v) from the graph.
`distance`(x, y): return the distance from vertex x to vertex y.
`path`(x, y): report a shortest path from vertex x to vertex y, if any.

A natural variant of this problem supports a generalized delete operation that removes a vertex and all edges incident to it. The algorithms addressed in this entry can deal with this generalized operation within the same bounds.

History of the Problem

A simple-minded solution to this problem would be to rebuild shortest paths from scratch after each deletion using the best static APSP algorithm so that distance and path queries can be reported in optimal time. The fastest known static APSP algorithm for arbitrary real weights has a running time of $O(mn + n^2 \log\log n)$, where m is the number of edges and n is the number of vertices in the graph [13]. This is $\Omega(n^3)$ in the worst case. Fredman [6] and later Takaoka [19] showed how to break this cubic barrier: the best asymptotic bound is by Takaoka, who showed how to solve APSP in $O(n^3\sqrt{\log\log n/\log n})$ time.

Another simple-minded solution would be to answer queries by running a point-to-point shortest paths computation, without the need to update shortest paths at each deletion. This can be done with Dijkstra's algorithm [3] in $O(m + n\log n)$ time using the Fibonacci heaps of Fredman and Tarjan [5]. With this approach, queries are answered in $O(m + n\log n)$ worst-case time and updates require optimal time.

The dynamic maintenance of shortest paths has a long history, and the first papers date back to 1967 [11, 12, 17]. In 1985 Even and Gazit [4] presented algorithms for maintaining shortest paths on directed graphs with arbitrary real weights. The worst-case bounds of their algorithm for edge deletions were comparable to recomputing APSP from scratch. Also Ramalingam and Reps [15, 16] and Frigioni et al. [7, 8] considered dynamic shortest path algorithms with real weights, but in a different model. Namely, the running time of their algorithm is analyzed in terms of the output change rather than the input size (*output bounded complexity*). Again, in the worst case the running times of output-bounded dynamic algorithms are comparable to recomputing APSP from scratch.

The first decremental algorithm that was provably faster than recomputing from scratch was devised by King for the special case of graphs with integer edge weights less than C: her algorithm can update shortest paths in a graph subject to a sequence of $\Omega(n^2)$ deletions in $O(C \cdot n^2)$ amortized time per deletion [9]. Later, Demetrescu and Italiano showed how to deal with graphs with real non-negative edge weights in $O(n^2 \log n)$ amortized time per deletion [2] in a sequence of $\Omega(m/n)$ operations. Both algorithms work in the more general case where edges are not deleted from the graph, but their weight is increased at each update. Moreover, since they update shortest paths explicitly after each deletion, queries are answered in

optimal time at any time during a sequence of operations.

Key Results

The decremental APSP algorithm by Demetrescu and Italiano hinges upon the notion of locally shortest paths [2].

Definition 1 A path is *locally shortest* in a graph if all of its proper subpaths are shortest paths.
