Notice that by the optimal-substructure property, a shortest path is locally shortest. The main idea of the algorithm is to keep information about locally shortest paths in a graph subject to edge deletions. The following theorem derived from [2] bounds the number of changes in the set of locally shortest paths due to an edge deletion:

Theorem 1 *If shortest paths are unique in the graph, then the number of paths that start or stop being shortest at each deletion is* $O(n^2)$ *amortized over* $\Omega(m/n)$ *update operations.*

The result of Theorem 1 is purely combinatorial and assumes that shortest paths are unique in the graph. The latter can be easily achieved using any consistent tie-breaking strategy (see, e.g., [2]). It is possible to design a deletions-only algorithm that pays only $O(\log n)$ time per change in the set of locally shortest paths, using a simple modification of Dijkstra's algorithm [3]. Since by Theorem 1 the amortized number of changes is bounded by $O(n^2)$, this yields the following result:

Theorem 2 *Consider a graph with n vertices and an initial number of m edges subject to a sequence of* $\Omega(m/n)$ *edge deletions. If shortest paths are unique and edge weights are nonnegative, it is possible to support each delete operation in* $O(n^2 \log n)$ *amortized time, each distance query in O(1) worst-case time, and each path query in* $O(\ell)$ *worst-case time, where* ℓ *is the number of vertices in the reported shortest path. The space used is O(mn).*

Applications

Application scenarios of dynamic shortest paths include network optimization [1], document formatting [10], routing in communication systems, robotics, incremental compilation, traffic information systems [18], and dataflow analysis. A comprehensive review of real-world applications of dynamic shortest path problems appears in [14].

URL to Code

An efficient C language implementation of the decremental algorithm addressed in section "Key Results" is available at the URL: http://www.dis.uniroma1.it/~demetres/experim/dsp.

Problem Definition

A dynamic graph algorithm maintains information about a graph that is changing over time. Given a property $\mathcal{P}$ of the graph (e.g., minimum spanning tree), the algorithm must support an online sequence of query and update operations, where an update operation changes the underlying graph, while a query operation asks for the state of $\mathcal{P}$ in the current graph. In the typical model studied, each update only affects a single edge. In a *fully dynamic* setting, an update can insert or delete an edge or change the weight of an existing edge; in a *decremental* setting an update can only delete an edge or increase a weight; in an *incremental* setting an update can insert an edge or decrease a weight.

This entry addresses the decremental $(1+\epsilon)$-approximate all-pairs shortest path problem (APSP) in weighted directed graphs. The goal is to maintain a directed graph G with real-valued nonnegative edge weights under an online intermixed sequence of the following operations:

- **delete**(u, v) (update): remove edge (u, v) from G.
- **increase-weight**(u, v, w) (update): increase the weight of edge (u, v) to w.
- **distance**(u, v) (query): return a $(1+\epsilon)$-approximation to the shortest $u - v$ distance in G.
- **path**(u, v) (query): return a $(1+\epsilon)$-approximate shortest path from u to v.

A History of Decremental APSP

The naive approach to the decremental APSP problem is to recompute shortest paths from scratch after every update, allowing queries to be answered in optimal time. Letting n be the number of vertices and m the number of edges, computing APSP requires $O(mn + n^2 \log\log(n))$

time in sparse graphs [11] or slightly less than n^3 in dense graphs (see [13, 14]). Another simple-minded approach would be to not perform any computation during the updates and to simply compute the shortest $u - v$ path from scratch when a query arrived. This would lead to a constant update time and a query time of $O(m + n\log(n))$ using Dijkstra's algorithm with Fibonacci heaps [6].

One can improve significantly upon both the above approaches by reusing information between updates. Decremental shortest path algorithms have a long history, with the current state of the art for the general case of directed graphs with real-valued weights being an algorithm of Demetrescu and Italiano which achieves constant query time and update time $O(n^2\log(n))$ [5]. Later papers improved upon $O(n^2)$ update time in restricted types of graph. In *unweighted* directed graphs, Baswana et al. achieve an amortized update of $O(n^3\log^2(n)/m)$ for exact distances and $\tilde{O}(\epsilon^{-1}n^2/\sqrt{m})$ for $(1+\epsilon)$ approximate distances [1]. (We say that $f(n) = \tilde{O}(g(n))$ if $f(n) = O(g(n)\text{polylog}(n)))$. Keeping the $(1 + \epsilon)$ approximation, Roditty and Zwick further reduced the amortized update time to $\tilde{O}(n/\epsilon)$ [12].

An amortized update time of $\tilde{O}(n)$ forms a natural barrier for decremental APSP because if edges are deleted from the graph one at a time, an $\tilde{O}(n)$ update time allows us to maintain APSP over the entire sequence of deletions in a *total* of $\tilde{O}(mn)$ time; excepting fast matrix multiplication in dense graphs, this $\tilde{O}(mn)$ matches the best known bound for the much simpler problem of computing APSP a single time in the *static* setting. Roddity and Zwick achieve this desired *total* update time of $\tilde{O}(mn)$ only for undirected, unweighted graphs; this entry focuses on a result of Bernstein that achieves the same $\tilde{O}(mn)$ for directed graphs with weights polynomial in n [3].

There have recently been several results on breaking through the $\tilde{O}(n)$ amortized update time barrier in undirected graphs by allowing a larger than $(1 + \epsilon)$ approximation (see [4, 7, 9]), as well in directed graphs for *single-source* shortest paths [8].

Key Results

Bernstein's result shows that in a directed graph with weights polynomial in n, we can maintain $(1 + \epsilon)$-approximate decremental APSP with constant query time and a *total* update time of $\tilde{O}(mn)$ over the entire sequence of deletions and weight increases (see Theorem 2 below). At a high level, Bernstein's result uses the framework from his earlier paper on fully dynamic APSP in undirected graphs [2], but all the details and techniques change significantly in the shift to directed graphs.

From Weighted Distances to Hop Distances

The majority of dynamic APSP algorithms use as a building block an algorithm of King for maintaining a *single-source* shortest path tree under deletions [10]. King's algorithm maintains a shortest path tree up to distance d (assuming integral weights) in the total update time $O(md)$ over all deletions (amortized $O(d)$ per update); hence, $O(mn)$ is the total update time in unweighted graphs where $d \leq n$. This makes it an extremely efficient building block for small distances, but with two main drawbacks: it is inefficient at handling vertices that are far apart and it completely fails in graphs with large weights where d can be very big. Bernstein's algorithm overcomes the second of these problems by showing that if we allow a $(1+\epsilon)$ approximation, then with a simple scaling approach, we can shift the dependency from the weighted distance d between two vertices to the unweighted *hop distance* between them.

Definition 1 The hop distance between two vertices x and y is the number of edges on the shortest $x-y$ path. The $(1 + \epsilon)$-approximate $x-y$ hop distance, denoted $h(x, y)$, is the minimum number of edges among any $(1 + \epsilon)$-approximate $x - y$ path.

Theorem 1 *Given a directed graph G with non-negative real weights and a source s and letting R be the ratio of the heaviest to the lightest nonzero edge weight in the graph, we can for any*

hop distance h decrementally maintain $(1+\epsilon)$*-shortest paths from s to all vertices v for which* $h(s,v) \le h$*. The total update time over the whole sequence of deletions and weight increases is* $O(nh\log(R)/\epsilon)$*, which is* $O(nh)$ *if weights are polynomial in n.*

We refer to the above decremental SSSP algorithm as h-SSSP. In short, Theorem 1 tells us that with a $(1+\epsilon)$ approximation, we can decrementally maintain a shortest path tree in time proportional not to the maximum distance of the tree ($O(nd)$) but to the maximum *hop distance* ($O(nh)$) of the tree. This is a big improvement in weighted graphs where $h \ll d$, but still inadequate as h can be $\Omega(n)$. Bernstein's key idea is that regardless of whether the original graph is weighted or not, we can add weighted edges that reduce hop distances in the graph and hence allow h-SSSP to run extremely efficiently.

Shortcut Edges

The algorithm of Bernstein works by adding many different (weighted) shortcut edges (x,y) to the original graph G, which are defined as edges that do not exist in G itself and have weight $w(x,y)$ satisfying $\delta(x,y) \le w(x,y) \le (1+\epsilon)\delta(x,y)$, where $\delta(x,y)$ is the shortest $x-y$ distance. Note that as the graph changes, $\delta(x,y)$ will increase, and so the algorithm will have to increase $w(x,y)$ for the shortcut edge to remain valid; a shortcut edge (x,y) is not simply computed once, but must be maintained over the whole sequence of edge deletions and weight increases.

It is clear that because the weight of a shortcut edge (x,y) is tethered to $\delta(x,y)$, the shortcut edges do not change shortest distances in the graph. But they do drastically reduce hop distances. In an unweighted graph with $\delta(x,y) = 1{,}000$, a single $x-y$ edge of weight 1,000 (or slightly larger) decreases $h(x,y)$ from 1,000 to 1. Moreover, any path that goes through x and y can also use the (x,y) shortcut edge to reduce its hop distance by 999.

Bernstein's algorithm runs in phases, each of which adds more shortcut edges to successively decrease all hop distances in the graph by a factor of 2. It starts by defining a small set of pairs S_1 for which it maintains approximate shortest paths over the entire sequence of updates; this first step can easily be done in the desired $\tilde{O}(mn\log(R))$ total update time as instead of maintaining *all-pairs* shortest paths, the algorithm only has to maintain $|S_1|$ pairs. Now that the algorithm maintains $\delta(x,y)$ for every pair (x,y) in S_1, it can add shortcut edges (x,y) to the graph. These shortcut edges decrease hop distances in the graph, thus increasing the efficiency of the h-SSSP building block and allowing it to maintain approximate shortest distances within a slightly larger set of pairs S_2 in the same $\tilde{O}(mn\log(R))$ total update time. Since knowing the shortest distance between two vertices allows us to maintain a corresponding shortcut edge, maintaining the larger set of distances S_2 directly leads to a larger set of shortcut edges, which further reduce hop distances in the graph, allowing h-SSSP to efficiently maintain shortest distances for an even larger set of pairs S_3; this in turn leads to more shortcut edges, thus further reducing hop distances and allowing h-SSSP to maintain a larger distance set S_4, and so on. After $\log(n)$ such layers, there are enough shortcut edges to ensure that all hop distances are constant, so by Theorem 1 h-SPPP can decrementally maintain a shortest path tree in the graph in a total update time of only $\tilde{O}(n\log(R)/\epsilon)$; doing this from every vertex yields the desired bound of $\tilde{O}(mn\log(R)/\epsilon)$ for decremental APSP.

Theorem 2 *Let G be a graph with nonnegative real-valued edge weights, n vertices, and m initial edges subject to an arbitrary sequence of* Σ *edge deletions and weight increases. Let R be the ratio of the heaviest weight that ever appears in G to the lightest nonzero weight. It is possible to support the whole sequence of updates in a* total *time* $\tilde{O}(mn\log(R)/\epsilon) + O(\Sigma)$ *while answering queries with a single* $O(1)$ *time lookup.*

Unified energy-efficient unicast and broadcast topology control

Years and Authors of Summarized Original Work

2005; Song, Li, Wang

Problem Definition

An important requirement of wireless ad hoc networks is that they should be self-organizing, and transmission ranges and data paths may need to be dynamically restructured with changing topology. Energy conservation and network performance are probably the most critical issues in wireless ad hoc networks, because wireless devices are usually powered by batteries only and have limited computing capability and memory. Hence, in such a dynamic and resource-limited environment, each wireless node needs to locally select communication neighbors and adjust its transmission power accordingly, such that all nodes together self-form a topology that

is energy efficient for both unicast and broadcast communications.

To support energy-efficient unicast, the topology is preferred to have the following features in the literature:

1. POWER SPANNER: [1, 9, 13, 16, 17] Formally speaking, a subgraph H is called a *power spanner* of a graph G if there is a positive real constant ρ such that for any two nodes, the power consumption of the shortest path in H is at most ρ times of the power consumption of the shortest path in G. Here ρ is called the *power stretch factor* or *spanning ratio*.
2. DEGREE BOUNDED: [1, 9, 11, 13, 16, 17] It is also desirable that the logical node degree in the constructed topology is bounded from above by a small constant. Bounded logical degree structures find applications in Bluetooth wireless networks since a *master* node can have only seven active slaves simultaneously. A structure with small logical node degree will save the cost of updating the routing table when nodes are mobile. A structure with a small degree and using shorter links could improve the overall network throughout [6].
3. PLANAR: [1, 4, 13, 14, 16] A network topology is also preferred to be planar (no two edges crossing each other in the graph) to enable some localized routing algorithms to work correctly and efficiently, such as *Greedy Face Routing* (GFG) [2], *Greedy Perimeter Stateless Routing* (GPSR) [5], *Adaptive Face Routing* (AFR) [7], and *Greedy Other Adaptive Face Routing* (GOAFR) [8]. Notice that with planar network topology as the underlying routing structure, these localized routing protocols guarantee the message delivery without using a routing table: each intermediate node can decide which logical neighboring node to forward the packet to using only local information and the position of the source and the destination.

To support energy-efficient broadcast [15], the locally constructed topology is preferred to be *low-weighted* [10, 12]: the total link length of the final topology is within a constant factor of that of *EMST*. Recently, several localized algorithms [10, 12] have been proposed to construct low-weighted structures, which indeed approximate the energy efficiency of EMST as the network density increases. However, none of them is power efficient for unicast routing.

Before this work, all known topology control algorithms could not support power efficient unicast and broadcast in the same structure. It is indeed challenging to design a unified topology, especially due to the trade off between spanner and low weight property. The main contribution of this algorithm is to address this issue.

Key Results

This algorithm is the *first* localized topology control algorithm for all nodes to maintain a *unified* energy-efficient topology for unicast and broadcast in wireless ad hoc/sensor networks. In one single structure, the following network properties are guaranteed:

1. **Power efficient unicast**: given any two nodes, there is a path connecting them in the structure with total power cost no more than $2\rho + 1$ times the power cost of any path connecting them in the original network. Here $\rho > 1$ is some constant that will be specified later in this algorithm. It assumes that each node u can adjust its power sufficiently to cover its next-hop v on any selected path for unicast.
2. **Power efficient broadcast**: the power consumption for broadcast is within a constant factor of the optimum among all *locally* constructed structures. As proved in [10], to prove this, it equals to prove that the structure is *low-weighted*. Here we called a structure low-weigthed, if its total edge length is within a constant factor of the total length of the Euclidean Minimum Spanning Tree (EMST). For broadcast or generally multicast, it assumes that each node u can adjust its power sufficiently to cover its farthest down-stream node on any selected structure (typically a tree) for multicast.
3. **Bounded logical node degree**: each node has to communicate with at most $k - 1$ logical

Algorithm 1 $S\Theta GG$: Power-Efficient Unicast Topology

1: First, each node self-constructs the Gabriel graph GG locally. The algorithm to construct GG locally is well-known, and a possible implementation may refer to [13]. Initially, all nodes mark themselves WHITE, i.e., *unprocessed*.
2: Once a WHITE node u has the smallest ID among all its WHITE neighbors in $N(u)$, it uses the following strategy to select neighbors:
   1. Node u first sorts all its BLACK neighbors (if available) in $N(u)$ in the distance-increasing order, then sorts all its WHITE neighbors (if available) in $N(u)$ similarly. The sorted results are then restored to $N(u)$, by first writing the sorted list of BLACK neighbors then appending the sorted list of WHITE neighbors.
   2. Node u scans the sorted list $N(u)$ from left to right. In each step, it keeps the current pointed neighbor w in the list, while deletes every *conflicted* node v in the remainder of the list. Here a node v is conflicted with w means that node v is in the θ-dominating region of node w. Here $\theta = 2\pi/k$ ($k \geq 9$) is an adjustable parameter.

   Node u then marks itself BLACK, i.e. *processed*, and notifies each deleted neighboring node v in $N(u)$ by a broadcasting message UPDATEN.
3: Once a node v receives the message UPDATEN from a neighbor u in $N(v)$, it checks whether itself is in the nodes set for deleting: if so, it deletes the sending node u from list $N(v)$, otherwise, marks u as BLACK in $N(v)$.
4: When all nodes are processed, all selected links $\{uv | v \in N(u), \forall v \in GG\}$ form the final network topology, denoted by $S\Theta GG$. Each node can shrink its transmission range as long as it sufficiently reaches its farthest neighbor in the final topology.

neighbors, where $k \geq 9$ is an adjustable parameter.

4. **Bounded average physical node degree**: the expected average physical node degree is at most a small constant. Here the physical degree of a node u in a structure H is defined as the number of nodes inside the disk centered at u with radius $\max_{uv \in H} \|uv\|$.
5. **Planar**: there are no edges crossing each other. This enables several localized routing algorithms, such as [2, 5, 7, 8], to be performed on top of this structure and guarantee the packet delivery without using the routing table.
6. **Neighbors Θ-separated**: the directions between any two logical neighbors of any node are separated by at least an angle θ, which reduces the communication interferences.

It is the *first* known *localized* topology control strategy for all nodes together to maintain such a *single* structure with these desired properties. Previously, only a centralized algorithm was reported in [1]. The first step is Algorithm 1 that can construct a power-efficient topology for unicast, then it extends to the final algorithm (Algorithm 2) that can support power-efficient broadcast at the same time.

Definition 1 (θ-Dominating Region) For each neighbor node v of a node u, the *θ-dominating region* of v is the 2θ-cone emanated from u, with the edge uv as its axis.

Let $N_{\text{UDG}}(u)$ be the set of neighbors of node u in UDG, and let $N(u)$ be the set of neighbors of node u in the final topology, which is initialized as the set of neighbor nodes in GG.

Algorithm 1 constructs a degree-$(k-1)$ planar power spanner.

Lemma 1 *Graph $S\Theta GG$ is connected if the underlying graph GG is connected. Furthermore, given any two nodes u and v, there exists a path $\{u, t_1, \ldots, t_r, v\}$ connecting them such that all edges have length less than $\sqrt{2}\|uv\|$.*

Theorem 1 *The structure $S\Theta GG$ has node degree at most $k-1$ and is planar power spanner with neighbors Θ-separated. Its power stretch factor is at most $\rho = \sqrt{2}^{\beta}/(1-(2\sqrt{2}\sin\frac{\pi}{k})^{\beta})$, where $k \geq 9$ is an adjustable parameter.*

Obviously, the construction is consistent for two endpoints of each edge: if an edge uv is kept by node u, then it is also kept by node v. It is worth mentioning that, the number 3 in criterion $\|xy\| > \max(\|uv\|, 3\|ux\|, 3\|vy\|)$ is carefully selected.

Theorem 2 *The structure $LS\Theta GG$ is a degree-bounded planar spanner. It has a constant power spanning ratio $2\rho + 1$, where ρ is the power spanning ratio of $S\Theta GG$. The node degree is bounded by $k-1$ where $k \geq 9$ is a customizable parameter in $S\Theta GG$.*

Algorithm 2 Construct $LS\Theta GG$: Planar Spanner with Bounded Degree and Low Weight

1: All nodes together construct the graph $S\Theta GG$ in a localized manner, as described in Algorithm 1. Then, each node marks its incident edges in $S\Theta GG$ *unprocessed*.
2: Each node u locally broadcasts its incident edges in $S\Theta GG$ to its one-hop neighbors and listens to its neighbors. Then, each node x can learn the existence of the set of 2-hop links $E_2(x)$, which is defined as follows: $E_2(x) = \{uv \in S\Theta GG \mid u \text{ or } v \in N_{\text{UDG}}(x)\}$. In other words, $E_2(x)$ represents the set of edges in $S\Theta GG$ with at least one endpoint in the transmission range of node x.
3: Once a node x learns that its *unprocessed* incident edge xy has the smallest ID among all *unprocessed* links in $E_2(x)$, it will delete edge xy if there exists an edge $uv \in E_2(x)$ (here both u and v are different from x and y), such that $\|xy\| > \max(\|uv\|, 3\|ux\|, 3\|vy\|)$; otherwise it simply marks edge xy *processed*. Here assume that $uvyx$ is the convex hull of u, v, x and y. Then the link status is broadcasted to all neighbors through a message UPDATESTATUS(XY).
4: Once a node u receives a message UPDATESTATUS(XY), it records the status of link xy at $E_2(u)$.
5: Each node repeats the above two steps until all edges have been *processed*. Let $LS\Theta GG$ be the final structure formed by all remaining edges in $S\Theta GG$.

Theorem 3 *The structure $LS\Theta GG$ is low-weighted.*

Theorem 4 *Assuming that both the ID and the geometry position can be represented by $\log n$ bits each, the total number of messages during constructing the structure $LS\Theta GG$ is in the range of $[5n, 13n]$, where each message has at most $O(\log n)$ bits.*

Compared with previous known low-weighted structures [10, 12], $LS\Theta GG$ not only achieves more desirable properties, but also costs much less messages during construction. To construct $LS\Theta GG$, each node only needs to collect the information $E_2(x)$ which costs at most $6n$ messages for n nodes. The Algorithm 2 can be generally applied to any known degree-bounded planar spanner to make it low-weighted while keeping all its previous properties, except increasing the spanning ratio from ρ to $2\rho + 1$ theoretically.

In addition, the expected average node interference in the structure is bounded by a small constant. This is significant on its own due to the following reasons: it has been taken for granted that "*a network topology with small logical node degree will guarantee a small interference*" and recently Burkhart et al. [3] showed that this is not true generally. This work also shows that, although generally a small logical node degree cannot guarantee a small interference, the expected average interference is indeed small if the logical communication neighbors are chosen carefully.

Theorem 5 *For a set of nodes produced by a Poisson point process with density n, the expected maximum node interferences of EMST, GG, RNG, and Yao are at least $\Theta(\log n)$.*

Theorem 6 *For a set of nodes produced by a Poisson point process with density n, the expected average node interferences of EMST are bounded from above by a constant.*

This result also holds for nodes deployed with uniform random distribution.

Applications

Localized topology control in wireless ad hoc networks are critical mechanisms to maintain network connectivity and provide feedback to communication protocols. The major traffic in networks are unicast communications. There is a compelling need to conserve energy and improve network performance by maintaining an energy-efficient topology in localized ways. This algorithm achieves this by choosing relatively smaller power levels and size of communication neighbors for each node (e.g., reducing interference). Also, broadcasting is often necessary in MANET routing protocols. For example, many unicast routing protocols

such as Dynamic Source Routing (DSR), Ad Hoc On Demand Distance Vector (AODV), Zone Routing Protocol (ZRP), and Location Aided Routing (LAR) use broadcasting or a derivation of it to establish routes. It is highly important to use power-efficient broadcast algorithms for such networks since wireless devices are often powered by batteries only.

Degree-Bounded Trees

Martin Fürer
Department of Computer Science and Engineering, The Pennsylvania State University, University Park, PA, USA

Keywords

Bounded degree spanning trees; Bounded degree Steiner trees

Years and Authors of Summarized Original Work

1994; Fürer, Raghavachari

Problem Definition

The problem is to construct a spanning tree of small degree for a connected undirected graph $G = (V, E)$. In the Steiner version of the problem, a set of distinguished vertices $D \subseteq V$ is given along with the input graph G. A Steiner tree is a tree in G which spans at least the set D.

As finding a spanning or Steiner tree of the smallest possible degree Δ^* is *NP*-hard, one is interested in approximating this minimization problem. For many such combinatorial optimization problems, the goal is to find an approximation in polynomial time (a constant or larger factor). For the spanning and Steiner tree problems, the iterative polynomial time approximation algorithms of Fürer and Raghavachari [8] (see also [14]) find much better solutions. The degree Δ of the solution tree is at most $\Delta^* + 1$.

There are very few natural *NP*-hard optimization problems for which the optimum can be achieved up to an additive term of 1. One such problem is coloring a planar graph, where coloring with four colors can be done in polynomial time. On the other hand, 3-coloring is *NP*-complete even for planar graphs. An other such problem is edge coloring a graph of degree Δ. While coloring with $\Delta + 1$ colors is always possible in polynomial time, Δ edge coloring is *NP*-complete.

Chvátal [3] has defined the *toughness* $\tau(G)$ of a graph as the minimum ratio $|X|/c(X)$ such that the subgraph of G induced by $V \setminus X$ has $c(X) \geq 2$ connected components. The inequality $1/\tau(G) \leq \Delta^*$ immediately follows. Win [17] has shown that $\Delta^* < \frac{1}{\tau(G)} + 3$; i.e., the inverse of the toughness is actually a good approximation of Δ^*.

A set X, such that the ratio $|X|/c(X)$ is the toughness $\tau(G)$, can be viewed as witnessing the upper bound $|X|/c(X)$ on $\tau(G)$ and therefore the lower bound $c(X)/|X|$ on Δ^*. Strengthening this notion, Fürer and Raghavachari [8] define X to be a witness set for $\Delta^* \geq d$ if d is the smallest integer greater or equal to $(|X| + c(X) - 1)/|X|$. Their algorithm not only outputs a spanning tree, but also a witness set X, proving that its degree is at most $\Delta^* + 1$.

Key Results

The minimum degree spanning tree and Steiner tree problems are easily seen to be *NP*-hard, as they contain the Hamiltonian path problem. Hence, we cannot expect a polynomial time algorithm to find a solution of minimal possible degree Δ^*. The same argument also shows that an approximation by a factor less than $3/2$ is impossible in polynomial time unless $P = NP$.

Initial approximation algorithms obtained solutions of degree $O(\Delta^* \log n)$ [6], where $n = |V|$ is the number of vertices. The optimal result for the spanning tree case has been obtained by Fürer and Raghavachari [7, 8].

Theorem 1 *Let Δ^* be the degree of an unknown minimum degree spanning tree of an input graph $G = (V, E)$. There is a polynomial time approximation algorithm for the minimum degree spanning tree problem that finds a spanning tree of degree at most $\Delta^* + 1$.*

Later this result has been extended to the Steiner tree case [8].

Theorem 2 *Assume a Steiner tree problem is defined by a graph $G = (V, E)$ and an arbitrary subset D of vertices V. Let Δ^* be the degree of an unknown minimum degree Steiner tree of G spanning at least the set D. There is a polynomial time approximation algorithm for the minimum degree Steiner tree problem that finds a Steiner tree of degree at most $\Delta^* + 1$.*

Both approximation algorithms run in time $O(mn \log n\, \alpha(m, n))$, where m is the number of edges and α is the inverse Ackermann function.

Applications

Some possible direct applications are in networks for noncritical broadcasting, where it might be desirable to bound the load per node, and in designing power grids, where the cost of splitting increases with the degree. Another major benefit of a small degree network is limiting the effect of node failure.

Furthermore, the main results on approximating the minimum degree spanning and Steiner tree problems have been the basis for approximating various network design problems, sometimes involving additional parameters.

Klein, Krishnan, Raghavachari and Ravi [11] find 2-connected subgraphs of approximately minimal degree in 2-connected graphs, as well as approximately minimal degree spanning trees (branchings) in directed graphs. Their algorithms run in quasi-polynomial time, and approximate the degree Δ^* by $(1+\epsilon)\Delta^* + O(\log_{1+\epsilon} n)$.

Often the goal is to find a spanning tree that simultaneously has a small degree and a small weight. For a graph having an minimum weight spanning tree (MST) of degree Δ^* and weight w, Fischer [5] finds a spanning tree with degree $O(\Delta^* + \log n)$ and weight w, (i.e., an MST of small weight) in polynomial time.

Könemann and Ravi [12, 13] provide a bi-criteria approximation. For a given $B^* \geq \Delta^*$, let w be the minimum weight of any spanning tree of degree at most B^*. The polynomial time algorithm finds a spanning tree of degree $O(B^* + \log n)$ and weight $O(w)$. In the second paper, the algorithm adapts to the case of a different degree bound on each vertex. Chaudhuri et al. [2] further improved this result to approximate both the degree B^* and the weight w by a constant factor.

In another extension of the minimum degree spanning tree problem, Ravi and Singh [15] have obtained a strict generalization of the $\Delta^* + 1$ spanning tree approximation [8]. Their polynomial time algorithm finds an MST of degree $\Delta^* + k$ for the case of a graph with k distinct weights on the edges.

Recently, there have been some drastic improvements. Again, let w be the minimum cost of a spanning tree of given degree B^*. Goemans [9] obtains a spanning tree of cost w and degree $B^* + 2$. Finally, Singh and Lau [16] decrease the degree to $B^* + 1$ and also handle individual degree bounds Δ_v^* for each vertex v in the same way.

Interesting approximation algorithms are also known for the 2-dimensional Euclidian minimum weight bounded degree spanning tree problem, where the vertices are points in the plane and edge weights are the Euclidian distances. Khuller, Raghavachari, and Young [10] show factor 1.5 and 1.25 approximations for degree bounds 3 and 4 respectively. These bounds have later been improved slightly by Chan [1]. Slightly weaker results are obtained by Fekete et al. [4], using flow-based methods, for the more general case where the weight function just satisfies the triangle inequality.

Open Problems

The time complexity of the minimum degree spanning and Steiner tree algorithms [8] is $O(mn\,\alpha(m,n)\log n)$. Can it be improved to $O(mn)$? In particular, what can be gained by initially selecting a reasonable Steiner tree with some greedy technique instead of starting the iteration with an arbitrary Steiner tree?

Is there an efficient parallel algorithm that can obtain a $\Delta^* + 1$ approximation in polylogarithmic time? Fürer and Raghavachari [6] have obtained such an NC-algorithm, but only with a factor $O(\log n)$ approximation of the degree.

Delaunay Triangulation and Randomized Constructions

Olivier Devillers
Inria Nancy – Grand-Est, Villers-lès-Nancy, France

Keywords

Convex hull; Delaunay triangulation; Randomization; Voronoi diagram

Years and Authors of Summarized Original Work

1989; Clarkson, Shor
1993; Seidel
2002; Devillers
2003;Amenta, Choi, Rote

Problem Definition

The Delaunay triangulation and the Voronoi diagram are two classic geometric structures in the field of computational geometry. Their success can perhaps be attributed to two main reasons: Firstly, there exist practical, efficient algorithms to construct them; and secondly, they have an enormous number of useful applications ranging from meshing and 3D-reconstruction to interpolation.

Given a set S of n sites in some space $\mathbb{E}$, we define the Voronoi region$V_S(p)$ of $p \in S$ to be

the set of points in $\mathbb{E}$ whose nearest neighbor in S is p (for some distance δ):

$$V(p) = \left\{x \in \mathbb{E}, \forall q \in S \setminus \{p\} \delta(x,p) < \delta(x,q)\right\}.$$

It is easily seen that these regions form a partition of $\mathbb{E}$ into convex regions which we refer to as *cells*. These concepts may be extended into more exotic spaces such as periodic and hyperbolic spaces or metric spaces using convex distances, though we restrict ourselves to the case where $\mathbb{E}$ is the Euclidean space $\mathbb{E} = \mathbb{R}^d$ and the distance δ is the L_2 norm.

The Voronoi diagram $\mathbb{V}(S)$ may now be defined as the limit between the different Voronoi cells

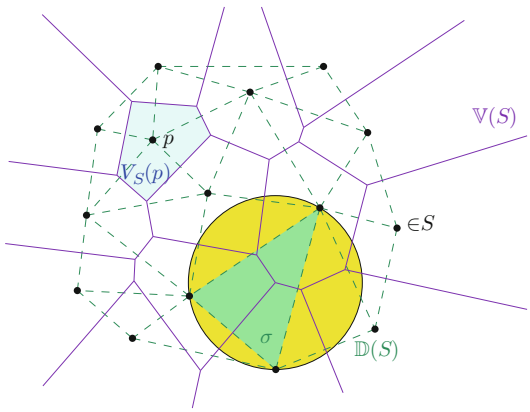
$$\mathbb{V}(S) = \mathbb{E} \setminus \bigcup_{p \in S} V_S(p).$$

The Delaunay triangulation $\mathbb{D}(S)$ is the geometric dual of $\mathbb{V}(S)$. More formally, $\mathbb{D}(S)$ is a simplicial complex defined by

$$\sigma \in \mathbb{D}(S) \Longleftrightarrow \bigcap_{p \in \sigma} \overline{V_S}(p) \neq \emptyset,$$

where $\overline{V_S}(p)$ is the closure of the Voronoi cell $V_S(p)$ (see Fig. 1).

Voronoi diagrams and Delaunay triangulations have received a lot of attention in the literature



Delaunay Triangulation and Randomized Constructions, Fig. 1 The Voronoi diagram of a set S of 15 points and its dual Delaunay triangulation

with several surveys, books, or book chapters (e.g., [4, 14]) and hundreds of papers. In this article, we will focus on randomized construction algorithms for the Delaunay triangulation. Such algorithms use randomness to speed up their running time but do not assume any randomness in the data distribution.

Key Results

Delaunay Properties

Empty Ball Property

One crucial property of the Delaunay triangulation, which is the basis of many algorithms, is the *empty ball property*, which guarantees that a triangle is a Delaunay triangle of S if and only if the interior of its circumball does not contain any point of S.

Size of the Triangulation

In the plane, the combinatorial properties of a triangulation (not necessarily Delaunay) are completely fixed by the Euler relation. In particular, given n vertices, h of which on the convex hull, every triangulation must have $2n-2-h$ triangles and $3n-3-h$ edges. In dimension d, the Dehn-Sommerville relations yield a linear dependence for the number of simplices of all dimensions on the number of simplices of dimensions k for $k \leq \left\lceil \frac{d}{2} \right\rceil$; this gives an $O\left(n^{\left\lceil \frac{d}{2} \right\rceil}\right)$ upper bound for the number of simplices of all dimension. For both Delaunay and more general triangulations, these bounds are tight in the worst case.

These bounds can be tightened given some assumptions on the distribution of the input sites. If the points are uniformly distributed in a compact convex of fixed volume, then the triangulation size (its total number of simplices) is $\Theta(n)$, with a constant exponential in d [9]. In 3D, and for reconstruction purposes, it is convenient to assume that the points lie on a surface. It is known that the Delaunay triangulation of points uniformly distributed on a convex polyhedron has size $\Theta(n)$ (for a constant depending on the polyhedron

complexity). For points uniformly distributed on a (non convex) polyhedron, the triangulation's size is between $\Omega(n)$ and $O(n \log n)$ [12]. If, instead of making a probabilistic assumption, we assume that the points are a "good sampling" of the surface such that every small ball centered on the surface contains between 1 and κ points (where κ is a constant), then the size of the Delaunay triangulation is $\Theta(n)$ for a polyhedron, $O(n \log n)$ for a *generic* smooth surface [3], and $\Omega(n\sqrt{n})$ for a nongeneric surface (e.g., a cylinder). In the case of the cylinder, a uniformly distributed point set has a triangulation of size $\Theta(n \log n)$. In dimension d, a p-dimensional polyhedron whose faces have a "good sampling" has size $O(n^k)$ where $k = \frac{d+1-\left\lceil \frac{d+1}{p+1} \right\rceil}{p}$ [2].

First Algorithms

Many classical techniques in algorithmic and computational geometry have been used to attack the problem of constructing the Delaunay triangulation and the Voronoi Diagram. The gift wrapping and the incremental approaches were introduced in the 1970s [11], followed by some worst case optimal algorithms in 2D, based on divide-and-conquer [13] and sweep line techniques [10]. In higher dimensions, the optimal worst case construction of Delaunay triangulation and convex hulls was solved in the 1990s.

In the remainder of the entry, we will describe some further algorithmic techniques that may be used to construct the Delaunay triangulation.

Randomized Construction

One popular and efficient method, applied to the Delaunay triangulation at the end of the 1980s [5], is Randomized Incremental Construction (RIC). The idea is to exploit the simplicity of an incremental algorithm while avoiding its worst case behavior by simply adjusting the order of insertion of the points.

Conflict Graph

Recalling that $\mathbb{D}(S)$ is the set of triangles with vertices in S whose circumballs are empty, the idea is to maintain for a sequence $\varnothing = S_0 \subset S_1 \subset S_2 \subset \ldots \subset S_n = S$, where $|S_i| = i$, a sequence of triangulations $\mathbb{D}(S_i)$ with associated *conflict graphs*. We define the conflict graph to be a bipartite graph that links a point p of $S \setminus S_i$ to a simplex σ in $\mathbb{D}(S_i)$ if the circumball of σ contains p (p *and* σ *are called in conflict*). The information contained in the conflict graph simplifies the construction of $\mathbb{D}(S_{i+1})$ from $\mathbb{D}(S_i)$ since it gives directly the simplices in $\mathbb{D}(S_i) \setminus \mathbb{D}(S_{i+1})$.

The key point comes from an analysis based on random sampling [6]; let's assume that S_i is a random sample of size i of S. We say that a simplex has *width* j if it has j points in conflict in S. In which case a Delaunay simplex is a simplex of width 0. Denote by Δ_j the number of simplices of width j and let $\Delta_{\leq k} = \sum_{j \leq k} \Delta_j$. We first bound $\Delta_{\leq k}$ using the following remark: a simplex of width j is a Delaunay simplex of a random sample R of size $\frac{n}{k}$ of S with probability $p_k = \frac{1}{k^{d+1}} \left(1 - \frac{1}{k}\right)^j$ (vertices of σ must be chosen in R and points in conflict must not). Notice that for $j \in [2 \ldots k]$, we have $\left(1 - \frac{1}{k}\right)^j \geq \left(1 - \frac{1}{k}\right)^k \geq \frac{1}{4}$ since $\left(1 - \frac{1}{x}\right)^x$ is an increasing function of value $\frac{1}{4}$ for $x = 2$. For $k \geq 2$, we have (using $\mathbb{P}$ to denote the probability measure)

$$|\mathbb{D}(R)| = O\left(\frac{n}{k}^{\lceil \frac{d}{2} \rceil}\right) = \sum_{\sigma \in S^{d+1}} \mathbb{P}(\sigma \in \mathbb{D}(R)) = \sum_{j \leq n} \Delta_j p_j \geq \frac{\Delta_0}{k^{d+1}} + \frac{\Delta_1 \frac{1}{2}}{k^{d+1}}$$

$$+ \sum_{j=2}^{k} \frac{\Delta_j \frac{1}{4}}{k^{d+1}} \geq \frac{\Delta_{\leq k}}{4k^{d+1}}, \Delta_{\leq k} \leq O\left(\frac{n}{k}^{\lceil \frac{d}{2} \rceil} k^{d+1}\right) = O\left(n^{\lceil \frac{d}{2} \rceil} k^{\lceil \frac{d+1}{2} \rceil}\right).$$

We can now analyze the incremental construction of $\mathbb{D}(S)$. The probability that a triangle of width j appears during the construction is

$$p'_j = \frac{\binom{d+1}{j+d+1}}{(j+d+1)!}$$

(the number of permutations that look at the vertices of σ before the points in conflict divided by the total number of permutations). Then the cost of the algorithm is given by the total number of conflicts occurring during the construction:

$$\sum_{\sigma \in S^{d+1}} \text{width}\,(\sigma)\mathbb{P}(\sigma \text{ appears}) = \sum_j \Delta_j \cdot j \cdot p'_j = \sum_j (\Delta_{\le j} - \Delta_{\le j-1}) j \cdot p'_j$$

$$= \sum_j \Delta_{\le j}(j \cdot p'_j - (j+1)p'_{j+1}) \le \sum_j n^{\lceil \frac{d}{2} \rceil} j^{\lceil \frac{d+1}{2} \rceil} O\left(\frac{1}{j^{d+2}}\right) \le O\left(n^{\lceil \frac{d}{2} \rceil} \sum_j j^{-\lceil \frac{d}{2} \rceil}\right)$$

which gives $O(n \log n)$ for $d = 2$ and $O\left(n^{\lceil \frac{d}{2} \rceil}\right)$ for higher d.

Backward Analysis

A simpler way of analyzing RIC is backward analysis [15], and we will sketch it in 2D. The idea is quite simple and consists in asking: *what is the cost of the last step?* The answer is that the cost of modifying the triangulation during last insertion is clearly proportional to the *degree* (number of simplices incident) of the last point inserted into the triangulation. Since the last point is a random point, its expected degree is

$$\mathbb{E}\text{xp}(\text{degree(last point)}) = \mathbb{E}\text{xp}(\text{degree(random point)}) = \frac{1}{n}\sum_{p \in S} \text{degree}(p) \le \frac{6n}{n} = 6,$$

and summing over all insertion steps gives a linear cost for updating the triangulation. It remains to count the cost of updating the conflict graph. We remark that there is a conflict between the last point p_n and a triangle created by the insertion of the jth point p_j if and only if the edge $p_j p_n$ exists in $\mathbb{D}(S_j \cup \{p_n\})$. Since p_j and p_n are both random points of $S_j \cup \{p_n\}$, it happens with probability $O\left(\frac{1}{j}\right)$, the expected number of conflicts for p_n is thus $O\left(\sum_j \frac{1}{j}\right) = O(\log n)$, and the total number of conflicts is $O\left(\sum_k \log k\right) = O(n \log n)$.

Delaunay Hierarchy

The conflict graph approach assumes complete knowledge of S to initialize the conflict graph. Using a lazy approach and postponing the conflict determination, it is possible to obtain online algorithms [5].

Among the online schemes to construct the Delaunay triangulation, the Delaunay hierarchy [7] gives good results both in theory and in practice. The Delaunay hierarchy constructs a sequence of random samples $S = S_0 \supset S_1 \supset \cdots \supset S_h$ such that $\mathbb{P}(p \in S_i \mid p \in S_{i-1}) = \alpha$. Then the Delaunay triangulations of $\mathbb{D}(S_i), 1 \le i \le h$ are maintained under point insertions. Pointers from a vertex of $\mathbb{D}(S_i)$ to the vertices at the same position in $\mathbb{D}(S_{i-1})$ (if $i < h$) and in $\mathbb{D}(S_{i+1})$ (if it actually belongs to S_{i+1}) are also computed.

When a new point p needs to be inserted, it is located by walking in $\mathbb{D}(S_h)$ (using neighborhood relations) to reach the closest vertex w_h of p in $\mathbb{D}(S_h)$. Then the hierarchy is descended, walking in $\mathbb{D}(S_i)$ from w_{i+1} to find w_i the closest neighbor in sample S_i. Using these neighbors, it is easy to insert p in $\mathbb{D}(S_h)$ and in the triangulation of other samples that the random process assigns to p.

In 2D, the expected cost of the walk at any level is $O(\alpha^{-1})$ and the expected value for h is

$O\left(\frac{\log n}{-\log \alpha}\right)$. Thus the theoretical complexity of the algorithm is $O(n \log n)$. The value of α can be optimized depending on the input distribution: for random points $\alpha = \frac{1}{30}$ gives good timings and a very low memory requirement in addition to the one needed for $\mathbb{D}(S)$.

A Less Randomized Construction

Constructing the Delaunay triangulation by inserting the points in a random order presents a drawback with respect to memory management. Since the inserted point is random in S, there is very little chance that the triangles needed are present in the cache memory. So, an idea is to sort the points using a space-filling curve (see Fig. 2-left) to ensure locality of the insertions. Unfortunately, when inserting the points in such an order, the randomized complexity results no longer apply and the number of created and destroyed triangles during the construction may explode on certain data sets.

A smart solution has been proposed: it is possible to use an insertion order random enough to apply randomized complexity results and allow some locality to benefit from cache memory. BRIO (Biased Randomized Insertion Order) [1] proposes to partition S in a set of random samples $S = \bigcup_{0 \le i \le h} S_i$ such that $|S_i| = \alpha |S_{i+1}|$ for $\alpha \le 1$, a small constant (e.g., $\alpha = \frac{1}{4}$), and to insert the samples by increasing size, each sample being sorted using a spatial filling curve (see Fig. 2-right).

In the random setting, we have seen that the probability for a triangle of width j to appear in the conflict graph algorithm was $\frac{1 \cdot 2 \cdot 3}{(j+1)(j+2)(j+3)} = \Theta(j^{-3})$. Using BRIO, this probability is a bit less intricate to compute, but it can be bounded in terms of α and it can be shown that it is still $\Theta(j^{-3})$ and thus randomized complexity results still apply.

Experimental Results

On a 16 GB, 2.3 GHz desktop CGAL currently computes the Delaunay triangulation of up to 200M points in 2D and 50M points in 3D [8].

Static timings are almost constant with respect to the total number of points and are about 1 µs per point in 2D and 8 µs per point in 3D. In the dynamic setting, one million points are processed in 6s in 2D and 25s in 3D.

URLs to Code and Data Sets

CGAL, among a big collection of computational geometry algorithms, provides implementations for Delaunay triangulations in 2D, 3D, and general dimension. It computes the Delaunay triangulation in 2D and 3D using the Delaunay hierarchy in a dynamic setting and using BRIO for static computation (http://cgal.org).

Keywords

Algorithms for satisfiability; Derandomization; Local search

Years and Authors of Summarized Original Work

2011; Moser, Scheder

Problem Definition

Satisfiability is *the* central NP-complete problem. Given a Boolean formula in conjunctive normal form, for example, $(x \vee \bar{y} \vee z) \wedge (\bar{x} \vee \bar{z}) \wedge \ldots$,

decide whether there is a satisfying assignment. An important subclass is k-SAT, where the input is restricted to k-CNF formulas: CNF formulas in which every clause has at most k literals. In 1999, Uwe Schöning [6] gave an extremely simple randomized algorithm for k-SAT of running time

$$\left(\frac{2(k-1)}{k}\right)^n \text{poly}(n).$$

In particular this solves 3-SAT in time $O^*(1.334^n)$, 4-SAT in $O^*(1.5^n)$ for 4-SAT, and so on (we use O^* to suppress polynomial factors in n). Several authors have attempted to derandomize Schöning's algorithm, albeit at the cost of a greater running time: an algorithm of Dantsin, Goerdt, Hirsch, Kannan, Kleinberg, Papadimitriou, Raghavan, and Schöning [2] runs in time $O^*((2k/(k+1))^n)$, which for $k = 3$ is $O^*(1.5^n)$. For $k = 3$ Brueggemann and Kern [1] achieve $O(1.473^n)$; Scheder [5] achieves $O(1.465^n)$; Kutzkov and Scheder [3] reduced this to $O(1.439^n)$. All improvements suffer from two drawbacks: they fall short of achieving the running time of Schöning's randomized algorithm; most of them are tailored to $k = 3$; finally, they are all fairly complicated.

Key Results

We describe a simple deterministic algorithm due to Moser and Scheder [4] with a running time that matches that of Schöning's up to subexponential overhead. That is, we prove the following theorem:

Theorem 1 *There is a deterministic algorithm deciding satisfiability of k-CNF formulas over n variables in time $\left(\frac{2(k-1)}{k}\right)^{n+o(n)}$.*

Notation

For a CNF formula F we denote by $\text{vbl}(F)$ the set of variables appearing in F. Usually $n = |\text{vbl}(F)|$ denotes the number of variables in a formula. By $\{0,1\}^{\text{vbl}(F)}$ (or $\{0,1\}^n$), we denote the set of all truth assignments to these variables. We make frequent use of the notation $F^{[u \mapsto b]}$, which is the CNF formula created from F by replacing every occurrence of the literal u by b and of $\bar{u}$ by $1-b$. For a literal u and a truth assignment α, we denote by $\alpha[u = b]$ the truth assignment that sets u to b and agrees with α otherwise.

A Promise Version of k-SAT

The heart of the proof will be an algorithm solving a promise version of k-SAT:

Theorem 2 *Let F be a k-CNF formula over n variables, $\alpha \in \{0,1\}^n$ a (not necessarily satisfying) assignment, and $r \in \mathbb{N}_0$. There is a deterministic algorithm* `sb-fast` *with the following properties:*

1. *If F is unsatisfiable,* `sb-fast` (F, r) *returns* `unsatisfiable`.
2. *If F has a satisfying assignment α^* with $d_H(\alpha, \alpha^*) \leq r$, then* `sb-fast`$(F, \alpha, r)$ *returns* `satisfiable`.
3. *Otherwise (i.e., if F is satisfiable but all satisfying assignments of F are too far from α), then* `sb-fast`(F, α, r) *might return* `unsatisfiable` *or* `satisfiable`.

Furthermore, `sb-fast` *runs in time* $(k-1)^{r+o(r)}\text{poly}(n)$.

The "inner random walk" in Schöning's algorithm has all properties stated in Theorem 2, except that it is randomized (with a small error probability). Combining Theorem 2 with the covering code machinery of Dantsin, Goerdt, Hirsch, Kannan, Kleinberg, Papadimitriou, Raghavan, and Schöning [2] yields our main result, Theorem 1.

Theorem 3 *Suppose there is an algorithm A which satisfies properties 1–4 of Theorem 2 and runs in time $c^r\text{poly}(n)$. Then there is an algorithm B solving k-SAT in time $\left(\frac{2c}{c+1}\right)^{n+o(n)}$. Furthermore, B is deterministic if A is.*

Plugging in $c = k-1$ yields Theorem 2.

Preliminaries: A Slower Algorithm

Dantsin et al. [2] give a deterministic algorithm, henceforth called `sb-slow`, satisfying Point 1–4 of Theorem 2 with a running time of $k^r \mathrm{poly}(n)$. We will start by explaining and analyzing this algorithm because our algorithm `sb-fast` uses it as a subroutine in case the input formula F is "well behaved."

> `Algorithm sb-slow`(F, α, r). F is a k-CNF formula over n variables, $\alpha \in \{0,1\}^{\mathrm{vbl}(F)}$ a truth assignment, and $r \in \mathbb{N}_0$.
>
> 1. If α satisfies F, return `satisfiable`.
> 2. Else if $r = 0$, return `unsatisfiable`.
> 3. Else:
>   (a) Pick some clause $C = (u_1 \vee \cdots \vee u_\ell)$ unsatisfied by α. Note that $\ell \le k$ holds in any case, but $\ell < k$ is possible.
>   (b) Set $F_i := F^{[u_i=1]}$.
>   (c) Call `sb-slow`$(F_i, \alpha, r-1)$ for all $1 \le i \le \ell$.
>   (d) If some of these ℓ recursive calls returns `satisfiable`, return `satisfiable`, otherwise return `unsatisfiable`.

It is obvious that `sb-slow` runs in time $k^r \mathrm{poly}(n)$. For correctness, note that `sb-slow` returns `unsatisfiable` if F is unsatisfiable. If F has a satisfying assignment $\alpha^* \neq \alpha$, let $(u_1 \vee \ldots \vee u_k)$ be the clause picked in step (3a). Now α^* satisfies some literal u_i in that clause, and thus the formula $F_i := F^{[u_i=1]}$ is satisfiable, as well. Since neither u_i nor $\bar{u}_i$ appears in F_i, we see that $\alpha^*[u_i = 0]$ satisfies F_i. Since $d_H(\alpha^*[u_i = 0], \alpha) = d_H(\alpha^*, \alpha) - 1 \le r - 1$, the call `sb-slow`$(F_i, \alpha, r-1)$ will return `satisfiable`.

Speeding Up the Algorithm

Let $k \in \mathbb{N}_0$ be fixed from now on.

Definition 1 Let F be a k-CNF formula and $\alpha \in \{0,1\}^{\mathrm{vbl}(F)}$. We say that F is good (with respect to α) if α satisfies all k-clauses of F (it might still violate smaller clauses).

Observe that if F is good, then $F^{[u=1]}$ is good for every literal u. If F is good with respect to α, then `sb-slow`(F, α, r) picks a clause of size at most $k-1$ in step (3a) and causes at most $k-1$ recursive calls, each again with a good formula:

Lemma 1 *Suppose F is a k-CNF that is good with respect to α. Then* `sb-slow` (F, α, r) *runs in time* $(k-1)^r \mathrm{poly}(n)$.

Great! The only thing that is left is to do something smart for formulas that are not good, i.e., have some unsatisfied clauses of size k. We will now describe how `sb-fast` proceeds and give a precise pseudocode description later. The algorithm `sb-fast` greedily finds a maximal set of pairwise disjoint k-clauses that are unsatisfied by α: $C_1, \ldots, C_m$, all over disjoint sets of variables. This can be done in polynomial time. Let β be an assignment to these variables.

Proposition 1 $F^{[\beta]}$ *is good with respect to α.*

This is easy to see: consider a k-clause C in F that is not satisfied by α. Then C might or might not be among $C_1, \ldots, C_m$, but by maximality it shares at least one variable with some i. This variable disappears in $F^{[\beta]}$, and C is either satisfied or shrinks to something smaller than k.

Fix $t = \lfloor \log_k \log_2 n \rfloor$. If $m \le t$ `sb-fast` can simply iterate over all $2^{km} \le 2^{kt} \le (\log_2 n)^k$ different assignments β to the variables in $C_1, \ldots, C_m$: each $F^{[\beta]}$ is good, and thus `sb-fast` $(F^{[\beta]}, \alpha, r)$ runs in time $(k-1)^r \mathrm{poly}(n)$. Also, if F is unsatisfiable then all $F^{[\beta]}$ are. If F has a satisfying assignment α^* with $d_H(\alpha^*, \alpha) \le r$, then at least one $F^{[\beta]}$ does, too. So this step is correct. We are left with the case that $m \ge t$. In this case we define $G := C_1, \ldots, C_t$.

k-ary Covering Codes

The set $[k]^t$ is endowed with a Hamming distance, just as the Hamming cube is: for

$w, w' \in [k]^t$, we define $d_H(w, w') := \left|\left\{i \in [t] \mid w_i \neq w'_i\right\}\right|$. The k-ary Hamming ball around w of radius s is the set $B_s^{(k)}(w) := \left\{w' \in [k]^t \mid d_H(w, w') \leq s\right\}$. The number of elements in such a ball is independent of w. We define and observe

$$\mathrm{vol}^{(k)}(t, s) := \left|B_s^{(k)}(w)\right| = \sum_{i=0}^{s} \binom{t}{i} (k-1)^i.$$

If $\mathcal{C} \subseteq [k]^t$ and $\cup_{w \in \mathcal{C}} B_s^{(k)}(w) = [k]^t$, we call $\mathcal{C}$ a k-ary code of length t and covering radius s. Using the probabilistic method it is easy to show the following result:

Lemma 2 *Let $t, k \in \mathbb{N}$, and $s \in \mathbb{N}_0$. There exists a k-ary code of length t and covering radius s with at most*

$$\left\lceil \frac{t \ln(k)\, k^t}{\mathrm{vol}^{(k)}(t, s)} \right\rceil$$

elements.

Observe that $k^t \leq \log_2 n$ and thus there are at most $2^{\log_2 n} = n$ subsets $\mathcal{C} \subseteq [k]^t$. We iterate through all of them and find a smallest code of covering radius s.

Consider $G = (C_1, \ldots, C_t)$, our maximal set of pairwise disjoint k-clauses not satisfied by α. Any satisfying assignment α^* of F must satisfy at least one literal in each C_i. Since they are pairwise disjoint, this implies $d_H(\alpha, \alpha^*) \geq t$. There are exactly k^t assignments that satisfy G and have distance exactly t from α. Each such assignment can be represented by a $w \in [k]^t$ in the obvious way. To be more precise, for $w \in [k]^t$ we define $\alpha[G, w]$ to be the assignment which we obtain from α by flipping the w_i^{th} literal in C_i, for $1 \leq i \leq t$. If G is understood from the context, we write $\alpha[w]$ instead of $\alpha[G, w]$.

Example 1 Consider $G = ((x_1, y_1, z_1), (x_2, y_2, z_2), (x_3, y_3, z_3))$, $\alpha = (0, \ldots, 0)$ and $t = 3$. Let $w = (2, 3, 3)$. Then $\alpha[w]$ is the assignment that sets y_1, z_2, and z_3 to 1 and all other variables to 0.

Proposition 2 *We observe the following facts about $\alpha[w]$:*

1. *$d_H(\alpha, \alpha[w]) = t$ for every $w \in [k]^t$.*
2. *If α^* satisfies F, then for some $w^* \in [k]^t$ we have $d_H(\alpha[w^*], \alpha^*) = d_H(\alpha, \alpha^*) - t$.*
3. *Let $w, w' \in [k]^t$. Then $d_H(\alpha[w], \alpha[w']) = 2 d_H(w, w')$.*

Lemma 3 *Let t and G be defined as above, and let $\mathcal{C} \subseteq [k]^t$ be a k-ary code of covering radius s. If α^* is a satisfying assignment of F, then there is some $w \in \mathcal{C}$ such that $d_H(\alpha[w^*], \alpha^*) \leq d_H(\alpha, \alpha^*) - t + 2s$.*

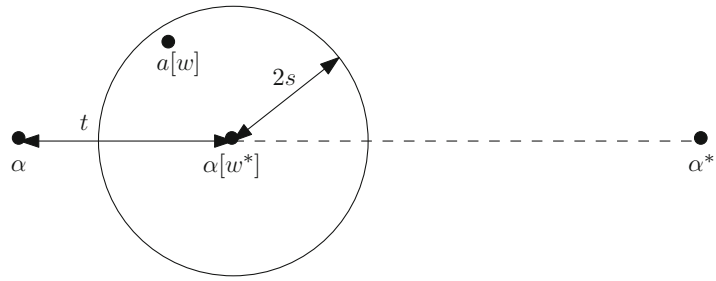
In particular, if $B_r(\alpha)$ contains a satisfying assignment, then there is some $w \in \mathcal{C}$ such that $B_{r-t+2s}(\alpha[w])$ contains it, too.

Proof (of Lemma 3) By Proposition 2, there is some $w^* \in [k]^t$ such that $d_H(\alpha[w^*], \alpha^*) = d_H(\alpha, \alpha^*) - t \leq r - t$. Since $\mathcal{C}$ has covering radius s, there is some $w \in \mathcal{C}$ such that $d_H(ww^*) \leq s$, and by Observation 2, $d_H(\alpha[w], \alpha[w^*]) \leq 2s$. The lemma now follows from the triangle inequality. The proof is illustrated in Fig. 1.

We now state `sb-fast` formally. We compute an optimal k-ary code $\mathcal{C}$ of length t and covering radius $s = t/k$ that is fixed throughout the run of the algorithm.

`Algorithm sb-fast`(F, α, r).

1. If α satisfies F, return `satisfiable`.
2. Else if $r = 0$, return `unsatisfiable`.
3. Else let G be maximal set of pairwise disjoint k-clauses of F unsatisfied by α.
4. If $|G| \geq t := \log_k \log_2 n$: Call `sb-slow`$(F^{[\beta]}, \alpha, r)$ for every $\beta \in \{0,1\}^{\mathrm{vbl}(G)}$ and return `satisfiable` iff at least one call returns `satisfiable`.
5. Else, if $|G| \geq t$ set $G = (C_1, \ldots, C_t)$ and call `sb-fast`$(F, \alpha[G, w], r - t + 2t/k)$ for every $w \in \mathcal{C}$ and return `satisfiable` iff at least one call returns `satisfiable`.



Derandomization of *k*-SAT Algorithm, Fig. 1 The distance from α^* to $\alpha[w]$ is at most the distance from α^* to $\alpha[w^*]$ plus $2s$

Correctness of `sb-fast` follows from the above discussion: If there is some $\alpha^* \in B_r(\alpha)$ that satisfies F, then for at least one $w \in \mathcal{C}$ it holds that $d_H(\alpha[w], \alpha^*) \leq r - t + 2t/k$, thus the corresponding recursive call to `sb-fast` will be successful.

What about the running time? If $|G| \leq t$, then every call to `sb-slow` $(F^{[\beta]}, \alpha, r)$ runs in time $O((k-l)^r \text{poly}(n))$. Otherwise, the procedure `sb-fast` calls itself recursively for each $w \in \mathcal{C}$. Every level further into the recursion, the parameter r decreases by $t - 2t/k$. The running time is therefore $|\mathcal{C}|^{r/(t-2t/k)}\,\text{poly}(n)$. To evaluate this we have to estimate the size of $\mathcal{C}$. Recall that $s = t/k$.

$$
\begin{aligned}
|\mathcal{C}| &\leq \frac{k^t \text{poly}(t)}{\text{vol}^{(k)}(t,s)} \leq \frac{k^t \text{poly}(t)}{\binom{t}{s}(k-1)^s} \\
&\leq \frac{k^t \text{poly}(t)}{\left(\frac{t}{s}\right)^s \left(\frac{t}{t-s}\right)^{t-s}(k-1)^s} \\
&= \frac{k^t \text{poly}(t)}{k^s \left(\frac{k}{k-1}\right)^{t-s}(k-1)^s} \\
&= (k-1)^{t-2s}\,\text{poly}(t).
\end{aligned}
$$

Therefore,

$$
\begin{aligned}
|\mathcal{C}|^{r/(t-2t/k)} &\leq \left((k-1)^{t-2s}\,\text{poly}(t)\right)^{r/(t-2s)} \\
&= (k-1)^r\,\text{poly}(t)^{r/(t-2s)}.
\end{aligned}
$$

Since t is a growing function in n, the term $\text{poly}(t)^{1/(t-2s)}$ converges to 1 as n grows, and the running time is at most $(k-1)^{r+o(r)\text{poly}(n)}$. This completes the proof of Theorem 2.

Deterministic Broadcasting in Radio Networks

Leszek Gąsieniec

Years and Authors of Summarized Original Work

2000; Chrobak, Gąsieniec, Rytter

Problem Definition

One of the most fundamental communication problems in wired as well as wireless networks is **broadcasting**, where one distinguished source node has a message that needs to be sent to all other nodes in the network.

The radio network abstraction captures the features of distributed communication networks with multi-access channels, with minimal assumptions on the channel model and processors' knowledge. Directed edges model unidirectional links, including situations in which one of two adjacent transmitters is more powerful than the other. In particular, there is no feedback mechanism (see, for example, [13]). In some applications, collisions may be difficult to distinguish from the noise that is normally present on the channel, justifying the need for protocols that do not depend on the reliability of the collision detection mechanism (see [9,10]). Some network configurations are subject to frequent changes. In other networks, topologies could be unstable or dynamic; for example, when mobile users are present. In such situations, algorithms that do not assume any specific topology are more desirable.

More formally a radio network is a directed graph where by n we denote the number of nodes in this graph. If there is an edge from u to v, then we say that v is an *out-neighbor* of u and u is an *in-neighbor* of v. Each node is assigned a unique identifier from the set $\{1, 2, \ldots, n\}$. In the broadcast problem, one node, for example, node 1, is distinguished as the *source node*. Initially, the nodes do not possess any other information. In particular, they do not know the network topology.

The time is divided into discrete time steps. All nodes start simultaneously, have access to a common clock, and work synchronously. A broadcasting algorithm is a protocol that for each identifier *id*, given all past messages received by *id*, specifies, for each time step t, whether *id* will transmit a message at time t, and if so, it also specifies the message. A message M transmitted at time t from a node u is sent instantly to all its out-neighbors. An out-neighbor v of u receives M at time step t only if no collision occurred, that is, if the other in-neighbors of v do not transmit at time t at all. Further, collisions cannot be distinguished from background noise. If v does not receive any message at time t, it knows that either none of its in-neighbors transmitted at time t or that at least two did, but it does not know which of these two events occurred. The *running time* of a broadcasting algorithm is the smallest t such that for any network topology, and any assignment of identifiers to the nodes, all nodes receive the source message no later than at step t.

All efficient radio broadcasting algorithms are based on the following purely combinatorial concept of selectors.

Selectors Consider subsets of $\{1, \ldots, n\}$. We say that a set S *hits* a set X iff $|S \cap X| = 1$, and that S *avoids* Y iff $S \cap Y = \emptyset$. A family $\mathcal{S}$ of sets is a *w-selector* if it satisfies the following property:

(*) For any two disjoint sets X, Y with $w/2 \leq |X| \leq w$, $|Y| \leq w$, there is a set in $\mathcal{S}$ which hits X and avoids Y.

A complete layered network is a graph consisting of layers $L_0, \ldots, L_{m-1}$, in which each node in layer L_i is directly connected to every node in layer L_{i+1}, for all $i = 0, \ldots, m-1$. The layer L_0 contains only the source node s.

Key Results

Theorem 1 ([5]) *For all positive integers w and n, s.t., $w \leq n$, there exists a w-selector $\bar{S}$ with $O(w \log n)$ sets.*

Theorem 2 ([5]) *There exists a deterministic $O(n \log^2 n)$-time algorithm for broadcasting in radio networks with arbitrary topology.*

Theorem 3 ([5]) *There exists a deterministic $O(n \log n)$-time algorithm for broadcasting in complete layered radio networks.*

Applications

Prior to this work, Bruschi and Del Pinto showed in [1] that radio broadcasting requires time $\Omega(n \log D)$ in the worst case. In [4], Chlebus et al. presented a broadcasting algorithm with time complexity $O(n^{11/6})$ – the first subquadratic upper bound. This upper bound was later improved to $O(n^{5/3} \log^3 n)$ by De Marco and Pelc [8] and by Chlebus et al. [3] to $O(n^{3/2})$ by application of finite geometries.

Recently, Kowalski and Pelc in [12] proposed a faster $O(n \log n \log D)$ – time radio broadcasting algorithm, where D is the eccentricity of the network. Later, Czumaj and Rytter showed in [6] how to reduce this bound to $O(n \log^2 D)$. The results presented in [5] (see Theorems 1–3, as well as further improvements in [6, 12]) are existential (non-constructive). The proofs are based on the probabilistic method. A discussion on efficient explicit construction of selectors was initiated by Indyk in [11] and then continued by Chlebus and Kowalski in [2].

More careful analysis and further discussion on selectors in the context of *combinatorial group testing* can be found in [7], where DeBonis et al. proved that the size of selectors is $\Theta(w \log \frac{n}{w})$.

Open Problems

The exact complexity of radio broadcasting remains an open problem, although the gap between the lower and upper bounds $\Omega(n \log D)$ and $O(n \log^2 D)$ is now only a factor of $\log D$. Another promising direction for further studies is improvement of efficient explicit construction of selectors.

Problem Definition

In the *Linear Search Problem* (LSP), we seek efficient strategies for locating an immobile target on the infinite line. More formally, the search environment consists of the infinite (i.e., unbounded) line, with a point O designated as a specific start point. A mobile searcher is initially located at O, whereas the target may be hidden at any point on the line. The searcher's strategy S defines the movement of the searcher on the line; on the other hand, the hider's strategy H is defined as the precise placement of the target on the line, and we denote by $|H|$ the distance of the target from the start point. Given strategies S, H, the *cost* of locating the target, denoted by $c(S, H)$ is the total distance traversed by the searcher at the first time the target is located. The *normalized cost* of the strategies is defined as the quantity $\overline{c}(S, H) = \frac{c(S,H)}{|H|}$.

The objective of the linear search problem is to determine a strategy S for the searcher that minimizes the worst-case normalized cost, namely, the quantity $\sup_H \overline{c}(S, H)$; the latter is often referred to as the *competitive ratio* of the strategy S, due to similarities of this setup with the competitive analysis of online algorithms. In game-theoretic terms, the problem can be described as a zero-sum game between the searcher and the hider in which we seek the minimax strategy of the game.

Extensions

A natural extension of the linear search problem is the *m-ray search* problem, also known as the *star search* problem. Here, the search environment consists of m infinite rays, with the start point O being their common intersection point. Clearly, the linear search problem is precisely the 2-ray search problem.

Constraints

It must be noted that if $|H|$ is arbitrarily small, no strategy of constant competitive ratio exists. Hence, a frequent and natural assumption in the field is to assume that $|H| \geq 1$, i.e., that the target is hidden at least at some minimum allowed distance from the start point. A different assumption that can be made in order to circumvent this complication is that the search strategy must incorporate an infinite sequence of infinitesimal steps (i.e., depths of exploration). In this entry we assume the former, namely, that $|H| \geq 1$.

In addition, we assume only deterministic (i.e., pure) strategies for both the searcher and the hider. We note that a substantial amount of previous work has addressed mixed strategies under given probability distributions on the placement of the target. We refer the reader to the textbook of Alpern and Gal [1].

Key Results

We consider two variants of the problem. In the first variant, the searcher lacks any information concerning the hidden target. In the second variant, the searcher knows that the target is within distance $h = |H|$ from the start point O.

Note that for the linear search problem, the searcher's strategy is completely determined by the sequence of search depths $\{x_i\}_{i \geq 1}$, where x_i denotes the total distance from the start point

in which the line is searched during the i-th exploration.

Searching with No Information

It has long been known that a *doubling* strategy, namely, the strategy $\{2^i\}_{i\geq 1}$ attains an optimal competitive ratio equal to 9 for this variant. The result is due to Beck and Newman [4] and rediscovered by Baeza-Yates et al. [2].

Calculating an upper bound on the competitive ratio is easy: if the target is at distance h from O, the doubling strategy will discover it at traversal $2k+1$, where $2^{2k-1} < h$ and $2^{2k+1} \geq h$. The total distance traversed by the searcher is equal to $2\sum_{i=1}^{2k} 2i + d = 4(2^{2k}-1)+h$. The competitive ratio is maximized when $h \to \infty$ and converges (from below) to 9.

An elegant approach for proving the tightness of this bound is based on lower bounds on certain functionals over positive sequences [8]. Let $\{x_i\}_{i\geq 1}$ be an optimal search strategy, then it is easy to see that its competitive ratio is at least equal to $\sup_k 1 + 2\frac{\sum_{i=1}^{k+1} x_i}{x_k}$. In addition, it can be readily seen that an optimal search strategy $\{x_i\}_{i\geq 1}$ must be *monotone*, i.e., $x_i \geq x_j$ for $i > j$. Given the above, Gal shows that there exists $a > 1$ such that

$$\sup_k 1 + 2\frac{\sum_{i=1}^{k+1} x_i}{x_k} \geq \sup_a \lim_{k\to\infty} 1 + 2\frac{\sum_{i=1}^{k+1} a^i}{a^k},$$

which in turn is at least equal to 9, for all $a > 1$.

Informally, the above argument shows that *geometric* strategies of the form $\{a^i\}_{i\geq 1}$ comprise the space of optimal strategies, and by choosing $a = 2$ one obtains the best strategy.

Searching with an Upper Bound on the Target Distance

In the setting in which the searcher has an upper bound h on the distance of the target from the start point, it is possible to obtain improved competitive ratios. Jaillet and Stafford [9] approach this problem by solving the following "dual" problem: given a target competitive ratio r, and the upper bound h, what is the largest "extent" (i.e., the furthest one can go in both directions) that can be searched while guaranteeing a competitive ratio at most r? A solution to this problem implies a solution to the (primal) search problem: it suffices to find the smallest r such that $e(r) \geq h$, where $e(h)$ is the best-possible extent.

The dual problem of finding $e(r)$ is addressed by means of a series of linear-program formulations. The solution to this series of linear programs defines a search strategy in which the search depths $\{x_i\}_{i\geq 1}$ are determined by an appropriate linear recurrence relation. As a last step, $e(r)$ is obtained as a particular element of the sequence that is generated by the linear recurrence in question. It should be noted that although the strategy is optimal, this technique does not yield a closed-form expression of the optimal competitive ratio (given h).

A similar approach leads to a solution for m-ray searching with an upper bound on the target distance. The crucial difficulty here, as opposed to the case $m = 2$, is in showing that an optimal strategy can be found in the class of *cyclic* strategies: these are strategies in which the searcher always visits the rays in some fixed round-robin order. This seemingly intuitive property is surprisingly hard to be established formally. To bypass this obstacle, one must first show that the property holds when the search depths form a nondecreasing sequence. Then one can argue that, once a searcher is at the start point, it will always choose to explore the ray that has been explored the least up to the current point. As noted in [9], this "least-extended-so-far discipline is the link between non-decreasing depths and the cyclic property that is sought." Once the optimality of cyclic strategies is established, a similar approach can be applied as in the case $m = 2$; namely, the search depths are determined by a (more complicated) linear recurrence.

Applications

The problem has obvious applications in the context of robotic navigation in an unknown environment. Strategies based on doubling are used in searching more complicated environments, e.g., a graph [11]. The linear search problem and its

generalization have connections with the design of black-box strategies for obtaining *interruptible* algorithms. The latter class consists of algorithms with the property that they return efficient solutions even if interrupted during their execution. Such algorithms are very desirable in the context of real-time and anytime applications in artificial intelligence [5].

Keywords

Approximate dictionary matching; Approximate text indexing

Years and Authors of Summarized Original Work

2004; Cole, Gottlieb, Lewenstein

Problem Definition

Indexing and *dictionary matching* are generalized models of pattern matching. These models have attained importance with the explosive growth of multimedia, digital libraries, and the Internet.

1. *Text Indexing:* In text indexing one desires to preprocess a text t, of length n, and to answer where subsequent queries p, of length m, appear in the text t.
2. *Dictionary Matching:* In dictionary matching one is given a dictionary D of strings $p_1, \ldots, p_d$ to be preprocessed. Subsequent queries provide a query string t, of length n, and ask for each location in t at which patterns of the dictionary appear.

Key Results

Text Indexing

The *indexing* problem assumes a large text that is to be preprocessed in a way that will allow the following efficient future queries. Given a query pattern, one wants to find all text locations that match the pattern in time proportional to the *pattern length and to the number of occurrences*.

To solve the indexing problem, Weiner [14] invented the *suffix tree* data structure (originally called a *position tree*), which can be constructed in linear time, and subsequent queries of length m are answered in time $O(m \log |\Sigma| + tocc)$, where $tocc$ is the number of pattern occurrences in the text.

Weiner's suffix tree in effect solved the indexing problem for exact matching of fixed texts. The construction was simplified by the algorithms of McCreight and, later, Chen and Seiferas. Ukkonen presented an online construction of the suffix tree. Farach presented a linear time construction for large alphabets (specifically, when the alphabet is $\{1, \ldots, n^c\}$, where n is the text size and c is some fixed constant). All results, besides the latter, work by handling one suffix at a time. The latter algorithm uses a divide-and-conquer approach, dividing the suffixes to be sorted to even-position suffixes and odd-position suffixes. See the entry on ▶ Suffix Tree Construction for full details. The standard query time for finding a pattern p in a suffix tree is $O(m \log |\Sigma|)$. By slightly adjusting the suffix tree, one can obtain a query time of $O(m + \log n)$; see [12].

Another popular data structure for indexing is suffix arrays. Suffix arrays were introduced by Manber and Myers. Others proposed linear time constructions for linearly bounded alphabets. All three extend the divide and conquer approach presented by Farach. The construction in [11] is especially elegant and significantly simplifies the divide-and-conquer approach, by dividing the suffix set into three groups instead of two. See the entry on ▶ Suffix Array Construction for full details. The query time for suffix arrays is $O(m + \log n)$ achievable by embedding additional lcp (longest common prefix) information into the data structure. See [11] for reference to other solutions. *Suffix Trays* were introduced in [6] as a merge between suffix trees and suffix arrays. The construction time of suffix trays is the same as for suffix trees and suffix arrays. The query time is $O(m + \log |\Sigma|)$.

Solutions for the indexing problem in *dynamic* texts, where insertions and deletions (of single characters or entire substrings) are allowed, appear in several Papers; see [2] and references therein.

Dictionary Matching

Dictionary matching is, in some sense, the "inverse" of text indexing. The large body to be preprocessed is a set of patterns, called the *dictionary*. The queries are texts whose length is typically significantly smaller than the dictionary size. It is desired to find all (exact) occurrences of dictionary patterns in the text in time proportional to the *text length and to the number of occurrences*.

Aho and Corasick [1] suggested an automaton-based algorithm that preprocesses the dictionary in time $O(d)$ and answers a query in time $O(n + docc)$, where $docc$ is the number of occurrences of patterns within the text. Another approach to solving this problem is to use a generalized suffix tree. A *generalized suffix tree* is a suffix tree for a collection of strings. Dictionary matching is done for the dictionary of patterns. Specifically, a suffix tree is created for the generalized string $p_1\$_1 p_2\$_2 \ldots \$_d p_d\$_d$, where the $\$_i$'s are not in the alphabet. A randomized solution using a fingerprint scheme was proposed in [3]. In [7] a parallel work-optimal algorithm for dictionary matching was presented. Ferragina and Luccio [8] considered the problem in the external memory model and suggested a solution based upon the String Btree data structure along with the notion of a certificate for dictionary matching. Two-dimensional dictionary matching is another fascinating topic which appears as a separate entry. See also the entry on ▶ Multidimensional String Matching.

Dynamic Dictionary Matching

Here one allows insertion and deletion of patterns from the dictionary D. The first solution to the problem was a suffix tree-based method for solving the dynamic dictionary matching problem. Idury and Schäffer [10] showed that the failure function (function mapping from one longest matching prefix to the next longest matching prefix; see [1]) approach and basic scanning loop of the Aho-Corasick algorithm can be adapted to dynamic dictionary matching for improved initial

dictionary preprocessing time. They also showed that faster search time can be achieved at the expense of slower dictionary update time.

A further improvement was later achieved by reducing the problem to maintaining a sequence of well-balanced parentheses under certain operations. In [13] an optimal method was achieved based on a labeling paradigm, where labels are given to, sometimes overlapping, substrings of different lengths. The running times are $O(|D|)$ preprocessing time, $O(m)$ update time, and $O(n + docc)$ time for search. See [13] for other references.

Text Indexing and Dictionary Matching with Errors

In most real-life systems, there is a need to allow errors. With the maturity of the solutions for *exact* indexing and *exact* dictionary matching, the quest for *approximate* solutions began. Two of the classical measures for approximating closeness of strings, Hamming distance and Edit distance, were the first natural measures to be considered.

Approximate Text Indexing

For approximate text indexing, given a distance k, one preprocesses a specified text t. The goal is to find all locations ℓ of t within distance k of the query p, i.e., for the Hamming distance all locations ℓ such that the length m substring of t beginning at that location can be made equal to p with at most k character substitutions. (An analogous statement applies for the edit distance.) For $k = 1$ [4] one can preprocess in time $O(n \log^2 n)$ and answer subsequent queries p in time $O(m\sqrt{\log n} \log\log n + occ)$. For small $k \geq 2$, the following naive solutions can be achieved. The first possible solution is to traverse a suffix tree checking all possible configurations of k, or less, mismatches in the pattern. However, while the preprocessing needed to build a suffix tree is cheap, the search is expensive, namely, $O(m^{k+1}|\Sigma|^k + occ)$. Another possible solution, for the Hamming distance measure only, leads to data structures of size approximately $O(n^{k+1})$ embedding all mismatch possibilities into the tree. This can be slightly improved by using the data structures for $k = 1$, which reduce the size to approximately $O(n^k)$.

Approximate Dictionary Matching

The goal is to preprocess the dictionary along with a threshold parameter k in order to support the following subsequent queries: Given a query text, seek all pairs of patterns (from the dictionary) and text locations which match within distance k. Here once again there are several algorithms for the case where $k = 1$ [4, 9]. The best solution for this problem has query time $O(m \log\log n + occ)$; the data structure uses space $O(n \log n)$ and can be built in time $O(n \log n)$.

The solutions for $k = 1$ in both problems (Approximate Text Indexing and Approximate Dictionary Matching) are based on the following, elegant idea, presented in Indexing terminology. Say a pattern p matches a text t at location i with one error at location j of p (and at location $i + j - 1$ of t). Obviously, the $j - 1$-length prefix of p matches the aligned substring of t and so does the $m - j - 1$ length suffix. If t and p are reversed, then the $j - 1$-th length prefix of p becomes a $j - 1$-th length suffix of p^R (that is p reverse). Notice that there is a match with, at most one error, if (1) the suffix of p starting at location $j + 1$ matches the (prefix of the) suffix of t starting at location $i + j$ and (2) the suffix of p^R starting at location $m - j + 1$ (the reverse of the $j - 1$-th length prefix of p) matches the (prefix of the) suffix of t^R starting at location $m - i - j + 3$. So, the problem now becomes a search for locations j which satisfy the above. To do so, the abovementioned solutions, naturally, use two suffix trees, one for the text and one for its reverse (with additional data structure tricks to answer the query fast). In dictionary matching the suffix trees are defined on the dictionary. The problem is that this solution does not carry over for $k \geq 2$. See the introduction of [5] for a full list of references.

Text Indexing and Dictionary Matching Within (Small) Distance *k*

Cole et al. [5] proposed a new method that yields a unified solution for approximate text indexing,

approximate dictionary matching, and other related problems. However, since the solution is somewhat involved, it will be simpler to explain the ideas on the following problem. The desire is to index a text t to allow fast searching for all occurrences of a pattern containing, at most, k don't cares (don't cares are special characters which match all characters).

Once again, there are two possible, relatively straightforward, solutions to be elaborated. The first is to use a suffix tree, which is cheap to preprocess, but causes the search to be expensive, namely, $O(m|\Sigma|^k + occ)$ (if considering k mismatches this would increase to $O(m^{k+1}|\Sigma|^k + occ)$. To be more specific, imagine traversing a path in a suffix tree. Consider the point where a don't care is reached. If in the middle of an edge the only text suffixes (representing substrings) that can match the pattern with this don't care must also go through this edge, so simply continue traversing. However, if at a node, then all the paths leaving this node must be explored. This explains the mentioned time bound.

The second solution is to create a tree that contains all strings that are at Hamming distance k from a suffix. This allows fast search but leads to trees of size exponential in k, namely, $O(n^{k+1})$ size trees. To elaborate, the tree, called a *k-error trie*, is constructed as follows. First, consider the case for one don't care, i.e., a 1-*error trie*, and then extend it. At any node v a don't care may need to be evaluated. Therefore, create a special subtree branching off this node that represents a don't care at this node. To understand this subtree, note that the subtree (of the suffix tree) rooted at v is actually a compressed trie of (some of the) suffixes of the text. Denote the collection of suffixes S_v. The first character of all these suffixes has to be removed (or, perhaps better imagined as a replacement with a don't care character). Each will be a new suffix of the text. Denote the new collection as S'_v. Now, create a new compressed trie of suffixes for S'_v, calling this new subtree an *error tree*. Do so for every v. The suffix tree along with its error trees is a 1-*error trie*. Turning to queries in the 1-*error trie*, when traversing the 1-*error trie*, do so with the suffix tree up till the don't care at node v. Move into the error tree at node v and continue the traversal of the pattern.

To create a 2-*error trie*, simply take each error tree and construct an error tree for each node within. A $(k+1)$-*error trie* is created recursively from a k-*error trie*. Clearly the 1-*error trie* is of size $O(n^2)$, since any node u in the original suffix tree will appear in all the new subtrees of the 1-*error trie* created for each of the nodes v which are ancestors of u. Likewise, the k-*error trie* is of size $O(n^{k+1})$.

The method introduced in Cole et al. [5] uses the idea of the error trees to form a new data structure, which is called a k-*errata trie*. The k-*errata trie* will be much smaller than $O(n^{k+1})$. However, it comes at the cost of a somewhat slower search time. To understand the k-*errata tries*, it is useful to first consider the 1-*errata tries* and to extend. The 1-*errata trie* is constructed as follows. The suffix tree is first decomposed with a centroid path decomposition (which is a decomposition of the nodes into paths, where all nodes along a path have their subtree sizes within a range 2^r and 2^{r+1}, for some integer r). Then, as before, error trees are created for each node v of the suffix tree with the following difference. Namely, consider the subtree, T_v, at node v and consider the edge (v, x) going from v to child x on the centroid path. T_v can be partitioned into two subtrees, $T_x \cup (v, x)$, and T'_v all the rest of T_v. An error tree is created for the suffixes in T'_v. The 1-*errata trie* is the suffix tree with all of its error trees. Likewise, a $(k+1)$-*errata trie* is created recursively from a k-*errata trie*. The contents of a k-*errata trie* should be viewed as a collection of error trees, k levels deep, where error trees at each level are constructed on the error trees of the previous level (at level 0 there is the original suffix tree). The following lemma helps in obtaining a bound on the size of the k-*errata trie*.

Lemma 1 *Let C be a centroid decomposition of a tree T. Let u be an arbitrary node of T and π be the path from the root to u. There are at most* $\log n$ *nodes v on π for which v and v's parent on π are on different centroid paths.*

The implication is that every node u in the original suffix tree will only appear in $\log n$ error trees of the 1-*errata trie* because each ancestor v of u is on the path π from the root to u and only $\log n$ such nodes are on different centroid paths than their children (on π). Hence, u appears in only $\log^k n$ error trees in the k-*errata trie*. Therefore, the size of the k-*errata trie* is $O(n \log^k n)$. Creating the k-*errata trie*s in $O(n \log^{k+1} n)$ can be done. To answer queries on a k-*errata trie*, given the pattern with (at most) k don't cares, the 0th level of the k-*errata trie*, i.e., the suffix tree, needs to be traversed. This is to be done until the first don't care, at location j, in the pattern is reached. If at node v in the 0th level of the k-*errata trie*, enter the (1st level) error tree hanging off of v and traverse this error tree from location $j + 2$ of the pattern (until the next don't care is met). However, the error tree hanging off of node v does not contain the subtree hanging off of v that is along the centroid path. Hence, continue traversing the pattern in the 0th level of the k-*errata trie*, starting along the edge on the centroid path leaving v (until the next don't care is met). The search is done recursively for k don't cares and, hence, yields an $O(2^k m)$ time search.

Recall that a solution for indexing text that supports queries of a pattern with k don't cares has been described. Unfortunately, when indexing to support k mismatch queries, not to mention k edit operation queries, the traversal down a k-*errata trie* can be very time consuming as frequent branching is required since an error may occur at any location of the pattern. To circumvent this problem, search many error trees in parallel. In order to do so, the error trees have to be grouped together. This needs to be done carefully; see [5] for the full details. Moreover, edit distance needs even more careful handling. The time and space of the algorithms achieved in [5] are as follows:

Approximate Text Indexing: The data structure for mismatches uses space $O(n \log^k n)$, takes time $O(n \log^{k+1} n)$ to build, and answers queries in time $O((\log^k n) \log \log n + m + occ)$. For edit distance, the query time becomes $O((\log^k n) \log \log n + m + 3^k \cdot occ)$. It must be pointed out that this result is mostly effective for constant k.

Approximate Dictionary Matching: For k mismatches the data structure uses space $O(n + d \log^k d)$, is built in time $O(n + d \log^{k+1} d)$, and has a query time of $O((m + \log^k d) \cdot \log \log n + occ)$. The bounds for edit distance are modified as in the indexing problem.

Applications

Approximate Indexing has a wide array of applications in signal processing, computational biology, and text retrieval, among others. Approximate Dictionary Matching is important in digital libraries and text retrieval systems.

Problem Definition

The problem of lossless data compression is the problem of compactly representing data in a format that admits the faithful recovery of the original information. Lossless data compression is achieved by taking advantage of the redundancy which is often present in the data generated by either humans or machines.

Dictionary-based data compression has been "the solution" to the problem of lossless data compression for nearly 15 years. This technique originated in two theoretical papers of Ziv and Lempel [15, 16] and gained popularity in the "1980s" with the introduction of the Unix tool `compress` (1986) and of the gif image format (1987). Although today there are alternative solutions to the problem of lossless data compression (e.g., Burrows-Wheeler compression and Prediction by Partial Matching), dictionary-based compression is still widely used in everyday applications: consider for example the zip utility and its variants, the modem compression standards V.42bis and V.44, and the transparent compression of pdf documents. The main reason for the success of dictionary-based compression is its unique combination of compression power and compression/decompression speed. The reader should refer to [13] for a review of several dictionary-based compression algorithms and of their main features.

Key Results

Let T be a string drawn from an alphabet Σ. Dictionary-based compression algorithms work by parsing the input into a sequence of substrings (also called words) $T_1, T_2, \ldots, T_d$ and by encoding a compact representation of these substrings. The parsing is usually done incrementally and

on-line with the following iterative procedure. Assume the encoder has already parsed the substrings $T_1, T_2, \ldots, T_{i-1}$. To proceed, the encoder maintains a dictionary of potential candidates for the next word T_i and associates a unique codeword with each of them. Then, it looks at the incoming data, selects one of the candidates, and emits the corresponding codeword. Different algorithms use different strategies for establishing which words are in the dictionary and for choosing the next word T_i. A larger dictionary implies a greater flexibility for the choice of the next word, but also longer codewords. Note that for efficiency reasons the dictionary is usually not built explicitly: the whole process is carried out implicitly using appropriate data structures.

Dictionary-based algorithms are usually classified into two families whose respective ancestors are two parsing strategies, both proposed by Ziv and Lempel and today universally known as LZ78 [16] and LZ77 [15].

The LZ78 Algorithm

Assume the encoder has already parsed the words $T_1, T_2, \ldots, T_{i-1}$, that is, $T = T_1 T_2 \cdots T_{i-1} \hat{T}_i$ for some text suffix $\hat{T}_i$. The LZ78 dictionary is defined as the set of strings obtained by adding a single character to one of the words $T_1, \ldots, T_{i-1}$ or to the empty word. The next word T_i is defined as the longest prefix of $\hat{T}_i$ which is a dictionary word. For example, for $T = aabbaaabaabaabba$ the LZ78 parsing is: a, ab, b, aa, aba, $abaa$, bb, a. It is easy to see that all words in the parsing are distinct, with the possible exception of the last one (in the example the word a). Let T_0 denote the empty word. If $T_i = T_j \alpha$, with $0 \le j < i$ and $\alpha \in \Sigma$, the codeword emitted by LZ78 for T_i will be the pair (j, α). Thus, if LZ78 parses the string T into t words, its output will be bounded by $t \log t + t \log |\Sigma| + \Theta(t)$ bits.

The LZ77 Algorithm

Assume the encoder has already parsed the words $T_1, T_2, \ldots, T_{i-1}$, that is, $T = T_1 T_2 \cdots T_{i-1} \hat{T}_i$ for some text suffix $\hat{T}_i$. The LZ77 dictionary is defined as the set of strings of the form $w\alpha$ where $\alpha \in \Sigma$ and w is a substring of T starting in the already parsed portion of T. The next word T_i is defined as the longest prefix of $\hat{T}_i$ which is a dictionary word. For example, for $T = aabbaaabaabaabba$ the LZ77 parsing is: a, ab, ba, $aaba$, $abaabb$, a. Note that, in some sense, $T_5 = abaabb$ is defined in terms of itself: it is a copy of the dictionary word $w\alpha$ with w starting at the second a of T_4 and extending into T_5! It is easy to see that all words in the parsing are distinct, with the possible exception of the last one (in the example the word a), and that the number of words in the LZ77 parsing is smaller than in the LZ78 parsing. If $T_i = w\alpha$ with $\alpha \in \Sigma$, the codeword for T_i is the triplet (s_i, ℓ_i, α) where s_i is the distance from the start of T_i to the last occurrence of w in $T_1 T_2 \cdots T_{i-1}$, and $\ell_i = |w|$.

Entropy Bounds

The performance of dictionary-based compressors has been extensively investigated since their introduction. In [15] it is shown that LZ77 is optimal for a certain family of sources, and in [16] it is shown that LZ78 achieves asymptotically the best compression ratio attainable by a finite-state compressor. This implies that, when the input string is generated by an ergodic source, the compression ratio achieved by LZ78 approaches the entropy of the source. More recent work has established similar results for other Ziv–Lempel compressors and has investigated the rate of convergence of the compression ratio to the entropy of the source (see [14] and references therein).

It is possible to prove compression bounds without probabilistic assumptions on the input, using the notion of *empirical entropy*. For any string T, the order k empirical entropy $H_k(T)$ is the maximum compression one can achieve using a uniquely decodable code in which the codeword for each character may depend on the k characters immediately preceding it [6]. The following lemma is a useful tool for establishing upper bounds on the compression ratio of dictionary-based algorithms which hold pointwise on every string T.

Lemma 1 ([6, Lemma 2.3]) *Let $T = T_1 T_2 \cdots T_d$ be a parsing of T such that each word T_i appears at most M times. Then, for any $k \geq 0$*

$$d \log d \leq |T| H_k(T) + d \log(|T|/d) + d \log M + \Theta(kd + d),$$

where $H_k(T)$ whereis the k-th order empirical entropy of T. □

Consider, for example, the algorithm LZ78. It parses the input T into t distinct words (ignoring the last word in the parsing) and produces an output bounded by $t \log t + t \log |\Sigma| + \Theta(t)$ bits. Using Lemma 1 and the fact that $t = O(|T|/\log T)$, one can prove that LZ78′s output is at most $|T| H_k(T) + o(|T|)$ bits. Note that the bound holds for any $k \geq 0$: this means that LZ78 is essentially "as powerful" as any compressor that encodes the next character on the basis of a finite context.

Algorithmic Issues

One of the reasons for the popularity of dictionary-based compressors is that they admit linear-time, space-efficient implementations. These implementations sometimes require non-trivial data structures: the reader is referred to [12] and references therein for further reading on this topic.

Greedy vs. Non-Greedy Parsing

Both LZ78 and LZ77 use a greedy parsing strategy in the sense that, at each step, they select the longest prefix of the unparsed portion which is in the dictionary. It is easy to see that for LZ77 the greedy strategy yields an optimal parsing; that is, a parsing with the minimum number of words. Conversely, greedy parsing is not optimal for LZ78: for any sufficiently large integer m there exists a string that can be parsed to $O(m)$ words and that the greedy strategy parses in $\Omega(m^{3/2})$ words. In [9] the authors describe an efficient algorithm for computing an optimal parsing for the LZ78 dictionary and, indeed, for any dictionary with the prefix-completeness property (a dictionary is prefix-complete if any prefix of a dictionary word is also in the dictionary). Interestingly, the algorithm in [9] is a one-step lookahead greedy algorithm: rather than choosing the longest possible prefix of the unparsed portion of the text, it chooses the prefix that results in the longest advancement in the *next* iteration.

Applications

The natural application field of dictionary-based compressors is lossless data compression (see, for example [13]). However, because of their deep mathematical properties, the Ziv–Lempel parsing rules have also found applications in other algorithmic domains.

Prefetching

Krishnan and Vitter [7] considered the problem of prefetching pages from disk into memory to anticipate users' requests. They combined LZ78 with a pre-existing prefetcher P_1 that is asymptotically at least as good as the best memoryless prefetcher, to obtain a new algorithm P that is asymptotically at least as good as the best finite-state prefetcher. LZ78′s dictionary can be viewed as a trie: parsing a string means starting at the root, descending one level for each character in the parsed string and, finally, adding a new leaf. Algorithm P runs LZ78 on the string of page requests as it receives them, and keeps a copy of the simple prefetcher P_1 for each node in the trie; at each step, P prefetches the page requested by the copy of P_1 associated with the node LZ78 is currently visiting.

String Alignment

Crochemore, Landau and Ziv-Ukelson [4] applied LZ78 to the problem of sequence alignment, i.e., finding the cheapest sequence of character insertions, deletions and substitutions that transforms one string T into another T' (the cost of an operation may depend on the character or characters involved). Assume, for simplicity, that $|T| = |T'| = n$. In 1980 Masek and Paterson proposed an $O(n^2/\log n)$-time algorithm with the restriction that the costs be rational; Crochemore et al.'s algorithm allows real-valued costs, has the same asymptotic cost

in the worst case, and is asymptotically faster for compressible texts.

The idea behind both algorithms is to break into blocks the matrix $A[1 \dots n, 1 \dots n]$ used by the obvious $O(n^2)$-time dynamic programming algorithm. Masek and Paterson break it into uniform-sized blocks, whereas Crochemore et al. break it according to the LZ78 parsing of T and T'. The rationale is that, by the nature of LZ78 parsing, whenever they come to solve a block $A[i \dots i', j \dots j']$, they can solve it in $O(i' - i + j' - j)$ time because they have already solved blocks identical to $A[i \dots i' - 1, j \dots j']$ and $A[i \dots i', j \dots j' - 1]$ [8]. Lifshits, Mozes, Weimann and Ziv-Ukelson [8] recently used a similar approach to speed up the decoding and training of hidden Markov models.

Compressed Full-Text Indexing

Given a text T, the problem of compressed full-text indexing is defined as the task of building an index for T that takes space proportional to the entropy of T and that supports the efficient retrieval of the occurrences of any pattern P in T. In [10] Navarro proposed a compressed full-text index based on the LZ78 dictionary. The basic idea is to keep two copies of the dictionary as tries: one storing the dictionary words, the other storing their reversal. The rationale behind this scheme is the following. Since any non-empty prefix of a dictionary word is also in the dictionary, if the sought pattern P occurs within a dictionary word, then P is a suffix of some word and easy to find in the second dictionary. If P overlaps two words, then some prefix of P is a suffix of the first word–and easy to find in the second dictionary–and the remainder of P is a prefix of the second word–and easy to find in the first dictionary. The case when P overlaps three or more words is a generalization of the case with two words. Recently, Arroyuelo et al. [1] improved the original data structure in [10]. For any text T, the improved index uses $(2 + \epsilon)|T|H_k(T) + o(|T| \log |\Sigma|)$ bits of space, where $H_k(T)$ is the k-th order empirical entropy of T, and reports all occ occurrences of P in T in $O(|P|^2 \log |P| + (|P| + occ) \log |T|)$ time.

Independently of [10], in [5] the LZ78 parsing was used together with the Burrows-Wheeler compression algorithm to design the first full-text index that uses $o(|T| \log |T|)$ bits of space and reports the occ occurrences of P in T in $O(|P| + occ)$ time. If $T = T_1 T_2 \cdots T_d$ is the LZ78 parsing of T, in [5] the authors consider the string $T_\$ = T_1 \$ T_2 \$ \cdots \$ T_d \$$ where \$ is a new character not belonging to Σ. The string $T_\$$ is then compressed using the Burrows-Wheeler transform. The \$'s play the role of anchor points: their positions in $T_\$$ are stored explicitly so that, to determine the position in T of any occurrence of P, it suffices to determine the position with respect to any of the \$'s. The properties of the LZ78 parsing ensure that the overhead of introducing the \$'s is small, but at the same time the way they are distributed within $T_\$$ guarantees the efficient location of the pattern occurrences.

Related to the problem of compressed full-text indexing is the compressed matching problem in which text and pattern are given together (so the former cannot be preprocessed). Here the task consists in performing string matching in a compressed text without decompressing it. For dictionary-based compressors this problem was first raised in 1994 by A. Amir, G. Benson, and M. Farach, and has received considerable attention since then. The reader is referred to [11] for a recent review of the many theoretical and practical results obtained on this topic.

Substring Compression Problems

Substring compression problems involve preprocessing T to be able to efficiently answer queries about compressing substrings: e.g., how compressible is a given substring s in T? what is s's compressed representation? or, what is the least compressible substring of a given length ℓ? These are important problems in bioinformatics because the compressibility of a DNA sequence may give hints as to its function, and because some clustering algorithms use compressibility to measure similarity. The solutions to these problems are often trivial for simple compressors, such as Huffman coding or run-length encoding, but they are open for more powerful algorithms, such as dictionary-based compressors, BWT

compressors, and PPM compressors. Recently, Cormode and Muthukrishnan [3] gave some preliminary solutions for LZ77. For any string s, let $C(s)$ denote the number of words in the LZ77-parsing of s, and let LZ77(s) denote the LZ77-compressed representation of s. In [3] the authors show that, with $O(|T|\ \text{polylog}(|T|))$ time preprocessing, for any substring s of T they can: a) compute LZ77(s) in $O(C(s)\log|T|\log\log|T|)$ time, b) compute an approximation of $C(s)$ within a factor $O(\log|T|\log^*|T|)$ in $O(1)$ time, c) find a substring of length ℓ that is close to being the least compressible in $O(|T|\ell/\log\ell)$ time. These bounds also apply to general versions of these problems, in which queries specify another substring t in T as context and ask about compressing substrings when LZ77 starts with a dictionary already containing the words in the LZ77 parsing of t.

Grammar Generation

Charikar et al. [2] considered LZ78 as an approximation algorithm for the NP-hard problem of finding the smallest context-free grammar that generates only the string T. The LZ78 parsing of T can be viewed as a context-free grammar in which for each dictionary word $T_i = T_j\alpha$ there is a production $X_i \to X_j\alpha$. For example, for $T = aabbaaabaabaabba$ the LZ78 parsing is: a, ab, b, aa, aba, $abaa$, bb, a, and the corresponding grammar is: $S \to X_1 \ldots X_7X_1, X_1 \to a, X_2 \to X_1b, X_3 \to b, X_4 \to X_1a, X_5 \to X_2a, X_6 \to X_5a, X_7 \to X_3b$. Charikar et al. showed LZ78's approximation ratio is in $O((|T|/\log|T|)^{2/3}) \cap \Omega(|T|^{2/3}\log|T|)$; i.e., the grammar it produces has size at most $f(|T|)\cdot m^*$, where $f(|T|)$ is a function in this intersection and m^* is the size of the smallest grammar. They also showed m^* is at least the number of words output by LZ77 on T, and used LZ77 as the basis of a new algorithm with approximation ratio $O(\log(|T|/m^*))$.

URL to Code

The source code of the gzip tool (based on LZ77) is available at the page http://www.gzip.org/. An LZ77-based compression library zlib is available from http://www.zlib.net/. A more recent, and more efficient, dictionary-based compressor is LZMA (Lempel–Ziv Markov chain Algorithm), whose source code is available from http://www.7-zip.org/sdk.html.

Problem Definition

Many datasets can be represented by graphs, where nodes correspond to individuals and edges capture relationships between them. On one hand, such datasets contain potentially sensitive information about individuals; on the other hand, there are significant public benefits from allowing access to *aggregate* information about the data. Thus, analysts working with such graphs are faced with two conflicting goals: protecting privacy of individuals and publishing accurate aggregate statistics. This article describes algorithms for releasing accurate graph statistics while preserving a rigorous notion of privacy, called *differential privacy*.

Differential privacy was introduced by Dwork et al. [6]. It puts a restriction on the algorithm that processes sensitive data and publishes the output. Intuitively, differential privacy requires that, for every individual, the output distribution of the algorithm is roughly the same whether or not this individual's data is present in the dataset. Next, we give a formal definition of differential privacy, specialized to datasets represented by graphs.

Two graphs are called *neighbors* if one can be obtained from the other by removing a node and its adjacent edges. Given a parameter $\epsilon > 0$, an algorithm A is *ϵ-node differentially private* if for all neighbor graphs G and G' and for all sets S of possible outputs produced by A:

$$\Pr[A(G) \subseteq S] \leq e^{\epsilon} \cdot \Pr[A(G) \subseteq S].$$

This variant of differential privacy is called *node-differential privacy* because neighbor graphs are defined with respect to node removals. Analogously, we can define *edge differential privacy* by letting graphs be neighbors if they differ in exactly one edge. Intuitively, edge differential privacy protects edges (which represent connections between people), while node-differential privacy protects nodes together with their adjacent edges (i.e., all information pertaining to individuals). Node-differential privacy is a stronger privacy definition, but it is much harder to attain because it requires the output distribution of the algorithm to hide much larger differences in the input graph.

We would like to design differentially private algorithms (preferably, node-differentially private) that compute accurate graph statistics on a large family of realistic graphs. Typically, graphs that contain sensitive information, such as friendships, sexual relationships, and communication patterns, are sparse. Some examples of graph statistics we would like to compute

on these graphs are the number of edges, small subgraph counts, and the degree distribution.

Most work on the topic considers an analyst who wants to evaluate a real-valued function f on the private input graph G (e.g., the number of triangles or the number of connected components in G). The goal is to release as good an approximation as possible to the true value $f(G)$. Differentially private algorithms must be randomized, so we try to minimize the expectation of the random variable $\text{error}_A(G) = |A(G) - f(G)|$. We will also discuss work on algorithms that release higher-dimensional summaries (i.e., output a real vector).

Bibliographical Notes

Edge privacy was first studied by Nissim et al. [16], and the distinction between node and edge privacy was laid out by Hay et al. [9]. Edge differentially private algorithms for a variety of tasks have been widely investigated. Examples include subgraph counts, degree distributions, and parameters of generative statistical models. Gehrke et al. [7] investigated a notion whose strength lies between edge and node privacy: node privacy for bounded-degree graphs. (The focus of their work is a generalization of differential privacy, called *zero-knowledge privacy*.)

Until recently, no node-differentially private algorithms (where privacy guarantees hold with respect to all graphs) were known that compute accurate graph statistics on realistic (namely, sparse) graphs. The first such algorithms were designed independently by Blocki et al. [3], Kasiviswanathan et al. [11], and Chen and Zhou [5]. Those algorithms look at releasing one real-valued statistic at a time. Two more recent works focus on higher-dimensional node-private releases: Raskhodnikova and Smith [17] and Borgs et al. [4].

This encyclopedia entry focuses on node-differentially private algorithms, since these offer the strongest privacy guarantees. Progress, however, continues on edge-private algorithms; see Lin and Kifer [13], Karwa and Slavkovic [10], Lu and Miklau [14], and Zhang et al. [18] for recent results.

Key Results

The main difficulty in the design of node-private algorithms is that techniques based on *local sensitivity* of a function (which are the basis of the best edge-private algorithms) yield node-private algorithms whose error on "typical" inputs swamps the statistic that one wants to release. The local sensitivity of a function f is a discrete analogue of the derivative of f – it measures how much the value of f can change when the input graph is replaced with its neighbor. On sparse graphs, the local sensitivity can be larger than the value of the function. Any method whose error is proportional to the local sensitivity will have large relative error.

Focus on a "Preferred Subset"

To get around the challenge of high local sensitivity, two works [3, 11] independently designed algorithms that are given a set S of "nice" graphs that hopefully contains G (e.g., graphs with an upper bound on the maximum degree). These algorithms are private on *all* graphs and return an accurate answer *on graphs in* S. What makes this approach work is that S is selected so that the sensitivity of f is small when restricted to inputs in S.

Let $\mathbb{G}$ denote the set of all labeled, undirected graphs. We will call $S \subseteq \mathbb{G}$ the "preferred" subset. Define the *Lipschitz constant* (also called the *restricted sensitivity*) of f on S to be

$$\Delta_f(S) = \sup_{G,G' \in S} \frac{\|f(G') - f(G)\|_1}{d_{\text{node}}(G, G')},$$

where d_{node} is the node distance between two graphs – the number of vertex insertions and deletions needed to go from G to G'. Blocki et al. [3] and Kasiviswanathan et al. [11] give methods for adding noise proportional to the Lipschitz constant of f on S.

Theorem 1 ([3, 11]) *For every $S \subseteq \mathbb{G}$, function $f : S \to \mathbb{R}$, and $\epsilon > 0$, there exists an algorithm A_S that is ϵ-differentially private (for all inputs) and such that, for all $G \in S$,*

$$\mathbb{E}|A_S(G) - f(G)| = O(\Delta_S(f)/\epsilon^2).$$

Moreover, for $S = \mathbb{G}_{\mathbb{D}}$ (the set of D-bounded graphs), the running time of A is the running time for one evaluation of f plus a fixed polynomial in the size of G.

The same works [3, 11] also give generic reductions showing that given any algorithm that is ϵ-differentially private when restricted to graphs in S, one can design an algorithm A that has similar behavior on graphs in S but is ϵ'-differentially private for *all* inputs, for ϵ' not too much larger than ϵ.

"Down" Sensitivity

Rather than focusing on a single "nice" subset, some works [5, 17] sought to add noise proportional to a quantity related to, but usually much smaller than, the local sensitivity.

Define the *down sensitivity* (called *empirical global sensitivity* when first defined by Chen and Zhou [5]) of f at a graph G to be the Lipschitz constant of f *when restricted to the set of induced subgraphs of G*. Specifically, we write $G \preceq H$ to denote that G is an induced subgraph of H (i.e., G can be obtained by deleting a set of vertices from H) and define the down sensitivity to be

$$DS_f(G) = \max_{H, H' \text{neighbors}, H \preceq H' \preceq G} |f(G') - f(G)|.$$

By carefully (and privately) selecting the "preferred" subset based on the input, one can add noise essentially proportional to the down sensitivity.

Theorem 2 ([17]) *For every monotone function $f : \mathbb{G} \to \mathbb{R}$ and $\epsilon > 0$, there is an algorithm A_f that is ϵ-differentially private and such that, for all $G \in \mathbb{G}$,*

$$\mathbb{E}|A_f(G) - f(G)| = \frac{DS_f(G) + 1}{\epsilon} \cdot O(\log\log \max_{G'} DS_f(G')).$$

Moreover, A_f can be made efficient when f is a generalized linear query (a class that includes counting occurrences of a fixed subgraph).

The down sensitivity is low for many commonly studied statistics in graphs that satisfy α-*decay*, a condition on the degree distribution that is satisfied by known generative models (including those that generate "scale-free"). (See [11] for a definition of α-decay.)

Lipschitz Extensions and Higher-Dimensional Releases

The main technical tool in the down-sensitivity-based results [5, 17] is the construction of *efficient* (i.e., polynomial time computable) *Lipschitz extensions* of the function f from subsets S of graphs to the space of all graphs. Kasiviswanathan et al. [11] and Chen and Zhou [5] give efficient Lipschitz extensions of several useful functions (including graph counts) that return a single real value. Raskhodnikova and Smith [17] give efficient Lipschitz extensions of higher-dimensional functions, namely, the degree distribution and adjacency matrix of a graph.

Borgs et al. [4] use the Lipschitz extension technique together with the *exponential mechanism* to provide the first node-differentially private algorithms for fitting high-dimensional statistical models to a given graph (specifically, they consider *stochastic block models* and generalizations thereof).

Applications

The algorithms discussed above address a real problem: datasets containing sensitive information about relationships among a collection of individuals are often valuable sources of information, but publishing useful summaries about such data without leaking individual information is difficult. Even when the graphs are "anonymized" by removing all obviously identifying information, such as names, addresses, birthdays, and zip codes, they present a privacy risk. For example, [1, 15] give de-anonymization attacks based only on unlabeled links. Node-differentially private

algorithms offer a principled method for releasing information about a network while providing rigorous privacy guarantees (though some authors argue that even stronger notions may be needed [7, 12]).

Open Problems

Gupta et al. [8] and Blocki et al. [2] give edge differentially private algorithms for releasing a data structure that approximates the sizes of all cuts in the input graph in the following sense: for any cut, with high probability, the estimated cut size is accurate (the first reference gives weaker approximation guarantees with a stronger quantifier order: with high probability, all cut sizes are accurate). It is open whether a node-differentially private algorithm can obtain similar results.

For datasets that do not contain information about relationships, but only contain personal attributes that come from a relatively small set, differentially private algorithms can output a large number of statistics at once (see ▸ Query Release via Online Learning and ▸ Geometric Approaches to Answering Queries cross-referenced below). It is open how to do achieve similar results for graph statistics, even with edge differential privacy.

Finally, all algorithms we discussed release numerical graph statistics. The subject of differentially private synthetic graphs is largely unexplored. See [10, 13] for initial results.

Problem Definition

Notations

Let $G = (V, E)$ be a plane geometric network, whose vertex set V is a finite set of point sites in $\mathbb{R}^2$, connected by an edge set E of non-crossing straight line segments with endpoints in V. For two points $p \neq q \in V$, let $\xi_G(p, q)$ denote a shortest path from p to q in G. Then

$$\sigma(p, q) := \frac{|\xi_G(p, q)|}{|pq|} \qquad (1)$$

is the detour one encounters when using network G, in order to get from p to q, instead of walking straight. Here, $|\ .\ |$ denotes the Euclidean length.

The *dilation* of G is defined by

$$\sigma(G) := \max_{p \neq q \in V} \sigma(p, q). \qquad (2)$$

This value is also known as the spanning ratio or the stretch factor of G. It should, however, not be confused with the geometric dilation of a network, where the points on the edges are also being considered, in addition to the vertices.

Given a finite set S of points in the plane, one would like to find a plane geometric network $G = (V, E)$ whose dilation $\sigma(G)$ is as small as possible, such that S is contained in V. The value of

$$\Sigma(S) := \inf\{\sigma(G); G = (V, E) \text{ finite plane geometric network where } S \subset V\}$$

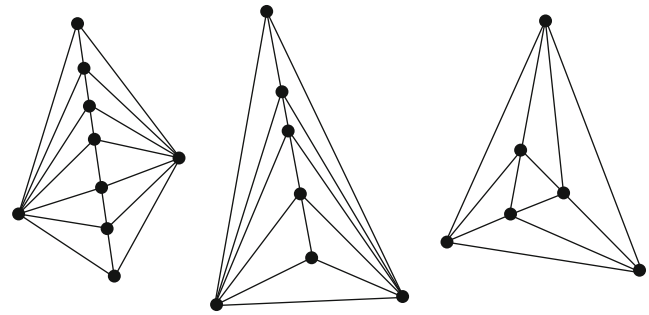
is called the *dilation of point set S*. The problem is in computing, or bounding, $\Sigma(S)$ for a given set S.

Related Work

If edge crossings were allowed, one could use spanners whose stretch can be made arbitrarily close to 1; see the monographs by Eppstein [6] or Narasimhan and Smid [12]. Different types of triangulations of S are known to have their stretch factors bounded from above by small constants, among them the Delaunay triangulation of stretch ≤ 2.42; see Dobkin et al. [3], Keil and Gutwin [10], and Das and Joseph [2]. Eppstein [5] has characterized all triangulations T of dilation $\sigma(T) = 1$; these triangulations are shown in Fig. 1. Trivially, $\Sigma(S) = 1$ holds for each point set S contained in the vertex set of such a triangulation T.

Key Results

The previous remark's converse also turns out to be true.



Dilation of Geometric Networks, Fig. 1 The triangulations of dilation 1

Theorem 1 ([11]) *If S is not contained in one of the vertex sets depicted in Fig. 1, then $\Sigma(S) > 1$.*

That is, if a point set S is not one of these special sets, then each plane network including S in its vertex set has a dilation larger than some lower bound $1 + \eta(S)$. The proof of Theorem 1 uses the following density result. Suppose one connects each pair of points of S with a straight line segment. Let S' be the union of S and the resulting crossing points. Now the same construction is applied to S' and repeated. For the limit point set S^{∞}, the following theorem holds. It generalizes work by Hillar and Rhea [8] and by Ismailescu and Radoičić [9] on the intersections of lines.

Theorem 2 ([11]) *If S is not contained in one of the vertex sets depicted in Fig. 1, then S^{∞} lies dense in some polygonal part of the plane.*

For certain infinite structures can concrete lower bounds be proven.

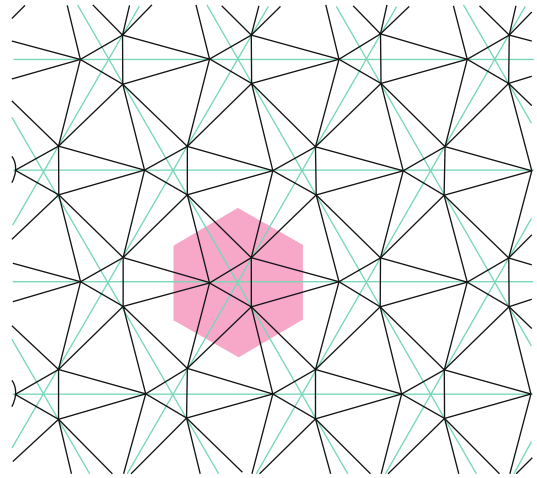
Theorem 3 ([4]) *Let N be an infinite plane network all of whose faces have a diameter bounded from above by some constant. Then $\sigma(N) > 1.00156$ holds.*

Theorem 4 ([4]) *Let C denote the (infinite) set of all points on a closed convex curve. Then $\Sigma(C) > 1.00157$ holds.*

Theorem 5 ([4]) *Given n families $F_i, 2 \leq i \leq n$, each consisting of infinitely many equidistant parallel lines. Suppose that these families are in general position.*

Then their intersection graph G is of dilation at least $2/\sqrt{3}$.

The proof of Theorem 5 makes use of Kronecker's theorem on simultaneous approximation. The bound is attained by the packing of equiangular triangles.



Dilation of Geometric Networks, Fig. 2 A network of dilation ∼1.1247

Finally, there is a general upper bound to the dilation of finite point sets.

Theorem 6 ([4]) *Each finite point set S is of dilation $\Sigma(S) < 1.1247$.*

To prove this upper bound, one can embed any given finite point set S in the vertex set of a scaled, and slightly deformed, finite part of the network depicted in Fig. 2. It results from a packing of equilateral triangles by replacing each vertex with a small triangle and by connecting neighboring triangles as indicated.

Applications

A typical university campus contains facilities like lecture halls, dorms, library, mensa, and

supermarkets, which are connected by some path system. Students in a hurry are tempted to walk straight across the lawn, if the shortcut seems worth it. After a while, this causes new paths to appear. Since their intersections are frequented by many people, they attract coffee shops or other new facilities. Now, people will walk across the lawn to get quickly to a coffee shop, and so on.

D. Eppstein [5] has asked what happens to the lawn if this process continues. The above results show that (1) part of the lawn will be completely destroyed, and (2) the temptation to walk across the lawn cannot, in general, be made arbitrarily small by a clever path design.

Open Problems

For practical applications, upper bounds to the weight (= total edge length) of a geometric network would be valuable, in addition to upper dilation bounds. Some theoretical questions require further investigation, too. Is $\Sigma(S)$ always attained by a finite network? How to compute, or approximate, $\Sigma(S)$ for a given finite set S? Even for a set as simple as S_5, the corners of a regular 5-gon, is the dilation unknown. The smallest dilation value known, for a triangulation containing S_5 among its vertices, equals 1.0204; see Fig. 3. Finally, what is the precise value of $\sup\{\Sigma(S); S \text{finite}\}$?

Direct Routing Algorithms

Costas Busch
Department of Computer Science, Lousiana State University, Baton Rouge, LA, USA

Keywords

Bufferless packet switching; Collision-free packet scheduling; Hot-potato routing

Years and Authors of Summarized Original Work

2006; Busch, Magdon-Ismail, Mavronicolas, Spirakis

Problem Definition

The performance of a communication network is affected by the *packet collisions* which occur when two or more packets appear simultaneously in the same network node (router) and all these packets wish to follow the same outgoing link from the node. Since network links have limited available bandwidth, the collided packets wait on buffers until the collisions are resolved. Collisions cause delays in the packet delivery time and also contribute to the network performance degradation.

Direct routing is a packet delivery method which avoids packet collisions in the network. In direct routing, after a packet is injected into the network it follows a path to its destination without colliding with other packets, and thus without delays due to buffering, until the packet is absorbed at its destination node. The only delay that a packet experiences is at the source node while it waits to be injected into the network.

In order to formulate the direct routing problem, the network is modeled as a graph where all the network nodes are synchronized with a common time clock. Network links are bidirectional, and at each time step any link can be crossed by at most two packets, one packet in each direction. Given a set of packets, the *routing time* is defined to be the time duration between the first packet injection and the last packet absorbtion.

Consider a set of N packets, where each packet has its own source and destination node. In the *direct routing problem*, the goal is first to find a set of paths for the packets in the network, and second, to find appropriate injection times for the packets, so that if the packets are injected at the prescribed times and follow their paths they will be delivered to their destinations without collisions. The *direct scheduling problem* is a variation of the above problem, where the paths for the packets are given a priori, and the only task is to compute the injection times for the packets.

A *direct routing algorithm* solves the direct routing problem (similarly, a *direct scheduling algorithm* solves the direct scheduling problem). The objective of any direct algorithm is to minimize the routing time for the packets. Typically, direct algorithms are *offline*, that is, the paths and the injection schedule are computed ahead of time, before the packets are injected into the network, since the involved computation requires knowledge about all packets in order to guarantee the absence of collisions between them.

Key Results

Busch, Magdon-Ismail, Mavronicolas, and Spirakis, present in [6] a comprehensive study of direct algorithms. They study several aspects of direct routing such as the computational complexity of direct problems and also the design of efficient direct algorithms. The main results of their work are described below.

Hardness of Direct Routing

It is shown in [Sect. 4 in 6] that the optimal direct scheduling problem, where the paths are given and the objective is to compute an optimal injection schedule (that minimizes the routing time) is an NP-complete problem. This result is obtained with a reduction from vertex coloring, where vertex coloring problems are transformed to appropriate direct scheduling problems in a 2-dimensional grid. In addition, it is shown in [6] that approximations to the direct scheduling problem are as hard to obtain as approximations to vertex coloring. A natural question is what kinds of approximations can be obtained in polynomial time. This question is explored in [6] for general and specific kinds of graphs, as described below.

Direct Routing in General Graphs

A direct algorithm is given in [Section 3 in 6] that solves approximately the optimal direct scheduling problem in general network

topologies. Suppose that a set of packets and respective paths are given. The injection schedule is computed in polynomial time with respect to the size of the graph and the number of packets. The routing time is measured with respect to the *congestion* C of the packet paths (the maximum number of paths that use an edge), and the *dilation* D (the maximum length of any path).

The result in [6] establishes the existence of a simple greedy direct scheduling algorithm with routing time $rt = O(C \cdot D)$. In this algorithm, the packets are processed in an arbitrary order and each packet is assigned the smallest available injection time. The resulting routing time is worst-case optimal, since there exist instances of direct scheduling problems for which no direct scheduling algorithm can achieve a better routing time. A trivial lower bound on the routing time of any direct scheduling problem is $\Omega(C + D)$, since no algorithm can deliver the packets faster than the congestion or dilation of the paths. Thus, in the general case, the algorithm in [6] has routing time $rt = O((rt^*)^2)$, where rt^* is the optimal routing time.

Direct Routing in Specific Graphs

Several direct algorithms are presented in [6] for specialized network topologies. The algorithms solve the direct routing problem where first good paths are constructed and then an efficient injection schedule is computed. Given a set of packets, let C^* and D^* denote the optimal congestion and dilation, respectively, for all possible sets of paths for the packets. Clearly, the optimal routing time is $rt^* = \Omega(C^* + D^*)$. The upper bounds in the direct algorithm in [6] are expressed in terms of this lower bound. All the algorithms run in time polynomial to the size of the input.

Tree

The graph G is an arbitrary tree. A direct routing algorithm is given in [Section 3.1 in 6], where each packet follows the shortest path from its source to the destination. The injection schedule is obtained using the greedy algorithm with a particular ordering of the packets. The routing time of the algorithm is asymptotically optimal: $rt \leq 2C^* + D^* - 2 < 3 \cdot rt^*$.

Mesh

The graph G is a d-dimensional mesh (grid) with n nodes [10]. A direct routing algorithm is proposed in [Section 3.2 in 6], which first constructs efficient paths for the packets with congestion $C = O(d \log n \cdot C^*)$ and dilation $D = O(d^2 \cdot D^*)$ (the congestion is guaranteed with high probability). Then, using these paths the injection schedule is computed giving a direct algorithm with the routing time:

$$\begin{aligned} rt &= O(d^2 \log^2 n \cdot C^* + d^2 \cdot D^*) \\ &= O(d^2 \log^2 n \cdot rt^*). \end{aligned}$$

This result follows from a more general result which is shown in [6], that says that if the paths contain at most b "bends", i.e., at most b dimension changes, then there is a direct scheduling algorithm with routing time $O(b \cdot C + D)$. The result follows because the constructed paths have $b = O(d \log n)$ bends.

Butterfly

The graph G is a butterfly network with n input and n output nodes [10]. In [Section 3.3 in 6] the authors examine permutation routing problems in the butterfly, where each input (output) node is the source (destination) of exactly one packet. An efficient direct routing algorithm is presented in [6] which first computes good paths for the packets using Valiant's method [14, 15]: two butterflies are connected back to back, and each path is formed by choosing a random intermediate node in the output of the first butterfly. The chosen paths have congestion $C = O(\lg n)$ (with high probability) and dilation $D = 2 \lg n = O(D^*)$. Given the paths, there is a direct schedule with routing time very close to optimal: $rt \leq 5 \lg n = O(rt^*)$.

Hypercube

The graph G is a hypercube with n nodes [10]. A direct routing algorithm is given in [Section 3.4 in 6] for permutation routing problems. The algorithm first computes good paths for the packets by selecting a single random intermediate node for each packet. Then an appropriate injection

schedule gives routing time $rt < 14 \lg n$, which is worst-case optimal since there exist permutations for which $D^* = \Omega(\lg n)$.

Lower Bound for Buffering

In [Section 5 in 6] an additional problem has been studied about the amount of buffering required to provide small routing times. It is shown in [6] that there is a direct scheduling problem for which every direct algorithm requires routing time $\Omega(C \cdot D)$; at the same time, $C + D = \Theta(\sqrt{C \cdot D}) = o(C \cdot D)$. If buffering of packets is allowed, then it is well known that there exist packet scheduling algorithms [11, 12] with routing time very close to the optimal $O(C + D)$. In [6] it is shown that for the particular packet problem, in order to convert a direct injection schedule of routing time $O(C \cdot D)$ to a packet schedule with routing time $O(C + D)$, it is necessary to buffer packets in the network nodes in total $\Omega(N^{4/3})$ times, where a packet buffering corresponds to keeping a packet in an intermediate node buffer for a time step, and N is the number of packets.

Related Work

The only previous work which specifically addresses direct routing is for permutation problems on trees [3, 13]. In these papers, the resulting routing time is $O(n)$ for any tree with n nodes. This is worst-case optimal, while the result in [6] is asymptotically optimal for all routing problems in trees.

Cypher et al. [7] study an online version of direct routing in which a worm (packet of length L) can be re-transmitted if it is dropped (they also allow the links to have bandwidth $B \geq 1$). Adler et al. [1] study time constrained direct routing, where the task is to schedule as many packets as possible within a given time frame.They show that the time constrained version of the problem is NP-complete, and also study approximation algorithms on trees and meshes. Further, they discuss how much buffering could help in this setting.

Other models of bufferless routing are *matching routing* [2] where packets move to their destinations by swapping packets in adjacent nodes, and *hot-potato routing* [4, 5, 8, 9] in which packets follow links that bring them closer to the destination, and if they cannot move closer (due to collisions) they are deflected toward alternative directions.

Applications

Direct routing represent collision-free communication protocols, in which packets spend the smallest amount of time possible time in the network once they are injected. This type of routing is appealing in power or resource constrained environments, such as optical networks, where packet buffering is expensive, or sensor networks where energy resources are limited. Direct routing is also important for providing quality of service in networks. There exist applications where it is desirable to provide guarantees on the delivery time of the packets after they are injected into the network, for example in streaming audio and video. Direct routing is suitable for such applications.

Problem Definition

Let $S = \{s_1, s_2, \ldots, s_n\}$ be a set of elements called *objects* and let $C = \{c_1, c_2, \ldots, c_m\}$ be a set of functions from S to $\{0, 1\}$ called *characters*. For each object $s_i \in S$ and character $c_j \in C$, we say that s_i *has* c_j if $c_j(s_i) = 1$ or that s_i *does not have* c_j if $c_j(s_i) = 0$, respectively (in this sense, characters are *binary*). Then the set S and its relation to C can be naturally represented by a matrix M of size $(n \times m)$ satisfying $M[i, j] = c_j(s_i)$ for every $i \in \{1, 2, \ldots, n\}$ and $j \in \{1, 2, \ldots, m\}$. Such a matrix M is called a *binary character state matrix*.

Next, for each $s_i \in S$, define the set $C_{s_i} = \{c_j \in C : s_i \text{ has } c_j\}$. A *phylogeny for* S is a tree whose leaves are bijectively labeled by S, and a *directed perfect phylogeny for* (S, C) (if one exists) is a rooted phylogeny T for S in which each $c_j \in C$ is associated with exactly one edge of T in such a way that for any $s_i \in S$, the set of all characters associated with the edges on the path in T from the root to leaf s_i is equal to C_{s_i}. See Figs. 1 and 2 for two examples.

Now, define the following problem.

Problem 1 (The Directed Perfect Phylogeny Problem for Binary Characters)

INPUT: An $(n \times m)$-binary character state matrix M for some S and C.

OUTPUT: A directed perfect phylogeny for (S, C), if one exists; otherwise, *null*.

Key Results

In the presentation below, define a set S_{c_j} for each $c_j \in C$ by $S_{c_j} = \{s_i \in S : s_i \text{ has } c_j\}$. The next lemma is the key to solving the Directed

Directed Perfect Phylogeny (Binary Characters), Fig. 2 This binary character state matrix admits no directed perfect phylogeny

Perfect Phylogeny Problem for Binary Characters efficiently. It is also known in the literature as *the pairwise compatibility theorem* [5].

Lemma 1 *There exists a directed perfect phylogeny for (S, C) if and only if for each pair $c_j, c_k \in C$, it holds that $S_{c_j} \cap S_{c_k} = \emptyset$, $S_{c_j} \subseteq S_{c_k}$, or $S_{c_k} \subseteq S_{c_j}$.*

Short constructive proofs of the lemma can be found in, e.g., [8] and [14]. An algebraic proof of a slightly more general version of the lemma was given earlier by Estabrook, Johnson, and McMorris [3,4].

Using Lemma 1, it is trivial to construct a top-down algorithm for the problem that runs in $O(nm^2)$ time. As one might expect, a faster algorithm is possible. Gusfield [7] observed that after sorting the columns of M in nonincreasing lexicographic order, all duplicate copies of a column appear in a consecutive block of columns and column j is to the right of column k if S_{c_j} is a proper subset of S_{c_k}, and then exploited these two facts together with Lemma 1 to obtain the following result:

Theorem 1 ([7]) *The Directed Perfect Phylogeny Problem for Binary Characters can be solved in $O(nm)$ time.*

For a description of the original algorithm and a proof of its correctness, see [7] or [14]. A conceptually simplified version of the algorithm based on keyword trees can be found in Chapter 17.3.4 in [8]. Gusfield [7] also gave an adversary argument to prove a corresponding lower bound of $\Omega(nm)$ on the running time, showing that his algorithm is time optimal:

Theorem 2 ([7]) *Any algorithm that decides if a given binary character state matrix M admits a directed perfect phylogeny must, in the worst case, examine all entries of M.*

Agarwala, Fernández-Baca, and Slutzki [1] noted that the input binary character state matrix is often sparse, i.e., in general, most of the objects will not have most of the characters. In addition, they noted that for the sparse case, it is more efficient to represent the input (S, C) by all the sets S_{c_j} for $j \in \{1, 2, \ldots, m\}$, where each set S_{c_j} is defined as above and each S_{c_j} is specified as a linked list, than by using a binary character state matrix. Agarwala et al. [1] proved that with this alternative representation of S and C, the algorithm of Gusfield can be modified to run in time proportional to the total number of 1s in the corresponding binary character state matrix:

Theorem 3 ([1]) *The variant of the Directed Perfect Phylogeny Problem for Binary*

Characters in which the input is given as linked lists representing all the sets S_{c_j} for $j \in \{1, 2, \ldots, m\}$ can be solved in $O(h)$ time, where $h = \sum_{j=1}^{m} |S_{c_j}|$.

For a description of the algorithm, refer to [1] or [6]. Observe that Theorem 3 does not contradict Theorem 2; in fact, Gusfield's lower bound argument for proving Theorem 2 considers an input matrix consisting mostly of 1s.

When only a portion of an $(n \times m)$-binary character state matrix is available, an $\tilde{O}(nm)$-time algorithm by Pe'er et al. [13] can fill in the missing entries with 0s and 1s so that the resulting matrix admits a directed perfect phylogeny, if possible. A ZDD-based algorithm for enumerating all such solutions was recently developed by Kiyomi et al. [11].

Theorem 4 ([13]) *The variant of the Directed Perfect Phylogeny Problem for Binary Characters in which the input consists of an incomplete binary character state matrix can be solved in $\tilde{O}(nm)$ time.*

Applications

Directed perfect phylogenies for binary characters are used to describe the evolutionary history for a set of objects (e.g., biological species) that share some observable traits and that have evolved from a "blank" ancestral object which has none of the traits. Intuitively, the root of a directed perfect phylogeny corresponds to the blank ancestral object, and each directed edge $e = (u, v)$ corresponds to an evolutionary event in which the hypothesized ancestor represented by u gains the characters associated with e, transforming it into the hypothesized ancestor or object represented by v. For simplicity, it may be assumed that each character can emerge once only during the evolutionary history and is never lost after it has been gained, so that a leaf s_i is a descendant of the edge associated with a character c_j if and only if s_i has c_j. When this requirement is too strict, one can relax it to permit errors, for example, by letting each character be associated with more than one edge in the phylogeny (i.e., allow each character to emerge many times) while minimizing the total number of such associations (*Camin-Sokal optimization*) or by keeping the requirement that each character emerges only once but allowing it to be lost multiple times (*Dollo parsimony*) [5, 6]. Such relaxations generally increase the computational complexity of the underlying computational problems; see, e.g., [2] and [15].

Binary characters are commonly used by biologists and linguists. Traditionally, morphological traits or directly observable features of species were employed by biologists as binary characters, and recently, binary characters based on genomic information such as substrings in DNA or protein sequences, SNP markers, protein regulation data, and shared gaps in a given multiple alignment have become more and more prevalent. Chapter 17.3.2 in [8] mentions several examples where phylogenetic trees have been successfully constructed based on such types of binary character data. In the context of reconstructing the evolutionary history of natural languages, linguists often use phonological and morphological characters with just two states [10].

The Directed Perfect Phylogeny Problem for Binary Characters is closely related to *the Perfect Phylogeny Problem*, a fundamental problem in computational evolutionary biology and phylogenetic reconstruction [5, 6, 14]. This problem (also described in more detail in Encyclopedia entry ▸ Perfect Phylogeny (Bounded Number of States)) introduces nonbinary characters so that each character $c_j \in C$ has a set of allowed states $\{0, 1, \ldots, r_j - 1\}$ for some integer r_j, and for each $s_i \in S$, character c_j is in one of its allowed states. Generalizing the notation used above, define the set $S_{c_j,\alpha}$ for every $\alpha \in \{0, 1, \ldots, r_j - 1\}$ by $S_{c_j,\alpha} = \{s_i \in S : \text{the state of } s_i \text{ on } c_j \text{ is } \alpha\}$. Then, the objective of *the Perfect Phylogeny Problem* is to construct (if possible) an *unrooted* phylogeny T for S such that the following holds: for each $c_j \in C$ and distinct states α, β of c_j, the minimal subtree of T that connects $S_{c_j,\alpha}$ and the minimal subtree of T that connects $S_{c_j,\beta}$ are vertex-disjoint. McMorris [12] showed that the special case with $r_j = 2$ for all $c_j \in C$ can be reduced to the

Directed Perfect Phylogeny Problem for Binary Characters in $O(nm)$ time: for each $c_j \in C$, if the number of 1s in column j of M is greater than the number of 0s, then set entry $M[i, j]$ to $1 - M[i, j]$ for all $i \in \{1, 2, \ldots, n\}$. Therefore, another application of Gusfield's algorithm [7] is as a subroutine for solving the Perfect Phylogeny Problem in $O(nm)$ time when $r_j = 2$ for all $c_j \in C$. Even more generally, the Perfect Phylogeny Problem for directed as well as undirected *cladistic* characters can be solved in polynomial time by a similar reduction to the Directed Perfect Phylogeny Problem for Binary Characters (see [6]).

In addition to the above, it is possible to apply Gusfield's algorithm to determine whether two given trees describe compatible evolutionary history, and if so, merge them into a single tree so that no branching information is lost (see [7] for details). Finally, Gusfield's algorithm has also been used by Hanisch, Zimmer, and Lengauer [9] to implement a particular operation on documents defined in their Protein Markup Language (ProML) specification.

Problem Definition

The problem is concerned about computing virtual coordinates for greedy routing in a wireless ad hoc network. Consider a set of wireless nodes S densely deployed inside a geometric domain $\mathcal{R} \subseteq \mathbb{R}^2$. Nodes within communication range can directly communicate with each other. We ask whether one can compute a set of virtual coordinates for S such that greedy routing has guaranteed delivery. In particular, each node forwards the message to the neighbor whose distance to the destination, computed under the virtual coordinates and some metric function d, is the smallest. If such a neighbor can always be found, greedy routing successfully delivers the message to the destination. The problem can be phrased as finding a *greedy embedding* of S in some geometric space, such that greedy routing always succeeds.

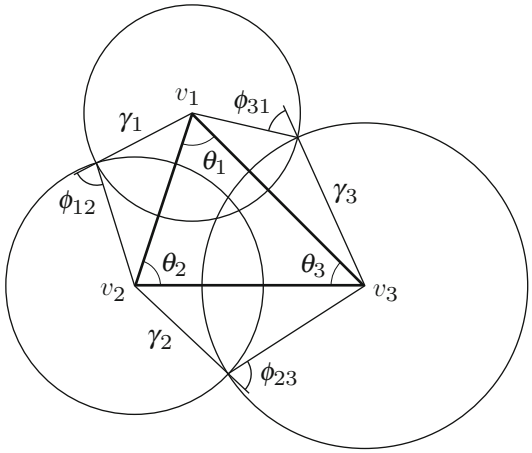
In the setting of this entry, we assume that the nodes are a dense sample of the domain $\mathcal{R}$ such that the communication graph on S contains a triangulated mesh Σ as a discrete approximation of $\mathcal{R}$.

Key Results

The key result is a family of distributed algorithms for computing the greedy embedding using discrete Ricci flow. Given a triangular mesh Σ with vertex set V, edge set E, and face set F, we can define a piecewise linear metric by the edge lengths on Σ: $l : E \to \mathbb{R}^+$ that satisfies the triangle inequality for each triangle face. The piecewise linear metric determines the corner angles of the triangles on Σ, by the cosine law. The *discrete curvature* K_i at a vertex v_i is defined as the angle deficit on the mesh. If v_i is an interior vertex, $K_i = 2\pi - \sum_j \theta_j$, where θ_j's are the corner angles at v_i. If v_i is a vertex on the boundary, $K_i = \pi - \sum_j \theta_j$, where θ_j's are the corner angles at v_i. Thus, the curvature at an interior vertex v_i is 0 if the surface is flat at v_i. The curvature at a boundary vertex v_i is 0 if the boundary is locally a straight line at v_i (see Fig. 1). The famous Gauss-Bonnet theorem states that the total curvature is a topological invariant: $\sum_{v_i \in V} K_i = 2\pi\chi(\Sigma)$, where $\chi(\Sigma)$ is the Euler characteristic number (The Euler characteristics number of a surface is $2 - 2g - h$, where g is the genus or the number of handles and h is the number of holes.) of Σ. Ricci flow is a process that deforms the surface metric to meet any target curvature that is admissible by the Gauss-Bonnet theorem.

A conformal map in the continuous surface preserves the intersection angle of any two curves. In the discrete case, the "intersection angle" is defined using the circle packing metric [10, 11]. We place a circle at each vertex v_i with radius γ_i such that for each edge e_{ij}, the circles at v_i, v_j intersect or are tangent to each other. The intersection angle is denoted by $\phi(e_{ij})$. The pair of vertex radii and the intersection angles on a mesh Σ, (Γ, Φ), are called a *circle packing metric* of Σ (see Fig. 1). Two circle packing metrics (Γ_1, Φ_1) and (Γ_2, Φ_2) on the same mesh are *conformal equivalent*, if $\Phi_1 \equiv \Phi_2$. Therefore, a conformal deformation of a circle packing metric only modifies the vertex radii γ_i's and preserves the intersection angles. Note that the circle packing metric and the edge lengths (the piecewise linear metric) on one mesh can be converted to each other by using the cosine law.

Now we are ready to introduce the discrete Ricci flow algorithm. Let u_i be $\log \gamma_i$ for each vertex. Then the discrete Ricci flow, introduced in the work of [2], is defined as follows: $\frac{du_i(t)}{dt} = \bar{K}_i - K_i$, where $K_i, \bar{K}_i$ are the current and target curvature at vertex v_i, respectively. Discrete Ricci



Discrete Ricci Flow for Geometric Routing, Fig. 1 The circle packing metric

flow can be formulated in the variational setting, namely, it is a negative gradient flow of some special energy form: $f(\mathbf{u}) = \int_{\mathbf{u_0}}^{\mathbf{u}} \sum_{i=1}^{n} (\bar{K}_i - K_i) d u_i$, where $\mathbf{u_0}$ is an arbitrary initial metric and $\bar{K}$ is the prescribed target curvature. The integration above is well defined and called the *Ricci energy*. The discrete Ricci flow is the negative gradient flow of the discrete Ricci energy. The discrete metric which induces $\bar{K}$ is the minimizer of the energy. Computing the desired circle packing metric with prescribed curvature $\bar{K}$ is equivalent to minimizing the discrete Ricci energy. The discrete Ricci energy is strictly convex (namely, its Hessian is positive definite after a normalization). The global minimum uniquely exists, corresponding to the metric $\bar{\mathbf{u}}$, which induces $\bar{K}$. The discrete Ricci flow converges to this global minimum and the convergence is exponentially fast [2], i.e., $|\bar{K}_i - K_i(t)| < c_1 e^{-c_2 t}$, where c_1, c_2 are two positive constants. This represents a centralized algorithm for computing the discrete Ricci flow on Σ. In the following, we describe the distributed algorithm for different types of greedy routing scenarios.

Discrete Ricci Flow Algorithm

To apply discrete Ricci flow for greedy routing, we take a triangular mesh Σ as a subgraph from the communication graph. All non-triangular faces are considered as network holes that will be mapped to circular holes in the embedding. All nodes not on hole boundaries have zero curvature under the mapping. Thus, the embedding is denoted as a circular domain. With the virtual coordinates and Euclidean distance metric, greedy routing guarantees delivery. (For a node in the interior of the triangulation, if the corner angle is greater than $2\pi/3$, we will adopt greedy routing on an edge that has provably guaranteed delivery.)

In particular, we set all edge lengths to be initially 1, which determines the initial curvature at each node. In particular, we choose the circle packing metric by placing a circle of initial radius $1/2$ on each node. The circles at adjacent nodes are tangent to each other. Thus, the intersection angle is kept at 0. We now set the target curvature at interior nodes to be zero and at hole boundary nodes to be $2\pi/k$ with k as the number of nodes on the hole boundary. The algorithms run in a gossip style. In each round, each node exchanges its radius with neighbors and computes its own Gaussian curvature. The algorithm stops when the current curvature is within error ϵ from the specified target curvature.

At each gossip round, node v_i is associated with a disk with radius e^{u_i}, where u_i is a scalar value. The length of the edge connecting v_i and v_j equals to $e^{u_i} + e^{u_j}$. The corner angles of each triangle can be estimated using cosine law by each node locally. That is, the angle θ_i^{jk} in triangle $[v_i, v_j, v_k]$ is

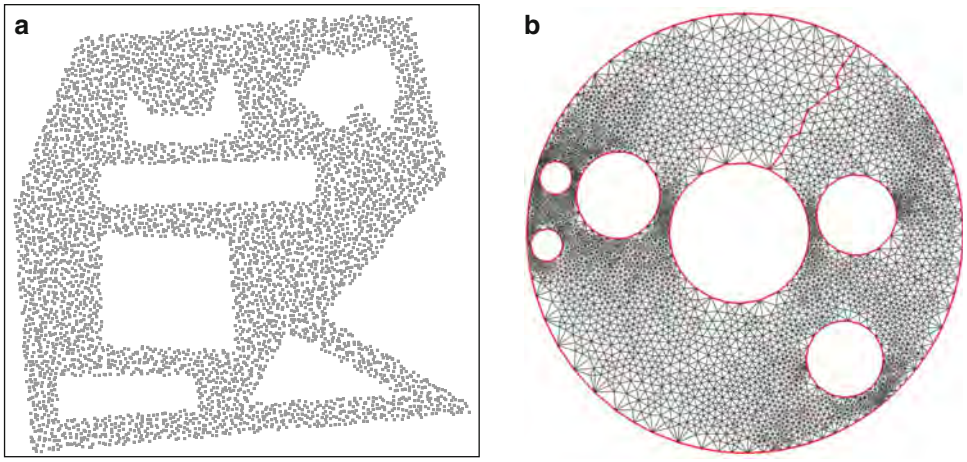
$$\theta_i^{jk} = \cos^{-1} \frac{l_{ij}^2 + l_{ki}^2 - l_{jk}^2}{2 l_{ij} l_{ki}}$$

The curvature k_i at v_i is

$$k_i = \begin{cases} 2\pi - \sum_{jk} \theta_i^{jk}, & v_i \notin \partial M \\ \pi - \sum_{jk} \theta_i^{jk}, & v_i \in \partial M \end{cases}$$

When the target curvature is not met, u_i is modified proportionally to the difference between the target curvature and the current curvature.

$$u_i \Leftarrow u_i + \delta(\bar{k}_i - k_i)$$



Discrete Ricci Flow for Geometric Routing, Fig. 2 (**a**) A network of 7,000 nodes with many holes; (**b**) virtual coordinates

Once the curvatures are computed, the triangulation is then flattened out by a simple flooding from a triangle root. Given three edge lengths of the root triangle $[v_0, v_1, v_2]$, the node coordinates can be constructed directly. Then the neighboring triangle of the root, e.g., $[v_1, v_0, v_i]$, can be flattened; the virtual coordinates of v_i are the intersection of two circles, one is centered at v_0 with radius l_{0i} and the other is centered at v_1 with radius l_{1i}. In a similar way, the neighbors of the newly flattened triangles can be further embedded. The virtual coordinates of the whole network are thus computed (Fig. 2).

Discrete Hyperbolic Ricci Flow

The key result in conformal geometry says that any surface with a Riemannian metric admits a Riemannian metric of constant Gaussian curvature, which is conformal to the original metric. Such metric is called the uniformization metric. Thus, depending on the surface topology, the uniformization metric has either positive constant, zero, or negative constant curvature everywhere. Simply connected surfaces with constant curvature are only of three canonical types: the sphere (constant positive curvature everywhere), the Euclidean plane (zero curvature everywhere), and the hyperbolic plane (negative curvature everywhere). Discrete Ricci flow is a powerful tool to compute the uniformization metric.

In our setting, when the triangulation Σ has two or more holes, it has negative total curvature. Thus, its uniformization metric is hyperbolic. To actually embed the surface and realize the uniformization metric, the holes in the network are cut open to get a simply connected triangulation T. Using discrete hyperbolic Ricci flow, we embed T in a convex region S in hyperbolic space. Each node is given a hyperbolic coordinate. Each edge uv has a length $d(u, v)$ as the geodesic between u, v in the hyperbolic space. In this way, greedy routing with the hyperbolic metric (i.e., send the message to the neighbor closer to the destination measured by hyperbolic distance) has *guaranteed delivery*.

The hyperbolic Ricci flow is very similar to the Euclidean version with a few modifications. First all metrics are hyperbolic. The edge length l_{ij} of e_{ij} is determined by the hyperbolic cosine law:

$$\cosh l_{ij} = \cosh \gamma_i \cosh \gamma_j + \sinh \gamma_i \sinh \gamma_j \cos \phi_{ij}. \tag{1}$$

Let $u_i = \log \tanh \frac{\gamma_i}{2}$; *the discrete Ricci flow* is defined as

$$\frac{du_i(t)}{dt} = -K_i, \tag{2}$$

where K_i is the discrete Gaussian curvature at v_i. Once the hyperbolic metric is computed, we can embed the triangulation isometrically onto the Poincare disk.

Generalized Discrete Surface Ricci Flow

There are many schemes for discrete surface Ricci flow [14], including tangential circle packing, Thurston's circle packing, inversive distance circle packing, Yamabe flow, virtual radius circle packing, and mixed typed schemes. All of them can be unified as follows. The combinatorial structure of the triangulation is Σ; it is with one of three background geometries: Euclidean $\mathbb{E}^2$, hyperbolic $\mathbb{H}^2$, and spherical $\mathbb{S}^2$. Each vertex is associated with a circle; the vertex radii function is $\gamma : V \to \mathbb{R}^+$. Each vertex is also associated with a constant ϵ, which indicates the scheme. Each edge has a conformal structure coefficient $\eta : E \to \mathbb{R}$. So a circle packing metric is given by $(\Sigma, \gamma, \eta, \epsilon)$. The discrete conformal factor is given by

$$u_i = \begin{cases} \log \gamma_i & , \mathbb{E}^2 \\ \log \tanh \frac{\gamma_i}{2} & , \mathbb{H}^2 \\ \log \tan \frac{\gamma_i}{2} & , \mathbb{S}^2 \end{cases}$$

The length of $[v_i, v_j]$ is given by

$$\begin{cases} l_{ij}^2 & = 2\eta_{ij} e^{u_i+u_j} + \epsilon_i e^{2u_i} + \epsilon_j e^{2u_j} & , \mathbb{E}^2 \\ \cosh l_{ij} & = \frac{4\eta_{ij} e^{u_i+u_j} + (1+\epsilon_i e^{2u_i})(1+\epsilon_j e^{2u_j})}{(1-\epsilon_i e^{2u_i})(1-\epsilon_j e^{2u_j})} & , \mathbb{H}^2 \\ \cos l_{ij} & = \frac{4\eta_{ij} e^{u_i+u_j} + (1-\epsilon_i e^{2u_i})(1-\epsilon_j e^{2u_j})}{(1+\epsilon_i e^{2u_i})(1+\epsilon_j e^{2u_j})} & , \mathbb{S}^2 \end{cases}$$

The discrete Ricci flow is given by

$$\frac{du_i(t)}{dt} = \bar{K}_i - K_i(t),$$

where $\bar{K} : V \to \mathbb{R}$ is the prescribed target curvature, which is the negative gradient flow of the discrete Ricci energy

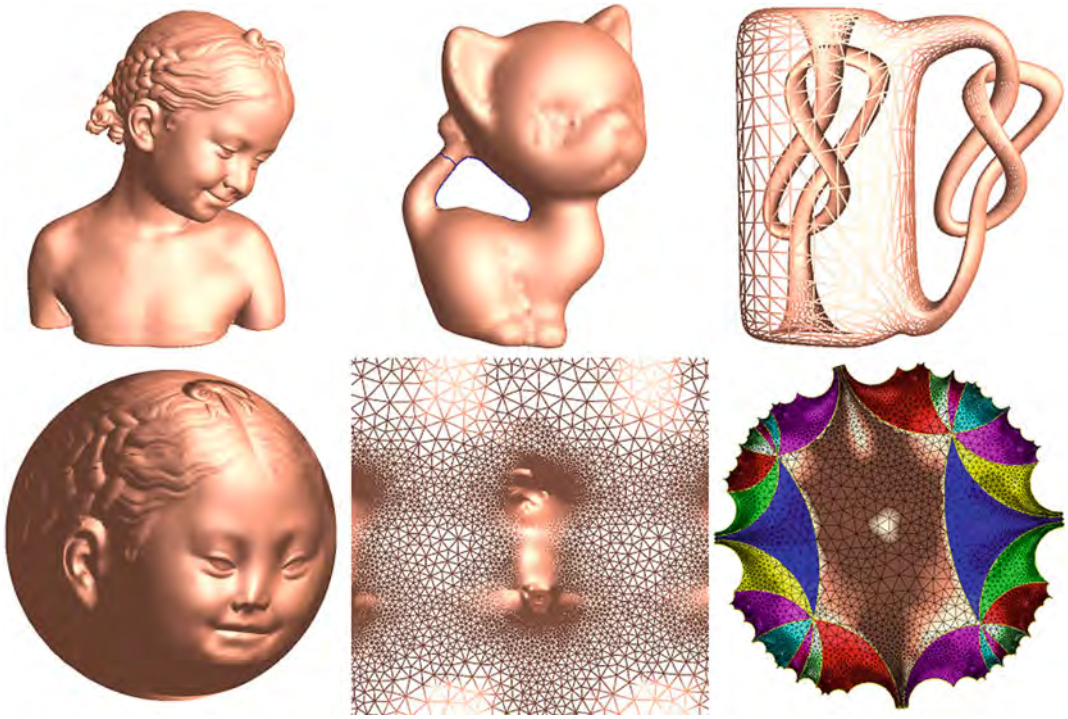
$$E(u) = \int^{\mathbf{u}} \sum_i (\bar{K}_i - K_i) du_i.$$

For the discrete surfaces with Euclidean background geometry, the Ricci energy is convex on the space $\sum_i u_i = 0$. For those with hyperbolic background geometry, the energy is convex. For spherical case, the energy is indefinite.

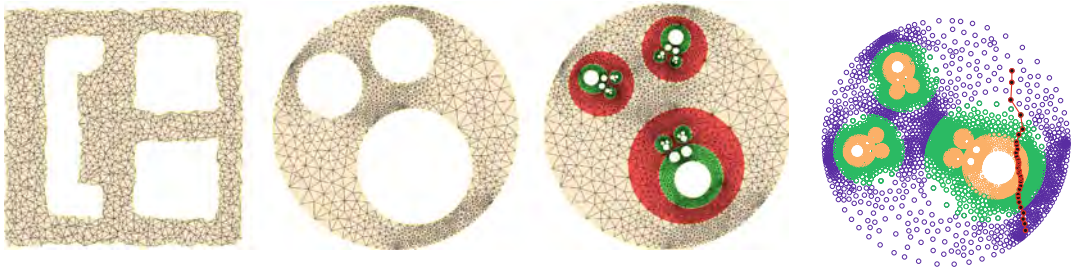
For Yamabe scheme (where $\epsilon \equiv 0$), the combinatorial structure Σ is Delaunay, if for each edge $[v_i, v_j]$ share by two faces $[v_i, v_j, v_k]$ and $[v_j, v_i, v_l]$, $\theta_{ij}^k + \theta_{ji}^l \leq \pi$. If during the Yamabe flow, the combinatorial structure can be updated to ensure the Delaunay condition, then for any $\bar{K} : V \to (-\infty, 2\pi)$ satisfying the Gauss-Bonnet constraint $\sum_{v \in V} \bar{K}(v) = 2\pi\chi(\Sigma)$, the Yamabe flow with surgery can lead to the discrete metric that realizes the target curvature; the convergence is exponentially fast. This theorem implies the discrete uniformization theorem: any closed polyhedral surface admits a polyhedral metric discretely conformal to the original one, which induces constant Gaussian curvature everywhere [4,5] (Fig. 3).

Applications

The presented Ricci flow algorithms can be applied for a variety of routing primitives for large-scale wireless sensor networks with nonuniform node distribution. Besides guaranteed delivery [8], we can also achieve multiple additional desirable routing objectives, all derived from the unique property of a conformal mapping. For example, greedy routing on a circular domain may accumulate high traffic load on the interior hole boundaries. To alleviate that, we can reflect the network along a hole boundary using a Mobius transformation and map a copy of the network to cover the interior of the hole, recursively [9] (see Fig. 4). Routing on this covering space makes traffic load more balanced as hole boundaries essentially "disappear." In another case, when there are sudden link or node failures, we can apply a Mobius transformation to generate a different circular domain, with the sizes and positions of the holes rearranged, on which greedy routing generates a different path [6]. Thus, quick recovery from a spontaneous failure is possible. The hyperbolic Ricci flow can be used to map the domain with the holes cut open to a convex polygon that can tile up the entire hyperbolic



Discrete Ricci Flow for Geometric Routing, Fig. 3 Discrete surface uniformization

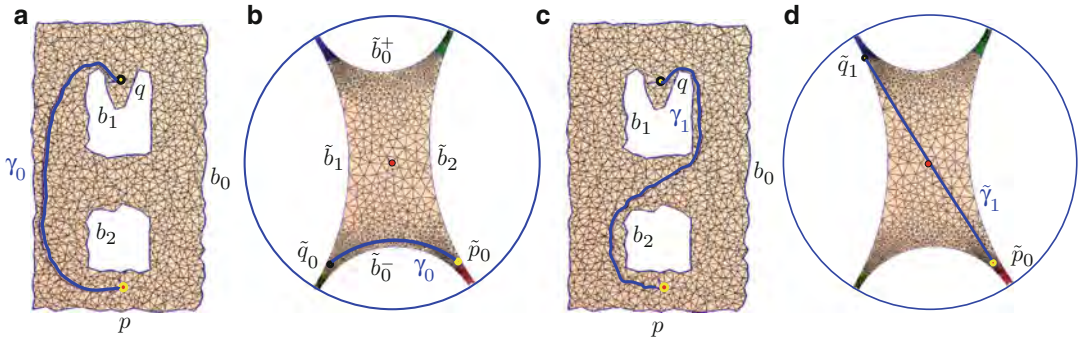


Discrete Ricci Flow for Geometric Routing, Fig. 4 Three-level circular reflections and a routing path

plane. This mapping supports greedy routing with specified "homotopy types," i.e., routes that go around holes in different ways [13] (see Fig. 5). Hyperbolic embedding can be generalized to 3D sensor networks with complex topology as in the case of monitoring underground tunnels [12]. Additional applications include generation of "space filling curves" for arbitrary domains [1], supporting greedy routing in mobile networks [7] and load balanced routing [3].

Open Problems

Given a smooth surface S with a Riemannian metric $\mathbf{g}$, the smooth Ricci flow leads to the uniformization metric $e^{2\lambda}\mathbf{g}$, where λ is the smooth conformal factor. If the surface is tessellated to get a discrete surface M_0 and discrete Ricci flow is performed on M_0, one obtains discrete conformal factor function u_0. When M is subdivided by n times, the discrete conformal factor is u_n, whether $\lim_{n\to\infty} u_n = \lambda$.



Discrete Ricci Flow for Geometric Routing, Fig. 5 Computing the shortest paths using the hyperbolic embedding of a 3-connected domain with 1,286 nodes. Two different paths are generated using greedy routing toward images of the destination in different patches. (**a**) Shortest path 1. (**b**) Geodesic of (**a**). (**c**) Shortest path 2. (**d**) Geodesic of (**c**)

Experimental Results

The convergence rate, i.e., the number of iterations is proportional to $O(\frac{log(1/\epsilon)}{\delta})$, where δ is the step size in the Ricci flow algorithm and ϵ is the error bound on the curvature. In our experiments we take ϵ to be $1e-6$. Routing with the virtual coordinates has 100 % delivery rate and the average path stretch (compared to the shortest path in the network) is no greater than 2.

Problem Definition

Let $G = (V, E)$ be a weighted undirected graph with n vertices and m edges. A distance oracle is a data structure capable of representing almost shortest paths efficiently, both in terms of space requirement and query time. Thorup and Zwick [7] showed that for any integer $k \geq 1$ it is possible to preprocess the graph in $\tilde{O}(mn^{1/k})$ time and generate a compact data structure of size $O(kn^{1+1/k})$ that answers approximate distance queries with $2k - 1$ multiplicative stretch in $O(k)$ time. This means that for every $u, v \in V$, it is possible to retrieve an estimate $\hat{d}(u, v)$ to the distance $d(u, v)$ in $O(k)$ time, such that $d(u, v) \leq \hat{d}(u, v) \leq (2k - 1)d(u, v)$. Recently, [8] showed, using a clever query algorithm, that the query time of Thorup and Zwick can be reduced from $O(k)$ to $O(\log k)$. Even more recently, [1] showed that the query time of Thorup and Zwick can be reduced to $O(1)$. Thorup and Zwick [7] showed, based on the girth conjecture of [2], that there are dense enough graphs which cannot be represented by a data structure of size less than $n^{1+1/k}$ without increasing the stretch above $2k - 1$ for any integer k. Therefore, for dense graphs their distance oracle is optimal assuming the girth conjecture holds.

This suggests that the distance oracle of Thorup and Zwick can be improved only for sparse graphs and in particular, graphs with less than $n^{1+1/k}$ edges. Alternatively, it might be possible to get below the $2k - 1$ multiplicative stretch by allowing an additive stretch as well.

Notice, however, that we cannot gain from introducing also additive stretch without getting an improved multiplicative stretch distance oracles for sparse graphs (i.e., $m = O(n)$). A data structure with size $S(m, n)$ and stretch (α, β), where α is multiplicative stretch and β is additive stretch, implies a data structure with size $S((\beta + 1)m, n + \beta m)$ and multiplicative stretch of α, as if we divide every edge into $\beta + 1$ edges then all distances become a multiply of $\beta + 1$ and additive stretch of β is useless. For graphs with $m = O(n)$, the size of the data structure is asymptotically the same.

Key Results

Pătraşcu and Roditty [4] obtained a distance oracle for sparse unweighted graphs with $m = \tilde{O}(n)$ of size $\tilde{O}(m^{5/3})$ that can supply in $O(1)$ time an estimate of the distance with multiplicative stretch 2. For dense graphs, the distance oracle has size of $\tilde{O}(n^{5/3})$ and stretch $(2, 1)$.

Pătraşcu et al. [5] extended this result for weighted graphs and generalized it. In particular, they show that for any fixed positive integers k and ℓ, there is a distance oracle with stretch $\alpha = 2k + 1 \pm \frac{2}{\ell} = 2k + 1 - \frac{2}{\ell}, 2k + 1 + \frac{2}{\ell}$, that uses $\tilde{O}(m^{1+2/(\alpha+1)})$ space. The query time is $O(k + \ell)$.

Sommer et al. [6] proved a three-way tradeoff between space, stretch, and query time of approximate distance oracles. They show that any distance oracle that can give stretch α answers to distance queries in time $O(t)$ must use $n^{1+\Omega(1/(t\alpha))}/\log n$ space. Their result is obtained by a reduction from lopsided set disjointness to distance oracles, using the framework introduced by [3]. Any improvement to this lower bound requires a major breakthrough in lower bounds techniques. In particular, it does not imply anything even for slightly non-constant query time as $\Omega(\log n)$ and slightly non-linear space as $n^{1.01}$.

Pătraşcu and Roditty [4] showed also a conditional lower bound for distance oracle that is based on a conjecture on the hardness of the set intersection problem. They showed that a distance oracle for unweighted graphs with $m = \tilde{O}(n)$ edges, which can distinguish between distances of 2 and 4 in constant time (as multiplicative stretch strictly less than 2 implies) requires $\tilde{\Omega}(n^2)$ space, assuming the conjecture holds. Thus, non-constant query time is essential to get stretch smaller than 2.

Pătraşcu et al. [5] showed, based also on a conjecture on the hardness of the set intersection problem, for any fixed positive integer ℓ, that there are graphs with m edges such that a distance oracle with constant query time and stretch below $3 - 2/(\ell + 1)$ must use space $\tilde{\Omega}(m^{1+1/(2-1/\ell)})$.

Open Problems

The conditional lower bounds of [5] for sparse graphs do not say anything on stretch 3. The best space upper bound for stretch 3 in sparse graphs and dense graphs is $\tilde{O}(n^{1.5})$. While in dense graphs this is tight due to the existence of graphs with $\Omega(n^{1.5})$ edges and girth 6, for sparse graphs nothing is known. Therefore, we have the following two open problems:

Can we get a $o(n^{1.5})$ space for stretch 3 in sparse graphs? Can we get stretch less than 3 for space $\tilde{O}(n^{1.5})$ in sparse graphs?

Problem Definition

Introduction

From a mathematical point of view, a phylogeny defines a probability space for random sequences observed at the leaves of a binary tree T. The tree T represents the unknown hierarchy

of common ancestors to the sequences. It is assumed that (unobserved) ancestral sequences are associated with the inner nodes. The tree along with the associated sequences models the evolution of a molecular sequence, such as the protein sequence of a gene. In the conceptually simplest case, each tree node corresponds to a species, and the gene evolves within the organismal lineages by vertical descent.

Phylogeny reconstruction consists of finding T from observed sequences. The possibility of such reconstruction is implied by fundamental principles of molecular evolution, namely, that random mutations within individuals at the genetic level spreading to an entire mating population are not uncommon, since often they hardly influence evolutionary fitness [15]. Such mutations slowly accumulate, and, thus, differences between sequences indicate their evolutionary relatedness.

The reconstruction is theoretically feasible in several known situations. In some cases, distances can be computed between the sequences, and used in a distance-based algorithm. Such an algorithm is fast-converging if it almost surely recovers T, using sequences that are polynomially long in the size of T. Fast-converging algorithms exploit statistical concentration properties of distance estimation.

Formal Definitions

An evolutionary *topology* $U(X)$ is an unrooted binary tree in which leaves are bijectively mapped to a set of species X. A *rooted topology* T is obtained by rooting a topology U on one of the edges uv: a new node ρ is added (the *root*), the edge uv is replaced by two edges ρv and ρu, and the edges are directed outwards on paths from ρ to the leaves. The edges, vertices, and leaves of a rooted or unrooted topology T are denoted by $\mathrm{E}(T)$, $\mathrm{V}(T)$ and $\mathrm{L}(T)$, respectively.

The edges of an unrooted topology U may be equipped with a a positive *edge length* function $d\colon E(U) \mapsto (0,\infty)$. Edge lengths induce a *tree metric* $d\colon \mathrm{V}(U) \times \mathrm{V}(U) \mapsto [0,\infty)$ by the extension $d(u,v) = \sum_{e \in u \rightsquigarrow v} d(e)$, where $u \rightsquigarrow v$ denotes the unique path from u to v. The value $d(u,v)$ is called the *distance* between u and v. The pairwise distances between leaves form a *distance matrix*.

An *additive tree metric* is a function $\delta\colon X \times X \mapsto [0,\infty)$ that is equivalent to the distance matrix induced by some topology $U(X)$ and edge lengths. In certain random models, it is possible to define an additive tree metric that can be estimated from dissimilarities between sequences observed at the leaves.

In a *Markov model of character evolution* over a rooted topology T, each node u has an associated *state*, which is a random variable $\xi(u)$ taking values over a fixed alphabet $\mathrm{A} = \{1, 2, \ldots r\}$. The vector of leaf states constitutes the *character* $\xi = \big(\xi(u)\colon u \in \mathrm{L}(T)\big)$. The states form a first-order Markov chain along every path. The joint distribution of the node states is specified by the marginal distribution of the root state, and the conditional probabilities $\mathbb{P}\{\xi(v) = b | \xi(u) = a\} = p_e(a \to b)$ on each edge e, called *edge transition probabilities*.

A *sample* of length ℓ consists of independent and identically distributed characters $\Xi = \big(\xi_i\colon i = 1, \ldots \ell\big)$. The *random sequence* associated with the leaf u is the vector $\Xi(u) = \big(\xi_i(u)\colon i = 1, \ldots \ell\big)$.

A *phylogeny reconstruction algorithm* is a function F mapping samples to unrooted topologies. The *success probability* is the probability that $\mathrm{F}(\Xi)$ equals the true topology.

Popular Random Models

Neyman Model [14]

The edge transition probabilities are

$$p_e(a \to b) = \begin{cases} 1 - \mu_e & \text{if a = b;} \\ \frac{\mu_e}{r-1} & \text{if a} \neq \text{b} \end{cases}$$

with some edge-specific mutation probability $0 < \mu_e < 1 - 1/r$. The root state is uniformly distributed. A distance is usually defined by

$$d(u,v) = -\tfrac{r-1}{r} \ln\Big(1 - \tfrac{r}{r-1}\mathbb{P}\{\xi(u) \neq \xi(v)\}\Big).$$

General Markov Model

There are no restrictions on the edge transition probabilities in the general Markov model. For identifiability [1, 16], however, it is usually assumed that $0 < \det \mathbf{P}_e < 1$, where $\mathbf{P}_e$ is the stochastic matrix of edge transition probabilities. Possible distances in this model include the *paralinear* distance [1, 12] and the *LogDet* distance [13, 16]. This latter is defined by $d(u, v) = -\ln \det \mathbf{J}_{uv}$, where J_{uv} is the matrix of joint probabilities for $\xi(u)$ and $\xi(v)$.

It is often assumed in practice that sequence evolution is effected by a continuous-time Markov process operating on the edges. Accordingly, the edge length directly measures time. In particular, $\mathbf{P}_e = e^{\mathbf{Q}\cdot d(e)}$ on every edge e, where $\mathbf{Q}$ is the instantaneous rate matrix of the underlying process.

Key Results

It turns out that the hardness of reconstructing an unrooted topology U from distances is determined by its *edge depth* $\rho(U)$. Edge depth is defined as the smallest integer k for which the following holds. From each endpoint of every edge $e \in \mathrm{E}(U)$, there is a path leading to a leaf, which does not include e and has at most k edges.

Theorem 1 (Erdős, Steel, Székely, Warnow [6]) *If U has n leaves, then $\rho(U) \leq 1 + \log_2(n-1)$. Moreover, for almost all random n-leaf topologies under the uniform or Yule-Harding distributions, $\rho(U) \in O(\log \log n)$*

Theorem 2 (Erdős, Steel, Székely, Warnow [6]) *For the Neyman model, there exists a polynomial-time algorithm that has a success probability $(1-\delta)$ for random samples of length*

$$\ell = O\Big(\frac{\log n + \log \frac{1}{\delta}}{f^2(1-2g)^{4\rho+6}}\Big), \qquad (1)$$

where $0 < f = \min_e \mu_e$ and $g = \max_e \mu_e < 1/2$ are extremal edge mutation probabilities, and ρ is the edge depth of the true topology.

Theorem 2 can be extended to the general Markov model with analogous success rates for LogDet distances [7], as well as to a number of other Markov models [2].

Equation (1) shows that phylogenies can be reconstructed with high probability from polynomially long sequences. Algorithms with such sample size requirements were dubbed *fast-converging* [9]. Fast convergence was proven for the short quartet methods of Erdős et al. [6, 7], and for certain variants [11] of the so-called disk-covering methods introduced by Huson et al. [9]. All these algorithms run in $\Omega(n^5)$ time. Csürös and Kao [3] initiated the study of computationally efficient fast-converging algorithms, with a cubic-time solution. Csürös [2] gave a quadratic-time algorithm. King et al. [10] designed an algorithm with an optimal running time of $O(n \log n)$ for producing a phylogeny from a matrix of estimated distances.

The short quartet methods were revisited recently: [4] described an $O(n^4)$-time method that aims at succeeding even if only a short sample is available. In such a case, the algorithm constructs a forest of "trustworthy" edges that match the true topology with high probability.

All known fast-converging distance-based algorithms have essentially the same sample bound as in (1), but Daskalakis et al. [5] recently gave a twist to the notion of fast convergence. They described a polynomial-time algorithm, which outputs the true topology almost surely from a sample of size $O(\log n)$, given that edge lengths are not too large. Such a bound is asymptotically optimal [6]. Interestingly, the sample size bound does not involve exponential dependence on the edge depth: the algorithm does not rely on a distance matrix.

Applications

Phylogenies are often constructed in molecular evolution studies, from aligned DNA or protein sequences. Fast-converging algorithms have mostly a theoretical appeal at this point. Fast convergence promises a way to handle the increasingly important issue of constructing

large-scale phylogenies: see, for example, the CIPRES project (http://www.phylo.org/).

Problem Definition

A phylogeny is an evolutionary tree tracing the shared history, including common ancestors, of a set of extant species or "taxa." Phylogenies are increasingly reconstructed on the basis of molecular data (DNA and protein sequences) using statistical techniques such as likelihood and Bayesian methods. Algorithmically, these techniques suffer from the discrete nature of tree topology space. Since the number of tree topologies increases exponentially as a function of the number of taxa, and each topology requires a separate likelihood calculation, it is important to restrict the search space and to design efficient heuristics. Distance methods for phylogeny reconstruction serve this purpose by inferring trees in a fraction of the time required for the more statistically rigorous methods. Distance methods also provide fairly accurate starting trees to be further refined by more sophisticated methods. Moreover, the input to a distance method is the matrix of pairwise evolutionary distances among taxa, which are estimated by maximum likelihood, so that distance methods also have sound statistical justifications.

Mathematically, a phylogenetic tree is a triple $T = (V, E, l)$ where V is the set of nodes (extant taxa correspond to leaves, ancestors to internal nodes), E is the set of edges (branches) representing relations of descent, and l is a function that assigns positive lengths to each edge in E, representing a measure of evolutionary divergence, for example, in terms of time, or amount of change between DNA and protein sequences. Any phylogenetic tree T defines a metric D_T on its leaf set L: let $P_T(u, v)$ define the unique path through T from u to v; then the distance from u to v is set to $D_T(u, v) = \sum_{e \in P_T(u,v)} l(e)$.

Distance methods for phylogeny reconstruction rely on the fundamental result [22] that the map $T \rightarrow D_T$ is reversible; i.e., a tree T can be reconstructed from its tree metric, a problem that can be solved in $O(n \log n)$ time [14]. However, in practice D_T is not known, and one must use molecular sequence data to estimate a distance matrix D that approximates D_T [9]. As the amount of sequence data increases, D can be assumed to converge to D_T. A minimal requirement for any distance method is *consistency*: for any tree T, and for distance matrices D "close enough" to D_T, the algorithm should output a tree with the same topology as T (i.e., with the same underlying graph (V,E)). The present chapter deals with the question of when any distance algorithm for phylogeny reconstruction can be guaranteed to output the correct phylogeny as a function of the divergence between D and D_T. Atteson [1] demonstrated that this question can be precisely answered for neighbor joining (NJ) [18], one of the most cited algorithms in computational biology (with more than 35,000 citations up to 2014), and a number of NJ's variants.

The Neighbor Joining (NJ) Algorithm of Saitou and Nei [18]

NJ is *agglomerative*: it works by using the input matrix D to identify a pair of taxa $x, y \in L$ that are neighbors in T, i.e., there exists a node $u \in V$ such that $\{(u,x), (u,y)\} \subset E$. Then, the algorithm creates a node c that is connected to x and y, extends the distance matrix to c, and solves the reduced problem on $L \cup \{c\} \setminus \{x,y\}$. The pair (x, y) is chosen to minimize the following sum:

$$S_D(x, y) = (|L| - 2) \cdot D(x, y) - \sum_{z \in L} (D(z, x) + D(z, y)).$$

The soundness of NJ is based on the observation that, if $D = D_T$ for a tree T, the value $S_D(x, y)$ will be minimized for a pair (x, y) that are neighbors in T.

Balanced Minimum Evolution and Algorithms Inspired by It

A number of papers (reviewed in [11]) have been dedicated to the various interpretations and properties of the S_D criterion. One of these interpreta-

tions consists of observing that agglomerating the pair of nodes that minimizes S_D is equivalent to choosing, among all the trees that can be obtained in this way, the one that minimizes a simple linear formula [16] to calculate the length of a tree from the distances between its leaves [11], thus connecting distance and parsimony methods [9]. As the optimization principle seeking the tree that minimizes this formula has been named balanced minimum evolution (BME) [6], NJ can then be seen as a greedy algorithm for BME.

This remarkable connection between NJ and BME naturally spurred the proposal of alternative algorithms for BME. One of these, GreedyBME, consists of iteratively adding taxa to a tree so that, at each step, the resulting tree is the one that minimizes BME among all the binary trees that can be obtained in this way [6]. More involved algorithms can be obtained by combining a simple tree construction algorithm such as NJ or GreedyBME, with a local search based on the traditional tree rearrangements used in phylogenetics [9], such as *nearest-neighbor interchange* (NNI) or *subtree pruning and regrafting* (SPR).

The Fast Neighbor Joining (FNJ) Algorithm of Elias and Lagergren [7]

Standard implementations of NJ require $O(n^3)$ computations, where n is the number of taxa in the data set. Since a distance matrix only has n^2 entries, many attempts have been made to construct a distance algorithm that would only require $O(n^2)$ computations while retaining the accuracy of NJ. To this end, one of the most interesting results is the fast neighbor joining (FNJ) algorithm of Elias and Lagergren [7].

Most of the computation of NJ is used in the recalculations of the sums $S_D(x, y)$ after each agglomeration step. Although each recalculation can be performed in constant time, and although it is not necessary to consider all pairs of taxa (x, y) in order to find the one that minimizes this sum [20], the number of pairs to consider remains, in the worst case, $O(k^2)$ when k nodes are left to agglomerate. Thus, summing over k, $O(n^3)$ computations are required in all.

Elias and Lagergren take a related approach to agglomeration, which does not exhaustively seek the minimum value of $S_D(x, y)$ at each step, but instead uses a heuristic to maintain a list of candidates of "visible pairs" (x, y) for agglomeration. At the $(n - k)$th step, when two neighbors are agglomerated from a k-taxa tree to form a $(k - 1)$-taxa tree, FNJ has a list of $O(k)$ visible pairs for which $S_D(x, y)$ is calculated. The pair joined is selected from this list. By trimming the number of pairs considered, Elias and Lagergren achieved an algorithm which requires only $O(n^2)$ computations. Other similar improvements to neighbor joining have also been proposed in recent years [8, 13, 20].

Safety Radius Performance Analysis (Atteson [1])

In order to provide accuracy guarantees for distance-based algorithms, Atteson [1] tackled the following question: if D is a distance matrix that approximates a tree metric D_T, can one have some confidence in the algorithm's ability to reconstruct T, or parts of it, given D, based on some measure of the distance between D and D_T? For two matrices, D_1 and D_2, the L_∞ distance between them is defined by $||D_1 - D_2||_\infty = \max_{i,j} |D_1(i, j) - D_2(i, j)|$. Moreover, let $\mu(T)$ denote the length of the shortest internal edge of a tree T. This is an important quantity, as short branches in a phylogeny are difficult to resolve, because of the relatively few (if any) molecular changes occurring on a short branch.

The *safety radius* of an algorithm A is then the greatest value of r with the property that given any phylogeny T, and any distance matrix D satisfying $||D - D_T||_\infty < r \cdot \mu(T)$, A will return a tree $\hat{T}$ with the same topology as T. Similarly, the *edge radius* of A is the greatest value of r, for which the presence in $\hat{T}$ of an edge $e \in E$ is guaranteed whenever $||D - D_T||_\infty < r \cdot l(e)$. As an easy consequence of these definitions, the safety radius is always at least as large as the edge radius. Moreover, both the safety radius and the edge radius can also be attributed to an optimization principle, assuming an exact optimization algorithm.

Key Results

Atteson [1] proved the following theorems:

Theorem 1 *The safety radius of NJ is* $1/2$.

Theorem 2 *The largest possible safety radius for any algorithm is* $1/2$.

Indeed, given any μ, one can find two different trees T_1, T_2 and a distance matrix D such that $\mu = \mu(T_1) = \mu(T_2)$, and $\|D - D_{T_1}\|_\infty = \mu/2 = \|D - D_{T_2}\|_\infty$. Since D is equidistant from two distinct tree metrics, no algorithm could assign it to the "closest" tree.

In their presentation of FNJ, Elias and Lagergren updated Atteson's results for their algorithm. They showed:

Theorem 3 *The safety radius of FNJ is* $1/2$.

An insight on the above results on neighbor-joining-type algorithms is provided by the fact that the optimization principle they are linked to, BME, has itself safety radius $1/2$ [15]. A simple consequence of this [15] is the fact that also GreedyBME has safety radius $1/2$, a result first proven by Shigezumi [19]. Finally, performing a local search guided by BME and based on SPR leads to an algorithm with safety radius greater or equal to $1/3$, regardless of the method used to construct the initial tree [2].

The edge radius of a number of algorithms has also been studied. As conjectured by Atteson [1] and formally proven by Dai et al. [5], the edge radius of NJ is $1/4$. Interestingly, other heuristics, related to NJ via the principle they seek to optimize (BME), perform better than NJ in terms of edge radius: GreedyBME has edge radius $1/3$ [3]; moreover, building an initial tree with GreedyBME and then performing a local search guided by BME and based on NNI or SPR operations constitute an algorithm with edge radius $1/3$ [3].

Finally, we note that the safety radius framework has also been applied to the ultrametric setting where the correct tree T is rooted and all tree leaves are at the same distance from the root [10]. These trees are called "molecular clock" trees in phylogenetics and "indexed hierarchies" in data analysis. In this setting, the optimal safety radius is equal to 1 (instead of $1/2$), and a number of standard algorithms (e.g., UPGMA, with time complexity in $O(n^2)$) have a safety radius of 1.

Open Problems

With increasing amounts of sequence data becoming available for an increasing number of species, distance algorithms such as NJ should be useful for quite some time. Currently, the bottleneck in the process of building phylogenies is estimating distances, rather than exploring tree topologies. Two algorithms were recently developed to reconstruct trees from incomplete distance matrices. These algorithms use character information as well as distances and hence cannot be categorized as pure distance methods.

FastTree [17] is an NJ-like heuristic that avoids computing the full distance matrix. For each taxon, FastTree computes the distances to $O(\sqrt{n})$ close neighbors. FastTree also uses sequence profiles to approximate $S_D(x, y)$ values in constant time. The overall algorithm takes $O(san\sqrt{n}\log n)$ time and $O(san + n\sqrt{n})$ memory, where s is the length of the input sequences and a is their alphabet size. FastTree has been shown to be highly accurate with simulated data [17], but no formal guarantee has yet been shown for this algorithm.

The only known $o(n^2)$ algorithm with theoretical guarantees is LSHTree [4]. It uses locality-sensitive hashing to rapidly find candidate pairs of close sequences for merging. After each merge, LSHTree reconstructs ancestral sequences at new internal nodes to ensure that a close pair of sequences can be found at each iteration. LSHTree is guaranteed to reconstruct the correct tree from sequences of logarithmic length under a Markov model of sequence evolution. The exact running time of LSHTree depends on the branch lengths.

As we have shown, a number of distance-based tree building algorithms have been analyzed in the safety radius framework. However,

computer simulations (e.g., [6, 7]) have shown that not all algorithms with optimal safety radius achieve the same accuracy: for example, NJ is slightly more accurate than FNJ (both having safety radius $= 1/2$), but is beaten by heuristics based on NNI or SPR moves (with demonstrated safety radius $>= 1/3$, but possibly $= 1/2$). Moreover, some well-established methods (e.g., based on least squares [10, 21]) have safety radius converging to 0 when the number of taxa increases, which contradicts the common practice. These experimental observations indicate that the safety radius approach should be sharpened to provide better theoretical analysis of method performance (see [12] for a work in this direction). In particular, the choice of the L_∞ norm to measure the error in a distance matrix seems to have little statistical or biological justification.

An alternative analysis framework, strictly linked to the one presented here, is the one seeking to estimate the minimum sequence length required for accurate reconstruction of the correct tree. It is discussed in a separate entry of this encyclopedia [A].

Problem Definition

Consider a communication network, modeled by an undirected weighted graph $G = (V, E)$, where $|V| = n$, $|E| = m$. Each vertex of V represents a processor of unlimited computational power; the processors have unique identity numbers (ids), and they communicate via the edges of E by sending messages to each other. Also, each edge $e \in E$ has associated a weight $w(e)$, known to the processors at the endpoints of e. Thus, a processor knows which edges are incident to it and their weights, but it does not know any other information about G. The network is *asynchronous:* each processor runs at an arbitrary speed, which is independent of the speed of other processors. A processor may wake up spontaneously or when it receives a message from another processor. There are no failures in the network. Each message sent arrives at its destination within a finite but arbitrary delay. A *distributed algorithm* A for G is a set of local algorithms, one for each processor of G, that include instructions for sending and receiving messages along the edges of the network. Assuming that A terminates (i.e., all the local algorithms eventually terminate), its *message complexity* is the total number of messages sent over any execution of the algorithm, in the worst case. Its *time complexity* is the worst-case execution time, assuming processor steps take negligible time, and message delays are normalized to be at most 1 unit.

A *minimum spanning tree* (MST) of G is a subset E' of E such that the graph $T = (V, E')$ is a tree (connected and acyclic) and its total weight, $w(E') = \sum_{e \in E'} w(e)$, is as small as possible. The computation of an MST is a central problem in combinatorial optimization, with a rich history dating back to 1926 [2], and up to now, the book [12] collects properties, classical results, applications, and recent research developments.

In the *distributed MST problem*, the goal is to design a distributed algorithm A that terminates always and computes an MST T of G. At the end of an execution, each processor knows which of its incident edges belong to the tree T and which do not (i.e., the processor writes in a local output register the corresponding incident edges). It is remarkable that in the distributed version of the MST problem, a communication network is solving a problem where the input is the network itself. This is one of the fundamental starting points of network algorithms.

It is not hard to see that if all edge weights are different, the MST is unique. Due to the assumption that processors have unique ids, it is possible to assume that all edge weights are different: whenever two edge weights are equal, ties are broken using the processor ids of the edge endpoints. Having a unique MST facilitates the design of distributed algorithms, as processors can locally select edges that belong to the unique MST. Notice that if processors do not have unique ids and edge weights are not different, there is no deterministic MST (nor any spanning tree) distributed algorithm, because it may be impossible to break the symmetry of the graph, for example, in the case it is a cycle with all edge weights equal.

Key Results

The distributed MST problem has been studied since 1977, and dozens of papers have been

written on the subject. In 1983, the fundamental distributed *GHS algorithm* in [5] was published, the first to solve the MST problem with $O(m + n \log n)$ message complexity. The paper has had a very significant impact on research in distributed computing and won the 2004 Edsger W. Dijkstra Prize in Distributed Computing.

It is not hard to see that any distributed MST algorithm must have $\Omega(m)$ message complexity (intuitively, at least one message must traverse each edge). Also, results in [3, 4] imply an $\Omega(n \log n)$ message complexity lower bound for the problem. Thus, the GHS algorithm is optimal in terms of message complexity.

The $\Omega(m + n \log n)$ message complexity lower bound for the construction of an MST applies also to the problem of finding an arbitrary spanning tree of the graph. However, for specific graph topologies, it may be easier to find an arbitrary spanning tree than to find an MST. In the case of a complete graph, $\Omega(n^2)$ messages are necessary to construct an MST [8], while an arbitrary spanning tree can be constructed in $O(n \log n)$ messages [7].

The time complexity of the GHS algorithm is $O(n \log n)$. In [1] it is described how to improve its time complexity to $O(n)$ while keeping the optimal $O(m + n \log n)$ message complexity. It is clear that $\Omega(D)$ time is necessary for the construction of a spanning tree, where D is the diameter of the graph. And in the case of an MST, the time complexity may depend on other parameters of the graph. For example, due to the need for information flow among processors residing on a common cycle, as in an MST construction, at least one edge of the cycle must be excluded from the MST. If messages of unbounded size are allowed, an MST can be easily constructed in $O(D)$ time, by collecting the graph topology and edge weights in a root processor. The problem becomes interesting in the more realistic model where messages are of size $O(\log n)$ and an edge weight can be sent in a single message. When the number of messages is not important, one can assume without loss of generality that the model is synchronous. For near-time optimal algorithms and lower bounds, see [10] and references herein.

Applications

The distributed MST problem is important to solve, both theoretically and practically, as an MST can be used to save on communication, in various tasks such as broadcast and leader election, by sending the messages of such applications over the edges of the MST.

Also, research on the MST problem, and in particular the MST algorithm of [5], has motivated a lot of work. Most notably, the algorithm of [5] introduced various techniques that have been in widespread use for multicasting, query and reply, cluster coordination and routing, protocols for handshake, synchronization, and distributed phases. Although the algorithm is intuitive and is easy to comprehend, it is sufficiently complicated and interesting that it has become a challenge problem for formal verification methods, e.g., [11].

Open Problems

There are many open problems in this area, and only a few significant ones are mentioned. As far as message complexity, although the asymptotically tight bound of $O(m + n \log n)$ for the MST problem in general graphs is known, finding the actual constants remains an open problem. There are smaller constants known for general spanning trees than for MST though [6].

As mentioned above, near-time optimal algorithms and lower bounds appear in [10] and references herein. The optimal time complexity remains an open problem. Also, in a synchronous model for overlay networks, where all processors are directly connected to each other, an MST can be constructed in sublogarithmic time, namely, $O(\log \log n)$ communication rounds [9], and no corresponding lower bound is known.

Problem Definition

This entry considers enumeration of combinatorial problems, which can be formulated as follows. Given a large search space $\mathcal{C}$ and a predicate of interest $P : \mathcal{C} \mapsto \{\text{true, false}\}$ the goal is to enumerate the solutions $\mathcal{S} \subseteq \mathcal{C}$ such that $\forall ?s \in \mathcal{S} \quad P(s) = \text{true}$. In most settings, $\mathcal{C}$ is the complete set of combinations of an initial set $\mathcal{G}$; hence, $|\mathcal{C}| = 2^{|\mathcal{G}|}$ and the problem is NP-hard. There are also cases where the elements to enumerate are not sets but other combinatorial structures such as sequences or graphs.

We restrict ourselves to the case where $\mathcal{C}$ can be organized as an *enumeration tree*:

- There exists a distinguished element of $\mathcal{C}$ called the root
- There exists (at least) a *parent* function *parent*: $\mathcal{C} \setminus \{\text{root}\} \mapsto \mathcal{C}$

Finding $\mathcal{S}$ implies, in the worst case, to enumerate all elements of $\mathcal{C}$. A large body of research has exploited properties of P together with *parent* to avoid enumerating some parts of $\mathcal{C}$, as described in the ▸ Reverse Search; Enumeration

Algorithms entry. The focus of the current entry is to exploit parallel computing devices in order to speedup the enumeration process. Due to the prevalence of multicore processors nowadays, they will be the main focus of this entry. However, many solutions presented also apply to a cluster setting.

Key Results

The main challenges of distributed enumeration, as well as existing solutions, are presented below.

Synchronization

For most distributed algorithms, one important challenge is to ensure the sharing of information between parallel processes, either by message passing in a cluster setting or by access to shared memory locations in a multicore setting.

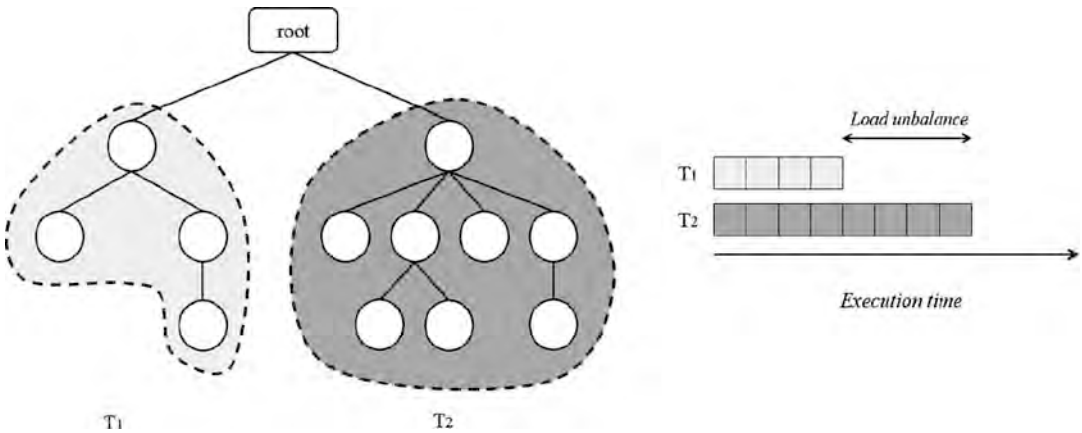
This entry considers a tree-shaped enumeration, where all branches of the enumeration tree are independent. In such setting, complex synchronization mechanisms are not needed. The main difficulty is thus to guarantee that such tree-shaped enumeration can take place, i.e., find (at least) one *parent* function (cf. ▸ Reverse Search; Enumeration Algorithms entry).

Note that in some parallel SAT solvers [6] using *portfolio*-based approaches, each computing resource exploits a different strategy (and thus a different *parent* function) to explore the search space. Ideally these strategies are orthogonal: they explore different parts of the space, and they exchange information to help mutual pruning.

Load Balancing

Most recent algorithms explore the enumeration tree with Depth-First Search (DFS). The simplest way to perform distributed enumeration is to partition the enumeration tree and assign each subtree to a parallel process. A simple example is shown in Fig. 1. The figure shows the enumeration tree. Each subtree of the root is assigned to a different computing resource (either to a node in a cluster or to a core of a multicore processor).

However, depending on the choice of *parent* function and of pruning strategies, each subtree is likely to be of a different size, resulting on large running time differences for the parallel processes. Such phenomenon is called *load unbalance*. On the right of Fig. 1, the execution time is represented for both computing resources, assuming that computing for any node of the enumeration tree takes exactly one time unit. Computing resource T_1 computes for four time units, while computing resource T_2 computes for eight time units. This means that T_1 has been idle for four time units: for more than half of the execution time, the execution has only exploited



Distributed Computing for Enumeration, Fig. 1 Partitioning of the enumeration tree

one of the two available computing resources, resulting in a longer execution time (in an ideal case, as there are 12 nodes to explore, the execution time should be 6 time units). The solution to this problem is to use dynamic load balancing strategies such as *work sharing* or *work stealing*.

Work sharing is based on a simple producer/consumer principle: tasks (here nodes of the enumeration tree) are not assigned statically but made available in a single pool. Each idle computing resource can request one or more tasks from this pool. By reducing the granularity of the work each computing resource has to perform, this technique effectively reduces load unbalance. A disadvantage of this technique is that if computation for a single node of the enumeration tree is short, the computing resource will make frequent requests to the central work pool, with an increased risk of synchronization overheads over accesses to the pool. This can be limited by passing more than one enumeration tree node to each computing resource [1]; however, if the computation time of each of these nodes is unpredictable, a new load unbalance situation may arise.

Work stealing [2] is an "optimistic" improvement over work sharing in cases where the computation time of each task is unpredictable (which is often the case in distributed enumeration). The idea is that each computing resource enqueues a list of tasks to perform, which can either come from a central pool (as in work sharing) or from a partition of the search space (as in a static partitioning). When a computing resource finishes its tasks and becomes idle, it will query the work queues of the other resources and "steal" part of a nonempty queue (usually from the biggest queue).

Recent works from Hanusse et al. [3] have proposed an enumeration approach that mixes DFS and BFS. The parallelism that takes place in the BFS steps naturally lead to a good load balancing without needing work-stealing mechanisms. Their approach show promising results.

Data Locality

In some classes of applications, such as pattern mining, testing the predicate P requires to access a large dataset $\mathcal{D}$. The enumeration tree is organized such that each branch explores a subset of the dataset, which allows to benefit from data locality effects and efficiently exploit the cache in case of multicore processors.

Techniques to limit load unbalance presented above tend to dispatch nodes from the same branch to different computing resources, which destroys data locality. This can lead to a vastly increased bandwidth usage (memory bus bandwidth for multicores and network bandwidth in clusters), resulting in a severe loss of performance.

Several solutions have been proposed by the pattern mining community in order to combine good load balance and good data locality. These solutions are designed for multicore processors. In the case of work stealing, Buehrer et al. [4] propose a method which dynamically decides, for a given node of the enumeration tree, if it has to be mined by the same thread as its parent (preserving locality) or if it can be enqueued and possibly stolen by another thread. This method takes into account the system load, which is a function of the size of the queues for the threads.

In the case of work sharing, Négrevergne et al. [5] divide the task pool in one queue per thread. Task assignement to threads prioritizes data locality.

Applications

The main applications of distributed enumeration are pattern mining (a field of data mining) and SAT problem solving [6]. Pattern mining consists in finding regularities in data, whereas solving SAT consists in finding if there exists a truth assignment for variables of a propositional formula. Both problems explore a huge search space and have numerous applications, they thus require to exploit as much as possible available parallel computing power.

Open Problems

Having an optimal parallel scaling for applications using distributed enumeration is still an

open problem. The techniques presented in this entry allow to design algorithms having satisfying results on existing multicore computers with tens of cores. However as the number of cores will grow towards *many-core processors* (hundreds of cores), the current algorithms are unlikely to exhibit a good parallel scalability. Novel approaches with fewer overheads for handling the parallelism will be required.

Problem Definition

Broadcasting is a fundamental problem in communication networks, where one distinguished node, called the *source*, holds a piece of information, and the goal is to disseminate this message to all other nodes in the network.

The *signal-to-interference-and-noise-ratio model*, *SINR* for short, generalizes the abstract radio networks model (RN) in the following way: nodes located in a metric space communicate by transmitting a signal to the wireless medium, and the quantitative accumulation of interference and signal attenuation are taken into account when deciding which nodes successfully receive the signal.

In more detail, a wireless network consists of n *nodes*, deployed into the Euclidean plane; each node v has its *transmission power* P_v, which is a positive real number. A network is *uniform* when transmission powers P_v are equal or *nonuniform* otherwise. In the following, the uniform networks are considered.

Nodes work synchronously in rounds; each node can either act as a transmitter or as a receiver during a round.

Interferences and collisions are determined by three fixed model parameters: path loss $\alpha > 2$, threshold $\beta \geq 1$, and ambient noise $\mathcal{N} > 0$. The $\mathrm{SINR}(v, u, \mathcal{T})$ ratio, for given nodes u, v and a set of transmitting nodes $\mathcal{T}$, is defined as

$$\mathrm{SINR}(v,u,\mathcal{T}) = \frac{P_v \mathrm{dist}(v,u)^{-\alpha}}{\mathcal{N} + \sum_{w \in \mathcal{T}\setminus\{v\}} P_w \mathrm{dist}(w,u)^{-\alpha}},$$

where $\mathrm{dist}(\cdot,\cdot)$ is the distance function on the plane. A node u successfully receives a message from a node v in a round if $v \in \mathcal{T}$, $u \notin \mathcal{T}$, and

$$\mathrm{SINR}(v, u, \mathcal{T}) \geq \beta, \tag{1}$$

where $\mathcal{T}$ is the set of nodes transmitting at that round.

A single message sent in an execution of any algorithm can carry the source message and at most logarithmic, in the size of the network, number of control bits. A node other than the source starts executing the broadcast protocol after the first successful receipt of the source message; it is often called a *non-spontaneous wake-up model*.

In an *ad hoc network*, there is no central knowledge of network topology. A node v participating in an execution of a protocol knows the size of a network n or only a linear upper bound on the size. In the case that a network is deployed in the Euclidean space, one can distinguish between the case that each node knows its coordinates and the case that it does not know them.

Assuming that the transmission power of nodes is equal to P, the largest distance from the transmitter in which a message can be received is equal to $r = (P/(\mathcal{N}\beta))^{1/\alpha}$, provided only one node is transmitting in the whole network.

Sensitivity. Due to physical constraints, it is often assumed that the actual distance on which message can be received is smaller than $r = (P/(\mathcal{N}\beta))^{1/\alpha}$. This assumption is expressed by the *sensitivity parameter* $0 < \varepsilon_s < 1$ such that a message transmitted by v is received at a node u in a round with the set of transmitters $\mathcal{T}$ if $\mathrm{SINR}(v, u, \mathcal{T}) \geq \beta$ and $\mathrm{dist}(v, u) \leq (1 - \varepsilon_s)r$.

The setting with $\varepsilon_s = 0$ is called the model with *strong sensitivity*, and $\varepsilon_s > 0$ defines the model with *weak sensitivity*.

Connectivity. In order to determine which nodes are connected in a network, the notion of a *communication graph* is introduced. To this aim, the *connectivity parameter* ε_c is introduced such that $1 > \varepsilon_c \geq \varepsilon_s \geq 0$. An edge (u, v) appears in the communication graph iff $\mathrm{dist}(u, v) \leq (1 - \varepsilon_c)r$. The setting with $\varepsilon_s = \varepsilon_c$ is called the model with *weak connectivity*, and the inequality $\varepsilon_s < \varepsilon_c$ defines the model with *strong connectivity*.

Time complexity of a randomized broadcasting algorithm is the number of rounds after which, for all communication networks defined by given SINR parameters α, β, and $\mathcal{N}$, and the parameters ε_s, ε_c, the source message is delivered to all nodes accessible from the source node in the communication graph with high probability (whp), i.e., with the probability at least $1 - 1/n$, where n is the number of nodes in the network.

Key Results

Complexity of the broadcasting problem significantly differs in various models obtained by constraints imposed on the sensitivity and connectivity parameters.

The Model with Strong Sensitivity and Strong Connectivity

In this setting reception of messages is determined merely by Eq. (1), and the communication graph does not contain links of distance close to r due to $\varepsilon_c > 0$.

Theorem 1 ([3]) *The broadcasting problem can be solved in time* $O\left(D \log n + \log^2 n\right)$ *with high probability in the model with strong connectivity and strong sensitivity for networks in Euclidean two-dimensional space with known coordinates.*

For the setting that nodes do not know their coordinates, Daum et al. [2] provided a broadcasting algorithm which relies on a parameter R_s equal to the maximum ratio among distances between pairs of nodes connected by an edge in the communication graph. That is, $R_s = \max\{\mathrm{dist}(u, v)/\mathrm{dist}(x, y) \mid (u, v), (x, y) \in E\}$, where $G(V, E)$ is the communication graph of a network.

Theorem 2 ([2]) *The broadcasting problem can be solved in time* $O\left(D \log n \log^{\alpha+1} R_s\right)$ *with high probability in the model with strong connectivity and strong sensitivity.*

As R_s might be even exponential with respect to n, the solution from Theorem 2 is inefficient for some networks. The following theorem gives a

solution independent of geometric properties of a network.

Theorem 3 ([6]) *The broadcasting problem can be solved in time* $O\left(D\log^2 n\right)$ *with high probability in the model with strong sensitivity and strong connectivity.*

The Model with Strong Sensitivity and Weak Connectivity

In this setting reception of messages is determined merely by Eq. (1), and an edge (u, v) belongs to the communication graph iff $\mathrm{SINR}(u, v, \emptyset) \geq \beta$.

Theorem 4 ([2]) *There exist families of networks with diameter* 2 *in the model with strong sensitivity and weak connectivity in which each broadcasting algorithm requires* $\Omega(n)$ *rounds to accomplish broadcast.*

Theorem 5 ([2]) *The broadcasting problem can be solved in time* $O(n\log^2 n)$ *with high probability in the model with strong sensitivity and weak connectivity.*

The Model with Weak Sensitivity and Strong Connectivity

In this setting, transmissions on unreliable links (i.e., on distance very close to r) are "filtered out." Moreover, the communication graph connects only nodes in distance at most $(1-\varepsilon_c)r$, which is strictly smaller than r.

Theorem 6 ([7]) *The broadcasting problem can be solved in time* $O\left(D+\log^2 n\right)$ *with high probability in the model with weak sensitivity and strong connectivity for networks deployed on the Euclidean plane, provided* $0 < \varepsilon_s < \varepsilon_c = 2/3$. *This solution works in the model with* ***spontaneous wake-up*** *and requires* ***power control mechanism****.*

When applied directly to the case of non-spontaneous wake-up, the algorithm from [7] gives time bound $O\left(D\log^2 n\right)$.

Corollary 1 *The broadcasting problem can be solved in time* $O\left(D\log^2 n\right)$ *with high probability in the model with weak sensitivity and strong connectivity for networks deployed on the Euclidean plane, provided* $0 < \varepsilon_s < \varepsilon_c = 2/3$. *This solution works in the model with* ***non-spontaneous wake-up*** *and requires* ***power control mechanism****.*

The Model with Weak Sensitivity and Weak Connectivity

In this setting, the maximal distances for a successful transmission and for connecting nodes by an edge are equal and both smaller than the largest theoretically possible range r following from Eq. (1).

Theorem 7 ([5]) *There exist (i) an infinite family of* n*-node networks requiring* $\Omega(n\log n)$ *rounds to accomplish broadcast whp and, (ii) for every* $D, \Delta = O(n)$*, an infinite family of* n*-node networks of diameter* D *and maximum degree of the communication graph* Δ *requiring* $\Omega(D\Delta)$ *rounds to accomplish broadcast whp in the model with weak sensitivity and weak connectivity (i.e.,* $0 < \varepsilon_s = \varepsilon_c < 1$*) for networks on the plane.*

Using appropriate combinatorial structures, deterministic broadcasting algorithms were obtained with complexities close to the above lower bounds, provided nodes know their coordinates.

Theorem 8 ([5]) *The broadcasting problem can be solved deterministically in time* $O\left(\min\left\{D\Delta\log^2 N, n\log N\right\}\right)$ *in the model with weak sensitivity and weak connectivity (i.e.,* $0 < \varepsilon_s = \varepsilon_c < 1$*) for networks in Euclidean two-dimensional space with known coordinates, with IDs in the range* $[1, N]$.

The above result translates to a randomized algorithm with complexity $O\left(\min\left\{D\Delta\log^2 n, n\log n\right\}\right)$, since nodes can choose unique IDs in the polynomial range with high probability.

Recently, Chlebus et al. [1] provided a randomized algorithm for the setting without knowledge of coordinates.

Theorem 9 ([1]) *The broadcasting problem can be solved in time* $O\left(n\log^2 n\right)$ *with high probability in the model with weak sensitivity and weak connectivity.*

Distributed Randomized Broadcasting in Wireless Networks under the SINR Model, Table 1 Complexity of randomized broadcasting with non-spontaneous wake-up for various sensitivity and connectivity settings. The result from [7] marked with $\star$ requires power control mechanism and $\varepsilon_c = 2/3$. The positive results requiring knowledge of coordinates apply only to the Euclidean space

	Coordinates	Strong connectivity: $\varepsilon_c > \varepsilon_s$	Weak connectivity: $\varepsilon_c = \varepsilon_s$
Strong sensitivity: $\varepsilon_s = 0$	Known	$O\left(D \log n + \log^2 n\right)$	$\Omega(n)$
	Unknown	$O\left(D \log^2 n\right), O\left(D \log n \log^{\alpha+1} R_s\right)$	$O\left(n \log^2 n\right)$
Weak sensitivity: $\varepsilon_s > 0$	Known		$\Omega\left(\min\{D\Delta, n\}\right)$ $O\left(\min\left\{D\Delta \log^2 n, n \log n\right\}\right)$
	Unknown	$O\left(D \log^2 n\right)$ $\star$	$O\left(n \log^2 n\right)$

Applications

Using similar techniques to those in [5], an efficient deterministic broadcasting algorithm was obtained in the model with strong connectivity and strong sensitivity.

Theorem 10 ([4]) *The broadcasting problem can be solved deterministically in time* $O\left(D \log^2 N\right)$ *in the model with strong connectivity and strong sensitivity for networks in Euclidean two-dimensional space with known coordinates, with IDs in the range* $[1, N]$.

The solution in [7] applies to a more general problem of multi-broadcast and was further generalized in [8] to the setting in which nodes wake up in various time steps.

Positive results from [1, 2, 6] work also in a more general setting when nodes are deployed in a bounded-growth metric space.

Open Problems

In all considered models, there is at least $\log n$ gap between the established lower and upper bounds for the complexity of broadcasting. A natural open problem is to tighten these bounds.

As seen in Table 1, it is not known whether the complexity of broadcasting depends on sensitivity for each connectivity setting.

Another interesting research direction is to explore the impact of additional features such as power control or carrier sensing on the complexity of the problem.

Preliminary Remark

The presentation of this entry of the Encyclopedia follows Chapter 6 of [15], to which it borrows the presentation style and all figures. The reader interested on this topic will find developments in [15].

The Notion of a Global State

Modeling the Execution of a Process: The Event Point of View

A distributed computation involving n asynchronous sequential processes $p_1, \ldots, p_n$, communicating by directed channels (hence, a directional channel can be represented by two directed channels). Channels can be FIFO (first in first out) or non-FIFO.

A distributed computation can be modeled by a (reflexive) partial order on the events produced by the processes. An event corresponds to the sending of a message, the reception of a message, or a nonempty sequence of operations which does not involve the sending or the reception of a message. This partial order, due to Lamport and called *happened before* relation [12], is defined as follows. Let e_1 and e_2 be two events; $e_1 \xrightarrow{ev} e_2$ is the smallest order relation such that:

- Process order: e_1 and e_2 are the same event or have been produced by the same process, and e_1 was produced before e_2.
- Message order: e_1 is the sending of a message m and e_2 is its reception.
- Transitive closure: There is an event e such that $e_1 \xrightarrow{ev} e \wedge e \xrightarrow{ev} e_2$.

Modeling the Execution of a Process: The Local State Point of View

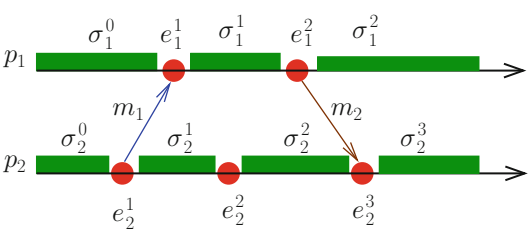
Let us consider a process p_i, which starts in the initial state σ_i^0. Let e_i^x be its xth event. The transition function $\delta_i()$ associated with p_i is consequently such that $\sigma_i^x = \delta_i(\sigma_i^x, e_i^x)$, where $x \geq 1$.

While a distributed computation can be modeled the partial order $\xrightarrow{ev}$ ("action" point of view), it follows from the previous definition that it can also be modeled by a partial order on its local states ("state" point of view). This partial order, denoted $\xrightarrow{\sigma}$, is defined as follows: $\sigma_i^x \xrightarrow{\sigma} \sigma_j^y \stackrel{\text{def}}{=} e_i^{x+1} \xrightarrow{ev} e_j^y$.

A two-process distributed execution is described in Fig. 1. The relation $\xrightarrow{ev}$ on event and the relation $\xrightarrow{\sigma}$ on local states can be easily extracted from it. As an example, we have $e_1^1 \xrightarrow{ev} e_2^3$ and $\sigma_2^0 \xrightarrow{\sigma} \sigma_1^2$. Two local states σ and σ' which are not related by $\xrightarrow{\sigma}$ are independent. This is denoted $\sigma || \sigma'$.

Orphan and In-Transit Messages

Let us consider an ordered pair of local states $\langle \sigma_i, \sigma_j \rangle$ from different processes p_i and p_j and a message m sent by p_i to p_j.



Distributed Snapshots, Fig. 1 A two-process distributed execution

- If m is sent by p_i after σ_i and received by p_j before σ_j, this message is *orphan* with respect to $\langle \sigma_i, \sigma_j \rangle$. This means that m is received and not sent with respect to the ordered pair $\langle \sigma_i, \sigma_j \rangle$.
- If m is sent by p_i before σ_i and received by p_j after σ_j, this message is *in-transit* with respect to $\langle \sigma_i, \sigma_j \rangle$. This means that m is sent and not yet received with respect to the ordered pair $\langle \sigma_i, \sigma_j \rangle$.

As an example, the message m_1 is orphan with respect to the ordered pair $\langle \sigma_2^0, \sigma_1^1 \rangle$, while the message m_2 is in-transit with respect to the ordered pair $\langle \sigma_1^2, \sigma_2^1 \rangle$.

Consistent Global State

A *global state* is a vector of n local states (one per process), plus a set of channel states (one per directed channel). The state of a channel is a sequence of messages if the channel is FIFO or a set of messages if the channel is non-FIFO.

A *consistent global state* (also called *snapshot*) is a global state in which the computation has passed or could have passed. More formally, a global state is a pair (Σ, M) where the vector of local states $\Sigma = [\sigma_1, \ldots, \sigma_n]$ and the set of channel states $M = \cup_{\{(i,j)\}} cs(i,j)$ are such that for any directed pair (i, j) we have:

- $\sigma_i || \sigma_j$. (This means that there is no orphan message with respect to the ordered pair $\langle \sigma_i, \sigma_j \rangle$.)
- $cs(i, j)$ contains all the messages which are in transit with respect to the ordered pair $\langle \sigma_i, \sigma_j \rangle$ and only them. (This means that $cs(i, j)$ contains all the messages (and only them) sent by p_i before σ_i and not yet received by p_j when it enters σ_j.)

As an example, when looking at Fig. 1, $\big([\sigma_1^2, \sigma_2^1], \{cs(1,2) = m_2,\ cs(2,1) = \emptyset\}\big)$ is a consistent global state, while both $\big([\sigma_1^1, \sigma_2^0], \{cs(1,2) = \ldots,\ cs(2,1) = \ldots\}\big)$ and $\big([\sigma_1^0, \sigma_2^2], \{cs(1,2) = \emptyset,\ cs(2,1) = \emptyset\}\big)$ are not consistent (the first because, as the message m_1 is orphan with respect to the ordered pair $\langle \sigma_1^1, \sigma_2^0 \rangle$, we do not have $\sigma_1^1 || \sigma_2^0$; the second because the message m_1 does not belong to the channel state $cs(2, 1)$.).

The Lattice of Global States

Let us consider a vector of local states $\Sigma = [\sigma_1, \ldots, \sigma_n]$ belonging to a consistent global state. The consistent global state, where $\Sigma' = [\sigma'_1, \ldots, \sigma'_n]$, is directly reachable from Σ if there is a process p_i whose next event e_i, and we have $\forall\ j \neq j :\ \sigma'_j = \sigma_j$ and $\sigma_i = \delta_i(\sigma_i, e_i)$. This is denoted $\Sigma \xrightarrow{GS} \Sigma'$. By definition $\Sigma \xrightarrow{GS} \Sigma$. More generally, $\Sigma \xrightarrow{GS} \Sigma_a \xrightarrow{GS} \Sigma_b \cdots \Sigma_y \xrightarrow{GS} \Sigma_z$ is denoted $\Sigma \xrightarrow{GS^*} \Sigma_z$.

It can be shown that the set of all the vectors Σ associated with the consistent global states produced by a distributed computation is a lattice [3, 16]. The lattice obtained from the computation of Fig. 1 is described in Fig. 2. In this lattice, the notation $\Sigma = [a, b]$ means $\Sigma = [\sigma_1^a, \sigma_2^b]$.

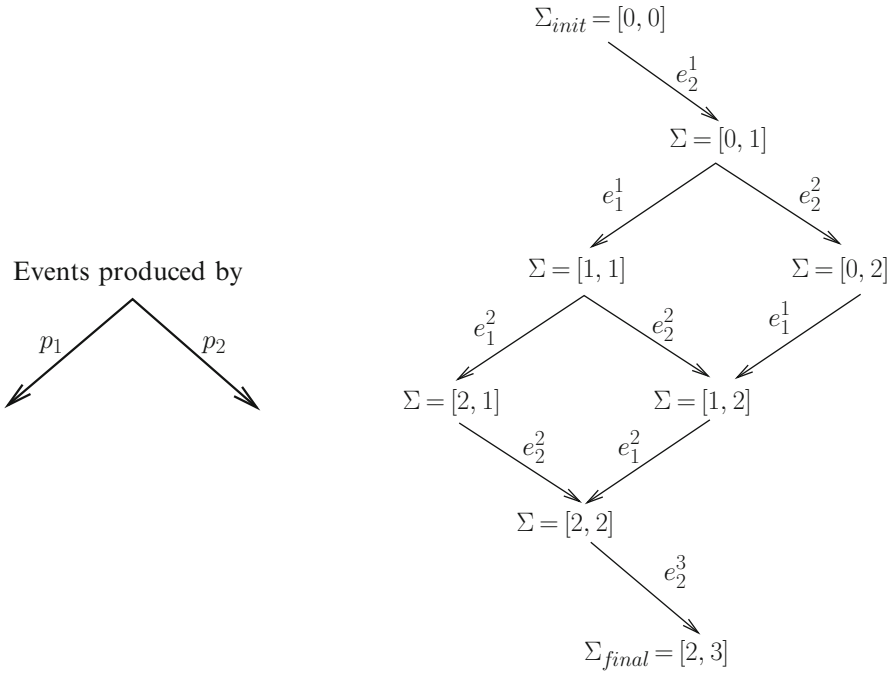
Problem Definition

Specification of the Computation of a Consistent Global State

The problem to determine on-the-fly a consistent global state (in short CGS) was introduced, precisely defined, and solved by Chandy and Lamport in 1985 [2]. It can be defined by the following properties. The first is liveness property, while the last two are safety properties.

- Termination. If one or more processes launch the computation of a consistent global state, then this global state computation terminates.
- Consistency. If a global state is computed, then it is consistent.
- Validity. Let Σ_{start} be the global state of the computation when CGS starts, Σ_{end} be its global state when CGS terminates, and Σ be the global state returned by CGS. We have $\Sigma_{\text{start}} \xrightarrow{GS^*} \Sigma$ and $\Sigma \xrightarrow{GS^*} \Sigma_{\text{end}}$.

The validity property states that the global state which is returned depends on the time at



Distributed Snapshots, Fig. 2 The lattice associated with the computation of Fig. 2

which its computation is launched. Without this property, returning always the initial global state would be a correct solution.

Principles of CGS Algorithms

To compute a consistent global state, each process p_i is in charge of (a) recording a copy of its local state σ_i (sometimes called its local snapshot) and (b) the states of its input (or output) channels. In order that the computed global state satisfies the safety properties, in one way or another, all CGS algorithms have two things to do.

- Synchronization. In order to ensure that there is no orphan messages with respect to each ordered pair of local states $\langle \sigma_i, \sigma_j \rangle$, such that there is a directed channel from p_i to p_j, the processes must synchronize the recording of their local states which will define the consistent global state that is computed.
- Message recording. Each process has to record all the messages it receives (or messages it sends) which are in transit with respect to the computed global state.

Key Result 1: Chandy-Lamport's Algorithm

Chandy and Lamport 's algorithm is denoted CL85 in the following.

Assumption

CL85 considers a failure-free asynchronous system. Asynchronous means that each process proceeds to its speed which can vary arbitrarily with time and remains always unknown to the other processes. Message transfer delays also are arbitrary (but finite).

CL85 assumes that the processes are connected by a directed communication graph, which is strongly connected (there is a directed path from any process to any other process). Each process has consequently a nonempty set of input channels and a nonempty set of output

channels. Moreover, each directed channel is a FIFO channel.

The Algorithm in Two Rules

CL85 requires that each process computes the state of its input channels. At a high abstraction level, it can formulated with two rules.

- "Local state recording" rule. When a process p_i records its local state σ_i, it sends a special control message (called *marker*) on each of its outgoing channels.

  It is important to notice that as channels are FIFO, a marker partitions the messages sent on a channel in two sets: the messages sent before the marker and the messages sent after the marker.
- "Input channel state recording" rule. When a process p_i receives a marker on one of its input channels $c(j,i)$, there are two cases.
  - If not yet done, it records its local state (i.e., it applies the first rule) and defines $cs(j,i)$ (the state of the input channel $c(j,i)$) as the empty sequence.
  - If it has already recorded its local state (i.e., executed the first rule), p_i defines $cs(j,i)$ as the sequence of application messages received on $c(j,i)$ between the recording of its local state and the reception of the marker on this input channel.

Properties of the Computed Global State

If one or more processes execute the first rule, it follows from this rule, and the fact that the communication graph is strongly connected, all the processes will execute this rule. Hence, a marker is sent on each directed channel, and each process records the state of its input channels. This proves the liveness property.

The consistency property follows from the following simple observation. Let us color processes and messages as follows. A process is initially green and becomes red when it sends a marker on each of its output channels. Moreover, a message has the color of its sender at the time the message is sent.

It is easy to see that the previous two rules guarantee that a green process turns red before receiving a red message (hence, there is no orphan messages). Moreover, the green messages received on a channel $c(j,i)$ by a red process p_i are the messages that are in transit with respect to the ordered pair $\langle \sigma_j, \sigma_i \rangle$. Hence, all the *in-transit* messages are recorded and only them.

The Inherent Uncertainty on the Computed Global State

The proof of the validity property is a little bit more involved. The interested reader will consult [2, 15]. When looking at the lattice of Fig. 2, let us consider that the CL85 algorithm is launched when the observed computation is in the global state $\Sigma_{\text{start}} = [0,1]$ and terminates when it is in the global state $\Sigma_{\text{end}} = [2,2]$. The consistency property states that the global state Σ which is returned is one of the following global states: $[0,1]$, $[1,1]$, $[0,2]$, $[2,1]$, $[1,2]$, or $[2,2]$.

This uncertainty on the computed global state is intrinsic to the nature of distributed computing. (Eliminate would require to freeze the execution of the application we are observing, which in some sense forces it to execute sequentially.)

The main property of the consistent global state Σ that is computed is that the application has passed through it or could have passed through it. While an external omniscient observer can know if the application passed or not through Σ, no process can know it. This noteworthy feature characterizes the relativistic nature of the observation of distributed computations.

Message-Passing Snapshot Versus Shared Memory Snapshot

The notion of a shared memory snapshot has been introduced in [1]. A snapshot object is an object that consists of an array of atomic multi-reader/single-write atomic registers, one per process (a process can read any register but can write only the register it is associated with). A snapshot object provides the processes with two operations denoted update() and snapshot(). The update() operation allows the invoking process to store a new value in its register, while the snapshot() operation allows it to obtain the values of all the atomic read/write registers as if that operation was executed instantaneously.

More precisely, the invocations of the operations update() and snapshot() are linearizable [8].

Differently from the snapshot values returned in a message-passing system (whose global structure is a lattice), the arrays of values returned by the snapshot() operations of a shared memory system can be totally ordered. This is a fundamental difference, which is related to the communication medium. In one case, the underlying shared memory is a centralized component, while in the second case, the underlying message-passing system is inherently distributed, making impossible to totally order all the message-passing snapshots.

Other Assumptions and Algorithms

Algorithms that compute consistent global states in systems equipped with non-FIFO channels have been designed. Such algorithms are described in [11, 13, 15].

A communication-induced (CI) algorithm is a distributed algorithm that does not use additional control messages (such as markers). In these algorithms, control information (if needed) has to be carried by application messages. CI algorithms that compute consistent global states have been investigated in [6].

Global states computation in large-scale distributed systems is addressed in [9].

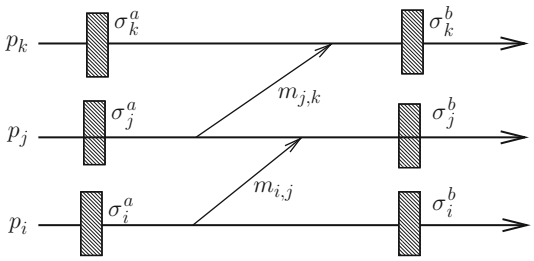
Key Result 2: A Necessary and Sufficient Condition

The Issue

An important question is the following one: Given a set of x, $1 \leq x \leq n$, local states from different processes do these local states belong to a consistent global state?

If $x = n$, the answer is easy: any ordered pair of local states $\langle \sigma_i, \sigma_j \rangle$ has to be such that $\sigma_i || \sigma_j$ (none of them causally depends on the other). Hence, the question is interesting when $1 \leq x < n$. This problem was addressed and solved by Netzer and Xu [14] and generalized in [7].

As a simple example, let us consider the execution in Fig. 3, where there are three processes p_i, p_j, and p_k that have recorded the local states



Distributed Snapshots, Fig. 3 A simple zigzag path

σ_x^a and σ_x^b, where $x \in \{i, j, k\}$. These local states produced by the computation are the only local states which have been recorded. Said another way, these recorded local states can be seen as local checkpoints.

An instance of the previous question is the following one: can the set $\{\sigma_i^a, \sigma_k^b\}$ be extended by the addition of a recorded local state σ_j of p_j (i.e., $\sigma_j = \sigma_j^a$ or $\sigma_j = \sigma_j^b$) such that the resulting global state $\Sigma = [\sigma_i^a, \sigma_j, \sigma_k^b]$ is a consistent?

It is easy to see that, despite the fact that the local states σ_i^a and σ_k^b are independent ($\sigma_i^a || \sigma_k^b$), neither $[\sigma_i^a, \sigma_j^a, \sigma_k^b]$ nor $[\sigma_i^a, \sigma_j^b, \sigma_k^b]$ is consistent. More precisely, $[\sigma_i^a, \sigma_j^a, \sigma_k^b]$ is not consistent because, due the message $m_{j,k}$, the local states σ_j^a and σ_k^b are not independent, while $[\sigma_i^a, \sigma_j^b, \sigma_k^b]$ is not consistent because, due the message $m_{i,j}$, σ_i^a and σ_j^b are not independent.

The Result

The notion of a *zigzag* path has been introduced by Netzer and Xu in [14]. An example of a simple zigzag path is the sequence of messages $\langle m_{i,j}, m_{j,k} \rangle$ of Fig. 3, where we see that the local states σ_i^a and σ_k^b are related by this zigzag path. A zigzag path captures hidden dependencies linking recorded local states. These dependencies are hidden in the sense that not all of them can be captured by the relation $\xrightarrow{\sigma}$ defined on local states (as shown in the figure).

The main result due to Netzer and Xu [14] is the following: a set x local states, with $1 \leq x < n$ and at most one local state per process, can be extended to a consistent global state if and only if no two of them are related by a zigzag path. This result has been extended in [7].

Applications: Global Snapshots in Action

Distributed snapshots are a key element to understand and master the uncertainty created by asynchrony. From a practical point of view, they are important in distributed checkpointing, in the detection of stable properties defined on the set of global states, and in the debugging of distributed programs.

Detection of Stable Properties

A stable property is a property that, one true, remains true forever. In the distributed context, examples of distributed stable properties are deadlock (once deadlocked, an application remains forever deadlocked), termination (once terminated, an application remains forever terminated) [4, 5], object inaccessibility, etc.

Algorithms that compute consistent global states satisfying the liveness, consistency, and validity properties previously stated can be used to detect stable properties. This follows from the observation that if the computed global state Σ satisfies a stable property P, then the global state Σ_{end} also satisfies P.

Checkpointing

A checkpoint is a global state from which a computation can be resumed. Trivially, checkpointing and consistent global states computation are problems which are very close [7]. The interested reader can consult [10, 15] for more details.

Distributed computation; Vertex coloring

Years and Authors of Summarized Original Work

2004; Finocchi, Panconesi, Silvestri

Problem Definition

The *vertex coloring problem* takes as input an undirected graph $G := (V, E)$ and computes a *vertex coloring*, i.e., a function, $c : V \to [k]$ for some positive integer k such that adjacent vertices are assigned different colors (that is, $c(u) \neq c(v)$ for all $(u, v) \in E$). In the $(\Delta + 1)$ vertex coloring problem, k is set equal to $\Delta + 1$ where Δ is the maximum degree of the input graph G. In general, $(\Delta + 1)$ colors could be necessary as the example of a clique shows. However, if the graph satisfies certain properties, it may be possible to find colorings with far fewer colors. Finding the minimum number of colors possible is a computationally hard problem: the corresponding decision problems are NP-complete [5]. In Brooks–Vizing colorings, the goal is to try to find colorings that are near optimal.

In this paper, the model of computation used is the synchronous, message passing framework as used in standard distributed computing [11]. The goal is then to describe very simple algorithms that can be implemented easily in this distributed model that simultaneously are *efficient* as measured by the number of rounds required and have good performance *quality* as measured by the number of colors used. For efficiency, the number of rounds is require to be poly-logarithmic in n, the number of vertices in the graph and for performance quality, the number of colors used is should be near-optimal.

Key Results

Key theoretical results related to distributed $(\Delta + 1)$-vertex coloring are due to Luby [9] and Johansson [7]. Both show how to compute a $(\Delta + 1)$-coloring in $O(\log n)$ rounds with high probability. For Brooks–Vizing colorings, Kim [8] showed that if the graph is square or triangle free, then it is possible to color it with $O(\Delta / \log \Delta)$ colors. If, moreover, the graph is regular of sufficiently high degree ($\Delta \gg \log n$), then Grable and Panconesi [6] show how to color it with $O(\Delta / \log \Delta)$ colors in $O(\log n)$ rounds. See [10] for a comprehensive discussion of probabilistic techniques to achieve such colorings.

The present paper makes a comprehensive experimental analysis of distributed vertex coloring algorithms of the kind analyzed in these papers on various classes of graphs. The results are reported in section "Experimental Results" below and the data sets used are described in section "Data Sets."

Applications

Vertex coloring is a basic primitive in many applications: classical applications are *scheduling problems* involving a number of pairwise restrictions on which jobs can be done simultaneously. For instance, in attempting to schedule classes at a university, two courses taught by the same faculty member cannot be scheduled for the same time slot. Similarly, two course that are required by the same group of students also should not conflict. The problem of determining the minimum number of time slots needed subject to these restrictions can be cast as a vertex coloring problem. One very active application for vertex coloring is *register allocation*. The register allocation problem is to assign variables to a limited number of hardware registers during program execution. Variables in registers can be accessed much quicker than those not in registers. Typically, however, there are far more variables than registers so it is necessary to assign multiple variables to registers. Variables conflict with each other if one is used both before and after the other within a short period of time (for instance, within a subroutine). The goal is to assign variables that do not conflict so as to minimize the use of non-register memory. A simple approach to this is to create a graph where the nodes represent variables and an edge represents conflict between its nodes. A coloring is then a conflict-free

assignment. If the number of colors used is less than the number of registers then a conflict-free register assignment is possible. Modern applications include *assigning frequencies* to mobile radios and other users of the electro-magnetic spectrum. In the simplest case, two customers that are sufficiently close must be assigned different frequencies, while those that are distant can share frequencies. The problem of minimizing the number of frequencies is then a vertex coloring problem. For more applications and references, see Michael Trick's coloring page [12].

Open Problems

The experimental analysis shows convincingly and rather surprisingly that the simplest, trivial, version of the algorithm actually performs best uniformly! In particular, it significantly outperforms the algorithms which have been analyzed rigorously. The authors give some heuristic recurrences that describe the performance of the trivial algorithm. It is a challenging and interesting open problem to give a rigorous justification of these recurrences. Alternatively, and less appealing, a rigorous argument that shows that the trivial algorithm dominates the ones analyzed by Luby and Johansson is called for. Other issues about how local structure of the graph impacts on the performance of such algorithms (which is hinted at in the paper) is worth subjecting to further experimental and theoretical analysis.

Experimental Results

All the algorithms analyzed start by assigning an initial *palette* of colors to each vertex, and then repeating the following simple iteration round:

1. *Wake up!*: Each vertex independently of the others wakes up with a certain probability to participate in the coloring in this round.
2. *Try!*: Each vertex independently of the others, selects a tentative color from its palette of colors at this round.
3. *Resolve conflicts!*: If no neighbor of a vertex selects the same tentative color, then this color becomes final. Such a vertex exits the algorithm, and the remaining vertices update their palettes accordingly. If there is a conflict, then it is resolved in one of two ways: Either all conflicting vertices are deemed unsuccessful and proceed to the next round, or an independent set is computed, using the so-called Hungarian heuristic, amongst all the vertices that chose the same color. The vertices in the independent set receive their final colors and exit. The Hungarian heuristic for independent set is to consider the vertices in random order, deleting all neighbors of an encountered vertex which itself is added to the independent set, see [1, p. 91] for a cute analysis of this heuristic to prove Turan's Theorem.
4. *Feed the Hungry!*: If a vertex runs out of colors in its palette, then fresh new colors are given to it.

Several parameters can be varied in this basic scheme: the wake up probability, the conflict resolution and the size of the initial palette are the most important ones.

In $(\Delta + 1)$-coloring, the initial palette for a vertex v is set to $[\Delta] := \{1, \cdots, \Delta + 1\}$ (global setting) or $[d(v) + 1]$ (where $d(v)$ is the degree of vertex v) (local setting). The experimental results indicate that (a) the best wake-up probability is 1, (b) the local palette version is as good as the global one in running time, but can achieve significant color savings and (c) the Hungarian heuristic can be used with vertex identities rather than random numbers giving good results.

In the Brooks–Vizing colorings, the initial palette is set to $[d(v)/s]$ where s is a *shrinking factor*. The experimental results indicate that uniformly, the best algorithm is the one where the wake-up probability is 1, and conflicts are resolved by the Hungarian heuristic. This is both with respect to the running time, as well as the number of colors used. Realistically useful values of s are between 4 and 6 resulting in Δ/s-colorings. The running time performance is excellent, with even graphs with a thousand vertices colored within 20–30 rounds. When compared to

the best sequential algorithms, these algorithms use between twice or thrice as many colors, but are much faster.

Data Sets

Test data was both generated synthetically using various random graph models, and benchmark real life test sets from the second DIMACS implementation challenge [3] and Joe Culberson's web-site [2] were also used.

Problem Definition

Indexing data so that it can be easily searched is one of the most fundamental problems in computer science. Especially in the fields of databases and information retrieval, indexing is at the heart of query processing. One of the most popular indexes, used by all search engines, is the inverted index. However, in many cases like bioinformatics, eastern language texts, and phrase queries for Web, one may not be able to assume word demarcations. In such cases, these documents are to be seen as a string of characters. Thus, more sophisticated solutions are required for these string documents.

Formally, we are given a collection of D documents $\mathcal{D} = \{d_1, d_2, d_3, \ldots, d_D\}$. Each document d_i is a string drawn from the character set Σ of size σ and the total number of characters across all the documents is n. Our task is to preprocess this collection and build a data structure so that queries can be answered as quickly as possible. The query consists of a pattern string P, of length p, drawn from Σ. As the answer to the query, we are supposed output all the documents d_i in which this pattern P occurs as a substring. This

is called the *document listing* problem. In a more advanced top-k version, the query consists of a tuple (P, k) where k is an integer. Now, we are supposed to output only the k most *relevant* documents. This is called the *top-k document retrieval* problem.

The notion of relevance is captured by a *score function*. The function score(P, d) denotes the score of the document d with respect to the pattern P. It can be the number of times P occurs in d, known as *term frequency*, or the distance between two closest occurrences of P in d, or any other function. Here, we will assume that score(P, d) is solely dependent on the set of occurrences of P in d and is known at the time of construction of the data structure.

Key Results

The first formal study of this problem was initiated by Muthukrishnan [4]. He took the approach of augmenting the generalized suffix tree with additional information. All subsequent works have used generalized suffix trees as their starting point. A generalized suffix tree GST is a compact trie of all the lexicographically sorted suffixes of all the documents. Thus, n total suffixes are stored and there are n leaves in this trie. Each edge in GST is labeled with a string and each root to leaf path (labels concatenated) represents some suffix of some document. The overall number of nodes in GST is $O(n)$. With each leaf, we associate a document id, which indicates the document to which that particular suffix belongs.

When the pattern P comes as a query, we first traverse from the root downward and find a vertex, which is known as locus(P). This can be done in $O(p)$ time. This is the first vertex below the edge where P finished in the root to leaf traversal. If v is locus(P) then all the leaves in the subtree of v represent the suffixes whose prefix is P. For any vertex v, let path(v) be the string obtained by concatenating all the labels from the root until v.

Document Listing Problem

Let us first see how the document listing problem is solved. One easy solution is to reach the locus v of P and then visit all the leaves in the subtree of v. But this is costly as the number of leaves `occ` may be much more than number of unique document labels `ndoc` among these leaves. Optimally, we want to achieve $O(p + \texttt{ndoc})$ time.

To overcome this issue, Muthukrishnan first proposed to use a document array D_A. To construct this, he traverses all the leaves in GST from left-to-right and takes the corresponding document id. Thus, $D_A[i]$ = document id of ith lexicographically smallest suffix in GST. It is easy to find boundary points sp and ep such that the subtree of locus v corresponds to entries form $D_A[sp, \ldots, ep]$. To uniquely find documents in $D_A[sp, \ldots ep]$, we must not traverse the entire subarray as this would cost us O(`occ`). To avoid this, we construct another array C called a chain array. $C[i] = j$, where $j < i$ is the largest index for which $D_A[i] = D_A[j]$. If no such j exists then $C[i] = -1$. Thus, every document entry $D_A[i]$ links to the previous entry with the same document id. Now, to solve the document listing problem, one needs to get all the i's such that $sp \leq i \leq ep$ and $C[i] < sp$. The second constraint guarantees that every document is output only once. Muthukrishnan shows how to repeatedly apply range minimum queries (RMQ) to achieve constant time per output id.

Theorem 1 ([4]) *Given a collection of documents of total length n, we can construct a data structure taking $O(n)$ space, such that document listing queries for pattern P can be answered in optimal $O(p + \texttt{ndoc})$ time.*

Top-*k* Document Retrieval

Hon et al. [3] brought in an additional constraint of *score function* which can capture various notions of relevance like frequency and proximity. Instead of reporting all the documents, we only care to output the k highest scoring documents, as these would be the most relevant. Thus, $O(p + \texttt{ndoc})$ time is not optimal. We briefly describe their solution.

Let ST_d denote a suffix tree only for suffixes of document d. They augment the GST with *Links*. Link L is a 4-tuple: origin_node o, target_node t, document_id d, score_value s.

Essentially, $(L.o,\ L.t,\ L.d,\ L.s)$ is a link if and only if (t', o') is an edge in the suffix tree ST_d of the document d. Here, t' is the node in ST_d for which $\text{path}(t') = \text{path}(L.t)$. Similarly, $\text{path}(o') = \text{path}(L.o)$. The score value of the link $L.s = \text{score}(\text{path}(o'), d)$. For $L.o$ and $L.t$, we use the preorder-id of those nodes in the GST. The total number of link entries is the same as the sum of number of edges in each individual suffix tree of all the documents, which is $O(n)$. They store these links in an array $\mathcal{L}$, sorted by target. In case of a tie among targets, we sort them further by their origin values.

When they execute the query (P, k), they first find the locus node v in GST. Now, the task is to find the top-k highest scoring documents within the subtree of v. Because the links are essentially edges in individual suffix trees, for any document d_i, there is at most one link whose origin o is within the subtree of v and whose target t is outside the subtree. Moreover, note that if the target t is outside the subtree then it must be one of the ancestors of v. The score of this link is exactly the $\text{score}(P, d_i)$. Then the query is: Among all the links, whose origin starts within the subtree of locus v and whose target is outside the subtree of v, find the top-k highest scoring links. The documents are to be output in sorted order of score values. Let f_v be the preorder value of v and l_v be the preorder value of the last node in the subtree of v, then any qualifying link L would satisfy $f_v \leq L.o \leq l_v$ and $L.t \leq f_v$. And then, among all such links, only get k with the highest scores.

Their main idea is that one needs to look for at most p different target values – one for each ancestor of v. In the sorted array $\mathcal{L}$, these links come as at most p different subarray chunks. Moreover, within every target value the links originating from the subtree of v also come contiguously. Let $(l_1, r_1), (l_2, r_2), \ldots, (l_g, r_g)$ with $g < p$ be the intervals of the array $\mathcal{L}$ in which any link L satisfies $f_v \leq L.o \leq l_v$ and $L.t \leq f_v$. We skip here the description of how these intervals are found in $O(p)$ time. Now, the task is to get top-k highest ranking links from these intervals. For this, they construct a Range Maximum Query (RMQ) structure on score values of $\mathcal{L}$. They apply RMQs over each interval and put these values in a heap. Then they do extract-min from the heap, which at most maintains $O(k)$ elements. If they output an element from (l_a, r_a), the next greatest element from the same interval is put in the heap. They stop when the heap outputs k links. This takes $O(p + k \log k)$ time.

Theorem 2 ([3]) *Given a collection of documents of total length n, we can construct a data structure taking $O(n)$ space, such that top-k document retrieval queries (P, k) can be answered in $O(p + k \log k)$ time.*

Navarro and Nekrich [5] further improved the time to optimal $O(p + k)$. To achieve this, they first change the target attribute of the link to target_depth td. They model the links as two dimensional points (x_i, y_i) with weights w_i as the score. They maintain a global array of these points sorted by their x-coordinates, which are the preorders of origins of the links, while y stands for target_depth. If h is the depth of locus v and v spans the preorders $[a, b]$, then their query is to obtain points in $[a, b] \times [0, h]$ with top-k highest weights. First, they make a basic unit structure for $m \leq n$ points and answer these queries in $O(m^f + k)$ time. Here, $0 < f < 1$ is a constant. This is done by partitioning points by weights. Within each partition, the weights are disregarded. Then they start executing query $Q = [a, b] \times [0, h]$ from the highest partition. If less than $k' < k$ points qualify, then they output these points, change k to $k - k'$ and go to the next partition and so on. At some stage, in some partition more than k points will qualify. One cannot output all of them, and must get only the highest weighted points from that partition. For this, the partitions are further recursively divided into next level partitions. The depth of this recursion is constant and there are at most $O(m^f)$ partitions to be queried and each point is output in constant time. This gives $O(m^f + k)$ time. For sorted reporting, they show how Radix sort can be applied in a constant number of rounds.

Next, with this as a basic unit, they show how to create a layerwise data structure, so that we choose the appropriate layer according to h when

the query comes. The parameters of that layer ensure that we get $O(h + k)$ time for the query.

Theorem 3 ([5]) *Given a collection of documents of total length n, we can construct a data structure taking $O(n)$ space, such that top-k document retrieval queries can be answered in $O(p + k)$ time.*

External Memory Document Retrieval

Shah et al. [6] obtained the first external memory results for this problem. In the external memory model, we take B as the block size and we count I/O (input/output) operations as the performance measure of the algorithm. They achieved optimal $O(p/B + \log_B n + k/B)$ I/Os for unsorted retrieval. They take $O(n \log^* n)$ space, which is slightly super linear. We briefly describe the structure here. They first make ranked components of GST. The rank of a node v with subtree size s_v is $\lfloor \log \lceil s_v/B \rceil \rfloor$. Ranked components are the contiguous set of vertices of the same rank. Apart from rank 0 vertices, all other components form downward paths (this is very similar to heavy path decomposition). Now, for links, instead of global array $\mathcal{L}$, they keep the set of links associated with each component. Basically, every link belongs to the component where its target is. They maintain two structures, one is a 3-sided structure in 2D [2] and the other is a 3D dominance structure [1].

The query processing first finds the locus v. Also, the query parameter k is converted into a score threshold τ using sketching structures. We are interested in links such that $f_v \le L.o \le l_v$, $L.t \le f_v$, and $L.s \ge \tau$. These are four constraints. In external memory, three constraints are manageable, but not four. So they decompose the query into those with three constraints. They categorize the answer set into two kinds of links (i) the links whose targets are in the same component as v, and (ii) the links whose targets are in components ranked higher than v. By the property of rank components there are at most $\log n/B$ such higher components. For the second kind of links, we query all the higher-ranked 3-sided (2D) structures [2] with f_v, l_v, τ as the parameters. As long as the links are coming from the subtree of v, the target values of links need not be checked. For the first kind of links, one cannot drop the target condition, i.e., $L.t \le f_v$ must be satisfied. However, they show that a slight renumbering of pre-orders based on visiting the child in its own rank component allows condition $L.o \le l_v$ to be dropped. Such queries are answered by 3D dominance structures. Using this, they obtain $O(p/B + \log^2(n/B) + k/B)$ query I/Os with linear space structure. They further bootstrap this to remove the middle term $\log \log^2(n/B)$ by doubling space requirements. This recursively leads to the following result.

Theorem 4 ([6]) *Given a document collection of size n, we can construct an $O(n \log^* n)$ space structure in external memory, which can answer the top-k document retrieval queries (P, k) in $O(p/B + \log_B n + k/B)$ I/Os. The output is unsorted.*

As a side effect of this result, they also obtain internal memory sorted top-k retrieval in $O(p + k)$ time like [5], and better, just $O(k)$ time if locus(P) is given. This is because the answers come from at most $\log n$ different components. For dominance and 3-sided queries, one can get sorted outputs. And then, atomic heaps are used to merge at most $\log n$ sorted streams. Since atomic heaps only have $O(\log n)$ elements at a time, they can generate each output in $O(1)$ time.

Approximation; Connected dominating set; Unit disk graph; Wireless network

Years and Authors of Summarized Original Work

2008; Gao, Huang, Zhang, Wu
2009; Huang, Gao, Zhang, Wu

Problem Definition

This problem deals with the design and analysis of a novel approximation algorithm for the minimum weight connected dominating set problem (MWCDS) under unit disk graph (UDG) model. The WCDS is proved to be NP-hard in 1970s, while for a long period researchers could not find a constant-factor approximation until 2006, when Ambühl et al. first introduced an approximation with ratio of 89 under UDG model. Inspired by their subroutines, we proposed a $(10 + \epsilon)$-approximation with double partition technique, which greatly improved the efficiency and effectiveness of the problem.

Given a homogeneous wireless ad hoc network, represented as an undirected graph $G = (V, E)$, where each vertex $v_i \in V$ in the network has the same communication range, we denote it as the *unit* 1 distance. Two nodes v_1, v_2 can communicate with each other when their Euclidean distance is smaller than 1, and correspondingly, the edge set $E = \{(v_i, v_j) \mid \text{dist}(v_i, v_j) \leq 1\}$. If v_i and v_j are connected, then we say that v_j is a neighbor of v_i (and vice versa). Such communication model is named as *unit disk graph* (UDG). Additionally, each vertex v_i has a weight w_i.

Objective

We hope to find a connected dominating subset $U \subseteq V$ in the given graph with the minimum weight, such that each vertex $v_i \in V$ is either in U or has a neighbor in U and the induced graph $G[U]$ is connected. In addition, the weight of U (defined as the sum of weights for elements in U, say, $W(U) = \sum_{v_i \in U} w_i$) is the minimum among all connected dominating subsets satisfying the above requirements.

Constraints

1. **Unit disk graph:** We restrict our discussion on two-dimensional space where each vertex has the same communication range, and edges between vertices are constructed according to the distance constraint.
2. **Weight minimization:** We focus on the weight version of minimum connected dominating set problem, which is much harder than the cardinality version, and thus providing a constant-factor approximation seems more difficult.

Problem 1 (Minimum Weight Connected Dominating Set in Unit Disk Graph)

INPUT: *A unit disk graph $G = (V, E)$ and a weight assigned on each vertex*

OUTPUT: *A minimum weight connected dominating vertex subset $U \subset V$ such that (1) wirelength is minimized and (2) the area-density constraints $D_{ij} \leq K$ are satisfied for all $B_{ij} \in B$*

Key Results

The minimum weight connected dominating set problem (MWCDS) can be divided into two parts: selecting a minimum weight dominating set (MWDS) and connecting the dominating set into a connected dominating set. In this chapter, we will focus on the former part, while the latter part is equivalent to solving a node-weighted Steiner tree problem in unit disk graphs.

The first constant-factor approximation algorithm for MWCDS under UDG was proposed by Ambühl C. et al. in 2006 [1], which is a polynomial-time 89-approximation. Later, Gao X. et al. [2] introduced a better approximation scheme with approximation ratio of $(6+\epsilon)$ for MWDS, and Huang Y. et al. [3] further extended this idea to MWCDS with approximation ratio of $(10+\epsilon)$. The main idea of their methods involves a double partition technique and a shifting strategy to reduce the redundant vertices selected through the algorithms.

In recent year, the approximation for MWDS in UDG received further improvements from $(6+\epsilon)$ to 5 by Dai and Yu [4], to 4 by Erlebach T. et al. [5] and Zou F. et al. [6] independently, and to 3.63 by Willson J. et al. [7]. Meanwhile, to connect the dominating set in UDG, Ambühl C. et al. [1] gave a 12-approximation, Huang Y. et al. [3] provided a 4-approximation, and Zou F. et al. [8] constructed a 2.5ρ-approximation with a known ρ-approximation algorithm for the minimum network Steiner tree problem. Recently, the minimum approximation for network Steiner tree problem has an approximation ratio of 1.39 [9], so the best approximation ratio for MWCDS problem in UDG is 7.105 up to now.

Double Partition Technique

Given a UDG G containing n disks in the plane. Let $\mu < \frac{\sqrt{2}}{2}$ be a real number which is sufficiently close to $\frac{\sqrt{2}}{2}$, say, $\mu = 0.7$. Partition the area into squares with side length μ. If the whole area has boundary $P(n) \times Q(n)$, where $P(n)$ and $Q(n)$ are two polynomial functions on n, then given the integer even constant K and letting $K \times K$ squares form a block, our partition will have at most $\left(\lceil \frac{P(n)}{K} \rceil + 1\right) \times \left(\lceil \frac{Q(n)}{K} \rceil + 1\right)$ blocks. We will discuss algorithm to compute MWDS for each block firstly and then combine them together.

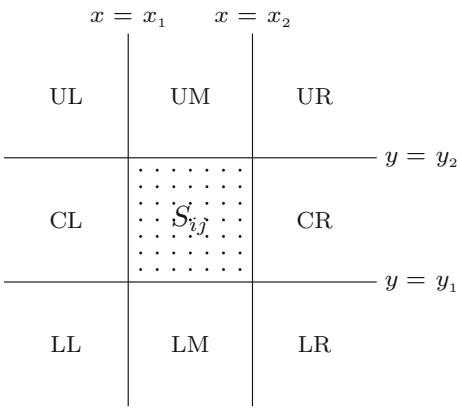
MWDS in $K \times K$ Squares

Assume each block B has K^2 squares S_{ij}, for $i, j \in \{0, 1, \ldots, K-1\}$. Let V_{ij} be the set of disks in S_{ij}. If we have a dominating set D for this block, then for each square S_{ij}, its corresponding dominating set is (1) either a disk from inside S_{ij} (since $\text{dist}(d, d') \leq 1$ for any two disks within this square) or (2) a group of disks from neighbor region around S_{ij}, the union of which can cover all disk centers inside the square. Then if we want to select a minimum weight dominating set, for each square we will have two choices. However, instead of selecting dominating sets square by square, we hope to select them strip by strip to avoid repeated computation for some disks. For this purpose, we have the following lemmas.

Lemma 1 ([1]) *Let P be a set of points located in a strip between lines $y = y_1$ and $y = y_2$ for some $y_1 < y_2$. Let D be a set of weighted disks with uniform radius whose centers are above the line $y = y_2$ or below the line $y = y_1$. Furthermore, assume that the union of the disks in D covers all points in P. Then a minimum weight subset of D that covers all points in P can be computed in polynomial time.*

The proof of result for Lemma 1 is in fact constructive. It gives a polynomial-time algorithm by a dynamic programming. It says that as long as the set of centers P in a horizontal strip can be dominated by a set of centers D above and/or below the strip, then an optimal subset of D dominating P can be found in polynomial time.

Our next work is to select some disks for each square within a strip so that those disks can be covered by disks from the upper and lower strips. To better illuminate the strategy, we divide the neighbor parts of S_{ij} into eight regions $UL, UM, UR, CL, CR, LL, LM, and LR$ as shown in Fig. 1. The four lines forming S_{ij} are $x = x_1$, $x = x_2$, $y = y_1$, and $y = y_2$.



Double Partition, Fig. 1 S_{ij} and its neighbor regions

Denote by $Left = UL \cup CL \cup LL$, $Right = UR \cup CR \cup LR$, $Up = UL \cup UM \cup UR$, and $Down = LL \cup LM \cup LR$. After that, we will have Lemma 2.

Lemma 2 *Suppose $p \in V_{ij}$ is a disk in S_{ij} which can be dominated by a disk $d \in LM$. We draw two lines p_l and p_r, which intersect $y = y_1$ by angle $\frac{\pi}{4}$ and $\frac{3\pi}{4}$. Then the shadow P_{LM} surrounded by $x = x_1$, $x = x_2$, $y = y_1$, p_l, and p_r (shown in Fig. 2) can also be dominated by d. Similar results can be held for shadow P_{UM}, P_{CL}, and P_{CR}, which can be defined with a rotation.*

Proof We split shadow P_{LM} into two halves with vertical line $x = x_p$, where x_p is x-coordinate of disk p. Then we prove that the right half of P_{LM} can be covered by d. The left half can be proved symmetrically. Let o be intersection point of $x = x_p$ and $y = y_1$, a that of p_r and $x = x_2$ (or p_r and $y = y_1$), and b that of $x = x_2$ and $y = y_1$. Intuitionally, the right half can be either a quadrangle $pabo$ or a triangle pao. We will prove both cases as follows:

Quadrangle case: Draw the perpendicular line of the line segment pa, namely, p_m. When d is under p_m as in Fig. 3a, we will have $\text{dist}(d, a) \leq \text{dist}(p, d) \leq 1$. Moreover, it is trivial that $\text{dist}(d, o)$ and $\text{dist}(d, b)$ are all < 1. Thus, d can cover the whole quadrangle. When d is above the line p_m as in Fig. 3b, we draw an auxiliary line $y = y_a$ parallel with $y = y_1$ and $x = x_d$ intersecting $y = y_a$ at point c. Since d lies above p_m, $\angle cad \leq \pi/4$, and thus

$$\text{dist}(d, a) = \frac{\text{dist}(c, a)}{\cos \angle cad} < \frac{\sqrt{2}/2}{\cos \frac{\pi}{4}} = 1.$$

Note that both $\text{dist}(d, o)$ and $\text{dist}(d, b)$ are less than 1, so d can cover the whole quadrangle.

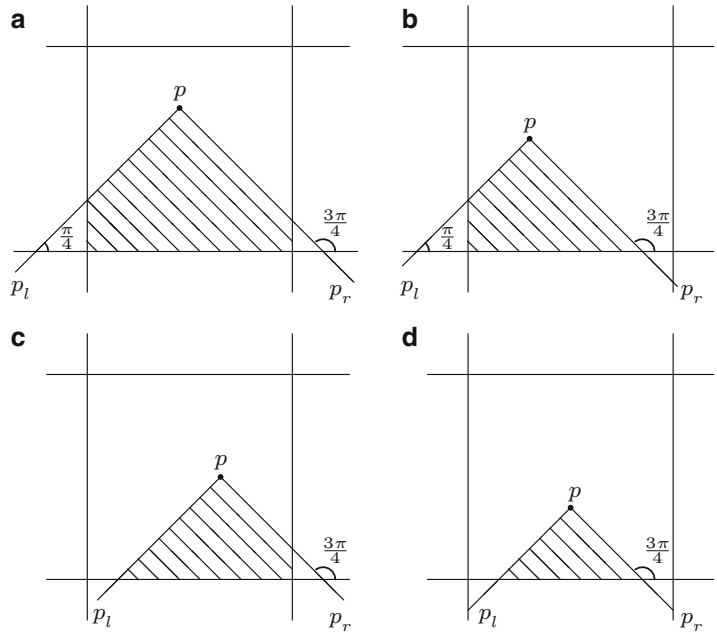
Triangle case: Similarly, draw p_m as described above. The proof remains when d is under p_m (see Fig. 3c). When d is above p_m as in Fig. 3d, we draw auxiliary line $x = x_d$ intersecting $y = y_1$ at c. Then we will get the same conclusion.

With the help of Lemma 2, we can select a region from S_{ij}, where the disks inside this region can be covered by disks from Up and $Down$ neighbor area. We name this region as "sandglass," with formal definition as follows:

Definition 1 (Sandglass) If D is a dominating set for square S_{ij} and $D \cap V_{ij} = \emptyset$, then there exists a subset $V_M \subseteq V_{ij}$ which can only be covered by disks from UM and LM (we can set $V_M = \emptyset$ if there are no such disks). Choose $V_{LM} \subseteq V_M$ the disks that can be covered by disks from LM, and draw p_l and p_r line for each $p \in V_{LM}$. Choose the leftmost p_l and rightmost p_r and form a shadow similar as that in Lemma 2. Symmetrically, choose V_{UM} and form a shadow with leftmost and rightmost lines. The union of the two shadows form a "sandglass" region Sand_{ij} of S_{ij} (see Fig. 4a, where solid circle represents V_{LM}, while hollow circle represents V_{UM}). Fig. 4b–4d gives other possible shapes of Sand_{ij}.

Lemma 3 *Suppose D is a dominating set for S_{ij} and Sand_{ij}s are chosen in the above way. Then any disks in $Sand_{ij}$ can be dominated by disks only from neighbor region $Up \cup Down$, and disks from $S_{ij} \setminus Sand_{ij}$ can be dominated by disks only from neighbor region $Left \cup Right$.*

Proof Suppose to the contrary, there exists a disk $d \in \text{Sand}_{ij}$ which cannot be dominated by disks from $Up \cup Down$. Since D is a dominating set, there must be a $d' \in CL \cup CR$ which dominates



Double Partition, Fig. 2
Different shapes for shadow P_{LM}

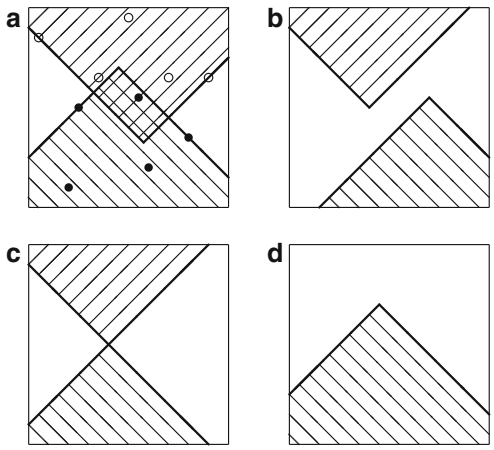
d. Without loss of generality, assume d belongs to lower half of the sandglass which is formed by p_1 and p_2, and let $d' \in CL$ (see Fig. 5). Based on our assumption, d cannot locate in p_1's triangle shadow to $Down$ region (otherwise, since p_1 can be dominated by a disk from LM, d can also be dominated by this disk). We then draw d_l and d_r to CL region and form a shadow to CL. Then by Lemma 2 every disk from this shadow can be dominated by d'. Obviously, p_1 belongs



Double Partition, Fig. 4 Sandglass Sand_{ij} for S_{ij}. (**a**) Form of sandglass. (**b**) Sandglass without intersection. (**c**) Sandglass with single disk. (**d**) Sandglass with half side

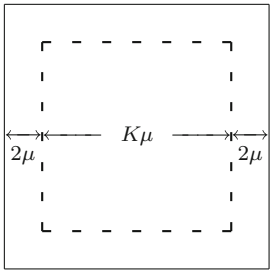
to this region, but p_1 is a disk which cannot be dominated by disks from CL, a contradiction.

Till now we already find "sandglass" region in which disks can be dominated by disks only from Up and $Down$ regions. In our algorithm, for each square S_{ij}, we can firstly decide whether to choose a disk inside this square as dominating set or to choose a dominating set from its neighbor region. If we choose the latter case, the algorithm will randomly select 4 disks d_1, d_2, d_3, and d_4 from S_{ij} and make corresponding sandglass (we can also choose less than 4 disks to form the sandglass). By enumeration of all possible sandglasses including the case of choosing one disk inside the square, for all squares within $K \times K$ area, there are at most $[\sum_{i=0}^{4} C_n^i \cdot 2^i]^{K^2}$ choices (n is the number of disks), which can be calculated within polynomial time. Moreover, when considering choosing a dominating set from neighbor



Double Partition, Fig. 6 Block selection

Algorithm 1 Calculate MWDS in $K \times K$ squares

Input: $K \times K$ squares with inner disks
Output: A local MWDS

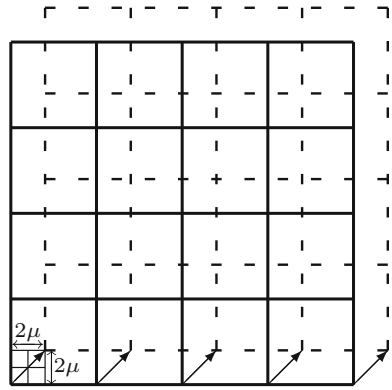
1: For each S_{ij}, choose its sandglass or randomly select $d \in S_{ij}$.
2: If $d \in S_{ij}$ is selected, then remove d and all disks dominated by d.
3: For each strip $\cup_{j=1}^{K} S_{ij}$ from $i = 1$ to K, calculate a dominating set for the union of disks in the sandglasses.
4: For each strip $\cup_{i=1}^{K} S_{ij}$ from $j = 1$ to K, calculate a dominating set for the remaining disks not covered by Step 3.
Return the union of disks chosen in the above steps for $K \times K$ squares.

regions, we should also include regions around this $K \times K$ areas such that we will not miss disks outside the region. Therefore, we should consider $(K+4) \times (K+4)$ area, where the inner region is our selected block and the surrounding four strips are the assistance (shown as Fig. 6).

In all, we will have Algorithm 1 with four steps to calculate an MWDS for $K \times K$ squares. We enumerate all possible cases for each S_{ij} and choose the solution with minimum weight, which forms an MWDS for S_{ij}.

MWDC for the Whole Region

As discussed above, if our plane has size $P(n) \times Q(n)$, then there are at most $\left(\lceil \frac{P(n)}{K} \rceil + 1\right) \times \left(\lceil \frac{Q(n)}{K} \rceil + 1\right)$ blocks in the plane. We name each block B^{xy}, where $0 \le x \le \lceil \frac{P(n)}{K} \rceil + 1$ and $0 \le y \le \lceil \frac{Q(n)}{K} \rceil + 1$. Then, using Algorithm 1 to calculate dominating set for each block and by combining them together, we obtain a dominating set for our original partition.



Double Partition, Fig. 7 Move blocks

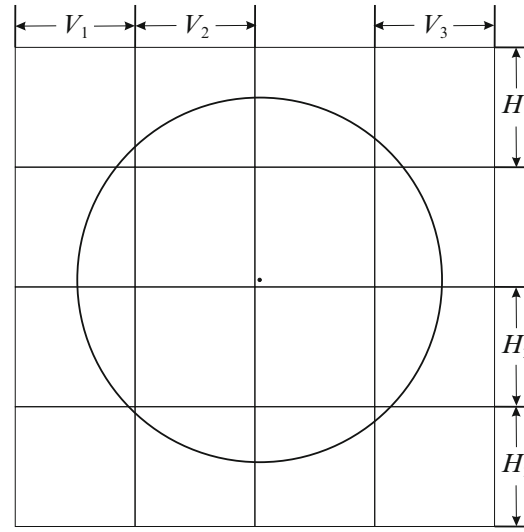
Algorithm 2 Calculate MWDS for the whole plane

Input: G in region $P(n) \times Q(n)$
Output: A global MWDS
1: For a certain partition, calculate MWDS for each block B^{xy}, sum the weight of MWSD for each block, and form a solution.
2: Move each block to two squares to the right and two squares to the top of the original block.
3: Repeat Step 1 for new partition, and get a new solution.
4: Repeat Step 2 for $\lceil \frac{K}{2} \rceil$ times, and choose the minimum solution among those steps.
Return the solution from Step 4 as our final result.

Next, we move our blocks to different positions by shifting policy. Move every block two squares right and two squares up to its original position, which can be seen from Fig. 7. Then calculate dominating set for each block again, and combine the solution together. We do this process $\frac{K}{2}$ times, choose the minimum solution as our final result. The whole process can be shown as Algorithm 2.

Performance Ratio

In the following, we extend our terminology "dominate" to points (a point is a location which is not necessarily a disk). A point p is *dominated* by a set of disks if the distance between p and at least one center of the disks is not more than 1. We say an area is *dominated* by a set of disks if every point in this area is dominated by the set of disks. Let OPT be optimal solution for our problem and $w(OPT)$ the weight of optimal solution.



Double Partition, Fig. 8 An example for disk cover region

Theorem 1 *Algorithm 2 always outputs a dominating set with weight within* $6 + \varepsilon$ *times of the optimum one.*

Proof Our proof mainly has two phases. The first phase analyzes that our Algorithm 1 gives a 6-approximation for disks in $K \times K$ squares. The second phase proves that result from Algorithm 2 is less than $(6 + \varepsilon) \cdot w(OPT)$.

Phase 1: If a disk has radius 2 and our partition has side length $\mu < \frac{\sqrt{2}}{2}$, then a disk may dominate disks from at most 16 squares, which can be shown in Fig. 8. Simply, if a disk in OPT is used to dominate the square it belongs to, then we will remove this disk before calculating MWDS for strips. Therefore, it will be used only once. If a disk is not used to dominate the square containing it, then it may be used 3 times in calculating its 3 horizontal neighbor strips (H_1, H_2, and H_3 as shown in Fig. 8) and another 3 times in calculating its 3 vertical neighbor strips (V_1, V_2, and V_3 in Fig. 8). Therefore, Algorithm 1 is a 6-approximation for each block.

Phase 2: Now we consider the disks in side strips for a block. As discussed above, when calculating MWDS for a strip, we may use disks

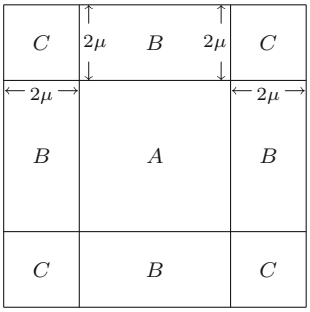
within $(K+2)\times(K+2)$ squares. Therefore, we can divide a block $B^{(xy)}$ into three kinds of squares, just as shown in Fig. 9 ($0 \le x \le \lceil \frac{P(n)}{K} \rceil$, and $0 \le y \le \lceil \frac{Q(n)}{K} \rceil$). If a disk belongs to inner part $\mathcal{A}$ of $B^{(xy)}$, it will be used at most 6 times during calculating process. We name those disks as d_{in}. If a disk belongs to side part $\mathcal{B}$ of $B^{(xy)}$, it may be used at most 5 times for calculating $B^{(xy)}$, but it may used at most 4 times when calculating $B^{(xy)}$'s neighbor block. We name those disks as d_{side}. If a disk belongs to corner squares $\mathcal{C}$ of $B^{(xy)}$, it may be used at most 4 times for calculating $B^{(xy)}$ and at most 8 times for neighbor blocks. We name those disks as d_{corner}. In addition, we know that during shifting process a node can stay at most 4 times in side or corner square. If we name l as the lth shifting, then our final solution will have the following inequality:

$$
\begin{aligned}
&W(\text{Solution}) \\
&= \min_{l} \Big\{ \sum_{\text{Sol}_l} [6w(d_{\text{in}}^{l}) + 9w(d_{\text{side}}^{l}) + 12w(d_{\text{corner}}^{l})] \Big\} \\
&\le \frac{1}{\frac{K}{2}} \sum_{l=0}^{\frac{K}{2}} \big\{ 6w(d_{in}^{l}) + 4 \cdot 12w(d_{\text{side}}^{l} + d_{\text{corner}}^{l}) \big\} \\
&= 6w(OPT) + \frac{42}{\frac{K}{2}} w(OPT) \\
&\le (6+\varepsilon) w(OPT)
\end{aligned}
$$

where $\varepsilon = 42/\frac{K}{2}$ can be arbitrarily small when K is sufficiently large.

Applications

Dominating set problem is widely used in network-related applications. For instance, in mobile and wireless ad hoc networks, it is implemented for communication virtual backbone selection to improve routing efficiency, for sensor coverage problem to extend network lifetime, and for clustering and data gathering problem to avoid flooding and energy waste. In optical network and data center networks, it is used for network management and switch-centric routing protocols. In social network applications, it is used for many cluster-related problems like positive influence, effective leader group, etc. A weighted dominating set is a generalized heterogeneous network model to describe real-world applications, which is more realistic and practical.



Double Partition, Fig. 9 Divide block $B^{(xy)}$ into 3 parts

Open Problems

There are two open problems for the minimum weighted connected dominating set (MWCDS) problem under unit disk graph (UDG). Firstly, there is another grid partition design to construct a constant approximation for domatic partition problem in unit disk graph [10]. Could this new technique result in an improvement in running time or performance ratio? Secondly, does MWCDS problem in UDG have a polynomial-time approximation scheme (PTAS)? Currently, no one has answered the above questions.

Problem Definition

Given an undirected, unweighted graph with n nodes and m edges that is modified by a sequence of edge insertions and deletions, the problem is to maintain a data structure that quickly answers queries that ask for the length $d(u, v)$ of the shortest path between two arbitrary nodes u and v in the graph, called the *distance* of u and v. The fastest *exact* algorithm for this problem is randomized and takes amortized $O\left(n^2\left(\log n + \log^2\left((m+n)/n\right)\right)\right)$ time per update and constant query time [6, 11]. In the *decremental* case, i.e., if only edge deletions are allowed, there exists a *deterministic* algorithm with amortized time $O(n^2)$ per deletion [7]. More precisely, its *total update time* for a sequence of up to m deletions is $O(mn^2)$. Additionally, there is a randomized algorithm with $O(n^3 \log^2 n)$ total update time and constant query time [1]. However, in the decremental case, when only α*-approximate* answers are required, i.e., when it suffices to output an estimate $\delta(u, v)$ such that $d(u, v) \leq \delta(u, v) \leq \alpha d(u, v)$ for all nodes u and v, the total update time can be significantly improved: Let $\epsilon > 0$ be a small constant. The fastest prior work was a class of randomized algorithms with total update time $\tilde{O}(mn)$ for $\alpha = 1+\epsilon$ [10], $\tilde{O}\left(n^{5/2+O(1/\sqrt{\log n})}\right)$ for $\alpha = 3+\epsilon$, and $\tilde{O}\left(n^{2+1/k+O(1/\sqrt{\log n})}\right)$ for $\alpha = 2k-1+\epsilon$ [4].

This leads to the question whether for $\alpha = 1+\epsilon$ (a), a total update time of $o(nm)$ is possible and (b) a deterministic algorithm with total update time $\tilde{O}(nm)$ exists.

As pointed out in [3] and several other places, a *deterministic* algorithm is interesting due to the fact that deterministic algorithms can deal with an *adaptive offline adversary* (the strongest adversary model in online computation [2, 5]), while the randomized algorithms developed so

far assume an *oblivious adversary* (the weakest adversary model) where the order of edge deletions must be fixed before an algorithm makes random choices.

Key Results

The paper of Henzinger, Krinninger, and Nanongkai [8] presents two algorithms for $\alpha = 1 + \epsilon$. The first one is a deterministic algorithm with total update time $\tilde{O}(mn)$. The second one studies a slightly relaxed version of the problem: Given a constant β, let $\delta(u, v)$ be an (α, β)-*approximation* if $d(u, v) \leq \delta(u, v) \leq \alpha d(u, v) + \beta$ for all nodes u and v. The second algorithm is a randomized algorithm with total update time $\tilde{O}(n^{5/2})$ that can guarantee both a $(1 + \epsilon, 2)$ and a $(2 + \epsilon, 0)$ approximation.

The results build on two prior techniques, namely, an exact decremental single-source shortest path data structure [7], called *ES-tree*, and the $(1 + \epsilon, 0)$-approximation algorithm of [10], called *RZ-algorithm*. The RZ-algorithm chooses for all integer i with $1 \leq i \leq \log n$, $\tilde{O}(n/(\epsilon 2^i))$ random nodes as *centers*, and maintains an ES-tree up to distance 2^{i+2} for each center. For correctness, it exploits the fact that the random choice of centers guarantees the following *invariant (I)*: For every pair of nodes u and v with distance $d(u, v)$, there exists with high probability a center c such that $d(u, c) \leq \epsilon d(u, v)$ and $d(c, v) \leq d(u, v)$. The total update time per center is $O(m2^i)$ resulting in a total update time of $\tilde{O}(mn)$. The deterministic algorithm of [8] derandomizes this algorithm by initially choosing centers fulfilling invariant (I) and after each update (a) greedily generating new centers to guarantee that (I) continues to hold and (b) moving the root of the existing ES-trees. To achieve a running time of $\tilde{O}(mn)$, the algorithm is not allowed to create more than $\tilde{O}(n/(\epsilon 2^i))$ many centers for each i. This condition is fulfilled by dynamically assigning each center a set of $\Omega(2^i)$ vertices such that no vertex is assigned to two centers.

The improved randomized algorithm uses the idea of an *emulator*, a sparser *weighted* graph that approximates the distances of the original graph. Emulators were used for dynamic shortest-path algorithms before [4]. The challenge when using an emulator is that edge deletions in the original graph might lead to edge deletions, edge insertions, or weight increases in the emulator, requiring in principle the use of a fully dynamic shortest-path algorithm on the emulator. Bernstein and Roditty [4] deal with this challenge by using an emulator where the number of *distance changes* between any two nodes can be bounded. However, the RZ-algorithm requires that the number of times that the distance between any two nodes changes is at most R before that distance exceeds R for any integer R with $1 \leq R \leq n$. As the emulator used by Bernstein and Roditty does not fulfill this property, they cannot run the RZ-algorithm on it. The new algorithm does not construct such an emulator either. Instead, it builds an emulator where the error introduced by edge insertions is limited and runs the RZ-algorithm with modified ES-trees, called *monotone ES-trees*, on this emulator. The analysis exploits the fact that the distance between any two nodes in the original graph can only *increase* after an edge deletion. Thus, even if an edge deletion leads to changes in the emulator that *decrease* their distance in the emulator, the corresponding ES-trees do not have to be updated, i.e., the distance of a vertex to its root in the ES-tree *never* decreases. The analysis shows that the error introduced through the use of monotone ES-trees in the RZ-algorithm is small so that the claimed approximation ratio is achieved. However, since the ES-trees are run on the sparse emulator the overall running time is $o(mn)$.

Open Problems

The main open problem is to find a similarly efficient algorithm in the *fully dynamic setting*, where both edge insertions and deletions are allowed. A further open problem is to extend the derandomization technique to the *exact* algorithm of [1].

Another challenge is to obtain similar results for *weighted, directed* graphs. We recently extended some of the above techniques to weighted, directed graphs and presented a randomized algorithm with $\tilde{O}\left(mn^{0.986}\right)$ total update time for $(1+\epsilon)$-approximate *single-source* shortest paths [9].

Dynamic Approximate-APSP

Aaron Bernstein
Department of Computer Science, Columbia University, New York, NY, USA

Keywords

Dynamic graph algorithms; Hop distances; Shortest paths

Years and Authors of Summarized Original Work

2009; Bernstein

Problem Definition

A dynamic graph algorithm maintains information about a graph that is changing over time. Given a property $\mathcal{P}$ of the graph (e.g., maximum matching), the algorithm must support an online sequence of query and update operations, where an update operation changes the underlying graph, while a query operation asks for the state of $\mathcal{P}$ in the current graph. In the typical model studied, each update affects a single edge, in which case the most general setting is the *fully dynamic* one, where an update can either insert an edge, delete an edge, or change the weight of an edge. Common restrictions of this include the *decremental* setting, where an update can only delete an edge or increase a weight, and the *incremental* setting where an update can insert an edge or decrease a weight.

This entry addresses the problem of maintaining α-approximate all-pairs shortest paths (APSP) in the fully dynamic setting in a weighted, undirected graph (the approximation factor α depends on the algorithm); the goal is to maintain an undirected graph G with real-valued nonnegative edge weights under an online intermixed sequence of the following operations:

- **delete**(u, v) (update): remove edge (u, v) from G.

- **insert**(u, v) (update): insert an edge (u, v) into G.
- **change weight**(u, v, w) (update): change the weight of edge (u, v) to w.
- **distance**(u, v) (query): return an α-approximation to the shortest $u - v$ distance in G.
- **path**(u, v) (query): return an α-approximate shortest path from u to v.

Approaches

The naive approach to the fully dynamic APSP problem is to recompute shortest paths from scratch after every update, allowing queries to be answered in optimal time. Letting n be the number of vertices and m the number of edges, computing APSP requires $O(mn + n^2 \text{loglog}(n))$ time in sparse graphs [8] or slightly less than n^3 in dense graphs [9, 13]. If we allow approximation, a slightly better approach would be to construct an *approximate distance oracle* after each update, i.e., a static data structure for answering approximate distance queries quickly; an oracle for returning k-approximate distances ($k \geq 3$) can be constructed in time $O(\min\{n^2 \log(n), kmn^{1/k}\})$ [1, 11]. Another simple-minded approach would be to not perform any work during the updates and to simply compute the shortest $u-v$ path from scratch when a query arrived; using Dijkstra's algorithm with Fibonacci heaps [7], this would lead to a constant update time and a query time of $O(m+n \log(n))$.

The goal of a dynamic algorithm is to improve upon the above approaches by taking advantage of the fact that each update only affects a single edge, so one can reuse information between updates and thus avoid recomputing from scratch. In a breakthrough result, Demetrescu and Italiano showed that in the most general case of a directed graph with arbitrary real weights, one can answer updates in amortized time $O(n^2 \log^3(n))$ while maintaining optimal $O(1)$ time for distance queries [6]; Thorup improved the update time slightly to $O(n^2(\log(n)+\log^2((m+n)/n)))$ [10]. This entry addresses a recent result of Bernstein [3] which shows that in undirected graphs, one can significantly improve upon this n^2 update time by settling for approximate distances.

Key Results

Bernstein's paper starts by showing that assuming integral weights, there is an algorithm for maintaining $(2 + \epsilon)$-approximate APSP *up to a bounded distance* d with amortized update time $O(md)$. This is efficient for small distances, but in the general case d can be very large, especially in weighted graphs. Bernstein overcomes this by introducing a high-level framework for extending shortest path-related algorithms that are efficient for small distances to ones that are efficient for general graphs; he later applied this approach to two other results [4, 5].

The first step of the approach is to show that with simple scaling techniques, an algorithm that is efficient for small (weighted) distances can be extended to an algorithm that is efficient for shortest paths with few edges (regardless of weight). Applying this technique to the above algorithm yields the following result:

Definition 1 Let the *hop distance* of a path be the number of edges it contains. A graph G is said to have *approximate hop diameter* h if for every pair of vertices (x, y), there is a $(1 + \epsilon)$-approximate shortest $x-y$ path with hop distance $\leq h$.

Theorem 1 ([3]) *Let G be an undirected graph with nonnegative real edge weights, and let R be the ratio of the heaviest to the lightest nonzero weight. One can maintain $(2 + \epsilon)$-APSP in the fully dynamic setting with amortized update time $O(mh \log(nR))$, where h is the approximate hop diameter of the graph.*

Shortcut Edges

Theorem 1 provides an efficient algorithm for small h, but on its own a result that is efficient for small hop diameter is not particularly powerful as even in unweighted graphs h can be $\Omega(n)$. The second step of Bernstein's approach is to show that regardless of whether the original graph is weighted, one can add weighted edges to reduce the hop diameter. A *shortcut edge* (x, y) is a new edge constructed by the algorithm that has weight $w(x, y)$ with $\delta(x, y) \leq w(x, y) \leq (1+\epsilon)\delta(x, y)$,

where $\delta(x, y)$ is the shortest $x - y$ distance. It is clear that because shortcut weights are tethered to shortest distances, they do not change (weighted) distances in the graph. But a shortcut edge can greatly reduce hop distances; for example, in an unweighted graph where $\delta(x, y) = 1000$, adding a single shortcut edge (x, y) of weight 1000 decreases the $x - y$ hop distance to 1 while also decreasing the hop distance of paths that go through x and y. Bernstein adapts techniques from spanner and emulator theory (see in particular Thorup and Zwick's result on graph sparsification [12]) to show that in fact a small number of shortcut edges suffice to greatly reduce the hop diameter of a graph.

Theorem 2 ([3]) *Let G be an undirected graph with nonnegative real edge weights, and let R be the ratio of the heaviest to the lightest edge weight in the graph. There exists an algorithm that in time $O(m \cdot n^{O(1/\sqrt{\log(n)})} \cdot \log(nR))$ constructs a set S of $O(n^{1+O(1/\sqrt{\log(n)})} \cdot \log(nR))$ shortcut edges such that adding S to the edges of the graph reduces the approximate hop diameter to $n^{O(1/\sqrt{\log(n)})}$.*

Theorems 1 and 2 combined encapsulate the approach of Bernstein's algorithm: take an algorithm that works well for small distances, use scaling to transform it into an algorithm that is efficient for graphs of small hop diameter, and then add shortcut edges to the original graph to ensure a small hop diameter. For dynamic APSP, there are additional complications that arise from edges being inserted and deleted over time, but the basic approach remains the same.

Theorem 3 ([3]) *Let G be an undirected graph with real nonnegative edge weights, and let R be the ratio of the maximum edge weight appearing in the graph during any point in the update sequence to the minimum nonzero edge weight. There is an algorithm that maintains fully dynamic $(2+\epsilon)$-approximate APSP in amortized update time $O(m \cdot n^{O(1/\sqrt{\log(n)})} \cdot \log(nR))$ and can answer distance queries in worst-case time $O(\log\log\log(n))$.*

Open Problems

The main open problem for fully dynamic approximate APSP is to develop an efficient algorithm for maintaining $(1 + \epsilon)$ approximate distances, possibly with a small additive error in the unweighted case. Another interesting problem would be to achieve $o(n^2)$ update times for dense graphs – this can already be done to some extent by combining the result of Bernstein discussed here with the fully dynamic spanner of Baswana et al. [2], but only for unweighted graphs and at the cost of a much worse approximation ratio. Other open problems include removing the dependence on $\log(R)$ and developing an efficient *deterministic* algorithm for the problem.

Keywords

Link-cut trees

Years and Authors of Summarized Original Work

2005; Tarjan, Werneck

Problem Definition

The *dynamic tree problem* is that of maintaining an arbitrary n-vertex forest that changes over time through edge insertions (*links*) and deletions (*cuts*). Depending on the application, one associates information with vertices, edges, or both. Queries and updates can deal with individual vertices or edges, but more commonly they refer to entire paths or trees. Typical operations include finding the minimum-cost edge along a path, determining the minimum-cost vertex in a tree, or adding a constant value to the cost of each edge on a path (or of each vertex of a tree). Each of these operations, as well as *links* and *cuts*, can be performed in $O(\log n)$ time with appropriate data structures.

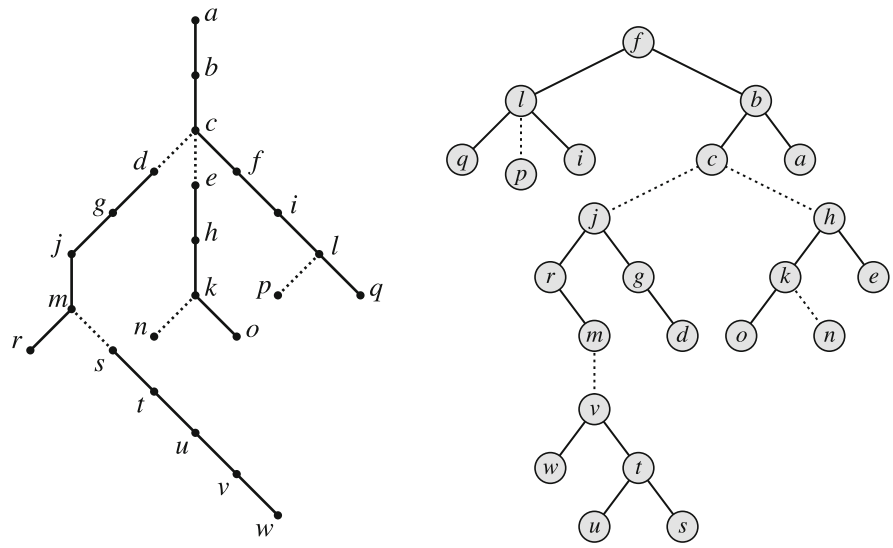
Key Results

The obvious solution to the dynamic tree problem is to represent the forest explicitly. This, however, is inefficient for queries dealing with entire paths or trees, since it would require actually traversing them. Achieving $O(\log n)$ time per operation requires mapping each (possibly unbalanced) input tree into a balanced tree, which is better suited to maintaining information about paths or trees implicitly. There are three main approaches to perform the mapping: path decomposition, tree contraction, and linearization.

Path Decomposition

The first efficient dynamic tree data structure was Sleator and Tarjan's *ST-trees* [13, 14], also known as *link-cut trees* or simply *dynamic trees*. They are meant to represent rooted trees, but the user can change the root with the *evert* operation. The data structure partitions each input tree into vertex-disjoint paths, and each path is represented as a binary search tree in which vertices appear in symmetric order. The binary trees are then connected according to how the paths are related in the forest. More precisely, the root of a binary tree becomes a *middle child* (in the data structure) of the parent (in the forest) of the topmost vertex of the corresponding path. Although a node has no more than two children (left and right) within its own binary tree, it may have arbitrarily many middle children. See Fig. 1. The path containing the root (*qlifcba* in the example) is said to be *exposed*, and is represented as the topmost binary tree. All path-related queries will refer to this path. The *expose* operation can be used to make any vertex part of the exposed path.

With standard balanced binary search trees (such as red-black trees), ST-trees support each dynamic tree operation in $O(\log^2 n)$ amortized



Dynamic Trees, Fig. 1 An ST-tree (Adapted from [14]). On the *left*, the original tree, rooted at *a* and already partitioned into paths; on the *right*, the actual data structure. *Solid edges* connect nodes on the same path; *dashed edges* connect different paths

time. This bound can be improved to $O(\log n)$ amortized with locally biased search trees, and to $O(\log n)$ in the worst case with globally biased search trees. Biased search trees (described in [5]), however, are notoriously complicated. A more practical implementation of ST-trees uses *splay trees*, a self-adjusting type of binary search trees, to support all dynamic tree operations in $O(\log n)$ amortized time [14].

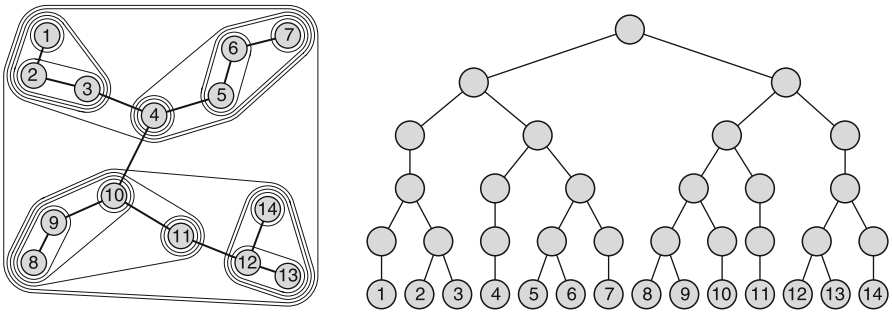
Tree Contraction

Unlike ST-trees, which represent the input trees directly, Frederickson's *topology trees* [6, 7, 8] represent a *contraction* of each tree. The original vertices constitute level 0 of the contraction. Level 1 represents a partition of these vertices into *clusters*: a degree-one vertex can be combined with its only neighbor; vertices of degree two that are adjacent to each other can be clustered together; other vertices are kept as singletons. The end result will be a smaller tree, whose own partition into clusters yields level 2. The process is repeated until a single cluster remains. The topology tree is a representation of the contraction, with each cluster having as children its constituent clusters on the level below. See Fig. 2.

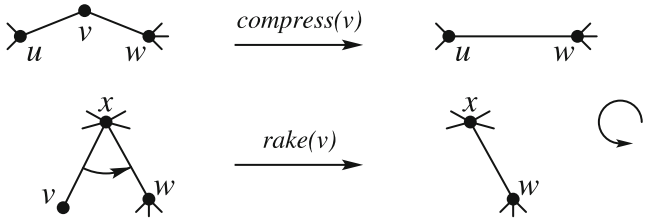
With appropriate pieces of information stored in each cluster, the data structure can be used to answer queries about the entire tree or individual paths. After a *link* or *cut*, the affected topology trees can be rebuilt in $O(\log n)$ time.

The notion of tree contraction was developed independently by Miller and Reif [11] in the context of parallel algorithms. They propose two basic operations, *rake* (which eliminates vertices of degree one) and *compress* (which eliminates vertices of degree two). They show that $O(\log n)$ rounds of these operations are sufficient to contract any tree to a single cluster. Acar et al. translated a variant of their algorithm into a dynamic tree data structure, *RC-trees* [1], which can also be seen as a randomized (and simpler) version of topology trees.

A drawback of topology trees and RC-trees is that they require the underlying forest to have vertices with bounded (constant) degree in order to ensure $O(\log n)$ time per operation. Similarly, although ST-trees do not have this limitation when aggregating information over paths, they require bounded degrees to aggregate over trees. Degree restrictions can be addressed by "ternarizing" the input forest (replacing high-degree vertices



Dynamic Trees, Fig. 2 A topology tree (Adapted from [7]). On the *left*, the original tree and its multilevel partition; on the *right*, a corresponding topology tree



Dynamic Trees, Fig. 3 The *rake* and *compress* operations, as used by top trees (From [16]))

with a series of low-degree ones [9]), but this introduces a host of special cases.

Alstrup et al.'s *top trees* [3, 4] have no such limitation, which makes them more generic than all data structures previously discussed. Although also based on tree contraction, their clusters behave not like vertices, but like *edges*. A *compress* cluster combines two edges that share a degree-two vertex, while a *rake* cluster combines an edge with a degree-one endpoint with a second edge adjacent to its other endpoint. See Fig. 3.

Top trees are designed so as to completely hide from the user the inner workings of the data structure. The user only specifies what pieces of information to store in each cluster, and (through call-back functions) how to update them after a cluster is created or destroyed when the tree changes. As long as the operations are properly defined, applications that use top trees are completely independent of how the data structure is actually implemented, i.e., of the order in which *rakes* and *compresses* are performed.

In fact, top trees were not even proposed as stand-alone data structures, but rather as an interface on top of topology trees. For efficiency reasons, however, one would rather have a more direct implementation. Holm, Tarjan, Thorup and Werneck have presented a conceptually simple stand-alone algorithm to update a top tree after a *link* or *cut* in $O(\log n)$ time in the worst case [17]. Tarjan and Werneck [16] have also introduced *self-adjusting top trees*, a more efficient implementation of top trees based on path decomposition: it partitions the input forest into edge-disjoint paths, represents these paths as splay trees, and connects these trees appropriately. Internally, the data structure is very similar to ST-trees, but the paths are edge-disjoint (instead of vertex-disjoint) and the ternarization step is incorporated into the data structure itself. All the user sees, however, are the *rakes* and *compresses* that characterize tree contraction.

Linearization

ET-trees, originally proposed by Henzinger and King [10] and later slightly simplified by Tarjan [15], use yet another approach to represent dynamic trees: *linearization*. It maintains an *Euler tour* of the each input tree, i.e., a closed path that traverses each edge twice–once in each direction. The tour induces a linear order among the vertices and arcs, and therefore can be represented as a balanced binary search tree. Linking

and cutting edges from the forest corresponds to joining and splitting the affected binary trees, which can be done in $O(\log n)$ time. While linearization is arguably the simplest of the three approaches, it has a crucial drawback: because each edge appears twice, the data structure can only aggregate information over trees, not paths.

Lower Bounds

Dynamic tree data structures are capable of solving the *dynamic connectivity* problem on acyclic graphs: given two vertices v and w, decide whether they belong to the same tree or not. P˘atraşcu and Demaine [12] have proven a lower bound of $\Omega(\log n)$ for this problem, which is matched by the data structures presented here.

Applications

Sleator and Tarjan's original application for dynamic trees was Dinic's blocking flow algorithm [13]. Dynamic trees are used to maintain a forest of arcs with positive residual capacity. As soon as the source s and the sink t become part of the same tree, the algorithm sends as much flow as possible along the s–t path; this reduces to zero the residual capacity of at least one arc, which is then *cut* from the tree. Several maximum flow and minimum-cost flow algorithms incorporating dynamic trees have been proposed ever since (some examples are [9, 15]). Dynamic tree data structures, especially those based on tree contraction, are also commonly used within dynamic graph algorithms, such as the dynamic versions of minimum spanning trees [6, 10], connectivity [10], biconnectivity [6], and bipartiteness [10]. Other applications include the evaluation of dynamic expression trees [8] and standard graph algorithms [13].

Experimental Results

Several studies have compared the performance of different dynamic-tree data structures; in most cases, ST-trees implemented with splay trees are the fastest alternative. Frederickson, for example, found that topology trees take almost 50 % more time than splay-based ST-trees when executing dynamic tree operations within a maximum flow algorithm [8]. Acar et al. [2] have shown that RC-trees are significantly slower than splay-based ST-trees when most operations are *links* and *cuts* (such as in network flow algorithms), but faster when queries and value updates are dominant. The reason is that splaying changes the structure of ST-trees even during queries, while RC-trees remain unchanged.

Tarjan and Werneck [17] have presented an experimental comparison of several dynamic tree data structures. For random sequences of *links* and *cuts*, splay-based ST-trees are the fastest alternative, followed by splay-based ET-trees, self-adjusting top trees, worst-case top trees, and RC-trees. Similar relative performance was observed in more realistic sequences of operations, except when queries far outnumber structural operations; in this case, the self-adjusting data structures are slower than RC-trees and worst-case top trees. The same experimental study also considered the "obvious" implementation of ST-trees, which represents the forest explicitly and require linear time per operation in the worst case. Its simplicity makes it significantly faster than the $O(\log n)$-time data structures for path-related queries and updates, unless paths are hundred nodes long. The sophisticated solutions are more useful when the underlying forest has high diameter or there is a need to aggregate information over trees (and not only paths).

Keywords

Block edit distance

Years and Authors of Summarized Original Work

2000; Cormode, Paterson, Sahinalp, Vishkin
2000; Muthukrishnan, Sahinalp

Problem Definition

Given two strings $S = s_1 s_2 \ldots s_n$ and $R = r_1 r_2 \ldots r_m$ (wlog let $n \geq m$) over an alphabet $\sigma = \{\sigma_1, \sigma_2, \ldots \sigma_\ell\}$, the *standard edit distance* between S and R, denoted $ED(S, R)$ is the minimum number of *single character edits*, specifically *insertions*, *deletions* and *replacements*, to transform S into R (equivalently R into S).

If the input strings S and R are permutations of the alphabet σ (so that $|S| = |R| = |\sigma|$) then an analogous *permutation edit distance* between S and R, denoted $PED(S, R)$ can be defined as the minimum number of single character *moves*, to transform S into R (or vice versa).

A generalization of the standard edit distance is *edit distance with moves*, which, for input strings S and R is denoted $EDM(S, R)$, and is defined as the minimum number of character edits and *substring (block) moves* to transform one of the strings into the other. A move of block $s[j, k]$ to position h transforms $S = s_1 s_2 \ldots s_n$ into $S' = s_1 \ldots s_{j-1} s_{k+1} s_{k+2} \ldots s_{h-1} s_j \ldots s_k s_h \ldots s_n$ [4].

If the input strings S and R are permutations of the alphabet σ (so that $|S| = |R| = |\sigma|$) then $EDM(S, R)$ is also called as the transposition distance and is denoted $TED(S, R)$ [1].

Perhaps the most general form of the standard edit distance that involves edit operations on blocks/substrings is the *block edit distance*, denoted $BED(S, R)$. It is defined as the minimum number of single character edits, block moves, as well as *block copies and block uncopies* to transform one of the strings into the other. Copying of a block $s[j, k]$ to position h transforms $S = s_1 s_2 \ldots s_n$ into $S' = s_1 \ldots s_j s_{j+1} \ldots s_k \ldots s_{h-1} s_j \ldots s_k s_h \ldots s_n$. A block uncopy is the inverse of a block copy: it deletes a block $s[j, k]$ provided there exists $s[j', k'] = s[j, k]$ which does not overlap with $s[j, k]$ and transforms S into $S' = s_1 \ldots s_{j-1} s_{k+1} \ldots s_n$.

Throughout this discussion all edit operations have unit cost and they may overlap; i.e., a character can be edited on multiple times.

DOI 10.1007/978-1-4939-2864-4

Key Results

There are exact and approximate solutions to computing the edit distances described above with varying performance guarantees. As can be expected, the best available running times as well as the approximation factors for computing these edit distances vary considerably with the edit operations allowed.

Exact Computation of the Standard and Permutation Edit Distance

The fastest algorithms for exactly computing the standard edit distance have been available for more than 25 years.

Theorem 1 (Levenshtein [9]) *The standard edit distance ED(S, R) can be computed exactly in time* $O(n \cdot m)$ *via dynamic programming.*

Theorem 2 (Masek-Paterson [11]) *The standard edit distance ED(S, R) can be computed exactly in time* $O(n + n \cdot m/\log^2_{|\sigma|} n)$ *via the "four-Russians trick".*

Theorem 3 (Landau-Vishkin [8]) *It is possible to compute ED(S, R) in time* $O(n \cdot ED(S, R))$.

Finally, note that if S and R are permutations of the alphabet σ, $PED(S, R)$ can be computed much faster than the standard edit distance for general strings: Observe that $PED(S, R) = n - LCS(S, R)$ where $LCS(S, R)$ represents the longest common subsequence of S and R. For permutations S, R, $LCS(S, R)$ can be computed in time $O(n \cdot \log \log n)$ [3].

Approximate Computation of the Standard Edit Distance

If some approximation can be tolerated, it is possible to considerably improve the $\tilde{O}(n \cdot m)$ time ($\tilde{O}$ notation hides polylogarithmic factors) available by the techniques above. The fastest algorithm that *approximately* computes the standard edit distance works by *embedding* strings S and R from alphabet σ into shorter strings S' and R' from a larger alphabet σ' [2]. The embedding is achieved by applying a general version of the *Locally Consistent Parsing* [13, 14] to partition the strings R and S into *consistent blocks* of size c to $2c - 1$; the partitioning is consistent in the sense that identical (long) substrings are partitioned identically. Each block is then replaced with a label such that identical blocks are identically labeled. The resulting strings S' and R' preserve the edit distance between S and R approximately as stated below.

Theorem 4 (Batu-Ergun-Sahinalp [2]) *ED(S, R) can be computed in time* $\tilde{O}(n^{1+\epsilon})$ *within an approximation factor of* $\min\{n^{\frac{1-\epsilon}{3}+o(1)}, (ED(S, R)/n^{\epsilon})^{\frac{1}{2}+o(1)}\}$.

For the case of $\epsilon = 0$, the above result provides an $\tilde{O}(n)$ time algorithm for approximating $ED(S, R)$ within a factor of $\min\{n^{\frac{1}{3}+o(1)}, ED(S, R)^{\frac{1}{2}+o(1)}\}$.

Approximate Computation of Edit Distances Involving Block Edits

For all edit distance variants described above which involve blocks, there are no known polynomial time algorithms; in fact it is NP-hard to compute $TED(S, R)$ [1], $EDM(S, R)$ and $BED(S, R)$ [10]. However, in case S and R are permutations of σ, there are polynomial time algorithms that approximate transposition distance within a constant factor:

Theorem 5 (Bafna-Pevzner [1]) *TED(S, R) can be approximated within a factor of 1.5 in* $O(n^2)$ *time.*

Furthermore, even if S and R are arbitrary strings from σ, it is possible to approximately compute both $BED(S, R)$ and $EDM(S, R)$ in near linear time. More specifically obtain an embedding of S and R to binary vectors $f(S)$ and $f(R)$ such that:

Theorem 6 (Muthukrishnan-Sahinalp [12]) $\frac{||f(S)-f(R)||_1}{\log^* n} \leq BED(S, R) \leq ||f(S) - f(R)||_1 \cdot \log n$.

In other words, the Hamming distance between $f(S)$ and $f(R)$ approximates $BED(S, R)$ within a factor of $\log n \cdot \log^* n$. Similarly for $EDM(S, R)$, it is possible to embed S and R to integer valued vectors $F(S)$ and $F(R)$ such that:

Theorem 7 (Cormode-Muthukrishnan [4]) $\frac{||F(S)-F(R)||_1}{\log^* n} \leq EDM(S,R) \leq ||F(S) - F(R)||_1 \cdot \log n$.

In other words, the L_1 distance between $F(S)$ and $F(R)$ approximates $EDM(S, R)$ within a factor of $\log n \cdot \log^* n$.

The embedding of strings S and R into binary vectors $f(S)$ and $f(R)$ is introduced in [5] and is based on the Locally Consistent Parsing described above. To obtain the embedding, one needs to hierarchically partition S and R into growing size *core* blocks. Given an alphabet σ, Locally Consistent Parsing can identify only a limited number of substrings as core blocks. Consider the lexicographic ordering of these core blocks. Each dimension i of the embedding $f(S)$ simply indicates (by setting $f(S)[i] = 1$) whether S includes the ith core block corresponding to the alphabet σ as a substring. Note that if a core block exists in S as a substring, Locally Consistent Parsing will identify it.

Although the embedding above is exponential in size, the resulting binary vector $f(S)$ is very sparse. A simple representation of $f(S)$ and $f(R)$, exploiting their sparseness can be computed in time $O(n \log^* n)$ and the Hamming distance between $f(S)$ and $f(R)$ can be computed in linear time by the use of this representation [12].

The embedding of S and R into integer valued vectors $F(S)$ and $F(R)$ are based on similar techniques. Again, the total time needed to approximate $EDM(S, R)$ within a factor of $\log n \cdot \log^* n$ is $O(n \log^* n)$.

Applications

Edit distances have important uses in computational evolutionary biology, in estimating the evolutionary distance between pairs of genome sequences under various edit operations. There are also several applications to the *document exchange problem* or *document reconciliation problem* where two copies of a text string S have been subject to edit operations (both single character and block edits) by two parties resulting in two versions S_1 and S_2, and the parties communicate to reconcile the differences between the two versions. An information theoretic lower bound on the number of bits to communicate between the two parties is then $\Omega(BED(S, R)) \cdot \log n$. The embedding of S and R to binary strings $f(S)$ and $f(R)$ provides a simple protocol [5] which gives a near-optimal tradeoff between the number of rounds of communication and the total number of bits exchanged and works with high probability.

Another important application is to the Sequence Nearest Neighbors (SNN) problem, which asks to preprocess a set of strings $S_1, \ldots, S_k$ so that given an on-line query string R, the string S_i which has the lowest distance of choice to R can be computed in time polynomial with $|R|$ and polylogarithmic with $\sum_{j=1}^{k} |S_j|$. There are no known exact solutions for the SNN problem under any edit distance considered here. However, in [12], the embedding of strings S_i into binary vectors $f(S_i)$, combined with the Approximate Nearest Neighbors results given in [6] for Hamming Distance, provides an approximate solution to the SNN problem under block edit distance as follows.

Theorem 8 (Muthukrishnan-Sahinalp [12]) *It is possible to preprocess a set of strings $S_1, \ldots, S_k$ from a given alphabet σ in $O(poly(\sum_{j=1}^{k} |S_j|))$ time such that for any on-line query string R from σ one can compute a string S_i in time $O(polylog(\sum_{j=1}^{k} |S_j|) \cdot poly(|R|))$ which guarantees that for all $h \in [1, k]$, $BED(S_i, R) \leq BED(S_h, R) \cdot \log(\max_j |S_j|) \cdot \log^*(\max_j |S_j|)$.*

Open Problems

It is interesting to note that when dealing with permutations of the alphabet σ the problem of computing both character edit distances and block edit distances become much easier; one can compute $PED(S, R)$ exactly and $TED(S, R)$ within an approximation factor of 1.5 in $\tilde{O}(n)$ time. For arbitrary strings, it is an open question whether one can approximate $TED(S, R)$ or $BED(S, R)$ within a factor of $o(\log n)$ in polynomial time.

One recent result in this direction shows that it is not possible to obtain a polylogarithmic approximation to $TED(S, R)$ via a greedy strategy [7]. Furthermore, although there is a lower bound of $\Omega(n^{\frac{1}{3}})$ on the approximation factor that can be achieved for computing the standard edit distance in $\tilde{O}(n)$ time by the use of string embeddings, there is no general lower bound on how closely one can approximate $ED(S, R)$ in near linear time.

Problem Definition

The basic group testing problem is to identify the unknown set of *positive items* from a large population of *items* using as few *tests* as possible. A test is a subset of items. A test returns positive if there is a positive item in the subset. The semantics of "positives," "items," and "tests" depend on the application.

In the original context [3], group testing was invented to solve the problem of identifying syphilis-infected blood samples from a large collection of WWII draftees' blood samples. In this case, items are blood samples, which are positive if they are infected. A test is a *pool* (group) of blood samples. Testing a group of samples at a time will save resources if the test outcome is negative. On the other

hand, if the test outcome is positive, then all we know is that at least one sample in the pool is positive, but we do not know which one(s).

In *nonadaptive combinatorial group testing* (NACGT), we assume that the number of positives is at most d for some fixed integer d and that all tests have to be specified in advance before any test outcome is known. The NACGT paradigm has found numerous applications in many areas of mathematics, computer science, and computational biology [4, 9, 10].

A NACGT strategy with t tests on a universe of N items is represented by a $t \times N$ binary matrix $\mathbf{M} = (m_{ij})$, where $m_{ij} = 1$ iff item j belongs to test i. Let $\mathbf{M}_i$ and $\mathbf{M}^j$ denote row i and column j of $\mathbf{M}$, respectively. Abusing notation, we will also use $\mathbf{M}_i$ (respectively, $\mathbf{M}^j$) to denote the set of rows (respectively, columns) corresponding to the 1-entries of row i (respectively, column j). In other words, $\mathbf{M}_i$ is the ith pool, and $\mathbf{M}^j$ is the set of pools that item j belongs to.

Let $D \subset [N]$ be the unknown subset of positive items, where $|D| \leq d$. Let $\boldsymbol{y} = (y_i)_{i=1}^t \in \{0,1\}^t$ denote the test outcome vector, i.e., $y_i = 1$ iff the ith test is positive. Then, the test outcome vector is precisely the (Boolean) union of the positive columns: $\boldsymbol{y} = \bigcup_{j \in D} \mathbf{M}^j$. The task of identifying the unknown subset D from the test outcome vector $\boldsymbol{y}$ is called *decoding*.

The main problem In many modern applications of NACGT, there are two key requirements for an NACGT scheme:

1. *Small number of tests*. "Tests" are computationally expensive in many applications.
2. *Efficient decoding*. As the item universe size N can be extremely large, it would be ideal for the decoding algorithm to run in time sublinear in N and more precisely in $\text{poly}(d, \log N)$ time.

Key Results

To be able to uniquely identify an arbitrary subset D of at most d positives, it is necessary and sufficient for the test outcome vectors $\boldsymbol{y}$ to be different for distinct subsets D of at most d positives. An NACGT matrix with the above property is called *d-separable*. However, in general such matrices only admit the brute force $\Omega(N^d)$-time decoding algorithm. A very natural decoding algorithm called the *naïve decoding algorithm* runs much faster, in time $O(tN)$.

Definition 1 (Naïve decoding algorithm) Eliminate all items that participate in negative tests; return the remaining items.

This algorithm does not work for arbitrary d-separable matrices. However, if the test matrix $\mathbf{M}$ satisfies a slightly stronger property called *d-disjunct*, then the naïve decoding algorithm is guaranteed to work correctly.

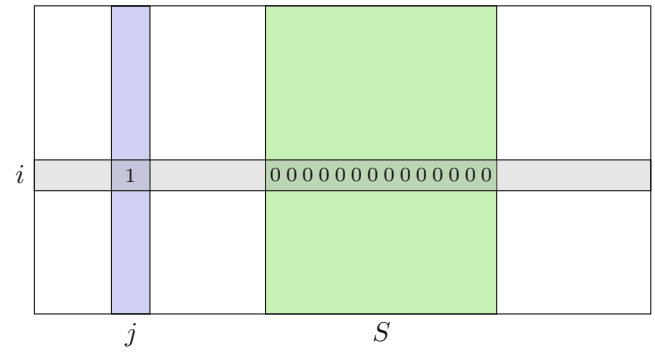
Definition 2 (Disjunct matrix) A $t \times N$ binary matrix $\mathbf{M}$ is said to be d-disjunct iff $\mathbf{M}^j \setminus \bigcup_{k \in S} \mathbf{M}^k \neq \emptyset$ for any set S of d columns and any $j \notin S$. (See Fig. 1.)

Minimize Number of Tests

It is remarkable that d-disjunct matrices not only allow for linear time decoding, which is a vast improvement over the brute-force algorithm for separable matrices, but also have asymptotically the same number of tests as d-separable matrices [4]. Let $t(d, N)$ denote the minimum number of rows of an N-column d-disjunct matrix. It has been known for about 40 years [5] that $t(\Omega(\sqrt{N}), N) = \Theta(N)$, and for $d = O(\sqrt{N})$ we have

$$\Omega\left(\frac{d^2}{\log d} \log N\right) \leq t(d, N) \leq O(d^2 \log N). \tag{1}$$

A $t \times N$ d-disjunct matrix with $t = O(d^2 \log N)$, rows can be constructed randomly or even deterministically (see [11]). However, the decoding time $O(tN)$ of the naïve decoding algorithm is still too slow for modern applications, where in most cases $d \ll N$ and thus $t \ll N$.



Efficient Decodable Group Testing, Fig. 1 A d-disjunct matrix has the following property: for any subset S of d (not necessarily contiguous) columns, and any column j that is not present in S, there exists a row i that has a 1 in column j and all zeros in S

Efficient Decoding

An ideal decoding time would be in the order of $\text{poly}(d, \log N)$, which is sublinear in N for practical ranges of d. Ngo, Porat, and Rudra [10] showed how to achieve this goal using a couple of ideas: (a) two-layer test matrix construction and (b) code concatenation using a list recoverable code.

(a) Two-layer test matrix construction The idea is to construct $\mathbf{M}$ by stacking on top of one another two matrices: a "filtering" matrix $\mathbf{F}$ and an "identification" matrix $\mathbf{D}$. (See Fig. 2.) The filtering matrix is used to quickly identify a "small" set of L candidate items including *all* the positives. Then, the identification matrix is used to pinpoint precisely the positives. For example, let $\mathbf{D}$ be any d-disjunct matrix, and that from the tests corresponding to the rows of $\mathbf{F}$, we can produce a set S of $L = \text{poly}(d, \log N)$ candidate items in time $\text{poly}(d, \log N)$. Then, by running the naïve decoding algorithm on S using test results corresponding to the rows of $\mathbf{D}$, we can identify all the positives in time $\text{poly}(d, \log N)$. To formalize the notion of "filtering matrix," we borrow a concept from coding theory, where producing a small list of candidate codewords is the *list decoding problem* [6].

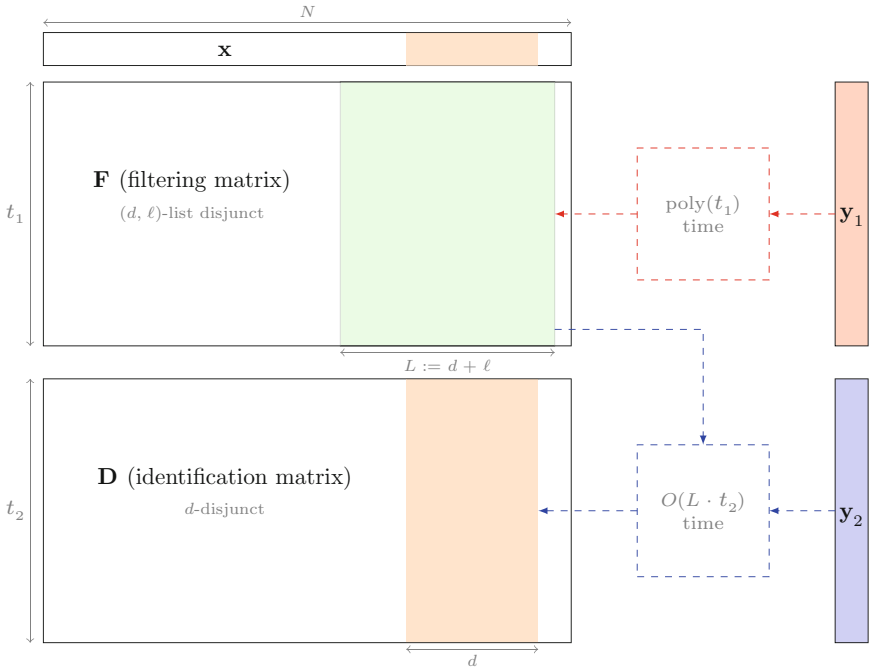
Definition 3 (List-disjunct matrix) Let $d + \ell \leq N$ be positive integers. A matrix $\mathbf{F}$ is (d, ℓ)-list disjunct if and only if $\bigcup_{j \in T} \mathbf{M}^j \setminus \bigcup_{k \in S} \mathbf{M}^k \neq \emptyset$ for any two disjoint sets S and T of columns of $\mathbf{F}$ with $|S| = d$ and $|T| = \ell$. (See Fig. 3.)

Note that a matrix is d-disjunct matrix iff it is $(d, 1)$-list disjunct. However, the relaxation to $\ell = \Theta(d)$ allows the existence (and construction) of $(d, O(d))$-list-disjunct matrices with $\Theta(d \log(N/d))$ rows. The existence of such small list-disjunct matrices is crucially used in the second idea below.

(b) Code Concatenation with list recoverable codes A $t \times N$ (d, ℓ)-list-disjunct matrix admits $O(tN)$-decoding time using the naïve decoding algorithm. However, to achieve $\text{poly}(d, \log N)$ decoding time overall, we will need to construct list-disjunct matrices that allow for a $\text{poly}(d, \log N)$ decoding time. In particular, to use such a matrix as a filtering matrix, it is necessary that $\ell = \text{poly}(d)$. To construct efficiently decodable list-disjunct matrices, we need other ideas. Ngo, Porat, and Rudra [10] used a connection to list recoverable codes [6] to construct such matrices. This connection was used to construct $(d, O(d^{3/2}))$-list-disjunct matrices with $t = o(d^2 \log_d N)$ rows that can be decoded in $\text{poly}(t)$ time. This along with the construction in Fig. 2 implies the following result:

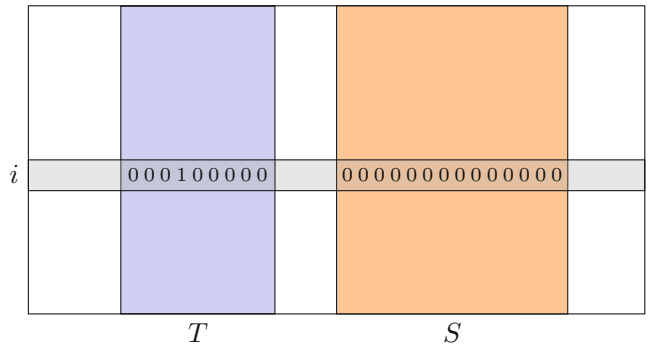
Theorem 1 ([10]) *Given any d-disjunct matrix, it can be converted into another matrix with $1 + o(1)$ times as many rows that is also efficiently decodable (even if the original matrix was not).*

Other constructions of list-disjunct matrices with worse parameters were obtained earlier by Indyk, Ngo and Rudra [7], and Cheraghchi [1] using connections to expanders and randomness extractors.



Efficient Decodable Group Testing, Fig. 2 The vector $\boldsymbol{x}$ denotes the characteristic vector of the d positives (illustrated by the *orange box*). The final matrix is the stacking of $\mathbf{F}$, which is a (d, ℓ)-list-disjunct matrix, and $\mathbf{D}$, which is a d-disjunct matrix. The result vector is naturally divided into $\boldsymbol{y}_1$ (the part corresponding to $\mathbf{F}$ and denoted by the *red vector*) and $\boldsymbol{y}_2$ (the part corresponding to $\mathbf{D}$ and denoted by the *blue vector*). The decoder first uses $\boldsymbol{y}_1$ to compute a superset of the set of positives (denoted by *green box*), which is then used with $\boldsymbol{y}_2$ to compute the final set of positives. The first step of the decoding is represented by the *red-dotted box*, while the second step (naïve decoder) is denoted by the *blue-dotted box*

Efficient Decodable Group Testing, Fig. 3 A (d, ℓ)-list-disjunct matrix satisfies the following property: for any subset S of size d and any disjoint subset T of size ℓ, there exists a row i that has a 1 in at least one column in T and all zeros in S



Applications

Heavy hitter is one of the most fundamental problems in data streaming [8]. Cormode and Muthukrishnan [2] showed that an NACGT scheme that is efficiently decodable and is also *explicit* solves a natural version of the heavy hitter problem. An explicit construction means one needs an algorithm that outputs a column or a specific entry of $\mathbf{M}$ instead of storing the entire matrix $\mathbf{M}$ which can be extremely space consuming. This is possible with Theorem 1 by picking the filtering and decoding matrices to be explicit.

Another important generalization of NACGT matrices are those that can handle errors in the

test outcomes. Again this is possible with the construction of Fig. 2 if the filtering and decoding matrices are also error tolerant. The list-disjunct matrices constructed by Cheraghchi are also error tolerant [1].

Open Problems

The outstanding open problem in group testing theory is to close the gap (1). An explicit construction of (d, d)-list-disjunct matrices is not known; solving this problem will lead to a scheme that is (near-)optimal in all desired objectives.

Problem Definition

For a hypergraph $H = (V, \mathcal{E})$, a subset of edges $\mathcal{E}' \subseteq \mathcal{E}$ is an *exact cover* of H, if every vertex of V is contained in exactly one hyperedge of $\mathcal{E}'$, that is, for all $e, f \in \mathcal{E}'$ with $e \neq f$, $e \cap f = \emptyset$ and $\bigcup \mathcal{E}' = V$. The Exact Cover (XC) problem asks for the existence of an exact cover in a given hypergraph H. Exact Cover is in Karp's famous list of 21 NP-complete problems; it is NP-complete even for 3-element hyperedges (problem X3C [SP2] in [14]).

Let G be a finite simple undirected graph with vertex set V and edge set E. A vertex *dominates* itself and all its neighbors, i.e., every vertex $v \in V$ dominates its closed neighborhood $N[v] = \{u \mid u = v \text{ or } uv \in E\}$. A vertex subset D of G is an *efficient dominating* (*e.d.*) set, if, for every vertex $v \in V$, there is exactly one $d \in D$ dominating v [1, 2]. An edge subset M of G is an *efficient edge dominating* (*e.e.d.*) set, if it is an efficient dominating set in the line graph $L(G)$ of G [15]. Efficient dominating sets are sometimes also called *independent perfect dominating sets*, and efficient edge dominating sets are also known as *dominating induced matchings*.

The EFFICIENT DOMINATION (ED) problem for a graph G asks for the existence of an e.d. set in G. The EFFICIENT EDGE DOMINATION (EED) problem asks for the existence of an e.d. set in the line graph $L(G)$.

For a graph G, let $\mathcal{N}(G)$ denote its closed neighborhood hypergraph, that is, for every vertex $v \in V$, the closed neighborhood $N[v]$ is a hyperedge in $\mathcal{N}(G)$; note that this is a multiset since distinct vertices may have the same closed neighborhood. For a graph G, the *square* G^2 has the same vertex set as G and two vertices, x and y, are adjacent in G^2, if and only if their distance in G is at most 2. Note that G^2 is isomorphic to $L(\mathcal{N}(G))$.

By definition, the ED problem on a graph G is the same as the Exact Cover problem on its closed neighborhood hypergraph $\mathcal{N}(G)$, and the EED problem is the same as the Exact Cover problem on $L(\mathcal{N}(G))$.

Key Results

ED and EED are NP-complete; their complexity on special graph classes was studied in various papers – see, e.g., [2, 3, 12, 16–18, 20, 22, 24, 25] for ED and [5, 7, 11, 15, 19, 21] for EED. In particular, ED remains NP-complete for chordal graphs as well as for (very restricted) bipartite graphs such as chordal bipartite graphs, and EED is NP-complete for bipartite graphs but solvable in linear time for chordal graphs.

ED for Graphs

A key tool in [8] is a reduction of ED for G to the maximum-weight independent set problem for G^2, which is based on the following observation:

For a hypergraph $H = (V, \mathcal{E})$ and $e \in \mathcal{E}$, let $\omega(e) := |e|$ be an edge weight function. For the line graph $L(H)$, let $\alpha_\omega(L(H))$ denote the maximum weight of an independent vertex set in $L(H)$. The weight of any independent vertex set in $L(H)$ is at most $|V|$, and H has an exact cover, if and only if $\alpha_\omega(L(H)) = |V|$. Using the fact that G^2 is isomorphic to $L(\mathcal{N}(G))$ and ED on G corresponds to Exact Cover on $\mathcal{N}(G)$, this means that ED on G can be reduced to the maximum weight of an independent vertex set in G^2, similarly for EED. This unified approach helps to answer some open questions on ED and EED for graph classes; one example is ED for strongly chordal graphs: Since for a dually chordal graph G, its square G^2 is chordal, ED is solvable in polynomial time for dually chordal graphs and thus for strongly chordal graphs [8] (recall that ED is NP-complete for chordal graphs). Similar properties of powers lead to polynomial time for ED on AT-free graphs using known results [8]. For P_5-free graphs having an e.d., G^2 is P_4-free [9].

ED is NP-complete for planar bipartite graphs of maximum degree 3 [9]. In [23], this is sharpened by adding a girth condition: ED is NP-complete for planar bipartite graphs of maximum degree 3 and girth at least g, for every fixed g.

From the known results, it follows that ED is NP-complete for F-free graphs whenever F contains a cycle or a claw. Thus, F can be assumed to be cycle- and claw-free (see, e.g., [9]); such graphs F are called *linear forests*. For $(P_3 + P_3)$-free graphs and thus for P_7-free graphs, ED is NP-complete. ED is robustly solvable in time $O(nm)$ for P_5-free graphs and for $(P_4 + P_2)$-free graphs [9, 23]. For every fixed $k \geq 1$, ED is solvable in polynomial time for $(P_5 + kP_2)$-free graphs [4]. For P_6-free graphs, the complexity of ED is an open problem, and correspondingly for $(P_6 + kP_2)$-free graphs; these are the only open cases for F-free graphs.

EED for Graphs

The fact that graphs having an e.e.d. are K_4-free leads to a simple linear time algorithm for EED on chordal graphs. More generally, EED is solvable in polynomial time for hole-free graphs and thus for weakly chordal graphs and for chordal bipartite graphs [7]. This also follows from the fact that, for a weakly chordal graph G, $L(G)^2$ is weakly chordal [10] and from the reduction of EED for G to the maximum-weight independent set problem for $L(G)^2$. In [23], this is improved to a robust $O(nm)$ time algorithm for EED on hole-free graphs. In [8], we show that EED is solvable in linear time for dually chordal graphs.

One of the open problems for EED was its complexity on P_k-free graphs. In [5], we show that EED is solvable in linear time for P_7-free graphs. The complexity of EED remains open for P_k-free graphs, $k \geq 8$. In [11], EED is solved in polynomial time on claw-free graphs. EED is NP-complete for planar bipartite graphs of maximum degree 3 [7]. In [23], it is shown that EED is NP-complete for planar bipartite graphs of maximum degree 3 and girth at least g, for every fixed g.

XC, ED, and EED for Hypergraphs

The notion of α-*acyclicity* [13] is one of the most important and most frequently studied hypergraph notions. Among the many equivalent conditions describing α-acyclic hypergraphs, we take the following: For a hypergraph $H = (V, \mathcal{E})$, a tree T with node set $\mathcal{E}$ and edge set E_T is a *join tree* of H, if, for all vertices $v \in V$, the set of hyperedges $\mathcal{E}_v := \{e \in \mathcal{E} \mid v \in e\}$ containing v induces a subtree of T. H is α-*acyclic*, if it has a join tree. Let $H^* := (\mathcal{E}, \{\mathcal{E}_v \mid v \in V\})$ be the *dual hypergraph* of H. The hypergraph $H = (V, \mathcal{E})$ is a *hypertree*, if there is a tree T with vertex set V such that, for all $e \in \mathcal{E}$, $T[e]$ is connected. Obviously, H is α-acyclic, if and only if its dual H^* is a hypertree.

By a result of Duchet, Flament, and Slater (see, e.g., [6]), it is known that H is a hypertree, if and only if H has the Helly property and its line graph $L(H)$ is chordal. In its dual version, it says that H is α-acyclic, if and only if H is conformal and its 2-section graph is chordal. In [8], we show:

(i) ED and XC are NP-complete for α-acyclic hypergraphs but solvable in polynomial time for hypertrees.
(ii) EED is NP-complete for hypertrees but solvable in polynomial time for α-acyclic hypergraphs.

Efficient Methods for Multiple Sequence Alignment with Guaranteed Error Bounds

S.M. Yiu and Francis Y.L. Chin
Department of Computer Science, University of Hong Kong, Hong Kong, China

Keywords

Multiple global alignment; Multiple string alignment

Years and Authors of Summarized Original Work

1993; Gusfield

Problem Definition

Multiple sequence alignment is an important problem in computational biology. Applications include finding highly conserved subregions in a given set of biological sequences and inferring the evolutionary history of a set of taxa from their associated biological sequences (e.g., see [9]). There are a number of measures proposed for evaluating the goodness of a multiple alignment, but prior to this work, no efficient methods are known for computing the optimal alignment for any of these measures. The work of Gusfield [7] gives two computationally efficient multiple alignment approximation algorithms for two of the measures with approximation ratio of less than 2. For one of the measures, they also derived a randomized algorithm, which is much faster and with high probability and reports a multiple alignment with small error bounds. To the best knowledge of the entry authors, this work is the first to provide approximation algorithms (with guarantee error bounds) for this problem.

Notations and Definitions

Let X and Y be two strings of alphabet Σ. The pairwise alignment of X and Y maps X and Y into strings X' and Y' that may contain spaces, denoted by '_', where (1) $|X'| = |Y'| = \ell$ and (2) removing spaces from X' and Y' returns X and Y, respectively. The score of the alignment is defined as $d(X', Y') = \sum_{i=1}^{\ell} s(X'(i), Y'(i))$ where $X'(i)$ (and $Y'(i)$) denotes the ith character in X' (and Y') and $s(a, b)$ with $a, b \in \Sigma \cup$ '_' is the distance-based scoring scheme that satisfies the following assumptions:

1. $s(\text{'\_'}, \text{'\_'}) = 0$;
2. Triangular inequality: for any three characters, $x, y, z, s(x, z) \leq s(x, y) + s(y, z)$.

Let $\chi = X_1, X_2, \ldots, X_k$ be a set of $k > 2$ strings of alphabet Σ. A multiple alignment A of these k strings maps $X_1, X_2, \ldots, X_k$ to $X_1', X_2', \ldots, X_k'$ that may contain spaces such that (1) $|X_1'| = |X_2'| = \cdots = |X_k'| = \ell$ and (2) removing spaces from X_i' returns X_i for all $1 \leq i \leq k$. The multiple alignment A can be represented as a $k \times \ell$ matrix.

The Sum of Pairs (SP) Measure

The score of a multiple alignment A, denoted by SP(A), is defined as the sum of the scores of pairwise alignments induced by A, that is, $\sum_{i<j} d(X_i', X_j') = \sum_{i<j} \sum_{p=1}^{\ell} s(X_i'[p], X_j'[p])$ where $1 \leq i < j \leq k$.

Problem 1 (Multiple Sequence Alignment with Minimum SP Score)

INPUT: A set of k strings, a scoring scheme s.
OUTPUT: A multiple alignment A of these k strings with minimum SP(A).

The Tree Alignment (TA) Measure

In this measure, the multiple alignment is derived from an evolutionary tree. For a given set χ of k strings, let $\chi' \supseteq \chi$. An evolutionary tree T_χ' for χ is a tree with at least k nodes, where there is a one-to-one correspondence between the nodes and the strings in χ'. Let $X_u' \in \chi'$ be the string for node u. The score of T_χ', denoted by TA $\left(T_\chi'\right)$, is defined as $\sum_{e=(u,v)} D\left(X_u', X_v'\right)$ where e is an edge in T_χ' and $D\left(X_u', X_v'\right)$ denotes the score of the optimal pairwise alignment for X_u' and X_v'. Analogously, the multiple alignment of χ under the TA measure can also be represented by a $|\chi'| \times \ell$ matrix, where $|\chi'| \geq k$, with a score defined as $\sum_{e=(u,v)} d\left(X_u', X_v'\right)$ (e is an edge in T_χ'), similar to the multiple alignment under the SP measure in which the score is the summation of the alignment scores of all pairs of strings. Under the TA measure, since it is always possible to construct the $|\chi'| \times \ell$ matrix such that $d\left(X_u', X_v'\right) = D\left(X_u', X_v'\right)$ for all $e = (u, v)$ in T_χ' and we are usually interested in finding the multiple alignment with the minimum TA value, so $D\left(X_u', X_v'\right)$ is used instead of $d\left(X_u', X_v'\right)$ in the definition of TA $\left(T_\chi'\right)$.

Problem 2 (Multiple Sequence Alignment with Minimum TA Score)

INPUT: A set of k strings, a scoring scheme s.
OUTPUT: An evolutionary tree T for these k strings with minimum TA(T).

Key Results

Theorem 1 *Let A^* be the optimal multiple alignment of the given k strings with minimum SP score. They provide an approximation algorithm (the center star method) that gives a multiple alignment A such that* $\frac{SP(A)}{SP(A^*)} \leq \frac{2(k-1)}{k} = 2 - \frac{2}{k}$.

The center star method is to derive a multiple alignment which is consistent with the optimal pairwise alignments of a center string with all the other strings. The bound is derived based on the triangular inequality of the score function. The time complexity of this method is $O(k^2\ell^2)$, where ℓ^2 is the time to solve the pairwise alignment by dynamic programming and k^2 is needed to find the center string, X_c, which gives the minimum value of $\sum_{i \neq c} D(X_c, X_i)$.

Theorem 2 *Let A^* be the optimal multiple alignment of the given k strings with minimum SP score. They provide a randomized algorithm that gives a multiple alignment A such that $\frac{SP(A)}{SP(A^*)} \leq 2 + \frac{1}{r-1}$ with probability at least $1 - \left(\frac{r-1}{r}\right)^p$ for any $r > 1$ and $p \geq 1$. Instead of computing $\binom{k}{2}$ optimal pairwise alignments to find the best center string, the randomized algorithm only considers p randomly selected strings to be candidates for the best center string; thus, this method needs to x compute only $(k-1)p$ optimal pairwise alignments in $O(kp\ell^2)$ time where $1 \leq p \leq k$.*

Theorem 3 *Let T^* be the optimal evolutionary tree of the given k strings with minimum TA score. They provide an approximation algorithm that gives an evolutionary tree T such that $\frac{TA(T)}{TA(T^*)} \leq \frac{2(k-1)}{k} = 2 - \frac{2}{k}$.*

In the algorithm, they first compute all the $\binom{k}{2}$ optimal pairwise alignments to construct a graph with every node representing a distinct string X_i and the weight of each edge (X_i, X_j) as $D(X_i X_j)$. This step determines the overall time complexity $O(k^2\ell^2)$. Then, they find a minimum spanning tree from the graph. The multiple alignment has to be consistent with the optimal pairwise alignments represented by the edges of this minimum spanning tree.

Applications

Multiple sequence alignment is a fundamental problem in computational biology. In particular, multiple sequence alignment is useful in identifying those common structures, which may only be weakly reflected in the sequence and not easily revealed by pairwise alignment. These common structures may carry important information for their evolutionary history, critical conserved motifs, and common 3D molecular structure, as well as biological functions.

More recently, multiple sequence alignment is also used in revealing noncoding RNAs (ncRNAs) [2]. In this type of multiple alignment, we are not only align the underlying sequences but also the secondary structures of the RNAs. Researchers believe that ncRNAs that belong to the same family should have common components giving a similar secondary structure. The multiple alignment can help to locate and identify these common components.

Open Problems

A number of open problems related to the work of Gusfield remain open. For the SP measure, the center star method can be extended to the q-star method ($q > 2$) with approximation ratio of $2 - q/k$ [1, 10], sect. 7.5 of [11]). Whether there exists an approximation algorithm with better approximation ratio or with better time complexity is still unknown. For the TA measure, to be the best knowledge of the entry authors, the approximation ratio in Theorem 3 is currently the best result.

Another interesting direction related to this problem is the constrained multiple sequence alignment problem [12] which requires the multiple alignment to contain certain aligned characters with respect to a given constrained sequence. The best known result [6] is an approximation algorithm (also follows the idea of center star method) which gives an alignment with approximation ratio of $2 - 2/k$ for k strings.

For the complexity of the problem, Wang and Jiang [13] were the first to prove the NP-hardness of the problem with SP score under a *nonmetric* distance measure over a 4-symbol alphabet. More recently, in [5], the multiple alignment problem with SP score, star alignment, and TA score have been proved to be NP-hard for all binary or larger alphabets under *any metric*. Developing efficient approximation algorithms with good bounds for any of these measures is desirable.

Experimental Results

Two experiments have been reported in the paper showing that the worst-case error bounds in

Theorems 1 and 2 (for the SP measure) are pessimistic compared to the typical situation arising in practice.

The scoring scheme used in the experiments is $s(a,b) = 0$ if $a = b$; $s(a,b) = 1$ it either a or b is a space; otherwise $s(a,b) = 2$. Since computing the optimal multiple alignment with minimum SP score has been shown to be NP-hard, they evaluate the performance of their algorithms using the lower bound of $\sum_{i<j} D(X_i, X_j)$ (recall that $D(X_i, X_j)$ is the score of the optimal pairwise alignment of X_i and X_j). They have aligned 19 similar amino acid sequences with average length of 60 of homeoboxs from different species. The ratio of the scores of reported alignment by the center star method to the lower bound is only 1.018 which is far from the worst-case error bound given in Theorem 1. They also aligned 10 not-so-similar sequences near the homeoboxes, and the ratio of the reported alignment to the lower bound is 1.162. Results also show that the alignment obtained by the randomized algorithm is usually not far away from the lower bound.

Data Sets

The exact sequences used in the experiments are not provided.

Problem Definition

We consider the following fundamental problem in scheduling theory. Suppose that there is a set $\mathcal{J}$ of n independent jobs J_j with processing time p_j and a set $\mathcal{P}$ of m nonidentical processors P_i that run at different speeds s_i. If job J_j is executed on processor P_i, then processor P_i needs p_j/s_i time units to complete the job. The goal is to find an assignment $a : \mathcal{J} \to \mathcal{P}$ for the jobs to the processors that minimizes the total length of the schedule $\max_{i=1,\ldots,m} \sum_{J_j : a(J_j)=P_i} p_j/s_i$. This is the minimum time needed to complete all jobs on the processors. The problem is denoted $Q||C_{\max}$ and it is also called the minimum makespan problem on uniform parallel processors. By simplicity we may assume that the number m of processors is bounded by the number of jobs; otherwise select only the fastest n machines in $O(m)$ time.

Key Results

The scheduling problem on uniform and also identical processors is NP-hard [7] and the existence of a polynomial time algorithm for it would imply $P = NP$. Hochbaum and Shmoys [9, 10] presented a family of polynomial time approximation algorithms $\{A_\epsilon | \epsilon > 0\}$ for both scheduling problems, where each algorithm A_ϵ generates a schedule of length $(1 + \epsilon)\, OPT(I)$ for each instance I and has running time polynomial in the input size $|I|$. Such a family of algorithms is called a polynomial time approximation scheme (PTAS). It is allowed that the running time of each algorithm A_ϵ is exponential in $1/\epsilon$. The running time of the PTAS for uniform processors by Hochbaum and Shmoys [10] is $(n/\epsilon)^{O(1/\epsilon^2)}$.

Two restricted classes of approximation schemes were defined to classify different faster approximation scheme. An efficient polynomial time approximation scheme (EPTAS) is a PTAS with running time $f(1/\epsilon)\, poly(|I|)$ for some function f, while a fully polynomial time approximation scheme (FPTAS) runs in time $poly(1/\epsilon, |I|)$; polynomial in $1/\epsilon$ and the size $|I|$ of the instance. Since the scheduling problem on identical and also uniform processors is NP-hard in the strong sense (it contains bin packing as special case), we cannot hope for an FPTAS. For identical processors, Hochbaum and Shmoys (see [8]) and Alon et al. [1] gave an EPTAS with running time $f(1/\epsilon) + O(n)$, where f is doubly exponential in $1/\epsilon$.

Known Techniques

Hochbaum and Shmoys [9] introduced the dual approximation approach for identical and uniform processors and used the relationship between these scheduling problems and the bin packing problem. This relationship between scheduling on identical processors and bin packing problem had been exploited already by Coffman et al. [3]. Using the dual approximation approach, Hochbaum and Shmoys [9] proposed a PTAS for scheduling on identical processors with running time $(n/\epsilon)^{O(1/\epsilon^2)}$.

The main idea in the approach is to guess the length of the schedule by using binary search and to consider the corresponding bin packing instance with scaled identical bin size equal to 1. Then they distinguish between large items with size $> \epsilon$ and small items with size $\leq \epsilon$. For the large items they use a dynamic programming approach to calculate the minimum number of bins needed to pack them all. Afterward, they pack the remaining small items in a greedy way in enlarged bins of size $1 + \epsilon$ (i.e., they pack into any bin that currently contains items of total size at most 1; and if no such bin exists, then they open a new bin).

Furthermore, Hochbaum and Shmoys (see [8]) and Alon et al. [1] achieved an improvement to linear time by using an integer linear program for the cutting stock formulation of bin packing for the large items and a result on integer linear programming with a fixed number of variables by Lenstra [15]. This gives an EPTAS for identical

processors with running time $f(1/\epsilon) + O(n)$ where f is doubly exponential in $1/\epsilon$.

For uniform processors, the decision problem for the scheduling problem with makespan at most T can be viewed as a bin packing problem with different bin sizes. Using an ϵ-relaxed version of this bin packing problem, Hochbaum and Shmoys [10] were also able to obtain a PTAS for scheduling on uniform processors with running time $(n/\epsilon)^{O(1/\epsilon^2)}$. The main underlying idea in their algorithm is a clever rounding technique and a nontrivial dynamic programming approach over the different bins ordered by their sizes.

New Results

Recently, Jansen [11] proposed an EPTAS for scheduling jobs on uniform machines:

Theorem 1 ([11]) *There is an EPTAS (a family of algorithms $\{A_\epsilon | \epsilon > 0\}$) which, given an instance I of $Q||C_{\max}$ with n jobs and m processors with different speeds and a positive number $\epsilon > 0$, produces a schedule for the jobs of length $A_\epsilon(I) \leq (1+\epsilon)OPT(I)$. The running time of A_ϵ is*

$$2^{O(1/\epsilon^2 \log^3(1/\epsilon))} + poly(n).$$

Interestingly, the running time of the EPTAS is only single exponential in $1/\epsilon$.

Integer Linear Programming and Grouping Techniques

The new algorithm uses the dual approximation method by Hochbaum and Shmoys [10] to transform the scheduling problem into a bin packing problem with different bin sizes. Next, the input is structured by rounding bin sizes and processing times to values of the form $(1+\delta)^i$ and $\delta(1+\delta)^i$ with $i \in \mathbb{Z}$ where δ depends on ϵ. After sorting the bins according to their sizes, $c_1 \geq \ldots \geq c_m$, three groups of bins are built: $\mathcal{B}_1$ with the largest K bins (where K is constant). Let G be the smallest index such that capacity $c_{K+G+1} \leq \gamma c_K$ where $\gamma < 1$ depends on ϵ; such an index G exists for $c_m \leq \gamma c_K$. In this case $\mathcal{B}_2$ is the set of the next G largest bins where the maximum size $c_{\max}(\mathcal{B}_2) = c_{K+1}$ divided by the minimum size $c_{\min}(\mathcal{B}_2) = c_{K+G}$ is bounded by a constant $1/\gamma$ and $\mathcal{B}_3$ is the set with the remaining smaller bins of size smaller than γc_K. This generates a gap of constant size between the capacities of bins in $\mathcal{B}_1$ and $\mathcal{B}_3$. If the rate c_m/c_K, where c_m is the smallest bin size, is larger the constant γ, then a simpler instance is obtained with only two groups $\mathcal{B}_1$ and $\mathcal{B}_2$ of bins.

For $\mathcal{B}_1$ all packings for the very large items are computed (those which only fit there). If there is a feasible packing, then a mixed integer linear program (MILP) or an integer linear program (ILP) in the simpler case is used to place the other items into the bins. The placement of the large items into the second group $\mathcal{B}_2$ is done via integral configuration variables; similar to the ILP formulation for bin packing by Fernandez de la Vega and Lueker [6]. Fractional configuration variables are used for the placement of large items into $\mathcal{B}_3$. Furthermore, additional fractional variables are taken to place small items into $\mathcal{B}_1$, $\mathcal{B}_2$, and $\mathcal{B}_3$. The MILP has only a constant number of integral variables and, therefore, can be solved via the algorithm by Lenstra or Kannan [14, 15].

In order to avoid that the running time is doubly exponential in $1/\epsilon$, a recent result by Eisenbrand and Shmonin [5] about integer cones is used. To apply their result a system of equalities for the integral configuration variables is considered and the corresponding coefficients are rounded. Then each feasible solution of the modified MILP contains at most $O(1/\delta \log^2(1/\delta))$ integral variables with values larger than zero. By choosing the strictly positive integral variables in the MILP, the number of integral configuration variables is reduced from $2^{O(1/\delta \log(1/\delta))}$ to $O(1/\delta \log^2(1/\delta))$. The number of choices is bounded by $2^{O(1/\delta^2 \log^3(1/\delta))}$.

Afterward, the fractional variables in the MILP solution are rounded to integral values using ideas from scheduling job shops [13] and scheduling on unrelated machines [16]. The effect of the rounding is that most of the items can be placed directly into the bins. Only a few of them cannot be placed this way, and here is where the K largest bins and the gap between $\mathcal{B}_1$ and $\mathcal{B}_3$ come into play. It can be proved that these items can be moved to the K largest bins by increasing their sizes only slightly.

Algorithm Avoiding the MILP

Recently an EPTAS for scheduling on uniform machines is presented by Jansen and Robenek [12] that avoids the use of an MILP or ILP solver. In the new approach instead of solving (M)ILPs, an LP-relaxation and structural information about the "closest" ILP solution is used.

In the following the main techniques are described for identical processors. For a given LP-solution x, the distance to the closest ILP solution y in the infinity norm is studied, i.e., $\|x - y\|_\infty$. For the constraint matrix A_δ of the considered LP, this distance is defined by

$$\max\text{-gap}(A_\delta) := \max\{\min\{\|y^\star - x^\star\|_\infty : y^\star \text{ solution of ILP}\} : x^\star \text{solution of LP}\}.$$

Let $C(A_\delta)$ denote an upper bound for $\max\text{-gap}(A_\delta)$. The running time of the algorithm is $2^{O(1/\epsilon \log(1/\epsilon) \log(C(A_\delta)))} + poly(n)$. The algorithm for uniform processors is more complex, but we obtain a similar running time $2^{O(1/\epsilon \log(1/\epsilon) \log(C(\tilde{A}_\delta)))} + poly(n)$, where the constraint matrix $\tilde{A}_\delta$ is slightly different. For the details we refer to [12].

It can be proved using a result by Cook et al. [4] that $C(A_\delta), C(\tilde{A}_\delta) \leq 2^{O(1/\epsilon \log^2(1/\epsilon))}$. Consequently, the algorithm has a running time at most $2^{O(1/\epsilon^2 \log^3(1/\epsilon))} + poly(n)$, the same as in [11]. But, to our best knowledge, no instance is known to take on the value $2^{O(1/\epsilon \log^2(1/\epsilon))}$ for $\max\text{-gap}(A_\delta)$. We conjecture $C(A_\delta) \leq poly(1/\epsilon)$. If that holds, the running time of the algorithm would be $2^{O(1/\epsilon \log^2(1/\epsilon))} + poly(n)$ and thus improve the result in [11].

Lower Bounds

Recently, Chen, Jansen, and Zhang [2] proved the following lower bound on the running time: For scheduling on an arbitrary number of identical machines, denoted by $P||C_{\max}$, a polynomial time approximation scheme (PTAS) of running time $2^{O((1/\epsilon)^{1-\delta})} * poly(n)$ for any $\delta > 0$ would imply that the exponential time hypothesis (ETH) for 3-SAT fails.

Open Problems

The main open question is whether there is an EPTAS for scheduling jobs on identical and uniform machines with a running time $2^{O(1/\epsilon \log^c(1/\epsilon))} * poly(n)$.

Experimental Results

None is reported.

High-performance computational biology

Years and Authors of Summarized Original Work

2002; Bader, Moret, Warnow

Problem Definition

In the 50 years since the discovery of the structure of DNA, and with new techniques for sequencing the entire genome of organisms, biology is rapidly moving towards a data-intensive, computational science. Many of the newly faced challenges require high-performance computing, either due to the massive-parallelism required by the problem, or the difficult optimization problems that are often combinatoric and NP-hard. Unlike the traditional uses of supercomputers for regular, numerical computing, many problems in biology are irregular in structure, significantly more challenging to parallelize, and integer-based using abstract data structures.

Biologists are in search of biomolecular sequence data, for its comparison with other genomes, and because its structure determines function and leads to the understanding of biochemical pathways, disease prevention and cure, and the mechanisms of life itself. Computational biology has been aided by recent advances in both technology and algorithms; for instance, the ability to sequence short contiguous strings of DNA and from these reconstruct the whole genome and the proliferation of high-speed microarray, gene, and protein chips for the study of gene expression and function determination. These high-throughput techniques have led to an exponential growth of available genomic data.

Algorithms for solving problems from computational biology often require parallel processing techniques due to the data- and compute-intensive nature of the computations. Many problems use polynomial time algorithms (e.g., all-to-all comparisons) but have long running times due to the large number of items in the input; for example, the assembly of an entire genome or the all-to-all comparison of gene sequence data. Other problems are compute-intensive due to their inherent algorithmic complexity, such as protein folding and reconstructing evolutionary histories from molecular data, that are known to be NP-hard (or harder) and often require approximations that are also complex.

Applications

Phylogeny Reconstruction

A phylogeny is a representation of the evolutionary history of a collection of organisms or genes (known as taxa). The basic assumption of process necessary to phylogenetic reconstruction is repeated divergence within species or genes. A phylogenetic reconstruction is usually depicted as a tree, in which modern taxa are depicted at the leaves and ancestral taxa occupy internal nodes, with the edges of the tree denoting evolutionary relationships among the taxa. Reconstructing phylogenies is a major component of modern

research programs in biology and medicine (as well as linguistics). Naturally, scientists are interested in phylogenies for the sake of knowledge, but such analyses also have many uses in applied research and in the commercial arena. Existing phylogenetic reconstruction techniques suffer from serious problems of running time (or, when fast, of accuracy). The problem is particularly serious for large data sets: even though data sets comprised of sequence from a single gene continue to pose challenges (e.g., some analyses are still running after 2 years of computation on medium-sized clusters), using whole-genome data (such as gene content and gene order) gives rise to even more formidable computational problems, particularly in data sets with large numbers of genes and highly-rearranged genomes.

To date, almost every model of speciation and genomic evolution used in phylogenetic reconstruction has given rise to NP-hard optimization problems. Three major classes of methods are in common use. Heuristics (a natural consequence of the NP-hardness of the problems) run quickly, but may offer no quality guarantees and may not even have a well-defined optimization criterion, such as the popular *neighbor-joining* heuristic [9]. Optimization based on the criterion of *maximum parsimony* (MP) [4] seeks the phylogeny with the least total amount of change needed to explain modern data. Finally, optimization based on the criterion of *maximum likelihood* (ML) [5] seeks the phylogeny that is the most likely to have given rise to the modern data.

Heuristics are fast and often rival the optimization methods in terms of accuracy, at least on datasets of moderate size. Parsimony-based methods may take exponential time, but, at least for DNA and amino acid data, can often be run to completion on datasets of moderate size. Methods based on maximum likelihood are very slow (the point estimation problem alone appears intractable) and thus restricted to very small instances, and also require many more assumptions than parsimony-based methods, but appear capable of outperforming the others in terms of the quality of solutions when these assumptions are met. Both MP- and ML-based analyses are often run with various heuristics to ensure timely termination of the computation, with mostly unquantified effects on the quality of the answers returned.

Thus there is ample scope for the application of high-performance algorithm engineering in the area. As in all scientific computing areas, biologists want to study a particular dataset and are willing to spend months and even years in the process: accurate branch prediction is the main goal. However, since all exact algorithms scale exponentially (or worse, in the case of ML approaches) with the number of taxa, speed remains a crucial parameter – otherwise few datasets of more than a few dozen taxa could ever be analyzed.

Experimental Results

As an illustration, this entry briefly describes a high-performance software suite, GRAPPA (Genome Rearrangement Analysis through Parsimony and other Phylogenetic Algorithms) developed by Bader et al. *GRAPPA* extends Sankoff and Blanchette's breakpoint phylogeny algorithm [10] into the more biologically-meaningful inversion phylogeny and provides a highly-optimized code that can make use of distributed- and shared-memory parallel systems (see [1, 2, 6, 7, 8, 11] for details). In [3], Bader et al. gives the first linear-time algorithm and fast implementation for computing inversion distance between two signed permutations. *GRAPPA* was run on a 512-processor IBM Linux cluster with Myrinet and obtained a 512-fold speedup (linear speedup with respect to the number of processors): a complete breakpoint analysis (with the more demanding inversion distance used in lieu of breakpoint distance) for the 13 genomes in the Campanulaceae data set ran in less than 1.5 h in an October 2000 run, for a *million-fold* speedup over the original implementation. The latest version features significantly improved bounds and new distance correction methods and, on the same dataset, exhibits a speedup factor of *over one billion*. GRAPPA achieves this speedup through a combination of parallelism and high-performance algorithm engineering.

Although such spectacular speedups will not always be realized, many algorithmic approaches now in use in the biological, pharmaceutical, and medical communities may benefit tremendously from such an application of high-performance techniques and platforms.

This example indicates the potential of applying high-performance algorithm engineering techniques to applications in computational biology, especially in areas that involve complex optimizations: Bader's reimplementation did not require new algorithms or entirely new techniques, yet achieved gains that turned an impractical approach into a usable one.

Engineering Algorithms for Large Network Applications

Christos Zaroliagis
Department of Computer Engineering and Informatics, University of Patras, Patras, Greece

Years and Authors of Summarized Original Work

2002; Schulz, Wagner, Zaroliagis

Problem Definition

Dealing effectively with applications in large networks, it typically requires the efficient solution of one ore more underlying algorithmic problems. Due to the size of the network, a considerable effort is inevitable in order to achieve the desired efficiency in the algorithm.

One of the primary tasks in large network applications is to answer queries for finding best routes or paths as efficiently as possible. Quite often, the challenge is to process a vast number of such queries on-line: a typical situation encountered in several real-time applications (e.g., traffic information systems, public transportation systems) concerns a query-intensive scenario, where a central server has to answer a huge number of on-line customer queries asking for their best routes (or optimal itineraries). The main goal in such an application is to reduce the (average) response time for a query.

Answering a best route (or optimal itinerary) query translates in computing a minimum cost (shortest) path on a suitably defined directed graph (digraph) with nonnegative edge costs. This in turn implies that the core algorithmic problem underlying the efficient answering of queries is the single-source single-target shortest path problem.

Although the straightforward approach of precomputing and storing shortest paths for all pairs of vertices would enabling the optimal answering of shortest path queries, the quadratic space requirements for digraphs with more than 10^5 vertices makes such an approach prohibitive for large and very large networks. For this reason, the main goal of almost all known approaches is to keep the space requirements as small as possible. This in turn implies that one can afford a heavy (in time) preprocessing, which does not blow up space, in order to speed-up the query time.

The most commonly used approach for answering shortest path queries employs Dijkstra's algorithm and/or variants of it. Consequently, the main challenge is how to reduce the algorithm's *search-space* (number of vertices visited), as this would immediately yield a better query time.

Key Results

All results discussed concern answering of *optimal* (or *exact* or *distance-preserving*) shortest paths under the aforementioned query-intensive scenario, and are all based on the following generic approach. A preprocessing of the input network $G = (V, E)$ takes place that results in a data structure of size $O(|V| + |E|)$ (i.e., linear to the size of G). The data structure contains additional information regarding certain shortest paths that can be used later during querying.

Depending on the pre-computed additional information as well as on the way a shortest path query is answered, two approaches can be distinguished. In the first approach, *graph annotation*, the additional information is attached to vertices or edges of the graph. Then, speed-up techniques to Dijkstra's algorithm are employed that, based on this information, decide quickly which part of the graph does not need to be searched. In the second approach, an *auxiliary graph* G' is constructed hierarchically. A shortest path query is then answered by searching only a small part of G', using Dijkstra's algorithm enhanced with heuristics to further speed-up the query time.

In the following, the key results of the first [3, 4, 9, 11] and the second approach [1, 2, 5, 7, 8, 10] are discussed, as well as results concerning modeling issues.

First Approach: Graph Annotation

The first work under this approach concerns the study in [9] on large railway networks. In that paper, two new heuristics are introduced: the *angle-restriction* (that tries to reduce the search space by taking advantage of the geometric layout of the vertices) and the *selection of stations* (a subset of vertices is selected among which all pairs shortest paths are pre-computed). These two heuristics along with a combination of the classical *goal-directed* or A^* *search* turned out to be rather efficient. Moreover, they motivated two important generalizations [10, 11] that gave further improvements to shortest path query times.

The full exploitation of geometry-based heuristics was investigated in [11], where both street and railway networks are considered. In that paper, it is shown that the search space of Dijkstra's algorithm can be significantly reduced (to 5–10 % of the initial graph size) by extracting geometric information from a given layout of the graph and by encapsulating pre-computed shortest path information in resulted geometric objects, called *containers*. Moreover, the dynamic case of the problem was investigated, where edge costs are subject to change and the geometric containers have to be updated.

A powerful modification to the classical Dijkstra's algorithm, called *reach-based routing*, was presented in [4]. Every vertex is assigned a so-called *reach value* that determines whether a particular vertex will be considered during Dijkstra's algorithm. A vertex is excluded from consideration if its reach value is small; that is, if it does not contribute to any path long enough to be of use for the current query.

A considerable enhancement of the classical A^* *search* algorithm using landmarks (selected vertices like in [9, 10]) and the triangle inequality with respect to the shortest path distances was shown in [3]. Landmarks and triangle inequality help to provide better lower bounds and hence boost A^* search.

Second Approach: Auxiliary Graph

The first work under this approach concerns the study in [10], where a new hierarchical decomposition technique is introduced called *multi-level graph*. A multi-level graph $\mathcal{M}$ is a digraph which is determined by a sequence of subsets of V and which extends E by adding multiple levels of edges. This allows to efficiently construct, during querying, a subgraph of $\mathcal{M}$ which is substantially smaller than G and in which the shortest path distance between any of its vertices is equal to the shortest path distance between the same vertices in G. Further improvements of this approach have been presented recently in [1]. A refinement of the above idea was introduced in [5], where the multi-level overlay graphs are introduced. In such a graph, the decomposition hierarchy is not determined by application-specific information as it happens in [9, 10].

An alternative hierarchical decomposition technique, called *highway hierarchies*, was presented in [7]. The approach takes advantage of the inherent hierarchy possessed by real-world road networks and computes a hierarchy of coarser views of the input graph. Then, the shortest path query algorithm considers mainly the (much smaller in size) coarser views, thus achieving dramatic speed-ups in query time. A revision and improvement of this method was given in [8]. A powerful combination of the highway hierarchies with the ideas in [3] was reported in [2].

Modeling Issues

The modeling of the original best route (or optimal itinerary) problem on a large network to a shortest path problem in a suitably defined directed graph with appropriate edge costs also plays a significant role in reducing the query time. Modeling issues are thoroughly investigated in [6]. In that paper, the first experimental comparison of two important approaches (time-expanded versus time-dependent) is carried out, along with new extensions of them towards realistic modeling. In addition, several new heuristics are introduced to speed-up query time.

Applications

Answering shortest path queries in large graphs has a multitude of applications, especially in traffic information systems under the aforementioned scenario; that is, a central server has to answer, as fast as possible, a huge number of on-line customer queries asking for their best routes or itineraries. Other applications of the above scenario involve route planning systems for cars, bikes and hikers, public transport systems for itinerary information of scheduled vehicles (like trains or buses), answering queries

in spatial databases, and web searching. All the above applications concern real-time systems in which users continuously enter their requests for finding their best connections or routes. Hence, the main goal is to reduce the (average) response time for answering a query.

Open Problems

Real-world networks increase constantly in size either as a result of accumulation of more and more information on them, or as a result of the digital convergence of media services, communication networks, and devices. This scaling-up of networks makes the scalability of the underlying algorithms questionable. As the networks continue to grow, there will be a constant need for designing faster algorithms to support core algorithmic problems.

Experimental Results

All papers discussed in section "Key Results" contain important experimental studies on the various techniques they investigate.

2004; Halperin

Problem Definition

Transforming a theoretical geometric algorithm into an effective computer program abounds with hurdles. Overcoming these difficulties is the concern of *engineering geometric algorithms*, which deals, more generally, with the design and implementation of certified and efficient solutions to algorithmic problems of geometric nature. Typical problems in this family include the construction of Voronoi diagrams, triangulations, arrangements of curves and surfaces (namely, space subdivisions), two- or higher-dimensional search structures, convex hulls and more.

Geometric algorithms strongly couple topological/combinatorial structures (e.g., a graph describing the triangulation of a set of points) on the one hand, with numerical information (e.g., the coordinates of the vertices of the triangulation) on the other. Slight errors in the numerical calculations, which in many areas of science and engineering can be tolerated, may lead to detrimental mistakes in the topological structure, causing the computer program to crash, to loop infinitely, or plainly to give wrong results.

Straightforward implementation of geometric algorithms as they appear in a textbook, using standard machine arithmetic, is most likely to fail. This entry is concerned only with *certified* solutions, namely, solutions that are guaranteed to construct the exact desired structure or a good approximation of it; such solutions are often referred to as *robust*.

The goal of engineering geometric algorithms can be restated as follows: *Design and implement geometric algorithms that are at once robust and efficient in practice*.

Much of the difficulty in adapting in practice the existing vast algorithmic literature in computational geometry comes from the assumptions that are typically made in the theoretical study of geometric algorithms that (1) the input is in general position, namely, degenerate input is precluded, (2) computation is performed on an ideal computer that can carry out real arithmetic to infinite precision (so-called real RAM), and (3) the cost of operating on a small number of simple geometric objects is "unit" time (e.g., equal cost is assigned to intersecting three spheres and to comparing two integer numbers).

Now, in real life, geometric input is quite often degenerate, machine precision is limited, and operations on a small number of simple geometric objects within the same algorithm may differ 100-fold and more in the time they take to execute (when aiming for certified results). Just implementing an algorithm carefully may not suffice and often redesign is called for.

Key Results

Tremendous efforts have been invested in the design and implementation of robust computational-geometry software in recent years. Two notable large-scale efforts are the CGAL library [1] and the geometric part of the LEDA library [14]. These are jointly reviewed in the survey by Kettner and Näher [13]. Numerous other relevant projects, which for space constraints are not reviewed here, are surveyed by Joswig [12] with extensive references to papers and Web sites.

A fundamental engineering decision to take when coming to implement a geometric

algorithm is what will the underlying arithmetic be, that is, whether to opt for exact computation or use the machine floating-point arithmetic. (Other less commonly used options exist as well.) To date, the CGAL and LEDA libraries are almost exclusively based on exact computation. One of the reasons for this exclusivity is that exact computation emulates the ideal computer (for restricted problems) and makes the adaptation of algorithms from theory to software easier. This is facilitated by major headway in developing tools for efficient computation with rational or algebraic numbers (GMP [3], LEDA [14], CORE [2] and more). On top of these tools, clever techniques for reducing the amount of exact computation were developed, such as floating-point filters and the higher-level geometric filtering.

The alternative is to use the machine floating-point arithmetic, having the advantage of being very fast. However, it is nowhere near the ideal infinite precision arithmetic assumed in the theoretical study of geometric algorithms and algorithms have to be carefully redesigned. See, for example, the discussion about imprecision in the manual of QHULL, the convex hull program by Barber et al. [5]. Over the years a variety of specially tailored floating-point variants of algorithms have been proposed, for example, the carefully crafted VRONI package by Held [11], which computes the Voronoi diagram of points and line segments using standard floating-point arithmetic, based on the topology-oriented approach of Sugihara and Iri. While VRONI works very well in practice, it is not theoretically certified. *Controlled perturbation* [9] emerges as a systematic method to produce certified approximations of complex geometric constructs while using floating-point arithmetic: the input is perturbed such that all predicates are computed accurately even with the limited-precision machine arithmetic, and a method is given to bound the necessary magnitude of perturbation that will guarantee the successful completion of the computation.

Another decision to take is how to represent the output of the algorithm, where the major issue is typically how to represent the coordinates of vertices of the output structure(s). Interestingly, this question is crucial when using exact computation since there the output coordinates can be prohibitively large or simply impossible to finitely enumerate. (One should note though that many geometric algorithms are *selective* only, namely, they do not produce new geometric entities but just select and order subsets of the input coordinates. For example, the output of an algorithm for computing the convex hull of a set of points in the plane is an ordering of a subset of the input points. No new point is computed. The discussion in this paragraph mostly applies to algorithms that output new geometric constructs, such as the intersection point of two lines.) But even when using floating-point arithmetic, one may prefer to have a more compact bit-size representation than, say, machine doubles. In this direction there is an effective, well-studied solution for the case of polygonal objects in the plane, called *snap rounding*, where vertices and intersection points are snapped to grid vertices while retaining certain topological properties of the exact desired structure. Rounding with guarantees is in general a very difficult problem, and already for polyhedral objects in 3-space the current attempts at generalizing snap rounding are very costly (increasing the complexity of the rounded objects to the third, or even higher, power).

Then there are a variety of engineering issues depending on the problem at hand. Following are two examples of engineering studies where the experience in practice is different from what the asymptotic resource measures imply. The examples relate to fundamental steps in many geometric algorithms: decomposition and point location.

Decomposition

A basic step in many geometric algorithms is to decompose a (possibly complex) geometric object into simpler subobjects, where each subobject typically has constant descriptive complexity. A well-known example is the triangulation of a polygon. The choice of decomposition may have a significant effect on the efficiency in practice of various algorithms that rely on decomposition. Such is the case

when constructing Minkowski sums of polygons in the plane. The Minkowski sum of two sets A and B in $\mathbb{R}^d$ is the vector sum of the two sets $A \oplus B = \{a + b | a \in A, b \in B\}$. The simplest approach to computing Minkowski sums of two polygons in the plane proceeds in three steps: triangulate each polygon, then compute the sum of each triangle of one polygon with each triangle of the other, and finally take the union of all the subsums. In asymptotic measures, the choice of triangulation (over alternative decompositions) has no effect. In practice though, triangulation is probably the worst choice compared with other convex decompositions, even fairly simple heuristic ones (not necessarily optimal), as shown by experiments on a dozen different decomposition methods [4]. The explanation is that triangulation increases the overall complexity of the subsums and in turn makes the union stage more complex – indeed by a constant factor, but a noticeable factor in practice. Similar phenomena were observed in other situations as well. For example, when using the prevalent vertical decomposition of arrangements – often it is too costly compared with sparser decompositions (i.e., decompositions that add fewer extra features).

Point Location

A recurring problem in geometric computing is to process given planar subdivision (planar map), so as to efficiently answer *point-location* queries: Given a point q in the plane, which face of the map contains q? Over the years a variety of point-location algorithms for planar maps were implemented in CGAL, in particular, a hierarchical search structure that guarantees logarithmic query time after expected $O(n \log n)$ preprocessing time of a map with n edges. This algorithm is referred to in CGAL as the *RIC* point-location algorithm after the preprocessing method which uses randomized incremental construction. Several simpler, easier-to-program algorithms for point location were also implemented. None of the latter beats the RIC algorithm in query time. However, the RIC is by far the slowest of all the implemented algorithms in terms of preprocessing, which in many scenarios renders it less effective. One of the simpler methods devised is a variant of the well-known *jump-and-walk* approach to point location. The algorithm scatters points (so-called *landmarks*) in the map and maintains the landmarks (together with their containing faces) in a nearest-neighbor search structure. Once a query q is issued it finds the nearest landmark ℓ to q, and "walks" in the map from ℓ toward q along the straight line segment connecting them. This landmark approach offers query time that is only slightly more expensive than the RIC method while being very efficient in preprocessing. The full details can be found in [10]. This is yet another consideration when designing (geometric) algorithms: the cost of preprocessing (and storage) versus the cost of a query. Quite often the effective (practical) tradeoff between these costs needs to be deduced experimentally.

Applications

Geometric algorithms are useful in many areas. Triangulations and arrangements are examples of basic constructs that have been intensively studied in computational geometry, carefully implemented and experimented with, as well as used in diverse applications.

Triangulations

Triangulations in two and three dimensions are implemented in CGAL [7]. In fact, CGAL offers many variants of triangulations useful for different applications. Among the applications where CGAL triangulations are employed are meshing, molecular modeling, meteorology, photogrammetry, and geographic information systems (GIS). For other available triangulation packages, see the survey by Joswig [12].

Arrangements

Arrangements of curves in the plane are supported by CGAL [15], as well as en-

velopes of surfaces in three-dimensional space. Forthcoming is support also for arrangements of curves on surfaces. CGAL arrangements have been used in motion planning algorithms, computer-aided design and manufacturing, GIS, computer graphics, and more (see Chap. 1 in [6]).

Open Problems

In spite of the significant progress in certified implementation of effective geometric algorithms, the existing theoretical algorithmic solutions for many problems still need adaptation or redesign to be useful in practice. One example where progress can have wide repercussions is devising effective decompositions for curved geometric objects (e.g., arrangements) in the plane and for higher-dimensional objects. As mentioned earlier, suitable decompositions can have a significant effect on the performance of geometric algorithms in practice.

Certified fixed-precision geometric computing lags behind the exact computing paradigm in terms of available robust software, and moving forward in this direction is a major challenge. For example, creating a certified floating-point counterpart to CGAL is a desirable (and highly intricate) task.

Another important tool that is largely missing is consistent and efficient rounding of geometric objects. As mentioned earlier, a fairly satisfactory solution exists for polygonal objects in the plane. Good techniques are missing for curved objects in the plane and for higher-dimensional objects (both linear and curved).

Enumeration of Non-crossing Geometric Graphs

Shin-ichi Tanigawa
Research Institute for Mathematical Sciences (RIMS), Kyoto University, Kyoto, Japan

Keywords

Enumeration; Non-crossing (crossing-free) geometric graphs; Triangulations

Years and Authors of Summarized Original Work

2009; Katoh, Tanigawa
2014; Wettstein

Problem Definition

Let P be a set of n points in the plane in general position, i.e., no three points are collinear. A *geometric graph on* P is a graph on the vertex set P whose edges are straight-line segments connecting points in P. A geometric graph is called *non-crossing* (or *crossing-free*) if any pair of its edges does not have a point in common except possibly their endpoints. We denote by $\mathcal{P}(P)$ the set of all non-crossing geometric graphs on P (which are also called *plane straight-line graphs* on P). A graph class $\mathcal{C}(P) \subseteq \mathcal{P}(P)$ can be defined by imposing additional properties such as connectivity, degree bound, or cycle-freeness. Examples of $\mathcal{C}(P)$ are the set of *triangulations* (i.e., inclusion-wise maximal graphs in $\mathcal{P}(P)$), the set of *non-crossing perfect matchings*, the set of *non-crossing spanning k-connected graphs*, the set of *non-crossing spanning trees*, and the set of *non-crossing spanning cycles* (i.e., simple polygons). The problem is to enumerate all graphs in $\mathcal{C}(P)$ for a given set P of n points in the plane.

The following notations will be used to denote the cardinality of $\mathcal{C}(P)$: $\mathsf{tri}(P)$ for triangulations, $\mathsf{pg}(P)$ for plane straight-line graphs, $\mathsf{st}(P)$ for non-crossing spanning trees, and $\mathsf{cg}(P)$ for non-crossing spanning connected graphs.

Key Results

Enumeration of Triangulations

The first efficient enumeration algorithm for triangulations was given by Avis and Fukuda [3] as an application of their reverse search technique. The algorithm relies on well-known properties of Delaunay triangulations.

A triangulation T on P is called *Delaunay* if no point in P is contained in the interior of the circumcircle of a triangle in T. If it is assumed for simplicity that no four points in P lie on a circle, then the Delaunay triangulation on P exists and is unique. The Delaunay triangulation has the lexicographically largest angle vector among all triangulations on P, where the angle vector of a triangulation is the list of all the angles sorted in nondecreasing order.

For a triangulation T, a *Lawson edge* is an edge ab which is incident to two triangles, say abc and abd in T, and the circumcircle of abc contains d in its interior. *Flipping* a Lawson edge ab (i.e., replacing ab with another diagonal edge cd) always creates a triangulation having a lexicographically larger angle vector. Moreover a triangulation has a Lawson edge if and only if it is not Delaunay. In other words, any triangulation can be converted to the Delaunay triangulation by flipping Lawson edges.

In the algorithm by Avis and Fukuda, a rooted search tree on the set of triangulations is defined such that the root is the Delaunay triangulation and the parent of a non-Delaunay triangulation T

is a triangulation obtained by flipping the smallest Lawson edge in T (assuming a fixed total ordering on edges). Since the Delaunay triangulation can be computed in $O(n \log n)$ time, all the triangulations can be enumerated by tracing the rooted search tree based on the reverse search technique. A careful implementation achieves $O(n \cdot \mathsf{tr}(P))$ time with $O(n)$ space.

An improved algorithm was given by Bespamyatnikh [5], which runs in $O(\log \log n \cdot \mathsf{tr}(P))$ time with $O(n)$ space. His algorithm is also based on the reverse search technique, but the rooted search tree is defined by using the lexicographical ordering of edge vectors rather than angle vectors. This approach was also applied to the enumeration of pointed pseudo-triangulations [4]. See [6] for another approach.

Enumeration of Non-crossing Geometric Graphs

In [3], Avis and Fukuda also developed an enumeration algorithm for non-crossing spanning trees, whose running time is $O(n^3 \cdot \mathsf{sp}(P))$. This was improved to $O(n \log n \cdot \mathsf{sp}(P))$ by Aichholzer et al. [1]. They also gave enumeration algorithms for plane straight-line graphs and non-crossing spanning connected graphs with running time $O(n \log n \cdot \mathsf{pg}(P))$ and $O(n \log n \cdot \mathsf{sc}(P))$, respectively.

Katoh and Tangiawa [8] proposed a simple enumeration technique for wider classes of non-crossing geometric graphs. The same approach was independently given by Razen and Welzl [9] for counting the number of plane straight-line graphs, and the following description in terms of Delaunay triangulations is from [9].

Since each graph in $\mathcal{C}(P)$ is a subgraph of a triangulation, one can enumerate all graphs in $\mathcal{C}(P)$ by first enumerating all triangulations and then enumerating all graphs in $\mathcal{C}(P)$ in each triangulation. The output may contain duplicates, but one can avoid duplicates by enumerating only graphs in $\{G \in \mathcal{C}(P) \mid L(T) \subseteq E(G) \subseteq E(T)\}$ for each triangulation T, where $L(T)$ denotes the set of the Lawson edges in T. This enumeration framework leads to an algorithm with time complexity $O((t^{\mathrm{pre}} + \log \log n)\mathsf{tri}(P) + t \cdot \mathsf{c}(P))$ and space complexity $O(n + s)$ provided that graphs in $\{G \in \mathcal{C}(G) \mid L(T) \subseteq E(G) \subseteq E(T)\}$ can be enumerated in $O(t)$ time per graph with $O(t^{\mathrm{pre}})$ time preprocessing and $O(s)$ space for each triangulation T. For example, in the case of non-crossing spanning trees, one can use a fast enumeration algorithm for spanning trees in a given undirected graph to solve each subproblem, and the current best implementation gives an enumeration algorithm for non-crossing spanning trees with time complexity $O(n \cdot \mathsf{tri}(P) + \mathsf{st}(P))$.

For plane straight-line graphs and spanning connected graphs, $\mathsf{pg}(P) \geq (\sqrt{8})^n \mathsf{tri}(P)$ [9] and $\mathsf{cs}(P) \geq 1.51^n \mathsf{tri}(P)$ [8] hold for any P in general position. Hence $\mathsf{tri}(P)$ is dominated by $\mathsf{pg}(P)$ and $\mathsf{cs}(P)$, respectively, and plane straight-line graphs or non-crossing spanning connected graphs can be enumerated in constant time on average with $O(n)$ space [8]. The same technique can be applied to the set of non-crossing spanning 2-connected graphs. It is not known whether there is a constant $c > 1$ such that $\mathsf{st}(P) \geq c^n \mathsf{tri}(P)$ for every P in general position.

In [8] an approach that avoids enumerating all triangulations was also discussed. Suppose that a nonempty subset $\mathcal{I}$ of $\mathcal{P}(P)$ satisfies a monotone property, i.e., for every $G, G' \in \mathcal{P}(P)$ with $G \subseteq G'$, $G' \in \mathcal{I}$ implies $G \in \mathcal{I}$, and suppose that $\mathcal{C}(P)$ is the set of all maximal elements in $\mathcal{I}$. Then all graphs in $\mathcal{C}(P)$ can be enumerated just by enumerating all triangulations T on P with $L(T) \in \mathcal{I}$, and this can be done efficiently based on the reverse search technique. This approach leads to an algorithm for enumerating non-crossing minimally rigid graphs in $O(n^2)$ time per output with $O(n)$ space, where a graph $G = (V, E)$ is called *minimally rigid* if $|E| = 2|V| - 3$ and $|E'| \leq 2|V'| - 3$ for any subgraph $G' = (V', E')$ with $|V'| \geq 2$.

Enumeration of Non-crossing Perfect Matchings

Wettstein [10] proposed a new enumeration (and counting) technique for non-crossing geometric graphs. This is motivated from a counting algorithm of triangulations by Alvarez and

Seidel [2] and can be used for enumerating, e.g., non-crossing perfect matchings, plane straight-line graphs, convex subdivisions, and triangulations. The following is a sketch of the algorithm for non-crossing perfect matchings.

A matching can be reduced to an empty graph by removing edges one by one. By fixing a rule for the removing edge in each matching, one can define a rooted search tree $\mathcal{T}$ on the set of non-crossing matchings, and the set of non-crossing matchings can be enumerated by tracing $\mathcal{T}$. To reduce time complexity, the first idea is to trace only a subgraph $\mathcal{T}'$ of $\mathcal{T}$ induced by a subclass of non-crossing matchings by a clever choice of removing edges. Another idea is a compression of the search tree $\mathcal{T}'$ by using an equivalence relation on the subclass of non-crossing matchings. The resulting graph $\mathcal{G}$ is a digraph on the set of equivalence classes, where there is a one-to-one correspondence between non-crossing perfect matchings and directed paths of length $n/2$ from the root. A crucial observation is that $\mathcal{G}$ has at most $2^n n^3$ edges while the number of non-crossing perfect matchings is known to be at least $\mathrm{poly}(n) \cdot 2^n$ for any P in general position [7]. Hence non-crossing perfect matchings can be enumerated in polynomial time on average by first constructing $\mathcal{G}$ and then enumerating all the dipaths of length $n/2$ in $\mathcal{G}$. It was also noted in [10] that the algorithm can be polynomial-time delay, but still the space complexity is exponential in n.

Open Problems

A challenging open problem is to design an efficient enumeration algorithm for the set of non-crossing spanning cycles, the set of highly connected triangulations, or the set of degree-bounded triangulations or non-crossing spanning trees. It is also not known whether triangulations can be enumerated in constant time per output.

Problem Definition

Let $G = (V, E)$ be a (directed or undirected) graph with $n = |V|$ vertices and $m = |E|$ edges. A *walk* of length k is a sequence of vertices $v_0, \ldots, v_k \in V$ such that v_i and v_{i+1} are connected by an edge of E, for any $0 \leq i < k$. A *path* π of length k is a walk $v_0, \ldots, v_k$ such that any two vertices v_i and v_j are distinct, for $0 \leq i < j \leq k$: this is also called *st-path* where $s = v_0$ and $t = v_k$. A *cycle* (or, equivalently, *elementary circuit*) C of length $k + 1$ is a path $v_0, \ldots, v_k$ such that v_k and v_0 are connected by an edge of E.

We denote by $\mathcal{P}_{st}(G)$ the set of *st*-paths in G for any two given vertices $s, t \in V$ and by $\mathcal{C}(G)$ the set of cycles in G. Given a graph G, the problem of *st-path enumeration* asks for generating all the paths in $\mathcal{P}_{st}(G)$. The problem of *cycle enumeration* asks for generating all the cycles in $\mathcal{C}(G)$.

We denote by $\mathcal{S}(G)$ the set of spanning trees in a connected graph G, where a spanning tree $T \subseteq E$ is a set of $|T| = n - 1$ edges such that no cycles are contained in T and each vertex in V is incident to at least an edge of T. Given a connected graph G, the problem of *spanning tree enumeration* asks for generating all the spanning trees in $\mathcal{S}(G)$.

Typical costs of enumeration algorithms are proportional to the output size times a polynomial function of the graph size. Sometimes enumeration is meant with the stronger property of *listing*, where each solution is explicitly output. In the latter case, we define an algorithm for a listing problem to be *optimally output sensitive* if its running time is $O(n + m + K)$ where K is the following output cost for the enumeration problem at hand, namely, $\mathcal{P}_{st}(G)$, $\mathcal{C}(G)$, or $\mathcal{S}(G)$.

- $K = \sum_{\pi \in \mathcal{P}_{st}(G)} |\pi|$ where $|\pi|$ is the number of nodes in the *st*-path π.
- $K = \sum_{C \in \mathcal{C}(G)} |C|$ where $|C|$ is the number nodes in the cycle C.
- $K = \sum_{T \in \mathcal{S}(G)} |T| = |\mathcal{S}(G)| \cdot (n - 1)$ for spanning trees.

Although the above is a notion of optimality for listing solutions explicitly, it is possible in some cases that the enumeration algorithm can efficiently encode the differences between consecutive solutions in the sequence produced by the enumeration. This is the case of spanning trees, where a cost of $K = |\mathcal{S}(G)|$ is possible when they are implicitly represented during enumeration. This is called CAT (constant amortized time) enumeration in [28].

Key Results

Some possible approaches to attack the enumeration problems are listed below, where the term "search" is meant as an exploration of the space of solutions.

Backtrack search. A backtracking algorithm finds the solutions for a listing problem by exploring the search space and abandoning a partial solution (thus the name "backtracking") that cannot be completed to a valid one.

Binary partition search. An algorithm divides the search space into two parts. In the case of graphs, this is generally done by taking an edge (or a vertex) and (i) searching for all solutions that include that edge (resp. vertex) and (ii) searching for all solutions that do not include that edge (resp. vertex). Point (i) can sometimes be implemented by contracting the edge, i.e., merging the endpoints of the edge and their adjacency list.

Differential encoding search. The space of solutions is encoded in such a way that consecutive solutions differ by a constant number of modifications. Although not every enumeration

problem has properties that allow such encoding, this technique leads to very efficient algorithms.

Reverse search. This is a general technique to explore the space of solutions by reversing a local search algorithm. This approach implicitly generates a tree of the search space that is traversed by the reverse search algorithm. One of the properties of this tree is that it has bounded height, a useful fact for proving the time complexity of the algorithm.

Although there is some literature on techniques for enumeration problems [38, 39, 41], many more techniques and "tricks" have been introduced when attacking particular problems. For a deep understanding of the topic, the reader is recommended to review the work of researchers such as David Avis, Komei Fukuda, Shin-ichi Nakano, and Takeaki Uno.

Path and Cycles

Listing all the cycles in a graph is a classical problem whose efficient solutions date back to the early 1970s. In particular, at the turn of the 1970s, several algorithms for enumerating all cycles of an undirected graph were proposed. There is a vast body of work, and the majority of the algorithms listing all the cycles can be divided into the following three classes (see [1, 23] for excellent surveys).

Search space algorithms. Cycles are looked for in an appropriate search space. In the case of undirected graphs, the *cycle vector space* [6] turned out to be the most promising choice: from a basis for this space, all vectors are computed, and it is tested whether they are a cycle. Since the algorithm introduced in [43], many algorithms have been proposed: however, the complexity of these algorithms turns out to be exponential in the dimension of the vector space and thus in n. For the special case of planar graphs, the paper in [34] describes an algorithm listing all the cycles in $O((|\mathcal{C}(G)| + 1)n)$ time.

Backtrack algorithms. All paths are generated by backtrack, and, for each path, it is tested whether it is a cycle. One of the first algorithms based on this approach is the one proposed in [37], which is however exponential in $|\mathcal{C}(G)|$. By adding a simple pruning strategy, this algorithm has been successively modified in [36]: it lists all the cycles in $O(nm(|\mathcal{C}(G)| + 1))$ time. Further improvements were proposed in [16], [35], and [27], leading to $O((|\mathcal{C}(G)| + 1)(m + n))$ time algorithms that work for both directed and undirected graphs. Apart from the algorithm in [37], all the algorithms based on this approach are *polynomial-time delay*, that is, the time elapsed between the outputting of two cycles is polynomial in the size of the graph (more precisely, $O(nm)$ in the case of the algorithm of [36] and $O(m)$ in the case of the other three algorithms).

Algorithms using the powers of the adjacency matrix. This approach uses the so-called variable adjacency matrix, that is, the formal sum of edges joining two vertices. A nonzero element of the pth power of this matrix is the sum of all walks of length p: hence, to compute all cycles, we compute the nth power of the variable adjacency matrix. This approach is not very efficient because of the non-simple walks. All algorithms based on this approach (e.g., [26] and [45]) basically differ only on the way they avoid to consider walks that are neither paths nor cycles.

For directed graphs, the best known algorithm for listing cycles is Johnson's [16]. It builds upon Tarjan's backtracking search [36], where the search starts from the least vertex of each strongly connected component. After that, a new strongly connected component is discovered, and the search starts again from the least vertex in it. When exploring a strongly connected component with a recursive backtracking procedure, it uses an enhanced marking system to avoid visiting the same cycle multiple times. A vertex is marked each time it enters the backtracking stack. Upon leaving the stack, if a cycle is found, then the vertex is unmarked. Otherwise, it remains marked until another vertex involved in a cycle is popped from the stack, and there exists a path of marked vertices (not in the stack) between these two vertices. This strategy is implemented using a collection of lists B, one list per vertex containing its marked neighbors not in the stack. Unmarking is done by a recursive procedure. The complexity of the algorithm is $O(n+m+|\mathcal{C}(G)|m)$ time and $O(n + m)$ space.

For undirected graphs, Johnson's bound can be improved with an optimal output-sensitive algorithm [2]. First of all, the cycle enumeration problem is reduced to the *st*-path enumeration by considering any spanning tree of the given graph G and its non-tree edges $b_1, b_2, \ldots, b_r$. Then, for $i = 1, 2, \ldots, r$, the cycles in $\mathcal{C}(G)$ can be listed as *st*-paths in $G \setminus \{b_1, \ldots, b_i\}$, where s and t are the endpoint of non-tree edge b_i. Hence, the subproblem to be solved with an optimal output-sensitive algorithm is the *st*-path enumeration problem. Binary partition search is adopted to avoid duplicated output, but the additional ingredient is the notion of *certificate*, which is a suitable data structure that maintains the biconnected components of the residual graph and guarantees that each recursive call thus produces at least one solution. Its amortized analysis is based on a lower bound on the number of *st*-paths that can be listed in the residual graph, so as to absorb the cost of maintaining the certificate. The final cost is $O(m+n+\sum_{\pi \in \mathcal{P}_{st}(G)} |\pi|)$ time and $O(n+m)$ space, which is optimal for listing.

Spanning Trees

Listing combinatorial structures in graphs has been a long-time problem of interest. In his 1970 book [25], Moon remarks that "many papers have been written giving algorithms, of varying degrees of usefulness, for listing the spanning trees of a graph" (citation taken from [28]). Among others, he cites [7, 9, 10, 13, 42] – some of these early papers date back to the beginning of the twentieth century. More recently, in the 1960s, Minty proposed an algorithm to list all spanning trees [24].

The first algorithmic solutions appeared in the 1960s [24] and the combinatorial papers even much earlier [25]. Other results from Welch, Tiernan, and Tarjan for this and other problems soon followed [36, 37, 43] and used backtracking search. Read and Tarjan presented an algorithm taking $O(m + n + |\mathcal{S}(G)| \cdot m)$ time and $O(m + n)$ space [27]. Gabow and Myers proposed the first algorithm [11] which is optimal when the spanning trees are explicitly listed, taking $O(m + n + |\mathcal{S}(G)| \cdot n)$ time and $O(m + n)$ space.

When the spanning trees are implicitly enumerated, Kapoor and Ramesh [17] showed that an elegant incremental representation is possible by storing just the $O(1)$ information needed to reconstruct a spanning tree from the previously enumerated one, requiring a total of $O(m + n + |\mathcal{S}(G)|)$ time and $O(mn)$ space [17], later reduced to $O(m)$ space by Shioura et al. [32]. These methods use the reverse search where the elements are the spanning trees. The rule for moving along these elements and for their differential encoding is based upon the observation that adding a non-tree edge and removing a tree edge of the cycle thus formed produces another spanning tree from the current one. Some machinery is needed to avoid duplicated spanning trees and to spend $O(1)$ amortized cost per generated spanning tree.

A simplification of the incremental enumeration of spanning trees is based on matroids and presented by Uno [39]. It is a binary partition search giving rise to a binary enumeration tree, where the two children calls generated by the current call correspond to the fact that the current edge is either contracted in $O(n)$ time or deleted in $O(m - n)$ time. There is a trimming and balancing phase in $O(n(m - n))$ time: trimming removes the edges that do not appear in any of the spanning trees that will be generated by the current recursive call and contracts the edges that appear in all of these spanning trees. Balancing splits the recursive calls as in the divide-and-conquer paradigm. A crucial property proved in [39] is that the residual graph will generate at least $\Omega(n(m - n))$ spanning trees, and thus the total cost per call, which is dominated by trimming and balancing, can be amortized as $O(1)$ per spanning tree. The method in [39] works also for directed spanning trees (arborescences) with an amortized $O(\log n)$ time cost per directed spanning tree.

Applications

The classical problem of listing all the cycles of a graph has been extensively studied for its many

applications in several fields, ranging from the mechanical analysis of chemical structures [33] to the design and analysis of reliable communication networks and the graph isomorphism problem [43]. Almost 40 years after, the problem of efficiently listing all cycles of a graph is still an active area of research (e.g., [14, 15, 22, 29, 30, 44]). New application areas have emerged in the last decade, such as bioinformatics: for example, two algorithms for this problem have been proposed in [20] and [21] while studying biological interaction graphs, with important network properties derived for feedback loops, signaling paths, and dependency matrix, to name a few.

When considering weighted cycles, the paper in [19] proves that there is no polynomial total time algorithm (unless $P = NP$) to enumerate negative-weight (simple) cycles in directed weighted graphs. Uno [40] and Ferreira et al. [8] considered the enumeration of chordless cycles and paths. A chordless or induced cycle (resp., path) in an undirected graph is a cycle (resp., path) such that the subgraph induced by its vertices contains exactly the edges of the cycle (resp., path). Both chordless cycles and paths are very natural structures in undirected graphs with an important history, appearing in many papers in graph theory related to chordal graphs, perfect graphs, and co-graphs (e.g., [4, 5, 31]), as well as many NP-complete problems involving them (e.g., [3, 12, 18]).

As for spanning trees, we refer to the section "K-best enumeration" of this book.

Problem Definition

A *priority queue* is an abstract data structure that maintains a set Q of elements, each with an associated value called a *key*, under the following set of operations [5,6]:

insert(Q, x, k): Inserts element x with key k into Q.
find-min(Q): Returns an element of Q with the minimum key but does not change Q.
delete(Q, x, k): Deletes element x with key k from Q.

Additionally, the following operations are often supported:

delete-min(Q): Deletes an element with the minimum key value from Q and returns it.
decrease-key(Q, x, k): Decreases the current key k' of x to k assuming $k < k'$.
meld(Q_1 , Q_2): Given priority queues Q_1 and Q_2, returns the priority queue $Q_1 \cup Q_2$.

Observe that a *delete-min* can be implemented as a *find-min* followed by a *delete*, a *decrease-key* as a *delete* followed by an *insert*, and a *meld* as a series of *find-min*, *delete* and *insert*. However, more efficient implementations of *decrease-key* and *meld* often exist [5, 6].

Priority queues have many practical applications including event-driven simulation, job scheduling on a shared computer, and computation of shortest paths, minimum spanning forests, minimum cost matching, optimum branching, etc. [5, 6].

A priority queue can trivially be used for sorting by first inserting all keys to be sorted into the priority queue and then by repeatedly extracting the current minimum. The major contribution of Mikkel Thorup's 2002 article (Full version published in 2007) titled "Equivalence between Priority Queues and Sorting" [17] is a reduction showing that the converse is also true. Taken together, these two results imply that priority queues are computationally equivalent to sorting, that is, asymptotically, the per key cost of sorting is the update time of a priority queue.

A result similar to those in the current work [17] was presented earlier by the same author [14] which resulted in monotone priority queues (i.e., meaning that the extracted minimums are nondecreasing) with amortized time bounds only. In contrast, the current work [17] constructs general priority queues with worst-case bounds.

In addition to establishing the equivalence between priority queues and sorting, Thorup's reductions [17] are also used to translate several known sorting results into new results on priority queues.

Background

Some relevant background information is summarized below which will be useful in understanding the key results in section "Key Results."

- A standard *word RAM* models what one programs in a standard imperative programming language such as C. In addition to direct and indirect addressing and conditional jumps, there are functions, such as addition and multiplication, operating on a constant number of words. The memory is divided into words, addressed linearly starting from 0. The running time of a program is the number of instructions executed and the space is the maximal address used. The word length is a machine-dependent parameter which is big enough to hold a key and at least logarithmic in the number of input keys so that they can be addressed.
- A pointer machine is like the word RAM except that addresses cannot be manipulated.
- The AC^0 complexity class consists of constant-depth circuits with unlimited fan-in [18]. Standard AC^0 operations refer to the operations available via C but where the functions on words are in AC^0. For example, this includes addition but not multiplication.
- Integer keys will refer to nonnegative integers. However, if the input keys are signed integers, the correct ordering of the keys is obtained by flipping their sign bits and interpreting them as unsigned integers. Similar tricks work for floating point numbers and integer fractions [14].
- The atomic heaps of Fredman and Willard [7] are used in one of Thorup's reductions [17]. These heaps can support updates and searches in sets of $\mathcal{O}\left(\log^2 n\right)$ keys in $\mathcal{O}(1)$ worst-case time [20]. However, atomic heaps use multiplication operations which are not in AC^0.

Key Results

The main results in this paper are two reductions from priority queues to sorting. The stronger of the two, stated in Theorem 1, is for integer priority queues running on a standard word RAM.

Theorem 1 *If for some nondecreasing function S, up to n integer keys can be sorted in $S(n)$ time per key, an integer priority queue can be im-*

plemented supporting find-min *in constant time, and updates, i.e.,* insert *and* delete*, in* $\mathcal{O}(S(n))$ *time. Here* n *is the current number of keys in the queue. The reduction uses linear space. The reduction runs on a standard word RAM assuming that each integer key is contained in a single word.*

The reduction above provides the following new bounds for linear space integer priority queues improving previous bounds given by Han [8] and Thorup [14], respectively:

1. **(Deterministic)** $\mathcal{O}(\log\log n)$ update time using a sorting algorithm by Han [9].
2. **(Randomized)** $\mathcal{O}\left(\sqrt{\log\log n}\right)$ expected update time using a sorting algorithm given by Han and Thorup [10].

The reduction in Theorem 1 employs atomic heaps [7] which, in addition to being very complicated, use AC^0 operations. The following slightly weaker recursive reduction which does not restrict the domain of the keys is completely combinatorial.

Theorem 2 *If for some nondecreasing function* S*, up to* n *keys can be sorted in* $S(n)$ *time per key, a priority queue can be implemented supporting* find-min *in constant time, and updates in* $T(n)$ *time where* n *is the current number of keys in the queue and* $T(n)$ *satisfies the recurrence:*

$$T(n) = \mathcal{O}(S(n)) + T(\mathcal{O}(\log n))$$

The reduction runs on a pointer machine in linear space using only standard AC^0 *operations.*

This reduction implies the following new integer priority queue bounds not implied by Theorem 1, which improve previous bounds given by Thorup in 1998 [13] and 1997 [15], respectively:

1. **(Deterministic in AC^0)** $\mathcal{O}\left((\log\log n)^{1+\epsilon}\right)$ update time for any constant $\epsilon > 0$ using a standard AC^0 sorting algorithm given by Han and Thorup [10].
2. **(Randomized in AC^0)** $\mathcal{O}(\log\log n)$ expected update time using a randomized AC^0 sorting algorithm given by Thorup [15].

The Reduction in Theorem 1

Given a sorting routine that can sort up to n keys in $S(n)$ time per key, the priority queue is constructed as follows. All keys are assumed to be distinct.

The data structure has two major components: a partially sorted list of keys called a *base list* and a set of *level buffers* (also called *update buffers*). Most keys of the priority queue reside in the base list partitioned into logarithmic-sized disjoint sets called *base sets*. While the keys inside any given base set are not required to be sorted, each of those keys must be larger than every key in the base set (if any) appearing before it in the list. Keys inside each base set are stored in a doubly linked list allowing constant time updates. The first base set in the list containing the smallest key among all base sets is also maintained in an atomic heap so that the current minimum can be found in constant time. Each level buffer has a different capacity and accumulates updates (*insert*/*delete*) with key values in a different range. Smaller level buffers accept updates with smaller keys. An atomic heap is used to determine in constant time which level buffer collects a new update. When a level buffer accumulates enough updates, they first enter a sorting phase and then a merging phase. In the merging phase each update is applied on the proper base set in the key list, and invariants on base set size and ranges of level buffers are fixed. These phases are not executed immediately, instead they are executed in fixed time increments over a period of time. A level buffer continues to accept new updates, while some updates accepted by it earlier are still in the sorting phase, and some even older updates are in the merging phase. Every time it accepts a new update, $\mathcal{O}(S(n))$ time is spent on the sorting phase associated with it and $\mathcal{O}(1)$ time on its merging phase including rebalancing of base sets and scanning. This strategy allows the sorting and merging phases to complete execution by the time the level buffer becomes full again and thus keep-

ing the movement of updates through different phases smooth while maintaining an $\mathcal{O}(S(n))$ worst-case time bound per update. Moreover, the size and capacity constraints ensure that the smallest key in the data structure is available in $\mathcal{O}(1)$ time. More details are given below.

The Base List: The base list consists of base sets $A_1, A_2, \ldots, A_k$, where $\frac{\Phi}{4} \leq |A_i| \leq \Phi$ for $i < k$, and $|A_k| \leq \Phi$ for some $\Phi = \Theta(\log n)$. The exact value of Φ is chosen carefully to make sure that it conforms with the requirements of the delicate worst-case base set rebalancing protocol used by the reduction. The base sets are partitioned by *base splitters* $s_0, s_1, \ldots, s_{k+1}$, where $s_0 = -\infty$, $s_{k+1} = \infty$, and for $i = 1, \ldots, k-1$, $\max A_{i-1} < s_i \leq \min A_i$. If a base set becomes too large or too small, it is split or joined with an adjacent set, respectively.

Level Buffers: Among the base splitters $l + 2 = \Theta(\log n)$ are chosen to become *level splitters* $t_0, t_1, \ldots, t_l, t_{l+1}$ with $t_0 = s_0 = -\infty$ and $t_{l+1} = s_{k+1} = \infty$, so that for $j > 0$, the number of keys in the base list below t_j is around $4^{j+1}\Phi$. These splitters are placed in an atomic heap. As the base list changes the level splitters are moved, as needed, in order to maintain their exponential distribution.

Associated with each level splitter t_j, $1 \leq j \leq l$, is a *level buffer* B_j containing keys in $[t_{j-1}, t_{j+2})$, where $t_{l+2} = \infty$. Buffer B_j consists of an *entrance* buffer, a *sorter*, and a *merger*, each with capacity for 4^j keys. Level j works in a cycle of 4^j steps. The cycle starts with an empty entrance, at most 4^j updates in the sorter, and a sorted list of at most 4^j updates in the merger. In each step one may accept an update for the entrance, spend $S\left(4^j\right) = \mathcal{O}(S(n))$ time in the sorter and $\mathcal{O}(1)$ time in merging the sorted list in the merger with the $\mathcal{O}\left(4^j\right)$ base splitters in $[t_{j-1}, t_{j+2})$ and scanning for a new t_j among them. Therefore, after 4^j such steps, the sorted list is correctly merged with the base list, a new t_j is found, and a new sorted list is produced. The sorter then takes the role of the merger, the entrance becomes the sorter, and the empty merger becomes the new entrance.

Handling Updates: When a new update key k (*insert*/*delete*) is received, the atomic heap of level splitters is used to find in $\mathcal{O}(1)$ time the t_j such that $k \in [t_{j-1}, t_j)$. If $k \in [t_0, t_1)$, its position is identified among the $\mathcal{O}(1)$ base splitters below t_1, and the corresponding base set is updated in $\mathcal{O}(1)$ time using the doubly linked list and the atomic heap (if exists) over the keys of that set. If $k \in [t_{j-1}, t_j)$ for some $j > 1$, the update is placed in the entrance of B_j, performing one step of the cycle of B_j in $\mathcal{O}(S(n))$ time. Additionally, during each update another splitter t_r is chosen in a round-robin fashion, and a step of a cycle of level r is executed in $\mathcal{O}(S(n))$ time. This additional work ensures that after every l updates some progress is made on moving each level splitter.

A *find-min* returns the minimum element of the base list which is available in $\mathcal{O}(1)$ time.

The Reduction in Theorem 2

This reduction follows from the previous reduction by replacing the atomic heap containing the level splitters with a data structure similar to a level buffer and the atomic heap over the keys of the first base set with a recursively defined priority queue satisfying the following recurrence for update time: $T(n) = \mathcal{O}(S(n)) + T(\mathcal{O}(\Phi))$.

Further Improvement

Alstrup et al. [1] presented a general reduction that transforms a priority queue to support *insert* in $\mathcal{O}(1)$ time while keeping the other bounds unchanged. This reduction can be used to reduce the cost of insertion to a constant in Theorems 1 and 2.

Applications

Thorup's equivalence results [17] can be used to translate known sorting results into new results on priority queues for integers and strings in different computational models (see section "Key Results"). These results can also be viewed as a

new means of proving lower bounds for sorting via priority queues.

A new RAM priority queue that matches the bounds in Theorem 1 and also supports *decrease-key* in $\mathcal{O}(1)$ time is presented by Thorup [16]. This construction combines Andersson's exponential search trees [2] with the priority queues implied by Theorem 1. The reduction in Theorem 1 is also used by Pagh et al. [12] in order to develop an adaptive integer sorting algorithm for the word RAM and by Arge and Thorup [3] to develop a sorting algorithm that is simultaneously I/O efficient and internal memory efficient in the RAM model of computation. Cohen et al. [4] use a priority queue generated through this reduction to obtain a simple and fast amortized implementation of a reservoir sampling scheme that provides variance optimal unbiased estimation of subset sums. Reductions from meldable priority queues to sorting presented by Mendelson et al. [11] use the reductions from non-meldable priority queues to sorting given in [17].

An external-memory version of Theorem 1 has been proved by Wei and Yi [19].

Open Problems

One major open problem is to find a general reduction (if one exists) that allows us to decrease the value of a key in constant time. Another open question is whether the gap between the bounds implied by Theorems 1 and 2 can be reduced or removed. For example, for a hypothetical linear time-sorting algorithm, Theorem 1 implies a priority queue with an update time of $\mathcal{O}(1)$, while Theorem 2 implies only $\mathcal{O}\left(\log^* n\right)$-time updates.

Problem Definition

A *graph parameter* σ is a real-valued function over graphs that is invariant under graph isomorphism. For example, the average degree of the graph, the average distance between pairs of vertices, and the minimum size of a vertex cover are graph parameters. For a fixed graph parameter σ and a graph $G = (V, E)$, we would like to compute an estimate of $\sigma(G)$. To this end we are given query access to G and would like to perform this task in time that is *sublinear* in the size of the graph and with high success probability. In particular, this means that we do not read the entire graph but rather only access (random) parts of it (via the query mechanism). Our main focus here is on a very basic graph parameter: its average degree, denoted $\overline{d}(G)$.

The estimation algorithm is given an approximation parameter $\epsilon > 0$. It should output a value $\hat{d}$ such that with probability at least $2/3$ (over the random choices of the algorithm) it holds that $\overline{d}(G) \leq \hat{d} \leq (1+\epsilon) \cdot \overline{d}(G)$. (The error probability can be decreased to 2^{-k} by invoking the algorithm $\Theta(k)$ times and outputting the median value.) For any vertex $v \in V = [n]$ of its choice, where $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$, the estimation algorithm may query the degree of v, denoted $d(v)$. We refer to such queries as *degree queries*. In addition, the algorithm may ask for the ith neighbor of v, for any $1 \leq i \leq d(v)$. These queries are referred to as *neighbor queries*. We assume for simplicity that G does not contain any isolated vertices (so that, in particular, $\overline{d}(G) \geq 1$). This assumption can be removed.

Key Results

The problem of estimating the average degree of a graph in sublinear time was first studied by Feige [7]. He considered this problem when the algorithm is allowed only degree queries, so that the problem is a special case of estimating the average value of a function given query access to the function. For a general function $d : [n] \to [n-1]$, obtaining a constant-factor estimate of the average value of the function (with constant success probability) requires $\Omega(n)$ queries to the function. Feige showed that when d is the degree function of a graph, for any $\gamma \in (0, 1]$, it is possible to obtain an estimate of the average degree that is within a factor of $(2+\gamma)$ by performing only $O(\sqrt{n}/\gamma)$ (uniformly selected) queries. He also showed that in order to go below a factor of 2 in the quality of the estimate, $\Omega(n)$ queries are necessary.

However, given that the object in question is a graph, it is natural to allow the algorithm to query the neighborhood of vertices of its choice and not only their degrees; indeed, the aforementioned problem definition follows this natural convention. Goldreich and Ron [10] showed that by giving the algorithm this extra power, it is possible to break the factor-2 barrier. They provide an algorithm that, given $\epsilon > 0$, outputs a $(1+\epsilon)$-factor estimate of the average degree (with probability at least $2/3$) after performing $O(\sqrt{n} \cdot$

poly$(\log n, 1/\epsilon)$) degree and neighbor queries. In fact, since a degree query to vertex v can be replaced by $O(\log d(v)) = O(\log n)$ neighbor queries, which implement a binary search, degree queries are not necessary. Furthermore, when the average degree increases, the performance of the algorithm improves, as stated next.

Theorem 1 *There exists an algorithm that makes only neighbor queries to the input graph and satisfies the following condition. On input $G = (V, E)$ and $\epsilon \in (0, 1)$, with probability at least $2/3$, the algorithm halts within $O\left(\sqrt{n/\overline{d}(G)} \cdot \text{poly}(\log n, 1/\epsilon)\right)$ steps and outputs a value in $[\overline{d}(G), (1+\epsilon) \cdot \overline{d}(G)]$.*

The running time stated in Theorem 1 is essentially optimal in the sense that (as shown in [10]) a $(1+\epsilon)$-factor estimate requires $\Omega(\sqrt{n/(\epsilon\overline{d}(G))})$ queries, for every value of n, for $\overline{d}(G) \in [2, o(n)]$, and for $\epsilon \in [\omega(n^{-1/4}), o(n/\overline{d}(G))]$.

The following is a high-level description of the algorithm and the ideas behind its analysis. For the sake of simplicity, we only show how to obtain a $(1+\epsilon)$-factor estimate by performing $O\left(\sqrt{n} \cdot \text{poly}(\log n, 1/\epsilon)\right)$ queries (under the assumption that $\overline{d}(G) \geq 1$). For the sake of the presentation, we also allow the algorithm to perform degree queries. We assume that $\epsilon \leq 1/2$, or else we run the algorithm with $\epsilon = 1/2$. We first show how to obtain a $(2+\epsilon)$-approximation by performing only degree queries and then explain how to improve the approximation by using neighbor queries as well.

Consider a partition of the graph vertices into *buckets* $B_1, \ldots, B_r$, where

$$B_i \stackrel{\text{def}}{=} \{v : (1+\epsilon/8)^{i-1} \leq d(v) < (1+\epsilon/8)^i\} \tag{1}$$

and $r = O(\log n/\epsilon)$. By this definition,

$$\frac{1}{n}\sum_{i=1}^{r} |B_i| \cdot (1+\epsilon/8)^i \in \left[\overline{d}(G), (1+\epsilon/8) \cdot \overline{d}(G)\right]. \tag{2}$$

Suppose we could obtain an estimate $\hat{b}_i$ of the size of each bucket B_i such that $\hat{b}_i \in [(1-\epsilon/8)|B_i|, (1+\epsilon/8)|B_i|]$. Then

$$\frac{1}{n}\sum_{i=1}^{r} \hat{b}_i \cdot (1+\epsilon/8)^i \in \left[(1-\epsilon/8) \cdot \overline{d}(G), (1+3\epsilon/8) \cdot \overline{d}(G)\right]. \tag{3}$$

Now, for each B_i, if we uniformly at random select $\Omega\left(\frac{n}{|B_i|} \cdot \frac{\log r}{\epsilon^2}\right)$ vertices, then, by a multiplicative Chernoff bound, with probability $1 - O(1/r)$, the fraction of sampled vertices that belong to B_i is in the interval $\left[(1-\epsilon/8)\frac{|B_i|}{n}, (1+\epsilon/8)\frac{|B_i|}{n}\right]$. By querying the degree of each sampled vertex, we can determine to which bucket it belongs and obtain an estimate of $|B_i|$. Unfortunately, if B_i is much smaller than $\sqrt{n}$, then the sample size required to estimate $|B_i|$ is much larger than the desired $O\left(\sqrt{n} \cdot \text{poly}(\log n, 1/\epsilon)\right)$. Let $L \stackrel{\text{def}}{=} \{i : |B_i| \geq \sqrt{\epsilon n/8r}\}$ denote the set of indices of *large* buckets. The basic observation is that if, for each $i \in L$, we have an estimate $\hat{b}_i \in [(1-\epsilon/8)|B_i|, (1+\epsilon/8)|B_i|]$, then

$$\frac{1}{n}\sum_{i\in L} \hat{b}_i \cdot (1+\epsilon/8)^i \in \left[(1/2-\epsilon/4) \cdot \overline{d}(G), (1+3\epsilon/8) \cdot \overline{d}(G)\right]. \tag{4}$$

The reasoning is essentially as follows. Recall that $\sum_v d(v) = 2|E|$. Consider an edge (u, v) where $u \in B_j$ and $v \in B_k$. If $j, k \in L$, then this edge contributes twice to the sum in Eq. (4): once when $i = j$ and once when $i = k$. If $j \in L$ and $k \notin L$ (or vice verse), then this edge contributes only once. Finally, if $j, k \notin L$, then the edge does not contribute at all, but there are at most $\epsilon n/8$ edges of this latter type. Since it is possible to obtain such estimates $\hat{b}_i$ for all $i \in L$ simultaneously, with constant success probability, by sampling $O\left((\sqrt{n} \cdot \text{poly}(\log n, 1/\epsilon)\right)$ vertices, we can get a

E

$(2+\epsilon)$-factor estimate by performing this number of degree queries. Recall that we cannot obtain an approximation factor below 2 by performing $o(n)$ queries if we use only degree queries.

In order to obtain the desired factor of $(1+\epsilon)$, we estimate the number of edges (u,v) such that $u \in B_j$ and $v \in B_k$ with $j \in L$ and $k \notin L$, which are counted only once in Eq. (4). Here is where neighbor queries come into play. For each $i \in L$ (more precisely, for each i such that $\hat{b}_i$ is sufficiently large), we estimate $e_i \stackrel{\text{def}}{=} |\{(u,v) : u \in B_i, v \in B_k \text{ for } k \notin L\}|$. This is done by uniformly sampling *neighbors* of vertices in B_i, querying their degree, and therefore estimating the fraction of edges incident to vertices in B_i whose other endpoint belongs to B_k for $k \notin L$. If we denote the estimate of e_i by $\hat{e}_i$, then we can get that by performing $O\left((\sqrt{n} \cdot \text{poly}(\log n, 1/\epsilon)\right)$ neighbor queries, with high constant probability, the $\hat{e}_i$'s are such that

$$\frac{1}{n}\sum_{i \in L}\left(\hat{b}_i \cdot (1+\epsilon/8)^i + \hat{e}_i\right) \in \left[(1-\epsilon/2)\cdot \overline{d}(G), (1+\epsilon/2)\cdot \overline{d}(G)\right]. \tag{5}$$

By dividing the left-hand side in Eq. (5) by $(1-\epsilon/2)$, we obtain the $(1+\epsilon)$-factor we sought.

Estimating the Average Distance

Another graph parameter considered in [10] is the average distance between vertices. For this parameter, the algorithm is given access to a *distance-query oracle*. Namely, it can query the distance between any two vertices of its choice. As opposed to the average degree parameter where neighbor queries could be used to improve the quality of the estimate (and degree queries were not actually necessary), distance queries are crucial for estimating the average distance, and neighbor queries are not of much use. The main (positive) result concerning the average distance parameter is stated next.

Theorem 2 *There exists an algorithm that makes only distance queries to the input graph and satisfies the following condition. On input $G = (V,E)$ and $\epsilon \in (0,1)$, with probability at least $2/3$, the algorithm halts within $O\left(\sqrt{n/\overline{D}(G)} \cdot \text{poly}(1/\epsilon)\right)$ steps and outputs a value in $[\overline{D}(G), (1+\epsilon)\cdot \overline{D}(G)]$, where $\overline{D}(G)$ is the average of the all-pairs distances in G. A corresponding algorithm exists for the average distance to a given vertex $s \in V$.*

Comments for the Recommended Reading

The current entry falls within the scope of sublinear-time algorithms (see, e.g., [4]).

Other graph parameters that have been studied in the context of sublinear-time algorithms include the minimum weight of a spanning tree [2,3,5], the number of stars [11] and the number of triangles [6], the minimum size of a vertex cover [13–15,17], the size of a maximum matching [14, 17], and the distance to having various properties [8, 13, 16]. Related problems over weighted graphs that represent distance metrics were studied in [12] and [1].

Problem Definition

This entry considers geometric optimization $\mathcal{NP}$-hard problems like the Euclidean traveling salesman problem and the Euclidean Steiner tree problem. These problems are geometric variants of standard graph optimization problems, and the restriction of the input instances to geometric or Euclidean case arises in numerous applications (see [1, 2]). The main focus of this entry is on the Euclidean traveling salesman problem.

The Euclidean Traveling Salesman Problem (TSP)

For a given set S of n points in the Euclidean space $\mathbb{R}^d$, find the minimum length path that visits each point exactly once. The cost $\delta(x, y)$ of an edge connecting a pair of points $x, y \in \mathbb{R}^d$ is equal to the Euclidean distance between points x and y, that is, $\delta(x, y) = \sqrt{\sum_{i=1}^{d} (x_i - y_i)^2}$, where $x = (x_1, \ldots, x_d)$ and $y = (y_1, \ldots, y_d)$. More generally, the distance could be defined using other norms, such as ℓ_p norms for any $p > 1$, $\delta(x, y) = \left(\sum_{i=1}^{p} (x_i - y_i)^p \right)^{1/p}$.

For a given set S of points in Euclidean space $\mathbb{R}^d$, for a certain integer d, $d \geq 2$, a *Euclidean graph* (network) is a graph $G = (S, E)$, where E is a set of straight-line segments connecting pairs of points in S. If all pairs of points in S are connected by edges in E, then G is called a *complete Euclidean graph on S*. The cost of the graph is equal to the sum of the costs of the edges of the graph, $\text{cost}(G) = \sum_{(x,y)\in E} \delta(x, y)$.

A *polynomial-time approximation scheme (PTAS)* is a family of algorithms $\{\mathcal{A}_\varepsilon\}$ such that, for each fixed $\varepsilon > 0$, $\mathcal{A}_\varepsilon$ runs in polynomial time in the size of the input and produces a $(1 + \varepsilon)$-approximation.

Related Work

The classical book by Lawler et al. [16] provides extensive information about the TSP. Also, the survey exposition of Bern and Eppstein [8] presents the state of the art for geometric TSP until 1995, and the survey of Arora [2] discusses the research after 1995.

Key Results

We begin with the hardness results. The TSP in general graphs is well known to be $\mathcal{NP}$-hard, and the same claim holds for the Euclidean TSP [14, 18].

Theorem 1 *The Euclidean TSP is $\mathcal{NP}$-hard.*

Perhaps rather surprisingly, it is still not known if the decision version of the problem is $\mathcal{NP}$-complete [14]. (The decision version of the Euclidean TSP: given a point set in the Euclidean space $\mathbb{R}^d$ and a number t, verify if there is a simple path of length smaller than t that visits each point exactly once.)

The approximability of TSP has been studied extensively over the last few decades. It is not hard to see that TSP is not approximable in polynomial time (unless $\mathcal{P} = \mathcal{NP}$) for arbitrary graphs with arbitrary edge costs. When the weights satisfy the triangle inequality (the so-called metric TSP), there is a polynomial-time 3/2-approximation algorithm due to Christofides [9], and it is known that no PTAS exists (unless $\mathcal{P} = \mathcal{NP}$). This result has been strengthened by Trevisan [21] to include Euclidean graphs in high dimensions (the same result holds also for any ℓ_p metric).

Theorem 2 (Trevisan [21]) *If $d \geq \log n$, then there exists a constant $\varepsilon > 0$ such that the Euclidean TSP in $\mathbb{R}^d$ is $\mathcal{NP}$-hard to approximate within a factor of $1 + \varepsilon$.*

In particular, this result implies that if $d \geq \log n$, then the Euclidean TSP in $\mathbb{R}^d$ has no PTAS unless $\mathcal{P} = \mathcal{NP}$.

The same result holds also for any ℓ_p metric. Furthermore, Theorem 2 implies that Euclidean TSP in $\mathbb{R}^{\log n}$ is *APX PB*-hard under E-reductions and *APX*-complete under AP-reductions.

It has been believed for some time that Theorem 2 might hold for smaller values of d, in particular even for $d = 2$, but this has been disproved independently by Arora [1] and Mitchell [17].

Theorem 3 (Arora [1] and Mitchell [17]) *The Euclidean TSP on the plane has a PTAS.*

The main idea of the algorithms of Arora and Mitchell is rather simple, but the details of the analysis are quite complicated. Both algorithms follow the same approach. One first proves a so-called structure theorem, which demonstrates that there is a $(1 + \varepsilon)$-approximation that has some local properties (in the case of the Euclidean TSP, there is a quadtree partition of the space containing all the points such that there is a $(1 + \varepsilon)$-approximation in which each cell of the quadtree is crossed by the tour at most a constant number of times and only in some prespecified locations). Then, one uses dynamic programming to find an optimal (or almost optimal) solution that obeys the local properties specified in the structure theorem.

The original algorithms presented in the first conference version of [1] and in the early version of [17] have the running times of the form $\mathcal{O}(n^{1/\epsilon})$ to obtain a $(1 + \varepsilon)$-approximation, but this has been subsequently improved. In particular, Arora's randomized algorithm in [1] runs in time $\mathcal{O}(n(\log n)^{1/\epsilon})$, and it can be derandomized with a slowdown of $\mathcal{O}(n)$. The result from Theorem 3 can be also extended to higher dimensions. Arora shows the following result.

Theorem 4 (Arora [1]) *For every constant d, the Euclidean TSP in $\mathbb{R}^d$ has a PTAS.*

For every fixed $c > 1$ and given any n points in $\mathbb{R}^d$, there is a randomized algorithm that finds a $\left(1 + \frac{1}{c}\right)$-approximation of the optimum traveling salesman tour in $\mathcal{O}\left(n(\log n)^{(\mathcal{O}(\sqrt{dc}))^{d-1}}\right)$ time. In particular, for any constant d and c, the running time is $\mathcal{O}\left(n(\log n)^{\mathcal{O}(1)}\right)$. The algorithm can be derandomized by increasing the running time by a factor of $\mathcal{O}(n^d)$.

This has been later extended by Rao and Smith [19], who proved the following.

Theorem 5 (Rao and Smith [19]) *There is a deterministic algorithm that computes a* $\left(1+\frac{1}{c}\right)$*-approximation of the optimum traveling salesman tour in* $\mathcal{O}\left(2^{(cd)^{\mathcal{O}(d)}}n + (cd)^{\mathcal{O}(d)}n \log n\right)$ *time.*

There is a randomized algorithm that succeeds with probability at least $\frac{1}{2}$ *and that computes a* $\left(1+\frac{1}{c}\right)$*-approximation of the optimum traveling salesman tour in expected* $\left(c\sqrt{d}\right)^{\mathcal{O}\left(d(c\sqrt{d})^{d-1}\right)} n + \mathcal{O}(d\, n \log n)$ *time.*

These results are essentially asymptotically optimal in the decision tree model thanks to a lower bound of $\Omega(n \log n)$ for any sublinear approximation for 1-dimensional Euclidean TSP due to Das et al. [12]. In the *real RAM* model, one can further improve the randomized results.

Theorem 6 (Bartal and Gottlieb [6]) *Given a set* S *of* n *points in* d*-dimensional grid* $\{0,\ldots,\Delta\}^d$ *with* $\Delta = 2^{(cd)^{\mathcal{O}(d)}}n$*, there is a randomized algorithm that with probability* $1 - e^{-\mathcal{O}_d(n^{1/3d})}$ *computes a* $\left(1+\frac{1}{c}\right)$*-approximation of the optimum traveling salesman tour for* S *in time* $2^{(cd)^{\mathcal{O}(d)}}n$ *in the integer RAM model.*

If the data is not given in the integral form, then one may round the data into this form using the floor or mod functions, and assuming these functions are atomic operations, the rounding can be done in $\mathcal{O}(dn)$ total time, leading to the following theorem.

Theorem 7 (Bartal and Gottlieb [6]) *Given a set of* n *points in* $\mathbb{R}^d$*, there is a randomized algorithm that with probability* $1 - e^{-\mathcal{O}_d(n^{1/3d})}$ *computes a* $\left(1+\frac{1}{c}\right)$*-approximation of the optimum traveling salesman tour in time* $2^{(cd)^{\mathcal{O}(d)}}n$ *in the real RAM model with atomic floor or mod operations.*

Applications

The techniques developed by Arora [1] and Mitchell [17] found numerous applications in the design of polynomial-time approximation schemes for geometric optimization problems.

Euclidean Minimum Steiner Tree

For a given set S of n points in the Euclidean space $\mathbb{R}^d$, find the minimum-cost network connecting all the points in S (where the cost of a network is equal to the sum of the lengths of the edges defining it).

Euclidean k-median

For a given set S of n points in the Euclidean space $\mathbb{R}^d$ and an integer k, find k-medians among the points in S so that the sum of the distances from each point in S to its closest median is minimized.

Euclidean k-TSP

For a given set S of n points in the Euclidean space $\mathbb{R}^d$ and an integer k, find the shortest tour that visits at least k points in S.

Euclidean k-MST

For a given set S of n points in the Euclidean space $\mathbb{R}^d$ and an integer k, find the shortest tree that visits at least k points in S.

Euclidean Minimum-Cost k-Connected Subgraph

For a given set S of n points in the Euclidean space $\mathbb{R}^d$ and an integer k, find the minimum-cost subgraph (of the complete graph on S) that is k-connected.

Theorem 8 *For every constant d, the following problems have a PTAS:*

- *Euclidean minimum Steiner tree problem in* $\mathbb{R}^d$ *[1, 19]*
- *Euclidean k-median problem in* $\mathbb{R}^d$ *[5]*
- *Euclidean k-TSP and the Euclidean k-MST problems in* $\mathbb{R}^d$ *[1]*
- *Euclidean minimum-cost k-connected subgraph problem in* $\mathbb{R}^d$ *(constant k) [10]*

The technique developed by Arora [1] and Mitchell [17] led also to some quasi-polynomial-time approximation schemes, that is, the algorithms with the running time of $n^{\mathcal{O}(\log n)}$. For example, Arora and Karokostas [4] gave a quasi-polynomial-time approximation scheme

for the Euclidean minimum latency problem, Das and Mathieu [13] gave a quasi-polynomial-time approximation scheme for the Euclidean capacitated vehicle routing problem, and Remy and Steger [20] gave a quasi-polynomial-time approximation scheme for the minimum-weight triangulation problem.

For more discussion, see the survey by Arora [2] and Czumaj and Lingas [11].

Extensions to Planar Graphs and Metric Spaces with Bounded Doubling Dimension

The dynamic programming approach used by Arora [1] and Mitchell [17] is also related to the recent advances for a number of optimization problems for planar graphs and in graphs in metric spaces with bounded doubling dimension. For example, Arora et al. [3] designed a PTAS for the TSP in weighted planar graphs (cf. [15] for a linear-time PTAS), and there is a PTAS for metric spaces with bounded doubling dimension [7].

Open Problems

An interesting open problem is if the quasi-polynomial-time approximation schemes mentioned above (for the minimum latency, the capacitated vehicle routing, and the minimum-weight triangulation problems) can be extended to obtain PTAS. For more open problems, see Arora [2].

Problem Definition

All problems in NP can be exactly solved in $2^{\text{poly}(n)}$ time via exhaustive search, but research has yielded faster exponential-time algorithms for many NP-hard problems. However, some key problems have not seen improved algorithms, and problems with improvements seem to converge toward $O(C^n)$ for some unknown constant $C > 1$.

The satisfiability problem for Boolean formulas in conjunctive normal form, CNF-SAT, is a central problem that has resisted significant improvements. The complexity of CNF-SAT and its special case k-SAT, where each clause has k literals, is the canonical starting point for the development of NP-completeness theory.

Similarly, in the last 20 years, two hypotheses have emerged as powerful starting points for understanding exponential-time complexity. In 1999, Impagliazzo and Paturi [5] defined the *exponential-time hypothesis* (ETH), which asserts that 3-*SAT cannot be solved in subexponential time*. Namely, it asserts there is an $\epsilon > 0$ such that 3-SAT cannot be solved in $O((1+\epsilon)^n)$ time. ETH has been a surprisingly useful assumption for ruling out subexponential-time algorithms for other problems [2, 6]. A stronger hypothesis has led to more fine-grained lower bounds, which is the focus of this article. Many NP-hard problems are solvable in C^n time via exhaustive search (for some $C > 1$) but are not known to be solvable in $(C-\epsilon)^n$ time, for any $\epsilon > 0$. The *strong exponential-time hypothesis* (SETH) [1,5] asserts that for every $\epsilon > 0$, there exists a k such that k-SAT cannot be solved in time $O((2-\epsilon)^n)$. SETH has been very useful in establishing tight (and

exact) lower bounds for many problems. Here we survey some of these tight results.

Key Results

The following results are reductions from k-SAT to other problems. They can be seen either as new attacks on the complexity of SAT or as lower bounds for exact algorithms that are conditional on SETH.

Lower Bounds on General Problems

The following problems have lower bounds conditional on SETH. The reduction for the first problem is given to illustrate the technique.

k-Dominating Set

A *dominating set* of a graph $G = (V, E)$ is a subset $S \subseteq V$ such that every vertex is either in S or is a neighbor of a vertex in S. The k-DOMINATING SET problem asks to find a dominating set of size k. Assuming SETH, for any $k \geq 3$ and $\epsilon > 0$, k-DOMINATING SET cannot be solved in $O(n^{k-\epsilon})$ time [8].

The reduction from SAT to k-DOMINATING SET proceeds as follows. Fix some $k \geq 3$ and let F be a CNF formula on n variables; we build a corresponding graph G_F. Partition its variables into k equally sized parts of n/k variables. For each part, take all $2^{n/k}$ partial assignments and make a node for each partial assignment. Make each of the k parts into a clique (disjoint from the others). Add a dummy node for each partial assignment clique that is connected to every node in that clique but has no other edges. Add m more nodes, one for each clause. Finally, make an edge from a partial assignment node to a clause node iff the partial assignment satisfies the clause. We observe that there is a k-dominating set in G_F if F is satisfiable.

2Sat+2Clauses

The 2SAT+2CLAUSES problem asks whether a Boolean formula is satisfiable, given that it is a 2-CNF with two additional clauses of arbitrary length. Assuming SETH, for any $m = n^{1+o(1)}$ and $\epsilon > 0$, 2SAT+2CLAUSES cannot be solved in $O(n^{2-\epsilon})$ time [8]. It is known that 2SAT+2CLAUSES can be solved in $O(mn + n^2)$ time [8].

HornSat+kClauses

The HORNSAT+kCLAUSES problem asks whether a Boolean formula is satisfiable, given that it is a CNF of clauses that contain at most one nonnegative literal per clause (a Horn CNF), conjoined with k additional clauses of arbitrary length but only positive literals. Assuming SETH, for any $k \geq 2$ and $\epsilon > 0$, HORNSAT+kCLAUSES cannot be solved in $O((n + m)^{k-\epsilon})$ time [8]. It can be trivially solved in $O(n^k \cdot (m + n))$ time by guessing a variable to set to true for each of the k additional clauses and checking if the remaining Horn CNF is satisfiable in linear time.

3-Party Set Disjointness

The 3-PARTY SET DISJOINTNESS problem is a communication problem with three parties and three subsets $S_1, S_2, S_3 \subseteq [m]$, where the ith party has access to all sets except for S_i. The parties wish to determine if $S_1 \cap \cdots \cap S_3 = \varnothing$. Clearly this can be done with $O(m)$ bits of communication. Assuming SETH, 3-PARTY SET DISJOINTNESS cannot be solved using protocols running in $2^{o(n)}$ time and communicating only $o(m)$ bits [8].

k-SUM

The k-SUM problem asks whether a set of n numbers contains a k-tuple that sums to zero. Assuming SETH, k-SUM on n numbers cannot be solved in $n^{o(k)}$ time for any $k < n^{0.99}$. (It is well known that k-SUM is in $O(n^{\lceil k/2 \rceil})$ time) [8].

For all the problems below, we can solve in $2^n n^{O}(1)$ time via exhaustive search.

k-Hitting Set

Given a set system $\mathcal{F} \subseteq 2^U$ in some universe U, a *hitting set* is a subset $H \subseteq U$ such that $H \cap S \neq \varnothing$ for every $S \in \mathcal{F}$. The k-HITTINGSET problem asks whether there is a hitting set of size at most t, given that each set $S \in \mathcal{F}$ has at most k elements. SETH is equivalent to the claim that for all $\epsilon > 0$,

there is a k for which k-HittingSet cannot be solved in time $O((2-\epsilon)^n)$ [3].

k-Set Splitting

Given a set system $\mathcal{F} \subseteq 2^U$ in some universe U, a set splitting is a subset $X \subseteq U$ such that the first element of the universe is in X and for every $S \in \mathcal{F}$, neither $S \subseteq X$ nor $S \subseteq (U \setminus X)$. The k-SetSplitting problem asks whether there is a set splitting, given that each set $S \in \mathcal{F}$ has at most k elements. SETH is equivalent to the claim that for all $\epsilon > 0$, there is a k for which k-SetSplitting cannot be solved in time $O((2-\epsilon)^n)$ [3].

k-NAE-Sat

The k-NAE-Sat problem asks whether a k-CNF has an assignment where the first variable is set to true and each clause has both a true literal and a false literal. SETH is equivalent to the claim that for all $\epsilon > 0$, there is a k for which k-NAE-Sat cannot be solved in time $O((2-\epsilon)^n)$ [3].

c-VSP-Circuit-SAT

The c-VSP-Circuit-SAT problem asks whether a cn-size Valiant series-parallel circuit over n variables has a satisfying assignment. SETH is equivalent to the claim that for all $\epsilon > 0$, there is a k for which c-VSP-Circuit-SAT cannot be solved in time $O((2-\epsilon)^n)$ [3].

Problems Parameterized by Treewidth

A variety of NP-complete problems have been shown to be much easier on graphs of bounded treewidth. Reductions starting from SETH given by Lokshtanov, Marx, and Saurabh [7] can also prove lower bounds that depend on the treewidth of an input graph, $\mathrm{tw}(G)$. The following are proven via analyzing the pathwidth of a graph, $\mathrm{pw}(G)$, and the fact that $\mathrm{tw}(G) \leq \mathrm{pw}(G)$.

Independent Set

An *independent set* of a graph $G = (V, E)$ is a subset $S \subseteq V$ such that the subgraph induced by S contains no edges. The Independent Set problem asks to find an independent set of maximum size. Assuming SETH, for any $\epsilon > 0$, Independent Set cannot be solved in $(2-\epsilon)^{\mathrm{tw}(G)} n^{O(1)}$ time.

Dominating Set

A *dominating set* of a graph $G = (V, E)$ is a subset $S \subseteq V$ such that every vertex is either in S or is a neighbor of a vertex in S. The Dominating Set problem asks to find a dominating set of minimum size. Assuming SETH, for any $\epsilon > 0$, Dominating Set cannot be solved in $(3-\epsilon)^{\mathrm{tw}(G)} n^{O(1)}$ time.

Max Cut

A *cut* of a graph $G = (V, E)$ is a partition of V into S and $V \setminus S$. The size of a cut is the number of edges that have one endpoint in S and the other in $V \setminus S$. The Max Cut problem asks to find a cut of maximum size. Assuming SETH, for any $\epsilon > 0$, Max Cut cannot be solved in $(2-\epsilon)^{\mathrm{tw}(G)} n^{O(1)}$ time.

Odd Cycle Transversal

An *odd cycle transversal* of a graph $G = (V, E)$ is a subset $S \subseteq V$ such that the subgraph induced by $V \setminus S$ is bipartite. The Odd Cycle Transversal problem asks to, given an integer k, determine whether there is an odd cycle transversal of size k. Assuming SETH, for any $\epsilon > 0$, Odd Cycle Transversal cannot be solved in $(3-\epsilon)^{\mathrm{tw}(G)} n^{O(1)}$ time.

Graph Coloring

A *q-coloring* of a graph $G = (V, E)$ is a function $\mu : V \to [q]$. A q-coloring is *proper* if for all edges $(u, v) \in E$, $\mu(u) \neq \mu(v)$. The q-coloring problem asks to decide whether the graph has a proper q-coloring. Assuming SETH, for any $q \geq 3$ and $\epsilon > 0$, q-coloring cannot be solved in $(q-\epsilon)^{\mathrm{tw}(G)} n^{O(1)}$ time.

Partition Into Triangles

A graph $G = (V, E)$ can be partitioned into triangles if there is a partition of the vertices into $S_1, S_2, \ldots, S_{n/3}$ such that each S_i induces a triangle in G. The Partition Into Triangles problem asks to decide whether the graph can be partitioned into triangles. Assuming SETH, for

any $\epsilon > 0$, PARTITION INTO TRIANGLES cannot be solved in $(2-\epsilon)^{\mathrm{tw}(G)} n^{O(1)}$ time.

All of the above results are tight, in the sense that when $\epsilon = 0$, there is an algorithm for each of them.

Showing Difficulty Via Set Cover

Given a set system $\mathcal{F} \subseteq 2^U$ in some universe U, a set cover is a subset $\mathcal{C} \subseteq \mathcal{F}$ such that $\bigcup_{S \in \mathcal{C}} S = U$. The SET COVER problem asks whether there is a set cover of size at most t.

Cygan et al. [3] also gave reductions from SET COVER to several other problems, showing lower bounds conditional on the assumption that for all $\epsilon > 0$, there is a k such that SET COVER where sets in $\mathcal{F}$ have size at most k cannot be computed in time $O^*((2-\epsilon)^n)$.

It is currently unknown how SET COVER is related to SETH; if there is a reduction from CNF-SAT to SET COVER, then all of these problems would have conditional lower bounds as well.

Steiner Tree

Given a graph $G = (V, E)$ and a set of terminals $T \subseteq V$, a *Steiner Tree* is a subset $X \subseteq V$ such that the graph induced by X is connected and $T \subseteq X$. The STEINER TREE problem asks whether G has a Steiner tree of size at most t. With the above SET COVER assumption, for all $\epsilon > 0$, STEINER TREE cannot be solved in $O^*((2-\epsilon)^t)$ time.

Connected Vertex Cover

A *connected vertex cover* of a graph $G = (V, E)$ is a subset $X \subseteq V$ such that the subgraph induced by X is connected and every edge contains at least one endpoint in X. The CONNECTED VERTEX COVER problem asks whether G has a connected vertex cover of size at most t. With the above SET COVER assumption, for all $\epsilon > 0$, CONNECTED VERTEX COVER cannot be solved in $O^*((2-\epsilon)^t)$ time.

Set Partitioning

Given a set system $\mathcal{F} \subseteq 2^U$ in some universe U, a set partitioning is a set cover $\mathcal{C}$ where pairwise disjoint elements have an empty intersection. The SET PARTITIONING problem asks whether there is a set partitioning of size at most t. With the above SET COVER assumption, for all $\epsilon > 0$, SET PARTITIONING cannot be solved in $O^*((2-\epsilon)^n)$ time.

Subset Sum

The SUBSET SUM problem asks whether a set of n positive numbers contains a subset that sums to a target t. With the above SET COVER assumption, for all $\delta < 1$, SUBSET SUM cannot be solved in $O^*(t^\delta)$ time. Note that there is a dynamic programming solution that runs in $O(nt)$ time.

Open Problems

- Does ETH imply SETH?
- Does SETH imply SET COVER requires $O^*((2-\epsilon)^n)$ time for all $\epsilon > 0$?
- Does SETH imply that the Traveling Salesman Problem in its most general, weighted form requires $O^*((2-\epsilon)^n)$ time for all $\epsilon > 0$?

Problem Definition

In the *subset sum problem*, we are given integers $a_1, \ldots, a_n, t$ and are asked to find a subset $X \subseteq \{1, \ldots, n\}$ such that $\sum_{i \in X} a_i = t$. In the *Knapsack problem*, we are given $a_1, \ldots, a_n, b_1, \ldots, b_n, t, u$ and are asked to find a subset $X \subseteq \{1, \ldots, n\}$ such that $\sum_{i \in X} a_i \leq t$ and $\sum_{i \in X} b_i \geq u$. It is well known that both problems can be solved in $O(nt)$ time using dynamic programming. However, as is typical for dynamic programming, these algorithms require a lot of working memory and are relatively hard to execute in parallel on several processors: the above algorithms use $O(t)$ space which may be *exponential* in the input size.

This raises the question: when can we avoid these disadvantages and still be (approximately) as fast as dynamic programming algorithms? It appears that by (slightly) loosening the time budget, space usage and parallelization can be significantly improved in many dynamic programs.

Key Results

A Space Efficient Algorithm for Subset Sum

In this article, we will use $\tilde{O}(\cdot)$ to suppress factors that are poly-logarithmic in the input size. In what follows, we will discuss how to prove the following theorem:

Theorem 1 (Lokshtanov and Nederlof, [7]) *There is an algorithm counting the number of solutions of a subset sum instance in* $\tilde{O}(n^2 t(n + \log t))$ *time and* $(n + lg(t))(\lg nt)$ *space.*

The Discrete Fourier Transform

We use Iverson's bracket notation: given a Boolean predicate b, $[b]$ denotes 1 if b is true

and 0 otherwise. Let $P(x)$ be a polynomial of degree $N-1$, and let $p_0,\ldots,p_{N-1}$ be its coefficients. Thus, $P(x) = \sum_{i=0}^{N-1} p_i x^i$. Let ω_N denote the N'th root of unity, that is, $\omega_N = e^{\frac{2\pi\iota}{N}}$. Let k,t be integers such that $k \neq t$. By the summation formula for geometric progressions $\left(\sum_{\ell=0}^{N-1} r^\ell = \frac{1-r^N}{1-r} \text{for } r \neq 1\right)$, we have:

$$\sum_{\ell=0}^{N-1} \omega_N^{\ell(k-t)} = \frac{1-\omega_N^{(k-t)N}}{1-\omega_N^{k-t}} = \frac{1-\left(\omega_N^N\right)^{k-t}}{1-\omega_N^{k-t}}$$
$$= \frac{1-(1)^{k-t}}{1-\omega_N^{k-t}} = 0.$$

On the other hand, if $k=t$, then $\sum_{\ell=0}^{N-1} \omega_N^{\ell(k-t)} = \sum_{\ell=0}^{N-1} 1 = N$. Thus, both cases can be compactly summarized as $\sum_{\ell=0}^{N-1} \omega_N^{\ell(k-t)} = [k=t]N$. As a consequence, we can express a coefficient p_t of $P(x)$ directly in terms of its evaluations:

$$\begin{aligned} p_t &= \sum_{k=0}^{N-1} [k=t] p_k \\ &= \sum_{k=0}^{N-1} \frac{1}{N} \sum_{\ell=0}^{N-1} \omega_N^{\ell(k-t)} \sum p_k \\ &= \frac{1}{N} \sum_{\ell=0}^{N-1} \omega_N^{-\ell t} \sum_{k=0}^{N-1} p_k \left(\omega_N^\ell\right)^k \\ &= \frac{1}{N} \sum_{\ell=0}^{N-1} \omega_N^{-\ell t} P(\omega_N^\ell) \end{aligned} \tag{1}$$

Using the Discrete Fourier Transform for Subset Sum

Given an instance $a_1,\ldots,a_n,t$ of subset sum, define the polynomial $P(x)$ to be $P(x) = \prod_{i=1}^n (1+x^{a_i})$. Clearly, we can discard integers a_i larger than t, and assume that $P(x)$ has degree at most $N = nt$. If we expand the products in this polynomial to get rid of the parentheses, we get a sum of 2^n products and each of these products is of the type x^k and corresponds to a subset $X \subseteq \{1,\ldots,n\}$ such that $\sum_{i\in X} a_i = k$. Thus, if we aggregate these products, we obtained the normal form $P(x) = \sum_{k=0}^{N-1} p_k x^k$, where p_k equals the number of subsets $X \subseteq [n]$ such that $\sum_{i\in X} a_i = k$. Plugging this into Eq. 1, we have that the number of subset sum solutions equals

$$p_t = \frac{1}{N} \sum_{\ell=0}^{N-1} \omega_N^{-\ell t} \prod_{i=1}^{n} \left(1+\omega_N^{\ell a_i}\right). \tag{2}$$

Given Eq. 2, the algorithm suggests itself: evaluation of the right-hand side gives the number of solutions of the subset sum instance. Given ω_N, this would be a straightforward on the unit-cost RAM model (recall that in this model arithmetic instructions as $+,-,*$ and $/$ are assumed to take constant time): the required powering operations are performed in $\log(N)$ arithmetic operations so an overall upper bound would be $O(n^2 t \log(nt))$ time.

However, still the value of this algorithm is not clear yet: for example, ω_N may be irrational, so it is not clear how to perform the arithmetic efficiently. This is an issue that also arises for the folklore fast Fourier transform (see, e.g., [3] for a nice exposition), and this issue is usually not addressed (a nice exception is Knuth [6]). Moreover in our case we should also be careful on the space budget: for example, we cannot even store 2^t in the usual way within our space budget. But, as we will now see, it turns out that we can simply evaluate Eq. 2 with finite precision and round to the nearest integer within the resource bounds claimed in Theorem 1.

Evaluating Equation 2 with Finite Precision

The algorithm establishing Theorem 1 is presented in Algorithm 1. Here, ρ represents the amount of precision the algorithm works with. The procedure $\texttt{tr}_\rho$ truncates ρ bits after the decimal point. The procedure $\texttt{apxr}_\rho(z)$ returns an estimate of ω_N^z. In order to do this, estimates of ω_N^z with z being powers of 2 are precomputed in Lines 3–4. We omit an explicit implementation of the right-hand side of Line 4 since this is very standard; for example, one can use an approximation of π together with a binary splitting approach

Algorithm 1 Approximate evaluation of Eq. 2

Algorithm: SSS$(a_1, \ldots, a_n, t)$
Require: for every $1 \le i \le n, a_i < t$.
1: $\rho \leftarrow 3n + 6 \log nt$
2: $s \leftarrow 0$
3: **for** $0 \le q \le \log N - 1$ **do**
4: //store roots of unity for powers of two
5: $r_q \leftarrow \mathtt{tr}_\rho(e^{\frac{2\pi 2^q}{Nt}})$
6: **end for**
7: **for** $0 \le \ell \le N - 1$ **do**
8: $p \leftarrow \mathtt{apxr}_\rho(-\ell t \ \% \ N)$
9: **for** $1 \le i \le n$ **do**
10: $p \leftarrow \mathtt{tr}_\rho(p * (1 + \mathtt{apxr}_\rho(\ell a_i \ \% \ N)))$
11: **end for**
12: $s \leftarrow s + p$
13: **end for**
14: **return** $\mathtt{rnd}(\mathtt{tr}_\rho(\frac{s}{N}))$ //round to nearest int

Algorithm: $\mathtt{apxr}_\rho(z)$
Require: $z < N$
15: $p' \leftarrow 1$
16: **for** $1 \le q \le \log N - 1$ **do**
17: **if** 2^q divides z **then**
18: $p \leftarrow \mathtt{tr}_\rho(p' * r_q)$
19: **end if**
20: **end for**
21: **return** p'

(see [1, Section 4.9.1]) or a Taylor expansion-based approach (see [2]). Crude upper bounds on the time and space usage of both approaches are $O(\rho^2 \log N)$ time and $O(n \log nt + \log nt)$ space.

Let us proceed with verifying whether Algorithm 1 satisfies the resource bounds of Theorem 1. It is easy to see that all intermediate numbers have modulus at most $2^n N$, so their estimates can be represented with $O(\rho)$ bits. For all multiplications we will use an asymptotically fast algorithm running in $\tilde{O}(n)$ time (e.g., [5]). Then, Line 3–4 take $\tilde{O}(\rho^2 \log N)$ time. Line 6 takes $\tilde{O}(\rho \lg N)$ time; Lines 7–8 take $n\rho \lg N$ time, which is the bottleneck. So overall, the algorithm uses $\tilde{O}(Nn\rho) = \tilde{O}(n^2 t(n + \log t))$ time. The space usage is dominated by the precomputed values which use $O(\log N\rho) = O(n + \log t(\log nt))$ space.

For the correctness of Algorithm 1, let us first study what happens if we work with infinite precision (i.e., $\rho = \infty$). Note that $\mathtt{apxr}_\infty(z) = \omega_N^z$ since it computes

$$\prod_{q=1}^{\log N - 1} [2^q \text{ divides } z] r_q = \prod_{q=1}^{\log N - 1} [2^q \text{ divides } z] \omega_N^{2^q} = \omega_N^{\sum_{q=1}^{\log N-1} [2^q \text{ divides } z] 2^q} = \omega^z.$$

Moreover, note that on iteration ℓ of the for-loop of Line 5, we will have on Line 9 that $p = P(\omega_N^\ell)$ by the definition of $P(x)$. Then, it is easy to see that Algorithm 1 indeed evaluates the right-hand side of Eq. 2.

Now, let us focus on the finite precision. The algorithm computes an N-sized sum of $(n + 2 \log N)$-sized products of precomputed values, (increased by one). Note that it is sufficient to guarantee that on Line 9 in every iteration ℓ, $|p - \omega_N^{-\ell t} \prod_{i=1}^n (1 + \omega_N^{\ell a_i})| \le 0.4$, since then the total error of s on Line 10 is at most $0.4N$ and the total error of s/N is 0.4, which guarantees rounding to the correct integer. Recall that p is the result of an $(n + 2 \log N)$-sized product, so let us analyze how the approximation error propagates in this situation. If $\hat{a}, \hat{b}$ are approximations of a, b and we approximate c by $\mathtt{tr}_\rho \hat{a} * \hat{b}$, we have

$$|c - \hat{c}| \le |a - \hat{a}||b| + |b - \hat{b}||a| + |a - \hat{a}||b - \hat{b}| + 2^{-\rho}.$$

Thus, if a is the result of a (i-1)-sized product, and using an upper bound of 2 for the modulus of any of the product terms in the algorithm, we can upper bound the error of E_i estimating an i-length product as follows: $E_1 \le 2^{-\rho}$ and for $i > 1$:

$$E_i \le 2E_{i-1} + 2^{-\rho} 2^{i-1} + 2^{-\rho} E_{i-1} + 2^{-\rho} \le 3E_{i-1} + 2^{-\rho} 2^i.$$

Using straightforward induction we have that $E_i \le 6^i 2^{-\rho}$ So indeed, setting $\rho = 3n + 6 \log nt$ suffices.

A Generic Framework

For Theorem 1, we only used that the to be determined value is a coefficient of a (relatively)

small degree polynomial that we can evaluate efficiently. Whether this is the case for other problems solved by dynamic programming can be seen from the structure of the used recurrence: when the recurrence can be formulated over a polynomial ring where the polynomials have small degree, we can evaluate it fast and interpolate with the same technique as above to find a required coefficient. For example, for Knapsack, one can use the polynomial $P(x, y) = \prod_{i=1}^{n}(x^{a_i} y^{b_i})$ and look for a nonzero coefficient of $x^{t'} y^{u'}$ where $t' \leq t$ and $u' \geq u$ to obtain a pseudo-polynomial time and polynomial space algorithm as well.

Naturally, this technique does not only apply to the polynomial ring. In general, if the ring would be $R \subseteq \mathcal{C}^{N \times N}$ equipped with matrix addition and multiplication, we just need a matrix that simultaneously diagonalizes all matrices of R (in the above case, R are all circulant matrices which are simultaneously diagonalized by the Fourier matrix).

Applications

The framework applies to many dynamic programming algorithms. A nice additional example is the algorithm of Dreyfus and Wagner for Steiner tree [4, 7, 8].

Bandwidth; Exponential time algorithms; Graph ordering

Years and Authors of Summarized Original Work

2000; Feige
2008; Cygan, Pilipczuk
2010; Cygan, Pilipczuk
2012; Cygan, Pilipczuk

Problem Definition

Given a graph G with n vertices, an *ordering* is a bijective function $\pi : V(G) \to \{1, 2, \ldots, n\}$. The bandwidth of π is a maximal length of an edge, i.e.,

$$\mathrm{bw}(\pi) = \max_{uv \in E(G)} |\pi(u) - \pi(v)|.$$

The bandwidth problem, given a graph G and a positive integer b, asks if there exists an ordering of bandwidth at most b.

Key Results

An exhaustive search for the bandwidth problem enumerates all the $n!$ orderings, trying to find one of bandwidth at most b. The first single exponential time algorithm is due to Feige and Kilian [6], which we are going to describe now.

Bucketing

Definition 1 For a positive integer k, let $\mathcal{I}_k$ be the collection of $\lceil n/k \rceil$ sets obtained by splitting the set $\{1, \ldots, n\}$ into equal parts (except the last one), i.e., $\mathcal{I}_k = \{\{1, \ldots, k\}, \{k+1, \ldots, 2k\}, \ldots\}$. A function $f : V(G) \to \mathcal{I}_k$ is called a k-bucket assignment, if for every edge $uv \in E(G)$ at least one of the following conditions is satisfied:

- $f(u) = f(v)$,
- $|\max f(u) - \min f(v)| \leq b$,
- $|\min f(u) - \max f(v)| \leq b$.

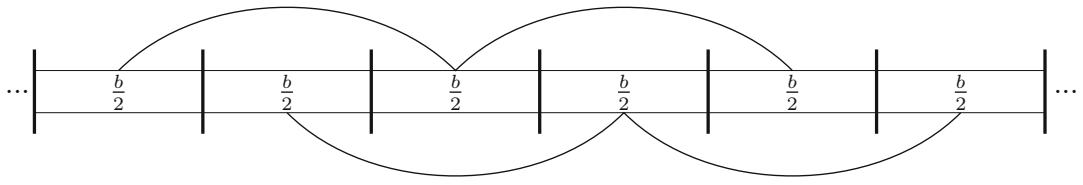
Clearly, if a function $f : V(G) \to \mathcal{I}_k$ is not a k-bucket assignment, then there is no ordering π of bandwidth at most b consistent with f, where π is *consistent* with f iff $\pi(v) \in f(v)$ for each $v \in V(G)$. A bucket function can be seen as a rough assignment – instead of assigning vertices to their final positions in the ordering, we assign them to intervals.

The $\mathcal{O}(10^n \text{poly}(n))$ time algorithm of [6] is based on two ideas, both related to the notion of bucket assignments. For the sake of presentation, let us assume that n is divisible by b, whereas b is a power of two. Moreover, we assume that G is connected, as otherwise it is enough to consider each connected component of G separately.

First, one needs to show that there is a family of at most $n3^{n-1}$ b-bucket assignments $\mathcal{F}$, such that any ordering of bandwidth at most b is consistent with some b-bucket assignment from $\mathcal{F}$. We create $\mathcal{F}$ recursively by branching. First, fix an arbitrary vertex v_0, and assign it to some interval from $\mathcal{I}_k$ (there are at most n choices here). Next, consider any vertex v without assigned interval, which has a neighbor u with already assigned interval. By the assumption that G is connected, v always exists. Note that in order to create a valid bucket assignment, v has to be assigned either to the same interval as u or to one of its two neighboring intervals. This gives at most three branches to be explored.

In the second phase, consider some b-bucket assignment $f \in \mathcal{F}$. We want to check whether there exists some ordering of bandwidth at most b consistent with f. To do this, for each vertex v, we branch into two choices, deciding whether v should be assigned to the left half of $f(v)$ or to the right half of $f(v)$. This leads to at most 2^n $b/2$-bucket assignments to be processed. The key observation is that each of those assignments can be naturally split into two independent subproblems. This is because each edge within an interval of length $b/2$ and each edge between two neighboring intervals of length $b/2$ will be of length at most $b-1$. Additionally, each edge connecting two vertices with at least two intervals of length $b/2$ in between would lead to violating the constraint of being a valid $b/2$-bucket assignment. Therefore, it is enough to consider vertices in even and odd intervals separately (see Fig. 1). Such routine of creating more and more refined bucket assignments can be continued, where the running time used for n vertices satisfies

$$T(n) = 2^n \cdot 2 \cdot T(\frac{n}{2})$$



Exact Algorithms for Bandwidth, Fig. 1 *Thick vertical lines* separate subsequent intervals from $\mathcal{I}_{b/2}$. Meaningful edges connect vertices with exactly one interval in between

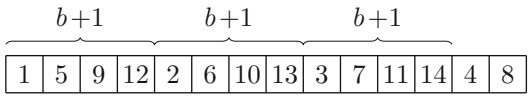
which in turn gives $T(n) = 4^n \text{poly}(n)$. Since we have $|\mathcal{F}| \leq n3^{n-1}$, we end up with $\mathcal{O}(12^n \text{poly}(n))$ time algorithm. If instead of generating b-bucket assignments one uses $b/2$-bucket assignments (there are at most $n5^{n-1}$ of them), then the running time can be improved to $10^n \text{poly}(n)$.

Dynamic Programming

In [2, 5], Cygan and Pilipczuk have shown that for a single $(b+1)$-bucket assignment, one can check in time and space $\mathcal{O}(2^n \text{poly}(n))$ whether there exists an ordering of bandwidth at most b consistent with it. Since there are at most $n3^{n-1}$ $(b+1)$-bucket assignments, this leads to $\mathcal{O}(6^n \text{poly}(n))$ time algorithm.

The key idea is to assign vertices to their final positions consistent with some $f \in \mathcal{F}$ in a very specific order. Let us color the set of positions $\{1, \ldots, n\}$ with $\text{color}(i) = (i-1) \bmod (b+1)$. Define a *color order* of positions, where positions from $\{1, \ldots, n\}$ are sorted by their color values, breaking ties with position values (see Fig. 2).

A lemma that proves usefulness of the color order shows that if we assign vertices to positions in the color order, then we can use the standard Held-Karp dynamic programming over subsets approach. In particular, in a state of dynamic programming, it is enough to store the subset $S \subseteq V(G)$ of vertices already assigned to the first $|S|$ positions in the color order (see Fig. 3).



Exact Algorithms for Bandwidth, Fig. 2 An index of each position in a color order for $n = 14$ and $b = 3$

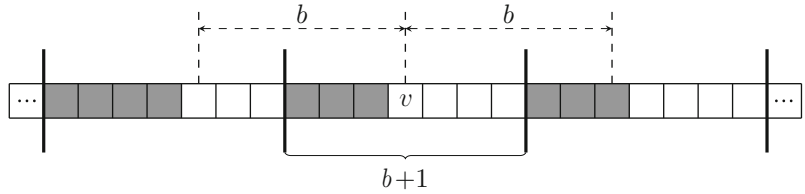
Further Improvements

Instead of upper bounding running time of the algorithm for each $(b+1)$-bucket assignment separately, one can count the number of states of the dynamic programming routine used by the algorithm throughout the processing of all the bucket assignments. As shown in [2], this leads to $\mathcal{O}(5^n \text{poly}(n))$ running time, which with more insights and more technical analysis can be further improved to $O(4.83^n)$ [5] and $O(4.383^n)$ [3]. If only polynomial space is allowed, then the best known algorithm needs $O(9.363^n)$ running time [4].

Related Work

Concerning small values of b, Saxe [8] presented a nontrivial $O(n^{b+1})$ time and space dynamic programming, consequently proving the problem to be in XP. However, Bodlaender et al. [1] have shown that bandwidth is hard for any fixed level of the W hierarchy.

For a related problem of minimum distortion embedding, Fomin et al. [7] obtained a $\mathcal{O}(5^n \text{poly}(n))$ time algorithm, improved by Cygan and Pilipczuk [4] to running times same as for the best known bandwidth algorithms.



Exact Algorithms for Bandwidth, Fig. 3 When a vertex v is to be assigned to the next position in the color order, then all its neighbors from the left interval cannot be yet assigned a position, whereas all its neighbors from the right interval have to be already assigned in order to obtain an ordering of bandwidth at most b

Open Problems

Many vertex ordering problems admit $\mathcal{O}(2^n \text{poly}(n))$ time and space algorithms, like Hamiltonicity, cutwidth, pathwidth, optimal linear arrangement, etc. In [2], Cygan and Pilipczuk have shown that a dynamic programming routine with such a running time is possible, provided a $(b+1)$-bucket assignment is given. A natural question to ask is whether it is possible to obtain $\mathcal{O}(2^n \text{poly}(n))$ without the assumption of having a fixed assignment to be extended.

Problem Definition

The dominating set problem is a classical NP-hard optimization problem which fits into the broader class of covering problems. Hundreds of papers have been written on this problem that has a natural motivation in facility location.

Definition 1 For a given undirected, simple graph $G = (V, E)$, a subset of vertices $D \subseteq V$ is called a *dominating set* if every vertex $u \in V - D$ has a neighbor in D. The minimum dominating set problem (abbr. MDS) is to find a *minimum dominating set* of G, i.e., a dominating set of G of minimum cardinality.

Problem 1 (MDS)

INPUT: Undirected simple graph $G = (V, E)$.
OUTPUT: A minimum dominating set D of G.

Various modifications of the dominating set problem are of interest, some of them obtained by putting additional constraints on the dominating set as, e.g., requesting it to be an independent set or to be connected. In graph theory, there is a huge literature on domination dealing with the problem and its many modifications. In graph algorithms, the MDS problem and some of its modifications like independent dominating set and connected dominating set have been studied as benchmark problems for attacking NP-hard problems under various algorithmic approaches.

Known Results

The algorithmic complexity of MDS and its modifications when restricted to inputs from a particular graph class has been studied extensively. Among others, it is known that MDS remains NP-hard on bipartite graphs, split graphs, planar graphs, and graphs of maximum degree 3. Polynomial time algorithms to compute a minimum dominating set are known, e.g., for permutation, interval, and k-polygon graphs. There is also a $O(3^k\, n^{O(1)})$ time algorithm to solve MDS on graphs of treewidth at most k.

The dominating set problem is one of the basic problems in parameterized complexity; it is W[2]-complete and thus it is unlikely that the problem is fixed parameter tractable. On the other hand, the problem is fixed parameter tractable on planar graphs. Concerning approximation, MDS is equivalent to MINIMUM SET COVER under L-reductions. There is an approximation algorithm solving MDS within a factor of $1 + \log|V|$, and it cannot be approximated within a factor of $(1-\epsilon)\ln|V|$ for any $\epsilon > 0$, unless NP $\subset$ DTIME($n^{\log\log n}$).

Exact Exponential Algorithms

If P $\neq$ NP, then no polynomial time algorithm can solve MDS. Even worse, it has been observed in [5] that unless SNP$\subseteq$ SUBEXP (which is considered to be highly unlikely), there is not even a subexponential time algorithm solving the dominating set problem.

The trivial $O(2^n\,(n+m))$ algorithm, which simply checks all the 2^n vertex subsets whether they are dominating, clearly solves MDS. Three faster algorithms have been established in 2004. The algorithm of Fomin et al. [5] uses a deep graph-theoretic result due to B. Reed, stating that every graph on n vertices with minimum degree at least three has a dominating set of size at most $3n/8$, to establish an $O(2^{0.955n})$ time algorithm solving MDS. The $O(2^{0.919n})$ time algorithm of Randerath and Schiermeyer [9] uses very nice ideas including matching techniques to restrict the search space. Finally, Grandoni [6] established an $O(2^{0.850n})$ time algorithm to solve MDS.

Key Results

Branch and Reduce and Measure and Conquer

The work of Fomin, Grandoni, and Kratsch presents a simple and easy way to implement a recursive branch and reduce algorithm to solve MDS. It was first presented at ICALP 2005 [2] and later published in 2009 in [3]. The running time of the algorithm is significantly faster than the ones stated for the previous algorithms. This is heavily based on the analysis of the running time by measure and conquer, which is a method to analyze the worst case running time of (simple) branch and reduce algorithms based on a sophisticated choice of the measure of a problem instance.

Theorem 1 *There is a branch and reduce algorithm solving* MDS *in time* $O(2^{0.610n})$ *using polynomial space.*

Theorem 2 *There is an algorithm solving* MDS *in time* $O(2^{0.598n})$ *using exponential space.*

The algorithms of Theorems 1 and 2 are simple consequences of a transformation from MDS to MINIMUM SET COVER (abbr. MSC) combined with new exact exponential time algorithms for MSC.

Problem 2 (MSC)

INPUT: Finite set $\mathcal{U}$ and a collection $\mathcal{S}$ of subsets $S_1, S_2, \ldots S_t$ of $\mathcal{U}$.

OUTPUT: A minimum set cover $\mathcal{S}'$, where $\mathcal{S}' \subseteq \mathcal{S}$ is a set cover of $(\mathcal{U}, \mathcal{S})$ if $\bigcup_{S_i \in \mathcal{S}'} S_i = \mathcal{U}$.

Theorem 3 *There is a branch and reduce algorithm solving* MSC *in time* $O(2^{0.305(|\mathcal{U}|+|\mathcal{S}|)})$ *using polynomial space.*

Applying memorization to the polynomial space algorithm of Theorem 3, the running time can be improved as follows.

Theorem 4 *There is an algorithm solving* MSC *in time* $O(2^{0.299(|\mathcal{S}|+|\mathcal{U}|)})$ *needing exponential space.*

The analysis of the worst case running time of the simple branch and reduce algorithm solving MSC (of Theorem 3) is done by a careful choice of the measure of a problem instance which allows to obtain an upper bound that is significantly smaller than the one that could be obtained using the standard measure. The refined analysis leads to a collection of recurrences. Then, random local search was used to compute the weights, used in the definition of the measure, aiming at the best achievable upper bound of the worst case running time. By now various other methods to do these time-consuming computations are available; see, e.g., [1].

Getting Faster MDS Algorithms

There is a lot of interest in exact exponential algorithms for solving MDS and in improving their best known running times. Two important improvements on the running times of the original algorithm stated in Theorems 1 and 2 have been achieved. To simplify the comparison, let us mention that in [4] those running times are stated as $O(1.5259^n)$ using polynomial space and $O(1.5132^n)$ needing exponential space.

Van Rooij and Bodlaender presented faster exact exponential algorithms solving MDS that are strongly based on the algorithms of Fomin et al. and the methods of their analysis. By introducing new reduction rules in the algorithm and a refined analysis, they achieved running time $O(1.5134^n)$ using polynomial space and time $O(1.5063^n)$, presented at STACS 2008. This analysis has been further improved in [11] to achieve a running time of $O(1.4969^n)$ using polynomial space, which was published in 2011. It should be emphasized that memorization cannot be applied to the latter algorithm.

The currently best known algorithms solving MDS have been obtained by Ywata [7] and presented at IPEC 2011.

Theorem 5 *There is a branch and reduce algorithm solving* MDS *in time* $O(1.4864^n)$ *using polynomial space.*

Theorem 6 *There is an algorithm solving* MDS *in time* $O(1.4689^n)$ *needing exponential space.*

Ywata's polynomial space branch and reduce algorithm is also strongly related to the algorithm of Fomin et al. and its analysis. The improvement in the running time is achieved by some crucial change in the order of branchings in the algorithm solving MSC, i.e., the algorithm branches on the same element consecutively. These consecutive branchings can then be exploited by a refined analysis using global weights called potentials. Thus, such an analysis is dubbed "potential method." By a variant of memorization where dynamic programming memorizes only solutions of subproblems with small number of elements, an algorithm of running time $O(1.4689^n)$ needing exponential space has been obtained.

Counting Dominating Sets

A strongly related problem is #DS that asks to determine for a given graph G the number of dominating sets of size k, for any k. In [8], Nederlof, van Rooij, and van Dijk show how to combine inclusion/exclusion and a branch and reduce algorithm while using measure and conquer, as to obtain an algorithm (needing exponential space) of running time $O(1.5002^n)$. Clearly, this also solves MDS.

Applications

There are various other NP-hard domination-type problems that can be solved by exact exponential algorithms based on an algorithm solving

MINIMUM SET COVER: any instance of the initial problem is transformed to an instance of MSC, and then an algorithm solving MSC is applied and thus the initial problem is solved. Examples of such problems are TOTAL DOMINATING SET, k-DOMINATING SET, k-CENTER, and MDS on split graphs. Measure and conquer and the strongly related quasiconvex analysis of Eppstein [1] have been used to design and analyze a variety of exact exponential branch and reduce algorithms for NP-hard problems, optimization, counting, and enumeration problems; see [4].

Open Problems

While for many algorithms it is easy to show that the worst case analysis is tight, this is not the case for the nowadays time analysis of branch and reduce algorithms. For example, the worst case running times of the branch and reduce algorithms of Fomin et al. [3] solving MDS and MSC remain unknown; a lower bound of $\Omega(3^{n/4})$ for the MDS algorithm is known. The situation is similar for many other branch and reduce algorithms. Consequently, there is a strong need for new and better tools to analyze the worst case running time of branch and reduce algorithms.

Boolean satisfiability; Exponential-time algorithms; SAT

Years and Authors of Summarized Original Work

1998; Hirsch
2003; Schuler

Problem Definition

The satisfiability problem (*SAT*) for Boolean formulas in conjunctive normal form (*CNF*) is one of the first **NP**-complete problems [2, 13]. Since its **NP**-completeness currently leaves no hope for polynomial-time algorithms, the progress goes by decreasing the exponent. There are several versions of this parametrized problem that differ in the parameter used for the estimation of the running time.

Problem 1 (SAT)

INPUT: Formula F in CNF containing n variables, m clauses, and l literals in total.
OUTPUT: "Yes" if F has a *satisfying assignment*, i.e., a substitution of Boolean values for the variables that makes F true. "No" otherwise.

The bounds on the running time of SAT algorithms can be thus given in the form $|F|^{O(1)} \cdot \alpha^n$, $|F|^{O(1)} \cdot \beta^m$, or $|F|^{O(1)} \cdot \gamma^l$, where $|F|$ is the length of a reasonable bit representation of F (i.e., the formal input to the algorithm). In fact, for the present algorithms, the bases β and γ are constants, while α is a function $\alpha(n, m)$ of the formula parameters (because no better constant than $\alpha = 2$ is known).

Notation

A formula in conjunctive normal form is a set of clauses (understood as the conjunction of these clauses), a clause is a set of literals (understood as the disjunction of these literals), and a literal is either a Boolean variable or the negation of a Boolean variable. A truth assignment assigns Boolean values (*false* or *true*) to one or more variables. An assignment is abbreviated as the list of literals that are made true under this assignment (e.g., assigning *false* to x and *true* to y is denoted by $\neg x, y$). The result of the application of an assignment A to a formula F (denoted $F[A]$) is the formula obtained by removing the clauses containing the true literals from F and removing the falsified literals from the remaining clauses. For example, if $F = (x \vee \neg y \vee z) \wedge (y \vee \neg z)$, then $F[\neg x, y] = (z)$. A *satisfying* assignment for F is an assignment A such that $F[A] =$ true. If such an assignment exists, F is called *satisfiable*.

Key Results

Bounds for β and γ

General Approach and a Bound for β

The trivial brute-force algorithm enumerating all possible assignments to the n variables runs in 2^n polynomial-time steps. Thus $\alpha \leq 2$, and by trivial reasons also $\beta, \gamma \leq 2$. In the early 1980s, Monien and Speckenmeyer noticed that β could be made smaller. (They and other researchers also noticed that α could be made smaller for a special case of the problem where the length of each clause is bounded by a constant; the reader is referred to another entry (*Local search algorithms for k-SAT*) of the *Encyclopedia* for relevant references and algorithms.) Then Kullmann and Luckhardt [12] set up a framework for divide-and-conquer (Also called *DPLL* due to the papers of Davis and Putnam [6] and Davis, Logemann, and Loveland [7].) algorithms for SAT that split the original problem into several (yet usually a constant number of) subproblems by substituting the values of some variables and simplifying the obtained formulas. This line of research resulted in the following upper bounds for β and γ:

Theorem 1 (Hirsch [8]) *SAT can be solved in time*

1. $|F|^{O(1)} \cdot 2^{0.30897m}$;
2. $|F|^{O(1)} \cdot 2^{0.10299l}$.

A typical divide-and-conquer algorithm for SAT consists of two phases: splitting of the original problem into several subproblems (e.g., reducing SAT(F) to SAT(F[x]) and SAT(F[¬x])) and simplification of the obtained subproblems using polynomial-time transformation rules that do not affect the satisfiability of the subproblems (i.e., they replace a formula by an equisatisfiable one). The subproblems $F_1, \ldots, F_k$ for splitting are chosen so that the corresponding recurrent inequality using the simplified problems

$F'_1, \ldots, F'_k$,

$$T(F) \leq \sum_{i=1}^{k} T\left(F'_i\right) + const,$$

gives a desired upper bound on the number of leaves in the recurrence tree and, hence, on the running time of the algorithm. In particular, in order to obtain the bound $|F|^{O(1)} \cdot 2^{0.30897m}$ *one takes either two subproblems* $F[x], F[\neg x]$ *with recurrent inequality*

$$t_m \leq t_{m-3} + t_{m-4}$$

or four subproblems $F[x, y], F[x, \neg y], F[\neg x, y], F[\neg x, \neg y]$ *with recurrent inequality*

$$t_m \leq 2t_{m-6} + 2t_{m-7}$$

where $t_i = max_{m(G)\leq i} T(G)$. *The simplification rules used in the* $|F|^{O(1)} \cdot 2^{0.30897m}$*-time and the* $|F|^{O(1)} \cdot 2^{0.10299l}$*-time algorithms are as follows*:

Simplification Rules

Elimination of 1-Clauses If F contains a 1-clause (a), replace F by $F[a]$.

Subsumption If F contains two clauses C and D such that $C \subseteq D$, replace F by $F \backslash \{D\}$.

Resolution with Subsumption Suppose a literal a and clauses C and D are such that a is the only literal satisfying both conditions $a \in C$ and $\neg a \in D$. In this case, the clause $(C \cup D) \backslash \{a, \neg a\}$ is called the *resolvent by the literal* a of the clauses C and D and denoted by $R(C, D)$.

The rule is: if $R(C, D) \subseteq D$, replace F by $(F \backslash \{D\}) \cup \{R(C, D)\}$.

Elimination of a Variable by Resolution [6] Given a literal a, construct the formula $\mathrm{DP}_a(F)$ by

1. Adding to F all resolvents by a
2. Removing from F all clauses containing a or $\neg a$

The rule is: if $\mathrm{DP}_a(F)$ is not larger in m (resp., in l) than F, then replace F by $\mathrm{DP}_a(F)$.

Elimination of Blocked Clauses A clause C is *blocked* for a literal a w.r.t. F if C contains the literal a, and the literal $\neg a$ occurs only in the clauses of F that contain the negation of at least one of the literals occurring in $C \backslash \{a\}$. For a CNF-formula F and a literal a occurring in it, the assignment $I(a, F)$ is defined as

$$\{a\} \cup \{\text{literals } x \notin \{a, \neg a\} \mid \text{the clause } \{\neg a, x\} \text{ is blocked for } \neg a \text{ w.r.t. } F\}.$$

Lemma 2 (Kullmann [11])

(1) If a clause C *is blocked for a literal* a *w.r.t.* F*, then* F *and* $F \backslash \{C\}$ *are equi-satisfiable.*
(2) Given a literal a*, the formula* F *is satisfiable iff at least one of the formulas* $F[\neg a]$ *and* $F[I(a, F)]$ *is satisfiable.*

The first claim of the lemma is employed as a simplification rule.

Application of the Black and White Literals Principle Let P be a binary relation between literals and formulas in CNF such that for a variable v and a formula F, at most one of $P(v, F)$ and $P(\neg v, F)$ holds.

Lemma 3 *Suppose that each clause of* F *that contains a literal* w *satisfying* $P(w, F)$ *contains also at least one literal* b *satisfying* $P(\neg b, F)$*. Then* F *and* $F[\{l \mid P(\neg l, F)\}]$ *are equi-satisfiable.*

A Bound for γ

To obtain the bound $|F|^{O(1)} \cdot 2^{0.10299l}$, it is enough to use a pair $F[\neg a], F[I(a, F)]$ of subproblems (see Lemma 2(2)) achieving the desired recurrent inequality $t_l \leq t_{l-5} + t_{l-17}$ and to switch to the $|F|^{O(1)} \cdot 2^{0.30897m}$-time algorithm if there are none. A recent (much more technically involved) improvement to this algorithm [16] achieves the bound $|F|^{O(1)} \cdot 2^{0.0926l}$.

A Bound for α

Currently, no non-trivial constant upper bound for α is known. However, starting with [14] there was an interest to non-constant bounds. A series of randomized and deterministic algorithms showing successive improvements was developed, and at the moment the best possible bound is achieved by a deterministic divide-and-conquer algorithm employing the following recursive procedure. The idea behind it is a dichotomy: either each clause of the input formula can be shortened to its first k literals (then a k-CNF algorithm can be applied), or all these literals in one of the clauses can be assumed false. (This clause-shortening approach can be attributed to Schuler [15], who used it in a randomized fashion. The following version of the deterministic algorithm achieving the best known bound both for deterministic and randomized algorithms appears in [5].)

Procedure S

Input: a CNF formula F and a positive integer k.

1. Assume F consists of clauses $C_1, \ldots, C_m$. Change each clause C_i to a clause D_i as follows: If $|C_i| > k$ then choose any k literals in C_i and drop the other literals; otherwise leave C_i as is, i.e., $D_i = C_i$. Let F' denote the resulting formula.
2. Test satisfiability of F' using the $m \cdot \text{poly}(n) \cdot (2 - 2/(k+1))^n$-time k-CNF algorithm defined in [4].
3. If F' is satisfiable, output "satisfiable" and halt. Otherwise, for each i, do the following:
   1. Convert F to F_i as follows:
      1. Replace C_j by D_j for all $j < i$.
      2. Assign *false* to all literals in D_i.
   2. Recursively invoke *Procedure S* on (F_i, k).
4. Return "unsatisfiable".

The algorithm just invokes *Procedure S* on the original formula and the integer parameter $k = k*(m,n)$. The most accurate analysis of this family of algorithms by Calabro, Impagliazzo, and Paturi [1] implies that, assuming that $m > n$, one can obtain the following bound by taking $k(m,n) = 2\log(m/n) + \text{const}$. (This explicit bound is not stated in [1] and is inferred in [3].)

Theorem 4 (Dantsin, Hirsch [3]) *Assuming $m > n$, SAT can be solved in time*

$$|F|^{O(1)} \cdot 2^n \left(1 - \frac{1}{O(\log(m/n))}\right).$$

Applications

While SAT has numerous applications, the presented algorithms have no direct effect on them.

Open Problems

Proving a constant upper bound on $\alpha < 2$ remains a major open problem in the field, as well as the hypothetic existence of $(1+\varepsilon)^l$-time algorithms for arbitrary small $\varepsilon > 0$.

It is possible to perform the analysis of a divide-and-conquer algorithm and even to generate simplification rules automatically [10]. However, this approach so far led to new bounds only for the (NP-complete) optimization version of 2-SAT [9].

Experimental Results

Jun Wang has implemented the algorithm yielding the bound on β and collected some statistics regarding the number of applications of the simplification rules [17].

2013; Bliznets, Fomin, Pilipczuk, Villanger

Problem Definition

A graph class Π is a set of simple graphs. One can also think of Π as a *property*: Π comprises all the graphs that satisfy a certain condition. We say that class (property) Π is *hereditary* if it is closed under taking induced subgraphs. More precisely, whenever $G \in \Pi$ and H is an induced subgraph of G, then also $H \in \Pi$.

We shall consider the MAXIMUM INDUCED Π-SUBGRAPH problem: given a graph G, find the largest (in terms of the number of vertices) induced subgraph of G that belongs to Π. Suppose now that class Π is polynomial-time recognizable: there exists an algorithm that decides whether a given graph H belongs to Π in polynomial time. Then MAXIMUM INDUCED Π-SUBGRAPH on an n-vertex graph G can be solved by brute force in time (The $\mathcal{O}^\star(\cdot)$ notation hides factors polynomial in the input size.) $\mathcal{O}^\star(2^n)$: we iterate through all the induced subgraphs of G, and on each of them, we run a polynomial-time test deciding whether it belongs to Π.

Can we do anything smarter? Of course, this very much depends on the class Π we are working with. MAXIMUM INDUCED Π-SUBGRAPH is a generic problem that encompasses many other problems as special cases; examples include CLIQUE (Π = complete graphs), INDEPENDENT SET (Π = edgeless graphs), or FEEDBACK VERTEX SET (Π = forests). It is convenient to assume that Π is also hereditary; this assumption is satisfied in many important examples, including the aforementioned special cases.

So far, the MAXIMUM INDUCED Π-SUBGRAPH problem has been studied for many graph classes Π, and basically in all the cases it turned out that it is possible to find an algorithm with running time $\mathcal{O}(c^n)$ for some $c < 2$. Obtaining a result of this type is often informally called *breaking the* 2^n *barrier*. While the algorithms share a common general methodology, vital details differ depending on the structural properties of the class Π. This makes each and every algorithm of this type contrived to a particular scenario. However, it is tempting to formulate the following general conjecture.

Conjecture 1 ([1]) *For every hereditary, polynomial-time recognizable class of graphs Π, there exists a constant $c_\Pi < 2$ for which there is an algorithm solving* MAXIMUM INDUCED Π-SUBGRAPH *in time $\mathcal{O}(c_\Pi^n)$.*

On one hand, current partial progress on this conjecture consists of scattered results exploiting different properties of particular classes Π, without much hope for proving more general statements. On the other hand, finding a counterexample refuting Conjecture 1 based, e.g., on the Strong Exponential Time Hypothesis seems problematic: the input to MAXIMUM INDUCED Π-SUBGRAPH consists only of $\binom{n}{2}$ bits of information about adjacencies between the vertices, and it seems difficult to model the search space of a general k-SAT using such input under the constraint that Π has to be hereditary and polynomial-time recognizable.

It can be that Conjecture 1 is either false or very difficult to prove, and therefore, one can postulate investigating its certain subcases connected to well-studied classes of graphs. For instance, one could assume that graphs from Π have constant treewidth or that Π is a subclass of chordal or interval graphs. Another direction is to strengthen the assumption about the description of the class Π by requiring that belonging to Π can be expressed in some formalism (e.g., some variant of logic). Finally, one can investigate the algorithms for MAXIMUM INDUCED Π-SUBGRAPH where Π is not required to be hereditary; here, natural nonhereditary properties are connectivity and regularity.

Key Results

Table 1 presents a selection of results on the MAXIMUM INDUCED Π-SUBGRAPH problem. Since the algorithms are usually quite technical when it comes to details, we now present an overview of the general methodology and most important techniques. In the following, we assume that Π is hereditary and polynomial-time recognizable.

Most often, the general approach is to examine the structure of the input instance and of a fixed, unknown optimum solution. The goal is to identify as broad spectrum of situations as possible where the solution can be found by examining $\mathcal{O}((2-\varepsilon)^n)$ candidates, for some $\varepsilon > 0$. By checking the occurrence of each of these situations, we eventually narrow down our investigations to the case where we have a well-defined structure of the input instance and

Exact Algorithms for Induced Subgraph Problems, Table 1 Known results for MAXIMUM INDUCED Π-SUBGRAPH. The first part of the table presents results for problems for which breaking the 2^n barrier follows directly from branching on forbidden subgraphs. The second part contains results for which breaking the barrier requires a nontrivial insight into the structure of Π. Finally, the last part contains results for nonhereditary classes Π. Here, ε denotes a small, positive constant, and its index specifies a parameter on which the value of this constant depends

a number of assumptions about how the solution looks like. Then, hopefully, a direct algorithm can be devised.

Let us consider a very simple example of this principle, which is also a technique used in many algorithms for breaking the 2^n barrier. Suppose the input graph has n vertices and assume the optimum solution is of size larger that $(1/2+\delta)n$, for some $\delta > 0$. Then, as candidates for the optimum solution, we can consider all the vertex subsets of at least this size: there is only $(2-\varepsilon)^n$ of them, where $\varepsilon > 0$ depends on δ. Similarly, if the optimum solution has size smaller than $(1/2-\delta)n$, then we can identify this situation by iterating through all the vertex subsets of size $(1/2-\delta)n$ (whose number is again $(2-\varepsilon)^n$ for some $\varepsilon > 0$) and verifying that none of them induces a graph belonging to Π; note that here we use the assumption that Π is hereditary. In this case we can solve the problem by looking at all vertex subsets of size at most $(1/2-\delta)n$. All in all, we can solve the problem faster than $\mathcal{O}^\star(2^n)$ provided that the number of vertices in the optimum solution differs by at least δn from $n/2$, for some $\varepsilon > 0$. More precisely, for every $\delta > 0$ we will obtain a running time of the form $\mathcal{O}((2-\varepsilon)^n)$, where ε tends to 0 when δ tends to 0. Hence, we can focus only on the situation when the number of vertices in the optimum solution is very close to $n/2$.

We now give an overview of some other important techniques.

Branching on Forbidden Induced Subgraphs

Every hereditary graph class Π can be characterized by giving a minimal set of forbidden induced subgraphs $\mathcal{F}$: a graph belongs to Π if and only if it does not contain any graph from $\mathcal{F}$ as an induced subgraph, and $\mathcal{F}$ is inclusion-wise minimal with this property. For instance, the class of forests is characterized by $\mathcal{F}$ being the family of all the cycles, whereas taking $\mathcal{F}$ to be the family of all the cycles of length at least 4 gives the class of chordal graphs. For many important classes the family $\mathcal{F}$ is infinite, but there are notable examples where it is finite, like cluster, trivially perfect, or split graphs.

If Π is characterized by a finite set of forbidden subgraphs $\mathcal{F}$, then already a simple branching strategy yields an algorithm working in time $\mathcal{O}((2-\varepsilon)^n)$, for some $\varepsilon > 0$ depending on $\mathcal{F}$. Without going into details, we iteratively find a forbidden induced subgraph that is not yet removed by the previous choices and branch on the fate of all the undecided vertices in this subgraph, omitting the branch where all of them are included in the solution. Since this forbidden induced subgraph is of constant size, a standard analysis shows that the running time of this algorithm is $\mathcal{O}((2-\varepsilon)^n)$ for some $\varepsilon > 0$ depending on $\max_{H\in\mathcal{F}} |V(H)|$. This simple observation can be combined with more sophisticated techniques in case when $\mathcal{F}$ is infinite. We can namely start the algorithm by branching on forbidden induced

subgraphs that are of constant size and, when their supply is exhausted, turn to some other algorithms. The following lemma provides a formalization of this concept; a graph is called $\mathcal{F}$-*free* if it does not contain any graph from $\mathcal{F}$ as an induced subgraph.

Lemma 1 ([1]) *Let $\mathcal{F}$ be a finite set of graphs and let ℓ be the maximum number of vertices in a graph from $\mathcal{F}$. Let Π be a hereditary graph class that is polynomial-time recognizable. Assume that there exists an algorithm $\mathcal{A}$ that for a given $\mathcal{F}$-free graph G on n vertices, in time $\mathcal{O}((2-\varepsilon)^n)$ finds a maximum induced subgraph of G that belongs to Π, for some $\varepsilon > 0$. Then there exists an algorithm $\mathcal{A}'$ that for a given graph G on n vertices, in time $\mathcal{O}((2-\varepsilon')^n)$ finds a maximum induced subgraph of G that is $\mathcal{F}$-free and belongs to Π, where $\varepsilon' > 0$ is a constant depending on ε and ℓ.*

Thus, for the purpose of breaking the 2^n barrier, it is sufficient to focus on the case when no constant-size forbidden induced subgraph is present in the input graph.

Exploiting a Large Substructure

Here, the general idea is to look for a large substructure in the graph that can be leveraged to design an algorithm breaking the barrier. Let us take as an example the Maximum Induced Chordal Subgraph problem, considered by Bliznets et al. [1]. Suppose that in the input graph G one can find a clique Q of size δn, for some $\delta > 0$; recall that the largest clique in a graph can be found as fast as in time $\mathcal{O}(1.2109^n)$ [10]. Then consider the following algorithm: guess, by considering $2^{n-|Q|}$ possibilities, the intersection of the optimum solution with $V(G) \setminus Q$. Then observe that, since Q is a clique, every induced cycle in G can have only at most two vertices in common with Q. Hence, the problem of optimally extending the choice on $V(G) \setminus Q$ to Q essentially boils down to solving a Vertex Cover instance on $|Q|$ vertices, which can be done in time $\mathcal{O}(1.2109^{|Q|})$. As Q constitutes a linear fraction of all the vertices, the overall running time is $\mathcal{O}(1.2109^{|Q|} \cdot 2^{n-|Q|})$, which is $\mathcal{O}((2-\varepsilon)^n)$ for some $\varepsilon > 0$ depending on δ. Thus, one can focus on the case where the largest clique in the input graph, and hence also in any maximum-sized induced chordal subgraph, has less than δn vertices.

Potential Maximal Cliques

A *potential maximal clique* (*PMC*) in a graph G is a subset of vertices that becomes a clique in some inclusion-wise minimal triangulation (By a triangulation of a graph we mean any its chordal supergraph.) of G. Fomin and Villanger in [2] observed two facts. Firstly, whenever H is an induced subgraph of G of treewidth t, then there exists a minimal triangulation TG of G that captures H in the following sense: every clique of TG intersects $V(H)$ only at a subset of some bag of a fixed width-t tree decomposition of H. Secondly, a graph G on n vertices can have only $\mathcal{O}(1.734601^n)$ PMCs, which can be enumerated in time $\mathcal{O}(1.734601^n)$. Intuitively, this means that we can effectively search the space of treewidth-t induced subgraphs of G in time $\mathcal{O}(1.734601^n \cdot n^{\mathcal{O}(t)})$ using dynamic programming. Slightly more precisely, treewidth-t induced subgraphs of G can be assembled in a dynamic programming manner using states of the form (Ω, X), where Ω is a PMC in G and X is a subset of Ω of size at most $t+1$, corresponding to $\Omega \cap V(H)$. In this manner one can obtain an algorithm with running time $\mathcal{O}(1.734601^n \cdot n^{\mathcal{O}(t)})$ for finding the maximum induced treewidth-t subgraph, which in particular implies a $\mathcal{O}(1.734601^n)$-time algorithm for Maximum Induced Forest, equivalent to Feedback Vertex Set. Recently, Fomin et al. [5] extended this framework to encapsulate also problems where the induced subgraph H is in addition required to satisfy a property expressible in *Monadic Second-Order Logic*.

Keywords

CNF satisfiability; Exponential-time algorithm; Local search

Years and Authors of Summarized Original Work

1999; Schöning

Problem Definition

The CNF satisfiability problem is to determine, given a CNF formula F with n variables, whether or not there exists a satisfying assignment for F. If each clause of F contains at most k literals, then F is called a k-CNF formula and the problem is called k-SAT, which is one of the most fundamental NP-complete problems. The trivial algorithm is to search 2^n 0/1-assignments for the n variables. But since [6], several algorithms which run significantly faster than this $O(2^n)$ bound have been developed. As a simple exercise, consider the following straightforward algorithm for 3-SAT, which gives us an upper bound of 1.913^n: choose an arbitrary clause in F, say, $(x_1 \vee \overline{x_2} \vee x_3)$. Then generate seven new formulas by substituting to these x_1, x_2, and x_3 all the possible values except $(x_1, x_2, x_3) = (0, 1, 0)$ which obviously unsatisfies F. Now one can check the satisfiability of these seven formulas and conclude that F is satisfiable iff at least one of them is satisfiable. (Let $T(n)$ denote the time complexity of this algorithm. Then one can get the recurrence $T(n) \leq 7 \times T(n-3)$ and the above bound follows.)

Key Results

In the long history of k-SAT algorithms, the one by Schöning [11] is an important breakthrough. It is a standard local search and the algorithm itself is not new (see, e.g., [7]). Suppose that y is the current assignment (its initial value is selected uniformly at random). If y is a satisfying assignment, then the algorithm answers yes and terminates. Otherwise, there is at least one clause whose three literals are all false under y. Pick an arbitrary such clause and select one of the three

literals in it at random. Then flip (true to false and vice versa) the value of that variable, replace y with that new assignment, and then repeat the same procedure. More formally:

SCH(CNF formula F, integer I)
repeat I times
$y =$ uniformly random vector $\in \{0,1\}^n$
$z =$ **RandomWalk**(F, y);
if z satisfies F
then output(z); exit;
end
output('Unsatisfiable');
RandomWalk(CNF formula $G(x_1, x_2, \ldots, x_n)$, assignment y);
$y' = y$;
for $3n$ times
if y' satisfies G
then return y'; exit;
$C \leftarrow$ an arbitrary clause of G that is not satisfied by y';
Modify y' as follows:
select one literal of C uniformly at random and flip the assignment to this literal;
end
return y'

Schöning's analysis of this algorithm is very elegant. Let $d(a, b)$ denote the Hamming distance between two binary vectors (assignments) a and b. For simplicity, suppose that the formula F has only one satisfying assignment y^* and the current assignment y is far from y^* by Hamming distance d. Suppose also that the currently false clause C includes three variables, x_i, x_j, and x_k. Then y and y^* must differ in at least one of these three variables. This means that if the value of x_i, x_j, or x_k is flipped, then the new assignment gets closer to y^* by Hamming distance one with probability at least 1/3. Also, the new assignment gets farther by Hamming distance one with probability at most 2/3. The argument can be generalized to the case that F has multiple satisfying assignments. Now here comes the key lemma:

Lemma 1 *Let F be a satisfiable formula and y^* be a satisfying assignment for F. For each assignment y, the probability that a satisfying assignment (that may be different from y^*) is found by* ***RandomWalk*** *(F, y) is at least $(1/(k-1))^{d(y,y^*)}/p(n)$, where $p(n)$ is a polynomial in n.*

By taking the average over random initial assignments, the following theorem follows:

Theorem 1 *For any satisfiable formula F on n variables, the success probability of* ***RandomWalk*** *(F, y) is at least $(k/2(k-1))^n/p(n)$ for some polynomial p. Thus, by setting $I = (2(k-1)/k)^n \cdot p(n)$,* ***SCH*** *finds a satisfying assignment with high probability. When $k = 3$, this value of I is $O(1.334^n)$.*

Applications

The Schöning's result has been improved by a series of papers [1, 3, 9] based on the idea of [3]. Namely, RandomWalk is combined with the (polynomial time) 2SAT algorithm, which makes it possible to choose better initial assignments. For derandomization of **SCH**, see [2]. Iwama and Tamaki [4] developed a nontrivial combination of **SCH** with another famous, backtrack-type algorithm by [8], resulting in the then fastest algorithm with $O(1.324^n)$ running time. The current fastest algorithm is due to [10], which is based on the same approach as [4] and runs in time $O(1.32216^n)$.

Open Problems

k-SAT is probably the most popular NP-complete problem for which numerous researchers are competing for its fastest algorithm. Thus, improving its time bound is always a good research target.

Experimental Results

AI researchers have also been very active in SAT algorithms including local search; see, e.g., [5].

Exact Algorithms for Maximum Independent Set

Fabrizio Grandoni
IDSIA, USI-SUPSI, University of Lugano, Lugano, Switzerland

Keywords

Exact exponential algorithms; Maximum independent set

Years and Authors of Summarized Original Work

1977; Tarjan, Trojanowski
1985; Robson
1999; Beigel
2009; Fomin, Grandoni, Kratsch

Problem Definition

Let $G = (V, E)$ be an n-node undirected, simple graph without loops. A set $I \subseteq V$ is called an *independent set* of G if the nodes of I are pairwise not adjacent. The *maximum independent set* (MIS) problem asks to determine the maximum cardinality $\alpha(G)$ of an independent set of G. MIS is one of the best studied NP-hard problems.

We will need the following notation. The (open) *neighborhood* of a vertex v is $N(v) = \{u \in V : uv \in E\}$, and its *closed neighborhood* is $N[v] = N(v) \cup \{v\}$. The degree $\deg(v)$ of v is $|N(v)|$. For $W \subseteq V$, $G[W] = (W, E \cap \binom{W}{2})$ is the *graph induced* by W. We let $G - W = G[V - W]$.

Key Results

A very simple algorithm solves MIS (exactly) in $O^*(2^n)$ time: it is sufficient to enumerate all the subsets of nodes, check in polynomial time whether each subset is an independent set

or not, and return the maximum cardinality independent set. We recall that the O^* notation suppresses polynomial factors in the input size. However, much faster (though still exponential-time) algorithms are known. In more detail, there exist algorithms that solve MIS in worst-case time $O^*(c^n)$ for some constant $c \in (1, 2)$. In this section, we will illustrate some of the most relevant techniques that have been used in the design and analysis of exact MIS algorithms. Due to space constraints, our description will be slightly informal (please see the references for formal details).

Bounding the Size of the Search Tree

All the nontrivial exact MIS algorithms, starting with [7], are recursive branching algorithms. As an illustration, consider the following simple MIS algorithm `Alg1`. If the graph is empty, output $\alpha(G) = 0$ (base instance). Otherwise, choose any node v of maximum degree, and output

$$\alpha(G) = \max\{\alpha(G - \{v\}), 1 + \alpha(G - N[v])\}.$$

Intuitively, the subgraph $G - \{v\}$ corresponds to the choice of not including v in the independent set (v is *discarded*), while the subgraph $G - N[v]$ to the choice of including v in the independent set (v is *selected*). Observe that, when v is selected, the neighbors of v have to be discarded. We will later refer to this branching as a *standard branching*.

The running time of the above algorithm, and of branching algorithms more in general, can be bounded as follows. The recursive calls induce a *search tree*, where the root is the input instance and the leaves are base instances (that can be solved in polynomial time). Observe that each branching step can be performed in polynomial time (excluding the time needed to solve subproblems). Furthermore, the height of the search tree is bounded by a polynomial. Therefore, the running time of the algorithm is bounded by $O^*(L(n))$, where $L(n)$ is the maximum number of leaves of any search tree that can be generated by the considered algorithm on an input instance with n nodes. Let us assume that $L(n) \leq c^n$ for some constant $c \geq 1$. When we branch at node v, we generate two subproblems containing $n - 1$ and $n - |N[v]|$ nodes, respectively. Therefore, c has to satisfy $c^n \geq c^{n-1} + c^{n-|N[v]|}$. Assuming pessimistically $|N[v]| = 1$, one obtains $c^n \geq 2c^{n-1}$ and therefore $c \geq 2$. We can conclude that the running time of the algorithm is $O^*(2^n)$. Though the running time of `Alg1` does not improve on exhaustive search, much faster algorithms can be obtained by branching in a more careful way and using a similar type of analysis. This will be discussed in the next subsections.

Refined Branching Rules

Several refined branching rules have been developed for MIS. Let us start with some *reduction rules*, which reduce the problem without branching (alternatively, by branching on a single subproblem). An isolated node v can be selected w.l.o.g.:

$$\alpha(G) = 1 + \alpha(G - N[v]).$$

Observe that if $N[u] \subseteq N[v]$, then node v can be discarded w.l.o.g. (*dominance*):

$$\alpha(G) = \alpha(G - \{v\}).$$

This rule implies that nodes of degree 1 can always be selected.

Suppose that we branch at a node v, and in the branch where we discard v we select exactly one of its neighbors, say w. Then by replacing w with v, we obtain a solution of the same cardinality including v: this means that the branch where we select v has to provide the optimal solution. Therefore, we can assume w.l.o.g. that the optimal solution either contains v or at least 2 of its neighbors. This idea is exploited in the *folding* operation [1], which we next illustrate only in the case of degree-2 nodes. Let $N[v] = \{w_1, w_2\}$. Remove $N[v]$. If $w_1w_2 \notin E$, create a node v' and add edges between v' and nodes in $N(w_1) \cup N(w_2) - \{v\}$. Let $G_{\text{fold}}(v)$ be the resulting graph. Then, one has

$$\alpha(G) = 1 + \alpha(G_{\text{fold}}(v)).$$

Intuitively, including node v' in the optimal solution to $G_{\text{fold}}(v)$ corresponds to selecting both w_1 and w_2, while discarding v' corresponds to selecting v.

Let `Alg2` be the algorithm that exhaustively applies the mentioned reduction rules and then performs a standard branching on a node of maximum degree. Reduction rules reduce the number of nodes at least by 1; hence, we have the constraint $c^n \geq c^{n-1}$. If we branch at node v, $\deg(v) \geq 3$. This gives $c^n \geq c^{n-1} + c^{n-4}$, which is satisfied by $c \geq 1.380\ldots$. Hence, the running time is in $O^*(1.381^n)$.

Let us next briefly sketch some other useful ideas that lead to refined branchings. A *mirror* [3] of a node v is a node u at distance 2 from v such that $N(v) - N(u)$ induces a clique. By the above discussion, if we branch by discarding v, we can assume that we select at least two neighbors of v and therefore we have also to discard the mirrors $M(v)$ of v. In other terms, we can use the refined branching

$$\alpha(G) = \max\{\alpha(G - \{v\} - M(v)), 1 + \alpha(G - N[v])\}.$$

A *satellite* [5] of a node v is a node u at distance 2 from v such that there exists a node $u' \in N(v) \cap N(u)$ that satisfies $N[u'] - N[v] = \{u\}$. Observe that if an optimal solution discards u, then we can discard v as well by dominance since $N[u'] \subseteq N[v]$ in $G - \{u\}$. Therefore, we can assume that in the branch where we select v, we also select its satellites $S(v)$. In other terms,

$$\alpha(G) = \max\{\alpha(G - \{v\}), 1 + |S(v)| + \alpha(G - N[v] - \cup_{u \in S(v)} N[u])\}.$$

Another useful trick [4] is to branch on nodes that form a *small separator* (of size 1 or 2 in the graph), hence isolating two or more connected components that can be solved independently (see also [2, 5]).

Measure and Conquer

Above we always used the number n of nodes as a *measure* of the size of subproblems. As observed in [3], much tighter running time bounds can be achieved by using smarted measures. As an illustration, we will present a refined bound on the running time of `Alg2`.

Let us measure the size of subproblems with the number n_3 of nodes of degree at least 3 (*large* nodes). Observe that, when $n_3 = 0$, G is a collection of isolated nodes, paths, and cycles. Therefore, in that case, `Alg2` only applies reduction rules, hence solving the problem in polynomial time. In other terms, $L(n_3) = L(0) = 1$ in this case. If the algorithm applies any reduction rule, the number of large nodes cannot increase and we obtain the trivial inequality $c^{n_3} \geq c^{n_3}$. Suppose next that `Alg2` performs a standard branching at a node v. Note that at this point all nodes in the graph are large. If $\deg(v) \geq 4$, then we obtain the inequality $c^{n_3} \geq c^{n_3-1} + c^{n_3-5}$ which is satisfied by $c \geq 1.324\ldots$. Otherwise ($\deg(v) = 3$), observe that the neighbors of v have degree 3 in G and at most 2 in $G - \{v\}$. Therefore, the number of large nodes is at most $n_3 - 4$ in both subproblems $G - \{v\}$ and $G - N[v]$. This gives the inequality $c^{n_3} \geq 2c^{n_3-4}$ which is satisfied by $c \geq 2^{1/4} < 1.1893$. We can conclude that the running time of the algorithm is in $O^*(1.325^n)$. In [3], each node is assigned a weight which is a growing function of its degree, and the measure is the sum of node weights (a similar measure is used also in [2, 5]).

In [2], it is shown how to use a fast MIS algorithm for graphs of maximum degree Δ to derive faster MIS algorithms for graphs of maximum degree $\Delta + 1$. Here the measure used in the analysis is a combination of the number of nodes and edges.

Memorization

So far we described algorithms with polynomial space complexity. *Memorization* [6] is a technique to speed up exponential-time branching algorithms at the cost of an exponential space complexity. The basic idea is to store the optimal solution to subproblems in a proper (exponential size) data structure. Each time a new subproblem is generated, one first checks (in polynomial time) whether that subproblem was already solved before. This way one avoids to solve the same subproblem several times.

In order to illustrate this technique, it is convenient to consider the variant `Alg3` of `Alg2` where we do not apply folding. This way, each subproblem corresponds to some induced subgraph $G[W]$ of the input graph. We will also use the standard measure though memorization is compatible with measure and conquer. By adapting the analysis of `Alg2`, one obtains the constraint $c^n \geq c^{n-1} + c^{n-3}$ and hence a running time of $O^*(1.466^n)$. Next, consider the variant `Alg3mem` of `Alg3` where we apply memorization. Let $L_k(n)$ be the maximum number of subproblems on k nodes generated by `Alg3mem` starting from an instance with n nodes. A slight adaptation of the standard analysis shows that $L_k(n) \leq 1.466^{n-k}$. However, since there are at most $\binom{n}{k}$ induced subgraphs on k nodes and we never solve the same subproblem twice, one also has $L_k(n) \leq \binom{n}{k}$. Using Stirling's formula, one obtains that the two upper bounds are roughly equal for $k = \alpha n$ and $\alpha = 0.107\ldots$. We can conclude that the running time of `Alg3mem` is in $O^*(\sum_{k=0}^{n} L_k(n)) = O^*(\sum_{k=0}^{n} \min\{1.466^{n-k}, \binom{n}{k}\}) = O^*(\max_{k=0}^{n} \min\{1.466^{n-k}, \binom{n}{k}\}) = O^*(1.466^{(1-0.107)n}) = O^*(1.408^n)$. The analysis can be refined [6] by bounding the number of *connected* induced subgraphs with k nodes in graphs of small maximum degree.

Exact Algorithms for Maximum Two-Satisfiability

Ryan Williams
Department of Computer Science, Stanford University, Stanford, CA, USA

Keywords

Max 2-SAT

Years and Authors of Summarized Original Work

2004; Williams

Problem Definition

In the maximum 2-satisfiability problem (abbreviated as MAX 2-SAT), one is given a Boolean formula in conjunctive normal form, such that each clause contains at most two literals. The task is to find an assignment to the variables of the formula such that a maximum number of clauses are satisfied.

MAX 2-SAT is a classic optimization problem. Its decision version was proved *NP*-complete by Garey, Johnson, and Stockmeyer [7], in stark contrast with 2-SAT which is solvable in linear time [2]. To get a feeling for the difficulty of the problem, the *NP*-completeness reduction is sketched here. One can transform any 3-SAT instance F into a MAX 2-SAT instance F', by replacing each clause of F such as

$$c_i = (\ell_1 \vee \ell_2 \vee \ell_3),$$

where ℓ_1, ℓ_2, and ℓ_3 are arbitrary literals, with the collection of 2-CNF clauses

$$(\ell_1), (\ell_2), (\ell_3), (c_i), (\neg\ell_1 \vee \neg\ell_2), (\neg\ell_2 \vee \neg\ell_3),$$
$$(\neg\ell_1 \vee \neg\ell_3), (\ell_1 \vee c_i), (\ell_2 \vee c_i), (\ell_3 \vee c_i),$$

where c_i is a new variable. The following are true:

- If an assignment satisfies c_i, then exactly seven of the ten clauses in the 2-CNF collection can be satisfied.
- If an assignment does not satisfy c_i, then exactly six of the ten clauses can be satisfied.

If F is satisfiable then there is an assignment satisfying 7/10 of the clauses in F', and if F is not satisfiable, then no assignment satisfies more than 7/10 of the clauses in F'. Since 3-SAT reduces to MAX 2-SAT, it follows that MAX 2-SAT (as a decision problem) is *NP*-complete.

Notation

A CNF formula is represented as a set of clauses.

The letter ω denotes the smallest real number such that for all $\epsilon > 0$, n by n matrix multiplication over a field can be performed in $O(n^{\omega+\epsilon})$ field operations. Currently, it is known that $\omega < 2.373$ [4, 16]. The field matrix product of two matrices A and B is denoted by $A \times B$.

Let A and B be matrices with entries from $\mathbb{R} \cup \{\infty\}$. The *distance product* of A and B (written in shorthand as $A \circledast B$) is the matrix C defined by the formula

$$C[i,j] = \min_{k=1,\ldots,n} \{A[i,k] + B[k,j]\}.$$

A word on m's and n's: in reference to graphs, m and n denote the number of edges and the number of nodes in the graph, respectively. In reference to CNF formulas, m and n denote the number of clauses and the number of variables, respectively.

Key Result

The primary result of this entry is a procedure solving Max 2-Sat in $O(m \cdot 2^{\omega n/3})$ time. The method can be generalized to *count* the number of solutions to *any* constraint optimization problem with at most two variables per constraint. Indeed, in the same running time, one can find a Boolean assignment that maximizes any given degree-two polynomial in n variables [18, 19]. In this entry, we shall restrict attention to be Max 2-Sat, for simplicity. There are several other known exact algorithms for Max 2-Sat that are more effective in special cases, such as sparse instances [3, 8, 9, 11–13, 15, 17]. The procedure described below is the only one known (to date) that runs in c^n steps for a constant $c < 2$.

Key Idea

The algorithm gives a reduction from MAX 2-SAT to the problem MAX TRIANGLE, in which one is given a graph with integer weights on its nodes and edges, and the goal is to output a 3-cycle of maximum weight. At first, the existence of such a reduction sounds strange, as MAX TRIANGLE can be trivially solved in $O(n^3)$ time by trying all possible 3-cycles. The key is that the reduction exponentially increases the problem size, from a MAX 2-SAT instance with m clauses and n variables to a MAX TRIANGLE instance having $O(2^{2n/3})$ edges, $O(2^{n/3})$ nodes, and weights in the range $\{-m, \ldots, m\}$.

Note that if MAX TRIANGLE required $\Theta(n^3)$ time to solve, then the resulting MAX 2-SAT algorithm would take $\Theta(2^n)$ time, rendering the above reduction pointless. However, it turns out that the brute-force search of $O(n^3)$ for MAX TRIANGLE is not the best one can do: using fast matrix multiplication, there is an algorithm for MAX TRIANGLE that runs in $O(Wn^\omega)$ time on graphs with weights in the range $\{-W, \ldots, W\}$.

Main Algorithm

First, a reduction from MAX 2-SAT to MAX TRIANGLE is described, arguing that each triangle of

weight K in the resulting graph is in one-to-one correspondence with an assignment that satisfies K clauses of the MAX 2-SAT instance. Let a, b be reals, and let $\mathbb{Z}[a,b] := [a,b] \cap \mathbb{Z}$.

Lemma 1 *If* MAX TRIANGLE *on graphs with n nodes and weights in $\mathbb{Z}[-W,W]$ is solvable in $O(f(W)\cdot g(n))$ time, for polynomials f and g, then* MAX 2-SAT *is solvable in $O(f(m)\cdot g(2^{n/3}))$ time, where m is the number of clauses and n is the number of variables.*

Proof Let C be a given 2-CNF formula. Assume without loss of generality that n is divisible by 3. Let F be an instance of MAX 2-SAT. Arbitrarily partition the n variables of F into three sets P_1, P_2, P_3, each having $n/3$ variables. For each P_i, make a list L_i of all $2^{n/3}$ assignments to the variables of P_i.

Define a graph $G = (V,E)$ with $V = L_1 \cup L_2 \cup L_3$ and $E = \{(u,v) | u \in P_i, v \in P_j, i \neq j\}$. That is, G is a complete tripartite graph with $2^{n/3}$ nodes in each part, and each node in G corresponds to an assignment to $n/3$ variables in C. Weights are placed on the nodes and edges of G as follows. For a node v, define $w(v)$ to be the number of clauses that are satisfied by the partial assignment denoted by v. For each edge $\{u,v\}$, define $w(\{u,v\}) = -W_{uv}$, where W_{uv} is the number of clauses that are satisfied by *both* u and v.

Define the weight of a triangle in G to be the total sum of all weights and nodes in the triangle.

Claim 1 There is a one-to-one correspondence between the triangles of weight K in G and the variable assignments satisfying exactly K clauses in F.

Proof Let a be a variable assignment. Then there exist unique nodes $v_1 \in L_1, v_2 \in L_2$, and $v_3 \in L_3$ such that a is precisely the concatenation of v_1, v_2, v_3 as assignments. Moreover, any triple of nodes $v_1 \in L_1, v_2 \in L_2$, and $v_3 \in L_3$ corresponds to an assignment. Thus, there is a one-to-one correspondence between triangles in G and assignments to F.

The number of clauses satisfied by an assignment is exactly the weight of its corresponding triangle. To see this, let $T_a = \{v_1, v_2, v_3\}$ be the triangle in G corresponding to assignment a. Then

$$\begin{aligned} w(T_a) &= w(v_1) + w(v_2) + w(v_3) + w(\{v_1,v_2\}) \\ &\quad + w(\{v_2,v_3\}) + w(\{v_1,v_3\}) \\ &= \sum_{i=1}^{3} |\{c \in F | v_i \text{ satisfies } F\}| \\ &\quad - \sum_{i,j:i\neq j} |\{c \in F | v_i \text{ and } v_j \text{ satisfy } F\}| \\ &= |\{c \in F | a \text{ satisfies } F\}|, \end{aligned}$$

where the last equality follows from the inclusion-exclusion principle.

Notice that the number of nodes in G is $3{\cdot}2^{n/3}$, and the absolute value of any node and edge weight is m. Therefore, running a MAX TRIANGLE algorithm on G, a solution to MAX 2-SAT, is obtained in $O(f(m)\cdot g(3{\cdot}2^{n/3}))$, which is $O(f(m)\cdot g(2^{n/3}))$ since g is a polynomial. This completes the proof of Lemma 1.

Next, a procedure is described for finding a maximum triangle faster than brute-force search, using fast matrix multiplication. Alon, Galil, and Margalit [1] (following Yuval [22]) showed that the distance product for matrices with entries drawn from $\mathbb{Z}[-W,W]$ can be computed using fast matrix multiplication as a subroutine.

Theorem 1 (Alon, Galil, Margalit [1]) *Let A and B be $n \times n$ matrices with entries from $\mathbb{Z}[-W,W] \cup \{\infty\}$. Then $A \circledast B$ can be computed in $O(Wn^{\omega}\log n)$ time.*

Proof (Sketch) One can replace ∞ entries in A and B with $2W+1$ in the following. Define matrices A' and B', where

$$A'[i,j] = x^{3W-A[i,j]},\ B'[i,j] = x^{3W-B[i,j]},$$

and x is a variable. Let $C = A' \times B'$. Then

$$C[i,j] = \sum_{k=1}^{n} x^{6W-A[i,k]-B[k,j]}.$$

The next step is to pick a number x that makes it easy to determine, from the sum of arbitrary powers of x, the largest power of x appearing in the sum; this largest power immediately gives the minimum $A[i,k] + B[k,j]$. Each $C[i,j]$ is a polynomial in x with coefficients from $\mathbb{Z}[0,n]$. Suppose each $C[i,j]$ is evaluated at $x = (n+1)$. Then each entry of $C[i,j]$ can be seen as an $(n+1)$-ary number, and the position of this number's most significant digit gives the minimum $A[i,k] + B[k,j]$.

In summary, $A \otimes_d B$ can be computed by constructing

$$A'[i,j] = (n+1)^{3W - A[i,j]},$$

$$B'[i,j] = (n+1)^{3W - B[i,j]}$$

in $O(W \log n)$ time per entry, computing $C = A' \times B'$ in $O(n^\omega \cdot (W \log n))$ time (as the sizes of the entries are $O(W \log n)$), then extracting the minimum from each entry of C, in $O(n^2 \cdot W \log n)$ time. Note if the minimum for an entry $C[i,j]$ is at least $2W+1$, then $C[i,j] = \infty$.

Using the fast distance product algorithm, one can solve MAX TRIANGLE faster than brute force. The following is based on an algorithm by Itai and Rodeh [10] for detecting if an unweighted graph has a triangle in less than n^3 steps. The result can be generalized to *counting* the number of *k-cliques*, for arbitrary $k \geq 3$. (To keep the presentation simple, the counting result is omitted. Concerning the k-clique result, there is unfortunately no asymptotic runtime benefit from using a k-clique algorithm instead of a triangle algorithm, given the current best algorithms for these problems.)

Theorem 2 MAX TRIANGLE *can be solved in* $O(W n^\omega \log n)$*, for graphs with weights drawn from* $\mathbb{Z}[-W, W]$.

Proof First, it is shown that a weight function on nodes and edges can be converted into an equivalent weight function with weights on only edges. Let w be the weight function of G, and redefine the weights to be:

$$w'(\{u,v\}) = \frac{w(u) + w(v)}{2} + w(\{u,v\}),$$

$$w'(u) = 0.$$

Note the weight of a triangle is unchanged by this reduction.

The next step is to use a fast distance product to find a maximum weight triangle in an edge-weighted graph of n nodes. Construe the vertex set of G as the set $\{1,\ldots,n\}$. Define A to be the $n \times n$ matrix such that $A[i,j] = -w(\{i,j\})$ if there is an edge $\{i,j\}$, and $A[i,j] = \infty$ otherwise. The claim is that there is a triangle through node i of weight at least K if and only if $(A \circledast A \circledast A)[i,i] \leq -K$. This is because $(A \circledast A \circledast A)[i,i] \leq -K$ if and only if there are distinct j and k such that $\{i,j\}, \{j,k\}, \{k,i\}$ are edges and $A[i,j] + A[j,k] + A[k,i] \leq -K$, i.e., $w(\{i,j\}) + w(\{j,k\}) + w(\{k,i\}) \geq K$.

Therefore, by finding an i such that $(A \circledast A \circledast A)[i,i]$ is minimized, one obtains a node i contained in a maximum triangle. To obtain the actual triangle, check all m edges $\{j,k\}$ to see if $\{i,j,k\}$ is a triangle.

Theorem 3 MAX 2-SAT *can be solved in* $O(m \cdot 1.732^n)$ *time.*

Proof Given a set of clauses C, apply the reduction from Lemma 1 to get a graph G with $O(2^{n/3})$ nodes and weights from $\mathbb{Z}[-m,m]$. Apply the algorithm of Theorem 2 to output a max triangle in G in $O(m \cdot 2^{\omega n/3} \log(2^{n/3})) = O(m \cdot 1.732^n)$ time, using the $O(n^{2.376})$ matrix multiplication of Coppersmith and Winograd [4].

Applications

By modifying the graph construction, one can solve other problems in $O(1.732^n)$ time, such as Max Cut, Minimum Bisection, and Sparsest Cut. In general, any constraint optimization problem for which each constraint has at most two variables can be solved faster using the above approach. For more details, see [18] and the survey by Woeginger [21]. Techniques similar to the above algorithm have also been used by Dorn

[6] to speed up dynamic programming for some problems on planar graphs (and in general, graphs of bounded branchwidth).

Open Problems

- Improve the space usage of the above algorithm. Currently, $\Theta(2^{2n/3})$ space is needed. A very interesting open question is if there is a $O(1.99^n)$ time algorithm for MAX 2-SAT that uses only *polynomial* space. This question would have a positive answer if one could find an algorithm for solving the k-CLIQUE problem that uses polylogarithmic space and $n^{k-\delta}$ time for some $\delta > 0$ and $k \geq 3$.
- Find a faster-than-2^n algorithm for MAX 2-SAT that does not require fast matrix multiplication. The fast matrix multiplication algorithms have the unfortunate reputation of being impractical.
- Generalize the above algorithm to work for MAX k-SAT, where k is any positive integer. The current formulation would require one to give an efficient algorithm for finding a small hyperclique in a hypergraph. However, no general results are known for this problem. It is conjectured that for all $k \geq 2$, MAX k-SAT is in $\bar{O}(2^{n(1-\frac{1}{k+1})})$ time, based on the conjecture that matrix multiplication is in $n^{2+o(1)}$ time [17].

Exact Algorithms for Treewidth

Ioan Todinca
INSA Centre Val de Loire, Universite d'Orleans, Orléans, France

Keywords

Extremal combinatorics; Potential maximal cliques; Treewidth

Years and Authors of Summarized Original Work

2008; Fomin, Kratsch, Todinca, Villanger
2012; Bodlaender, Fomin, Koster, Kratsch, Thilikos
2012; Fomin, Villanger

Problem Definition

The *treewidth* parameter intuitively measures whether the graph has a "treelike" structure. Given an undirected graph $G = (V, E)$, a *tree decomposition* of G is a pair $(\mathcal{X}, T)$, where $T = (I, F)$ is a tree and $\mathcal{X} = \{X_i \mid i \in I\}$ is a collection of subsets of V called *bags* satisfying:

1. $\bigcup_{i \in I} X_i = V$,
2. For each edge uv of G, there is a bag X_i containing both endpoints,
3. For all $v \in V$, the set $\{i \in I \mid v \in X_i\}$ induces a connected subtree of T.

The *width* of a tree decomposition $(\mathcal{X}, T)$ is the size of its largest bag, minus one. The *treewidth* of G, denoted by $\mathrm{tw}(G)$, is the minimum width over all possible tree decompositions. One can easily observe that n-vertex graphs have treewidth at most $n - 1$ and that the graphs of treewidth at most one are exactly the forests.

Given a graph G and a number k, the TREEWIDTH problem consists in deciding if $\mathrm{tw}(G) \leq k$. Arnborg, Corneil, and Proskurowski show that the problem is NP-hard [1]. On the positive side, Bodlaender [2] gives an algorithm solving the problem in time $2^{\mathcal{O}(k^3)}n$. Bouchitté and Todinca [4,5] prove that the problem is polynomial on classes of graphs with polynomially many minimal separators, with an algorithm based on the notion of *potential maximal clique*. This latter technique is also employed by several exact, moderately exponential algorithms for TREEWIDTH.

Key Results

TREEWIDTH can be solved in $\mathcal{O}^*(2^n)$ time by adapting the $\mathcal{O}(n^k)$ algorithm of Arnborg et al. [1] or the Held-Karp technique initially designed for the TRAVELING SALESMAN problem [12]. (We use here the $\mathcal{O}^*$ notation that suppresses polynomial factors.) Fomin et al. [9] break this "natural" 2^n barrier with an algorithm running in time $\mathcal{O}^*(1.8135^n)$, using the same space complexity. Bodlaender et al. [3] present a polynomial-space algorithm running in $\mathcal{O}^*(2.9512^n)$ time. A major improvement for both results is due to Fomin and Villanger [8].

Theorem 1 ([8]) *The* TREEWIDTH *problem can be solved in* $\mathcal{O}^*(1.7549^n)$ *time using exponential space and in* $\mathcal{O}^*(2.6151^n)$ *time using polynomial space.*

These algorithms use an alternative definition for treewidth. A graph $H = (V, E)$ is *chordal* or *triangulated* if it has no induced cycle with four

or more vertices. It is well-known that a chordal graph has tree decompositions whose bags are exactly its maximal cliques. Given an arbitrary graph $G = (V, E)$, a chordal graph $H = (V, F)$ on the same vertex set is called a *minimal triangulation* of G if H contains G as a subgraph and no chordal subgraph of H contains G. The treewidth of G can be defined as the minimum clique size of H minus one, over all minimal triangulations H of G.

A vertex subset S of graph G is a *minimal separator* if there are two distinct components $G[C]$ and $G[D]$ of the graph $G[V \setminus S]$ such that $N_G(C) = N_G(D) = S$ ($N_G(C)$ denotes the neighborhood of C in graph G).

A vertex subset Ω of G is a *potential maximal clique* if there exists some minimal triangulation H of G such that Ω induces a maximal clique in H. Potential maximal cliques are characterized as follows [4]: Ω is a potential maximal clique of G if and only if (i) for each pair of vertices $u, v \in \Omega$, u and v are adjacent or see a same component of $G[V \setminus \Omega]$, and (ii) no component of $G[V \setminus \Omega]$ sees the whole set Ω. As an example, when G is a cycle, its minimal separators are exactly the pairs of nonadjacent vertices, and the potential maximal cliques are exactly the triples of vertices.

A *block* is pair (S, C) such that S is a minimal separator of G and $G[C]$ is a component of $G[V \setminus S]$. Denote by $R_G(S, C)$ the graph obtained from $G[S \cup C]$ by turning S into a clique, i.e., by adding all missing edges with both endpoints in S. The treewidth of G can be obtained as follows:

$$\mathrm{tw}(G) = \min_S \left(\max_C \mathrm{tw}(R(S, C)) \right) \quad (1)$$

where the minimum is taken over all minimal separators S and the maximum is taken over all connected components $G[C]$ of $G[V \setminus S]$.

All quantities $\mathrm{tw}(R_G(S, C))$ can be computed by dynamic programming over blocks (S, C), by increasing the size of $S \cup C$. We only consider here blocks (S, C) such that $S = N_G(C)$ (see [4] for more details).

$$\mathrm{tw}(R_G(S, C)) = \min_{S \subset \Omega \subseteq S \cup C} \left(\max_{1 \le i \le p} (|\Omega| - 1, \mathrm{tw}(R_G(S_i, C_i))) \right) \quad (2)$$

where the minimum is taken over all potential maximal cliques Ω with $S \subset \Omega \subseteq S \cup C$ and the maximum is taken over all pairs (S_i, C_i), where $G[C_i]$ is a component of $G[C \setminus \Omega]$ and $S_i = N_G(C_i)$. Let Π_G denote the set of all potential maximal cliques of graph G. It was pointed in [9] that the number of triples (S, Ω, C) like in Eq. 2 is at most $n|\Pi_G|$, which proves that TREEWIDTH can be computed in $\mathcal{O}^*(|\Pi_G|)$ time and space, if Π_G is given in the input.

Therefore, it remains to give a good upper bound for the number $|\Pi_G|$ of potential maximal cliques of G, together with efficient algorithms for listing these objects. Based on the previously mentioned characterization of potential maximal cliques, Kratsch et al. provide an algorithm listing them in time $\mathcal{O}^*(1.8135^n)$. Fomin and Villanger [8] improve this result, thanks to the following combinatorial theorem:

Theorem 2 ([8]) *Let $G = (V, E)$ be an n-vertex graph, let v be a vertex of G, and b, f be two integers. The number of vertex subsets B containing v such that $G[B]$ is connected, $|B| = b + 1$, and $|N_G(B)| = f$ is at most $\binom{b+f}{f}$.*

The elegant inductive proof also leads to an $\mathcal{O}^*(\binom{b+f}{f})$ time algorithm listing all such sets B. Eventually, the potential maximal cliques of an input graph G can be listed in $\mathcal{O}^*(1.7549^n)$ time [8]. This bound was further improved to $\mathcal{O}^*(1.7347^n)$ in [7].

In order to obtain polynomial-space algorithms for TREEWIDTH, Bodlaender et al. [3] provide a relatively simple divide-and-conquer algorithm, based on the Held-Karp approach, running in $\mathcal{O}^*(4^n)$ time. They also observe that Eq. 1 can be used for recursive, polynomial-space algorithms, by replacing the minimal separators S by *balanced* separators, in the sense that each component of $G[V \setminus S]$ contains at most $n/2$ vertices. This leads to polynomial-space algorithm with $\mathcal{O}^*(2.9512^n)$ running time.

Fomin and Villanger [8] restrict the balanced separators to a subset of the potential maximal cliques, and based on Theorem 2 they obtain, still using polynomial space, a running time of $\mathcal{O}^*(2.6151^n)$.

We refer to the book of Fomin and Kratsch [6] for more details on the TREEWIDTH problem and more generally on exact algorithms.

Applications

Exact algorithms based on potential maximal cliques have been extended to many other problems like FEEDBACK VERTEX SET, LONGEST INDUCED PATH, or MAXIMUM INDUCED SUBGRAPH WITH A FORBIDDEN PLANAR MINOR. More generally, for any constant t and any property $\mathcal{P}$ definable in counting monadic second-order logic, consider the problem of finding, in an arbitrary graph G, a maximum-size induced subgraph $G[F]$ of treewidth at most t and with property $\mathcal{P}$. This generic problem can be solved in $\mathcal{O}^*(|\Pi_G|)$ time, if Π_G is part of the input [7, 10]. Therefore, there is an algorithm in $\mathcal{O}^*(1.7347^n)$ time for the problem, significantly improving the $\mathcal{O}^*(2^n)$ time for exhaustive search.

Open Problems

Currently, the best known upper bound on the number of potential maximal cliques in n-vertex graphs is of $\mathcal{O}^*(1.7347^n)$ and does not seem to be tight [7]. Simple examples show that this bound is of at least $3^{n/3} \sim 1.4425^n$. A challenging question is to find a tight upper bound and efficient algorithms enumerating all potential maximal cliques of arbitrary graphs.

Experimental Results

Several experimental results are reported in [3], especially on an "engineered" version of the $\mathcal{O}^*(2^n)$ time and space algorithm based on the Held-Karp approach. This dynamic programming algorithm is compared with the branch and bound approach of Gogate and Dechter [11] on instances of up to 50 vertices. The results are relatively similar. Bodlaender et al. [3] also observe that the polynomial-space algorithms become too slow even for small instances.

Problem Definition

We focus on the following question: how an assumption on the sparsity of an input graph, such as bounded (average) degree, can help in designing exact (exponential-time) algorithms for NP-hard problems. The following classic problems are studied:

Traveling Salesman Problem Find a minimum-length Hamiltonian cycle in an input graph with edge weights.

Chromatic Number Find a minimum number k for which the vertices of an input graph can be colored with k colors such that no two adjacent vertices receive the same color.

Counting Perfect Matchings Find the number of perfect matchings in an input graph.

Key Results

The classic algorithms of Bellman [1] and Held and Karp [10] for traveling salesman problem run in $2^n n^{\mathcal{O}(1)}$ time for n-vertex graphs. Using the inclusion-exclusion principle, the chromatic number of an input graph can be determined within the same running time bound [4]. Finally, as long as counting perfect matchings is concerned, a half-century-old $2^{n/2} n^{\mathcal{O}(1)}$-time algorithm of Ryser for bipartite graphs [12] has only recently been transferred to arbitrary graphs by Björklund [2].

In all three aforementioned cases, it is widely open whether the 2^n or $2^{n/2}$ factor in the running time bound can be improved. In 2008, Björklund, Husfeldt, Kaski, and Koivisto [5,6] observed that such an improvement can be made if we restrict ourselves to bounded degree graphs. Further work of Cygan and Pilipczuk [8] and Golovnev, Kulikov, and Mihajlin [9] extended these results to graphs of bounded average degree.

Bounded Degree Graphs

Traveling Salesman Problem

Let us present the approach of Björklund, Husfeldt, Kaski, and Koivisto on the example of traveling salesman problem. Assume we are given an n-vertex edge-weighted graph G. The classic dynamic programming algorithm picks a root vertex r and then, for every vertex $v \in V(G)$ and every set $X \subseteq V(G)$ containing v and r, computes $T[X, v]$: the minimum possible length of a path in G with vertex set X that starts in r and ends in v. The running time bound $2^n n^{\mathcal{O}(1)}$ is dominated by the number of choices of the set X.

The simple, but crucial, observation is as follows: if a set X satisfies $X \cap N_G[u] = \{u\}$ for some $u \in V(G) \setminus \{r\}$, then the values $T[X, v]$ are essentially useless, as no path starting in r can visit the vertex u without visiting any neighbor of u (here $N_G[u] = N_G(u) \cup \{u\}$ stands for the closed neighborhood of u). Let us call a set $X \subseteq V(G)$ *useful* if $X \cap N_G[u] \neq \{u\}$ for every $u \in V(G) \setminus \{r\}$. The argumentation so far proved that we may skip the computation of $T[X, v]$ for all sets X that are not useful. The natural question is how many different useful sets may exist in an n-vertex graph?

Consider the following greedy procedure: initiate $A = \emptyset$ and, as long as there exists a vertex $u \in V(G)$ such that $N_G[u] \cap N_G[A] = \emptyset$,

add an arbitrarily chosen vertex u to the set A. By construction, the set A satisfies the following property: for every $u_1, u_2 \in A$, we have $N_G[u_1] \cap N_G[u_2] = \emptyset$. An interesting fact is that $|A| = \Omega(n)$ for graphs of bounded degree: whenever we insert a vertex u into the set A, we cannot later insert into A any neighbor of u nor any neighbor of a neighbor of u. However, if the maximum degree of G is bounded by d, then there are at most d neighbors of u, and every such neighbor has at most $d-1$ further neighbors. Consequently, when we insert a vertex u into A, we prohibit at most $d + d(d-1) = d^2$ other vertices from being inserted into A, and $|A| \geq n/(1+d^2)$.

It is easy to adjust the above procedure such that the root vertex r does not belong to A. Observe that for every useful set X and every $u \in A$, we have $X \cap N_G[u] \neq \{u\}$ and, furthermore, the sets $N_G[u]$ for $u \in A$ are pairwise disjoint. We can think of choosing a useful set X as follows: first, for every $u \in A$, we choose the intersection $X \cap N_G[u]$ (there are $2^{|N_G[u]|} - 1$ choices, as the choice $\{u\}$ is forbidden), and, second, we choose the set $X \setminus N_G[A]$. Hence, the number of useful sets is bounded by

$$\begin{aligned}\left(\prod_{u\in A} 2^{|N_G[u]|} - 1\right) \cdot 2^{n-|N_G[A]|} &= 2^n \cdot \prod_{u\in A}\left(1 - 2^{-|N_G[u]|}\right) \leq 2^n \cdot \prod_{u\in A}(1-2^{-d-1}) \\ &= 2^n \cdot (1-2^{-d-1})^{|A|} \leq 2^n \cdot (1-2^{-d-1})^{\frac{n}{1+d^2}} \\ &= \left(2 \cdot \sqrt[1+d^2]{1-2^{-d-1}}\right)^n.\end{aligned}$$

Thus, for every degree bound d, there exists a constant $\varepsilon_d > 0$ such that the number of useful sets in an n-vertex graph of maximum degree d is bounded by $(2-\varepsilon_d)^n$, yielding a $(2-\varepsilon_d)^n n^{\mathcal{O}(1)}$-time algorithm for traveling salesman problem. A better dependency on d in the formula for ε_d can be obtained using a projection theorem of Chung, Frankl, Graham, and Shearer [7] (see [5]).

Chromatic Number

A similar reasoning can be performed for the problem of determining the chromatic number of an input graph. Here, it is useful to rephrase the problem as follows: find a minimum number k such that the vertex set of an input graph can be covered by k maximal independent sets; note that we do not insist that the independent sets are disjoint. Observe that if X is a set of vertices covered by one or more such maximal independent sets, we have $X \cap N_G[u] \neq \emptyset$ for every $u \in V(G)$, as otherwise the vertex u should have been included into one of the covering sets. Hence, we can call a set $X \subseteq V(G)$ *useful* if it intersects every closed neighborhood in G, and we obtain again a $(2-\varepsilon_d)^n$ bound on the number of useful sets. An important contribution of Björklund, Husfeldt, Kaski, and Koivisto [5] can be summarized as follows: using the fact that the useful sets are upward-closed (any superset of a useful set is useful as well), we can trim the fast subset convolution algorithm of [3] to consider useful sets only. Consequently, we obtain a $(2-\varepsilon_d)^n n^{\mathcal{O}(1)}$-time algorithm for computing the chromatic number of an input graph of maximum degree bounded by d.

Bounded Average Degree

Generalizing Algorithms for Bounded Degree Graphs

The above approach for traveling salesman problem has been generalized to graphs of bounded average degree by Cygan and Pilipczuk [8] using the following observation. Assume a graph G has n vertices and average degree bounded by d. Then, a simple Markov-type inequality implies that for every $\zeta > 1$ there are at most n/ζ vertices of degree larger than ζd. However, this bound

cannot be tight for all values of ζ at once, and one can prove the following: if we want at most $n/(\alpha\zeta)$ vertices of degree larger than ζd for some $\alpha > 1$, then we can always find such a constant ζ of order roughly exponential in α.

An appropriate choice of α and the corresponding value of ζ allow us to partition the vertex set of an input graph into a large part of bounded degree and a very small part of unbounded degree. The extra multiplicative gap of α in the size bound allows us to hide the cost of extensive branching on the part with unbounded degree in the gains obtained by considering only (appropriately defined) useful sets in the bounded degree part.

With this line of reasoning, Cygan and Pilipczuk [8] showed that for every degree bound d, there exists a constant $\varepsilon_d > 0$ such that traveling salesman problem in graphs of bounded average degree by d can be solved in $(2 - \varepsilon_d)^n n^{\mathcal{O}(1)}$ time. It should be noted that the constant ε_d depends here doubly exponentially on d, as opposed to single-exponential dependency in the works for bounded degree graphs.

Furthermore, Cygan and Pilipczuk showed how to express the problem of counting perfect matchings in an n-vertex graph as a specific variant of a problem of counting Hamiltonian cycles in an $n/2$-vertex graph. This reduction not only gives a simpler $2^{n/2}n^{\mathcal{O}(1)}$-time algorithm for counting perfect matchings, as compared to the original algorithm of Björklund [2], but since the reduction does not increase the number of edges in a graph, it also provides a $(2 - \varepsilon_d)^{n/2}n^{\mathcal{O}(1)}$-time algorithm in the case of bounded average degree.

In a subsequent work, Golovnev, Kulikov, and Mihajlin [9] showed how to use the aforementioned multiplicative gap of α to obtain a $(2 - \varepsilon_d)^n n^{\mathcal{O}(1)}$-time algorithm for computing the chromatic number of a graph with average degree bounded by d. Furthermore, they expressed all previous algorithms as the task of determining one coefficient in a carefully chosen polynomial, obtaining polynomial space complexity without any significant loss in time complexity.

Counting Perfect Matchings in Bipartite Graphs

A somewhat different line of research concerns counting perfect matchings in bipartite graphs. Here, a $2^{n/2}n^{\mathcal{O}(1)}$-time algorithm is known for several decades [12]. Cygan and Pilipczuk presented a very simple $2^{(1-1/(3.55d))n/2}n^{\mathcal{O}(1)}$-time algorithm for this problem in graphs of average degree at most d, improving upon the previous works of Servedio and Wan [13] and Izumi and Wadayama [11]. Furthermore, this result generalizes to the problem of computing the permanent of a matrix over an arbitrary commutative ring with the number of nonzero entries linear in the dimension of the matrix.

Exact Graph Coloring Using Inclusion-Exclusion

Andreas Björklund and Thore Husfeldt
Department of Computer Science, Lund University, Lund, Sweden

Keywords

Vertex coloring

Years and Authors of Summarized Original Work

2006; Björklund, Husfeldt

Problem Definition

A *k-coloring* of a graph $G = (V, E)$ assigns one of k colors to each vertex such that neighboring vertices have different colors. This is sometimes called *vertex coloring*.

The smallest integer k for which the graph G admits a k-coloring is denoted $\chi(G)$ and called the *chromatic number*. The number of k-colorings of G is denoted $P(G;k)$ and called the *chromatic polynomial*.

Key Results

The central observation is that $\chi(G)$ and $P(G;k)$ can be expressed by an inclusion-exclusion formula whose terms are determined by the number of independent sets of induced subgraphs of G. For $X \subseteq V$, let $s(X)$ denote the number of nonempty independent vertex subsets disjoint from X, and let $s_r(X)$ denote the number of ways to choose r nonempty independent vertex subsets $S_1, \ldots, S_r$ (possibly overlapping and with repetitions), all disjoint from X, such that $|S_1| + \cdots + |S_r| = |V|$.

Theorem 1 ([1]) *Let G be a graph on n vertices.*

1.

$$\chi(G) = \min_{k \in \{1,\ldots,n\}} \left\{ k : \sum_{X \subseteq V} (-1)^{|X|} s(X)^k > 0 \right\}.$$

2. For $k = 1, \ldots, n$,

$$P(G;k) = \sum_{r=1}^{k} \binom{k}{r} \left(\sum_{X \subseteq V} (-1)^{|X|} s_r(X) \right).$$

The time needed to evaluate these expressions is dominated by the 2^n evaluations of $s(X)$ and $s_r(X)$, respectively. These values can be precomputed in time and space within a polynomial factor of 2^n because they satisfy

$$s(X) = \begin{cases} 0, & \text{if } X = V, \\ s(X \cup \{v\}) + s(X \cup \{v\} \cup N(v)) + 1, & \text{for } v \notin X, \end{cases}$$

where $N(v)$ are the neighbors of v in G. Alternatively, the values can be computed using exponential-time, polynomial-space algorithms from the literature.

This leads to the following bounds:

Theorem 2 ([3]) *For a graph G on n vertices, $\chi(G)$ and $P(G;k)$ can be computed in*

1. *Time and space $2^n n^{O(1)}$.*
2. *Time $O(2.2461^n)$ and polynomial space*

The space requirement can be reduced to $O(1.292^n)$ *[4].*

The techniques generalize to arbitrary families of subsets over a universe of size n, provided membership in the family can be decided in polynomial time [3, 4], and to the Tutte polynomial and the Potts model [2].

Applications

In addition to being a fundamental problem in combinatorial optimization, graph coloring also arises in many applications, including register allocation and scheduling.

Exact Quantum Algorithms

Ashley Montanaro
Department of Computer Science, University of Bristol, Bristol, UK

Keywords

Exact algorithms; Quantum algorithms; Quantum query complexity

Years and Authors of Summarized Original Work

2013; Ambainis

Problem Definition

Many of the most important known quantum algorithms operate in the query complexity model. In the simplest variant of this model, the goal is to compute some Boolean function of n input bits by making the minimal number of queries to the bits. All other resources (such as time and space) are considered to be free. In the model of *exact* quantum query complexity, one insists that the algorithm succeeds with certainty on every allowed input. The aim is then to find quantum algorithms which satisfy this constraint and still outperform any possible classical algorithm. This can be a challenging task, as achieving a probability of error equal to zero requires delicate cancellations between the amplitudes in the quantum algorithm. Nevertheless, efficient exact quantum algorithms are now known for certain functions.

Some basic Boolean functions which we will consider below are:

- Parity^n: $f(x_1, \ldots, x_n) = x_1 \oplus x_2 \oplus \cdots \oplus x_n$.
- Threshold^n_k: $f(x_1, \ldots, x_n) = 1$ if $|x| \geq k$, and $f(x) = 0$ otherwise, where $|x| := \sum_i x_i$

is the Hamming weight of x. The special case $k = n/2$ is called the majority function.
- Exact_k^n: $f(x_1, \ldots, x_n) = 1$ if $|x| = k$, and $f(x) = 0$ otherwise.
- NE ("not-all-equal") on 3 bits: $f(x_1, x_2, x_3) = 0$ if $x_1 = x_2 = x_3$, and $f(x_1, x_2, x_3) = 1$ otherwise.

Key Results

Early Results

One of the earliest results in quantum computation was that the parity of 2 bits can be computed with certainty using only 1 quantum query [6], implying that Parity^n can be computed using $\lceil n/2 \rceil$ quantum queries. By contrast, any classical algorithm which computes this function must make n queries. The quantum algorithm for Parity^n can be used as a subroutine to obtain speedups over classical computation for other problems. For example, based on this algorithm the majority function on n bits can be computed exactly using $n + 1 - w(n)$ quantum queries, where $w(n)$ is the number of 1s in the binary expansion of n [8]; this result has recently been improved (see below).

If the function to be computed is partial, i.e., some possible inputs are disallowed, the separation between exact quantum and classical query complexity can be exponential. For example, in the Deutsch-Jozsa problem we are given query access to an n-bit string x (with n even) such that either all the bits of x are equal or exactly half of them are equal to 1. Our task is to determine which is the case. Any exact classical algorithm must make at least $n/2 + 1$ queries to bits of x to solve this problem, but it can be solved with only one quantum query [7]. An exponential separation is even known between exact quantum and *bounded-error* classical query complexity for a different partial function [5].

Recent Developments

For some years, the best known separation between exact quantum and classical query complexity of a total Boolean function (i.e., a function $f : \{0,1\}^n \to \{0,1\}$ with all possible n-bit strings allowed as input) was the factor of 2 discussed above. However, recently the first example has been presented of an exact quantum algorithm for a family of total Boolean functions which achieves a lower asymptotic query complexity than the best possible classical algorithm [1].

The family of functions used can be summarized as a "not-all-equal tree of depth d." It is based around the recursive use of the NE function. Define the function $\text{NE}^0(x_1) = x_1$ and then for $d > 0$

$$\text{NE}^d(x_1, \ldots, x_{3^d}) = \text{NE}(\text{NE}^{d-1}(x_1, \ldots, x_{3^{d-1}}), \text{NE}^{d-1}(x_{3^{d-1}+1}, \ldots, x_{2\cdot 3^{d-1}}), \text{NE}^{d-1}(x_{2\cdot 3^{d-1}+1}, \ldots, x_{3^d})).$$

Then the following separation is known:

Theorem 1 (Ambainis [1]) *There is an exact quantum algorithm which computes* NE^d *using* $O(2.593\ldots^d)$ *queries. Any classical algorithm which computes* NE^d *must make* $\Omega(3^d)$ *queries, even if it is allowed probability of failure* $1/3$.

In addition, Theorem 1 implies the first known asymptotic separation between exact quantum and classical communication complexity for a total function. Improvements over the best possible classical algorithms are also known for the other basic Boolean functions previously mentioned.

Theorem 2 (Ambainis, Iraids, and Smotrovs [2]) *There is an exact quantum algorithm which computes* Exact_k^n *using* $\max\{k, n-k\}$ *queries and an exact quantum algorithm which computes* Threshold_k^n *using* $\max\{k, n-k+1\}$ *queries. Both of these complexities are optimal.*

By contrast, it is easy to see that any exact classical algorithm for these functions must make

n queries. An optimal exact quantum algorithm for the special case Exact_2^4 had already been found prior to this, in work which also gave optimal exact quantum query algorithms for all Boolean functions on up to 3 bits [9].

Methods

We briefly describe the main ingredients of the efficient quantum algorithm for NE^d [1]. The basic idea is to fix some small d_0, start with an exact quantum algorithm which computes NE^{d_0} using fewer queries than the best possible classical algorithm, and then amplify the separation by using the algorithm recursively. A difficulty with this approach is that the standard approach for using a quantum algorithm recursively incurs a factor of 2 penalty in the number of queries with each recursive call. This factor of 2 is required to "uncompute" information left over after the algorithm has completed. Therefore, a query complexity separation by a factor of 2 or less does not immediately give an asymptotic separation.

This problem can be addressed by introducing the notion of p-computation. Let $p \in [-1, 1]$. A quantum algorithm $\mathcal{A}$ is said to p-compute a function $f(x_1, \ldots, x_n)$ if, for some state $|\psi_{\text{start}}\rangle$:

- Whenever $f(x_1, \ldots, x_n) = 0$, $\mathcal{A}|\psi_{\text{start}}\rangle = |\psi_{\text{start}}\rangle$.
- Whenever $f(x_1, \ldots, x_n) = 1$, $\mathcal{A}|\psi_{\text{start}}\rangle = p|\psi_{\text{start}}\rangle + \sqrt{1-p^2}|\psi\rangle$ for some $|\psi\rangle$, which may depend on x, such that $\langle\psi|\psi_{\text{start}}\rangle = 0$.

It can be shown that if there exists an algorithm which p-computes some function f for some $p \leq 0$, there exists an exact quantum algorithm which computes f using the same number of queries. Further, if an algorithm (-1)-computes some function f, the same algorithm can immediately be used recursively, without needing any additional queries at each level of recursion. Thus, to obtain an asymptotic quantum-classical separation for NE^d, it suffices to obtain an algorithm which (-1)-computes NE^{d_0} using strictly fewer than 3^{d_0} queries, for some d_0.

The NE^d problem also behaves particularly well with respect to p-computation for general values of p:

Lemma 1 *If there is an algorithm $\mathcal{A}$ which p-computes NE^{d-1} using k queries, there is an algorithm $\mathcal{A}'$ which p'-computes NE^d with $2k$ queries, for $p' = 1 - 4(1-p)^2/9$.*

This lemma allows algorithms for NE^{d-1} to be lifted to algorithms for NE^d, at the expense of making the value of p worse. Nevertheless, given that it is easy to write down an algorithm which (-1)-computes NE^0 using one query, the lemma is sufficient to obtain an exact quantum algorithm for NE^2 using 4 queries. This is already enough to prove an asymptotic quantum-classical separation, but this separation can be improved using the following lemma (a corollary of a variant of amplitude amplification):

Lemma 2 *If there is an algorithm $\mathcal{A}$ which p-computes NE^d using k queries, there is an algorithm $\mathcal{A}'$ which p'-computes NE^d with $2k$ queries, for $p' = 2p^2 - 1$.*

Interleaving Lemmas 1 and 2 allows one to derive an algorithm which (-1)-computes NE^8 using 2,048 queries, which implies an exact quantum algorithm for NE^d using $O(2{,}048^{d/8}) = O(2.593\ldots^d)$ queries.

Experimental Results

It is a difficult task to design exact quantum query algorithms, even for small functions, as these algorithms require precise cancellations between amplitudes. One way to gain numerical evidence for what the exact quantum query complexity of a function should be is to use the formulation of quantum query complexity as a semidefinite programming (SDP) problem [4]. This allows one to estimate the optimal success probability of any quantum algorithm using a given number of queries to compute a given function. If this success probability is very close to 1, this gives numerical evidence that there exists an exact quantum algorithm using that number of queries.

This approach has been applied for all Boolean functions on up to 4 bits, giving strong evidence that the only function on 4 bits which requires 4 quantum queries is the AND function and functions equivalent to it [9]. This has led to the conjecture that, for any n, the only function on n bits which requires n quantum queries to be computed exactly is the AND function and functions equivalent to it. This would be an interesting contrast with the classical case where most functions on n bits require n queries. This conjecture has recently been proven for various special cases: symmetric functions, monotone functions, and functions with formula size n [3].

Problem Definition

From the earliest works on tile self-assembly, abstract theoretical models and experimental implementations have been linked. In 1998, in addition to developing the abstract and kinetic Tile Assembly Models (aTAM and kTAM) [14], Winfree et al. demonstrated the use of DNA tiles to construct a simple, periodic lattice [16]. Periodic lattices and "uniquely addressed" assemblies, where each tile type appears once in each assembly, have been widely studied, with systems employing up to a thousand unique tiles in three dimensions [8, 13]. While these systems provide insight into the behavior of DNA tile systems, *algorithmic* tile systems of more theoretical interest

pose specific challenges for experimental implementation.

In the aTAM, abstract tiles attach individually to empty lattice sites if bonds of a sufficient total strength b (at least abstract "temperature" τ) can be made, and once attached, never detach. Experimentally, free tiles and assemblies of bound tiles are in solution. Tiles have short single-stranded "sticky ends" regions that form bonds with complementary regions on other tiles. Tiles attach to assemblies at rates dependent only upon their concentrations, regardless of the strength of bonds that can be made. Once attached, tiles can detach and do so at a rate that is exponentially dependent upon the total strength of the bonds [6]. Thus, for a tile t_i with concentration $[t_i]$ binding by a total abstract bond strength b, we have attachment and detachment rates of

$$r_f = k_f[t_i] \qquad r_b = k_f e^{-b\Delta G^\circ_{se}/RT+\alpha} \tag{1}$$

where k_f is an experimentally determined rate constant, α is a constant binding free energy change (e.g., from entropic considerations), ΔG°_{se} is the free energy change of a single-strength bond, and T is the (physical) temperature. Using the substitutions $[t_i] = e^{-G_{mc}+\alpha}$, $G_{se} = -\Delta G^\circ_{se}/RT$, and $\hat{k}_f = k_f e^{\alpha}$, these can be simplified to

$$r_f = \hat{k}_f e^{-G_{mc}} \qquad r_b = \hat{k}_f e^{-bG_{se}} \tag{2}$$

where G_{se} is a (positive) unitless free energy for a single-strength bond (larger values correspond to stronger bonds), G_{mc} is a free energy analogue of concentration (larger values correspond to lower concentrations), and $\hat{k}_f$ is an adjusted rate constant.

These rates are the basis of the kinetic Tile Assembly Model (kTAM), which is widely used as a physical model of tile assembly [14]. Tiles that attach faster than they detach will tend to remain attached and allow further growth: for example, if $G_{mc} < 2G_{se}$, tile attachments by $b \geq 2$ will be favorable. Tiles that detach faster than they attach will tend to remain detached and not allow further growth. Since G_{mc} is dependent upon tile concentration, and G_{se} is dependent upon physical temperature (lower temperatures result in larger G_{se} values), the attachment and detachment rates can be tuned such that attachment is slightly more favorable than detachment for tiles attaching by a certain total bond strength and less favorable for less strongly bound tiles. In this way, in the limit of low concentrations and slow growth, the kTAM approximates the aTAM at a given abstract temperature τ. When moving away from this limit and toward experimentally feasible conditions, however, the kTAM provides insight into many of the challenges faced in experimental implementation of algorithmic tile assembly:

Growth errors: While tile assembly in the aTAM is error-free, tiles can attach in erroneous locations in experiments. Even ignoring the possibility of lattice defects, malformed tiles, and other experimental peculiarities, errors can arise in the kTAM via tiles that attach by less than the required bond strength (e.g., one single-strength bond for a $\tau = 2$ system) and are then "frozen" in place by further attachments [4]. As the further growth of algorithmic systems depends on the tiles already present in an assembly, a single erroneously incorporated tile can propagate undesired growth via further, valid attachments. These errors can arise both in growth sites where another tile could attach correctly ("growth errors") and lattice sites where no correct tile could attach ("facet nucleation errors") [3, 14].

Seeding: Tile assembly in the aTAM is usually initiated from a designated "seed" tile. In solution, however, tiles are free to attach to all other tiles and can form assemblies without starting from a seed, even if this requires several unfavorable attachments to form a stable structure that can allow further growth. Depending upon the tile system, these "spuriously nucleated" structures can potentially form easily. For example, a $T = 2$ system with boundaries of identical tiles that attach by double bonds on both sides can readily form long strings of boundary tiles [10, 11].

Tile depletion: As free tiles in solution are incorporated into assemblies, their concentrations are

correspondingly reduced. This depletion lowers the attachment rates for those tiles and in turn changes the favorability of growth. If different tile types are incorporated in different quantities, their attachment rates will become unequal, and at some point in assembly, attachment by two single-strength bonds may be favorable for one tile type and unfavorable for another.

Tile design: While theoretical constructions may employ an arbitrary number of sticky ends types, this number is limited by tile designs in practice. Most tiles use short single-stranded DNA regions of 5–10 nucleotides (nt), limiting the number of possible sticky ends to 4^5–4^{10} at best. However, since partial bonds can form between subsequences of the sticky ends, sequences with sufficient orthogonality are required, and since DNA binding strength is sequence dependent, sequences with similar binding energies are required [5]. Both of these effects place considerably more stringent limits on the number of sticky ends and change the behavior of experimental systems.

Key Results

Winfree and Bekbolatov developed a tileset transformation, "uniform proofreading," that reduced per-site *growth* error rates from $r_{\text{err}} \approx me^{-G_{se}}$ (where m is the number of possible errors) to $\approx me^{-KG_{se}}$ by scaling each tile into a $K \times K$ block of individually attaching tiles with unique internal bonds [15]. However, this transformation did not reduce facet nucleation errors. Chen and Goel later created a modified transformation, "snaked proofreading," that reduced both growth and facet nucleation errors by changing the strengths of the internal bonds used [3]. These and other proofreading methods have the potential to drastically reduce error rates in experimental systems.

Schulman et al. analyzed tile system nucleation through the consideration of "critical nuclei," tile assemblies where melting and further growth are equally favorable, and showed that by ensuring a sufficient number of unfavorable attachments would be required for a critical nucleus to form, the rate of spurious nucleation can be kept arbitrarily low [11]. Using this analysis, Schulman et al. constructed the "zigzag" ribbon system, which forms a ribbon where each row must assemble completely before the next can begin growth, as an example of a system where spurious nucleation can be made arbitrarily low by increasing ribbon width. To nucleate desired structures, this system makes use of a large, preformed seed structure to allow the growth of the first ribbon row.

Schulman et al. also devised a "constant-temperature" growth technique where the concentrations of assemblies, controlled by the concentration of initial seeds in a nucleation-controlled system, are kept small enough in comparison to the concentrations of free tiles that growth does not significantly deplete tile concentrations, which thus remain approximately constant [12]. After growth is completed, the remaining free tiles are "deactivated" by adding an excess of DNA strands complementary to specific sticky ends sequences.

In analyzing the effects of DNA sequences on tile assembly, Evans and Winfree showed an exponential increase of error rates in the kTAM for partial binding between different sticky ends sequences and for differing sequence-dependent binding energies and developed algorithms for sequence design and assignment to reduce these effects [5]. With reasonable design constraints, their algorithms suggested limits of around 80 sticky ends types for tiles using 5 nt sticky ends and around 360 for tiles using 10 nt sticky ends before significant sequence effects begin to become unavoidable and must be incorporated into tile system design.

Experimental Results

While numerous designs exist for tile structures, experimental implementations have usually used either double-crossover (DX) tiles with 5 or 6 nt sticky ends [16] or single-stranded tiles (SST) with 10 and 11 nt sticky ends [17]. SSTs potentially offer a significantly larger sequence

space and have been employed in large, non-algorithmic systems [8, 13] but have not yet been used for complex algorithmic systems.

Early experiments in algorithmic tile assembly using DX tiles did not employ any of the key results discussed above. Rothemund et al. implemented a simple XOR system of four logical tiles (eight tiles were needed owing to structural considerations), using DNA hairpins on "one-valued" tiles as labels [9] and flexible, one-dimensional seeds (Fig. 1a,b). While assemblies grew, and Sierpinski triangle patterns were visible, error rates were between 1 and 10 % per tile. Barish et al. implemented more complex bit-copying and binary counting systems in a similar way, finding per-tile error rates of around 10 % [1].

More recently, Fujibayashi et al. used rigid DNA origami structures to serve as seeds for the growth of a fixed-width XOR ribbon system and, in doing so, reduced error rates to 1.4 % per tile without incorporating proofreading [7] (Fig. 1c). This seeding mechanism was also used by Barish et al. to seed zigzag bit-copying and binary counting ribbon systems that implemented 2×2 uniform proofreading [2]. With nucleation control and proofreading, these systems resulted in dramatically reduced error rates of 0.26 % per proofreading block for copying and 4.1 % for the more algorithmically complex binary counting, which only partially implemented uniform proofreading (Fig. 1d).

A similar bit-copying ribbon was later implemented by Schulman et al., with the

addition of the constant-temperature, constant-concentration growth method and the use of biotin-streptavidin labels rather than DNA hairpins. The result was a decrease in error rates by almost a factor of ten to 0.034 % per block [12] (Fig. 1e). At this error rate, structures of around 2,500 error-free blocks, or 10,000 individual tiles, could be grown with reasonable yields, suggesting that with the incorporation of proofreading, nucleation control and constant-concentration growth methods, low-error experimental implementations of increasingly complex algorithmic tile systems may be feasible up to sequence space limitations.

Years and Authors of Summarized Original Work

2001; McGeoch

Problem Definition

Experimental analysis of algorithms describes not a specific algorithmic problem, but rather an approach to algorithm design and analysis. It complements, and forms a bridge between, traditional *theoretical analysis*, and the application-driven methodology used in *empirical analysis*.

The traditional theoretical approach to algorithm analysis defines algorithm efficiency in terms of counts of dominant operations, under some abstract model of computation such as a RAM; the input model is typically either worst-case or average-case. Theoretical results are usually expressed in terms of asymptotic bounds on the function relating input size to number of dominant operations performed.

This contrasts with the tradition of empirical analysis that has developed primarily in fields such as operations research, scientific computing, and artificial intelligence. In this tradition, the efficiency of implemented programs is typically evaluated according to CPU or wall-clock times; inputs are drawn from real-world applications or collections of benchmark test sets, and experimental results are usually expressed in comparative terms using tables and charts.

Experimental analysis of algorithms spans these two approaches by combining the sensibilities of the theoretician with the tools of the empiricist. Algorithm and program performance can be measured experimentally according to a wide variety of *performance indicators*, including the dominant cost traditional to theory, bottleneck operations that tend to dominate running time, data structure updates, instruction counts, and memory access costs. A researcher in experimental analysis selects performance indicators most appropriate to the scale and scope of the specific research question at hand. (Of course time is not the only metric of interest in algorithm studies; this approach can be used to analyze other properties such as solution quality or space use.)

Input instances for experimental algorithm analysis may be randomly generated or derived from application instances. In either case, they typically are described in terms of a small- to medium-sized collection of *controlled parameters*. A primary goal of experimentation is to investigate the cause-and-effect relationship between input parameters and algorithm/program performance indicators.

Research goals of experimental algorithmics may include discovering functions (not necessarily asymptotic) that describe the relationship between input and performance, assessing the strengths and weaknesses of different algorithm/data structures/programming strategies, and finding best algorithmic strategies for different input categories. Results are typically presented and illustrated with graphs showing comparisons and trends discovered in the data.

The two terms "empirical" and "experimental", are often used interchangeably in the literature. Sometimes the terms "old style" and "new style" are used to describe, respectively, the empirical and experimental approaches to this type of research. The related term "algorithm engineering" refers to a systematic design process that takes an abstract algorithm all the way to an implemented program, with an emphasis on program efficiency. Experimental and empirical analysis is often used to guide the algorithm engineering process. The general term *algorithmics* can refer to both design and analysis in algorithm research.

Key Results

None

Applications

Experimental analysis of algorithms has been used to investigate research problems originating in theoretical computer science. One example arises in the average-case analysis of algorithms for the One-Dimensional Bin Packing problem. Experimental analyses have led to new theorems about the performance of the optimal algorithm; new asymptotic bounds on average-case performance of approximation algorithms; extensions

of theoretical results to new models of inputs; and to new algorithms with tighter approximation guarantees. Another example is the experimental discovery of a type of phase-transition behavior for random instances of the 3CNF-Satisfiabilty problem, which has led to new ways to characterize the difficulty of problem instances.

A second application of experimental algorithmics is to find more realistic models of computation, and to design new algorithms that perform better on these models. One example is found in the development of new memory-based models of computation that give more accurate time predictions than traditional unit-cost models. Using these models, researchers have found new cache-efficient and I/O-efficient algorithms that exploit properties of the memory hierarchy to achieve significant reductions in running time.

Experimental analysis is also used to design and select algorithms that work best in practice, algorithms that work best on specific categories of inputs, and algorithms that are most robust with respect to bad inputs.

Data Sets

Many repositories for data sets and instance generators to support experimental research are available on the Internet. They are usually organized according to specific combinatorial problems or classes of problems.

URL to Code

Many code repositories to support experimental research are available on the Internet. They are usually organized according to specific combinatorial problems or classes of problems. Skiena's *Stony Brook Algorithm Repository* (www.cs.sunysb.edu/~algorith/) provides a comprehensive collection of problem definitions and algorithm descriptions, with numerous links to implemented algorithms.

Problem Definition

Given a propositional formula in conjunctive normal form, such as $(x \vee y) \wedge (\bar{x} \vee \bar{y} \vee z) \wedge (\bar{z})$, one wants to find an assignment of truth values to the variables that makes the formula evaluate to true. Here, $[x \mapsto 1, y \mapsto 0, z \mapsto 0]$ does the job. We call such formulas *CNF formulas* and such assignments *satisfying assignments*. SAT is the problem of deciding whether a given CNF formula is satisfiable. If every clause (such as $(\bar{x} \vee \bar{y} \vee z)$ above) has at most k literals, we call this a k-CNF formula. The above example is a 3-CNF formula. The problem of deciding whether a given k-CNF formula is satisfiable is called k-SAT. This is one of the most fundamental NP-complete problems.

Several clever algorithms have been developed for k-SAT. In this note we are mostly concerned with the PPSZ algorithm [3]. This is itself an improved version of the older PPZ algorithm [4]. Another prominent SAT algorithm is Schöning's random walk algorithm [6], which is slower than PPSZ, but has the benefit that it can be turned into a deterministic algorithm [5].

Given that we currently cannot prove P $\neq$ NP, all super-polynomial lower bounds on the running time of k-SAT algorithms must be either conditional, that is, rest on widely believed but yet unproven assumptions, or must be for a particular family of algorithms. In this note we sketch exponential lower bounds for the PPSZ algorithm, which is the currently fastest algorithm for k-SAT. We measure the running time of a SAT algorithm in terms of n, the number of variables. Often probabilistic algorithms for k-SAT (like PPSZ) have polynomial running time and success probability p^n for some $p < 1$. One can turn this into a Monte Carlo algorithm with success probability at least $1/2$ by repeating it $(1/p)^n$ times. We prefer the formulation of PPSZ as having polynomial running time, and we are interested in the worst-case success probability p^n.

Key Results

The worst-case behavior of PPSZ is exponential. That is, there are satisfiable k-CNF formulas on n variables, for which PPSZ finds a satisfying assignment with probability at most $2^{-\Omega(n)}$. More precisely, there is a constant C and a sequence $\epsilon_k \leq \frac{C \log^2 k}{k}$ such that the worst-case success probability of PPSZ for k-SAT is at most $2^{-(1-\epsilon_k)n}$. See Theorem 3 below for a formal statement.

The PPSZ Algorithm

The PPSZ algorithm, named after its inventors Paturi, Pudlák, Saks, and Zane [3], is the fastest

known algorithm for k-SAT. We now give a brief description of it: Choose a random ordering σ of the n variables $x_1, \ldots, x_n$ of F. Choose random truth values $b = (b_1, \ldots, b_n) \in \{0,1\}$. Iterate through the variables in the ordering given by σ. When processing x_i check whether it is "obvious" what the correct value of x_i should be. If so, fix x_i to that value. Otherwise, fix x_i to b_i. By fixing we mean replacing each occurrence of x_i in F by that value (and each occurrence of $\bar{x}_i$ by the negation of that value). After all variables have been processed, the algorithm returns the satisfying assignment it has found or returns `failure` if it has run into a contradiction.

It remains to specify what "obvious" means: Given a CNF formula F and a variable x_i, we say that the correct value of x_i is *obviously* b if the statement $x_i = b$ can be derived from F by width-w resolution, where w is some large constant (think of $w = 1{,}000$). This can be checked in time $O(n^w)$, which is polynomial.

Let $\mathrm{ppsz}(F, \sigma, b)$ be the return value of ppsz. That is, $\mathrm{ppsz}(F, \sigma, b) \in \mathrm{sat}(F) \cup \{\texttt{failure}\}$, where $\mathrm{sat}(F)$ is the set of satisfying assignments of F.

A Very Brief Sketch of the Analysis of PPSZ

Let σ be a permutation of $x_1, \ldots, x_n$ and let $b = (b_1, \ldots, b_n) \in \{0,1\}^n$. Suppose we run PPSZ on F using this permutation σ and the truth values b. For $1 \le i \le n$, define Z_i to be 1 if PPSZ did not find it obvious what the correct value of x_i should be. Let $Z = Z_1 + \cdots + Z_n$. To underline the dependence on F, σ, and b, we sometimes write $Z(F, \sigma, b)$. It is not difficult to show the following lemma.

Lemma 1 ([3]) *Let F be a satisfiable CNF formula over n variables. Let σ be a random permutation of its variables and let $a \in \{0,1\}^n$ be satisfying assignment of F. Then*

$$\Pr_{\sigma,b}[\mathrm{ppsz}(F, \sigma, b) = a] = \mathbb{E}_\sigma[2^{-Z(F,\sigma,a)}] \quad (1)$$

Since $x \mapsto 2^x$ is a convex function, Jensen's inequality implies that $\mathbb{E}_\sigma[2^{-Z}] \ge 2^{-\mathbb{E}[Z]}$, and by linearity of expectation, it holds that $\mathbb{E}[Z] = \sum_{i=1}^n \mathbb{E}[Z_i]$.

Lemma 2 ([3]) *There are numbers $c_k \in [0,1]$ such that the following holds: If F is a k-CNF formula over n variables with a unique satisfying assignment a, then $\mathbb{E}_\sigma[Z_i(F, \sigma, a)] \le c_k$ for all $1 \le i \le n$. Furthermore, for large k we have $c_k \approx 1 - \frac{\pi^2}{6k}$, and in particular $c_3 = 2\ln(2) - 1 \approx 0.38$.*

Combining everything, Paturi, Pudlák, Saks, and Zane obtain their main result:

Theorem 1 ([3]) *Let F be a k-CNF formula with a unique satisfying assignment a. Then PPSZ finds this satisfying assignment with probability at least $2^{-c_k n}$.*

It takes a considerable additional effort to show that the same bound holds also if F has multiple satisfying assignments:

Theorem 2 ([2]) *Let F be a satisfiable k-CNF formula. Then PPSZ finds a satisfying assignment with probability at least $2^{-c_k n}$.*

We sketch the intuition behind the proof of Lemma 2. It turns out that in the worst case the event $Z_i = 1$ can be described by the following random experiment: Let $T = (V, E)$ be the infinite rooted $(k-1)$-ary tree. For each node $v \in V$ choose $\tau(v) \in [0,1]$ randomly and independently. Call a node v *alive* if $\tau(v) \ge \tau(\mathrm{root})$. Then $\Pr[Z_i = 1]$ is (roughly) equal to the probability that T contains an infinite path of alive vertices, starting with the root. Call this probability c_k. A simple calculation shows that $c_3 = 2\ln(2) - 1$. For larger values of c_k, there is not necessarily a closed form, but Paturi, Pudlák, Saks, and Zane show that $c_k \approx 1 - \frac{\pi^2}{6k}$ for large k.

Hard Instances for the PPSZ Algorithm

One can construct instances on which the success probability of PPSZ is exponentially small. The construction is probabilistic and rather simple. Its analysis is quite technical, so we can only sketch it here. We start with some easy estimates. By Lemma 1 we can write the success probability of PPSZ as

$$\Pr_{\sigma,b}[\mathrm{ppsz}(F,\sigma,b) \in \mathrm{sat}(F)] = \sum_{a \in \mathrm{sat}(F)} \mathbb{E}_\sigma[2^{-Z(F,\sigma,a)}]. \quad (2)$$

Above we used Jensen's inequality to prove $\mathbb{E}[2^{-Z}] \geq 2^{-\mathbb{E}[Z]}$. In this section we want to construct *hard instances*, that is, instances on which the success probability (2) is exponentially small. Thus, we cannot use Jensen's inequality, as it gives a lower bound, not an upper. Instead, we use the following trivial estimate:

$$\sum_{a \in \mathrm{sat}(F)} \mathbb{E}_\sigma[2^{-Z(F,\sigma,a)}] \leq \sum_{a \in \mathrm{sat}(F)} \max_\sigma 2^{-Z(F,\sigma,a)} \leq |\mathrm{sat}(F)| \cdot \max_{a \in \mathrm{sat}(F),\sigma} 2^{-Z(F,\sigma,a)}. \quad (3)$$

We would like to construct a satisfiable k-CNF formula F for which (i) $|\mathrm{sat}(F)|$ is small, i.e., F has few satisfying assignments, and (ii) $Z(F,\sigma,a)$ is large for every permutation and every satisfying assignment a. It turns out there are formulas satisfying both requirements:

Theorem 3 *There are numbers ϵ_k converging to 0 such that the following holds: For every k, there is a family $(F_n)_{n\geq 1}$, where each F_n is a satisfiable k-CNF formula over n variables such that*

1. $|\mathrm{sat}(F_n)| \leq 2^{\epsilon_k n}$.
2. $Z(F,\sigma,a) \geq (1-\epsilon_k)n$ *for all* σ *and all* $a \in \mathrm{sat}(F_n)$.

Thus, the probability of PPSZ finding a satisfying assignment of F_n is at most $2^{-(1-2\epsilon_k)n}$. Furthermore, $\epsilon_k \leq \frac{C\log^2(k)}{k}$ for some universal constant C.

This theorem shows that PPSZ has exponentially small success probability. Also, it shows that the *strong exponential time hypothesis* (SETH) holds for PPSZ: As k grows, the advantage over the trivial success probability 2^{-n} becomes negligible.

The Probabilistic Construction

Let $A \in \mathbb{F}_2^{n\times n}$. The system $Ax = 0$ defines a Boolean function $f_A : \{0,1\}^n \to \{0,1\}$ as follows: $f_A(x) = 1$ if and only if $A \cdot x = 0$. Say A is *k-sparse* if every row of A has at most k nonzero entries. If A is k-sparse, then f_A can be written as a k-CNF formula with n variables and $2^{k-1}n$ clauses. Our construction will be probabilistic. For this, we define a distribution over k-sparse matrices in $\mathbb{F}_2^{n\times n}$. Our distribution will have the form $\mathcal{D}^n$, where $\mathcal{D}$ is a distribution over row vectors from $\mathbb{F}_2^n$. That is, we sample each row of A independently from $\mathcal{D}$. Let us describe $\mathcal{D}$. Define $\mathbf{e}_i \in \mathbb{F}_2^n$ to be the vector with a 1 at the i^{th} position and 0 elsewhere. Sample $i_1,\ldots,i_k \in \{1,\ldots,n\}$ uniformly and independently and let $X = \mathbf{e}_{i_1} + \cdots + \mathbf{e}_{i_k}$. Clearly, $X \in \mathbb{F}_2^n$ has at most k nonzero entries. This is our distribution $\mathcal{D}$.

Let A be a random matrix sampled as described, and write f_A as a k-CNF formula F. Note that $\mathrm{sat}(F) = \ker A$. The challenge is to show that F satisfies the two conditions of Theorem 3.

Lemma 3 (A has high rank) *With probability $1-o(1)$, $|\ker(A)| \leq 2^{\epsilon_k n}$.*

This shows that F satisfies the first condition of the theorem, i.e., it has few satisfying assignments. Lemma 3 is quite straightforward to prove, though not trivial. The next lemma shows that $Z(F,\sigma,a)$ is large.

Lemma 4 *With probability $1-o(1)$, it holds that $Z(F,\sigma,a) \geq (1-\epsilon_k)n$ for all permutations σ and all $a \in \mathrm{sat}(F)$.*

Proving this lemma is the main technical challenge. The proof uses ideas from proof complexity (indeed, the above construction is inspired by constructions in proof complexity).

Open Problems

Suppose the true worst-case success probability of PPSZ on k-CNF formulas is $2^{-r_k n}$. Paturi, Pudlák, Saks, and Zane have proved that $r_k \leq 1 - \Omega(1k)$. Chen, Scheder, Talebanfard, and

Tang showed that $r_k \geq 1 - O\left(\frac{\log^2 k}{k}\right)$. Can one close this gap by construction harder instances or maybe even improve the analysis of PPSZ?

What is the average-case success probability of PPSZ on F when we sample A from $\mathcal{D}^n$? Note that F is exponentially hard with probability $1 - o(1)$, but this might leave a $1/n$ probability that F is very easy for PPSZ.

The construction of [1] is probabilistic. Can one make it explicit? The proof of Lemma 4 uses (implicit in [1]) a nonstandard notion of expansion. We do not know of explicit construction of those expanders.

Problem Definition

Notations The main properties of magnetic disks and multiple disk systems can be captured by the commonly used *parallel disk model* (PDM), which is summarized below in its current form as developed by Vitter and Shriver [22]:

N = problem size (in units of data items);

M = internal memory size(inunitsofdata items);

B = block transfer size (in units of data items);

D = number of independent disk drives;

P = number of CPUs,

where $M < N$, and $1 \leq DB \leq M/2$. The data items are assumed to be of fixed length. In a single I/O, each of the D disks can simultaneously transfer a block of B contiguous data items. (In the original 1988 article [2], the D blocks per I/O were allowed to come from the same disk, which is not realistic.) If $P \leq D$, each of the P processors can drive about D/P disks; if $D < P$, each disk is shared by about P/D processors. The internal memory size is M/P per processor, and the P processors are connected by an interconnection network.

It is convenient to refer to some of the above PDM parameters in units of disk blocks rather than in units of data items; the resulting formulas are often simplified. We define the lowercase notation

$$n = \frac{N}{B}, \quad m = \frac{M}{B}, \quad q = \frac{Q}{B}, \quad z = \frac{Z}{B} \tag{1}$$

to be the problem input size, internal memory size, query specification size, and query output size, respectively, in units of disk blocks.

The primary measures of performance in PDM are:

1. The number of I/O operations performed
2. The amount of disk space used
3. The internal (sequential or parallel) computation time

For reasons of brevity in this survey, focus is restricted onto only the first two measures. Most of the algorithms run in $O(N \log N)$ CPU time with one processor, which is optimal in the comparison model, and in many cases are optimal for parallel CPUs. In the word-based RAM model, sorting can be done more quickly in $O(N \log \log N)$ CPU time. Arge and Thorup [5] provide sorting algorithms that are theoretically optimal in terms of both I/Os and time in the word-based RAM model. In terms of auxiliary storage in external memory, algorithms and data structures should ideally use linear space, which means $O(N/B) = O(n)$ disk blocks of storage. Vitter [20] gives further details about the PDM model and provides optimal algorithms and data structures for a variety of problems. The content of this chapter comes largely from an abbreviated form of [19].

Problem 1 External sorting
INPUT: The input data records $R_0, R_1, R_2, \ldots$ are initially "striped" across the D disks, in units of blocks, so that record R_i is in block $\lfloor i/B \rfloor$ and block j is stored on disk $j \bmod D$.
OUTPUT: A striped representation of a permuted ordering $R_{\sigma(0)}, R_{\sigma(1)}, R_{\sigma(2)}, \ldots$ of the input records with the property that $key(R_{\sigma(i)}) \leq key(R_{\sigma(i+1)})$ for all $i \geq 0$.

Permuting is the special case of sorting in which the permutation that describes the final position of the records is given explicitly and does not have to be discovered, for example, by comparing keys.

Problem 2 Permuting
INPUT: Same input assumptions as in external sorting. In addition, a permutation σ of the integers $\{0, 1, 2, \ldots, N-1\}$ is specified.
OUTPUT: A striped representation of a permuted ordering $R_{\sigma(0)}, R_{\sigma(1)}, R_{\sigma(2)}, \ldots$ of the input records.

Key Results

Theorem 1 ([2, 15]) *The average-case and worst-case number of I/Os required for sorting $N = nB$ data items using D disks is*

$$Sort(N) = \Theta\left(\frac{n}{D} \log_m n\right). \tag{2}$$

Theorem 2 ([2]) *The average-case and worst-case number of I/Os required for permuting N data items using D disks is*

$$\Theta\left(\min\left\{\frac{N}{D}, Sort(N)\right\}\right). \tag{3}$$

A more detailed lower bound is provided in (9) in section "Lower Bounds on I/O."

Matrix transposition is the special case of permuting in which the permutation can be represented as a transposition of a matrix from row-major order into column-major order.

Theorem 3 ([2]) *With D disks, the number of I/Os required to transpose a $p \times q$ matrix from row-major order to column-major order is*

$$\Theta\left(\frac{n}{D}\log_m \min\{M, p, q, n\}\right), \qquad (4)$$

where $N = pq$ and $n = N/B$.

Matrix transposition is a special case of a more general class of permutations called *bit-permute/complement* (BPC) permutations, which in turn is a subset of the class of *bit-matrix-multiply/complement* (BMMC) permutations. BMMC permutations are defined by a $\log N \times \log N$ nonsingular 0-1 matrix A and a $(\log N)$-length 0-1 vector c. An item with binary address x is mapped by the permutation to the binary address given by $Ax \oplus c$, where $\oplus$ denotes bitwise exclusive-or. BPC permutations are the special case of BMMC permutations in which A is a permutation matrix, that is, each row and each column of A contain a single 1. BPC permutations include matrix transposition, bit-reversal permutations (which arise in the FFT), vector-reversal permutations, hypercube permutations, and matrix re-blocking. Cormen et al. [8] characterize the optimal number of I/Os needed to perform any given BMMC permutation solely as a function of the associated matrix A, and they give an optimal algorithm for implementing it.

Theorem 4 ([8]) *With D disks, the number of I/Os required to perform the BMMC permutation defined by matrix A and vector c is*

$$\Theta\left(\frac{n}{D}\left(1 + \frac{\text{rank}(\gamma)}{\log m}\right)\right), \qquad (5)$$

where γ is the lower-left $\log n \times \log B$ submatrix of A.

The two main paradigms for external sorting are *distribution* and *merging*, which are discussed in the following sections for the PDM model.

Sorting by Distribution

Distribution sort [12] is a recursive process that uses a set of $S - 1$ partitioning elements to partition the items into S disjoint buckets. All the items in one bucket precede all the items in the next bucket. The sort is completed by recursively sorting the individual buckets and concatenating them together to form a single fully sorted list.

One requirement is to choose the $S - 1$ partitioning elements so that the buckets are of roughly equal size. When that is the case, the bucket sizes decrease from one level of recursion to the next by a relative factor of $\Theta(S)$, and thus there are $O(\log_S n)$ levels of recursion. During each level of recursion, the data are scanned. As the items stream through internal memory, they are partitioned into S buckets in an online manner. When a buffer of size B fills for one of the buckets, its block is written to the disks in the next I/O, and another buffer is used to store the next set of incoming items for the bucket. Therefore, the maximum number of buckets (and partitioning elements) is $S = \Theta(M/B) = \Theta(m)$, and the resulting number of levels of recursion is $\Theta(\log_m n)$. How to perform each level of recursion in a linear number I/Os is discussed in [2, 14, 22].

An even better way to do distribution sort, and deterministically at that, is the BalanceSort method developed by Nodine and Vitter [14]. During the partitioning process, the algorithm keeps track of how evenly each bucket has been distributed so far among the disks. It maintains an invariant that guarantees good distribution across the disks for each bucket.

The distribution sort methods mentioned above for parallel disks perform write operations in complete stripes, which make it easy to write parity information for use in error correction and recovery. But since the blocks written in each stripe typically belong to multiple buckets, the buckets themselves will not be striped on the disks, and thus the disks must be used independently during read operations. In the write phase, each bucket must therefore keep track of the last block written to each disk so that the blocks for the bucket can be linked together.

An orthogonal approach is to stripe the contents of each bucket across the disks so that read operations can be done in a striped manner. As a result, the write operations must use disks independently, since during each write, multiple buckets will be writing to multiple stripes. Error correction and recovery can still be handled efficiently by devoting to each bucket one block-sized buffer in internal memory. The buffer is continuously updated to contain the exclusive-or (parity) of the blocks written to the current stripe, and after $D - 1$ blocks have been written, the parity information in the buffer can be written to the final (Dth) block in the stripe.

Under this new scenario, the basic loop of the distribution sort algorithm is, as before, to read one memory load at a time and partition the items into S buckets. However, unlike before, the blocks for each individual bucket will reside on the disks in contiguous stripes. Each block therefore has a predefined place where it must be written. With the normal round-robin ordering for the stripes (namely, $\ldots, 1, 2, 3, \ldots, D, 1, 2, 3, \ldots, D, \ldots$), the blocks of different buckets may "collide," meaning that they need to be written to the same disk, and subsequent blocks in those same buckets will also tend to collide. Vitter and Hutchinson [21] solve this problem by the technique of *randomized cycling*. For each of the S buckets, they determine the ordering of the disks in the stripe for that bucket via a random permutation of $\{1, 2, \ldots, D\}$. The S random permutations are chosen independently. If two blocks (from different buckets) happen to collide during a write to the same disk, one block is written to the disk and the other is kept on a write queue. With high probability, subsequent blocks in those two buckets will be written to different disks and thus will not collide. As long as there is a small pool of available buffer space to temporarily cache the blocks in the write queues, Vitter and Hutchinson [21] show that with high probability the writing proceeds optimally.

The randomized cycling method or the related merge sort methods discussed at the end of section "Sorting by Merging" are the methods of choice for sorting with parallel disks. Distribution sort algorithms may have an advantage over the merge approaches presented in section "Sorting by Merging" in that they typically make better use of lower levels of cache in the memory hierarchy of real systems, based upon analysis of distribution sort and merge sort algorithms on models of hierarchical memory.

Sorting by Merging

The *merge* paradigm is somewhat orthogonal to the distribution paradigm of the previous section. A typical merge sort algorithm works as follows [12]: In the "run formation" phase, the n blocks of data are scanned, one memory load at a time; each memory load is sorted into a single "run," which is then output onto a series of stripes on the disks. At the end of the run formation phase, there are $N/M = n/m$ (sorted) runs, each striped across the disks. (In actual implementations, "replacement selection" can be used to get runs of $2M$ data items, on the average, when $M \gg B$ [12].) After the initial runs are formed, the merging phase begins. In each pass of the merging phase, R runs are merged at a time. For each merge, the R runs are scanned and its items merged in an online manner as they stream through internal memory. Double buffering is used to overlap I/O and computation. At most $R = \Theta(m)$ runs can be merged at a time, and the resulting number of passes is $O(\log_m n)$.

To achieve the optimal sorting bound (2), each merging pass must be done in $O(n/D)$ I/Os, which is easy to do for the single-disk case. In the more general multiple-disk case, each parallel read operation during the merging must on the average bring in the next $\Theta(D)$ blocks needed for the merging. The challenge is to ensure that those blocks reside on different disks so that they can be read in a single I/O (or a small constant number of I/Os). The difficulty lies in the fact that the runs being merged were themselves formed during the previous merge pass. Their blocks were written to the disks in the previous pass without knowledge of how they would interact with other runs in later merges.

The Greed Sort method of Nodine and Vitter [15] was the first optimal deterministic EM algorithm for sorting with multiple disks. It works

by relaxing the merging process with a final pass to fix the merging. Aggarwal and Plaxton [1] developed an optimal deterministic merge sort based upon the Sharesort hypercube parallel sorting algorithm. To guarantee even distribution during the merging, it employs two high-level merging schemes in which the scheduling is almost oblivious. Like Greed Sort, the Sharesort algorithm is theoretically optimal (i.e., within a constant factor of optimal), but the constant factor is larger than the distribution sort methods.

One of the most practical methods for sorting is based upon the *simple randomized merge sort* (SRM) algorithm of Barve et al. [7], referred to as "randomized striping" by Knuth [12]. Each run is striped across the disks, but with a random starting point (the only place in the algorithm where randomness is utilized). During the merging process, the next block needed from each disk is read into memory, and if there is not enough room, the least needed blocks are "flushed" (without any I/Os required) to free up space.

Further improvements in merge sort are possible by a more careful prefetching schedule for the runs. Barve et al. [6], Kallahalla and Varman [11], Shah et al. [17], and others have developed competitive and optimal methods for prefetching blocks in parallel I/O systems.

Hutchinson et al. [10] have demonstrated a powerful duality between parallel writing and parallel prefetching, which gives an easy way to compute optimal prefetching and caching schedules for multiple disks. More significantly, they show that the same duality exists between distribution and merging, which they exploit to get a provably optimal and very practical parallel disk merge sort. Rather than use random starting points and round-robin stripes as in SRM, Hutchinson et al. [10] order the stripes for each run independently, based upon the randomized cycling strategy discussed in section "Sorting by Distribution" for distribution sort. These approaches have led to successfully faster external memory sorting algorithms [9]. Clever algorithm engineering optimizations on multicore architectures have won recent big data sorting competitions [16].

Handling Duplicates: Bundle Sorting

For the problem of *duplicate removal*, in which there are a total of K distinct items among the N items, Arge et al. [4] use a modification of merge sort to solve the problem in $O\left(n \max\left\{1, \log_m(K/B)\right\}\right)$ I/Os, which is optimal in the comparison model. When duplicates get grouped together during a merge, they are replaced by a single copy of the item and a count of the occurrences. The algorithm can be used to sort the file, assuming that a group of equal items can be represented by a single item and a count.

A harder instance of sorting called *bundle sorting* arises when there are K distinct key values among the N items, but all the items have different secondary information that must be maintained, and therefore items cannot be aggregated with a count. Matias et al. [13] develop optimal distribution sort algorithms for bundle sorting using

$$O\left(n \max\left\{1, \log_m \min\{K, n\}\right\}\right) \tag{6}$$

I/Os and prove the matching lower bound. They also show how to do bundle sorting (and sorting in general) *in place* (i.e., without extra disk space).

Permuting and Transposition

Permuting is the special case of sorting in which the key values of the N data items form a permutation of $\{1, 2, \ldots, N\}$. The I/O bound (3) for permuting can be realized by one of the optimal sorting algorithms except in the extreme case $B \log m = o(\log n)$, where it is faster to move the data items one by one in a nonblocked way. The one-by-one method is trivial if $D = 1$, but with multiple disks, there may be bottlenecks on individual disks; one solution for doing the permuting in $O(N/D)$ I/Os is to apply the randomized balancing strategies of [22].

Matrix transposition can be as hard as general permuting when B is relatively large (say, $\frac{1}{2}M$) and N is $O(M^2)$, but for smaller B, the special structure of the transposition permutation makes transposition easier. In particular, the matrix can be broken up into square submatrices of B^2 elements such that each submatrix contains B

blocks of the matrix in row-major order and also B blocks of the matrix in column-major order. Thus, if $B^2 < M$, the transpositions can be done in a simple one-pass operation by transposing the submatrices one at a time in internal memory. Thonangi and Yang [18] discuss other types of permutations realizable with fewer I/Os than sorting.

Fast Fourier Transform and Permutation Networks

Computing the fast Fourier transform (FFT) in external memory consists of a series of I/Os that permit each computation implied by the FFT directed graph (or butterfly) to be done while its arguments are in internal memory. A permutation network computation consists of an oblivious (fixed) pattern of I/Os such that any of the $N!$ possible permutations can be realized; data items can only be reordered when they are in internal memory. A permutation network can be realized by a series of three FFTs.

The algorithms for FFT are faster and simpler than for sorting because the computation is nonadaptive in nature, and thus the communication pattern is fixed in advance [22].

Lower Bounds on I/O

The following proof of the permutation lower bound (3) of Theorem 2 is due to Aggarwal and Vitter [2]. The idea of the proof is to calculate, for each $t \geq 0$, the number of distinct orderings that are realizable by sequences of t I/Os. The value of t for which the number of distinct orderings first exceeds $N!/2$ is a lower bound on the average number of I/Os (and hence the worst-case number of I/Os) needed for permuting.

Assuming for the moment that there is only one disk, $D = 1$, consider how the number of realizable orderings can change as a result of an I/O. In terms of increasing the number of realizable orderings, the effect of reading a disk block is considerably more than that of writing a disk block, so it suffices to consider only the effect of read operations. During a read operation, there are at most B data items in the read block, and they can be interspersed among the M items in internal memory in at most $\binom{M}{B}$ ways, so the number of realizable orderings increases by a factor of $\binom{M}{B}$. If the block has never before resided in internal memory, the number of realizable orderings increases by an extra $B!$ factor, since the items in the block can be permuted among themselves. (This extra contribution of $B!$ can only happen once for each of the N/B original blocks.) There are at most $n + t \leq N \log N$ ways to choose which disk block is involved in the tth I/O (allowing an arbitrary amount of disk space). Hence, the number of distinct orderings that can be realized by all possible sequences of t I/Os is at most

$$(B!)^{N/B} \left(N(\log N) \binom{M}{B} \right)^t. \tag{7}$$

Setting the expression in (7) to be at least $N!/2$, and simplifying by taking the logarithm, the result is

$$N \log B + t \left(\log N + B \log \frac{M}{B} \right) = \Omega(N \log N). \tag{8}$$

Solving for t gives the matching lower bound $\Omega(n \log_m n)$ for permuting for the case $D = 1$. The general lower bound (3) of Theorem 2 follows by dividing by D.

Hutchinson et al. [10] derive an asymptotic lower bound (i.e., one that accounts for constant factors) from a more refined argument that analyzes both input operations and output operations. Assuming that $m = M/B$ is an increasing function, the number of I/Os required to sort or permute n indivisible items, up to lower-order terms, is at least

$$\frac{2N}{D} \frac{\log n}{B \log m + 2 \log N} \sim \begin{cases} \frac{2n}{D} \log_m n & \text{if } B \log m = \omega(\log N); \\ \frac{N}{D} & \text{if } B \log m = o(\log N). \end{cases} \tag{9}$$

For the typical case in which $B \log m = \omega(\log N)$, the lower bound, up to lower order terms, is $2n \log_m n$ I/Os. For the pathological in which $B \log m = o(\log N)$, the I/O lower bound is asymptotically N/D.

Permuting is a special case of sorting, and hence the permuting lower bound applies also to sorting. In the unlikely case that $B \log m = o(\log n)$, the permuting bound is only $\Omega(N/D)$, and in that case the comparison model must be used to get the full lower bound (2) of Theorem 1 [2]. In the typical case in which $B \log m = \Omega(\log n)$, the comparison model is not needed to prove the sorting lower bound; the difficulty of sorting in that case arises not from determining the order of the data but from permuting (or routing) the data.

The proof used above for permuting also works for permutation networks, in which the communication pattern is oblivious (fixed). Since the choice of disk block is fixed for each t, there is no $N \log N$ term as there is in (7), and correspondingly there is no additive $\log N$ term in the inner expression as there is in (8). Hence, solving for t gives the lower bound (2) rather than (3). The lower bound follows directly from the counting argument; unlike the sorting derivation, it does not require the comparison model for the case $B \log m = o(\log n)$. The lower bound also applies directly to FFT, since permutation networks can be formed from three FFTs in sequence. The transposition lower bound involves a potential argument based upon a togetherness relation [2].

For the problem of bundle sorting, in which the N items have a total of K distinct key values (but the secondary information of each item is different), Matias et al. [13] derive the matching lower bound.

The lower bounds mentioned above assume that the data items are in some sense "indivisible," in that they are not split up and reassembled in some magic way to get the desired output. It is conjectured that the sorting lower bound (2) remains valid even if the indivisibility assumption is lifted. However, for an artificial problem related to transposition, removing the indivisibility assumption can lead to faster algorithms. Whether the conjecture is true is a challenging theoretical open problem.

Applications

Sorting and sorting-like operations account for a significant percentage of computer use [12], with numerous database applications. In addition, sorting is an important paradigm in the design of efficient EM algorithms, as shown in [20], where several applications can be found. With some technical qualifications, many problems that can be solved easily in linear time in internal memory, such as permuting, list ranking, expression tree evaluation, and finding connected components in a sparse graph, require the same number of I/Os in PDM as does sorting.

Open Problems

Several interesting challenges remain. One difficult theoretical problem is to prove lower bounds for permuting and sorting without the indivisibility assumption. Another question is to determine the I/O cost for each individual permutation, as a function of some simple characterization of the permutation, such as number of inversions. A continuing goal is to develop optimal EM algorithms and to translate theoretical gains into observable improvements in practice.

Many interesting challenges and opportunities in algorithm design and analysis arise from new architectures being developed. For example, Arge et al. [3] propose the *parallel external memory (PEM)* model for the design of efficient algorithms for chip multiprocessors, in which each processor has a private cache and shares a larger main memory with the other processors. The paradigms described earlier form the basis for efficient algorithms for sorting, selection, and prefix sums. Further architectures to explore include other forms of multicore architectures, networks of workstations, hierarchical storage devices, disk drives with processing capabilities, and storage devices based upon microelectrome-

chanical systems (MEMS). Active (or intelligent) disks, in which disk drives have some processing capability and can filter information sent to the host, have been proposed to further reduce the I/O bottleneck, especially in large database applications. MEMS-based nonvolatile storage has the potential to serve as an intermediate level in the memory hierarchy between DRAM and disks. It could ultimately provide better latency and bandwidth than disks, at less cost per bit than DRAM.

URL to Code

Two systems for developing external memory algorithms are TPIE and STXXL, which can be downloaded from http://www.madalgo.au.dk/tpie/ and http://stxxl.sourceforge.net/, respectively. Both systems include subroutines for sorting and permuting and facilitate development of more advanced algorithms.

Problem Definition

Facility location problems concern situations where a planner needs to determine the location of facilities intended to serve a given set of clients. The objective is usually to minimize the sum of the cost of opening the facilities and the cost of serving the clients by the facilities, subject to various constraints, such as the number and the type of clients a facility can serve. There are many variants of the facility location problem, depending on the structure of the cost function and the constraints imposed on the solution. Early references on facility location problems include Kuehn and Hamburger [35], Balinski and Wolfe [8], Manne [40], and Balinski [7]. Review works include Krarup and Pruzan [34] and Mirchandani and Francis [42]. It is interesting to notice that the algorithm that is probably one of the most effective ones to solve the uncapacitated facility location problem to optimality is the primal-dual algorithm combined with branch-and-bound due to Erlenkotter [16] dating back to 1978. His primal-dual scheme is similar to techniques used in the modern literature on approximation algorithms.

More recently, extensive research into approximation algorithms for facility location problems has been carried out. Review articles on this topic include Shmoys [49, 50] and Vygen [55]. Besides its theoretical and practical importance, facility location problems provide a showcase of common techniques in the field of approximation algorithms, as many of these techniques such as linear programming rounding, primal-dual methods, and local search have been applied successfully to this family of problems. This entry defines several facility location problems, gives a few historical pointers, and lists approximation algorithms with an emphasis on the results derived in the paper by Shmoys, Tardos, and Aardal [51]. The techniques applied to the *uncapacitated facility location* (UFL) problem are discussed in some more detail.

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

In the UFL problem, a set $\mathcal{F}$ of n_f *facilities* and a set C of n_c *clients* (also known as *cities*, or *demand points*) are given. For every facility $i \in \mathcal{F}$, the *facility opening* cost is equal to f_i. Furthermore, for every facility $i \in \mathcal{F}$ and client $j \in C$, there is a *connection cost* c_{ij}. The objective is to open a subset of the facilities and connect each client to an open facility so that the total cost is minimized. Notice that once the set of open facilities is specified, it is optimal to connect each client to the open facility that yields smallest connection cost. Therefore, the objective is to find a set $S \subseteq \mathcal{F}$ that minimizes $\sum_{i \in S} f_i + \sum_{j \in C} \min_{i \in S}\{c_{ij}\}$. This definition and the definitions of other variants of the facility location problem in this entry assume unit demand at each client. It is straightforward to generalize these definitions to the case where each client has a given demand. The UFL problem can be formulated as the following integer program due to Balinski [7]. Let y_i, $i \in \mathcal{F}$ be equal to 1 if facility i is open, and equal to 0 otherwise. Let x_{ij}, $i \in \mathcal{F}$, $j \in C$ be the fraction of client j assigned to facility i.

$$\min \sum_{i \in \mathcal{F}} f_i y_i + \sum_{i \in \mathcal{F}} \sum_{j \in C} c_{ij} x_{ij} \tag{1}$$

$$\text{subject to} \sum_{i \in \mathcal{F}} x_{ij} = 1, \quad \text{for all } j \in C, \tag{2}$$

$$x_{ij} - y_i \leq 0, \quad \text{for all } i \in \mathcal{F},\ j \in C \tag{3}$$

$$x \geq 0,\ y \in \{0,1\}^{n_f} \tag{4}$$

In the *linear programming (LP) relaxation* of UFL the constraint $y \in \{0,1\}^{n_f}$ is substituted by the constraint $y \in [0,1]^{n_f}$. Notice that in the uncapacitated case, it is not necessary to require $x_{ij} \in \{0,1\}$, $i \in \mathcal{F}$, $j \in C$ if each client has to be serviced by precisely one facility, as $0 \leq x_{ij} \leq 1$ by constraints (2) and (4). Moreover, if x_{ij} is not integer, then it is always possible to create an integer solution with the same cost by assigning client j completely to one of the facilities currently servicing j.

A γ-approximation algorithm is a polynomial algorithm that, in case of minimization, is guaranteed to produce a feasible solution having value *at most* γz^*, where z^* is the value of an optimal solution, and $\gamma \geq 1$. If $\gamma = 1$ the algorithm produces an optimal solution. In case of maximization, the algorithm produces a solution having value *at least* γz^*, where $0 \leq \gamma \leq 1$.

Hochbaum [25] developed an $O(\log n)$-approximation algorithm for UFL. By a straightforward reduction from the Set Cover problem, it can be shown that this cannot be improved unless $NP \subseteq DTIME[n^{O(\log \log n)}]$ due to a result by Feige [17]. However, if the connection costs are restricted to come from distances in a metric space, namely $c_{ij} = c_{ji} \geq 0$ for all $i \in \mathcal{F}, j \in C$ (nonnegativity and symmetry) and $c_{ij} + c_{ji'} + c_{i'j'} \geq c_{ij'}$ for all $i, i' \in \mathcal{F}, j, j' \in C$ (triangle inequality), then constant approximation guarantees can be obtained. In all results mentioned below, except for the maximization objectives, it is assumed that the costs satisfy these restrictions. If the distances between facilities and clients are Euclidean, then for some location problems approximation schemes have been obtained [5].

Variants and Related Problems

A variant of the uncapacitated facility location problem is obtained by considering the objective coefficients c_{ij} as the per unit profit of servicing client j from facility i. The *maximization version* of UFL, max-UFL is obtained by maximizing the profit minus the facility opening cost, i.e., $\max \sum_{i \in \mathcal{F}} \sum_{j \in C} c_{ij} x_{ij} - \sum_{i \in \mathcal{F}} f_i y_i$. This variant was introduced by Cornuéjols, Fisher, and Nemhauser [15].

In the *k-median problem* the facility opening cost is removed from the objective function (1) to obtain $\min \sum_{i \in M} \sum_{j \in N} c_{ij} x_{ij}$, and the constraint that no more than k facilities may be opened, $\sum_{i \in M} y_i \leq k$, is added. In the *k-center problem* the constraint $\sum_{i \in M} y_i \leq k$ is again included, and the objective function here is to minimize the maximum distance used on a link between an open facility and a client.

In the *capacitated facility location problem* a capacity constraint $\sum_{j \in C} x_{ij} \leq u_i y_i$ is added for all $i \in \mathcal{F}$. Here it is important to distinguish between the *splittable* and the *unsplittable*

case, and also between *hard capacities* and *soft capacities*. In the splittable case one has $x \geq 0$, allowing for a client to be serviced by multiple depots, and in the unsplittable case one requires $x \in \{0,1\}^{n_f \times n_c}$. If each facility can be opened at most once (i.e., $y_i \in \{0,1\}$), the capacities are called hard; otherwise, if the problem allows a facility i to be opened any number r of times to serve ru_i clients, the capacities are called soft.

In the k-level facility location problem, the following are given: a set C of clients, k disjoint sets $\mathcal{F}_1, \ldots, \mathcal{F}_k$ of facilities, an opening cost for each facility, and connection costs between clients and facilities. The goal is to connect each client j through a path $i_1, \ldots, i_k$ of open facilities, with $i_\ell \in \mathcal{F}_\ell$. The connection cost for this client is $c_{ji_1} + c_{i_1 i_2} + \cdots + c_{i_{k-1} i_k}$. The goal is to minimize the sum of connection costs and facility opening costs.

The problems mentioned above have all been considered by Shmoys, Tardos, and Aardal [51], with the exceptions of max-UFL, and the k-center and k-median problems. The max-UFL variant is included for historical reasons, and k-center and k-median are included since they have a rich history and since they are closely related to UFL. Results on the capacitated facility location problem with hard capacities are mentioned as this, at least from the application point of view, is a more realistic model than the soft capacity version, which was treated in [51]. For k-level facility location, Shmoys et al. considered the case $k = 2$. Here, the problem for general k is considered.

There are many other variants of the facility location problem that are not discussed here. Examples include K-facility location [33], universal facility location [24, 38], online facility location [3, 18, 41], fault tolerant facility location [28, 30, 54], facility location with outliers [12, 28], multicommodity facility location [48], priority facility location [37, 48], facility location with hierarchical facility costs [52], stochastic facility location [23, 37, 46], connected facility location [53], load-balanced facility location [22, 32, 37], concave-cost facility location [24], and capacitated-cable facility location [37, 47].

Key Results

Many algorithms have been proposed for location problems. To begin with, a brief description of the algorithms of Shmoys, Tardos, and Aardal [51] is given. Then, a quick overview of some key results is presented. Some of the algorithms giving the best values of the approximation guarantee γ are based on solving the LP-relaxation by a polynomial algorithm, which can actually be quite time consuming, whereas some authors have suggested fast combinatorial algorithms for facility location problems with less competitive γ-values. Due to space restrictions the focus of this entry is on the algorithms that yield the best approximation guarantees. For more references the survey papers by Shmoys [49, 50] and by Vygen [55] are recommended.

The Algorithms of Shmoys, Tardos, and Aardal

First the algorithm for UFL is described, and then the results that can be obtained by adaptations of the algorithm to other problems are mentioned.

The algorithm solves the LP relaxation and then, in two stages, modifies the obtained fractional solution. The first stage is called *filtering* and it is designed to bound the connection cost of each client to the most distant facility fractionally serving him. To do so, the facility opening variables y_i are scaled up by a constant and then the connection variables x_{ij} are adjusted to use the closest possible facilities.

To describe the second stage, the notion of *clustering*, formalized later by Chudak and Shmoys [13] is used. Based on the fractional solution, the instance is cut into pieces called *clusters*. Each cluster has a distinct client called the *cluster center*. This is done by iteratively choosing a client, not covered by the previous clusters, as the next cluster center, and adding to this cluster the facilities that serve the cluster center in the fractional solution, along with other clients served by these facilities. This construction of clusters guarantees that the facilities in each cluster are open to a total extent of one, and therefore after opening the facility with the smallest opening cost in each cluster, the total

facility opening cost that is paid does not exceed the facility opening cost of the fractional solution. Moreover, by choosing clients for the cluster centers in a greedy fashion, the algorithm makes each cluster center the minimizer of a certain cost function among the clients in the cluster. The remaining clients in the cluster are also connected to the opened facility. The triangle inequality for connection costs is now used to bound the cost of this connection. For UFL, this filtering and rounding algorithm is a 4-approximation algorithm. Shmoys et al. also show that if the filtering step is substituted by *randomized filtering*, an approximation guarantee of 3.16 is obtained.

In the same paper, adaptations of the algorithm, with and without randomized filtering, was made to yield approximation algorithms for the soft-capacitated facility location problem, and for the 2-level uncapacitated problem. Here, the results obtained using randomized filtering are discussed.

For the problem with soft capacities two versions of the problem were considered. Both have equal capacities, i.e., $u_i = u$ for all $i \in \mathcal{F}$. In the first version, a solution is "feasible" if the y-variables either take value 0, or a value between 1 and $\gamma' \geq 1$. Note that γ' is not required to be integer, so the constructed solution is not necessarily integer. This can be interpreted as allowing for each facility i to expand to have capacity $\gamma' u$ at a cost of $\gamma' f_i$. A (γ, γ')-approximation algorithm is a polynomial algorithm that produces such a feasible solution having a total cost within a factor of γ of the true optimal cost, i.e., with $y \in \{0, 1\}^{n_f}$. Shmoys et al. developed a $(5.69, 4.24)$-approximation algorithm for the splittable case of this problem, and a $(7.62, 4.29)$-approximation algorithm for the unsplittable case.

In the second soft-capacitated model, the original problem is changed to allow for the y-variables to take nonnegative integer values, which can be interpreted as allowing multiple facilities of capacity u to be opened at each location. The approximation algorithms in this case produces a solution that is feasible with respect to this modified model. It is easy to show that the approximation guarantees obtained for the previous model also hold in this case, i.e., Shmoys et al. obtained a 5.69-approximation algorithm for splittable demands and a 7.62-approximation algorithm for unsplittable demands. This latter model is the one considered in most later papers, so this is the model that is referred to in the paragraph on soft capacity results below.

UFL

The first algorithm with constant performance guarantee was the 3.16-approximation algorithm by Shmoys, Tardos, and Aardal, see above. Since then numerous improvements have been made. Guha and Khuller [19, 20] proved a lower bound on approximability of 1.463, and introduced a *greedy augmentation procedure*. A series of approximation algorithms based on LP-rounding was then developed (see e.g., [10, 13]). There are also greedy algorithms that only use the LP-relaxation implicitly to obtain a lower bound for a primal-dual analysis. An example is the JMS 1.61-approximation algorithm developed by Jain, Mahdian, and Saberi [29]. Some algorithms combine several techniques, like the 1.52-approximation algorithm of Mahdian, Ye, and Zhang [39], which uses the JMS algorithm and the greedy augmentation procedure. Currently, the best known approximation guarantee is 1.5 reported by Byrka [10]. It is obtained by combining a randomized LP-rounding algorithm with the greedy JMS algorithm.

max-UFL

The first constant factor approximation algorithm was derived in 1977 by Cornuéjols et al. [15] for max-UFL. They showed that opening one facility at a time in a greedy fashion, choosing the facility to open as the one with highest marginal profit, until no facility with positive marginal profit can be found, yields a $(1 - 1/e) \approx 0.632$-approximation algorithm. The current best approximation factor is 0.828 by Ageev and Sviridenko [2].

k-Median, *k*-Center

The first constant factor approximation algorithm for the k-median problem is due to Charikar,

Guha, Tardos, and Shmoys [11]. This LP-rounding algorithm has the approximation ratio of $6\frac{2}{3}$. The currently best known approximation ratio is $3 + \epsilon$ achieved by a local search heuristic of Arya, et al. [6] (see also a separate entry *k-median and Facility Location*).

The first constant factor approximation algorithm for the *k*-center problem was given by Hochbaum and Shmoys [26], who developed a 2-approximation algorithm. This performance guarantee is the best possible unless $P = NP$.

Capacitated Facility Location

For the soft-capacitated problem with equal capacities, the first constant factor approximation algorithms are due to Shmoys et al. [51] for both the splittable and unsplittable demand cases, see above. Recently, a 2-approximation algorithm for the soft capacitated facility location problem with unsplittable unit demands was proposed by Mahdian et al. [39]. The integrality gap of the LP relaxation for the problem is also 2. Hence, to improve the approximation guarantee one would have to develop a better lower bound on the optimal solution.

In the hard capacities version it is important to allow for splitting the demands, as otherwise even the feasibility problem becomes difficult. Suppose demands are splittable, then we may to distinguish between the equal capacity case, where $u_i = u$ for all $i \in \mathcal{F}$, and the general case. For the problem with equal capacities, a 5.83-approximation algorithm was given by Chudak and Wiliamson [14]. The first constant factor approximation algorithm, with $\gamma = 8.53 + \epsilon$, for general capacities was given by Pál, Tardos, and Wexler [44]. This was later improved by Zhang, Chen, and Ye [57] who obtained a 5.83-approximation algorithm also for general capacities.

k-Level Problem

The first constant factor approximation algorithm for $k = 2$ is due to Shmoys et al. [51], with $\gamma = 3.16$. For general k, the first algorithm, having $\gamma = 3$, was proposed by Aardal, Chudak, and Shmoys [1]. For $k = 2$, Zhang [56] developed a 1.77-approximation algorithm. He also showed that the problem for $k = 3$ and $k = 4$ can be approximated by $\gamma = 2.523$ (This value of γ deviates slightly from the value 2.51 given in the paper. The original argument contained a minor calculation error.) and $\gamma = 2.81$ respectively.

Applications

Facility location has numerous applications in the field of operations research. See the book edited by Mirchandani and Francis [42] or the book by Nemhauser and Wolsey [43] for a survey and a description of applications of facility location in problems such as plant location and locating bank accounts. Recently, the problem has found new applications in network design problems such as placement of routers and caches [22, 36], agglomeration of traffic or data [4, 21], and web server replications in a content distribution network [31, 45].

Open Problems

A major open question is to determine the exact approximability threshold of UFL and close the gap between the upper bound of 1.5 [10] and the lower bound of 1.463 [20]. Another important question is to find better approximation algorithms for *k*-median. In particular, it would be interesting to find an LP-based 2-approximation algorithm for *k*-median. Such an algorithm would determine the integrality gap of the natural LP relaxation of this problem, as there are simple examples that show that this gap is at least 2.

Experimental Results

Jain et al. [28] published experimental results comparing various primal-dual algorithms. A more comprehensive experimental study of several primal-dual, local search, and heuristic algorithms is performed by Hoefer [27]. A collection of data sets for UFL and several other location problems can be found in the OR-library maintained by Beasley [9].

Problem Definition

A distributed system is comprised of a collection of processes. The processes typically seek to achieve some common task by communicating through message passing or shared memory. Most interesting tasks require, at least at certain points of the computation, some form of *agreement* between the processes. An abstract form of such agreement is *consensus* where processes need to agree on a single value among a set of proposed values. Solving this seemingly elementary problem is at the heart of reliable distributed computing and, in particular, of distributed database commitment, total ordering of messages, and emulations of many shared object types.

Fischer, Lynch, and Paterson's seminal result in the theory of distributed computing [13] says that consensus cannot be deterministically solved in an *asynchronous* distributed system that is prone to process failures. This impossibility holds consequently for all distributed computing problems which themselves rely on consensus.

Failures and *asynchrony* are fundamental ingredients in the consensus impossibility. The impossibility holds even if only *one* process *fails*, and it does so only by *crashing*, i.e., stopping its activities. Tolerating crashes is the least one would expect from a distributed system for the goal of distribution is in general to avoid single points of failures in centralized architectures. Usually, actual distributed applications exhibit more severe failures where processes could deviate arbitrarily from the protocol assigned to them.

Asynchrony refers to the absence of assumptions on process speeds and communication delays. This absence prevents any process from distinguishing a crashed process from a correct one and this inability is precisely what leads to the consensus impossibility. In practice, however, distributed systems are not completely asynchronous: some timing assumptions can typically be made. In the best case, if precise lower and upper bounds on communication delays and process speeds are assumed, then it is easy to show that consensus and related impossibilities can be circumvented despite the crash of any number of processes [20].

Intuitively, the way that such timing assumptions circumvent asynchronous impossibilities is by providing processes with *information about failures*, typically through *time-out* (or *heart-beat*) mechanisms, usually underlying actual distributed applications. Whereas certain information about failures can indeed be obtained in distributed systems, the accuracy of such information might vary from a system to another, depending on the underlying network, the load

of the application, and the mechanisms used to detect failures. A crucial problem in this context is to characterize such information, in an abstract and precise way.

Key Results

The Failure Detector Abstraction

Chandra and Toueg [5] defined the *failure detector* abstraction as a simple way to capture failure information that is needed to circumvent asynchronous impossibilities, in particular the consensus impossibility. The model considered in [5] is a message passing one where processes can fail by *crashing*. Processes that crash stop their activities and do not recover. Processes that do not crash are said to be *correct*. At least one process is supposed to be correct in every execution of the system.

Roughly speaking, a failure detector is an oracle that provides processes with information about failures. The oracle is accessed in each computation step of a process and it provides the process with a value conveying some failure information. The value is picked from some set of values, called the *range* of the failure detector. For instance, the range could be the set of subsets of processes in the system, and each subset could depict the set of processes detected to have crashed, or considered to be correct. This would correspond to the situation where the failure detector is implemented using a time-out: every process q that does not communicate within some time period with some process p, would be included in subset of processes suspected of having crashed by p.

More specifically, a failure detector is a function, D, that associates to each *failure pattern*, F, a set of *failure detector histories* $\{H_i\} = D(F)$. Both the failure pattern and the failure detector history are themselves functions.

- A failure pattern F is a function that associates to each time t, the set of processes $F(t)$ that have indeed crashed by time t. This notion assumes the existence of a global clock, outside the control of the processes, as well as a specific concept of *crash* event associated with time. A set of failure pattern is called an *environment*.
- A failure detector history H is also a function, which associates to each process p and time t, some value v from the range of failure detector values. (The range of a failure detector D is denoted R_D.) This value v is said to be output by the failure detector D at process p and time t.

Two observations are in order.

- By construction, the output of a failure detector does not depend on the computation, i.e., on the actual steps performed by the processes, on their algorithm or the input of such algorithm. The output of the failure detector depends solely on the failure pattern, namely on whether and when processes crashed.
- A failure detector might associate several histories to each failure pattern. Each history represents a suite of possible combinations of outputs for the same given failure pattern. This captures the inherent non-determinism of a failure detection mechanism. Such a mechanism is typically itself implemented as a distributed algorithm and the variations in communication delays for instance could lead the same mechanism to output (even slightly) different information for the same failure pattern.

To illustrate these concepts, consider two classical examples of failure detectors.

1. The *perfect* failure detector outputs a subset of processes, i.e., the range of the failure detector is the set of subsets of processes in the system. When a process q is output at some time t at a process p, then q is said to be *detected* (of having crashed) by p. The *perfect* failure detector guarantees the two following properties:
   - Every process that crashes is eventually permanently detected;
   - No correct process is ever detected.

2. The *eventually strong* failure detector outputs a subset of processes: when a process q is output at some time t at a process p, then q is said to be *suspected* (of having crashed) by p. An *eventually strong* failure detector ensures the two following properties:
   - Every process that crashes is eventually suspected;
   - Eventually, some correct process is never suspected.

The *perfect* failure detector is *reliable*: if a process q is detected, then q has crashed. An *eventually strong* failure detector is *unreliable*: there never is any guarantee that the information that is output is accurate. The use of the term *suspected* conveys that idea. The distinction between *unreliability* and *reliability* was precisely captured in [14] for the general context where the range of the failure detector can be arbitrary.

Consensus Algorithms

Two important results were established in [5].

Theorem 1 (Chandra-Toueg [5]) *There is an algorithm that solves consensus with a perfect failure detector.*

The theorem above implicitly says that if the distributed system provides means to implement perfect failure detection, then the consensus impossibility can be circumvented, even if all but one process crashes. In fact, the result holds for any failure pattern, i.e., in any environment.

The second theorem below relates the existence of a consensus algorithm to a resilience assumption. More specifically, the theorem holds in the *majority* environment, which is the set of failure patterns where more than half of the processes are correct.

Theorem 2 (Chandra-Toueg [5]) *There is an algorithm that implements consensus with an eventually strong failure detector in the majority environment.*

The algorithm underlying the result above is similar to *eventually synchronous* consensus algorithms [10] and share also some similarities with the *Paxos* algorithm [18]. It is shown in [5] that no algorithm using solely the *eventually strong* failure detector can solve consensus without the majority assumption. (This result is generalized to any unreliable failure detector in [14].) This resilience lower bound is intuitively due to the possibility of partitions in a message passing system where at least half of the processes can crash and failure detection is unreliable. In shared memory for example, no such possibility exists and consensus can be solved with the *eventually strong* failure [19].

Failure Detector Reductions

Failure detectors can be compared. A failure detector D_2 is said to be *weaker* than a failure detector D_1 if there is an asynchronous algorithm, called a *reduction* algorithm, which, using D_1, can emulate D_2. Three remarks are important here.

- The fact that the reduction algorithm is asynchronous means that it does not use any other source of failure information, besides D_1.
- Emulating failure detector D_2 means implementing a distributed variable that mimics the output that could be provided by D_2.
- The existence of a reduction algorithm depends on environment. Hence, strictly speaking, the fact that a failure detector is weaker than another one depends on the environment under consideration.

If failure detector D_1 is weaker than D_2, and vice et versa, then D_1 and D_2 are said to be *equivalent*. Else, if D_1 is weaker than D_2 and D_2 is not weaker than D_1, then D_1 is said to be *strictly weaker* than D_2. Again, strictly speaking, these notions depend on the considered environment.

The ability to compare failure detectors help define a notion of *weakest* failure detector to solve a problem. Basically, a failure detector D is the weakest to solve a problem P if the two following properties are satisfied:

- There is an algorithm that solves P using D.
- If there is an algorithm that solves P using some failure detector D', then D is weaker than D'.

Theorem 3 (Chandra-Hadzilacos-Toueg [4]) *The eventually strong failure detector is the weakest to solve consensus in the majority environment.*

The weakest failure detector to implement consensus in any environment was later established in [8].

Applications

A Practical Perspective

The identification of the failure detector concept had an impact on the design of reliable distributed architectures. Basically, a failure detector can be viewed as a first class service of a distributed system, at the same level as a name service or a file service. Time-out and heartbeat mechanisms can thus be hidden under the failure detector abstraction, which can then export a unified interface to higher level applications, including consensus and state machine replication algorithms [2, 11, 21].

Maybe more importantly, a failure detector service can encapsulate synchrony assumptions: these can be changed without impact on the rest of the applications. Minimal synchrony assumptions to devise specific failure detectors could be explored leading to interesting theoretical results [1, 7, 12].

A Theoretical Perspective

A second application of the failure detector concept is a theory of distributed computability. Failure detectors enable to classify problems. A problem A is *harder* (resp. *strictly harder*) than problem B if the weakest failure detector to solve B is weaker (resp. strictly weaker) than the weakest failure detector to solve A. (This notion is of course parametrized by a specific environment.)

Maybe surprisingly, the induced failure detection reduction between problems does not exactly match the classical *black-box* reduction notion. For instance, it is well known that there is no asynchronous distributed algorithm that can use a *Queue* abstraction to implement a *Compare-Swap* abstraction in a system of $n > 2$ processes where $n - 1$ can fail by crashing [15]. In this sense, a *Compare-Swap* abstraction is strictly more powerful (in a *black-box* sense) than a *Queue* abstraction. It turns out that:

Theorem 4 (Delporte-Fauconnier-Guerraoui [9]) *The weakest failure detector to solve the Queue problem is also the weakest to solve the Compare-Swap problem in a system of $n > 2$ processes where $n - 1$ can fail by crashing.*

In a sense, this theorem indicates that reducibility as induced by the failure detector notion is different from the traditional *black-box* reduction.

Open Problems

Several issues underlying the failure detector notion are still open. One such issue consists in identifying the weakest failure detector to solve the seminal *set-agreement* problem [6]: a decision task where processes need to agree on up to k values, instead of a single value as in consensus. Three independent groups of researchers [3, 16, 22] proved the impossibility of solving this problem in an asynchronous system with k failures, generalizing the consensus impossibility [13]. Determining the weakest failure detector to circumvent this impossibility would clearly help understand the fundamentals of failure detection reducibility.

Another interesting research direction is to relate the complexity of distributed algorithm with the underlying failure detector [17]. Clearly, failure detectors circumvents asynchronous impossibilities, but to what extend do they boost the complexity of distributed algorithms? One would of course expect the complexity of a solution to a problem to be higher if the failure detector is weaker. But to what extend?

False-Name-Proof Auction

Makoto Yokoo

Keywords

False-name-proof auctions; Pseudonymous bidding; Robustness against false-name bids

Years and Authors of Summarized Original Work

2004; Yokoo, Sakurai, Matsubara

Problem Definition

In Internet auctions, it is easy for a bidder to submit multiple bids under multiple identifiers (e.g., multiple e-mail addresses). If only one item/good

is sold, a bidder cannot make any additional profit by using multiple bids. However, in combinatorial auctions, where multiple items/goods are sold simultaneously, submitting multiple bids under fictitious names can be profitable. A bid made under a fictitious name is called a *false-name bid*.

Here, use the same model as the GVA section. In addition, false-name bids are modeled as follows.

- Each bidder can use multiple identifiers.
- Each identifier is unique and cannot be impersonated.
- Nobody (except the owner) knows whether two identifiers belongs to the same bidder or not.

The goal is to design a *false-name-proof protocol*, i.e., a protocol in which using false-names is useless, thus bidders voluntarily refrain from using false-names.

The problems resulting from collusion have been discussed by many researchers. Compared with collusion, a false-name bid is easier to execute on the Internet since obtaining additional identifiers, such as another e-mail address, is cheap. False-name bids can be considered as a very restricted subclass of collusion.

Key Results

The Generalized Vickrey Auction (GVA) protocol is (dominant strategy) incentive compatible, i.e., for each bidder, truth-telling is a dominant strategy (a best strategy regardless of the action of other bidders) if there exists no false-name bids. However, when false-name bids are possible, truth-telling is no longer a dominant strategy, i.e., the GVA is not false-name-proof.

Here is an example, which is identical to Example 1 in the GVA section.

Example 1 Assume there are two goods a and b, and three bidders, bidder 1, 2, and 3, whose types are θ_1, θ_2, and θ_3, respectively. The evaluation value for a bundle $v(B, \theta_i)$ is determined as follows.

	$\{a\}$	$\{b\}$	$\{a, b\}$
θ_1	\$6	\$0	\$6
θ_2	\$0	\$0	\$8
θ_3	\$0	\$5	\$5

As shown in the GVA section, good a is allocated to bidder 1, and b is allocated to bidder 3. Bidder 1 pays \$3 and bidder 3 pays \$2.

Now consider another example.

Example 2 Assume there are only two bidders, bidder 1 and 2, whose types are θ_1 and θ_2, respectively. The evaluation value for a bundle $v(B, \theta_i)$ is determined as follows.

	$\{a\}$	$\{b\}$	$\{a, b\}$
θ_1	\$6	\$5	\$11
θ_2	\$0	\$0	\$8

In this case, the bidder 1 can obtains both goods, but he/she requires to pay \$8, since if bidder 1 does not participate, the social surplus would have been \$8. When bidder 1 does participate, bidder 1 takes everything and the social surplus except bidder 1 becomes 0. Thus, bidder 1 needs to pay the decreased amount of the social surplus, i.e., \$8.

However, bidder 1 can use another identifier, namely, bidder 3 and creates a situation identical to Example 1. Then, good a is allocated to bidder 1, and b is allocated to bidder 3. Bidder 1 pays \$3 and bidder 3 pays \$2. Since bidder 3 is a false-name of bidder 1, bidder 1 can obtain both goods by paying \$3 + \$2 = \$5. Thus, using a false-name is profitable for bidder 1.

The effects of false-name bids on combinatorial auctions are analyzed in [4]. The obtained results can be summarized as follows.

- As shown in the above example, the GVA protocol is not false-name-proof.
- There exists no false-name-proof combinatorial auction protocol that satisfies Pareto efficiency.
- If a surplus function of bidders satisfies a condition called *concavity*, then the GVA is guaranteed to be false-name-proof.

Also, a series of protocols that are false-name-proof in various settings have been developed: combinatorial auction protocols [2, 3], multi-unit auction protocols [1], and double auction protocols [5].

Furthermore, in [2], a distinctive class of combinatorial auction protocols called a Price-oriented, Rationing-free (PORF) protocol is identified. The description of a PORF protocol can be used as a guideline for developing strategy/false-name proof protocols.

The outline of a PORF protocol is as follows:

1. For each bidder, the price of each bundle of goods is determined independently of his/her own declaration, while it depends on the declarations of other bidders. More specifically, the price of bundle (a set of goods) B for bidder i is determined by a function $p(B, \Theta_X)$, where Θ_X is a set of declared types by other bidders X.
2. Each bidder is allocated a bundle that maximizes his/her utility independently of the allocations of other bidders (i.e., rationing-free). The prices of bundles must be determined so that *allocation feasibility* is satisfied, i.e., no two bidders want the same item.

Although a PORF protocol appears to be quite different from traditional protocol descriptions, surprisingly, it is a sufficient and necessary condition for a protocol to be strategy-proof. Furthermore, if a PORF protocol satisfies the following additional condition, it is guaranteed to be false-name-proof.

Definition 1 (No Super-Additive price increase (NSA)) For any subset of bidders $S \subseteq N$ and $N' = N \setminus S$, and for $i \in S$, denote B_i as a bundle that maximizes i's utility, then $\sum_{i \in S} p(B_i, \bigcup_{j \in S \setminus \{i\}} \{\theta_j\} \cup \Theta_{N'}) \geq p(\bigcup_{i \in S} B_i, \Theta_{N'})$.

An intuitive description of this condition is that the price of buying a combination of bundles (the right side of the inequality) must be smaller than or equal to the sum of the prices for buying these bundles separately (the left side). This condition is also a necessary condition for a protocol to be false-name-proof, i.e., any false-name-proof protocol can be described as a PORF protocol that satisfies the NSA condition.

Here is a simple example of a PORF protocol that is false-name-proof. This protocol is called the Max Minimal-Bundle (M-MB) protocol [2]. To simplify the protocol description, a concept called a *minimal* bundle is introduced.

Definition 2 (minimal bundle) Bundle B is called minimal for bidder i, if for all $B' \subset B$ and $B' \neq B$, $v(B', \theta_i) < v(B, \theta_i)$ holds.

In this new protocol, the price of bundle B for bidder i is defined as follows:

- $p(B, \Theta_X) = \max_{B_j \subseteq M, j \in X} v(B_j, \theta_j)$, where $B \cap B_j \neq \emptyset$ and B_j is minimal for bidder j.

How this protocol works using Example 1 is described here. The prices for each bidder is determined as follows.

	$\{a\}$	$\{b\}$	$\{a, b\}$
bidder 1	\$8	\$8	\$8
bidder 2	\$6	\$5	\$6
bidder 3	\$8	\$8	\$8

The minimal bundle for bidder 1 is $\{a\}$, the minimal bundle for bidder 2 is $\{a, b\}$, and the minimal bundle for bidder 3 is $\{b\}$. The price of bundle $\{a\}$ for bidder 1 is equal to the largest evaluation value of conflicting bundles. In this case, the price is \$8, i.e., the evaluation value of bidder 2 for bundle $\{a, b\}$. Similarly, the price of bidder 2 for bundle $\{a, b\}$ is 6, i.e., the evaluation value of bidder 1 for bundle $\{a\}$. As a result, bundle $\{a, b\}$ is allocated to bidder 2.

It is clear that this protocol satisfies the allocation feasibility. For each good l, choose bidder j^* and bundle B_j^* that maximize $v(B_j, \theta_j)$ where $l \in B_j$ and B_j is minimal for bidder j. Then, only bidder j^* is willing to obtain a bundle that contains good l. For all other bidders, the price of a bundle that contains l is higher than (or equal to) his/her evaluation value.

Furthermore, it is clear that this protocol satisfies the NSA condition. In this pricing scheme, $p(B \cup B', \Theta_X) = \max(p(B, \Theta_X), p(B', \Theta_X))$ holds for all B, B', and Θ_X. Therefore, the following formula holds

$$p\left(\bigcup_{i \in S} B_i, \Theta_X\right) = \max_{i \in S} p(B_i, \Theta_X) \leq \sum_{i \in S} p(B_i, \Theta_X).$$

Furthermore, in this pricing scheme, prices increase monotonically by adding opponents, i.e., for all $X' \supseteq X$, $p(B, \Theta_{X'}) \geq p(B, \Theta_X)$ holds. Therefore, for each i, $p(B_i, \bigcup_{j \in S \setminus \{i\}} \{\theta_j\} \cup \Theta_{N'}) \geq p(B_i, \Theta_{N'})$ holds. Therefore, the NSA condition, i.e., $\sum_{i \in S} p(B_i, \bigcup_{j \in S \setminus \{i\}} \{\theta_j\} \cup \Theta_{N'}) \geq p(\bigcup_{i \in S} B_i, \Theta_{N'})$ holds.

Applications

In Internet auctions, using multiple identifiers (e.g., multiple e-mail addresses) is quite easy and identifying each participant on the Internet is virtually impossible. Combinatorial auctions have lately attracted considerable attention. When combinatorial auctions become widely used in Internet auctions, false-name-bids could be a serious problem.

Open Problems

It is shown that there exists no false-name-proof protocol that is Pareto efficient. Thus, it is inevitable to give up the efficiency to some extent. However, the theoretical lower-bound of the efficieny loss, i.e., the amount of the efficiency loss that is inevitabe for any false-name-proof protocol, is not identified yet. Also, the efficiency loss of existing false-name-proof protocols can be quite large. More efficient false-name-proof protocols in various settings are needed.

2005; Heggernes, Telle, Villanger

Problem Definition

Minimal triangulation is the addition of an inclusion minimal set of edges to an arbitrary undirected graph, such that a chordal graph is obtained. A graph is *chordal* if every cycle of length at least 4 contains an edge between two nonconsecutive vertices of the cycle.

More formally, Let $G = (V, E)$ be a simple and undirected graph, where $n = |V|$ and $m = |E|$. A graph $H = (V, E \cup F)$, where

$E \cap F = \emptyset$ is a *triangulation* of G if H is chordal, and H is a *minimal* triangulation if there exists no $F' \subset F$, such that $H' = (V, E \cup F')$ is chordal. Edges in F are called *fill edges*, and a triangulation is minimal if and only if the removal of any single fill edge results in a chordless four cycle [10].

Since minimal triangulations were first described in the mid-1970s, a variety of algorithms have been published. A complete overview of these along with different characterizations of chordal graphs and minimal triangulations can be found in the survey of Heggernes et al. [5] on minimal triangulations. Minimal triangulation algorithms can roughly be partitioned into algorithms that obtain the triangulation through elimination orderings, and those that obtain it through vertex separators. Most of these algorithms have an $O(nm)$ running time, which becomes $O(n^3)$ for dense graphs. Among those that use elimination orderings, Kratsch and Spinrad's $O(n^{2.69})$-time algorithm [8] is currently the fastest one. The fastest algorithm is an $o(n^{2.376})$-time algorithm by Heggernes et al. [5]. This algorithm is based on vertex separators, and will be discussed further in the next section. Both the algorithm of Kratsch and Spinrad [8] and the algorithm of Heggernes et al. [5] use the matrix multiplication algorithm of Coppersmith and Winograd [3] to obtain an $o(n^3)$-time algorithm.

Key Results

For a vertex set $A \subset V$, the subgraph of G induced by A is $G[A] = (A, W)$, where $uv \in W$ if $u, v \in A$ and $uv \in E\}$). The closed neighborhood of A is $N[A] = U$, where $u, v \in U$ for every $uv \in E$, where $u \in A\}$ and $N(A) = N[A] \setminus A$. A is called a *clique* if $G[A]$ is a complete graph. A vertex set $S \subset V$ is called a *separator* if $G[V \setminus S]$ is disconnected, and S is called a *minimal* separator if there exists a pair of vertices $a, b \in V \setminus S$ such that a, b are contained in different connected components of $G[V \setminus S]$, and in the same connected component of $G[V \setminus S']$ for any $S' \subset S$. A vertex set $\Omega \subseteq V$ is a *potential maximal clique* if there exists no connected component of $G[V \setminus \Omega]$ that contains Ω in its neighborhood, and for every vertex pair $u, v \in \Omega$, uv is an edge or there exists a connected component of $G[V \setminus \Omega]$ that contains both u and v in its neighborhood.

From the results in [1, 7], the following recursive minimal triangulation algorithm is obtained. Find a vertex set A which is either a minimal separator or a potential maximal clique. Complete $G[A]$ into a clique. Recursively for each connected component C of $G[V \setminus A]$ where $G[N[C]]$ is not a clique, find a minimal triangulation of $G[N[C]]$. An important property here is that the set of connected components of $G[V \setminus A]$ defines independent minimal triangulation problems.

The recursive algorithm just described defines a tree, where the given input graph G is the root node, and where each connected component of $G[V \setminus A]$ becomes a child of the root node defined by G. Now continue recursively for each of the subproblems defined by these connected components. A node H which is actually a subproblem of the algorithm is defined to be at *level* i, if the distance from H to the root in the tree is i. Notice that all subproblems at the same level can be triangulated independently. Let k be the number of levels. If this recursive algorithm can be completed for every subgraph at each level in $O(f(n))$ time, then this trivially provides an $O(f(n) \cdot k)$-time algorithm.

The algorithm in Fig. 1 uses queues to obtain this level-by-level approach, and matrix multiplication to complete all the vertex separators at a given level in $O(n^\alpha)$ time, where $\alpha < 2.376$ [3]. In contrast to the previously described recursive algorithm, the algorithm in Fig. 1 uses a partitioning subroutine that either returns a *set* of minimal separators or a potential maximal clique.

Even though all subproblems at the same level can be solved independently they may share vertices and edges, but no nonedges (i.e., pair of vertices that are not adjacent). Since triangulation involves edge addition, the number of nonedges will decrease for each level, and the sum of nonedges for all subproblems at the same level will never exceed n^2. The partitioning algorithm

Algorithm FMT - Fast Minimal Triangulation
Input: An arbitrary graph $G = (V,E)$.
Output: A minimal triangulation G' of G.

Let Q_1, Q_2 and Q_3 be empty queues; Insert G into Q_1; $G' = G$;
repeat
  Construct a zero matrix M with a row for each vertex in V (columns are added later);
  while Q_1 is nonempty **do**
    Pop a graph $H = (U, D)$ from Q_1;
    Call **Algorithm Partition**(H) which returns a vertex subset $A \subset U$;
    Push vertex set A onto Q_3;
    for each connected component C of $H[U \setminus A]$ **do**
      Add a column in M such that $M(v, C) = 1$ for all vertices $v \in N_H(C)$;
      if there exists a non-edge uv in $H[N_H[C]]$ with $u \in C$ **then**
        Push $H_C = (N_H[C], D_C)$ onto Q_2, where $uv \notin D_C$ if $u \in C$ and $uv \notin D$;
  Compute MM^T;
  Add to G' the edges indicated by the nonzero elements of MM^T;
  while Q_3 is nonempty **do**
    Pop a vertex set A from Q_3;
    if $G'[A]$ is not complete **then** Push $G'[A]$ onto Q_2;
  Swap names of Q_1 and Q_2;
until Q_1 is empty

Fast Minimal Triangulation, Fig. 1 Fast minimal triangulation algorithm

in Fig. 2 exploits this fact and has an $O(n^2 - m)$ running time, which sums up to $O(n^2)$ for each level. Thus, each level in the fast minimal triangulation algorithm given in Fig. 1 can be completed in $O(n^2 + n^\alpha)$ time, where $O(n^\alpha)$ is the time needed to compute MM^T. The partitioning algorithm in Fig. 2 actually finds a set A that defines a set of minimal separators, such that no subproblem contains more than four fifths of the nonedges in the input graph. As a result, the number of levels in the fast minimal triangulation algorithm is at most $\log_{4/5}(n^2) = 2\log_{4/5}(n)$, and the running time $O(n^\alpha \log n)$ is obtained.

Applications

The first minimal triangulation algorithms were motivated by the need to find good pivotal orderings for Gaussian elimination. Finding an optimal ordering is equivalent to solving the minimum triangulation problem, which is a nondeterministic polynomial-time hard problem. Since any minimum triangulation is also a minimal triangulation, and minimal triangulations can be found in polynomial time, then the set of minimal triangulations can be a good place to search for a pivotal ordering.

Probably because of the desired goal, the first minimal triangulation algorithms were based on orderings, and produced an ordering called a minimal elimination ordering. The problem of computing a minimal triangulation has received increasing attention since then, and several new applications and characterizations related to the vertex separator properties have been published. Two of the new applications are computing the tree-width of a graph, and reconstructing evolutionary history through phylogenetic trees [6]. The new separator-based characterizations of minimal triangulations have increased the knowledge of minimal triangulations [1, 7, 9]. One result based on these characterizations is an algorithm that computes

Algorithm Partition
Input: A graph $H = (U, D)$ (a subproblem popped from Q_I).
Output: A subset A of U such that either $A = N[K]$ for some connected $H[K]$ or A is a potential maximal clique of H (and G').

Part I: defining *P*
Unmark all vertices of H; $k = 1$;
while there exists an unmarked vertex u **do**
  if $\mathcal{E}_{\bar{H}}(U \setminus N_H[u]) < \frac{2}{5}|\bar{E}(H)|$ **then** Mark u as an **s**-vertex (stop vertex);
  else
    $C_k = \{u\}$; Mark u as a **c**-vertex (component vertex);
    while there exists a vertex $v \in N_H[C_k]$ which is unmarked or marked as an **s**-vertex **do**
      if $\mathcal{E}_{\bar{H}}(U \setminus N_H[C_k \cup \{v\}]) \geq \frac{2}{5}|\bar{E}(H)|$ **then**
        $C_k = C_k \cup \{v\}$; Mark v as a **c**-vertex (component vertex);
      else
        Mark v as a **p**-vertex (potential maximal clique vertex); Associate v with C_k;
    $k = k + 1$;
P = the set of all **p**-vertices and **s**-vertices;

Part II: defining *A*
if $H[U \setminus P]$ has a full component C **then** $A = N_H[C]$;
else if there exist two non-adjacent vertices u,v such that u is an **s**-vertex and v is an **s**-vertex or a **p**-vertex **then** $A = N_H[u]$;
else if there exist two non-adjacent **p**-vertices u and v,where u is associated with C_i and v is associated with C_j and $u \notin N_H(C_j)$ and $v \notin N_H(C_i)$ **then** $A = N_H[C_i \cup \{u\}]$;
else $A = P$;

Fast Minimal Triangulation, Fig. 2 Partitioning algorithm. Let $\bar{E}(H) = W$, where $uv \in W$ if $uv \notin D$ be the set of nonedges of H. Define $\mathcal{E}_{\bar{H}}(S)$ to be the sum of degrees in $\bar{H} = (U, \bar{E})$ of vertices in $S \subseteq U = V(H)$

the tree-width of a graph in polynomial time if the number of minimal separators is polynomially bounded [2]. A second application is faster exact (exponential-time) algorithms for computing the tree-width of a graph [4].

Open Problems

The algorithm described shows that a minimal triangulation can be found in $O((n^2 + n^\alpha) \log n)$ time, where $O(n^\alpha)$ is the time required to preform an $n \times n$ binary matrix multiplication. As a result, any improved binary matrix multiplication algorithm will result in a faster algorithm for computing a minimal triangulation. An interesting question is whether or not this relation goes the other way as well. Does there exist an $O((n^2 + n^\beta) f(n))$ algorithm for binary matrix multiplication, where $O(n^\beta)$ is the time required to find a minimal triangulation and $f(n) = o(n^{\alpha-2})$ or at least $f(n) = O(n)$. A possibly simpler and related question previously asked in [8] is: Is it at least as hard to compute a minimal triangulation as to determine whether a graph contains at least one triangle? A more algorithmic question is if there exists an $O(n^2 + n^\alpha)$-time algorithm for computing a minimal triangulation.

Problem Definition

A basic strategy to solve hard problems by dynamic programming is to express the partial solutions using a recurrence over the 2^n subsets of an n-element set U. Our interest here is in recurrences that have the following structure:

> For each subset $S \subseteq U$, in order to obtain the partial solution at S, we consider all possible ways to *partition* S into two disjoint parts, T and $S \setminus T$, with $T \subseteq S$.

Fast subset convolution [1] is a technique to speed up the evaluation of such recurrences, assuming the recurrence can be reduced to a suitable algebraic form. In more precise terms, let R be an algebraic ring, such as the integers equipped with the usual arithmetic operations (addition, negation, multiplication). We seek a fast solution to:

Problem (Subset Convolution)

INPUT: *Two functions* $f : 2^U \to R$ *and* $g : 2^U \to R$.
OUTPUT: *The function* $f * g : 2^U \to R$, *defined for all* $S \subseteq U$ *by*

$$(f * g)(S) = \sum_{T \subseteq S} f(T) g(S \setminus T). \qquad (1)$$

Here, we may view the output $f * g$ and the inputs f and g each as a table with 2^n entries, where each entry is an element of R. If we evaluate the sum (1) directly for each $S \subseteq U$ in turn, in total we will execute $\Theta\left(\sum_{s=0}^{n} \binom{n}{s} 2^s\right) = \Theta(3^n)$ arithmetic operations in R to obtain $f * g$ from f and g.

Key Results

We can considerably improve on the $\Theta(3^n)$ direct evaluation by taking advantage of the ring

structure of R (i.e., the possibility to form and, after multiplication, *cancel* linear combinations of the entries in f and g):

Theorem 1 (Fast Subset Convolution [1]) *There exists an algorithm that solves* SUBSET CONVOLUTION *in* $O(2^n n^2)$ *arithmetic operations in* R.

In what follows, we present an algorithm that proceeds via reduction to the union product and fast Möbius inversion; an alternative proof is possible via reduction to the symmetric difference product and fast Walsh–Hadamard (Fourier) transforms.

Fast Evaluation via the Union Product

Let us start with a relaxed version of subset convolution. Namely, instead of *partitioning* S, we split S in all possible ways into a *cover* (A, B) with $A \cup B = S$; this cover need not be disjoint (i.e., we need not have $A \cap B = \emptyset$) as would be required by subset convolution. For f and g as earlier, define the *union product* (*covering product*) $f \cup g : 2^U \to R$ for all $S \subseteq U$ by

$$(f \cup g)(S) = \sum_{\substack{A,B \subseteq U \\ A \cup B = S}} f(A)g(B).$$

The union product diagonalizes into a pointwise product via a pair of mutually inverse linear transforms. For a given $f : 2^U \to R$, the *zeta transform* $f\zeta : 2^U \to R$ is defined for all $S \subseteq U$ by $f\zeta(S) = \sum_{T \subseteq S} f(T)$, and its inverse the *Möbius transform* $f\mu : 2^U \to R$ is defined for all $S \subseteq U$ by $f\mu(S) = (-1)^{|S|} \sum_{T \subseteq S} (-1)^{|T|} f(T)$. Using the zeta and Möbius transforms to diagonalize into a pointwise product, the union product can be evaluated as

$$f \cup g = ((f\zeta) \cdot (g\zeta))\mu. \tag{2}$$

We can now reduce subset convolution to a union product over a polynomial ring with coefficients in the original ring R. Denote by $R[w]$ the univariate polynomial ring with indeterminate w and coefficients in the ring R. Let $f, g : 2^U \to R$ be the given input to subset convolution. Extend the input $f : 2^U \to R$ to the input $f_w : 2^U \to R[w]$ defined for all $S \subseteq U$ by $f_w(S) = f(S)w^{|S|}$. Extend g similarly to g_w. Compute the union product $f_w \cup g_w$ using (2) over $R[w]$. For all $S \subseteq U$, it now holds that the coefficient of the monomial $w^{|S|}$ in the polynomial $(f_w \cup g_w)(S)$ is equal to $(f * g)(S)$.

To compute (2) fast, we require algorithms that evaluate zeta and Möbius transforms over an arbitrary ring in $O(2^n n)$ arithmetic operations. We proceed via the following recurrence for $j = 1, 2, \ldots, n$. Let us assume that $U = \{1, 2, \ldots, n\}$. Let $z_0 = f$. Suppose $z_{j-1} : 2^U \to R$ is available. Then, we compute $z_j : 2^U \to R$ for all $S \subseteq U$ by

$$z_j(S) = \begin{cases} z_{j-1}(S) & \text{if } j \notin S; \\ z_{j-1}(S) + z_{j-1}(S \setminus \{j\}) & \text{if } j \in S. \end{cases}$$

We have $f\zeta = z_n$. The recurrence carries out exactly $2^{n-1}n$ additions in R. To compute the Möbius transform $f\mu$ of a given input f, first transform the input by negating the values of all sets that have odd size, then run the previous recurrence with the transformed input as z_0, and transform the output z_n by negating the values of all sets that have odd size. The result is $f\mu$.

Remarks The fast algorithm (2) for the union product (in a dual form that considers intersections instead of unions) is due to Kennes [9], who used the algorithm to speed up an implementation of the Dempster–Shafer theory of evidence. The fast recurrences for the zeta and Möbius transforms are special cases of an algorithm of Yates [12] for multiplying a vector with an iterated Kronecker product; see Knuth [10, §4.6.4].

Extensions and Variations

A number of extensions and variations of the basic framework are possible [1]. Iterated subset convolution (union product) enables one to solve set partitioning and packing (covering) problems. Assuming the input is sparse, more careful control over the space usage of the framework can be obtained by splitting the fast zeta transform

into two parts [5]. Similarly, the running time can be controlled by *trimming* [4] the transforms, for example, to the down-closure (subset-closure) of the desired outputs and/or the up-closure (superset-closure) of the supports of the inputs in 2^U. A trimmed complementary dual to the union product is investigated in [3].

Beyond the subset lattice $(2^U, \subseteq, \cup, \cap)$, fast algorithms are known for the zeta and Möbius transforms of lattices $(L, \leq, \vee, \wedge)$ with few join-irreducible elements [6]. This implies fast analogs of the union product (the *join product*) for such lattices.

Applications

Fast subset convolution and its variants are applied to speed up dynamic programming algorithms that build up a solution from partitions of smaller solutions such that *there is little or no interaction between the parts*. Connectivity, partitioning, and subgraph counting problems on graphs are natural examples [1–3, 8, 11].

To apply fast subset convolution, it is necessary to reduce the recurrence at hand into the algebraic form (1). Let us briefly discuss two types of recurrences as examples.

Boolean Subset Convolution

Suppose that f and g are $\{0, 1\}$-valued, and we are seeking to decide whether there exists a valid partition of S into two parts so that one part is valid by f and the other part valid by g. This can be modeled as a Boolean (OR–AND) subset convolution:

$$(f *_{\vee,\wedge} g)(S) = \bigvee_{T \subseteq S} f(T) \wedge g(S \setminus T).$$

Boolean subset convolutions can be efficiently reduced into a subset convolution (1) over the integers simply by replacing the OR with a sum and the AND with multiplication.

Min-Sum Subset Convolution

Another common situation occurs when we are seeking the *minimum cost* to partition S so that the cost of one part is measured by f and the other by g, where both f and g take nonnegative integer values. This can be modeled as a min-sum subset convolution:

$$(f *_{\min,+} g)(S) = \min_{T \subseteq S} f(T) + g(S \setminus T).$$

A min-sum subset convolution over nonnegative integers can be reduced to a subset convolution (1) over a univariate polynomial ring $\mathbb{Z}[x]$ with integer coefficients. Extend $f : 2^U \to \mathbb{Z}_{\geq 0}$ to $f_x : 2^U \to \mathbb{Z}[x]$ by setting $f_x(S) = x^{f(S)}$ for all $S \subseteq U$. Extend g similarly to g_x. Now observe that the degree of the least-degree monomial with a nonzero coefficient in the polynomial $(f_x * g_x)(S)$ equals $(f *_{\min,+} g)(S)$. This reduction requires computation with polynomials of degree $O(D)$ with $D = \max\{\max_{S \subseteq U} f(S), \max_{S \subseteq U} g(S)\}$, which may not be practical compared with the $O(3^n)$ baseline if D is large.

We refer to [1] for a more detailed discussion and examples.

Problem Definition

We consider the fully dynamic graph connectivity problem. Here we wish to maintain a data structure for a simple graph that changes over time. We assume a fixed set of n vertices and updates consist of adding and deleting single edges. The data structure should support queries for vertex pairs (u, v) of whether u and v are connected in the current graph.

Key Results

The first nontrivial data structure is due to Frederickson [2] who showed how to achieve deterministic worst-case update time $O(\sqrt{m})$ and query time $O(1)$, where m is the current number of edges of the graph. Using a sparsification technique, Eppstein et al. [1] obtained $O(\sqrt{n})$ update time. Much faster amortized bounds can be achieved. Henzinger and King [3] gave a data structure with $O(\log^3 n)$ randomized expected amortized update time and $O(\log n / \log\log n)$ query time. Update time was improved to $O(\log^2 n)$ by Henzinger and Thorup [4]. A deterministic data structure with $O(\log^2 n)$ amortized update time and $O(\log n / \log\log n)$ query time was given by Holm et al. [5]. Thorup [8] achieved a randomized expected amortized update time of $O(\log n(\log\log n)^3)$ and a query time of $O(\log n / \log\log\log n)$. The fastest known deterministic amortized data structure was given in [9]. Its update time is $O(\log^2 n / \log\log n)$ and query time is $O(\log n / \log\log n)$. Kapron et al. [6] gave a Monte Carlo algorithm with polylogarithmic worst-case operation time. A general cell-prove lower bound of $\Omega(\log n)$ was shown by Pătraşcu and Demaine [7].

In the following, we sketch the main ideas in the data structure presented in [9].

A Simple Data Structure

We start with a simple data structure similar to that of Thorup [8] (which is based on the data structure of Holm et al. [5]) that achieves $O(\log^2 n)$ update time and $O(\log n)$ query time. In the subsection below, we give the main ideas for improving these bounds by a factor of $\log \log n$.

In the following, denote by $G = (V, E)$ the current graph. The data structure maintains for each edge $e \in E$ a *level* $\ell(e)$ between 0 and $\ell_{\max} = \lfloor \log n \rfloor$. Initially, an edge has level 0 and its level can only increase over time. For the amortization, we can think of $\ell_{\max} - \ell(e)$ as the amount of credits associated with edge e, and every time $\ell(e)$ increases, e pays one credit (which may correspond to more than one unit of time). Let G_i denote the subgraph of G with vertex set V and containing the edges of level at least i and refer to each connected component of G_i as a *level i cluster*. The following invariant is maintained:

Invariant: For each i, any level i cluster contains at most $n/2^i$ vertices.

The clusters nest and thus have a forest representation. More specifically, the *cluster forest* of G is a forest $\mathcal{C}$ of rooted trees where a node u at depth i corresponds to a level i cluster $C(u)$ and the children of u correspond to level $i+1$ clusters contained in $C(u)$. Note that roots of $\mathcal{C}$ correspond to components of $G_0 = G$ and leaves correspond to vertices of G. Hence, if we can maintain $\mathcal{C}$, we can answer a connectivity query (u, v) in $O(\log n)$ time by traversing the leaf-to-root paths from u and v, respectively, and checking whether the roots are distinct.

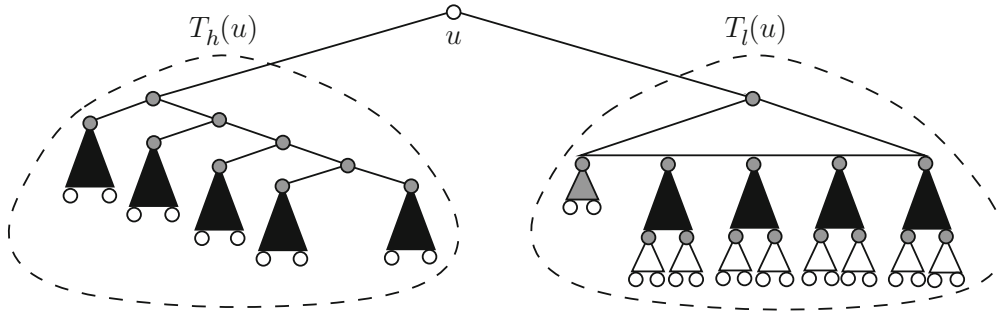
In the following, for each node $w \in \mathcal{C}$, denote by $n(w)$ the number of vertices of G contained in $C(w)$; equivalently, $n(w)$ is the number of leaves in the subtree of $\mathcal{C}$ rooted at w.

Edge insertions: When a new edge e is inserted into G, its level $\ell(e)$ is initialized to 0. Updating $\mathcal{C}$ amounts to merging the roots corresponding to the endpoints of e if these roots are distinct.

Edge deletions: Handling the deletion of an edge $e = (u, v)$ is more involved. Let $i = \ell(e)$, let $C(w_i)$ be the level i cluster containing e, and let $C(u_{i+1})$ and $C(v_{i+1})$ be the level $i+1$ clusters containing u and v, respectively. If $C(u_{i+1}) = C(v_{i+1})$, no changes occur in $\mathcal{C}$. Otherwise, consider the multigraph M obtained from $C(w_i)$ by contracting its level $i+1$ child clusters to single vertices. We search in parallel in M from $C(u_{i+1})$ and $C(v_{i+1})$, respectively, using a standard search procedure like BFS or DFS. Note that all edges visited have level i. If a search procedure visits a vertex a already visited by the other procedure, the removal of e does not disconnect the level i cluster containing e. In this case, we terminate both search procedures. Consider the two sets V_u and V_v of vertices of M visited by the procedures from $C(u_{i+1})$ resp. $C(v_{i+1})$ where we only include a in one of the sets. Then $V_u \cap V_v = \emptyset$, and since $n(w_i) \leq n/2^i$ by our invariant, either $\sum_{w \in V_u} n(w) \leq n/2^{i+1}$ or $\sum_{w \in V_v} n(w) \leq n/2^{i+1}$. Assume w.l.o.g. the former. Then we increase the level of all visited edges between vertices in V_u to $i+1$ without violating the invariant. These level increases pay for the search procedure from $C(u_{i+1})$, and since we ran the two procedures in parallel, they also pay for the search procedure from $C(v_{i+1})$.

If the two search procedures do not meet, we increase edge levels on one side as above but now $C(w_i)$ is split into two subclusters since we did not manage to reconnect it with level i edges. In this case, we recursively try to connect these two subclusters in the level $i-1$ cluster containing them. If we are in this case at level 0, it means that a connected component of $G_0 = G$ is split in two.

Performance: To show how to implement the above with $O(\log^2 n)$ update time, let us assume for now that $\mathcal{C}$ is a forest of *binary* trees. In order for a search procedure to visit a level i edge from a level $i+1$ cluster $C(a_{i+1})$ to a level $i+1$ cluster $C(b_{i+1})$, it identifies the start point a of this edge (a, b) in G by traversing the path in $\mathcal{C}$ from a_{i+1} down to leaf a. It then visits (a, b) and traverses the path in $\mathcal{C}$ from leaf b up to



Faster Deterministic Fully-Dynamic Graph Connectivity, Fig. 1 Hybrid local tree for u. Left subtree $T_h(u)$ is a simple local tree for the heavy children and the black subtrees are rank trees attached to a rank path ending in the root of $T_h(u)$. Right subtree $T_l(u)$ is a lazy local tree for the light children; see [8, 9] for details on the structure of this tree

b_{i+1}. To guide the downward searches for level i edges, we maintain for every node w of $\mathcal{C}$ a bitmap whose ith bit is 1 iff there is a level i-edge incident to a leaf in the subtree of $\mathcal{C}$ rooted at w. Since trees in $\mathcal{C}$ are binary, the start point a of (a, b) can be identified from a_{i+1} in $O(\log n)$ time using these bitmaps. Hence, each edge level increase costs $O(\log n)$. Since edge levels can only increase, an edge pays a total of $O(\log^2 n)$. Hence, we achieve an amortized update time of $O(\log^2 n)$.

Above, we assumed that trees in $\mathcal{C}$ are binary. To handle the general case, we modify $\mathcal{C}$ to a different forest $\mathcal{C}_L$ by adding a *simple local tree* $L(u)$ between each non-leaf node u and its children. Associate with each node $v \in \mathcal{C}$ a *rank* $\text{rank}(v) = \lfloor \log n(v) \rfloor$. To form $L(u)$, let C be the set of its children. As long as there are nodes in C with the same rank r, we give them a common parent with rank $r + 1$ and replace them by this parent in C. When this procedure terminates, we have at most $\log n$ *rank trees* whose roots have pairwise distinct ranks and we attach these roots to a *rank path* whose root is u; rank tree roots with bigger rank are attached closer to u than rank tree roots of smaller rank. The resulting tree $L(u)$ is binary; see the left subtree in Fig. 1 for an illustration. Hence, the trees in $\mathcal{C}_L$ are binary as well, and it is easy to see that they have height $O(\log n)$. The performance analysis above for $\mathcal{C}$ then carries through to $\mathcal{C}_L$, and we still have an amortized update time of $O(\log^2 n)$.

A Faster Data Structure

The above data structure has update time $O(\log^2 n)$ and query time $O(\log n)$. We now sketch how to speed up both bounds by a factor of $\log \log n$. We can get the speedup for query time by adding an upward shortcutting system in $\mathcal{C}_L$ where for each leaf-to-root path, we have shortcuts each skipping $\Theta(\log \log n)$ vertices. Maintaining this shortcutting system can be done efficiently. This system also gives a factor $\log \log n$ speedup for each of the upward searches performed by the search procedures described earlier. Speeding up downward searches can be done using a variant of a downward shortcutting system of Thorup [8].

These two shortcutting systems alone do not suffice to improve update time to $O(\log^2 n / \log \log n)$. The data structure needs to support merges and splits of clusters, and with the simple local trees defined above, this costs $O(\log n)$ time per merge/split, and each edge needs to pay a total of $O(\log^2 n)$ for this over all its level increases. Thorup [8] considered *lazy local trees* which can be maintained much more efficiently under cluster merges/splits. However, using these trees to form $\mathcal{C}_L$ may increase the height of trees in this forest to order $\log n \log \log n$ which will slow down our upward shortcutting system by a factor of $\log \log n$. To handle this, consider a hybrid of the simple local tree and Thorup's lazy local tree. For a non-leaf node u in $\mathcal{C}$, a child v is called *heavy* if $n(v) \geq n(u)/\log^{\epsilon} n$ where $\epsilon > 0$ is a constant that we

can pick arbitrarily small. A child that is not heavy is called *light*. Now, the *hybrid local tree* of u consists of a simple local tree $T_h(u)$ for the heavy children and a lazy local tree $T_l(u)$ for the light children; see Fig. 1 for an illustration. It can be shown that trees in $\mathcal{C}_L$ have height $O(\frac{1}{\epsilon}\log n)$ if we use hybrid local trees. Furthermore, $\mathcal{C}_L$ can be maintained efficiently under cluster merges and splits. The reason is that, although the hybrid local trees contain simple local trees which are expensive to maintain, these simple local trees are very small as each of them has at most $\log^{\epsilon} n$ leaves. Hence, maintaining them is not a bottleneck in the data structure.

Combining hybrid local trees with the two shortcutting systems suffice to obtain a factor $\log\log n$ speedup for updates and queries. This gives a deterministic data structure with $O(\log^2 n/\log\log n)$ update time and $O(\log n/\log\log n)$ query time.

Open Problems

Two main open problems for dynamic connectivity are:

- Is there a data structure with $O(\log n)$ operation time (which would be optimal by the lower bound in [7])?
- Is there a data structure with worst-case polylogarithmic operation time which is not Monte Carlo?

Problem Definition

The problem of interest is to find a virtual backbone with a certain level of fault tolerance. Virtual backbone is a subset of nodes to be in charge of routing messages among the other nodes and is a very effective tool to improve the communication efficiency of various wireless networks such as mobile ad hoc networks and wireless sensor networks [3]. It is known that a virtual backbone with smaller cardinality works more efficiently. Without the fault-tolerance consideration, the problem of computing minimum cardinality virtual backbone can be formulated as a minimum connected dominating set problem [1], which is a well-known NP-hard problem [2]. To improve the fault tolerance of a connected dominating set C in homogenous wireless networks, C needs to exhibit two additional properties [4]:

- k-connectivity: C has to be k-vertex-connected so that the virtual backbone can survive even after $k-1$ backbone nodes fail.
- m-domination: each node v has to be adjacent to at least m nodes in C so that v can be still connected even after $m-1$ neighboring backbone nodes fail.

The actual value of the two integers, k and m, can be determined by a network operator based on the degree of fault tolerance desired. The majority of the results on this topic consider homogenous wireless networks which is a wireless network of uniform hardware functionality. In this case, the network can be abstracted using the unit disk graph model [6].

Mathematical Formulation

Given a unit disk graph $G = (V, E)$, a subset $C \subseteq V$ is a dominating set in G if for each node $v \in V \backslash C$, v has a neighboring node in C. C is an m-dominating set in G if for each node $v \in V \backslash C$, v has at least m neighboring nodes in C. C is a connected dominating set in G if C is a dominating set in G and if $G[C]$, the subgraph of G induced by C, is connected. C is a k-connected dominating set in G if $G[C]$ is a dominating set in G and $G[C]$ is k-vertex-connected. Finally, C is a k-connected m-dominating set if (a) $G[C]$ is k-vertex-connected and (b) C is an m-dominating set in G. Given $G = (V, E)$, the minimum k-connected m-dominating set problem is to find a minimum cardinality subset C of V satisfying those two requirements.

Key Results

The initial discussion about the need of fault tolerance in virtual backbones has been made by Dai and Wu [4]. Since the minimum k-connected m-dominating set problem in NP-hard, many efforts are made to design a constant factor approximation algorithm for the problem. In [7], Wang et al. proposed a constant factor approximation algorithm for the problem with $k = 2$ and $m = 1$. In [8], Shang et al. introduced a constant factor approximation algorithm for arbitrary integer m and $k = 1, 2$. Later, lots of efforts are made to introduce a constant factor approximation algorithm for arbitrary k and m pairs [9–13]. However, all of them do not work or lose the claimed constant approximation bound in some instances when $k \geq 3$ [14, 15].

In [16], the authors introduce an $O(1)$ approximation algorithm, Fault-Tolerant Connected Dominating Sets Computation Algorithm (FT-CDS-CA), which computes $(3, m)$-CDSs in UDGs. The core part of the algorithm is for computing a $(3, 3)$-CDS, and then it can be easily adapted to compute $(3, m)$-CDS for any $m \geq 1$. The following sections will introduce some key ideas and results of this work.

Constant Approximation for 3-Connected m-Dominating Set

Core Idea

The algorithm starts from a 2-connected 3-dominating set $Y_0 := C_{2,3}$, which can be done

by the algorithm in [8]. Then, it augments the connectivity of the subset by adding a set of nodes $C_0 \subset V \setminus Y_0$ into Y_0 while guaranteeing the number of the newly added nodes C_0 is within a constant factor of $|Y_0|$. In order to do so, the entry introduces the concept of a good node and a bad node. A node u in a 2-connected graph G_2 is called *a good node* if $G_2 \setminus \{u\}$ is still 2-connected, that is, it cannot constitute a separator with any other node in G_2; otherwise it is *a bad node*. An important observation is that a 2-connected graph without bad nodes is 3-connected. Then the entry shows that one can always convert a bad node into a good node by adding a constant number of nodes into Y_0 while not introducing new bad nodes, and they gave an efficient way to achieve this goal. By repeatedly changing bad nodes in Y_0 into good nodes until no bad node is left, Y_0 eventually becomes 3-connected whose size is guaranteed to be within a constant factor of the optimal solution.

Brief Description

A. Removing Separators If a 2-connected graph G_2 is not 3-connected, then there exists a pair of nodes u and v, called separator of G_2, such that $G_2 \setminus \{u, v\}$ splits into several parts. It can be shown, due to the properties of UDG, that by adding the internal nodes of at most a constant number of H_3-paths (by an H_3-path we mean a path with length at most three connecting two nodes of a subgraph H of G_2, the internal nodes of which do not belong to H) into Y_0, $\{u, v\}$ is no longer a separator of Y_0, and the nodes newly added are good nodes because $Y_0 = C_{2,3}$ is a 3-dominating set.

B. Decomposition of a Connected Graph into a Leaf-Block Tree In graph theory, a block of a graph is a maximal 2-connected subgraph [5]. Given a 2-connected subgraph Y_0 (initially, this is a $C_{2,3}$) and the set X of bad points in Y_0, we select $v \in X$ as a root and compute a leaf-block tree T_0 of $Y_0 \setminus \{v\}$ [5]. Then, T_0 constitutes of a set of blocks $\{B_1, B_2, \ldots, B_s\}$ and a set of cut vertices $\{c_1, \ldots, c_t\}$. An important fact is that v can constitute a separator only with another node in $\{c_1, \ldots, c_t\}$.

C. Good Blocks vs Bad Blocks In the process of decomposing a block B with root v into a leaf-block tree, it is important to identify those blocks B_i containing *internal bad nodes*, that is, those bad nodes in B_i that cannot be connected with nodes outside B_i directly without going through v (otherwise, it is called *external bad nodes*). We call such a block B_i with (resp. without) an internal bad node *a bad block* (resp. *a good block*). A key fact is that an internal bad node in B_i can only constitute a separator of Y_0 with another node inside B_i, while this may not be true for external bad nodes.

D. Multilevel Decomposition The purpose of the multilevel decomposition is to find a block B with root v such that $B \setminus \{v\}$ contains only good blocks. We assume that $X \neq \emptyset$, since otherwise Y_0 is already 3-connected. After setting $B \leftarrow Y_0$, FT-CDS-CA first picks one $v \in X$ and starts the initial decomposition process (say level-0 decomposition). Then, $B \setminus \{v\}$ is decomposed into a (level-0) leaf-block graph T_0, which is a tree whose vertices consist of a set of blocks $\{B_1, \ldots, B_s\}$ and a set of cut vertices $\{c_1, c_2, \ldots, c_t\}$ ($s \geq 2$ and $t \geq 1$). Now, FT-CDS-CA examines each block in T_0 to see if there is a block B_i having an internal bad node in it. If all blocks are good blocks, then we are done in this step. Otherwise, there must exist some B_i having an internal node $w \in B_i$ which constitutes a separator $\{w, u\}$ of Y_0 with another node $u \in B_i \subset Y_0$. Now, set $v \leftarrow w$ and $B \leftarrow B_i$, start next level (level-1) decomposition. By repeating such process, we can keep making our problem smaller and eventually can find a block B with root v such that $B \setminus \{v\}$ contains only good blocks.

E. Merging Blocks (Reconstructing the Leaf-Block Tree with a New Root) After the multilevel decomposition process, we obtain a series of blocks: $Y_l \subset Y_{l-1} \subset \cdots Y_1 \subset Y_0$, where $Y_l = B$ is the final block with a root v such that there is no bad block in the leaf-block tree of $Y_l \setminus \{v\}$. In the induced subgraph $G[Y_l]$, v constitutes a separator with any of $c_1, c_2, \ldots, c_t$, but in Y_0 this is not necessarily true, since there exist some blocks B_i having external nodes that are adjacent

to some nodes in $Y_0 \setminus Y_l$ (otherwise, Y_l and $Y_0 \setminus Y_l$ cannot be connected with each other). So these blocks that can be connected directly with $Y_0 \setminus Y_l$ without going through v should be merged together with $Y_0 \setminus Y_l$ into a larger block. After merging all possible blocks into one bigger block, we obtain a modified leaf-block tree T_l' in which one bigger block VB (we call it a *virtual block*) is added representing all the merged blocks and $Y_0 \setminus Y_l$, and all the cut vertices c_i which do not constitute a separator with v have to be removed. Moreover, we mark every remaining cut vertex of VB as a *virtual cut vertex*. In essence, the above merging process can be considered as a process to generate a leaf-block tree directly from $Y_0 \setminus \{v\}$ with all blocks being good except possibly for the virtual block.

F. One Bad-Node Elimination At this point, we have a leaf-block tree T_l' with $V(T_l') = \{B_1, B_2, \ldots, B_s, VB\} \cup \{c_1, \ldots, c_t\}$, which is obtained through the decomposition of $Y_0 \setminus \{v\}$ (or, equivalently, through the merging process), where v is the internal bad node chosen as root in $B = Y_l$. Note in T_l', every B_i is a good block except possibly for the virtual block VB. The key point here is that we must have $s \geq 1$; otherwise v would be a good node. In this step, a simple process is employed to make either v or one of the cut vertices in $\{v_1, v_2, \ldots, v_t\} \setminus C$ (C is the set of cut vertices in the virtual block VB) to be a good node. Consider two cases: (i) if the leaf-block tree T_l' has only virtual cut vertices (i.e., T_l is a star centered at VB), then the bad node v becomes a good node by removing the separators consisting of v and the virtual cut vertices, and (ii) if the leaf-block tree T_l' has a cut vertex which is not a virtual cut vertex, then we can find a path $P = (\tilde{B}_0, \tilde{c}_1, \ldots, R)$ in T_l' with one endpoint $\tilde{B}_0$ being a leaf in the tree T_l' and the other endpoint R being a block (cut vertex) with degree larger than two or the virtual block VB (a virtual cut vertex c), if the former does not exist. In this case, two consecutive blocks $\tilde{B}_i$ and $\tilde{B}_{i+1}$ can be found which share a common cut vertex $\tilde{c}_i$. Then it can be shown that at most five H_3-paths are needed such that $\tilde{c}_i$ cannot constitute a pair of separator of Y_0 with any of the remaining cut vertex or v. Meanwhile, it is still possible that $\tilde{c}_i$ may constitute separators of Y_0 with the external nodes $\tilde{B}_i$ and $\tilde{B}_{i+1}$ (clearly $\tilde{c}_i$ cannot constitute separators of Y_0 with the internal nodes $\tilde{B}_i$ and $\tilde{B}_{i+1}$). It can be proved that the total number of external nodes in $\tilde{B}_i$ and $\tilde{B}_{i+1}$ that may constitute separators of Y_0 with $\tilde{c}_i$ is at most five. In both cases, the number of H_3-paths added to change one bad node (v or $\tilde{c}_i$) into a good node is at most a constant.

Open Problems

While Wang et al. [16] manage to introduce a constant factor approximation algorithm for the minimum k-connected m-dominating set problem in unit disk graph with $k = 3$ and arbitrary integer $m \geq 1$, it is still open to design an approximation algorithm for the case with $k \geq 4$.

Experimental Results

Wang et al.'s work [16] presents some simulation results. The results show that when a 2-connected 3-dominating set computed by Shang et al.'s approach [8] is augmented to a 3-connected 3-dominating set using their algorithm, the size of the connected dominating set will modestly increase roughly less than 25 %. Their algorithm is also compared with an optimal solution using an exhaustive computation within small-scale random unit disk graphs. The result shows the performance gap between exact algorithm and their algorithm is no greater than 39.27 %.

Keywords

Quantum noise threshold

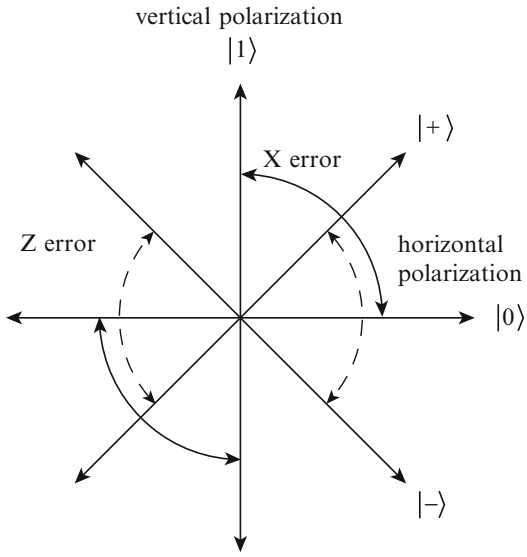
Years and Authors of Summarized Original Work

1996; Shor, Aharonov, Ben-Or, Kitaev

Problem Definition

Fault tolerance is the study of reliable computation using unreliable components. With a given noise model, can one still reliably compute? For example, one can run many copies of a classical calculation in parallel, periodically using majority gates to catch and correct faults. Von Neumann showed in 1956 that if each gate fails independently with probability p, flipping its output bit $0 \leftrightarrow 1$, then such a fault tolerance scheme still allows for arbitrarily reliable computation provided that p is below some constant threshold (whose value depends on the model details) [10].

In a quantum computer, the basic gates are much more vulnerable to noise than classical transistors – after all, depending on the implementation, they are manipulating single electron spins, photon polarizations, and similarly fragile subatomic particles. It might not be possible to engineer systems with noise rates less than



Fault-Tolerant Quantum Computation, Fig. 1 Bit-flip X errors flip 0 and 1. In a qubit, $|0\rangle$ and $|1\rangle$ might be represented by *horizontal* and *vertical polarization* of a photon, respectively. Phase-flip Z errors flip the $\pm 45°$ polarized states $|+\rangle$ and $|-\rangle$

10^{-2}, or perhaps 10^{-3}, per gate. Additionally, the phenomenon of entanglement makes quantum systems *inherently* fragile. For example, in Schrödinger's cat state – an equal superposition between a living cat and a dead cat, often idealized as $1/\sqrt{2}(|0^n\rangle + |1^n\rangle)$ – an interaction with just one quantum bit ("qubit") can collapse, or decohere, the entire system. Fault tolerance techniques will therefore be essential for achieving the considerable potential of quantum computers. Practical fault tolerance techniques will need to control high noise rates and do so with low overhead, since qubits are expensive.

Quantum systems are continuous, not discrete, so there are many possible noise models. However, the essential features of quantum noise for fault tolerance results can be captured by a simple discrete model similar to the one Von Neumann used. The main difference is that, in addition to bit-flip X errors which swap 0 and 1, there can also be phase-flip Z errors which swap $|+\rangle \equiv 1/\sqrt{2}(|0\rangle + |1\rangle)$ and $|-\rangle \equiv 1/\sqrt{2}(|0\rangle - |1\rangle)$ (Fig. 1). A noisy gate is modeled as a perfect gate followed by independent introduction of X, Z, or Y (which is both X and Z) errors with respective probabilities p_X, p_Z, p_Y. One popular model is independent depolarizing noise ($p_X = p_Z = p_Y \equiv p/3$); a depolarized qubit is completely randomized.

Faulty measurements and preparations of single-qubit states must additionally be modeled, and there can be memory noise on resting qubits. It is often assumed that measurement results can be fed into a classical computer that works perfectly and dynamically adjusts the quantum gates, although such control is not necessary. Another common, though unnecessary, assumption is that any pair of qubits in the computer can interact; this is called a *nonlocal* gate. In many proposed quantum computer implementations, however, qubit mobility is limited so gates can be applied only locally, between physically nearby qubits.

Key Results

The key result in fault tolerance is the existence of a noise *threshold*, for certain noise and computational models. The noise threshold is a positive, constant noise rate (or set of model parameters) such that with noise below this rate, reliable computation is possible. That is, given an inputless quantum circuit $\mathcal{C}$ of perfect gates, there exists a "simulating" circuit $FT\mathcal{C}$ of faulty gates such that with probability at least 2/3, say, the measured output of $\mathcal{C}$ agrees with that of $FT\mathcal{C}$. Moreover, $FT\mathcal{C}$ should be only polynomially larger than $\mathcal{C}$.

A quantum circuit with N gates can a priori tolerate only $O(1/N)$ error per gate, since a single failure might randomize the entire output. In 1996, Shor showed how to tolerate $O(1/\text{poly}(\log N))$ error per gate by encoding each qubit into a poly(log N)-sized quantum error-correcting code and then implementing each gate of the desired circuit directly on the encoded qubits, alternating computation and error correction steps (similar to Von Neumann's scheme) [8]. Shor's result has two main technical pieces:

1. The discovery of quantum error-correcting codes (QECCs) was a major result. Remarkably, even though quantum errors can be continuous, codes that correct discrete errors suffice. (Measuring the syndrome of a code block projects into a discrete error event.) The first quantum code, discovered by Shor, was a nine-qubit code consisting of the concatenation of the three-qubit repetition code $|0\rangle \rightarrow |000\rangle$, $|1\rangle \rightarrow |111\rangle$ to protect against bit-flip errors, with its dual $|+\rangle \mapsto |++\rangle$, $|-\rangle \mapsto |--\rangle$ to protect against phase-flip errors. Since then, many other QECCs have been discovered. Codes like the nine-qubit code that can correct bit- and phase-flip errors separately are known as Calderbank-Shor-Steane (CSS) codes and have quantum code words which are simultaneously superpositions over code words of classical codes in both the $|0/1\rangle$ and $|+/-\rangle$ bases.
2. QECCs allow for quantum memory or for communicating over a noisy channel. For computation, however, it must be possible to compute on encoded states without first decoding. An operation is said to be *fault tolerant* if it cannot cause correlated errors within a code block. With the n-bit majority code, all classical gates can be applied *transversely* – an encoded gate can be implemented by applying the unencoded gate to bit i of each code block, $1 \leq i \leq n$. This is fault tolerant because a single failure affects at most 1 bit in each block, and thus, failures can't spread too quickly. For CSS quantum codes, the controlled-NOT gate CNOT, $|a, b\rangle \rightarrow |a, a \oplus b\rangle$, can similarly be applied transversely. However, the CNOT gate by itself is not universal, so Shor also gave a fault-tolerant implementation of the Toffoli gate $|a, b, c\rangle \rightarrow |a, b, c \oplus (a \wedge b)\rangle$. Procedures are additionally needed for error correction using faulty gates and for the initial preparation step. The encoding of $|0\rangle$ will be a highly entangled state and difficult to prepare (unlike 0^n for the classical majority code).

However, Shor did not prove the existence of a *constant* tolerable noise rate, a noise threshold. Several groups – Aharonov/Ben-Or, Kitaev, and Knill/Laflamme/Zurek – each had the idea of using smaller codes and *concatenating* the procedure repeatedly on top of itself. Intuitively, with a distance-three code (i.e., code that corrects any one error), one expects the "effective" logical error rate of an encoded gate to be at most cp^2 for some constant c, because one error can be corrected but two errors cannot. The effective error rate for a twice-encoded gate should then be at most $c(cp^2)^2$; and since the effective error rate is dropping doubly exponentially fast in the number of levels of concatenation, the overhead in achieving a $1/N$ error rate is only poly(log N). The threshold for improvement, $cp^2 < p$, is $p < 1/c$. However, this rough argument is not rigorous, because the effective error rate is ill defined, and logical errors need not fit the same model as physical errors (e.g., they will not be independent).

Aharonov and Ben-Or and Kitaev gave independent rigorous proofs of the existence of a positive constant noise threshold, in 1997 [1, 5].

Broadly, there has since been progress on two fronts of the fault tolerance problem:

1. First, work has proceeded on extending the set of noise and computation models in which a fault tolerance threshold is known to exist. For example, correlated or even adversarial noise, leakage errors (where a qubit leaves the $|0\rangle$, $|1\rangle$ subspace), and non-Markovian noise (in which the environment has a memory) have all been shown to be tolerable in theory, even with only local gates.
2. Threshold existence proofs establish that building a working quantum computer is possible *in principle*. Physicists need only engineer quantum systems with a low enough constant noise rate. But realizing the potential of a quantum computer will require *practical* fault tolerance schemes. Schemes will have to tolerate a high noise rate (not just some constant) and do so with low overhead (not just polylogarithmic).

However, rough estimates of the noise rate tolerated by the original existence proofs are not promising – below 10^{-6} noise per gate. If the true threshold is only 10^{-6}, then building a quantum computer will be next to impossible. Therefore, second, there has been substantial work on optimizing fault tolerance schemes primarily in order to improve the tolerable noise rate. These optimizations are typically evaluated with simulations and heuristic analytical models. Recently, though, Aliferis, Gottesman, and Preskill have developed a method to prove reasonably good threshold lower bounds, up to 2×10^{-4}, based on counting "malignant" sets of error locations [3].

In a breakthrough, Knill has constructed a novel fault tolerance scheme based on very efficient distance-*two* codes [6]. His codes cannot correct any errors, and the scheme uses extensive postselection on no detected errors – i.e., on detecting an error, the enclosing subroutine is restarted. He has estimated a threshold above 3 % per gate, an order of magnitude higher than previous estimates. Reichardt has proved a threshold lower bound of 10^{-3} for a similar scheme [7], somewhat supporting Knill's high estimate. However, reliance on postselection leads to an enormous overhead at high error rates, greatly limiting practicality. (A classical fault tolerance scheme based on error detection could not be efficient, but quantum teleportation allows Knill's scheme to be at least theoretically efficient.) There seems to be tradeoff between the tolerable noise rate and the overhead required to achieve it.

There are several complementary approaches to quantum fault tolerance. For maximum efficiency, it is wise to exploit any known noise structure before switching to general fault tolerance procedures. Specialized techniques include careful quantum engineering, techniques from nuclear magnetic resonance (NMR) such as dynamical decoupling and composite pulse sequences, and decoherence-free subspaces. For very small quantum computers, such techniques may give sufficient noise protection.

It is possible that an inherently reliable quantum-computing device will be engineered or discovered, like the transistor for classical computing, and this is the goal of *topological* quantum computing [4].

Applications

As quantum systems are noisy and entanglement fragile, fault tolerance techniques will probably be essential in implementing any quantum algorithms – including efficient factoring and quantum simulation.

The quantum error-correcting codes originally developed for fault tolerance have many other applications, including quantum key distribution.

Open Problems

Dealing with noise may turn out to be the most daunting task in building a quantum computer. Currently, physicists' low-end estimates of achievable noise rates are only slightly below theorists' high-end (mostly simulation based) estimates of tolerable noise rates, at reasonable levels of overhead. However, these estimates are made with different noise models – most simulations are based on the simple independent depolarizing noise model, and threshold lower bounds for more general noise are much lower. Also, both communities may be being too optimistic. Unanticipated noise sources may well appear as experiments progress. The probabilistic noise models used by theorists in simulations may not match reality closely enough, or the overhead/threshold tradeoff may be impractical. It is not clear if fault-tolerant quantum computing will work in practice, unless inefficiencies are wrung out of the system. Developing more efficient fault tolerance techniques is a major open problem. Quantum system engineering, with more realistic simulations, will be required to understand better various tradeoffs and strategies for working with gate locality restrictions.

The gaps between threshold upper bounds, threshold estimates, and rigorously proven threshold lower bounds are closing, at least for simple noise models. Our understanding of what to expect with more realistic noise models

is less developed, though. One current line of research is in extending threshold proofs to more realistic noise models – e.g., [2]. A major open question here is whether a noise threshold can be shown to even *exist* where the bath Hamiltonian is unbounded – e.g., where system qubits are coupled to a non-Markovian, harmonic oscillator bath. Even when a threshold is known to exist, rigorous threshold lower *bounds* in more general noise models may still be far too conservative (according to arguments, mostly intuitive, known as "twirling") and, since simulations of general noise models are impractical, new ideas are needed for more efficient analyses.

Theoretically, it is of interest what is the best asymptotic overhead in the simulating circuit FTC versus C? Overhead can be measured in terms of size N and depth/time T. With concatenated coding, the size and depth of FTC are $O(N\text{polylog } N)$ and $O(T\text{polylog } N)$, respectively. For classical circuit C, however, the depth can be only $O(T)$. It is not known if the quantum depth overhead can be improved.

Experimental Results

Fault tolerance schemes have been simulated for large quantum systems, in order to obtain threshold estimates. For example, extensive simulations including geometric locality constraints have been run by Thaker et al. [9].

Error correction using very small codes has been experimentally verified in the lab.

2011; Grohe, Kawarabayashi, Marx, Wollan

Problem Definition

To *subdivide* an edge e in a graph G with endpoints u and v, delete the edge from the graph and add a path of length two connecting the vertices u and v. A graph G is a *subdivision* of graph H if G can be obtained from H by repeatedly subdividing edges. A graph H is a *topological subgraph* (or *topological minor*) of graph G if a subdivision of H is a subgraph of G. Equivalently, H is a topological subgraph of G if H can be obtained from G by deleting edges, deleting vertices, and suppressing vertices of degree 2 (to *suppress* a vertex of degree 2, delete the vertex and add an edge connecting its two neighbors). The notion of topological subgraphs appears in the classical result of Kuratowski in 1935 stating that a graph is planar if and only if it does not have a topological subgraph isomorphic to K_5 or $K_{3,3}$. This entry considers the problem of determining, given a graph G and H, whether G contains H as a topological minor.

Topological Subgraph Testing

Input: Graphs G and H
Output: Determine if H is a topological subgraph of G

Observe that a graph G on n vertices contains the cycle of length n as a topological subgraph if and only if G contains a Hamiltonian cycle. Thus, it is NP-complete to decide if H is a topological subgraph of a graph G with no further restrictions on G or H.

Previous Work

The algorithmic problem of testing for topological subgraphs was already studied in the 1970s by Lapaugh and Rivest [12] (also see [7]). Fortune, Hopcroft, and Wyllie [6] showed that the analogous problem in directed graphs is NP-complete even when H is a fixed small graph. Robertson and Seymour, as a consequence of their seminal work on graphs minors, showed that for a fixed graph H, there exists a polynomial time algorithm to check whether H is a topological subgraph of a graph G given in input. However, the running time of the Robertson-Seymour algorithm is $|V(G)|^{O(|V(H)|)}$. Following this, Downey and Fellows [4] (see also [5]) conjectured that the problem of topological subgraph testing is fixed parameter tractable: they conjectured that there exists a function f and a constant c such that there exists an algorithm for testing whether a graph H is a topological subgraph of G which runs in time $f(|V(H)|) \cdot |V(G)|^c$.

The problem of topological subgraph testing is closely related to that of minor testing and the k-disjoint paths problem. A graph H is a *minor* of G if H can be obtained from a subgraph of G by contracting edges. The k-disjoint paths problem instead takes as input k pairs of vertices $(s_1, t_1), \ldots, (s_k, t_k)$ of vertices in a graph G and asks if there exist pairwise internally vertex disjoint paths $P_1, \ldots, P_k$ such that the endpoints of P_i are s_i and t_i for all $1 \leq i \leq k$. Robertson and Seymour [13] considered a model of *labeled minor containment* that unites these two problems and showed that there is an $O(|V(G)|^3)$ time algorithm for both H-minor testing for a fixed graph H and the k-disjoint paths problem for a fixed value k.

For every H, there exists a finite list $H_1, \ldots, H_t$ of graphs such that a graph G contains H as a minor if and only if G contains H_i as a topological minor for some index i; this follows from the definition of minor and topological minor. Thus, the problem of minor testing reduces to the harder problem of topological minor testing. It is not difficult to reduce the problem of topological subgraph containment for a fixed graph H to the k-disjoint paths problem. For each vertex v of H, guess a vertex v' of G, and then for each edge uv of H, and seek to find a path connecting u' and v' in G such that these $|E(H)|$ paths are pairwise internally vertex disjoint. This approach yields the $|V(G)|^{O(|V(H)|)}$ time algorithm for topological subgraph testing mentioned above.

Key Results

The following theorem of Grohe, Kawarabayashi, Marx, and Wollan [8] shows that topological

subgraph testing is fixed parameter tractable, confirming the conjecture of Downey and Fellows.

Theorem 1 *For every fixed, undirected graph H, there is an $O(|V(G)|^3)$ time algorithm that decides if H is a topological subgraph of G.*

Outline of the Proof

The algorithm given by Theorem 1 builds on the techniques first developed by Robertson and Seymour in their algorithm for minor testing and the k-disjoint paths problem. Fix a graph H and let G be a graph given in input. The algorithm separately considers each of the following three cases:

1. The tree-width of G is bounded (by an appropriate function on $|V(H)|$);
2. G has large tree-width, but the size of the largest clique minor is bounded (again by an appropriate function on $|V(H)|$);
3. G has a large clique minor.

Note that in the third case, the existence of a large clique minor necessarily forces the graph G to have large tree-width. We do not use any technical aspects of the parameter tree-width here and direct interested readers to [1, 2] for further discussion of this topic.

The Robertson-Seymour algorithm for minor testing offers a roadmap for the proof of Theorem 1; the discussion of the proof of Theorem 1 highlights where the proof builds on the tools of Robertson and Seymour and where new techniques are required. As in Robertson-Seymour's algorithm for minor testing, the algorithm considers a rooted version of the problem.

G has Bounded Tree-Width

Numerous problems can be efficiently solved when the input graph is restricted to have bounded tree-width (see [1, 3] for examples). For example, the k-disjoint paths problem can be solved in linear time in graphs of bounded tree-width [15]. Standard dynamic programming techniques can be used to solve the more general rooted version of the topological subgraph problem which the algorithm considers.

G has Large Tree-Width, but no Large Clique Minor

Robertson and Seymour showed that graphs of large tree-width which do not contain a fixed clique minor must contain a large, almost planar subgraph [11, 13]; this result is sometimes known as the flat-wall theorem. The proof of correctness for their disjoint paths algorithm hinges upon this theorem by showing that a vertex in the planar subgraph can be deleted without affecting the feasibility of a given disjoint paths problem. The proof of Theorem 1 builds on this approach. Given graphs G and H, say a vertex $v \in V(G)$ is *irrelevant* for the problem of topological subgraph testing if G contains H as a topological minor if and only if $G - v$ contains H as a topological minor. If the algorithm can efficiently find an irrelevant vertex v, then it can proceed by recursing on the graph $G - v$. In order to apply a similar irrelevant vertex argument to that developed by Robertson and Seymour for the disjoint paths problem, the proof of Theorem 1 shows that a large flat wall contains an irrelevant vertex for a given topological subgraph testing problem by first generalizing several technical results on rerouting systems of paths in graphs [10, 13] as well as deriving a stronger version of the flat-wall theorem.

G has a Large Clique Minor

In the Robertson and Seymour algorithm for minor testing, once the graph can be assumed to have a large clique minor, the algorithm trivially terminates. When considering the k-disjoint paths problem, again it is a relatively straightforward matter to find an irrelevant vertex for a given disjoint paths problem assuming the existence of a large clique minor. Instead, if we are considering the problem of testing topological subgraph containment, the presence of a large clique minor does not yield an easy recursion. Consider the case where we are testing for the existence of a topological subgraph of a 4-regular graph H in a graph G which contains a subcubic subgraph G' such that G' has a large clique minor. Whether or not G' will prove useful in finding a topological subgraph of H in G will depend entirely on whether

or not it is possible to link many vertices of degree four (in G) to the clique minor in G' and not on the size itself of the clique minor in G'. Similar issues arise in [9] when developing structure theorems for excluded topological subgraphs.

The proof of Theorem 1 proceeds by considering separately the case when the large-degree vertices can be separated from the clique minor by a bounded sized separator or not. If they cannot, one can find the necessary rooted topological minors. Alternatively, if they can, the algorithm recursively calculates the rooted topological minors in subgraphs of G and replaces a portion of the graph with a bounded size gadget. This portion of the argument is substantially different from the approach of Robertson and Seymour to minor testing and comprises the major new development in the proof.

Applications

An *immersion* of a graph H into a graph G is defined like a topological embedding, except that the paths in G corresponding to the edges of H are only required to be pairwise edge disjoint instead of pairwise internally vertex disjoint. Formally, an immersion of H into G is a mapping ν that associates with each vertex $v \in V(H)$ a distinct vertex $\nu(v) \in V(G)$ and with each edge $e = vw \in E(H)$ a path $\nu(e)$ in G with endpoints $\nu(v)$ and $\nu(w)$ in such a way that the paths $\nu(e)$ for $e \in E(H)$ are mutually edge disjoint. Robertson and Seymour [14] showed that graphs are well quasi-ordered under the immersion relation, proving a conjecture of Nash-Williams. In [8], the authors give a construction which implies the following corollary of Theorem 1.

Corollary 1 *For every fixed undirected graph H, there is an $O(|V(G)|^3)$ time algorithm that decides if there is an immersion of H into G.*

Again, the algorithm is uniform in H, which implies that the immersion problem is fixed parameter tractable. This answers another open question by Downey and Fellows [4, 5]. Corollary 1 also holds for the more restrictive "strong immersion" version, where $\nu(v)$ cannot be the internal vertex of the path $\nu(e)$ for any $v \in V(G)$ and $e \in E(G)$.

2013; Dósa, Sgall

Problem Definition

In the classical bin packing (BP) problem, we are given a set of items with rational sizes between 0 and 1, and we try to pack them into a minimum number of bins of unit size so that no bin contains items with total size more than 1. The problem definition originates in the early 1970s: Johnson's thesis [10] on bin packing together with Graham's work on scheduling [8, 9] (among other pioneering works) started and formed the whole area of approximation algorithms. The First Fit (FF) algorithm is one among the first algorithms which were proposed to solve the BP problem and analyzed in the early works. FF performs as follows: The items are first given in some list L and then are handled by the algorithm in this given order. Then, algorithm FF packs each item into the first bin where it fits; in case the item does not fit into any already opened bin, the algorithm opens a new bin and puts the actual item there. A closely related algorithm is Best Fit (BF); it packs the items also according to a given list, but each item is packed into the most full bin where it fits or the item is packed into a new bin only if it does not fit into any open bin. If the items are ordered in the list by decreasing sizes, the algorithms are called as FFD (first fit decreasing) and BFD (best fit decreasing).

Applications

There are many applications for bin packing (in industry, computer science, etc), and BP has many different versions. It is worth noting that BP has a strong relationship to the area of scheduling. So the scientific communities of packing and scheduling are almost the same.is a major

Key Results

It was immediately shown in the early works [6,12,15] that the asymptotic approximation ratio of FF and BF bin packing is 1.7. It means that if the optimum packing needs OPT bins, algorithm FF never uses more than $1.7 \cdot OPT + C$ bins, where C is a fixed constant (The same holds for the BF algorithm). It is easy to see that the multiplicative factor, i.e., 1.7, cannot be smaller. But the minimum value of the C constant, for which the statement remains valid, is not a simple issue.

First, Ullman in 1971 [15] showed that C can be chosen to be 3. But this is not the best choice.

Soon, the additive term was decreased in [6] to 2 and then in [7] to $FF \leq \lceil 1.7 \cdot OPT \rceil$; since both FF and OPT denote integer numbers, this is the same as $FF \leq 1.7 \cdot OPT + 0.9$.

Then, for many years, no new results were published regarding the possible decreasing of the additive term.

Another direction is considered in the many-times-cited work of Simchi-Levy [14]. He showed that the absolute approximation ratio of FF (and BF) is at most 1.75. It means that if we do not use an additive term in the inequality, then $FF \leq 1.75 \cdot OPT$ is valid.

Now, if we are interested in the tight result, we have two options. One is that we can try to decrease the multiplicative factor in the inequality of the absolute approximation ratio, i.e., the question is the following: What is the smallest number, say α, that can be substituted in the place of 1.75 such that the inequality $FF \leq \alpha \cdot OPT$ is valid for any input? The other direction is the following: What is the smallest possible value of the additive constant C such that the $FF \leq 1.7 \cdot OPT + C$ inequality is true for every input?

The next step was made independently from each other in two works. Xia and Tan [17] and Boyar et al. [1] proved that the absolute approximation ratio of FF is not larger than $12/7 \approx 1.7143$.

Moreover, [17] also dealt with the other direction and decreased the value of C to $FF \leq 1.7 \cdot OPT + 0.7$.

If we are interested in how much the additive term (or the α factor) can be decreased, we must also deal with the lower bound of the algorithm. Regarding this, the early works give examples for both the asymptotic and absolute ratios. For the asymptotic bound, there exists such input for which $FF = 17k$ holds whenever $OPT = 10k + 1$; thus, the asymptotic upper bound 1.7 is tight, see [6, 12, 15]. For the absolute ratio, an example is given with $FF = 17$ and $OPT = 10$, i.e., an instance with approximation ratio exactly 1.7 [6, 12]. But no example was shown for large values of OPT.

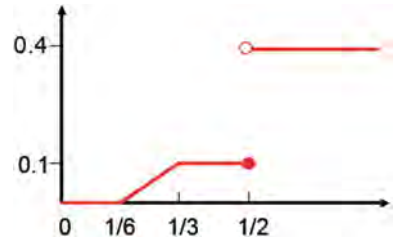
It means that soon, it turned out that the value of the multiplicative factor of the absolute approximation ratio (i.e., α) cannot be smaller than 1.7 or, regarding the another measure, the additive constant cannot be chosen to be smaller than zero. But this remained an open question for 40 years whether the smallest possible choice of α is really 1.7 or, in other words, the smallest possible choice of the additive term is really zero.

Finally, the papers [3, 4] answered the question. Lower-bound instances are given with $FF = BF = \lfloor 1.7 \cdot OPT \rfloor$ for any value of OPT, and it is also shown that $FF = BF \leq \lfloor 1.7 \cdot OPT \rfloor$ holds for any value of OPT. So this is the tight bound which was looked for 40 years.

Methods

To prove the upper bound, the main technique is the usage of a weighting function. Any item gets some weight according to its size. Then, to get the asymptotic ratio, it is only needed that any optimal bin has a weight at most 1.7 and any bin in the FF packing (with bounded exception) has a weight at least 1.

In the recent paper [13], a nice and surprising idea is presented: The same weight function that was used traditionally in the analysis is divided into two parts: scaled size and bonus. Thus, the weight of any item a is $w(a) = s(a) + b(a)$, where $s(a) = 6/5 \cdot a$ is the scaled size of the item and the remaining part $b(a)$ is the bonus of the item, which is defined as follows:



First Fit Algorithm for Bin Packing, Fig. 1 The bonus function

$b(a)$ is zero if the size of the item is below 1/6. The bonus is just 0.1 if a is between 1/3 and 1/2, and it is 0.4 if the size is above 1/2. Between 1/6 and 1/3, the bonus function is continuous and linear. We emphasize that this is the *same* old weighting function, only in a new costume. The bonus function can be seen in Fig. 1.

By this separation, it is easy to show that the weight of any optimal bin is at most 1.7, and this implies that the weight of the whole instance is at most $1.7 \cdot OPT$.

The key part is to show that on average, the weight of each FF bin is at least 1. This property trivially holds if the total size of the items in the bin is at least 5/6. It is not hard to handle the bins with single items; here, almost all of them must be bigger than 1/2, and such items have huge bonus (i.e., 0.4), together with the scaled size, that is, at least 0.6, we are again done. In the remaining bins, the next tricky calculation is used: The scaled size of the bin plus the bonus of the *following* bin is at least 1. By this trick, the proof will be almost done, but several further examinations are also needed for completing the tightness result.

New Lower Bound Construction

The lower bound construction works in the following way. Suppose, for the sake of simplicity,

that OPT = 10k for some integer k, and let $\varepsilon > 0$, a small value.

The input consists of OPT small items of size approximately 1/6, followed by OPT medium-sized items of size approximately 1/3, followed by OPT large items of size exactly $1/2 + \varepsilon$. The optimum packs in each bin one item from each group. FF packs the small items into 2k bins with 5 items with the exception of the first and last of these bins, which will have 6 and 4 items, respectively. The sizes of items differ from 1/3, or differ from 1/6, in both directions by a small amount δ_i. Finally, every large item will occupy its own bin.

In the original construction, the choice of the small and medium-sized items is a bit difficult, so one could think that the construction *must* be so difficult, and thus, the construction cannot be tightened. It turns out, however, that this is not the case. The construction can be modified in the way that δ_i is exponentially decreasing but remains greater than ε for all i. This guarantees that only the item with the largest δ_i in a bin is relevant for its final size, and this in turn enables us to order the items so that no additional later item fits into these bins. Thus, by the modification, not only the construction is simpler but it also makes possible to prove the tightness.

Open Problems

There are many open problems regarding bin packing. For example, the tight absolute approximation ratio of BFD is an open question (For FFD, it was recently proved that $FFD \leq (11/9) \cdot OPT + 6/9$ and this is the tight result, see [5].).

Problem Definition

NP-hard problems are believed to be intractable. This is the widely believed assumption that $P \neq NP$. For all our problems, the size of their input is denoted by n. In parameterized complexity, the input is refined to (I, k) with k a parameter related to the input, and the goal is to find an exact algorithm for the problem that runs in time $f(k) \cdot n^{O(1)}$, for some function f. In this survey, we parameterize by the optimum value of the instance unless stated otherwise. In addition, the optimum is always integral. In approximation algorithms, a ρ approximation for a minimization (maximization) problem P is a polynomial time algorithm A, such that for any instance I, A returns a solution of value $A(I)$ and $A(I)/\text{OPT}(I) \leq \rho$ ($\text{OPT}(I)/A(I) \leq \rho$) with $\text{OPT}(I)$ the optimum value for the instance. In both subjects, there are intractability results. The class FPT are the problems that admit an $f(k)n^{O(1)}$ time, exact solution for some function f. The classes $W[i]$ for every integer $i \geq 1$ satisfy FPT $\subseteq W[1] \subseteq W[2] \subseteq \ldots$. It is widely believed that all inclusions are strict. Consider the CLIQUE problem. Given a graph $G(V, E)$, a subset $U \subseteq V$, forms a *clique*, if for every $u, v \in U$, $(u, v) \in E$. The problem is

Input: A graph G and a parameter k.
Question: Is there in G a clique U of size $|U| \geq k$?

In [21], it is proved that CLIQUE admits no $n^{1-\epsilon}$ approximation unless $P = NP$. It is known that CLIQUE is $W[1]$-complete. Thus it is considered highly unlikely that CLIQUE $\in$ FPT. The SETCOVER problem is defined as follows:

Input: A universe U and a collection $\mathcal{S} = \{S_i\}$ of subsets of $\mathcal{U}$ and a parameter k.
Question: Is there a subcollection $\mathcal{S}' \subseteq \mathcal{S}$ containing at most k sets so that $\bigcup_{S_i \in \mathcal{S}'} S_i = \mathcal{U}$?

SETCOVER is $W[2]$-complete. In addition, Raz and Safra [27] show that unless $P = NP$, SETCOVER admits no $c \ln n$ algorithm for some constant c, almost matching the simple greedy $\ln n + 1$ ratio approximation algorithm.

Our Subject

Formally, we deal with the following subject: An algorithm for a minimization (resp., maximization) problem P is called an (r, t)-FPT-approximation algorithm for P with input parameter k, if the algorithm takes as input an instance I with value OPT and an integer parameter k and either computes a feasible solution to I with value at most $k \cdot r(k)$ (resp., at least $k/r(k)$ and $k/r(h) = o(k)$) or computes a certificate that $k <$ OPT (resp., $k >$ OPT) in time $t(k) \cdot |I|^{O(1)}$. The requirement that $k/r(k) = o(k)$ avoids returning a single vertex in the clique problem, claiming OPT approximation.

A problem is called (r, t)-FPT-inapproximable (or, (r, t)-FPT-hard) if it does not admit an (r, t)-FPT-approximation algorithm. An FPT approximation is mainly interesting if the problem is $W[1]$-hard and allowing running time $f(k) \cdot n^{O(1)}$ gives improved approximation. We restrict our attention to this scenario. Thus, we do not discuss many subjects such as approximations in OPT that run in *polynomial*

Supported in part by NSF grant number 1218620.

time in n and upper and lower bounds, on algorithms with sub exponential time in n, for several conbinatorial problems.

Our Complexity Assumption

We assume the following conjecture throughout Impagliazzo et al. [4] conjectured the following:

> *Exponential Time Hypothesis (*ETH*)*
> 3-SAT cannot be solved in $2^{o(q)}(q+m)^{O(1)}$ time where q is the number of variables and m is the number of clauses.

The following is due to [4].

Lemma 1 *Assuming* ETH, *3-SAT cannot be solved in* $2^{o(m)}(q+m)^{O(1)}$ *time where* q *is the number of variables and* m *is the number of clauses.*

It is known that the ETH implies that $W[1] \neq$ FPT. This implies that $W[2] \neq$ FPT as well.

Key Results

We survey some FPT-approximability and FPT-inapproximability results. Our starting point is a survey by Marx [23], and we also discuss recent results. The simplest example we are aware of in which combining FPT running time and FPT-approximation algorithm gives an improved result is for the strongly connected directed subgraph (SCDS) problem.

Input: A directed graph $G(V, E)$, a set $T = \{t_1, t_2, \ldots, t_p\}$ of terminals, and an integer k.
Question: Is there a subgraph $G'(V, E')$ so that $|E'| \leq k$ and for every $t_i, t_j \in T$, there is a directed path in G' from t_i to t_j and vice versa?

The problem is in $W[1]$-hard. The best approximation algorithm known for this problem is n^{ϵ} for any constant ϵ. See Charikar et al. [5].

The following is due to [7].

Theorem 1 *The SCDS problem admits an* FPT *time* 2 *approximation ratio.*

Proof The directed Steiner tree problem is given a directed edge-weighted graph and a root r and a set $T = \{t_1, t_2, \ldots, t_p\}$ of terminals; find a minimum cost-directed tree rooted by r containing T. This problem belongs to FPT. See Dreyfus and Wagner [12]. Note that for every terminal t_i, any feasible solution contains a directed tree from t_i to T and a a reverse-directed Steiner tree from T to t_i. These two problems can be solved optimally in FPT time. In the second application, we reverse the direction of edges before we find the directed Steiner tree. Moreover, two such trees give a feasible solution for the SCDS problem as every two terminals t_j, t_k have a path via t_i. Clearly, the solution has value at most $2 \cdot$ OPT with OPT the optimum value for the SCDS instance. The claim follows.

Definition 1 A *polynomial time approximation scheme* (PTAS) for a problem P is a $1+\epsilon$ approximation for any constant ϵ that runs in time $n^{f(1/\epsilon)}$. An *EPTAS* is such an algorithm that runs in time $f(1/\epsilon)n^{O(1)}$.

The *vertex cover* problem is to select the smallest possible subset U of V so that for every edge (u, v), either $u \in U$ or $v \in U$ (or both). In the *partial vertex cover problem*, a graph $G(V, E)$ and an integer k are given. The goal is to find a set U of k vertices that is touched by the largest number of edges. An edge (u, v) is touched by a set U if $u \in U$ or $v \in U$ or both. It is known that this problem admits no *PTAS* unless $P = NP$ (see Dinur and Safra [10]). The corresponding minimum partial vertex cover problem requires a set of k vertices touched by the *least number of edges*. This problem admits no better than 2-ratio, under the *small set expansion conjecture*. See [15]. Both problems belong to $W[1]$-hard. The following theorem of [23] relies on a technique called *color coding* [1].

Theorem 2 ([23]) *For every constant* ϵ*, the partial vertex cover problem (and in a similar proof the minimum partial vertex cover problem) admits an EPTAS that runs in time* $f(k, 1/\epsilon) \cdot n^{O(1)}$ *with* n *the number of vertices in the graph.*

Proof Let $D = \binom{k}{2}/\epsilon$. Sort the vertices $v_1, v_2, \ldots, v_n$ by nonincreasing degrees. If for

the largest degree, $d(v_1)$ satisfies $d(v_1) \geq D$, the algorithm outputs the set $\{v_1, v_2, \ldots, v_k\}$. These k vertices cover at least $\sum_{i=1}^{k} \deg(v_i) - \binom{k}{2}$ edges. Clearly, OPT $\leq \sum_{i=1}^{k} \deg(v_i)$. Hence, the value of the constructed solution is at least

$$\frac{\sum_{i=1}^{k} \deg(v_i) - \binom{k}{2}}{\sum_{i=1}^{k} \deg(v_i)} \geq 1 - \frac{\binom{k}{2}}{D} \geq 1 - \frac{\epsilon}{2} \geq \frac{1}{1+\epsilon}$$

times the optimum for a $1+\epsilon$ approximation. In the other case, the optimum OPT $\leq k \cdot D$. We guess the correct value of the optimum by trying all values between $1, \ldots, k \cdot D$. Fix the run with the correct OPT. Let E^* be the set of OPT edges that are touched by the optimum. An OPT labeling is an assignment of a label in $\{1, \ldots, \text{OPT}\}$ to the edges of E. We show that if the labels of E^* are pairwise distinct, we can solve the problem in time $h(k, 1/\epsilon)$. Let $\{u_1, u_2, \ldots, u_k\}$ be the optimum set. Let L_i be the labels of the edges of u_i. As all labels of E^* are pairwise distinct, $\{L(u_i)\}$ is a disjoint partition of all labels (as otherwise there is a labeling with less than OPT labels). The number of possible partitions of the labels into k sets is at most k^{OPT}. Given the *correct* partition $\{L_i\}$, we need to match every L_i with a vertex u_i so that the labels of u_i are L_i. This can be done in polynomial time by matching computation. To get a labeling with different pairwise labels on E^*, we draw for every edges a label between 1 and OPT, randomly and independently. The probability that the labels of E^* are disjoint is more than $1/\text{OPT}^{\text{OPT}}$. Repeating the random experiment for OPT^{OPT} times implies that with probability at least $1 - 1/e$, one of the labeling has different pairwise labels for E^*. This result can be derandomized [1].

We consider one example in which OPT is not the parameter [23]. Consider a graph that contains a set $X = \{x_1, \ldots, x_k\}$. so that $G \setminus X$ is a planar graph. Thus the parameter here is the number of vertices that need to be removed to make the graph. Consider the minimum coloring problem on G. We can determine the best coloring of X in time k^k. Then we can color $G \setminus X$ by four (different) colors. A simple calculation shows that this algorithm has approximation ratio at most $7/3$.

The following is a simple relation exist between *EPTAS* and FPT theory.

Proposition 1 *If an optimization problem P admits an EPTAS, then $P \in$ FPT.*

Proof We prove the theorem for minimization problems. For maximization problems, the proof is similar. Assume that P has a $1+\epsilon$ approximation that runs in time $f(1/\epsilon) \cdot n^{O(1)}$. Set $\epsilon = 1/(2k)$. Using the EPTAS algorithm gives an $f(2k)n^{O(1)}$ time $(1+\epsilon)$ approximation. If the optimum is at most k, we get a solution of size at most $(1+\epsilon)k = k + 1/2 < k + 1$. As the solution is integral, the cost is at most k. If the minimum is $k+1$, the approximation will not return a better than $k+1$ size solution. Thus the approximation returns cost at most k if and only if there is a solution of size at most k.

Thus we can rule out the possibility of an *EPTAS* if a problem is $W[1]$-hard. For example, this shows that the maximum independent set for unit disks graphs admits no *EPTAS* as it belongs to $W[1]$. See many more examples in [23]. Chen Grohe and Grüber [6] provide an early discussion of our topic. Lange wrote a PDF presentation for recent FPT approximation. The following theorem is due to Grohe and Grüber (see [19]).

Theorem 3 *If a maximization problem admits an FPT-approximation algorithm with performance ratio $\rho(k)$, then for some function ρ', there exists a $\rho'(k)$ polynomial time approximation algorithm for the problem.*

In the traveling salesperson with a deadline, the input is a metric on n points and a set $D \subseteq V$ with each $v \in D$ having a deadline t_v. A feasible solution is a simple path containing all vertices, so that *for every* $v \in D$, the length of the tour until v is at most t_v. The problem admits no constant approximation and is not in FPT when parameterized by $|D|$. See Bockenhauer, Hromkovic, Kneis, and Kupke [2]. In this entry, the authors give a 2.5 approximation that runs in time $n^{O(1)} + |D|! \cdot |D|$. The parameterized

undirected multicut problem is given an undirected graph and a collection $\{s_i, t_i\}_{i=1}^{m}$ of pairs, and a parameter k is possible to remove at most k edges and disconnect all pairs. Garg, Vazirani, and Yannakakis give an $O(\log n)$ approximation for the problem [16]. In 2009, it was given a ratio 2 fixed-parameter approximation (Marx and Razgon) algorithm. However, Marx and Razgon [25] and Bousquet et al. [3] show that this problem is in fact in FPT. Fellows, Kulik, Rosamond, and Shachnai give the following tradeoff (see [14]). The best known exact time algorithm for the vertex cover problem has running time 1.273^k. The authors show that if we settle for an approximation result, then the running time can be improved. Specifically, they gave $\alpha \geq 1$ approximation for vertex cover that runs in time $1.237^{(2-\alpha)k}$. The minimum edge dominating set problem is given a graph and a parameter k, and there is a subset $E' \subset E$ of size at most k so that every edge in $E \setminus E'$ is adjacent to at least one edge in E'. Escoffier, Monnot, Paschos, and Mingyu Xiao (see [13]) prove that the problem admits a $1 + \epsilon$ ratio for any $0 \leq \epsilon \leq 1$ that runs in time $2^{(2-\epsilon)\cdot k}$. A kernel for a problem P is a reduction from an instance I to an instance I' whose size is $g(k)$, namely, a function of k, so that a yes answer for I implies a yes answer for I' and a no answer for I implies a no answer for I'. If a kernel exists, it is clear that $P \in$ FPT. However, the size of the kernel may determine what is the function of k in the $f(k)\cdot n^{O(1)}$ exact solution. The following result seems interesting because it may not be intuitive. In the *tree deletion* problem, we are given a graph $G(V, E)$ and a number k and the question is if we can delete up to k vertices and get a tree. Archontia Giannopoulou, Lokshtanov, Saket, and Suchy prove (see [17]) that the tree deletion problem admits a kernel of size $O(k^4)$. However, the problem does not admit an approximation ratio of OPT^c for any constant c.

Other Parameters

An *independent set* is a set vertices so that no two vertices in the set share an edge. In parameterized version given k, the question is if there is an independent set of size at least k. Clearly, the problem is $W[1]$-complete. Grohe [18] show that the maximum independent set admits a FPT-approximation scheme if the parameter is the genus of the graph. E. D. Demaine, M. Hajiaghayi, and K. Kawarabayashi [9] showed that vertex coloring has a ratio 2 approximation when parameterized by the *genus* of a graph. The tree augmentation problem is given an edge-weighted graph and a spanning tree whose edges have cost 0; find a minimum cost collection of edges to add to the tree, so that the resulting graph is 2-edge connected. The problem admits several polynomial time, ratio 2, and approximation algorithms. Breaking the 2 ratio for the problem is an important challenge in approximation algorithms. Cohen and Nutov parameterized the problem by the diameter D of the tree and gave an $f(D) \cdot n^{O(1)}$ time, $1 + \ln 2 < 1.7$ approximation algorithm for the problem [8].

Fixed-Parameter Inapproximability

The following inapproximability is from [11]. The additive maximum independent set problem is given a graph and a parameter k and a constant c, and the question is if the problem admits an independent set of size at least $k - c$ or no independent set of size k exists.

It turns out that the problem is equivalent to the independent set problem.

Theorem 4 *Unless* $W[1] =$ FPT *(hence, under the* ETH*), the independent set problem admits no additive c approximation.*

Proof Let I be the instance. Find the smallest d so that

$$\left\lceil \frac{dk - c}{d} \right\rceil \geq k.$$

Output d copies of G and let $k \cdot d$ be the parameter of the new instance I'. We show that the new graph has independent set of size $dk - c$ if and only if the original instance has an independent set of size k. If the original instance has an independent set of size k, taking union of d independent sets, we get an independent set of size $k \cdot d$.

Now say that I' has an independent set of size $dk - c$. The average size of an independent set in a graph in I' is then $(dk - c)/d$. Since the size

of the independent set is integral, there is a copy that admits an independent set of size

$$\left\lceil \frac{dk - c}{d} \right\rceil \geq k.$$

An independent set I is *maximal* if for every $v \notin I$, $v + I$ is not an independent set. The problem of minimum size maximal independent set (MSDIS) is shown to be completely inapproximable in [11]. Namely, this problem is $(r(k), t(k))$-FPT-hard for any r, t, unless FPT $=$ $W[2]$ (hence, under the ETH). The problem admits no $n^{1-\epsilon}$ approximation (see [20]). In the min-WSAT problem, a Boolean circuit is given and the task is to find a satisfying assignment of minimum weight. The weight of an assignment is the number of true variables. Min-WSAT was given a complete inapproximability by Chen, Grohe, Grüber (see [6]) 2006.

The above two problems are not monotone. This implies that the above results are non-surprising. The most meaningful complete inapproximability is given by Marx [24] who shows that the weighted circuit satisfiability for monotone or antimonotone circuits is completely FPT inapproximable.

Of course, if the problem has almost no gap, namely, the instance can have value k or $k - 1$, it is hard to get a strong hardness.

A natural question is if we can use gap reductions from approximation algorithms theory to get some strong lower bounds, in particular for clique and setcover. It turns out that this is very difficult even under the ETH conjecture. This subject is related to almost linear PCP (see [26]). In this entry, Moshkovitz poses a conjecture called *the projection game conjecture* (PGC). M. Hajiaghayi, R. Khandekar, and G. Kortsarz show the following theorem.

Theorem 5 *Under the* ETH *and* PGC *conjectures,* SETCOVER *is* (r, t)-FPT-*hard for* $r(k) = (\log k)^{\gamma}$ *and* $t(k) = \exp(\exp((\log k)^{\gamma})) \cdot \text{poly}(n) = \exp\left(k^{(\log^f k)}\right) \cdot \text{poly}(n)$ *for some constant* $\gamma > 1$ *and* $f = \gamma - 1$.

Years and Authors of Summarized Original Work

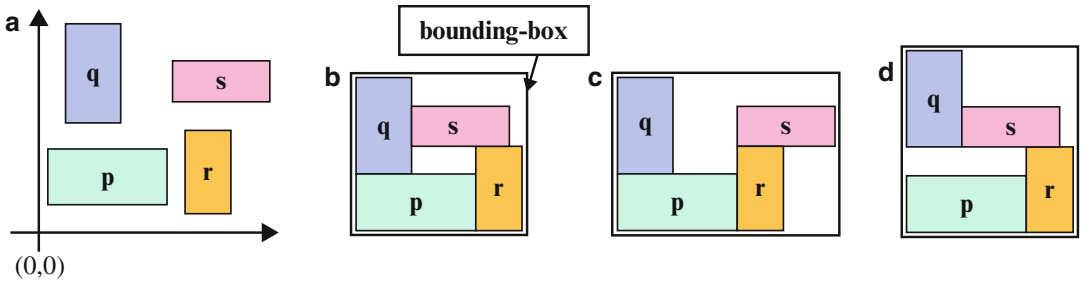
1994; Kajitani, Nakatake, Murata, Fujiyoshi

Problem Definition

The problem is concerned with efficient coding of the constraint that defines the placement of objects on a plane without mutual overlapping. This has numerous motivations, especially in the design automation of integrated semiconductor chips, where almost hundreds of millions of rectangular modules shall be placed within a small rectangular area (chip). Until 1994, the only known coding efficient in computer-aided design was *Polish-Expression* [1]. However, this can only handle a limited class of placements of the *slicing structure*. In 1994 Nakatake, Fujiyoshi, Murata, and Kajitani [2] and Murata, Fujiyoshi, Nakatake, and Kajitani [3] were finally successful to answer this long-standing problem in two contrasting ways. Their code names are *Bounded-Sliceline-Grid* (BSG) for floorplanning and *Sequence-Pair* (SP) for placement.

Notations

1. *Floorplanning, placement, compaction, packing, layout:* Often they are used as exchangeable terms. However, they have their own implications to be used in the following context. *Floorplanning* concerns the design of the plane by restricting and partitioning a given area on which objects are able to be properly *placed. Packing* tries a placement with an intention to reduce the area occupied by the objects. *Compaction* supports packing by pushing objects to the center of the placement. The result, including other environments, is the *layout*. BSG and SP are paired concepts, the former for "floorplanning," the latter for "placement."
2. *ABLR-relation:* The objects to be placed are assumed rectangles in this entry though they could be more general depending on the problem. For two objects p and q, p is said to be *above* q (denoted as pAq) if the bottom edge (boundary) of p is above the top edge of q. Other relations with respect to "*below*"



Floorplan and Placement, Fig. 1 (**a**) A feasible placement whose ABLR-relations could be observed differently. (**b**) Compacted placement if ABLR-relations are (qLr), (sAp), ... Its sequence-pair is SP = (qspr,pqrs) and single-sequence is SS = (2413). (**c**) Compacted placement for (qLr), (sRp), ... SP = (qpsr,pqrs). SS = (2143). (**d**) Compacted placement if (qAr), (sAp), ... SP = (qspr,prqs). SS = (3412)

(pBq), "*left-of*" (pLq), and "*right-of*" (pRq) are analogously defined. These four relations are generally called *ABLR-relations*.

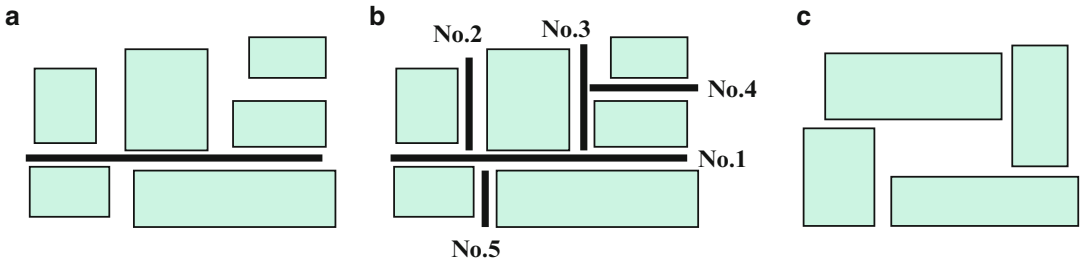
A placement without mutual overlapping of objects is said to be *feasible*. Trivially, a placement is feasible if and only if every pair of objects is in one of ABLR-relations. The example in Fig. 1 will help these definitions.

It must be noted that a pair of objects may satisfy two ABLR-relations simultaneously, but not three. Furthermore, an arbitrary set of ABLR-relations is not necessarily *consistent* for any feasible placement. For example, any set of ABLR-relations including relations (pAq), (qAr), and (rAp) is not consistent.

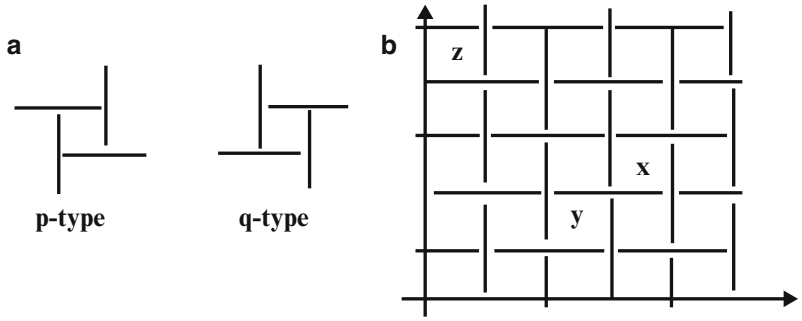
3. *Compaction:* Given a placement, its *bounding-box* is the minimum rectangle that encloses all the objects. A placement of objects is evaluated by the smallness of the bounding-box's area, abbreviated as the *bb-area*. An ABLR-relation set is also evaluated by the minimum bb-area of all the placements that satisfy the set. However, given a consistent ABLR-relation set, the corresponding placement is not unique in general. Still, the minimum bb-area is easily obtained by a common technique called the "Longest-Path Algorithm." (See, e.g., [4].)

   Consider the placement whose objects are all inside the 1st quadrant of the xy-coordinate system, without loss of generality with respect to minimizing the bb-area. It is evident that if a given ABLR-relation set is feasible, there is an object that has no object left or below it. Place it such that its left-bottom corner is at the origin. From the remaining objects, take one that has no object left of or below it. Place it as leftward and downward as long as any ABLR-relation with already fixed objects is not violated. See Fig. 1 to catch the concept, where the ABLR-relation set is the one obtained the placement in (a) (so that it is trivially feasible). It is possible to obtain different ABLR-relation sets, according to which compaction would produce different placements.
4. *Slice-line:* If it is possible to draw a straight horizontal line or vertical line to separate the objects into two groups, the line is said a *slice-line*. If each group again has a slice-line, and so does recursively, the placement is said to be a *slicing structure*. Figure 2 shows placements of slicing and non-slicing structures.
5. *Spiral:* Two structures each consisting of four line segments connected by a *T-junction* as shown in Fig. 3a are *spirals*. Their regular alignment in the first quadrant as shown in (b) is the *Bounded-Sliceline-Grid* or BSG. A BSG is a *floorplan*, or a *T-junction dissection*, of the rectangular area into rectangular regions called *rooms*. It is denoted as an $n \times m$ BSG if the numbers of rows and columns of its rooms are n and m, respectively. According to the left-bottom room being p-type or q-type, the BSG is said to be p-type or q-type, respectively.

In a BSG, take two rooms x and y. The ABLR-relations between them are all that is defined by



Floorplan and Placement, Fig. 2 (**a**) A placement with a slice-line. (**b**) A slicing structure since a slice-line can be found in each ith hierarchy No. $k(k = 1, 2, 3, 4)$. (**c**) A placement that has no slice-line



Floorplan and Placement, Fig. 3 (**a**) Two types of the spiral structure (**b**) 5 × 5 p-type bounded-slice line-grid (BSG)

the rule: If the bottom segment of x is the top segment of y (Fig. 3), room x is above room y. Furthermore, *Transitive Law* is assumed: If "x is above y" and "z is above x," then "z is above y."

Other relations are analogously defined.

Lemma 1 *A room is in a unique ABLR-relation with every other room.*

An $n \times n$ BSG has n^2 rooms. A BSG-assignment is a *one-to-one mapping* of n objects into the rooms of $n \times n$ BSG. ($n^2 - n$ rooms remain vacant.)

After a BSG-assignment, a pair of two objects inherits the same ABLR-relation as the ABLR-relation defined between corresponding rooms. In Fig. 3, if x, y, and z are the names of objects, the ABLR-relations among them are {(xAy), (xRz), (yBx), (yBz), (zLx), (zAy)}.

Key Results

The input is n objects that are rectangles of arbitrary sizes. The main concern is the *solution space*, the collection of distinct consistent ABLR-relation sets, to be generated by BSG or SP.

Theorem 1 ([4,5])

1. *For any feasible ABLR-relation set, there is a BSG-assignment into $n \times n$ BSG of any type that generates the same ABLR-relation set.*
2. *The size $n \times n$ is a minimum: if the number of rows or columns is less than n, there is a feasible ABLR-relation set that is not obtained by any BSG-assignment.*

The proof to (1) is not trivial [5] (Appendix). The number of solutions is ${}_{n^2}C_n$. A remarkable feature of an $n \times n$ BSG is that any ABLR-relation set of n objects is generated by a proper BSG-assignment. By this property, BSG is said to be *universal* [11].

In contrast to the BSG-based generation of consistent ABLR-relation sets, SP directly imposes the ABLR-relations on objects.

A pair of permutations of object names, represented as (Γ^+, Γ^-), is called the sequence-pair, or SP. See Fig. 1. An SP is decoded to a unique ABLR-relation set by the rule:

Consider a pair (x, y) of names such that x is before y in Γ^-. Then (xLy) or (xAy) if x is before or after y in Γ^+, respectively. ABLR-relations

"B" and "R" can be derived as the inverse of "A" and "L." Examples are given in Fig. 1.

A remarkable feature of sequence-pair is that its generation and decoding are both possible by simple operations. The question is what the solution space of all SPs is.

Theorem 2 *Any feasible placement has a corresponding SP that generates an ABLR-relation set satisfied by the placement. On the other hand, any SP has a corresponding placement that satisfies the ABLR-relation set derived from the SP.*

Using SP, a common compaction technique mentioned before is described in a very simple way:

Minimum Area Placement from $SP = (\Gamma^+, \Gamma^-)$

1. Relabel the objects such that $\Gamma^- = (1, 2, \ldots, n)$. Then $\Gamma^+ = (p_1, p_2, \ldots, p_n)$ will be a permutation of numbers $1, 2, \ldots, n$. It is simply a kind of normalization of SP [6]. But Kajitani [11] considers it a concept derived from Q-sequence [10] and studies its implication by the name of *single-sequence* or SS. In the example in Fig. 1b, p, q, r, and s are labeled as 1, 2, 3, and 4 so that SS = (2413).
2. Take object 1 and place it at the left-bottom corner in the 1st quadrant.
3. For $k = 2, 3, \ldots, n$, place k such that its left edge is at the rightmost edge of the objects with smaller numbers than k and lie before k in SS, and its bottom edge is at the topmost edge of the objects with smaller numbers than k and lie after k in SS.

Applications

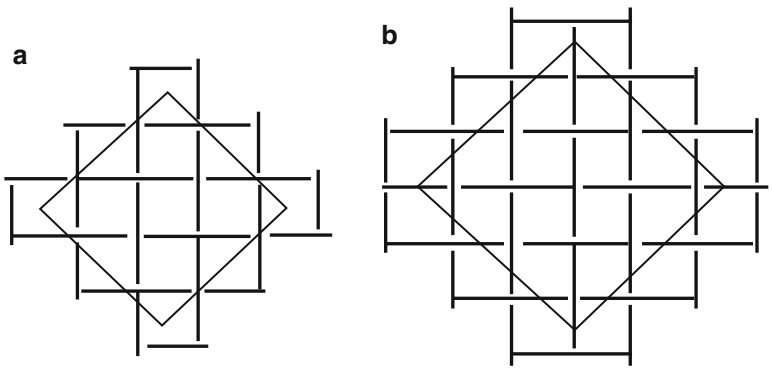
Many ideas followed after BSG and SP [2–5] as seen in the reference. They all applied a common methodology of a stochastic heuristic search, called simulated annealing, to generate feasible placements one after another based on some evaluation (with respect to the smallness of the bb-area) and to keep the best-so-far as the output. This methodology has become practical by the speed achieved due to their simple data structure. The first and naive implementation of BSG [2] could output the layout of sufficiently small area placement of 500 rectangles in several minutes. (Finding a placement with the minimum bb-area is NP-hard [3].) Since then many ideas followed, including currently widely used codes such as O-tree [7], B*-tree [8], corner block list [9], Q-sequence [10], single-sequence [11], and others. Their common feature is in coding the nonoverlapping constraint along horizontal and vertical directions, which is the inheritant property of rectangles.

As long as applications are concerned with the rectangle placement in the minimum area and do not mind mutual interconnection, the problem can be solved practically enough by BSG, SP, and those related ideas. However, in an integrated circuit layout problem, mutual connection is a major concern. Objects are not restricted to rectangles, even soft objects are used for performance. Many efforts have been devoted with a certain degree of success. For example, techniques concerned with rectilinear objects, rectilinear chip, insertion of small but numerous elements like buffers and decoupling capacitors, replacement for design change, symmetric placement for analog circuit design, three-dimensional placement, etc. have been developed. Here few of them is cited but it is recommended to look at proceedings of ICCAD (International Conference on Computer-Aided Design), DAC (Design Automation Conference), ASPDAC (Asia and South Pacific Design Automation Conference), DATE (Design Automation and Test in Europe), and journals TCAD (IEEE Trans. on Computer-Aided Design) and TCAS (IEEE Trans. on Circuit and Systems), particularly those that cover VLSI (Very Large Scale Integration) physical design.

Open Problems

BSG

The claim of Theorem 1 that a BSG needs n rows to provide any feasible ABLR-relation set is reasonable if considering a placement of all objects



Floorplan and Placement, Fig. 4 Octagonal BSG of size n, p-type: (**a**) If n is odd, it has $(n^2+1)/2$ rooms. (**b**) If n is even, it has $(n^2+2n)/2$ rooms

aligned vertically. This is due to the rectangular framework of a BSG. However, experiments have been suggesting a question if from the beginning [5] if we need such big BSGs. The octagonal BSG is defined in Fig. 4. It is believed to hold the following claim expecting a drastic reduction of the solution space.

Conjecture (BSG): For any feasible ABLR-relation set, there is an assignment of n objects into octagonal BSG of size n, any type, that generates the same ABLR-relation set.

If this is true, then the size of the solution space needed by a BSG reduces to ${}_{(n^2+1)/2}C_n$ or ${}_{(n^2+2n)/2}C_n$.

SP or SS

It is possible to define the universality of SP or SS in the same manner as defined for BSG. In general, two sequences of arbitrary k numbers $\mathrm{P} = (\mathrm{p}_1, \mathrm{p}_2, \ldots, \mathrm{p}_k)$ and $\mathrm{Q} = (\mathrm{q}_1, \mathrm{q}_2, \ldots, \mathrm{q}_k)$ are said *similar* with each other if $\mathrm{ord}(\mathrm{p}_i) = \mathrm{ord}(\mathrm{q}_i)$ for every i where $\mathrm{ord}(\mathrm{p}_i) = j$ implies that p_i is the jth smallest in the sequence. If they are single-sequences, two similar sequences generate the same set of ABLR-relations under the natural one-to-one correspondence between numbers.

An SS of length m (necessarily $\geq n$) is said *universal of order n* if SS has a subsequence (a sequence obtained from SS by deleting some of the numbers) that is similar to any sequence of length n. Since rooms of a BSG are considered n^2 objects, Theorem 1 implies that there is a universal SS of order n whose length is n^2. The known facts about smaller universal SS are:

1. For $n = 2, 132, 231, 213$, and 312 are the shortest universal SS. Note that 123 and 321 are not universal.
2. For $n = 3$, SS $=$ 41352 is the shortest universal SP.
3. For $n = 4$, the shortest length of universal SS 10 or less.
4. The size of universal SS is $\Omega(n^2)$ (Imahori S, Dec 2005, Private communication).

Open Problem (SP)

It is still an open problem to characterize the universal SP. For example, give a way to (1) certify a sequence as universal and (2) generate a minimum universal sequence for general n.

Problem Definition

Shortest-job-first heuristics arise in sequencing problems, when the goal is minimizing the perceived latency of users of a multiuser or multitasking system. In this problem, the algorithm has to schedule a set of jobs on a pool of m identical machines. Each job has a release date and a processing time, and the goal is to minimize the average time spent by jobs in the system. This is normally considered a suitable measure of the quality of service provided by a system to interactive users. This optimization problem can be more formally described as follows:

Input

A set of m identical machines and a set of n jobs $1, 2, \ldots, n$. Every job j has a release date r_j and a processing time p_j. In the sequel, $\mathcal{I}$ denotes the set of feasible input instances.

Goal

The goal is minimizing the *average flow* (also known as *average response*) time of the jobs. Let C_j denote the time at which job j is completed by the system. The flow time or response time F_j of job j is defined by $F_j = C_j - r_j$. The goal is thus minimizing

$$\min \frac{1}{n} \sum_{j=1}^{n} F_j \ .$$

Since n is part of the input, this is equivalent to minimizing the *total* flow time, i.e., $\sum_{j=1}^{n} F_j$.

Off-line versus On-line

In the *off-line setting*, the algorithm has full knowledge of the input instance. In particular, for every $j = 1, \ldots, n$, the algorithm knows r_j and p_j.

Conversely, in the *on-line setting*, at any time t, the algorithm is only aware of the set of jobs released up to time t.

In the sequel, A and OPT denote, respectively, the algorithm under consideration and the optimal, off-line policy for the problem. $A(I)$ and $OPT(I)$ denote the respective costs on a specific input instance I.

Further Assumptions in the On-line Case

Further assumptions can be made as to the algorithm's knowledge of processing times of jobs. In particular, in this survey an important case is considered, realistic in many applications, i.e., that p_j is completely unknown to the on-line algorithms until the job eventually completes (*non-clairvoyance*) [1, 3].

Performance Metric

In all cases, as is common in combinatorial optimization, the performance of the algorithm is measured with respect to its optimal, off-line counterpart. In a minimization problem such as those considered in this survey, the competitive ratio ρ_A is defined as:

$$\rho_A = \max_{I \in \mathcal{I}} \frac{A(I)}{OPT(I)} .$$

In the off-line case, ρ_A is the *approximation ratio* of the algorithm. In the on-line setting, ρ_A is known as the *competitive ratio* of A.

Preemption

When *preemption* is allowed, a job that is being processed may be interrupted and resumed later after processing other jobs in the interim. As shown further, preemption is necessary to design efficient algorithms in the framework considered in this survey [5, 6].

Key Results

Algorithms

Consider any job j in the instance and a time t in A's schedule, and denote by $w_j(t)$ the amount of time spent by A on job j until t. Denote by $x_j(t) = p_j - w_j(t)$ its *remaining processing time* at t.

The best known heuristic for minimizing the average flow time when preemption is allowed is *shortest remaining processing time* (SRPT). At any time t, SRPT executes a pending job j such that $x_j(t)$ is minimum. When preemption is not allowed, this heuristic translates to *shortest job first* (SJF): at the beginning of the schedule, or when a job completes, the algorithm chooses a pending job with the shortest processing time and runs it to completion.

Complexity

The problem under consideration is polynomially solvable on a single machine when preemption is allowed [9, 10]. When preemption is allowed, SRPT is optimal for the single-machine case. On parallel machines, the best known upper bound for the preemptive case is achieved by SRPT, which was proven to be $O(\log \min n/m, P)$-approximate [6], P being the ratio between the largest and smallest processing times of the instance. Notice that SRPT is an on-line algorithm, so the previous result holds for the on-line case as well. The authors of [6] also prove that this lower bound is tight in the on-line case. In the off-line case, no non-constant lower bound is known when preemption is allowed.

In the non-preemptive case, no off-line algorithm can be better than $\Omega(n^{1/3-\epsilon})$-approximate, for every $\epsilon > 0$, the best upper bound being $O(\sqrt{n/m}\log(n/m))$ [6]. The upper and lower bound become $O(\sqrt{n})$ and $\Omega(n^{1/2-\epsilon})$ for the single machine case [5].

Extensions

Many extensions have been proposed to the scenarios described above, in particular for the preemptive, on-line case. Most proposals concern the power of the algorithm or the knowledge of the input instance. For the former aspect, one interesting case is the one in which the algorithm is equipped with faster machines than its optimal counterpart. This aspect has been considered in [4]. There the authors prove that even a moderate increase in speed makes some very

simple heuristics have performances that can be very close to the optimum.

As to the algorithm's knowledge of the input instance, an interesting case in the on-line setting, consistent with many real applications, is the non-clairvoyant case described above. This aspect has been considered in [1, 3]. In particular, the authors of [1] proved that a randomized variant of the MLF heuristic described above achieves a competitive ratio that in the average is at most a polylogarithmic factor away from the optimum.

Applications

The first and traditional field of application for scheduling policies is resource assignment to processes in multitasking operating systems [11]. In particular, the use of shortest-job-like heuristics, notably the MLF heuristic, is documented in operating systems of wide use, such as UNIX and WINDOWS NT [8, 11]. Their application to other domains, such as access to Web resources, has been considered more recently [2].

Open Problems

Shortest-job-first-based heuristics such as those considered in this survey have been studied in depth in the recent past. Still, some questions remain open. One concerns the off-line, parallel-machine case, where no non-constant lower bound on the approximation is known yet. As to the on-line case, there still is no tight lower bound for the non-clairvoyant case on parallel machines. The current $\Omega(\log n)$ lower bound was achieved for the single-machine case [7], and there are reasons to believe that it is below the one for the parallel case by a logarithmic factor.

Problem Definition

Given a connected undirected graph, the problem is to determine a straight-line layout such that the structure of the graph is represented in a readable and unbiased way. Part of the problem is the definition of readable and unbiased.

Formally, we are given a simple, undirected graph $G = (V, E)$ with vertex set V and edge set $E \subseteq \binom{V}{2}$. Let $n = |V|$ be the number of vertices and $m = |E|$ the number of edges. The *neighbors* of a vertex v are defined as $N(v) = \{u : \{u, v\} \in E\}$, and $\deg(v) = |N(v)|$ is its *degree*. We assume that G is connected, for otherwise the connected components can be treated separately.

A (two-dimensional) layout for G is a vector $p = (p_v)_{v \in V}$ of vertex positions $p_v = \langle x_y, y_v \rangle \in \mathbb{R}^2$. Since edges are drawn as line segments, the drawing is completely determined by these vertex positions. All approaches in this chapter generalize to higher-dimensional layouts, and there are variants for various graph classes and desired layout features; we only discuss some of them briefly at the end.

The main idea is to make use of physical analogies. A graph is likened to a system of objects (the vertices) that are subject to varying forces (derived from structural features). Forces cause the objects to move around until those pushing and pulling into different directions cancel each other out and the graph layout reaches an equilibrium state. Equivalently, states might be described by an energy function so that forces are not specified directly, but derived from gradients of the energy function.

As a reference model, consider the layout energy function

$$A(p) = \sum_{\{u,v\} \in E} \|p_u - p_v\|^2 \qquad (1)$$

where $\|p_u - p_v\|^2 = (x_u - x_v)^2 + (y_u - y_v)^2$ is the squared Euclidean distance of the endpoints of edge $\{u, v\}$. It associates with a layout the sum of squared edge lengths, so that its minimization marks an attempt to position adjacent vertices close to each other. Because of its straightforward physical analogy, we refer to the minimization of Eq. (1) as the *attraction model*.

Note that minimum-energy layouts of this pure attraction model are degenerate in that all vertices are placed in the same position, since such layouts p are exactly those for which $A(p) = 0$ for a connected graph.

Even if it has not been the starting point of any of the approaches sketched in the next section, it is instructive to think of them as different solutions to the degeneracy problem inherent in the attraction model.

Key Results

We present force-directed layout methods as variations on the attraction model. The first two variants retain the objective but introduce constraints, whereas the other two modify the objective (Fig. 1).

For the constraint-based variants, it is more convenient to analyze the attraction model in matrix form. A necessary condition for a (local) minimum of any objective function is that all partial derivatives vanish. For the attraction model (1), this amounts to

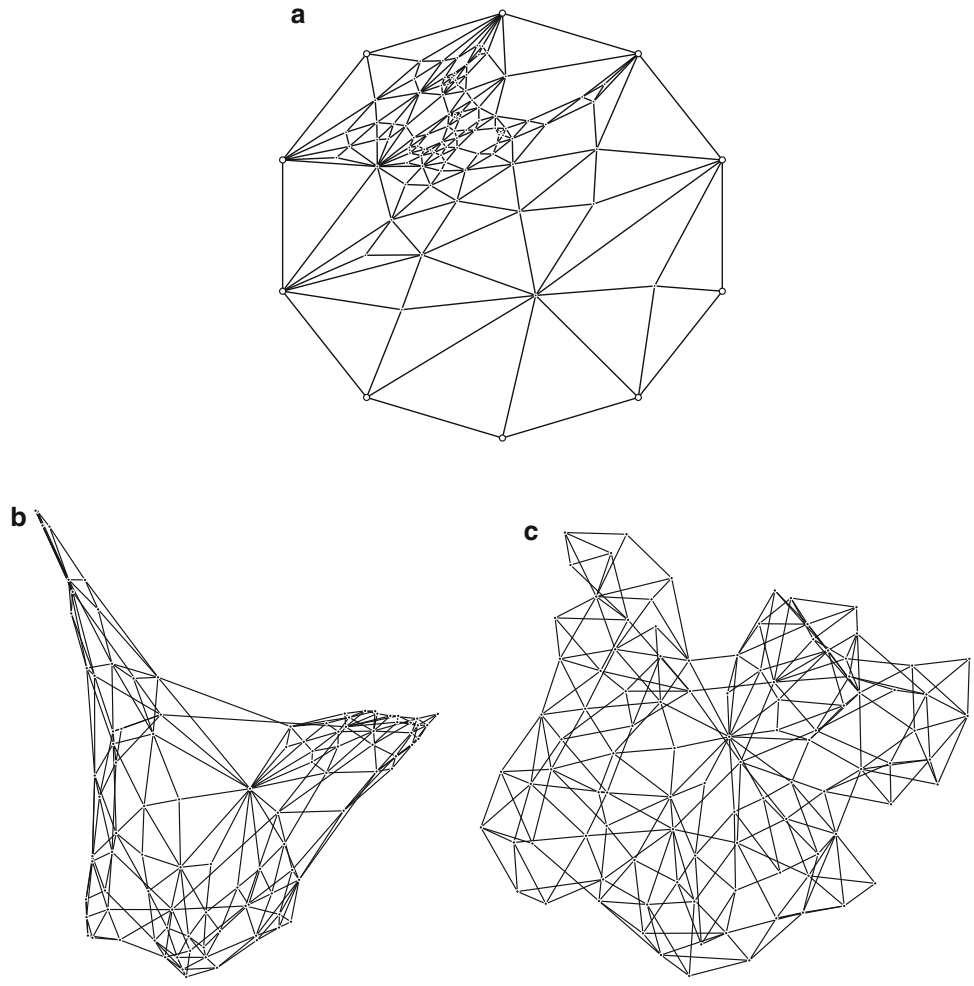
$$\frac{\partial}{\partial x_v} A(p) = \frac{\partial}{\partial y_v} A(p) = 0 \quad \text{for all } v \in V.$$

For any $v \in V$,

$$\frac{\partial}{\partial x_v} A(p) = \sum_{u \in N(v)} 2(x_v - x_u) \stackrel{!}{=} 0,$$

and likewise for $\frac{\partial}{\partial y_v} A(p)$. The necessary conditions can therefore be translated into

$$x_v = \frac{\sum_{u \in N(v)} x_u}{\deg(v)} \quad \text{and} \quad y_v = \frac{\sum_{u \in N(v)} y_u}{\deg(v)}$$



Force-Directed Graph Drawing, Fig. 1 Three different layouts of the same planar triconnected graph. (**a**) Barycentric. (**b**) Spectral. (**c**) Stress

for all $v \in V$, i.e., every vertex must lie in the barycenter of its neighbors. Bringing all variables to the left-hand side, we obtain a system of linear equations whose coefficients form an eminent graph-related matrix, the *Laplacian matrix* $L(G) = D(G) - A(G)$, where $D(G)$ is a diagonal matrix with diagonal entries $\deg(v)$, $v \in V$, and $A(G)$ is the adjacency matrix of G. The entries of $L = L(G) = (\ell_{uv})_{u,v \in V}$ are thus

$$\ell_{uv} = \begin{cases} \deg(v) & \text{if } u = v \\ -1 & \text{if } u \neq v \text{ and } \{u, v\} \in E \\ 0 & \text{otherwise.} \end{cases}$$

so that the optimality conditions can be written as

$$L \cdot p = \mathbf{0}, \tag{2}$$

where $\mathbf{0}$ is an $n \times 2$-matrix of zeros. As discussed above, the solutions to this system of linear equations are given by those layouts p in which all x- and all y-coordinates are identical.

Fixed Boundary

An intuitive approach to prevent attraction from collapsing an entire graph onto a single point is to grab a few of its vertices and drag them apart. Technically, this corresponds to constraining

the layout by fixing select vertices to distinct positions.

Let $B \subseteq V$ be a nonempty subset of *boundary vertices* for which positions $\hat{p}_v = \langle \hat{x}_v, \hat{y}_v \rangle$, $v \in B$ are pre-specified. A layout is called *barycentric* (with respect to these constraints) if it satisfies

$$p_v = \begin{cases} \hat{p}_v & \text{if } v \in B \\ \frac{1}{\deg(v)} \sum_{u \in N(v)} p_u & \text{otherwise.} \end{cases}$$

We next show that the solution of the attraction model with a proper boundary constraint is unique by showing that the reduced system of linear equations has a coefficient matrix with a nonzero determinant. Let L^B denote the matrix obtained by striking out the rows and columns of L indexed by B. Then, a barycentric layout is a solution of

$$L^B \cdot p_{V \setminus B} = \left(\sum_{u \in N(v) \cap B} \hat{p}_u \right)_{V \setminus B} . \quad (3)$$

Different from the pure attraction model, the barycentric model (with a nondegenerate boundary) has a nondegenerate solution that is uniquely defined. Recall that a system of linear equations has a unique solution if and only if the determinant of its matrix of coefficients is positive. The Matrix Tree Theorem [9] asserts that the determinant of every principal minor of a Laplacian matrix equals the number of spanning trees of its associated multigraph, and L^B is a principal minor of the Laplacian of the graph obtained from G by contracting the vertices in B. Since this graph has at least one spanning tree, the determinant of L^B is positive and the solution of (3) is thus unique.

The barycentric approach was introduced in Tutte [15]. The main result shown in this paper is, in fact, that barycentric layouts of a triconnected planar graph with one face constrained to a convex polygon are planar. For the purpose of graph drawing, less desirable properties are exponentially small resolution of angles and edge lengths as evidenced by a family of triangular graphs obtained by starting from a triangle and adding vertices adjacent to the same two initial vertices and the most recently added one. For nontriconnected graphs, degenerate subgraph layouts are possible because components lacking boundary vertices are mapped to a line if between a separation pair, or to a point if hinging on a cut vertex.

Orthogonality

Barycentric layouts are systematically biased by the choice of boundary. An alternative constraint avoiding the single-point collapse is to constrain the coordinate vector of each dimension to be orthogonal to the degenerate layout.

Observe that the one-dimensional version of Eq. (2) can also be read as a special case of the eigenequation $Lx = \lambda x$, since $\lambda = 0$ is, in fact, an eigenvalue of L associated with eigenvector $x = \mathbf{1}$. The Laplacian of a simple undirected graph is a real, symmetric, and positive semidefinite matrix so that the eigenvalues are real and nonnegative, and eigenvectors associated with different eigenvalues are orthogonal.

Rearranging the eigenequation yields $\lambda = \frac{x^T L x}{x^T x}$, where $x^T x$ only normalizes for scale. Since $x^T L x = A(x)$, eigenvectors $x \perp y$ associated with the smallest positive eigenvalues yield the best layout in the attraction model subject to orthogonality also with the degenerate layout $\mathbf{1}$. Note that $\mathbf{1} \perp x$ implies that the average of all coordinates x_v is zero, so that the layouts are centered on the origin.

Spectral drawings based on the Laplacian have been proposed by Hall [7], but can be also be defined via other matrices [11]. It is interesting to note that Laplacian spectral layout corresponds to classical multidimensional scaling using the square root of effective resistance as a measure of distance between vertices. While spectral layouts display symmetries, they are highly cluttered and imbalanced for graphs of low algebraic connectivity as measured by their smallest positive eigenvalue.

Distances

The terms in the objective function of the attraction model correspond to the potential energy of a spring with ideal length zero. To avoid

collapse, one can thus replace them by springs of some nonzero ideal length. While this takes care of the adjacent pairs of vertices, vertices that are more than one edge away from each other can be connected by springs of different length, say proportional to their shortest-path distance. Down-weighting the influence of distant pairs, we obtain the *stress-minimization model* with objective

$$S(p) = \sum_{u,v \in V} \frac{1}{d(u,v)^2} \left(\|p_u - p_v\| - d(u,v) \right)^2 ,$$

constituting another special case of MDS [12] with graph-theoretic distances $d(u,v)$ as input and inverse quadratic weights. This instantiation has been proposed as a graph drawing method by Kamada and Kawai [8] using gradient descent to determine locally optimal layouts. The use of majorization [13] was shown to be superior by Gansner, Koren, and North [6]. A comprehensive survey of variant layout objective functions is given in Chen and Buja [3].

Repulsion

Instead of springs with nonzero ideal length, a dual physical analogy motivates another approach to counter the collapse caused by attraction, namely, repulsion.

The classic *spring embedder* of Eades [4] specifies forces rather than an energy function. While there is a logarithmic force $\log \frac{\|p_u - p_v\|}{l} \cdot (p_u - p_v)$ between adjacent vertices that is neutral if their distance equals a desired value l, nonadjacent vertices push each other apart with quadratically with $\frac{(p_u - p_v)}{\|p_u - p_v\|}$. Both forces are up to scaling constants. A layout is obtained by iteratively evaluating the forces exerted on a vertex by all others and then moving it in the direction of the resulting force, until an approximate equilibrium is obtained.

Many, many variants of the spring embedder have been proposed. The most widely used from Fruchterman and Reingold [5] replaces the forces by quadratically declining repulsion between all pairs of vertices and additional quadratic attraction between adjacent pairs and also introduces several pragmatic improvements. Brandes and Pich [2] find that suitably initialized stress MDS yields superior results, though.

More force-directed methods are surveyed in Brandes [1] and Kobourov [10], and forces have been used very creatively to realize different layout objectives such as common direction of edges, edge curvatures, angles between incident edges, preferred locations, and many more. A relation with graph clustering is pointed out in Noack [14].

Problem Definition

Introduction

Field-programmable gate array (FPGA) is a type of integrated circuit (IC) device that can be (re)programmed to implement custom logic functions. A majority of FPGA devices use lookup table (LUT) as the basic logic element, where a LUT of K logic inputs (K-LUT) can implement any Boolean function of up to K variables. An FPGA also contains other logic elements, such as registers, programmable interconnect resources, dedicated logic resources such as memory blocks and digital signal processing (DSP) blocks, and input/output resources [6].

The programming of an FPGA involves the transformation of a logic design into a form suitable for implementation on the target FPGA device. This generally takes multiple steps. For LUT-based FPGAs, *technology mapping* is to transform a general Boolean logic network (obtained from the design specification through earlier transformations) into a functionally equivalent K-LUT network that can be implemented by the target FPGA device. The objective of a technology mapping algorithm is to generate, among many possible solutions, an optimized one according to certain criteria, some of which are timing optimization, which is to make the resultant implementation operable at faster speed; area minimization, which is to make the resultant implementation compact in size; and power minimization, which is to make the resultant implementation low in power consumption. The algorithm presented here, named *FlowMap* [2], is for timing optimization; it was the first provably optimal polynomial time algorithm for technology mapping problems on general Boolean networks, and the concepts and approach it introduced have since generated numerous useful derivations and applications.

Data Representation and Preliminaries

The input data to a technology mapping algorithm for LUT-based FPGA is a *general Boolean network*, which can be modeled as a direct acyclic graph $N = (V, E)$. A node $v \in V$ can either represent a logic signal source from outside of the network, in which case it has no incoming edge and is called a *primary input* (PI) node, or it can represent a *logic gate*, in which case it has incoming edge(s) from PIs and/or other gates, which are its logic input(s). If the logic output of the gate is also used outside of the network, its node is a *primary output* (PO), which can have no outgoing edge if it is only used outside.

If edge $\langle u, v\rangle \in E, u$ is said to be a *fanin* of v and v a *fanout* of u. For a node $v, input(v)$ denotes the set of its fanins; similarly, for a subgraph $H, input(H)$ denotes the set of distinct nodes outside of H that are fanins of nodes in H. If there is a direct path in N from a node u to a node v, u is said to be a *predecessor* of v and v a *successor* of u. The *input network* of a node v, denoted N_v, is the subgraph containing v and all of its predecessors. A *cone* of a non-PI node

v, denoted C_v, is a subgraph of N_v containing v and possibly some of its *non-PI* predecessors, such that for any node $u \in C_v$, there is a path from u to v in C_v. If $|input(C_v)| \leq K, C_v$ is called a *K-feasible* cone. The network N is *K-bounded* if every non-PI node has a K-feasible cone. A *cut* of a non-PI node v is a bipartition (X, X') of nodes in N_v such that X' is a cone of v; $input(X')$ is called the *cut-set* of (X, X') and $n(X, X') = |input(X')|$ the *size* of the cut. If $n(X, X') \leq K$, (X, X') is a *K-feasible* cut. The *volume* of (X, X') is $vol(X, X') = |X'|$.

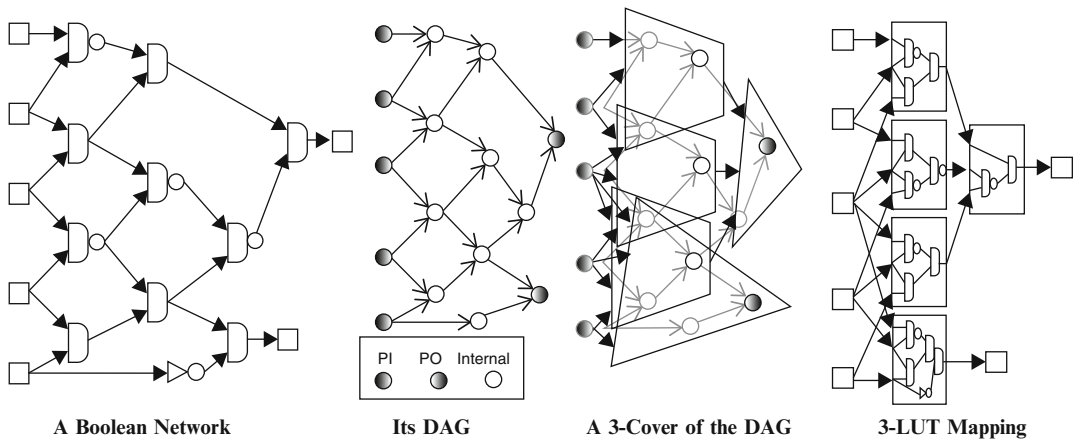
A *topological order* of the nodes in the network N is a linear ordering of the nodes in which each node appears after all of its predecessors and before any of its successors. Such an order is always possible for an acyclic graph.

Problem Formulation

A *K-cover* of a given Boolean network N is a network $N_M = (V_M, E_M)$, where V_M consists of the PI nodes of N and some K-feasible cones of nodes in N, such that for each PO node v of N, V_M contains a cone C_v of v; and if $C_u \in V_M$, then for each non-PI node $v \in input(C_u)$, V_M also contains a cone C_v of v. Edge $\langle u, C_v \rangle \in E_M$ if and only if PI node $u \in input(C_v)$; edge $\langle C_u, C_v \rangle \in E_M$ if and only if non-PI node $u \in input(C_v)$. Since each K-feasible cone can be implemented by a K-LUT, a K-cover can be implemented by a network of K-LUTs. Therefore, the *technology mapping* problem for K-LUT based FPGA, which is to transform N into a network of K-LUTs, is to find a K-cover N_M of N.

The *depth* of a network is the number of edges in its longest path. A technology mapping solution N_M is *depth optimal* if among all possible mapping solutions of N it has the minimum depth. If each level of K-LUT logic is assumed to contribute a constant amount of logic delay (known as the *unit delay* model), the minimum depth corresponds to the smallest logic propagation delay through the mapping solution, or in other words, the fastest K-LUT implementation of the network N. The problem solved by the *FlowMap* algorithm is *depth-optimal technology mapping for K-LUT based FPGAs*.

A Boolean network that is not K-bounded may not have a mapping solution as defined above. To make a network K-bounded, *gate decomposition* may be used to break larger gates into smaller ones. The *FlowMap* algorithm applies, as preprocessing, an algorithm named *DMIG* [3] that converts all gates into 2-input ones in a depth-optimal fashion, thus making the network K-bounded for $K \geq 2$. Different decomposition schemes may result in different K-bounded networks and consequently different mapping solutions; the optimality of *FlowMap* is with respect to a given K-bounded network Fig. 1 illustrates a Boolean network, its DAG, a covering with 3-feasible cones, and the resultant 3-LUT network. As illustrated, the cones in



FPGA Technology Mapping, Fig. 1 A Boolean network, its DAG. a 3-feasible cone covering, and a 3-LUT mapping

the covering may overlap; this is allowed and often beneficial. (When the mapped network is implemented, the overlapped portion of logic will be replicated into each of the K-LUTs that contain it)

Key Results

The *FlowMap* algorithm takes a two-phase approach. In the first phase, it determines for each non-PI node a preferred K-feasible cone as a candidate for the covering; the cones are computed such that if used, they will yield a depth-optimal mapping solution. This is the central piece of the algorithm. In the second phase, the cones necessary to form a cover are chosen to generate a mapping solution.

Structure of Depth-Optimal *K*-Covers

Let $M(v)$ denote a K-cover (or equivalently, K-LUT mapping solution) of the input network N_v of v. If v is a PI, $M(v)$ consists of v itself. (For simplicity, in the rest of the article, $M(v)$ shall be referred as *a K-cover of v*.) With that defined, first there is

Lemma 1 *If C_v is the K-feasible cone of v in a K-cover $M(v)$, then $M(v) = \{C_v\} + \cup\{M(u) : u \in input(C_v)\}$ where $M(u)$ is a certain K-cover of u. Conversely, if C_v is a K-feasible cone of v, and for each $u \in input(C_v)$, $M(u)$ a K-cover of u, then $M(v) = \{C_v\} + \cup\{M(u) : u \in input(C_v)\}$ is a K-cover of v.*

In other words, a K-cover of a node consists of a K-feasible cone of the node and a K-cover of each input of the cone. Note that for $u_1 \in input(C_v), u_2 \in input(C_v), M(u_1)$ and $M(u_2)$ may overlap, and an overlapped portion may or may not be covered the same way; the union above includes all *distinct* cones from all parts. Also note that for a given C_v, there can be different K-covers of v containing C_v, varying by the choice of $M(u)$ for each $u \in input(C_v)$.

Let $d(M(v))$ denote the depth of $M(v)$. Then

Lemma 2 *For K-cover $M(v) = \{C_v\} + \cup\{M(u) : u \in input(C_v)\}$,*

$$d(M(v)) = max\{d(M(u)) : u \in input(C_v)\} + 1.$$

In particular, let $M^*(u)$ denote a K-cover of u with minimum depth, then $d(M(v)) \geq max\{d(M^*(u)) : u \in input(C_v)\} + 1$; the equality holds when every $M(u)$ in $M(v)$ is of minimum depth.

Recall that C_v defines a K-feasible cut (X, X') where $X' = C_v, X = N_v - C_v$. Let $H(X, X')$ denote the *height* of the cut (X, X'), defined as $H(X, X') = max\{d(M^*(u)) : u \in input(X')\} + 1$. Clearly, $H(X, X')$ gives the minimum depth of any K-cover of v containing $C_v = X'$. Moreover, by properly choosing the cut, $H(X, X')$ height can be minimized, which leads to a K-cover with minimum depth:

Theorem 1 *If K feasible cut (X, X') of v has the minimum height among all K-feasible cuts of v, then the K-cover $M^*(v) = \{X'\} + \cup\{M^*(u) : u \in input(X')\}$ is of minimum depth among all K-covers of v.*

That is, a minimum height K-feasible cut defines a minimum depth K-cover. So the central task for depth-optimal technology mapping becomes the computation of a minimum height K-feasible cut for each PO node.

By definition, the height of a cut depends on the (depths of) minimum depth K-covers of nodes in $N_v - \{v\}$. This suggests a *dynamic programming* procedure that follows topological order, so that when the minimum depth K-cover of v is to be determined, a minimum depth K-cover of each node in $N_v - \{v\}$ is already known and the height of a cut can be readily determined. This is how the first phase of the *FlowMap* algorithm is carried out.

Minimum Height *K*-Feasible Cut Computation

The first phase of *FlowMap* was originally called the *labeling phase,* as it involves the computation of a *label* for each node in the K-bounded graph. The label of a non-PI node v, denoted $l(v)$, is defined as the minimum height of any cut of v. For convenience, the labels of PI nodes are defined to be 0.

The so-defined label has an important *monotonic* property.

Lemma 3 *Let* $p = max\{l(u) : u \in input(v)\}$, *then* $p \leq l(v) \leq p + 1$.

Note that this also implies that for any node $u \in N_v - \{v\}, l(u) \leq p$. Based on this, in order to find a minimum height K-feasible cut, it is sufficient to check if there is one of height p; if not, then any K-feasible cut will be of minimum height $(p + 1)$, and one always exists for a K-bounded graph.

The search for a K-feasible cut of a height p ($p > 0$; $p = 0$ is trivial) in *FlowMap* is done by transforming N_v into a *flow network* F_v and computing a *network flow* [5] on it (hence the name). The transformation is as follows. For each node $u \in N_v - \{v\}, l(u) < p, F_v$ has two nodes u_1 and u_2, linked by a *bridge* edge $\langle u_1, u_2\rangle$; F_v has a single *sink* node t for all other nodes in N_v, and a single *source* node s. For each PI node u of N_v, which corresponds to a bridge edge $\langle u_1, u_2\rangle$inF_v, F_v contains edge $\langle s, u_1\rangle$; for each edge $\langle u, w\rangle$ in N_v, if both u and w have bridge edges in F_v, then F_v contains edge $\langle u_2, w_1\rangle$; if u has a bridge edge but w does not, F_v contains edge $\langle u_2, t\rangle$; otherwise (neither has bridge) no corresponding edge is in F_v. The bridging edges have unit capacity; all others have infinite capacity. Noting that each edge in F_v with finite (unit) capacity corresponds to a node $u \in N_v$ with $l(u) < p$ and vice versa, and according to the max-flow min-cut theorem [5], it can be shown that.

Lemma 4 *Node v has a K-feasible cut of height p if and only if F_v has a maximum network flow of size no more than K.*

On the flow network F_v, a maximum flow can be computed by running the augmenting path algorithm [5]. Once a maximum flow is obtained, the *residual graph* of the flow network is disconnected, and the corresponding *min-cut* (X, X') can be identified as follows: $v \in X'$; for $u \in N_v - \{v\}$, if it is bridged in F_v, and u_1 can be reached in a depth-first search of the residual graph from s, then $u \in X$; otherwise $u \in X'$.

Note that as soon as the flow size exceeds K, the computation can stop, knowing there will not be a desired K-feasible cut. In this case, one can modify the flow network by bridging all nodes in $N_v - \{v\}$ allowing the inclusion of nodes u with $l(u) = p$ in the cut computation, and find a K-feasible cut with height $p + 1$ the same way.

An augmenting path is found in linear time to the number of edges, and there are at most K augmentations for each cut computation. Applying the algorithm to every node in topological order, one would have the following result.

Theorem 2 *In a K-bounded Boolean network of n nodes and m edges, the computation of a minimum height K-feasible cut for every node can be completed in $O(Kmn)$ time.*

The cut found by the algorithm has another property:

Lemma 5 *The cut (X, X') computed as above is the unique maximum volume min-cut; moreover, if (Y, Y') is another min-cut, then $Y' \subseteq X'$.*

Intuitively, a cut of larger volume defines a larger cone which covers more logic, therefore a cut of larger volume is preferred. Note however that Lemma 5 only claims maximum among min-cuts; if $n(X, X') < K$, there can be other cuts that are still K-feasible but with larger cut size and larger cut volume. A post-processing algorithm used by *FlowMap* tries to grow (X, X') by collapsing all nodes in X', plus one or more in the cut-set, into the sink, and repeat the flow computation; this will force a cut of larger volume, an improvement if it is still K-feasible.

K-Cover Construction

Once minimum height K-feasible cuts have been computed for all nodes, each node v has a K-feasible cone C_v defined by its cut, which has minimum depth. From here, constructing the K-cover $N_M = (V_M, E_M)$ is straight-forward. First, the cones of all PO nodes are included in V_M. Then, for any cone $C_v \in V_M$, cone C_u for each non-PI node $u \in input(C_v)$ is also included in V_M; so is every PI node $u \in input(C_v)$. Similarly, an edge $\langle C_u, C_v\rangle \in E_M$ for each non-

PI node $u \in input(C_v)$; an edge $\langle u, C_v \rangle \in E_M$ for each PI node $u \in input(C_v)$.

Lemma 6 *The K-cover constructed as above is depth optimal.*

This is a linear time procedure, therefore

Theorem 3 *The problem of depth-optimal technology mapping for K-LUT based FPGAs on a Boolean network of n nodes and m edges can be solved in $O(Kmn)$ time.*

Applications

The *FlowMap* algorithm has been used as a centerpiece or a framework for more complicated FPGA logic synthesis and technology mapping algorithms. There are many possible variations that can address various needs in its applications. Some are briefed below; details of such variations/applications can be found in [1,3].

Complicated Delay Models

With minimal change, the algorithm can be applied where non-unit delay model is used, allowing delay of the nodes and/or the edges to vary, as long as they are static. Dynamic delay models, where the delay of a net is determined by its post-mapping structure, cannot be applied to the algorithm. In fact, delay-optimal mapping under dynamic delay models is NP-hard [3].

Complicated Architectures

The algorithm can be adapted to FPGA architectures that are more sophisticated than homogeneous K-LUT arrays. For example, mapping for FPGA with two LUT sizes can be carried out by computing a cone for each size and dynamically choosing the best one.

Multiple Optimization Objectives

While the algorithm is for delay minimization, area minimization (in terms of the number of cones selected) as well as other objectives can also be incorporated, by adapting the criteria for cut selection. The original algorithm considers area minimization by maximizing the volume of the cuts; substantially, more minimization can be achieved by considering more K-feasible cuts and making smart choices to, e.g., increase sharing among input networks, allow cuts of larger heights along no-critical paths, etc. [4] Achieving area optimality, however, is NP-hard [3].

Integration with Other Optimizations

The algorithm can be combined with other types of optimizations, including retiming, logic resynthesis, and physical synthesis.

Problem Definition

This entry presents results on fast algorithms that produce approximate solutions to problems which can be formulated as linear programs (LP) and therefore can be solved exactly, albeit with slower running times. The general format of the family of these problems is the following: Given a set of m inequalities on n variables, and an oracle that produces the solution of an appropriate optimization problem over a convex set $P \in \mathbb{R}^n$, find a solution $x \in P$ that satisfies the inequalities, or detect that no such x exists. The basic idea of the algorithm will always be to start from an infeasible solution x, and use the optimization oracle to find a direction in which the violation of the inequalities can be decreased; this is done by calculating a vector y that is a *dual solution corresponding to* x. Then, x is carefully updated towards that direction, and the process is repeated until x becomes "approximately" feasible. In what follows, the particular problems tackled, together with the corresponding optimization oracle, as well as the different notions of "approximation" used are defined.

- The **fractional packing problem** and its oracle are defined as follows:

PACKING: Given an $m \times n$ matrix A, $b > 0$, and a convex set P in $\mathbb{R}^n$ such that $Ax \geq 0$, $\forall x \in P$, is there $x \in P$ such that $Ax \leq b$?

PACK_ORACLE: Given m-dimensional vector $y \geq 0$ and P as above, return $\bar{x} := \arg\min\{y^{\mathrm{T}} Ax : x \in P\}$.

- The **relaxed fractional packing problem** and its oracle are defined as follows:

RELAXED PACKING: Given $\varepsilon > 0$, an $m \times n$ matrix A, $b > 0$, and convex sets P and $\hat{P}$ in $\mathbb{R}^n$ such that $P \subseteq \hat{P}$ and $Ax \leq 0$, $\forall x \in \hat{P}$, find $x \in \hat{P}$ such that $Ax \leq (1+\varepsilon)b$, or show that $\nexists x \in P$ such that $Ax \leq b$.

REL_PACK_ORACLE: Given m-dimensional vector $y \geq 0$ and P, $\hat{P}$ as above, return $\bar{x} \in \hat{P}$ such that $y^{\mathrm{T}} A\bar{x} \leq \min\{y^{\mathrm{T}} Ax : x \in P\}$.

- The **fractional covering problem** and its oracle are defined as follows:

COVERING: Given an $m \times n$ matrix A, $b > 0$, and a convex set P in $\mathbb{R}^n$ such that $Ax \geq 0$, $\forall x \in P$, is there $x \in P$ such that $Ax \geq b$?

COVER_ORACLE: Given m-dimensional vector $y \geq 0$ and P as above, return $\bar{x} := \arg\max\{y^{\mathrm{T}} Ax : x \in P\}$.

- The **simultaneous packing and covering problem** and its oracle are defined as follows:

SIMULTANEOUS PACKING AND COVERING: Given $\hat{m} \times n$ and $(m-\hat{m}) \times n$ matrices $\hat{A}$, A respectively, $b > 0$ and $\hat{b} > 0$, and a convex set P in $\mathbb{R}^n$ such that $Ax \geq 0$ and $\hat{A}x \leq 0$, $\forall x \in P$, is there $x \in P$ such that $Ax \leq b$, and $\hat{A}x \geq \hat{b}$?

SIM_ORACLE: Given P as above, a constant ν and a dual solution $(y, \hat{y})$, return $\bar{x} \in P$ such that $A\bar{x} \leq \nu b$, and $y^{\mathrm{T}} A\bar{x} - \sum_{i \in I(\nu,\bar{x})} \hat{y}_i \hat{a}_i \bar{x} = \min\{y^{\mathrm{T}} Ax - \sum_{i \in I(\nu,x)} \hat{y}_i \hat{a}_i x : x \text{ a vertex of } P \text{ such that } Ax \leq \nu b\}$, where $I(\nu, x) := \{i : \hat{a}_i x \leq \nu b_i\}$.

- The **general problem** and its oracle are defined as follows:

GENERAL: Given an $m \times n$ matrix A, an arbitrary vector b, and a convex set P in $\mathbb{R}^n$, is there $x \in P$ such that $Ax \leq b$,?

GEN_ORACLE: Given m-dimensional vector $y \geq 0$ and P as above, return $\bar{x} := \arg\min\{y^T Ax : x \in P\}$.

Definitions and Notation

For an error parameter $\varepsilon > x0$, a point $x \in P$ is an *ε-approximation solution* for the fractional packing (or covering) problem if $Ax \leq (1+\varepsilon)b$ (or $Ax \geq (1-\varepsilon)b$). On the other hand, if $x \in P$ satisfies $Ax \leq b$ (or $Ax \geq b$), then x is an *exact solution*. For the GENERAL problem, given an error parameter $\varepsilon > 0$ and a positive tolerance vector d, $x \in P$ is an *ε-approximation solution* if $Ax \leq b + \varepsilon d$ and an *exact solution* if $Ax \leq b$. An *ε-relaxed decision procedure* for these problems either finds an ε-approximation solution or correctly reports that no exact solution exists. In general, for a minimization (maximization) problem, an $(1+\varepsilon)$-approximation ($(1-\varepsilon)$-*approximation*) *algorithm* returns a solution at most $(1+\varepsilon)$ (at least $(1-\varepsilon)$) times the optimal.

The algorithms developed work within time that depends polynomially on ε^{-1}, for any error parameter $\varepsilon > 0$. Their running time will also depend on the *width* ρ of the convex set P relative to the set of inequalities $Ax \leq b$ or $Ax \geq b$ defining the problem at hand. More specifically, the width ρ is defined as follows for each one of the problems considered here:

- PACKING: $\rho := \max_i \max_{x \in P} \frac{a_i x}{bi}$.
- RELAXED PACKING: $\hat{\rho} := \max_i \max_{x \in \hat{P}} \frac{a_i x}{b_i}$.
- COVERING: $\rho := \max_i \max_{x \in P} \frac{a_i x}{bi}$.
- SIMULTANEOUS PACKING AND COVERING: $\rho := \max_{x \in P} \max\{\max_i \frac{a_i x}{bi}, \max_i \frac{\hat{a}_i x}{\hat{b}_i}\}$.
- GENERAL: $\rho := \max_i \max_{x \in P} \frac{|a_i x - b_i|}{d_i} + 1$, where d is the tolerance vector defined above.

Key Results

Many of the results below were presented in [8] by assuming a model of computation with exact arithmetic on real numbers and exponentiation in a single step. But, as the authors mention [8], they can be converted to run on the RAM model by using approximate exponentiation, a version of the oracle that produces a *nearly* optimal solution, and a limit on the numbers used that is polynomial in the input length similar to the size of numbers used in exact linear programming algorithms. However, they leave as an open problem the construction of ε-approximate solutions using polylogarithmic precision for the general case of the problems they consider (as can be done, e.g., in the multicommodity flow case [4]).

Theorem 1 *For $0 < \varepsilon \leq 1$, there is a deterministic ε-relaxed decision procedure for the fractional packing problem that uses $O(\varepsilon^{-2}\rho \log(m\varepsilon^{-1}))$ calls to* PACK_ORACLE*, plus the time to compute Ax for the current iterate x between consecutive calls.*

For the case of P being written as a product of smaller-dimension polytopes, i.e., $P = P^1 \times \ldots \times P^k$, each P^l with width ρ^l $\left(\text{obviously} \rho \leq \sum_l \rho^l\right)$, and a separate PACK_ORACLE for each P^l,A^l, then randomization can be used to potentially speed up the algorithm. By using the notation $PACK\_ORACLE_l$ for the P^l,A^l oracle, the following holds:

Theorem 2 *For $0 < \varepsilon \leq 1$, there is a randomized ε-relaxed decision procedure for the fractional packing problem that is expected to use*

$$O\left(\varepsilon^{-2}\left(\sum_l \rho^l\right)\log(m\varepsilon^{-1}) + k\log(\rho\varepsilon^{-1})\right)$$

calls to $PACK\_ORACLE_l$ for some $l \in \{1,\ldots,k\}$ (possibly a different l in every call), plus the time to compute $\sum_l A^l x^l$ for the

current iterate $x = (x^1, x^2, \ldots, x^k)$ *between consecutive calls.*

Theorem 2 holds for RELAXED PACKING as well, if ρ is replaced by $\hat{\rho}$ and PACK_ORACLE by REL_PACK_ORACLE.

In fact, one needs only an *approximate* version of PACK_ORACLE. Let $C_{\mathcal{P}}(y)$ be the minimum cost $y^{\mathrm{T}}Ax$ achieved by PACK_ORACLE for a given y.

Theorem 3 *Let* PACK_ORACLE *be replaced by an oracle that, given vector* $y \geq 0$*, finds a point* $\bar{x} \in P$ *such that* $y^{\mathrm{T}}A\bar{x} \leq (1+\varepsilon/2)C_{\mathcal{P}}(y) + (\varepsilon/2)\lambda y^{\mathrm{T}}b$*, where* λ *is minimum so that* $Ax \leq \lambda b$ *is satisfied by the current iterate* x*. Then, Theorems 1 and 2 still hold.*

Theorem 3 shows that even if no efficient implementation exists for an oracle, as in, e.g., the case when this oracle solves an NP-hard problem, a fully polynomial approximation scheme for it suffices.

Similar results can be proven for the fractional covering problem ($COVER\_ORACLE_l$ is defined similarly to $PACK\_ORACLE_l$ above):

Theorem 4 *For* $0 < \varepsilon < 1$*, there is a deterministic* ε*-relaxed decision procedure for the fractional covering problem that uses* $O(m + \rho \log^2 m + \varepsilon^{-2}\rho \log(m\varepsilon^{-1}))$ *calls to* COVER_ORACLE*, plus the time to compute* Ax *for the current iterate* x *between consecutive calls.*

Theorem 5 *For* $0 < \varepsilon < 1$*, there is a randomized* ε*-relaxed decision procedure for the fractional packing problem that is expected to use* $O\left(mk + \left(\sum_i \rho^l\right)\log^2 m + k\log\varepsilon^{-1} + \varepsilon^{-2}\left(\sum_l \rho^l\right)\log(m\varepsilon^{-1})\right)$ *calls to* $COVER\_ORACLE_l$ *for some* $l \in \{1,\ldots,k\}$ *(possibly a different* l *in every call), plus the time to compute* $\sum_l A^l x^l$ *for the current iterate* $x = (x^1, x^2, \ldots, x^k)$ *between consecutive calls.*

Let $C_{\mathcal{C}}(y)$ be the maximum cost $y^{\mathrm{T}}Ax$ achieved by COVER_ORACLE for a given y.

Theorem 6 *Let* COVER_ORACLE *be replaced by an oracle that, given vector* $y \geq 0$*, finds a point* $\bar{x} \in P$ *such that* $y^{\mathrm{T}}A\bar{x} \geq (1-\varepsilon/2)C_{\mathcal{C}}(y) - (\varepsilon/2)\lambda y^{\mathrm{T}}b$*, where* λ *is maximum so that* $Ax \geq \lambda b$ *is satisfied by the current iterate* x*. Then, Theorems 4 and 5 still hold.*

For the simultaneous packing and covering problem, the following is proven:

Theorem 7 *For* $0 < \varepsilon \leq 1$*, there is a randomized* ε*-relaxed decision procedure for the simultaneous packing and covering problem that is expected to use* $O(m^2(\log^2 \rho)\varepsilon^{-2}\log(\varepsilon^{-1}m\log\rho))$ *calls to* SIM_ORACLE*, and a deterministic version that uses a factor of* $\log\rho$ *more calls, plus the time to compute* $\hat{A}x$ *for the current iterate* x *between consecutive calls.*

For the GENERAL problem, the following is shown:

Theorem 8 *For* $0 < \varepsilon < 1$*, there is a deterministic* ε*-relaxed decision procedure for the* GENERAL *problem that uses* $O(\varepsilon^{-2}\rho^2\log(m\rho\varepsilon^{-1}))$ *calls to* GEN_ORACLE*, plus the time to compute* Ax *for the current iterate* x *between consecutive calls.*

The running times of these algorithms are proportional to the width ρ, and the authors devise techniques to reduce this width for many special cases of the problems considered. One example of the results obtained by these techniques is the following: If a packing problem is defined by a convex set that is a product of k smaller-dimension convex sets, i.e., $P = P^1 \times \ldots \times P^k$, and the inequalities $\sum_l A^l x^l \leq b$, then there is a randomized ε-relaxed decision procedure that is expected to use $O(\varepsilon^{-2}k\log(m\varepsilon^{-1}) + k\log k)$ calls to a subroutine that finds a minimum-cost point in $\hat{P}^l = \{x^l \in P^l : A^l x^l \leq b\}$, $l = 1, \ldots, k$ and a deterministic version that uses $O(\varepsilon^{-2}k^2\log(m\varepsilon^{-1}))$ such calls, plus the time to compute Ax for the current iterate x between consecutive calls. This result can be applied to the multicommodity flow problem, but the required subroutine is a single-source minimum-cost flow computation, instead of a shortest-path calculation needed for the original algorithm.

Applications

The results presented above can be used in order to obtain fast approximate solutions to linear programs, even if these can be solved exactly by LP algorithms. Many approximation algorithms are based on the rounding of the solution of such programs, and hence one might want to solve them approximately (with the overall approximation factor absorbing the LP solution approximation factor), but more efficiently. Two such examples, which appear in [8], are mentioned here.

Theorems 1 and 2 can be applied for the improvement of the running time of the algorithm by Lenstra, Shmoys, and Tardos [5] for the scheduling of unrelated parallel machines without preemption $(R||C_{\max})$: N jobs are to be scheduled on M machines, with each job i scheduled on exactly one machine j with processing time p_{ij}, so that the maximum total processing time over all machines is minimized. Then, for any fixed $r > 1$, there is a deterministic $(1 + r)$-approximation algorithm that runs in $O(M^2 N \log^2 N \log M)$ time and a randomized version that runs in $O(MN \log M \log N)$ expected time. For the version of the problem with preemption, there are polynomial-time approximation schemes that run in $O(MN^2 \log^2 N)$ time and $O(MN \log N \log M)$ expected time in the deterministic and randomized case, respectively.

A well-known lower bound for the metric Traveling Salesman Problem (metric TSP) on N nodes is the Held-Karp bound [2], which can be formulated as the optimum of a linear program over the *subtour elimination polytope*. By using a randomized minimum-cut algorithm by Karger and Stein [3], one can obtain a randomized approximation scheme that computes the Held-Karp bound in $O(N^4 \log^6 N)$ expected time.

Open Problems

The main open problem is the further reduction of the running time for the approximate solution of the various fractional problems. One direction would be to improve the bounds for specific problems, as has been done very successfully for the multicommodity flow problem in a series of papers starting with Shahrokhi and Matula [9]. Currently, the best running times for several versions of the multicommodity flow problems are achieved by Madry [6]. Shahrokhi and Matula [9] also led to a series of results by Grigoriadis and Khachiyan developed independently to [8], starting with [1] which presents an algorithm with a number of calls smaller than the one in Theorem 1 by a factor of $\log(m\varepsilon^{-1})/\log m$. Considerable effort has been dedicated to the reduction of the dependence of the running time on the width of the problem or the reduction of the width itself (e.g., see [10] for sequential and parallel algorithms for mixed packing and covering), so this can be another direction of improvement.

A problem left open by [8] is the development of approximation schemes for the RAM model that use only *polylogarithmic in the input length* precision and work for the general case of the problems considered.

Problem Definition

This problem is to enumerate all subgraphs appearing with frequencies not less than a threshold value in a given graph data set. Let $G(V, E, L, \ell)$ be a labeled graph where V is a set of vertices, $E \subseteq V \times V$ a set of edges, L a set of labels and $\ell : V \cup E \rightarrow L$ a labeling function. A labeled graph $g(v, e, L, \ell)$ is a subgraph of $G(V, E, L, \ell)$, *i.e.*, $g \sqsubseteq G$, if and only if a mapping $f : v \rightarrow V$ exists such that $\forall u_i \in v, f(u_i) \in V, \ell(u_i) = \ell(f(u_i))$, and $\forall (u_i, u_j) \in e, (f(u_i), f(u_j)) \in E, \ell(u_i, u_j) = \ell(f(u_i), f(u_j))$. Given a graph data set $D = \{G_i | i = 1, \ldots, n\}$, a support of g in D is a set of all G_i involving g in D, *i.e.*, $D(g) = \{G_i | g \sqsubseteq G_i \in D\}$. Under a given threshold frequency called a minimum support $minsup > 0$, g is said to be frequent, if the size of $D(g)$ *i.e.*, $|D(g)|$, is greater than or equal to $minsup$. Generic frequent graph mining is a problem to enumerate all frequent subgraphs g of D, while most algorithms focus on connected and undirected subgraphs. Some focus on induced subgraphs or limit the enumeration to closed frequent subgraphs where each of them is maximal in the frequent subgraphs having an identical support.

Key Results

Study of the frequent graph mining was initiated in the mid-1990s under motivation to analyze complex structured data acquired and accumulated in our society. Their major issue has been principles to efficiently extract frequent subgraphs embedded in a given graph data set. They invented many original canonical graph representations adapted to the data-driven extraction, which are different from these proposed in studies of efficient isomorphism checking [1] and graph enumeration without duplications [2].

Pioneering algorithms of frequent graph mining, SUBDUE [3] and GBI [4], did not solve the aforementioned standard problem but greedily extracted subgraphs concisely describing the original graph data under some measures such as minimum description length (MDL). The earliest algorithms for deriving a complete set of the frequent subgraphs are WARMR [5] and its extension FARMER [6]. They can flexibly focus on various types of frequent subgraphs for the enumeration by applying inductive logic program-

ming (ILP) in artificial intelligence, while they are not very scalable in the size of the enumerated subgraphs.

AGM proposed in 2000 [7, 8] was an epoch-making study in the sense that it combined frequent item set mining [9] and the graph enumeration and enhanced the scalability for practical applications. It introduced technical strategies of (1) incremental candidate enumeration based on anti-monotonicity of the subgraph frequency, (2) canonical graph representation to avoid duplicated candidate subgraph extractions, and (3) data-driven pruning of the candidates by the minimum support. The anti-monotonicity is a fundamental nature of the subgraph frequency that $|D(g_1)| \leq |D(g_2)|$ for any subgraphs g_1 and g_2 in D if $g_2 \sqsubseteq g_1$. Dozens of frequent graph mining algorithms have been studied along this line after 2000. In the rest of this entry, gSpan [10] and Gaston [11], considered to be the most efficient up to date, are explained.

gSpan

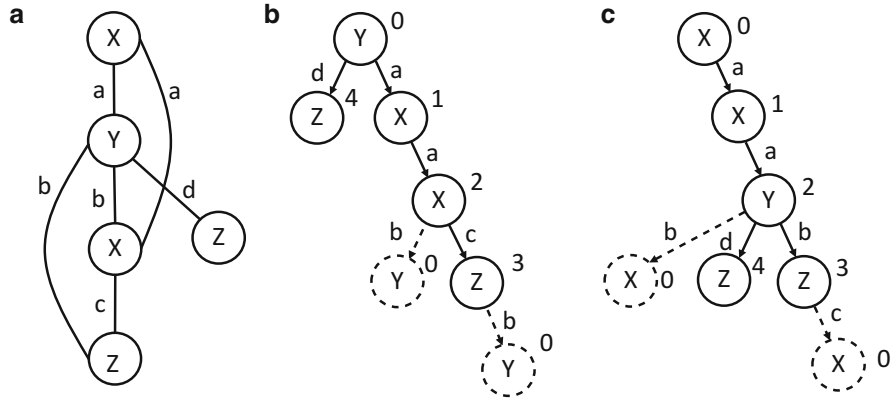
gSpan derives all frequent connected subgraphs in a given data set of connected and undirected graphs [10]. For the aforementioned strategy (1), it applies a pattern growth technique which is data-driven enumeration of candidate frequent subgraphs. It is performed by tracing vertices and edges of each data graph G in a DFS manner. Figure 1b is an example search tree generated by starting from the vertex labeled as Y in the graph (a). In a search tree T, the vertex for the next visit is the one reachable from the current vertex by passing through an edge untraced yet in G. If the vertex for the next visit is the one visited earlier in G, the edge is called a backward edge otherwise a forward edge. They are depicted by dashed and solid lines, respectively, in Fig. 1b. When no more untraced edges are available from the current vertex, the search backtracks to the nearest vertex having the untraced edges. Any subtree of T represents a subgraph of G. We denote the sets of the forward and the backward edges in T as $E_{f,T} = \{e | \forall i, j, i < j, e = (v_i, v_j) \in E\}$ and $E_{b,T} = \{e | \forall i, j, i > j, e = (v_i, v_j) \in E\}$, respectively, where i and j are integer indices numbered at the vertices in their visiting order in T.

There exist many trees T representing an identical graph G as another tree of the graph (a) shown in Fig. 1c. This ambiguity causing duplication and miss in the candidate graph enumeration is avoided by introducing the strategy (2). gSpan applied the following three types of partial orders of the edges in T. Given $e_1 = (v_{i_1}, v_{j_1})$ and $e_2 = (v_{i_2}, v_{j_2})$,

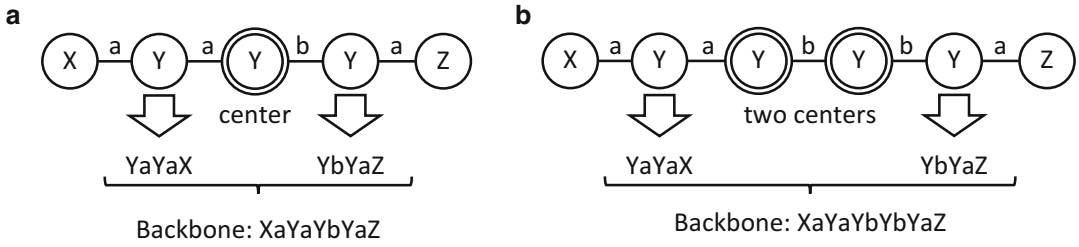
$$
\begin{aligned}
e_1 \prec_{f,T} e_2 \quad & \text{if and only if } j_1 < j_2 \text{ for } e_1, e_2 \in E_{f,T}, \\
e_1 \prec_{b,T} e_2 \quad & \text{if and only if (i) } i_1 < i_2 \text{ or (ii) } i_1 = i_2 \text{ and } j_1 < j_2, \text{ for } e_1, e_2 \in E_{b,T}, \\
e_1 \prec_{bf,T} e_2 \quad & \text{if and only if (i) } i_1 < j_2 \text{ for } e_1 \in E_{b,T}, e_2 \in E_{f,T} \\
& \text{or (ii) } j_1 \leq i_2 \text{ for } e_1 \in E_{f,T}, e_2 \in E_{b,T}.
\end{aligned}
$$

The combination of these partial orders is known to give a linear order of the edges. We also assume a total order of the labels in L and define a representation of T, a DFS code, as a sequence of 5-tuples $((v_i, v_j), \ell(v_i), \ell((v_i, v_j)), \ell(v_j))$ following the trace order of the DFS in T. A DFS code is smaller if smaller edges and smaller labels appear in earlier 5-tuples in the sequence. Accordingly, we define the search tree T having the minimum DFS code as a canonical representation of G. The search tree in Fig. 1c is canonical, since its DFS code is the minimum. As any subtree of a canonical T has its minimum DFS code, it is also canonical for its corresponding subgraph.

Moreover, gSpan applies the DFS which chooses the untraced edge having the smallest 5-tuples at the current vertex for visiting the next vertex. This focuses on the minimum DFS code and ensures to enumerate the canonical



Frequent Graph Mining, Fig. 1 A data graph and its search trees



Frequent Graph Mining, Fig. 2 Examples of paths and their backbones

subtree of every subgraph before finding its other noncanonical subtrees. This efficiently prunes an infrequent subgraph without matching its multiple DSF codes in (3). In this manner, the canonical graph representation of gSpan is fully adapted to its search algorithm.

Gaston

Gaston also derives all frequent connected subgraphs in a given data set of connected and undirected graphs [11]. It uses the polynomial time complexity of the enumeration of paths and free trees. Gaston uses a canonical path representation, a backbone, in (2). Two sequences of the labels of the vertices and edges starting from a center, which is a middle vertex, in the path to the both terminals are derived as shown in Fig. 2a, and the reverse of the lexicographically smaller sequence with the appended larger sequence is defined to be the backbone. In case of a path having an even number of vertices, two centers, which are two middle vertices, are used as shown in Fig. 2b. Starting from a single vertex, Gaston extends a path by adding a vertex to one of the terminals in the strategy (1). Finally, it efficiently counts the frequency of the extended path in the data set by using its backbone and prunes the infrequent paths in (3).

Gaston further enumerates free trees involving a frequent path as the longest path by iteratively adding vertices to the vertices in the free trees except for the terminal vertices of the path. Since the set of the free trees having a distinct backbone as its longest path is also distinct, the set does not intersect each other. This reduces the complexity of the enumeration in (1). Moreover, Gaston derives a canonical representation of a free tree, a canonical depth sequence, for (2) by transforming the tree to a rooted and ordered tree where the root is the center of its longest path, and its vertices and edges are arranged in a lexicographically descending order of the labels. If the two center exists in the path, the free tree is partitioned for each center, and each free tree

is represented by its canonical depth sequence. Similarly to the DFS code of gSpan, any subtree involving the root in this rooted and ordered tree is a canonical depth sequence. This is beneficial for (1), since all canonical depth sequences are incrementally obtained in the depth first search. Gaston efficiently prunes the infrequent free trees in the data set by using the canonical depth sequence in (3).

Gaston further enumerates cyclic subgraphs from a frequent free tree by iteratively adding edges bridging vertex pairs in the tree in (1). For (2), Gaston avoids duplicated enumerations of the cyclic subgraphs by using Nauty algorithm for the graph isomorphism checking [1]. It prunes the infrequent cyclic subgraphs of the data set in (3) and finally derives the frequent subgraphs. Gaston works very efficiently for the sparse data graphs, since the candidate cyclic subgraphs is less in such graphs.

Problem Definition

Pattern mining is a fundamental problem in data mining. The problem is to find all the patterns appearing in the given database frequently. For a set $E = \{1, \ldots, n\}$ of items, an *itemset* (also called a pattern) is a subset of E. Let $\mathcal{D}$ be a given *database* composed of *transactions* $R_1, \ldots, R_m$, $R_i \subseteq E$. For an itemset P, an *occurrence* of P is a transaction of $\mathcal{D}$ such that $P \subseteq R$, and the *occurrence set* $\mathrm{Occ}(P)$ is the set of occurrences of P. The *frequency* of P, also called *support*, is $|\mathrm{Occ}(P)|$ and denoted by $\mathrm{frq}(P)$. For a given constant σ called *minimum support*, an itemset P is *frequent* if $\mathrm{frq}(P) \geq \sigma$. For given a database and a minimum support, *frequent itemset mining* is the problem of enumerating all frequent itemsets in $\mathcal{D}$.

Key Results

The enumeration is solved in output polynomial time [1], and the space complexity is input polynomial [5]. Many algorithms have been proposed for practical efficiency on real-world data [7, 8, 10, 11] that are drastically fast. We show algorithm LCM that is the winner in the competition [6], and several techniques used in LCM.

Algorithms

There have been a lot of algorithms for this problem. The itemsets satisfy the following *monotone property*, and this is used in almost all existing algorithms.

Lemma 1 *For any itemsets P and Q such that $P \supseteq Q$, there holds $\mathrm{frq}(P) \leq \mathrm{frq}(Q)$. In particular, $\mathrm{Occ}(P) \subseteq \mathrm{Occ}(Q)$.* □

Using the monotone property, we can enumerate all frequent itemsets from $\emptyset$ by recursively adding items. □

Lemma 2 *Any frequent itemset P of size k is generated by adding an item to a frequent itemset of size $k-1$.*

Apriori

Apriori algorithm was proposed in the first paper of frequent pattern mining, by Agrawal et al. in 1993 [1]. The computational resources are not enough in the era, and the database could not fit memory, thus stored in an HDD. Apriori is designed to be efficient in such environments so that it scans the database only few times. Apriori is a breadth-first search algorithm that iteratively generates all frequent itemsets of size 1, size 2, and so on. Apriori generates candidate itemsets by adding an item to each frequent itemset of size $k-1$. From the monotone property, any frequent itemset of size k is in the candidate itemsets. Apriori then checks the inclusion relation between a transaction and all candidates. By doing this for all transactions, the frequencies of candidates are computed and infrequent candidates are removed. The algorithm is written as follows:

Algorithm Apriori($\mathcal{D}, \sigma$):

1. $\mathcal{P}_0 = \{\emptyset\}$; $k := 0$;
2. **while** $\mathcal{P}_k \neq \emptyset$ **do**
3. $\mathcal{P}_{k+1} := \emptyset$;
4. **for** each $P \in \mathcal{P}_k$, $\mathrm{frq}(P) := 0$; $\mathcal{P}_{k+1} := \mathcal{P}_{k+1} \cup \{P \cup \{i\} \mid i \in E\}$
5. **for** each $R \in \mathcal{D}$, $\mathrm{frq}(P) := \mathrm{frq}(P) + 1$ for all $P \in \mathcal{P}_{k+1}, P \subseteq R$.
6. remove all P from $\mathcal{P}_{k+1}$ satisfying $\mathrm{frq}(P) < \sigma$
7. **output** all $P \in \mathcal{P}_{k+1}$; $k := k + 1$
8. **end while**

The space complexity of Apriori is $O(n\mu)$ where μ is the number of frequent itemsets of $\mathcal{D}$. The time complexity is $O(n||\mathcal{D}||\mu)$ where $||\mathcal{D}|| = \sum_{R \in \mathcal{D}} |R|$ is the size of $\mathcal{D}$. Hence Apriori is output polynomial time.

Backtrack Algorithm

Backtrack algorithm is a depth-first search-based frequent itemset mining algorithm that is first proposed Bayardo et al. [5] in 1998. The amount of memory in a computer was rapidly increasing in the era, and thus the databases began to fit the memory. We can then reduce the memory space for storing candidate itemsets and thus huge amount of itemsets can be enumerated. Moreover, a technique so-called down project accelerates the computation. According to the monotone property, we can see that $P \cup \{i\}$ is included in a transaction R only if $R \in \mathrm{Occ}(P)$ holds. By using this, down project reduces the checks only with transactions in $\mathrm{Occ}(P)$. Particularly, we can see that $\mathrm{Occ}(P \cup \{i\}) = \mathrm{Occ}(P) \cap \mathrm{Occ}(\{i\})$. Moreover, we can reduce the check for the duplication by using a technique so-called tail extension. We denote the maximum item in P by $tail(P)$. Tail extension generates itemsets $P \cup \{i\}$ only with $i, i > tail(P)$. In this way, any frequent itemset P is generated uniquely from another frequent itemset; thus duplications are efficiently avoided, by recursively generating with tail extensions.

Algorithm BackTrack $(P, \mathrm{Occ}(P), \sigma)$:

1. **output** P
2. **for** each item $i > tail(P)$ **do**
3. **if** $|\mathrm{Occ}(P) \cap \mathrm{Occ}(\{i\})| \geq \sigma$, then **call** BackTrack $(P \cup \{i\}, \mathrm{Occ}(P) \cap \mathrm{Occ}(\{i\}), \sigma)$
4. **end for**

The space complexity of BackTrack is $O(||\mathcal{D}||)$; thereby BackTrack is polynomial space. The time complexity is $O(||\mathcal{D}||\mu)$, since step 3 is done by marking transactions in $\mathrm{Occ}(P)$ and checking whether each transaction of $\mathrm{Occ}(\{i\})$ is marked in constant time. Moreover, since the depth of recursion is at most n, the delay of BackTrack is $O(n||\mathcal{D}||)$. BackTrack with down project reduces practical computation time in order of magnitude, in implementation competitions FIMI03 and FIMI04 [6].

Database Reduction

The technique of database reduction was first developed in FP-growth by Han et al. [8] and modified in LCM by Uno et al. [11]. Database reduction drastically reduces practical computation time, as shown in the experiments in [6].

We observe that down project removes the unnecessary transactions from the database given to a recursive call, where unnecessary transactions are those never used in the recursion, and this fastens the computation. The idea of database reduction is to further remove unnecessary items from the database. The unnecessary items are (1) items i satisfying $i < tail(P)$ and (2) items i such that $P \cup \{i\}$ is not frequent. Items of (1) are never used because of the rule of tail extension. (2) comes from that $P \cup \{i\} \cup \{j\}$ is not frequent for any item j, by the monotone property. Thus, the removal of these items never disturbs the enumeration. The database obtained by removing unnecessary items from each transaction of $\mathrm{Occ}(P)$ is called the *conditional database*.

In the deep of recursion, the conditional database tends to have few items since $tail(P)$ is large and $\mathrm{frq}(P)$ is small. In such cases, several transactions would be identical. The computation for the identical transactions is the same, and thus we unify these transactions and put a mark of their quantity to the unified transaction as the representation of the multiplicity. For example, three transactions $R_1, R_2, R_3 = \{100, 105, 110\}$ are replaced by $R_j = \{100, 105, 110\}$ and a mark "three" is put to R_j. By this, the computation time on the bottom levels of the recursion is drastically shortened when σ is large. This is because conditional databases usually have k items in the bottom levels where k is a small constant and thus can have at most 2^k different transactions. The obtained database is called the *reduced database* and is denoted by $\mathcal{D}^*(P, \sigma)$.

The computation for the unification of identical transactions can be done by, for example, radix sort in $O(||\mathcal{D}^*(P, \sigma)||)$ time [11]. FP-growth further reduces by representing the database by a trie [7, 8]. However, experiments in [6] show that the overheads of trie are often larger than the gain; thus in many cases FP-growth is slower than LCM. The computation of frequent itemset mining generates recursions widely spread as the depth, thus so-called bottom expanded. In such case, the computation time on

the bottom levels dominates the total computation time [9]; thus database reduction performs very well.

Delivery

Delivery [10, 11] is a technique to compute $\mathrm{Occ}(P \cup \{i\})$ for all $i > tail(P)$ at once. Down project computes $\mathrm{Occ}(P \cup \{i\})$ in $O(|\mathrm{Occ}(\{i\})|)$ time and thus takes $O(||\mathcal{D}||)$ time for all i. Delivery computes $\mathrm{Occ}(P \cup \{i\})$ for all i at once in $(||\mathrm{Occ}(P)||)$ time. The idea is to find all $P \cup \{i\}$ that are included in R, for each transaction $R \in \mathrm{Occ}(P)$. Actually, $P \cup \{i\} \subseteq R$ iff $i \in R$; thus this is done by just scanning items $i > tail(P)$. The algorithm is described as follows:

1. $\mathrm{Occ}(P \cup \{i\}) := \emptyset$ for each $i > tail(P)$
2. **for** each $R \in \mathrm{Occ}(P)$ **do**
3. **for** each item $i \in R, i > tail(P)$, insert R to $\mathrm{Occ}(P \cup \{i\})$
4. **end for**

By using the reduced database $\mathcal{D}^*(P, \sigma)$, delivery is done in $O(||\mathcal{D}^*(P, \sigma)||)$ time. Note that the frequency is the sum of multiplications of transactions in the reduced database.

Generalizations and Extensions

The frequent itemset mining problem is extended by varying patterns and databases, such as trees in XML databases, labeled graphs in chemical compound databases, and so on. Let $\mathcal{L}$ be a class of structures, and $\preceq$ be an binary relation on $\mathcal{L}$. A member of $\mathcal{L}$ is called a *pattern*. Suppose that we are given a *database* $\mathcal{D}$ composed of records $R_1, \ldots, R_m$, $R_i \in \mathcal{L}$. Itemset mining is the case that $\mathcal{L} = 2^E$ and $a \preceq b$ holds iff $a \subseteq b$. For a pattern $P \in \mathcal{L}$, an *occurrence* of P is a record $R \in \mathcal{D}$ such that $P \preceq R$, and the other notations are defined in the same way. For given a database and a minimum support, *frequent pattern mining* is the problem of enumerating all the frequent patterns in $\mathcal{D}$.

When $\mathcal{L}$ is arbitrary, the frequent pattern mining is hard. Thus, we often assume that $(\mathcal{L}, \preceq)$ is a lattice, and there is an element $\perp$ of $\mathcal{L}$ such that $\perp \preceq P$ holds for any $P \in \mathcal{L}$. We then have the monotone property.

Lemma 3 *For any $P, Q \in \mathcal{L}$ satisfying $P \preceq Q$, there holds* $\mathrm{frq}(P) \geq \mathrm{frq}(Q)$. □

Let $\mathrm{suc}(P)$ (resp., $\mathrm{prc}(P)$) be the set of elements $Q \in \mathcal{L} \setminus \{P\}$ such that $P \preceq Q$ (resp., $Q \preceq P$) holds and no $X \in \mathcal{L} \setminus \{P, Q\}$ satisfies $P \preceq X \preceq Q$ (resp., $Q \preceq X \preceq P$). Using the monotone property, we can enumerate all frequent patterns from $\perp$ by recursively generating all elements of $\mathrm{suc}(P)$.

In this general setting, Apriori needs an assumption that $(\mathcal{L}, \preceq)$ is modular; thus for any P, Q such that $P \preceq Q$, the length of any maximal chain $P \preceq X_1 \cdots X_k \preceq Q$ is identical. By this assumption, we can define the size of a pattern P by the length of the maximal chain from $\perp$ to P. Apriori then works by replacing $\{P \cup \{i\} \mid i \in E\}$ of step 4 by $\mathrm{suc}(P)$.

Let T be the time to generate a pattern in $\mathrm{suc}(P)$ and T' be the time to evaluate $a \preceq b$. Note that T' may be large, for example, in the case that $\mathcal{L}$ is the set of graphs and T' is the time for graph isomorphism. Apriori generates $|\mathrm{suc}(P)|$ patterns for each pattern P, and we have to check whether each generated pattern is already in $\mathcal{P}_{i+1}$ by comparing P and each member of $\mathcal{P}_{i+1}$. Thus, the total computation time is $O(s(T + T'(\mu + |\mathcal{D}|)))$ where s is the maximum size of $\mathrm{suc}(P)$.

The depth-first search algorithm needs an alternative for tail extension. The alternative is given by reverse search technique proposed by Avis and Fukuda [4]. A pattern Q is generated from many patterns in $\mathrm{prc}(Q)$, and this makes duplications. We avoid this by defining the parent $P(Q)$ by one of $\mathrm{prc}(Q)$ and allow to generate Q only from $P(Q)$, so that Q is uniquely generated. For example, the same as tail extension, we define an order in $\mathrm{prc}(Q)$ and define $P(Q)$ by the minimum one in the order.

Algorithm Backtrack2 $(P, \mathrm{Occ}(P), \sigma)$:

1. **output** P
2. **for** each $Q \in \mathrm{suc}(P)$ **do**
3. compute $\mathrm{Occ}(Q)$ from $\mathrm{Occ}(P)$
4. **if** $\mathrm{frq}(Q) \geq \sigma$ and $P = P(Q)$ **then call** Backtrack2 $(Q, \mathrm{Occ}(Q), \sigma)$
5. **end for**

The time complexity of BackTrack2 is $O(s(T + T'' + T'|\mathcal{D}|)\mu)$ where T'' is the time to compute the parent of a pattern. The heaviest part of $T'|\mathcal{D}|$ is usually reduced by down project. The algorithm will be efficient if all patterns Q satisfying $P = P(Q)$ are efficiently enumerated. Such examples are sequences [12], trees [3], and motifs with wildcards [2].

Frequent Sequence Mining

$\mathcal{L}$ is composed of strings on alphabet Σ, and $a, b \in \mathcal{L}$ satisfy $a \preceq b$ iff a is a subsequence of b, i.e., a is obtained from b by deleting some letters. For a pattern P, $\mathrm{suc}(P)$ is the set of strings obtained by inserting a letter to P at some position.

We define the parent of P by the string obtained by removing the last letter from P. Then, the children of P is generated by appending a letter to the tail of P. Since $\preceq$ can be tested in linear time, BackTrack2 runs in $O(|\Sigma| \times ||\mathcal{D}||)$ time for each frequent sequence.

Frequent Ordered Tree Mining

$\mathcal{L}$ is composed of rooted trees such that each vertex has a label and an ordering of children. Such a tree is called a labeled ordered tree. $a, b \in \mathcal{L}$ satisfy $a \preceq b$ iff a is a subtree of b with correspondence keeping the children orders and vertex labels; a vertex of label "A" has to be mapped to a vertex having label "A," and children orders do not change. For a pattern P, $\mathrm{suc}(P)$ is the set of labeled ordered trees obtained by inserting a vertex as a leaf.

The rightmost path of an ordered tree is $\{v_1, \ldots, v_k\}$ where v_1 is the root, and v_i is the last child of v_{i-1}. We define the parent of P by that obtained by removing the rightmost leaf v_k. Then, the children of P is generated by appending a vertex with a label so that the vertex is the last child of a vertex in the rightmost path. Since $\preceq$ can be tested in linear time, BackTrack2 runs in $O(t|\Sigma| \times ||\mathcal{D}||)$ time for each frequent ordered tree, where t is the maximum height of the pattern tree.

Fully Dynamic All Pairs Shortest Paths

Giuseppe F. Italiano

Department of Information and Computer Systems, University of Rome, Rome, Italy

Years and Authors of Summarized Original Work

2004; Demetrescu, Italiano

Problem Definition

The problem is concerned with efficiently maintaining information about all-pairs shortest paths in a dynamically changing graph. This problem has been investigated since the 1960s [17, 18, 20], and plays a crucial role in many applications, including network optimization and routing, traffic information systems, databases, compilers, garbage collection, interactive verification systems, robotics, dataflow analysis, and document formatting.

A dynamic graph algorithm maintains a given property $\mathcal{P}$ on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property $\mathcal{P}$ quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. An algorithm is said to be *fully dynamic* if it can handle both edge insertions and edge deletions. A *partially dynamic* algorithm can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only. In this entry, fully dynamic algorithms for maintaining shortest paths on general directed graphs are presented.

In the *fully dynamic All Pairs Shortest Path (APSP) problem* one wishes to maintain a directed graph $G = (V, E)$ with real-valued edge weights under an intermixed sequence of the following operations:

***Update*(x, y, w):** update the weight of edge (x, y) to the real value w; this includes as a special case both edge insertion (if the weight is set from $+\infty$ to $w < +\infty$) and edge deletion (if the weight is set to $w = +\infty$);

***Distance*(x, y):** output the shortest distance from x to y.

***Path*(x, y):** report a shortest path from x to y, if any.

More formally, the problem can be defined as follows.

Problem 1 (Fully Dynamic All-Pairs Shortest Paths)
INPUT: A weighted directed graph $G = (V, E)$, and a sequence σ of operations as defined above.
OUTPUT: A matrix D such entry $D[x, y]$ stores the distance from vertex x to vertex y throughout the sequence σ of operations.

Throughout this entry, m and n denotes respectively the number of edges and vertices in G.

Demetrescu and Italiano [3] proposed a new approach to dynamic path problems based on maintaining classes of paths characterized by local properties, i.e., properties that hold for all proper subpaths, even if they may not hold for the entire paths. They showed that this approach can play a crucial role in the dynamic maintenance of shortest paths.

Key Results

Theorem 1 *The fully dynamic shoretest path problem can be solved in* $O(n^2 \log^3 n)$ *amortized time per update during any intermixed sequence of operations. The space required is* $O(mn)$.

Using the same approach, Thorup [22] has shown how to slightly improve the running times:

Theorem 2 *The fully dynamic shoretest path problem can be solved in* $O(n^2(\log n +$

$\log^2(m/n)))$ *amortized time per update during any intermixed sequence of operations. The space required is* $O(mn)$.

Applications

Dynamic shortest paths find applications in many areas, including network optimization and routing, transportation networks, traffic information systems, databases, compilers, garbage collection, interactive verification systems, robotics, dataflow analysis, and document formatting.

Open Problems

The recent work on dynamic shortest paths has raised some new and perhaps intriguing questions. First, can one reduce the space usage for dynamic shortest paths to $O(n^2)$? Second, and perhaps more importantly, can one solve efficiently fully dynamic *single-source* reachability and shortest paths on general graphs? Finally, are there any general techniques for making increase-only algorithms fully dynamic? Similar techniques have been widely exploited in the case of fully dynamic algorithms on undirected graphs [11–13].

Experimental Results

A thorough empirical study of the algorithms described in this entry is carried out in [4].

Data Sets

Data sets are described in [4].

Fully dynamic graph algorithm for maintaining connectivity; Incremental algorithms for graphs

Years and Authors of Summarized Original Work

2001; Holm, de Lichtenberg, Thorup

Problem Definition

Design a data structure for an undirected graph with a fixed set of nodes which can process queries of the form "Are nodes i and j connected?" and updates of the form "Insert edge $\{i,j\}$"; "Delete edge $\{i,j\}$." The goal is to minimize update and query times, over the worst-case sequence of queries and updates. Algorithms to solve this problem are called "fully dynamic" as opposed to "partially dynamic" since both insertions and deletions are allowed.

Key Results

Holm et al. [4] gave the first deterministic fully dynamic graph algorithm for maintaining connectivity in an undirected graph with polylogarithmic amortized time per operation, specifically, $O(\log^2 n)$ amortized cost per update operation and $O(\log n / \log\log n)$ worst-case per query, where n is the number of nodes. The basic technique is extended to maintain minimum spanning trees in $O(\log^4 n)$ amortized cost per update operation and 2-edge connectivity and biconnectivity in $O(\log^5 n)$ amortized time per operation.

The algorithm relies on a simple novel technique for maintaining a spanning forest in a graph which enables efficient search for a replacement edge when a tree edge is deleted. This technique ensures that each nontree edge is examined no more than $\log_2 n$ times. The algorithm relies on previously known tree data structures, such as top trees or ET-trees to store and quickly retrieve information about the spanning trees and the nontree edges incident to them.

Algorithms to achieve a query time $O(\log n / \log\log\log n)$ and expected amortized update time $O(\log n(\log\log n)^3)$ for connectivity and $O(\log^3 n \log\log n)$ expected amortized update time for 2-edge and biconnectivity were given in [6]. Lower bounds showing a continuum of tradeoffs for connectivity between query and update times in the cell probe model which match the known upper bounds were proved in [5]. Specifically, if t_u and t_q are the amortized update

and query time, respectively, then $t_q \cdot \log(t_u/t_q) = \Omega(\log n)$ and $t_u \cdot \log(t_q/t_u) = \Omega(\log n)$.

A previously known, somewhat different, randomized method for computing dynamic connectivity with $O(\log^3 n)$ amortized expected update time can be found in [2], improved to $O(\log^2 n)$ in [3]. A method which minimizes worst-case rather than amortized update time is given in [1] $O(\sqrt{n})$ time per update for connectivity as well as 2-edge connectivity and bipartiteness.

Open Problems

Can the worst-case update time be reduced to $O(n^{1/2})$, with polylogarithmic query time?

Can the lower bounds on the trade-offs in [6] be matched for all possible query costs?

Applications

Dynamic connectivity has been used as a subroutine for several static graph algorithms, such as the maximum flow problem in a static graph [7], and for speeding up numerical studies of the Potts spin model.

URL to Code

See http://www.mpi-sb.mpg.de/LEDA/friends/dyngraph.html for software which implements the algorithm in [2] and other older methods.

Problem Definition

The problem is concerned with efficiently maintaining information about connectivity in a dynamically changing graph. A dynamic graph algorithm maintains a given property $\mathcal{P}$ on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property $\mathcal{P}$ quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. An algorithm is said to be *fully dynamic* if it can handle both edge insertions and edge deletions. A *partially dynamic* algorithm can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only.

In the fully dynamic connectivity problem, one wishes to maintain an undirected graph $G = (V, E)$ under an intermixed sequence of the following operations:

***Connected*(u, v):** Return *true* if vertices u and v are in the same connected component of the graph. Return *false* otherwise.

***Insert*(x, y):** Insert a new edge between the two vertices x and y.

***Delete*(x, y):** Delete the edge between the two vertices x and y.

Key Results

In this section, a high level description of the algorithm for the fully dynamic connectivity problem in undirected graphs described in [11] is presented: the algorithm, due to Holm, de Lichtenberg and Thorup, answers connectivity queries in $O(\log n / \log \log n)$ worst-case running time while supporting edge insertions and deletions in $O(\log^2 n)$ amortized time.

The algorithm maintains a spanning forest F of the dynamically changing graph G. Edges in F are referred to as *tree edges*. Let e be a tree edge of forest F, and let T be the tree of F containing it. When e is deleted, the two trees T_1 and T_2 obtained from T after the deletion of e can be reconnected if and only if there is a non-tree edge in G with one endpoint in T_1 and the other endpoint in T_2. Such an edge is called a *replacement edge* for e. In other words, if there is a replacement edge for e, T is reconnected via this replacement edge; otherwise, the deletion of e creates a new connected component in G.

To accommodate systematic search for replacement edges, the algorithm associates to each edge e a level $\ell(e)$ and, based on edge levels, maintains a set of sub-forests of the spanning forest F: for each level i, forest F_i is the sub-forest induced by tree edges of level $\geq i$. Denoting by L denotes the maximum edge level, it follows that:

$$F = F_0 \supseteq F_1 \supseteq F_2 \supseteq \cdots \supseteq F_L \,.$$

Initially, all edges have level 0; levels are then progressively increased, but never decreased. The changes of edge levels are accomplished so as to maintain the following invariants, which obviously hold at the beginning.

Invariant (1): F is a maximum spanning forest of G if edge levels are interpreted as weights.

Invariant (2): The number of nodes in each tree of F_i is at most $n/2^i$.

Invariant (1) should be interpreted as follows. Let (u, v) be a non-tree edge of level $\ell(u, v)$ and let $u \cdots v$ be the unique path between u and v in F (such a path exists since F is a spanning forest of G). Let e be any edge in $u \cdots v$ and let $\ell(e)$ be its level. Due to (1), $\ell(e) \geq \ell(u, v)$. Since this holds for each edge in the path, and by construction $F_{\ell(u,v)}$ contains all the tree edges of level $\geq \ell(u, v)$, the entire path is contained in $F_{\ell(u,v)}$, i.e., u and v are connected in $F_{\ell(u,v)}$.

Invariant (2) implies that the maximum number of levels is $L \leq \lfloor \log_2 n \rfloor$.

Note that when a new edge is inserted, it is given level 0. Its level can be then increased at most $\lfloor \log_2 n \rfloor$ times as a consequence of edge deletions. When a tree edge $e = (v, w)$ of level $\ell(e)$ is deleted, the algorithm looks for a replacement edge at the highest possible level, if any.

Due to invariant (1), such a replacement edge has level $\ell \leq \ell(e)$. Hence, a replacement subroutine `Replace`$((u, w),\ell(e))$ is called with parameters e and $\ell(e)$. The operations performed by this subroutine are now sketched.

`Replace`$((u, w), \ell)$ finds a replacement edge of the highest level $\leq \ell$, if any. If such a replacement does not exist in level ℓ, there are two cases: if $\ell > 0$, the algorithm recurses on level $\ell - 1$; otherwise, $\ell = 0$, and the deletion of (v, w) disconnects v and w in G.

During the search at level ℓ, suitably chosen tree and non-tree edges may be promoted at higher levels as follows. Let T_v and T_w be the trees of forest F_ℓ obtained after deleting (v, w) and let, w.l.o.g., T_v be smaller than T_w. Then T_v contains at most $n/2^{\ell+1}$ vertices, since $T_v \cup T_w \cup \{(v, w)\}$ was a tree at level ℓ and due to invariant (2). Thus, edges in T_v of level ℓ can be promoted at level $\ell + 1$ by maintaining the invariants. Non-tree edges incident to T_v are finally visited one by one: if an edge does connect T_v and T_w, a replacement edge has been found and the search stops, otherwise its level is increased by 1.

Trees of each forest are maintained so that the basic operations needed to implement edge insertions and deletions can be supported in $O(\log n)$ time. There are few variants of basic data structures that can accomplish this task, and one could use the Euler Tour trees (in short ET-tree), first introduced in [17], for this purpose.

In addition to inserting and deleting edges from a forest, ET-trees must also support operations such as finding the tree of a forest that contains a given vertex, computing the size of a tree, and, more importantly, finding tree edges of level ℓ in T_v and non-tree edges of level ℓ incident to T_v. This can be done by augmenting the ET-trees with a constant amount of information per node: the interested reader is referred to [11] for details.

Using an amortization argument based on level changes, the claimed $O(\log^2 n)$ bound on the update time can be proved. Namely, inserting an edge costs $O(\log n)$, as well as increasing its level. Since this can happen $O(\log n)$ times, the total amortized insertion cost, inclusive of level increases, is $O(\log^2 n)$. With respect to edge deletions, cutting and linking $O(\log n)$ forest has a total cost $O(\log^2 n)$; moreover, there are $O(\log n)$ recursive calls to `Replace`, each of cost $O(\log n)$ plus the cost amortized over level increases. The ET-trees over $F_0 = F$ allows it to answer connectivity queries in $O(\log n)$ worst-case time. As shown in [11], this can be reduced to $O(\log n / \log\log n)$ by using a $\Theta(\log n)$-ary version of ET-trees.

Theorem 1 *A dynamic graph G with n vertices can be maintained upon insertions and deletions of edges using $O(\log^2 n)$ amortized time per update and answering connectivity queries in $O(\log n / \log\log n)$ worst-case running time.*

Later on, Thorup [18] gave another data structure which achieves slightly different time bounds:

Theorem 2 *A dynamic graph G with n vertices can be maintained upon insertions and deletions of edges using $O(\log n \cdot (\log\log n)^3)$ amortized time per update and answering connectivity queries in $O(\log n / \log\log\log n)$ time.*

The bounds given in Theorems 1 and 2 are not directly comparable, because each sacrifices the running time of one operation (either query or update) in order to improve the other.

The best known lower bound for the dynamic connectivity problem holds in the bit-probe model of computation and is due to Pătraşcu and Tarniţă [16]. The bit-probe model is an instantiation of the cell-probe model with one-bit cells. In this model, memory is organized in cells, and the algorithms may read or write a cell in constant time. The number of cell probes is taken as the measure of complexity. For formal definitions of this model, the interested reader is referred to [13].

Theorem 3 *Consider a bit-probe implementation for dynamic connectivity, in which updates take expected amortized time t_u, and queries take expected time t_q. Then, in the average case of an input distribution, $t_u = \Omega\left(log^2 n / log^2(t_u + t_q)\right)$. In particular*

$$\max\{t_u, t_q\} = \Omega\left(\left(\frac{\log n}{\log\log n}\right)^2\right).$$

In the bit-probe model, the best upper bound per operation is given by the algorithm of Theorem 2, namely it is $O(\log^2 n/\log\log\log n)$. Consequently, the gap between upper and lower bound appears to be limited essentially to doubly logarithmic factors only.

Applications

Dynamic graph connectivity appears as a basic subproblem of many other important problems, such as the dynamic maintenance of minimum spanning trees and dynamic edge and vertex connectivity problems. Furthermore, there are several applications of dynamic graph connectivity in other disciplines, ranging from Computational Biology, where dynamic graph connectivity proved to be useful for the dynamic maintenance of protein molecular surfaces as the molecules undergo conformational changes [6], to Image Processing, when one is interested in maintaining the connected components of a bitmap image [3].

Open Problems

The work on dynamic connectivity raises some open and perhaps intruiguing questions. The first natural open problem is whether the gap between upper and lower bounds can be closed. Note that the lower bound of Theorem 3 seems to imply that different trade-offs between queries and updates could be possible: can we design a data structure with $o(\log n)$ time per update and $O(\text{poly}(\log n))$ per query? This would be particulary interesting in applications where the total number of queries is substantially larger than the number of updates.

Finally, is it possible to design an algorithm with matching $O(\log n)$ update and query bounds for general graphs? Note that this is possible in the special case of plane graphs [5].

Experimental Results

A thorough empirical study of dynamic connectivity algorithms has been carried out in [1, 12].

Data Sets

Data sets are described in [1, 12].

Problem Definition

The problem is concerned with efficiently maintaining information about edge and vertex connectivity in a dynamically changing graph. Before defining formally the problems, a few preliminary definitions follow.

Given an undirected graph $G = (V, E)$, and an integer $k \geq 2$, a pair of vertices $\langle u, v \rangle$ is said to be *k-edge-connected* if the removal of any $(k-1)$ edges in G leaves u and v connected. It is not difficult to see that this is an equivalence relationship: the vertices of a graph G are partitioned by this relationship into equivalence classes called *k-edge-connected components*. G is said to be *k-edge-connected* if the removal of any $(k-1)$ edges leaves G connected. As a result of these definitions, G is k-edge-connected if and only if any two vertices of G are k-edge-connected. An edge set $E' \subseteq E$ is an *edge-cut for vertices x and y* if the removal of all the edges in E' disconnects G into two graphs, one containing x and the other containing y. An edge set $E' \subseteq E$ is an *edge-cut for G* if the removal of all the edges in E' disconnects G into two graphs. An edge-cut E' for G (for x and y, respectively) is *minimal* if removing any edge from E' reconnects G (for x and y, respectively). The cardinality of an edge-cut E', denoted by $|E'|$, is given by the number of edges in E'. An edge-cut E' for G (for x and y, respectively) is said to be a *minimum cardinality edge-cut* or in short a *connectivity edge-cut* if there is no other edge-cut E'' for G (for x and y respectively) such that $|E''| < |E'|$. Connectivity edge-cuts are of course minimal edge-cuts. Note that G is k-edge-connected if and only if a connectivity edge-cut for G contains at least k edges, and vertices x and y are k-edge-connected if and only if a connectivity edge-cut for x and y contains at least k edges. A connectivity edge-cut of cardinality 1 is called a *bridge*.

The following theorem due to Ford and Fulkerson, and Elias, Feinstein and Shannon (see [7]) gives another characterization of k-edge connectivity.

Theorem 1 (Ford and Fulkerson, Elias, Feinstein and Shannon) *Given a graph G and two vertices x and y in G, x and y are k-edge-connected if and only if there are at least k edge-disjoint paths between x and y.*

In a similar fashion, a vertex set $V' \subseteq V - \{x, y\}$ is said to be a *vertex-cut* for vertices x and y if the removal of all the vertices in V' disconnects x and y. $V' \subset V$ is a *vertex-cut* for vertices G if the removal of all the vertices in V' disconnects G.

The cardinality of a vertex-cut V', denoted by $|V'|$, is given by the number of vertices in V'. A vertex-cut V' for x and y is said to be a *minimum cardinality vertex-cut* or in short a *connectivity vertex-cut* if there is no other vertex-cut V'' for x and y such that $|V''| < |V'|$. Then x and y are k-vertex-connected if and only if a connectivity vertex-cut for x and y contains at least k vertices. A graph G is said to be *k-vertex-connected* if all its pairs of vertices are k-vertex-connected. A connectivity vertex-cut of cardinality 1 is called an *articulation point*, while a connectivity vertex-cut of cardinality 2 is called a *separation pair*. Note that for vertex connectivity it is no longer true that the removal of a connectivity vertex-cut splits G into two sets of vertices.

The following theorem due to Menger (see [7]) gives another characterization of k-vertex connectivity.

Theorem 2 (Menger) *Given a graph G and two vertices x and y in G, x and y are k-vertex-connected if and only if there are at least k vertex-disjoint paths between x and y.*

A dynamic graph algorithm maintains a given property $\mathcal{P}$ on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property $\mathcal{P}$ quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. An algorithm is *fully dynamic* if it can handle both edge insertions and edge deletions. A *partially dynamic* algorithm can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only.

In the *fully dynamic k-edge connectivity problem* one wishes to maintain an undirected graph $G = (V, E)$ under an intermixed sequence of the following operations:

- *k-EdgeConnected(u, v):* Return *true* if vertices u and v are in the same k-edge-connected component. Return *false* otherwise.
- *Insert(x, y):* Insert a new edge between the two vertices x and y.
- *Delete(x, y):* Delete the edge between the two vertices x and y.

In the *fully dynamic k-vertex connectivity problem* one wishes to maintain an undirected graph $G = (V, E)$ under an intermixed sequence of the following operations:

- *k-VertexConnected(u, v):* Return *true* if vertices u and v are k-vertex-connected. Return *false* otherwise.
- *Insert(x, y):* Insert a new edge between the two vertices x and y.
- *Delete(x, y):* Delete the edge between the two vertices x and y.

Key Results

To the best knowledge of the author, the most efficient fully dynamic algorithms for k-edge and k-vertex connectivity were proposed in [3, 12]. Their running times are characterized by the following theorems.

Theorem 3 *The fully dynamic k-edge connectivity problem can be solved in:*

1. $O(\log^4 n)$ *time per update and* $O(\log^3 n)$ *time per query, for* $k = 2$

2. $O(n^{2/3})$ *time per update and query, for* $k = 3$
3. $O(n\alpha(n))$ *time per update and query, for* $k = 4$
4. $O(n \log n)$ *time per update and query, for* $k \geq 5$.

Theorem 4 *The fully dynamic k-vertex connectivity problem can be solved in:*

1. $O(\log^4 n)$ *time per update and* $O(\log^3 n)$ *time per query, for* $k = 2$
2. $O(n)$ *time per update and query, for* $k = 3$
3. $O(n\alpha(n))$ *time per update and query, for* $k = 4$.

Applications

Vertex and edge connectivity problems arise often in issues related to network reliability and survivability. In computer networks, the vertex connectivity of the underlying graph is related to the smallest number of nodes that might fail before disconnecting the whole network. Similarly, the edge connectivity is related to the smallest number of links that might fail before disconnecting the entire network. Analogously, if two nodes are k-vertex-connected then they can remain connected even after the failure of up to $(k-1)$ other nodes, and if they are k-edge-connected then they can survive the failure of up to $(k-1)$ links. It is important to investigate the dynamic versions of those problems in contexts where the networks are dynamically evolving, say, when links may go up and down because of failures and repairs.

Open Problems

The work of Eppstein et al. [3] and Holm et al. [12] raises some intriguing questions. First, while efficient dynamic algorithms for k-edge connectivity are known for general k, no efficient fully dynamic k-vertex connectivity is known for $k \geq 5$. To the best of the author's knowledge, in this case even no static algorithm is known. Second, fully dynamic 2-edge and 2-vertex connectivity can be solved in polylogarithmic time per update, while the best known update bounds for higher edge and vertex connectivity are polynomial: Can this gap be reduced, i.e., can one design polylogarithnmic algorithms for fully dynamic 3-edge and 3-vertex connectivity?

Problem Definition

In this entry, the problem of maintaining a dynamic planar graph subject to edge insertions and edge deletions that preserve planarity but that can change the embedding is considered. In particular, in this problem one is concerned with the problem of efficiently maintaining information about edge and vertex connectivity in such a dynamically changing planar graph. The algorithms to solve this problem must handle insertions that keep the graph planar without regard to any particular embedding of the graph. The interested reader is referred to the chapter ▸ Fully Dynamic Planarity Testing of this encyclopedia for algorithms to learn how to check efficiently whether a graph subject to edge insertions and deletions remains planar (without regard to any particular embedding).

Before defining formally the problems considered here, a few preliminary definitions follow.

Given an undirected graph $G = (V, E)$, and an integer $k \geq 2$, a pair of vertices $\langle u, v \rangle$ is said to be *k-edge-connected* if the removal of any $(k-1)$ edges in G leaves u and v connected. It is not difficult to see that this is an equivalence relationship: the vertices of a graph G are partitioned by this relationship into equivalence classes called *k-edge-connected components*. G is said to be *k-edge-connected* if the removal of any $(k-1)$ edges leaves G connected. As a result of these definitions, G is k-edge-connected if and only if any two vertices of G are k-edge-connected. An edge set $E' \subseteq E$ is an *edge-cut for vertices x and y* if the removal of all the edges in E' disconnects G into two graphs, one containing x and the other containing y. An edge set $E' \subseteq E$ is an *edge-cut for G* if the removal of all the edges in E' disconnects G into two graphs. An edge-cut E' for G (for x and y, respectively) is *minimal* if removing any edge from E' reconnects G (for x and y, respectively). The cardinality of an edge-cut E', denoted by $|E'|$, is given by the number of edges in E'. An edge-cut E' for G (for x and y, respectively) is said to be a *minimum cardinality edge-cut* or in short a *connectivity edge-cut* if there is no other edge-cut E'' for G (for x and y, respectively) such that $|E''| < |E'|$. Connec-

tivity edge-cuts are of course minimal edge-cuts. Note that G is k-edge-connected if and only if a connectivity edge-cut for G contains at least k edges, and vertices x and y are k-edge-connected if and only if a connectivity edge-cut for x and y contains at least k edges. A connectivity edge-cut of cardinality 1 is called a *bridge*.

In a similar fashion, a vertex set $V' \subseteq V - \{x, y\}$ is said to be a *vertex-cut* for vertices x and y if the removal of all the vertices in V' disconnects x and y. $V' \subset V$ is a *vertex-cut* for vertices G if the removal of all the vertices in V' disconnects G.

The cardinality of a vertex-cut V', denoted by $|V'|$, is given by the number of vertices in V'. A vertex-cut V' for x and y is said to be a *minimum cardinality vertex-cut* or in short a *connectivity vertex-cut* if there is no other vertex-cut V'' for x and y such that $|V''| < |V'|$. Then x and y are k-vertex-connected if and only if a connectivity vertex-cut for x and y contains at least k vertices. A graph G is said to be *k-vertex-connected* if all its pairs of vertices are k-vertex-connected. A connectivity vertex-cut of cardinality 1 is called an *articulation point*, while a connectivity vertex-cut of cardinality 2 is called a *separation pair*. Note that for vertex connectivity it is no longer true that the removal of a connectivity vertex-cut splits G into two sets of vertices.

A dynamic graph algorithm maintains a given property $\mathcal{P}$ on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property $\mathcal{P}$ quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. An algorithm is *fully dynamic* if it can handle both edge insertions and edge deletions. A *partially dynamic* algorithm can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only.

In the *fully dynamic k-edge connectivity problem for a planar graph* one wishes to maintain an undirected planar graph $G = (V, E)$ under an intermixed sequence of edge insertions, edge deletions and queries about the k-edge connectivity of the underlying planar graph. Similarly, in the *fully dynamic k-vertex connectivity problem for a planar graph* one wishes to maintain an undirected planar graph $G = (V, E)$ under an intermixed sequence of edge insertions, edge deletions and queries about the k-vertex connectivity of the underlying planar graph.

Key Results

The algorithms in [2, 3] solve efficiently the above problems for small values of k:

Theorem 1 *One can maintain a planar graph, subject to insertions and deletions that preserve planarity, and allow queries that test the 2-edge connectivity of the graph, or test whether two vertices belong to the same 2-edge-connected component, in $O(\log n)$ amortized time per insertion or query, and $O(\log^2 n)$ per deletion.*

Theorem 2 *One can maintain a planar graph, subject to insertions and deletions that preserve planarity, and allow testing of the 3-edge and 4-edge connectivity of the graph in $O(n^{1/2})$ time per update, or testing of whether two vertices are 3- or 4-edge-connected, in $O(n^{1/2})$ time per update or query.*

Theorem 3 *One can maintain a planar graph, subject to insertions and deletions that preserve planarity, and allow queries that test the 3-vertex connectivity of the graph, or test whether two vertices belong to the same 3-vertex-connected component, in $O(n^{1/2})$ amortized time per update or query.*

Note that these theorems improve on the bounds known for the same problems on general graphs, reported in the chapter ▸ Fully Dynamic Higher Connectivity

Applications

The interest reader is referred to the chapter ▸ Fully Dynamic Higher Connectivity for applications of dynamic edge and vertex connectivity.

The case of planar graphs is especially important, as these graphs arise frequently in applications.

Open Problems

A number of problems related to the work of Eppstein et al. [2, 3] remain open. First, can the running times per operation be improved? Second, as in the case of general graphs, also for planar graphs fully dynamic 2-edge connectivity can be solved in polylogarithmic time per update, while the best known update bounds for higher edge and vertex connectivity are polynomial: Can this gap be reduced, i.e., can one design polylogarithnmic algorithms at least for fully dynamic 3-edge and 3-vertex connectivity? Third, in the special case of planar graphs can one solve fully dynamic k-vertex connectivity for general k?

Problem Definition

Let $G = (V, E)$ be an undirected weighted graph. The problem considered here is concerned with maintaining efficiently information about a minimum spanning tree of G (or minimum spanning forest if G is not connected), when G is subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. One expects from the dynamic algorithm to perform update operations faster than recomputing the entire minimum spanning tree from scratch.

Throughout, an algorithm is said to be *fully dynamic* if it can handle both edge insertions and edge deletions. A *partially dynamic* algorithm can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only.

Key Results

The dynamic minimum spanning forest algorithm presented in this section builds upon the dynamic connectivity algorithm described in the entry ▸ Fully Dynamic Connectivity. In particu-

lar, a few simple changes to that algorithm are sufficient to maintain a minimum spanning forest of a weighted undirected graph upon deletions of edges [13]. A general reduction from [11] can then be applied to make the deletions-only algorithm fully dynamic.

This section starts by describing a decremental algorithm for maintaining a minimum spanning forest under deletions only. Throughout the sequence of deletions, the algorithm maintains a minimum spanning forest F of the dynamically changing graph G. The edges in F are referred to as *tree edges* and the other edges (in $G - F$) are referred to as *non-tree edges*. Let e be an edge being deleted. If e is a non-tree edge, then the minimum spanning forest does not need to change, so the interesting case is when e is a tree edge of forest F. Let T be the tree of F containing e. In this case, the deletion of e disconnects the tree T into two trees T_1 and T_2: to update the minimum spanning forest, one has to look for the minimum weight edge having one endpoint in T_1 and the other endpoint in T_2. Such an edge is called a *replacement edge* for e.

As for the dynamic connectivity algorithm, to search for replacement edges, the algorithm associates to each edge e a level $\ell(e)$ and, based on edge levels, maintains a set of sub-forests of the minimum spanning forest F: for each level i, forest F_i is the sub-forest induced by tree edges of level $\geq i$. Denoting by L the maximum edge level, it follows that:

$$F = F_0 \supseteq F_1 \supseteq F_2 \supseteq \cdots \supseteq F_L.$$

Initially, all edges have level 0; levels are then progressively increased, but never decreased. The changes of edge levels are accomplished so as to maintain the following invariants, which obviously hold at the beginning.

Invariant (1): F is a maximum spanning forest of G if edge levels are interpreted as weights.

Invariant (2): The number of nodes in each tree of F_i is at most $n/2^i$.

Invariant (3): Every cycle $\mathcal{C}$ has a non-tree edge of maximum weight and minimum level among all the edges in $\mathcal{C}$.

Invariant (1) should be interpreted as follows. Let (u,v) be a non-tree edge of level $\ell(u, v)$ and let $u \cdots v$ be the unique path between u and v in F (such a path exists since F is a spanning forest of G). Let e be any edge in $u \cdots v$ and let $\ell(e)$ be its level. Due to (1), $\ell(e) \geq \ell(u, v)$. Since this holds for each edge in the path, and by construction $F_{\ell(u,v)}$ contains all the tree edges of level $\geq \ell(u, v)$, the entire path is contained in $F_{\ell(u,v)}$, i.e., u and v are connected in $F_{\ell(u,v)}$.

Invariant (2) implies that the maximum number of levels is $L \leq \lfloor \log_2 n \rfloor$.

Invariant (3) can be used to prove that, among all the replacement edges, the lightest edge is on the maximum level. Let e_1 and e_2 be two replacement edges with $w(e_1) < w(e : 2)$, and let $\mathcal{C}_i$ be the cycle induced by e_i in F, $i = 1, 2$. Since F is a minimum spanning forest, e_i has maximum weight among all the edges in $\mathcal{C}_i$. In particular, since by hypothesis $w(e_1) < w(e : 2)$, e_2 is also the heaviest edge in cycle $\mathcal{C} = (\mathcal{C}_1 \cup \mathcal{C}_2) \setminus (\mathcal{C}_1 \cap \mathcal{C}_2)$. Thanks to Invariant (3), e_2 has minimum level in $\mathcal{C}$, proving that $\ell(e_2) \leq \ell(e_1)$. Thus, considering non-tree edges from higher to lower levels is correct.

Note that initially, an edge is is given level 0. Its level can be then increased at most $\lfloor \log_2 n \rfloor$ times as a consequence of edge deletions. When a tree edge $e = (v, w)$ of level $\ell(e)$ is deleted, the algorithm looks for a replacement edge at the highest possible level, if any. Due to invariant (1), such a replacement edge has level $\ell \leq \ell(e)$. Hence, a replacement subroutine `Replace`$((u, w), \ell(e))$ is called with parameters e and $\ell(e)$. The operations performed by this subroutine are now sketched.

`Replace`$((u, w), \ell)$ finds a replacement edge of the highest level $\leq \ell$, if any, considering edges in order of increasing weight. If such a replacement does not exist in level ℓ, there are two cases: if $\ell > 0$, the algorithm recurses on level $\ell - 1$; otherwise, $\ell = 0$, and the deletion of (v,w) disconnects v and w in G.

It is possible to show that `Replace` returns a replacement edge of minimum weight on the highest possible level, yielding the following lemma:

Lemma 1 *There exists a deletions-only minimum spanning forest algorithm that can be initialized on a graph with n vertices and m edges and supports any sequence of edge deletions in* $O(m \log^2 n)$ *total time.*

The description of a fully dynamic algorithm which performs updates in $O(\log^4 n)$ time now follows. The reduction used to obtain a fully dynamic algorithm is a slight generalization of the construction proposed by Henzinger and King [11] and works as follows.

Lemma 2 *Suppose there is a deletions-only minimum spanning tree algorithm that, for any* k *and* ℓ*, can be initialized on a graph with* k *vertices and* ℓ *edges and supports any sequence of* $\Omega(\ell)$ *deletions in total time* $O(\ell \cdot t(k, \ell))$*, where* t *is a non-decreasing function. Then there exists a fully-dynamic minimum spanning tree algorithm for a graph with n nodes starting with no edges, that, for m edges, supports updates in time*

$$O\left(\log^3 n + \sum_{i=1}^{3+\log_2 m} \sum_{j=1}^{i} t\left(min\{n, 2^j\}, 2^j\right)\right).$$

The interested reader is referred to references [11] and [13] for the description of the construction that proves Lemma 2. From Lemma 1 one gets $t(k, \ell) = O(\log^2 k)$. Hence, combining Lemmas 1 and 2, the claimed result follows:

Theorem 3 *There exists a fully-dynamic minimum spanning forest algorithm that, for a graph with n vertices, starting with no edges, maintains a minimum spanning forest in* $O(\log^4 n)$ *amortized time per edge insertion or deletion.*

There is a lower bound of $\Omega(\log n)$ for dynamic minimum spanning tree, given by Eppstein et al. [6], which uses the following argument. Let A be an algorithm for maintaining a minimum spanning tree of an arbitrary (multi)graph G. Let A be such that change weight(e, Δ) returns the edge f that replace e in the minimum spanning tree, if e is replaced. Clearly, any dynamic spanning tree algorithm can be modified to return f. One can use algorithm A to sort n positive numbers $x_1, x_2, \ldots, x_n$, as follows. Construct a multigraph G consisting of two nodes connected by $(n + 1)$ edges $e_0, e_1, \ldots, e_n$, such that edge e_0 has weight 0 and edge e_i has weight x_i. The initial spanning tree is e_0. Increase the weight of e_0 to $+\infty$. Whichever edge replaces e_0, say e_i, is the edge of minimum weight. Now increase the weight of e_i to $+\infty$: the replacement of e_i gives the second smallest weight. Continuing in this fashion gives the numbers sorted in increasing order. A similar argument applies when only edge decreases are allowed. Since Paul and Simon [14] have shown that any sorting algorithm needs $\Omega(n \log n)$ time to sort n numbers on a unit-cost random access machine whose repertoire of operations include additions, subtractions, multiplications and comparisons with 0, but not divisions or bit-wise Boolean operations, the following theorem follows.

Theorem 4 *Any unit-cost random access algorithm that performs additions, subtractions, multiplications and comparisons with 0, but not divisions or bit-wise Boolean operations, requires* $\Omega(\log n)$ *amortized time per operation to maintain a minimum spanning tree dynamically.*

Applications

Minimum spanning trees have applications in many areas, including network design, VLSI, and geometric optimization, and the problem of maintaining minimum spanning trees dynamically arises in such applications.

Algorithms for maintaining a minimum spanning forest of a graph can be used also for maintaining information about the connected components of a graph. There are also other applications of dynamic minimum spanning trees algorithms, which include finding the k smallest spanning trees [3–5, 8, 9], sampling spanning

trees [7] and dynamic matroid intersection problems [10]. Note that the first two problems are not necessarily dynamic: however, efficient solutions for these problems need dynamic data structures.

Open Problems

The first natural open question is to ask whether the gap between upper and lower bounds for the dynamic minimum spanning tree problem can be closed. Note that this is possible in the special case of plane graphs [6].

Second, the techniques for dynamic minimum spanning trees can be extended to dynamic 2-edge and 2-vertex connectivity, which indeed can be solved in polylogarithmic time per update. Can one extend the same technique also to higher forms of connectivity? This is particularly important, since the best known update bounds for higher edge and vertex connectivity are polynomial, and it would be useful to design polylogarithnmic algorithms at least for fully dynamic 3-edge and 3-vertex connectivity.

Experimental Results

A thorough empirical study on the performance evaluation of dynamic minimum spanning trees algorithms has been carried out in [1, 2].

Data Sets

Data sets are described in [1, 2].

Years and Authors of Summarized Original Work

1999; Galil, Italiano, Sarnak

Problem Definition

In this entry, the problem of maintaining a dynamic planar graph subject to edge insertions and edge deletions that preserve planarity but that can change the embedding is considered. Before formally defining the problem, few preliminary definitions follow.

A graph is *planar* if it can be embedded in the plane so that no two edges intersect. In a dynamic framework, a planar graph that is committed to an embedding is called *plane*, and the general term *planar* is used only when changes in the embedding are allowed. An edge insertion that preserves the embedding is called *embedding-preserving*, whereas it is called *planarity-preserving* if it keeps the graph planar, even though its embedding can change; finally, an edge insertion is called *arbitrary* if it is not known to preserve planarity. Extensive work on dynamic graph algorithms has used ad hoc techniques to solve a number of problems such as minimum spanning forests, 2-edge-connectivity and planarity testing for plane graphs (with embedding-preserving insertions) [5–7, 9–12]: this entry is concerned with more general planarity-preserving updates.

The work of Galil et al. [8] and of Eppstein et al. [3] provides a general technique for dynamic planar graph problems, including those mentioned above: in all these problems, one can deal with either arbitrary or planarity-preserving insertions and therefore allow changes of the embedding.

The *fully dynamic planarity testing problem* can be defined as follows. One wishes to maintain a (not necessarily planar) graph subject to *arbitrary* edge insertions and deletions, and allow queries that test whether the graph is currently planar, or whether a potential new edge would violate planarity.

Key Results

Eppstein et al. [3] provided a way to apply the sparsification technique [2] to families of graphs that are already sparse, such as planar graphs.

The new ideas behind this technique are the following. The notion of a certificate can be expanded to a definition for graphs in which a subset of the vertices are denoted as *interesting*; these *compressed certificates* may reduce the size of the graph by removing uninteresting vertices. Using this notion, one can define a type of sparsification based on *separators*, small sets of vertices the removal of which splits the graph into roughly equal size components. Recursively finding separators in these components gives a *separator tree* which can also be used as a *sparsification tree*; the interesting vertices in each certificate will be those vertices used in separators at higher levels of the tree. The notion of a *balanced separator tree*, which also partitions the interesting vertices evenly in the tree, is introduced: such a tree can be computed in linear time, and can be maintained dynamically. Using this technique, the following results can be achieved.

Theorem 1 *One can maintain a planar graph, subject to insertions and deletions that preserve planarity, and allow queries that test whether a new edge would violate planarity, in amortized time* $O(n^{1/2})$ *per update or query.*

This result can be improved, in order to allow arbitrary insertions or deletions, even if they might let the graph become nonplanar, using the following approach. The data structure above can be used to maintain a planar subgraph of the given

graph. Whenever one attempts to insert a new edge, and the resulting graph would be nonplanar, the algorithm does not actually perform the insertion, but instead adds the edge to a list of *nonplanar edges*. Whenever a query is performed, and the list of nonplanar edges is nonempty, the algorithm attempts once more to add those edges one at a time to the planar subgraph. The time for each successful addition can be charged to the insertion operation that put that edge in the list of nonplanar edges. As soon as the algorithm finds some edge in the list that can not be added, it stops trying to add the other edges in the list. The time for this failed insertion can be charged to the query the algorithm is currently performing. In this way the list of nonplanar edges will be empty if and only if the graph is planar, and the algorithm can test planarity even for updates in nonplanar graphs.

Theorem 2 *One can maintain a graph, subject to arbitrary insertions and deletions, and allow queries that test whether the graph is presently planar or whether a new edge would violate planarity, in amortized time* $O(n^{1/2})$ *per update or query.*

Applications

Planar graphs are perhaps one of the most important interesting subclasses of graphs which combine beautiful structural results with relevance in applications. In particular, planarity testing is a basic problem, which appears naturally in many applications, such as VLSI layout, graphics, and computer aided design. In all these applications, there seems to be a need for dealing with dynamic updates.

Open Problems

The $O(n^{1/2})$ bound for planarity testing is amortized. Can we improve this bound or make it worst-case?

Finally, the complexity of the algorithms presented here, and the large constant factors involved in some of the asymptotic time bounds, make some of the results unsuitable for practical applications. Can one simplify the methods while retaining similar theoretical bounds?

Fully Dynamic Transitive Closure

Valerie King
Department of Computer Science, University of Victoria, Victoria, BC, Canada

Keywords

All-pairs dynamic reachability; Fully dynamic graph algorithm for maintaining transitive closure; Incremental algorithms for digraphs;

Years and Authors of Summarized Original Work

1999; King

Problem Definition

Design a data structure for a directed graph with a fixed set of node which can process queries of the form "Is there a path from i to j ?" and updates of the form: "Insert edge (i, j)"; "Delete edge (i, j)". The goal is to minimize update and query times, over the worst case sequence of queries and updates. Algorithms to solve this problem are called "fully dynamic" as opposed to "partially dynamic" since both insertions and deletions are allowed.

Key Results

This work [4] gives the first deterministic fully dynamic graph algorithm for maintaining the transitive closure in a directed graph. It uses $O(n^2 \log n)$ amortized time per update and $O(1)$ worst case query time where n is number of nodes in the graph. The basic technique is extended to give fully dynamic algorithms for approximate and exact all-pairs shortest paths problems.

The basic building block of these algorithms is a method of maintaining all-pairs shortest paths with insertions and deletions for distances up to d. For each vertex v, a single-source shortest path tree of depth d which reach v ("In_v") and another tree of vertices which are reached by v ("Out_v") are maintained during any sequence of deletions. Each insert of a set of edges incident to v results in the rebuilding of In_v and Out_v I. For each pair of vertices x, y and each length, a count is kept of the number of v such that there is a path from x in In_v to y in Out_v of that length.

To maintain transitive closure, log n levels of these trees are maintained for trees of depth 2, where the edges used to construct a forest on one level depend on the paths in the forest of the previous level.

Space required was reduced from $O(n^3)$ to $O(n^2)$ in [6]. A log n factor was shaved off [7, 10]. Other tradeoffs between update and query time are given in [1, 7–10]. A deletions only randomized transitive closure algorithm running in $O(mn)$ time overall is given by [8] where m is the initial number of edges in the graph. A simple monte carlo transitive closure algorithm for acyclic graphs is presented in [5]. Dynamic single source reachability in a digraph is presented in [8, 9]. All-pairs shortest paths can be maintained with nearly the same update time [2].

Applications

None

Open Problems

Can reachability from a single source in a directed graph be maintained in $o(mn)$ time over a worst case sequence of m deletions?

Can strongly connected components be maintained in $o(mn)$ time over a worst case sequence of m deletions?

Experimental Results

Experimental results on older techniques can be found in [3].

Problem Definition

For a detailed exposition of the solution approach presented in this entry, please refer to [15]. As evidenced by the successive announcement of ever-faster computer systems in the past decade, increasing the speed of VLSI systems continues to be one of the major requirements for VLSI system designers today. Faster integrated circuits are making possible newer applications that were traditionally considered difficult to implement in hardware. In this scenario of increasing circuit complexity, reduction of circuit delay in integrated circuits is an important design objective. Transistor sizing is one such task that has been employed for speeding up circuits for quite some time now [6]. Given the circuit topology, the delay of a combinational circuit can be controlled by varying the sizes of transistors in the circuit. Here, the size of a transistor is measured in terms of its channel width, since the channel lengths of MOS transistors in a digital circuit are generally uniform. In any case, what really matters is the ratio of channel width to channel length, and if channel lengths are not uniform, this ratio can be considered as the size. In coarse terms, the circuit delay can usually be reduced by increasing the sizes of certain transistors in the circuit from the minimum size. Hence, making the circuit faster usually entails the penalty of increased circuit area relative to a minimum-sized circuit, and the area-delay trade-off involved here is the problem of transistor size optimization. A related problem to transistor sizing is called gate sizing, where a logic gate in a circuit is modeled as an equivalent inverter and the sizing optimization is carried out on this modified circuit with equivalent inverters in place of more complex gates. There is, therefore, a reduction in the number of size parameters corresponding to every gate in the circuit. Needless to say, this is an easier problem to solve than the general transistor sizing problem. Note that gate sizing mentioned here is distinct from library-specific gate sizing that is a discrete optimization problem targeted to selecting appropriate gate sizes from an underlying cell library. The gate sizing problem targeted here is one of continuous gate sizing where the gate sizes are allowed to vary in a continuous manner between a minimum and a maximum size. There has been a large amount of work done on transistor sizing

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

[1–3, 5, 6, 9, 10, 12, 13], that underlines the importance of this optimization technique. Starting from a minimum-sized circuit, TILOS, [6], uses a greedy strategy for transistor sizing by iteratively sizing transistors in the critical path. A sensitivity factor is calculated for every transistor in the critical path to quantify the gain in circuit speed achieved by a unit upsizing of the transistor. The most sensitive transistor is then bumped up in size by a small constant factor to speed up the circuit. This process is repeated iteratively until the timing requirements are met. The technique is extremely simple to implement and has run-time behavior proportional to the size of the circuit. Its chief drawback is that it does not have guaranteed convergence properties and hence is not an exact optimization technique.

Key Results

The solution presented in the entry heretofore referred to as MINFLOTRANSIT was a novel way of solving the transistor sizing problem exactly and in an extremely fast manner. Even though the entry treats transistor sizing, in the description, the results apply as well to the less general problem of continuous gate sizing as described earlier. The proposed approach has some similarity in form to [2, 5, 8] which will be subsequently explained, but the similarity in content is minimal and the details of implementation are vastly different.

In essence, the proposed technique and the techniques in [2, 5, 8] are iterative relaxation approaches that involve a two-step optimization strategy. The first step involves a delay budgeting step where optimal delays are computed for transistors/gates. The second step involves sizing transistors optimally under this "constant delay" model to achieve these delay budgets. The two steps are iteratively alternated until the solution converges, i.e., until the delay budgets calculated in the first step are exactly satisfied by the transistor sizes determined by the second step.

The primary features of the proposed approach are:

- It is computationally fast and is comparable to TILOS in its run-time behavior.
- It can be used for true transistor sizing as well as the relaxed problem of gate sizing. Additionally, the approach can easily incorporate wire sizing [15].
- It can be adapted for more general delay models than the Elmore delay model [15].

The starting point for the proposed approach is a fast guess solution. This could be obtained, for example, from a circuit that has been optimized using TILOS to meet the given delay requirements. The proposed approach, as outlined earlier, is an iterative relaxation procedure that involves an alternating two-phase relaxed optimization sequence that is repeated iteratively until convergence is achieved. The two phases in the proposed approach are:

- The **D-phase** where transistor sizes are assumed fixed and transistor delays are regarded as variable parameters. Irrespective of the delay model employed, this phase can be formulated as the dual of a min-cost network flow problem. Using $|V|$ to denote the number of transistors and $|E|$ the number of wires in the circuit, this step in our application has worst-case complexity of $O(|V||E|\log(\log|V|))$ [7].
- The **W-phase** where transistor/gate delays are assumed fixed and their sizes are regarded as variable parameters. As long as the gate delay can be expressed as a separable function of the transistor sizes, this step can be solved as a Simple Monotonic Program (SMP) [11]. The complexity of SMP is similar to an all-pairs shortest-path algorithm in a directed graph, [4, 11], i.e., $O(V||E|)$.

The objective function for the problem is the minimization of circuit area. In the W-phase, this

Gate Sizing, Table 1 Comparison of TILOS and MINFLOTRANSIT on a Sun Ultrasparc 10 workstation for ISCAS85 and MCNC91 benchmarks for 0.13 um technology. The delay specs are with respect to a minimum-sized circuit. The optimization approach followed here was gate sizing

objective is addressed directly, and in the D-phase the objective is chosen to facilitate a move in the solution space in a direction that is known to lead to a reduction in the circuit area.

Applications

The primary application of the solution provided here is circuit and system optimization in automated VLSI design. The solution provided here can enable electronic design automation (EDA) tools that take a holistic approach toward transistor sizing. This will in turn enable making custom circuit design flows more realizable in practice. The mechanics of some of the elements of the solution provided here especially the **D-phase** have been used to address other circuit optimization problems [14].

Open Problems

The related problem of discrete gate sizing optimization matching gate sized to available gate sizes from a standard cell library is a provably hard optimization problem which could be aided by the development of efficient heuristics and probabilistic algorithms.

Experimental Results

A relative comparison of MINFLOTRANSIT with TILOS is provided in Table 1 for gate sizing of ISACS85 and mcnc91 benchmark circuits. As can be seen a significant performance improvement is observed with a tolerable loss in execution time.

General Equilibrium

Li-Sha Huang
Department of Computer Science and Technology, Tsinghua University, Beijing, China

Keywords

Competitive market equilibrium

Years and Authors of Summarized Original Work

2002; Deng, Papadimitriou, Safra

Problem Definition

This problem is concerned with the computational complexity of finding an exchange market equilibrium. The exchange market model consists of a set of agents, each with an initial endowment of commodities, interacting through a market, trying to maximize each's utility function. The equilibrium prices are determined by a clearance condition. That is, all commodities are bought, collectively, by all the utility maximizing agents, subject to their budget constraints (determined by the values of their initial endowments of commodities at the market price). The work of Deng, Papadimitriou and Safra [3] studies the complexity, approximability, inapproximability, and communication complexity of finding equilibrium prices. The work shows the NP-hardness

of approximating the equilibrium in a market with indivisible goods. For markets with divisible goods and linear utility functions, it develops a pseudo-polynomial time algorithm for computing an ϵ-equilibrium. It also gives a communication complexity lower bound for computing Pareto allocations in markets with non-strictly concave utility functions.

Market Model

In a pure exchange economy, there are m traders, labeled by $i = 1, 2, ..., m$, and n types of commodities, labeled by $j = 1, 2, ..., n$. The commodities could be divisible or indivisible. Each trader i comes to the market with initial endowment of commodities, denoted by a vector $w_i \in \mathbb{R}^n_+$, whose j-th entry is the amount of commodity j held by trader i.

Associate each trader i a *consumption set* X_i to represents the set of possible commodity bundles for him. For example, when there are n_1 divisible commodities and $(n - n_1)$ indivisible commodities, X_i can be $\mathbb{R}^{n_1}_+ \times \mathbb{Z}^{n-n_1}_+$. Each trader has a utility function $X_i \mapsto \mathbb{R}_+$ to present his utility for a bundle of commodities. Usually, the utility function is required to be concave and nondecreasing.

In the market, each trader acts as both a buyer and a seller to maximize his utility. At a certain price $p \in \mathbb{R}^n_+$, trader i is is solving the following optimization problem, under his budget constraint:

$$\max \ u_i(x_i) \ \ s.t. \quad x_i \in X_i \text{ and } \langle p, x_i \rangle \leq \langle p, w_i \rangle.$$

Definition 1 An equilibrium in a pure exchange economy is a price vector $\bar{p} \in \mathbb{R}^n_+$ and bundles of commodities $\{\bar{x}_i \in \mathbb{R}^n_+, i = 1, ..., m\}$, such that

$$\bar{x_i} \in \text{argmax}\{u_i(x_i) | x_i \in X_i \text{ and } \langle x_i, \bar{p} \rangle \leq \langle w_i, \bar{p} \rangle\},$$
$$\forall 1 \leq i \leq m$$
$$\sum_{i=1}^{m} \bar{x}_{ij} \leq \sum_{i=1}^{m} w_{ij}, \forall 1 \leq j \leq n.$$

The concept of approximate equilibrium was introduced in [3]:

Definition 2 ([3)] An ϵ-approximate equilibrium in an exchange market is a price vector $\bar{p} \in \mathbb{R}^n_+$ and bundles of goods $\{\bar{x}_i \in \mathbb{R}^n_+, i = 1, ..., m\}$, such that

$$u_i(\bar{x}_i) \geq \frac{1}{1+\epsilon} \max\{u_i(x_i) | x_i \in X_i, \langle x_i, \bar{p} \rangle \leq \langle w_i, \bar{p} \rangle\}, \forall i \quad (1)$$

$$\langle \bar{x}_i, \bar{p} \rangle \leq (1+\epsilon) \langle w_i, \bar{p} \rangle, \forall i \quad (2)$$

$$\sum_{i=1}^{m} \bar{x}_{ij} \leq (1+\epsilon) \sum_{i=1}^{m} w_{ij}, \forall j \ . \quad (3)$$

Key Results

A linear market is a market in which all the agents have linear utility functions. The deficiency of a market is the smallest $\epsilon \geq 0$ for which an ϵ-approximate equilibrium exists.

Theorem 1 *The deficiency of a linear market with indivisible goods is NP-hard to compute, even if the number of agents is two. The deficiency is also NP-hard to approximate within 1/3.*

Theorem 2 *There is a polynomial-time algorithm for finding an equilibrium in linear markets with bounded number of divisible goods. Ditto for a polynomial number of agents.*

Theorem 3 *If the number of goods is bounded, there is a polynomial-time algorithm which, for any linear indivisible market for which a price equilibrium exists, and for any $\epsilon > 0$, finds an ϵ-approximate equilibrium.*

If the utility functions are strictly concave and the equilibrium prices are broadcasted to all agents, the equilibrium allocation can be computed distributely without any communication, since each agent's basket of goods is uniquely determined. However, if the utility functions are not strictly concave, e.g., linear functions, communications are needed to coordinate the agents' behaviors.

Theorem 4 *Any protocol with binary domains for computing Pareto allocations of m agents and n divisible commodities with concave utility functions (resp. ϵ-Pareto allocations for indivisible commodities, for any $\epsilon < 1$) must have market communication complexity $\Omega(m \log(m+n))$ bits.*

Applications

This concept of market equilibrium is the outcome of a sequence of efforts trying to fully understand the laws that govern human commercial activities, starting with the "invisible hand" of Adam Smith, and finally, the mathematical conclusion of Arrow and Debreu [1] that there exists a set of prices that bring supply and demand into equilibrium, under quite general conditions on the agent utility functions and their optimization behavior.

The work of Deng, Papadimitriou and Safra [3] explicitly called for an algorithmic complexity study of the problem, and developed interesting complexity results and approximation algorithms for several classes of utility functions. There has since been a surge of algorithmic study for the computation of the price equilibrium problem with continuous variables, discovering and rediscovering polynomial time algorithms for many classes of utility functions, see [2, 4–9].

Significant progress has been made in the above directions but only as a first step. New ideas and methods have already been invented and applied in reality. The next significant step will soon manifest itself with many active studies in microeconomic behavior analysis for E-commercial markets. Nevertheless the algorithmic analytic foundation in [3] will be an indispensable tool for further development in this reincarnated exciting field.

Open Problems

The most important open problem is what is the computational complexity for finding the equilibrium price, as guaranteed by the Arrow–Debreu theorem. To the best of the author's knowledge, only the markets whose set of equilibria is convex can be solved in polynomial time with current techniques. And approximating equilibria in some markets with disconnected set of equilibria, e.g., Leontief economies, are shown to be PPAD-hard. Is the convexity or (weakly) gross substitutability a necessary condition for a market to be polynomial-time solvable?

Second, how to handle the dynamic case is especially interesting in theory, mathematical modeling, and algorithmic complexity as bounded rationality. Great progress must be made in those directions for any theoretical work to be meaningful in practice.

Third, incentive compatible mechanism design protocols for the auction models have been most actively studied recently, especially with the rise of E-Commerce. Especially at this level, a proper approximate version of the equilibrium concept handling price dynamics should be especially important.

Generalized Steiner Network

Julia Chuzhoy
Toyota Technological Institute, Chicago, IL, USA

Keywords

Survivable network design

Years and Authors of Summarized Original Work

2001; Jain

Problem Definition

The generalized Steiner network problem is a network design problem, where the input consists of a graph together with a collection of connectivity requirements, and the goal is to find the cheapest subgraph meeting these requirements.

Formally, the input to the generalized Steiner network problem is an undirected multigraph $G = (V, E)$, where each edge $e \in E$ has a non-negative cost $c(e)$, and for each pair of vertices $i, j \in V$, there is a connectivity requirement $r_{i,j} \in \mathbb{Z}$. A feasible solution is a subset $E' \subseteq E$ of edges, such that every pair $i, j \in V$ of vertices is connected by at least $r_{i,j}$ edge-disjoint path in graph $G' = (V, E')$. The generalized Steiner network problem asks to find a solution E' of minimum cost $\sum_{e \in E'} c(e)$.

This problem generalizes several classical network design problems. Some examples include minimum spanning tree, Steiner tree and Steiner forest. The most general special case for which a 2-approximation was previously known is the Steiner forest problem [1, 4].

Williamson et al. [8] were the first to show a non-trivial approximation algorithm for the generalized Steiner network problem, achieving a $2k$-approximation, where $k = \max_{i,j \in V}\{r_{i,j}\}$. This result was improved to $O(\log k)$-approximation by Goemans et al. [3].

Key Results

The main result of [6] is a factor-2 approximation algorithm for the generalized Steiner network problem. The techniques used in the design and the analysis of the algorithm seem to be of independent interest.

The 2-approximation is achieved for a more general problem, defined as follows. The input is a multigraph $G = (V, E)$ with costs $c(\cdot)$ on edges, and connectivity requirement function $f : 2^V \to \mathbb{Z}$. Function f is weakly submodular, i.e., it has the following properties:

1. $f(V) = 0$.
2. For all $A, B \subseteq V$, at least one of the following two conditions holds:
   - $f(A) + f(B) \leq f(A \setminus B) + f(B \setminus A)$.
   - $f(A) + f(B) \leq f(A \cap B) + f(A \cup B)$.

For any subset $S \subseteq V$ of vertices, let $\delta(S)$ denote the set of edges with exactly one endpoint in S. The goal is to find a minimum-cost subset of edges $E' \subseteq E$, such that for every subset $S \subseteq V$ of vertices, $|\delta(S) \cap E'| \geq f(S)$.

This problem can be equivalently expressed as an integer program. For each edge $e \in E$, let x_e be the indicator variable of whether e belongs to the solution.

$$\text{(IP)} \qquad \min \sum_{e \in E} c(e) x_e$$

subject to:

$$\sum_{e \in \delta(S)} x_e \geq f(S) \qquad \forall S \subseteq V \qquad (1)$$

$$x_e \in \{0, 1\} \qquad \forall e \in E \qquad (2)$$

It is easy to see that the generalized Steiner network problem is a special case of (IP), where for each $S \subseteq V$, $f(S) = \max_{i \in S, j \notin S}\{r_{i,j}\}$.

Techniques

The approximation algorithm uses the LP-rounding technique. The initial linear program (LP) is obtained from (IP) by replacing the integrality constraint (2) with:

$$0 \leq x_e \leq 1 \qquad \forall e \in E \qquad (3)$$

It is assumed that there is a separation oracle for (LP). It is easy to see that such an oracle exists if (LP) is obtained from the generalized Steiner network problem. The key result used in the design and the analysis of the algorithm is summarized in the following theorem.

Theorem 1 *In any basic solution of (LP), there is at least one edge $e \in E$ with $x_e \geq 1/2$.*

The approximation algorithm works by iterative LP-rounding. Given a basic optimal solution of (LP), let $E^* \subseteq E$ be the subset of edges e with $x_e \geq 1/2$. The edges of E^* are removed from the graph (and are eventually added to the solution), and the problem is then solved recursively on the residual graph, by solving (LP) on $G^* = (V, E \setminus E^*)$, where for each subset $S \subseteq V$, the new requirement is $f(S) - |\delta(S) \cap E^*|$. The main observation that leads to factor-2 approximation is the following: if E' is a 2-approximation for the residual problem, then $E' \cup E^*$ is a 2-approximation for the original problem.

Given any solution to (LP), set $S \subseteq V$ is called *tight* iff constraint (1) holds with equality for S. The proof of Theorem 1 involves constructing a large *laminar family* of tight sets (a family where for every pair of sets, either one set contains the other, or the two sets are disjoint). After that a clever accounting scheme that charges edges to the sets of the laminar family is used to show that there is at least one edge $e \in E$ with $x_e \geq 1/2$.

Applications

Generalized Steiner network is a very basic and natural network design problem that has many applications in different areas, including the design of communication networks, VLSI design and vehicle routing. One example is the design of survivable communication networks, which remain functional even after the failure of some network components (see [5] for more details).

Open Problems

The 2-approximation algorithm of Jain [6] for generalized Steiner network is based on LP-rounding, and it has high running time. It would be interesting to design a combinatorial approximation algorithm for this problem.

It is not known whether a better approximation is possible for generalized Steiner network. Very few hardness of approximation results are known for this type of problems. The best current hardness factor stands on 1.01063 [2], and this result is valid even for the special case of Steiner tree.

Generalized Two-Server Problem

René A. Sitters
Department of Econometrics and Operations Research, VU University, Amsterdam, The Netherlands

Keywords

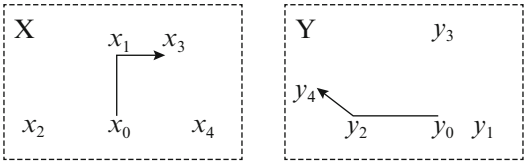
CNN problem

Years and Authors of Summarized Original Work

2006; Sitters, Stougie

Problem Definition

In the *generalized two-server problem*, we are given two servers: one moving in a metric space $\mathbb{X}$ and one moving in a metric space $\mathbb{Y}$. They are to serve requests $r \in \mathbb{X} \times \mathbb{Y}$which arrive one by one. A request $r = (x, y)$ is served by moving either the $\mathbb{X}$-server to point x or the $\mathbb{Y}$-server to point y. The decision as to which server to move to the next request is irrevocable and has to be taken without any knowledge about future requests. The objective is to minimize the total distance traveled by the two servers (Fig. 1).



Generalized Two-Server Problem, Fig. 1 In this example, both servers move in the plane and start from the configuration (x_0, y_0). The $\mathbb{X}$-server moves through requests 1 and 3, and the $\mathbb{Y}$-server takes care of requests 2 and 4. The cost of this solution is the sum of the path-lengths

Online Routing Problems

The generalized two-server problem belongs to a class of routing problems called *metrical service systems* [4, 10]. Such a system is defined by a metric space $\mathbb{M}$ of all possible system configurations, an initial configuration $\mathcal{C}_0$, and a set $\mathcal{R}$ of possible requests, where each request $r \in \mathcal{R}$ is a subset of $\mathbb{M}$. Given a sequence, $r_1, r_2 \ldots, r_n$, of requests, a feasible solution is a sequence, $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_n$, of configurations such that $C_i \in r_i$ for all $i \in \{1,\ldots,n\}$.

When we model the generalized two-server problem as a metrical service system we have $\mathbb{M} = \mathbb{X} \times \mathbb{Y}$ and $\mathcal{R} = \{\{x \times \mathbb{Y}\} \cup \{\mathbb{X} \times y\} | x \in \mathbb{X}, y \in \mathbb{Y}\}$. In the classical *two-server problem*, both servers move in the same space and receive the same requests, that is, $\mathbb{M} = \mathbb{X} \times \mathbb{X}$ and $\mathcal{R} = \{\{x \times \mathbb{Y}\} \cup \{\mathbb{X} \times x\} | x \in \mathbb{X}\}$.

The performance of algorithms for online optimization problems is often measured using *competitive analysis*. We say that an algorithm is α*-competitive* ($\alpha \geq 1$) for some minimization problem if for every possible instance the cost of the algorithm's solution is at most α times the cost of an optimal solution for the instance.

A standard algorithm that performs provably well for several elementary routing problems is the so-called work function algorithm [2, 5, 8]; after each request, the algorithm moves to a configuration with low cost and which is not too far from the current configuration. More precisely, if the system's configuration after serving a sequence σ is $\mathcal{C}$ and $r \subseteq \mathbb{M}$ is the next request, then the work function algorithm with parameter $\lambda \geq 1$ moves to a configuration $\mathcal{C}' \in r$ that minimizes

$$\lambda W_{\sigma,r}(\mathcal{C}') + d(\mathcal{C}, \mathcal{C}'),$$

where $d(\mathcal{C}, \mathcal{C}')$ is the distance between configurations $\mathcal{C}$ and $\mathcal{C}'$, and $W_{\sigma,r}(\mathcal{C}')$ is the cost of an optimal solution that serves all requests (in order) in σ plus request r with the restriction that it ends in configuration $\mathcal{C}'$.

Key Results

The main result in [11] is a sufficient condition for a metrical service system to have a constant-competitive algorithm. Additionally, the authors show that this condition holds for the generalized two-server problem.

For a fixed metrical service system $\mathcal{S}$ with metric space $\mathbb{M}$, denote by $A(\mathcal{C}, \sigma)$ the cost of algorithm A on input sequence σ, starting in configuration $\mathcal{C}$. Let $\mathrm{OPT}(\mathcal{C}, \sigma)$ be the cost of the corresponding optimal solution. We say that a path T in $\mathbb{M}$ *serves* a sequence σ if it visits all requests in order. Hence, a feasible path is a path that serves the sequence and starts in the initial configuration.

Paths T_1 and T_2 are said to be *independent* if they are far apart in the following way: $|T_1| + |T_2| < d(\mathcal{C}_1^g, \mathcal{C}_1^t) + d(\mathcal{C}_1^g, \mathcal{C}_1^t)$, where $\mathcal{C}_i^g$ and $\mathcal{C}_i^t$ are, respectively, the start and end point of path $T_i (i \in \{1,2\})$. Notice, for example, that two intersecting paths are not independent.

Theorem 1 *Let $\mathcal{S}$ be a metrical service system with metric space $\mathbb{M}$. Suppose there exists an algorithm A and constants $\alpha \geq 1$, $\beta \geq 0$, and $m \geq 2$ such that for any point $\mathcal{C} \in \mathbb{M}$, sequence σ and pairwise independent paths $T_1, T_2, \ldots, T_m$ that serve σ*

$$A(\mathcal{C}, \sigma) \leq \alpha \mathrm{OPT}(\mathcal{C}, \sigma) + \beta \sum_{i=1}^{m} |T_i|. \quad (1)$$

Then there exists an algorithm B that is constant competitive for $\mathcal{S}$.

The proof in [11] of the theorem above provides an explicit formulation of B. This algorithm combines algorithm A with the work function algorithm and operates in phases. In each phase, it applies algorithm A until its cost becomes too large compared to the optimal cost. Then, it makes one step of the work function algorithm and a new phase starts. In each phase, algorithm A makes a restart, that is, it takes the final configuration of the previous phase as the initial configuration, whereas the work function algorithm remembers the whole request sequence.

For the generalized two-server problem the so-called balance algorithm satisfies condition (1). This algorithm stores the cumulative costs of the two servers and with each request it moves the server that minimizes the maximum of the two new values. The balance algorithm itself is not constant competitive but Theorem 1 says that, if we combine it in a clever way with the work function algorithm, then we get an algorithm that is constant competitive.

Applications

A set of metrical service systems can be combined to get what is called in [9] the *sum system*. A request of the sum system consists of one request for each system, and to serve it we need to serve at least one of the individual requests. The generalized two-server problem should be considered as one of the simplest sum systems since the two individual problems are completely trivial: There is one server and each request consists of a single point.

Sum systems are particularly interesting to model systems for information storage and retrieval. To increase stability or efficiency, one may store copies of the same information in multiple systems (e.g., databases, hard disks). To retrieve one piece of information, we may read it from any system. However, to read information it may be necessary to change the configuration of the system. For example, if the database is stored in a binary search tree, then it is efficient to make online changes to the structure of the tree, that is, to use dynamic search trees [12].

Open Problems

A proof that the work function algorithm is competitive for the generalized two-server problem (as conjectured in [9] and [11]) is still lacking.

Also, a randomized algorithm with a smaller competitive ratio than that of [11] is not known. No results (except for a lower bound) are known for the generalized problem with more than two servers. It is not even clear if the work function algorithm may be competitive here.

There are systems for which the work function algorithm is not competitive. It would be interesting to have a nontrivial property that implies competitiveness of the work function algorithm.

Generalized Vickrey auction; GVA; VCG; Vickrey–Clarke–Groves mechanism

Years and Authors of Summarized Original Work

1995; Varian

Problem Definition

Auctions are used for allocating goods, tasks, resources, etc. Participants in an auction include an auctioneer (usually a seller) and bidders (usually buyers). An auction has well-defined rules that enforce an agreement between the auctioneer and the winning bidder. Auctions are often used when a seller has difficulty in estimating the value of an auctioned good for buyers.

The Generalized Vickrey Auction protocol (GVA) [5] is an auction protocol that can be used for combinatorial auctions [3] in which multiple items/goods are sold simultaneously. Although conventional auctions sell a single item at a time, combinatorial auctions sell multiple items/goods. These goods may have interdependent values, e.g., these goods are complementary/substitutable and bidders can bid on any combination of goods. In a combinatorial auction, a bidder can express complementary/substitutable preferences over multiple bids. By taking into account complementary/substitutable preferences, the participants' utilities and the revenue of the seller can be increased. The GVA is one instance of the Clarke mechanism [2, 4]. It is also called the Vickrey–Clarke–Groves mechanism (VCG). As

its name suggests, it is a generalized version of the well-known Vickrey (or second-price) auction protocol [6], proposed by an American economist W. Vickrey, a 1996 Nobel Prize winner.

Assume there is a set of bidders $N = \{1, 2, \ldots, n\}$ and a set of goods $M = \{1, 2, \ldots, m\}$. Each bidder i has his/her preferences over a bundle, i.e., a subset of goods $B \subseteq M$. Formally, this can be modeled by supposing that bidder i privately observes a parameter, or signal, θ_i, which determines his/her preferences. The parameter θ_i is called the *type* of bidder i. A bidder is assumed to have a *quasilinear*, *private value* defined as follows.

Definition 1 (Utility of a Bidder) The utility of bidder i, when i obtains $B \subseteq M$ and pays p_i, is represented as $v(B, \theta_i) - p_i$.

Here, the valuation of a bidder is determined independently of other bidders' valuations. Also, the utility of a bidder is linear in terms of the payment. Thus, this model is called a quasilinear, private value model.

Definition 2 (Incentive Compatibility) An auction protocol is (dominant-strategy) *incentive compatible* (or *strategy-proof*) if declaring the true type/evaluation values is a dominant strategy for each bidder, i.e., an optimal strategy regardless of the actions of other bidders.

A combination of dominant strategies of all bidders is called a *dominant-strategy equilibrium*.

Definition 3 (Individual Rationality) An auction protocol is *individually rational* if no participant suffers any loss in a dominant-strategy equilibrium, i.e., the payment never exceeds the evaluation value of the obtained goods.

Definition 4 (Pareto Efficiency) An auction protocol is *Pareto efficient* when the sum of all participants' utilities (including that of the auctioneer), i.e., the social surplus, is maximized in a dominant-strategy equilibrium.

The goal is to design an auction protocol that is incentive compatible, individually rational, and Pareto efficient. It is clear that individual rationality and Pareto efficiency are desirable. Regarding the incentive compatibility, the *revelation principle* states that in the design of an auction protocol, it is possible to restrict attention only to incentive compatible protocols without loss of generality [4]. In other words, if a certain property (e.g., Pareto efficiency) can be achieved using some auction protocol in a dominant-strategy equilibrium, then the property can also be achieved using an incentive-compatible auction protocol.

Key Results

A *feasible* allocation is defined as a vector of n bundles $\vec{B} = \langle B_1, \ldots, B_n \rangle$, where $\bigcup_{j \in N} B_j \subseteq M$ and for all $j \neq j'$, $B_j \cap B_{j'} = \emptyset$ hold.

The GVA protocol can be described as follows.

1. Each bidder i declares his/her type $\hat{\theta}_i$, which can be different from his/her true type θ_i.
2. The auctioneer chooses an optimal allocation $\vec{B}^*$ according to the declared types. More precisely, the auctioneer chooses $\vec{B}^*$ defined as follows:

$$\vec{B}^* = \arg\max_{\vec{B}} \sum_{j \in N} v\left(B_j, \hat{\theta}_j\right).$$

3. Each bidder i pays p_i, which is defined as follows ($B_j^{\sim i}$ and B_j^* are the jth element of $\vec{B}^{\sim i}$ and $\vec{B}^*$, respectively):

$$p_i = \sum_{j \in N \setminus \{i\}} v\left(B_j^{\sim i}, \hat{\theta}_j\right) - \sum_{j \in N \setminus \{i\}} v\left(B_j^*, \hat{\theta}_j\right),$$
$$\text{where } \vec{B}^{\sim i} = \arg\max_{\vec{B}} \sum_{j \in N \setminus \{i\}} v\left(B_j, \hat{\theta}_j\right). \tag{1}$$

The first term in Eq. (1) is the social surplus when bidder i does not participate. The second term is the social surplus except bidder i when i does participate. In the GVA, the payment of bidder i can be considered as the decreased amount of

the other bidders' social surplus resulting from his/her participation.

A description of how this protocol works is given below.

Example 1 Assume there are two goods a and b, and three bidders, 1, 2, and 3, whose types are θ_1, θ_2, and θ_3, respectively. The evaluation value for a bundle $v(B, \theta_i)$ is determined as follows.

	$\{a\}$	$\{b\}$	$\{a, b\}$
θ_1	\$6	\$0	\$6
θ_2	\$0	\$0	\$8
θ_3	\$0	\$5	\$5

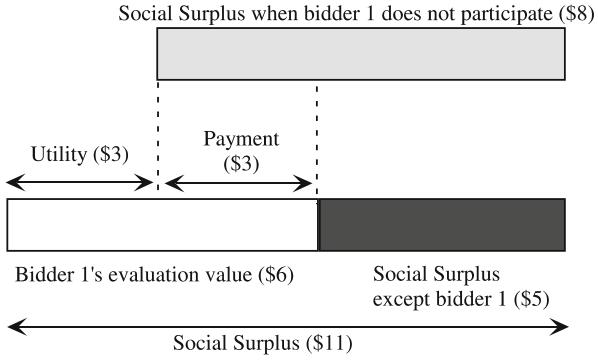
Here, bidder 1 wants good a only, and bidder 3 wants good b only. Bidder 2's utility is all-or-nothing, i.e., he/she wants both goods at the same time and having only one good is useless.

Assume each bidder i declares his/her true type θ_i. The optimal allocation is to allocate good a to bidder 1 and b to bidder 3, i.e., $\vec{B}^* = \langle \{a\}, \{\}, \{b\} \rangle$. The payment of bidder 1 is calculated as follows. If bidder 1 does not participate, the optimal allocation would have been allocating both items to bidder 2, i.e., $\vec{B}^{\sim 1} = \langle \{\}, \{a, b\}, \{\} \rangle$ and the social surplus, i.e., $\sum_{j \in N \setminus \{1\}} v\left(B_j^{\sim 1}, \hat{\theta}_j\right)$ is equal to \$8. When bidder 1 does participate, bidder 3 obtains $\{b\}$, and the social surplus except for bidder 1, i.e., $\sum_{j \in N \setminus \{1\}} v\left(B_j^*, \hat{\theta}_j\right)$, is 5. Therefore, bidder 1 pays the difference $\$8 - \$5 = \$3$. The obtained utility of bidder 1 is $\$6 - \$3 = \$3$. The payment of bidder 3 is calculated as $\$8 - \$6 = \$2$.

The intuitive explanation of why truth telling is the dominant strategy in the GVA is as follows. In the GVA, goods are allocated so that the social surplus is maximized. In general, the utility of society as a whole does not necessarily mean maximizing the utility of each participant. Therefore, each participant might have an incentive for lying if the group decision is made so that the social surplus is maximized.

However, the payment of each bidder in the GVA is cleverly determined so that the utility of each bidder is maximized when the social surplus is maximized. Figure 1 illustrates the relationship between the payment and utility of bidder 1 in Example 1. The payment of bidder 1 is defined as the difference between the social surplus when bidder 1 does not participate (i.e., the length of the upper shaded bar) and the social surplus except bidder 1 when bidder 1 does participate (the length of the lower black bar), i.e., $\$8 - \$5 = \$3$.

On the other hand, the utility of bidder 1 is the difference between the evaluation value of the obtained item and the payment, which equals $\$6 - \$3 = \$3$. This amount is equal to the difference between the total length of the lower bar and the upper bar. Since the length of the upper bar is determined independently of bidder 1's declaration, bidder 1 can maximize his/her utility by maximizing the length of the lower bar. However, the length of the lower bar represents the social surplus. Thus, bidder 1 can maximize his/her utility when the social surplus is maximized. Therefore, bidder 1 does not have an incentive for lying since the group decision is made so that the social surplus is maximized.



Generalized Vickrey Auction, Fig. 1 Utilities and Payments in the GVA

Theorem 1 *The GVA is incentive compatible.*

Proof Since the utility of bidder i is assumed to be quasilinear, it can be represented as

$$\begin{aligned} v(B_i, \theta_i) - p_i &= v(B_i, \theta_i) \\ &- \left[\sum_{j \in N \setminus \{i\}} v\left(B_j^{\sim i}, \hat{\theta}_j\right) - \sum_{j \in N \setminus \{i\}} v\left(B_j^*, \hat{\theta}_j\right) \right] \\ &= \left[v(B_i, \theta_i) + \sum_{j \in N \setminus \{i\}} v\left(B_j^*, \hat{\theta}_j\right) \right] \\ &- \sum_{j \in N \setminus \{i\}} v\left(B_j^{\sim i}, \hat{\theta}_j\right) \end{aligned} \tag{2}$$

The second term in Eq. (2) is determined independently of bidder i's declaration. Thus, bidder 1 can maximize his/her utility by maximizing the first term. However, $\vec{B}^*$ is chosen so that $\sum_{j \in N} v\left(B_j, \hat{\theta}_j\right)$ is maximized. Therefore, bidder i can maximize his/her utility by declaring $\hat{\theta}_i = \theta_i$, i.e., by declaring his/her true type. □

Theorem 2 *The GVA is individually rational.*

Proof This is clear from Eq. (2), since the first term is always larger than (or at least equal to) the second term. □

Theorem 3 *The GVA is Pareto efficient.*

Proof From Theorem 1, truth telling is a dominant-strategy equilibrium. From the way of choosing the allocation, the social surplus is maximized if all bidders declare their true types. □

Applications

The GVA can be applied to combinatorial auctions, which have lately attracted considerable attention [3]. The US Federal Communications Commission has been conductingauctions for allocating spectrum rights. Clearly, there exist interdependencies among the values of spectrum rights. For example, a bidder may desire licenses for adjoining regions simultaneously, i.e., these licenses are complementary. Thus, the spectrum auctions is a promising application field of combinatorial auctions and have been a major driving force for activating the research on combinatorial auctions.

Open Problems

Although the GVA has these good characteristics (Pareto efficiency, incentive compatibility, and individual rationality), these characteristics cannot be guaranteed when bidders can submit *false-name* bids. Furthermore, [1] pointed out several other limitations such as vulnerability to the collusion of the auctioneer and/or losers.

Also, to execute the GVA, the auctioneer must solve a complicated optimization problem. Various studies have been conducted to introduce search techniques, which were developed in the artificial intelligence literature, for solving this optimization problem [3].

Geographic Routing

Aaron Zollinger
Department of Electrical Engineering and Computer Science, University of California, Berkeley, CA, USA

Keywords

Directional routing; Geometric routing; Location-based routing; Position-based routing

Years and Authors of Summarized Original Work

2003; Kuhn, Wattenhofer, Zollinger

Problem Definition

Geographic routing is a type of routing particularly well suited for dynamic ad hoc networks. Sometimes also called directional, geometric, location-based, or position-based routing, it is based on two principal assumptions. First, it is assumed that every node knows its own and its network neighbors' positions. Second, the source of a message is assumed to be informed about the position of the destination. Geographic routing is defined on a Euclidean graph, that is a graph whose nodes are embedded in the Euclidean plane. Formally, geographic ad hoc routing algorithms can be defined as follows:

Definition 1 (Geographic Ad Hoc Routing Algorithm) Let $G = (V, E)$ be a Euclidean graph. The task of a geographic ad hoc routing algorithm $\mathcal{A}$ is to transmit a message from a source $s \in V$ to a destination $t \in V$ by sending packets over the edges of G while complying with the following conditions:

- All nodes $v \in V$ know their geographic positions as well as the geographic positions of all their neighbors in G.
- The source s is informed about the position of the destination t.
- The control information which can be stored in a packet is limited by $O(\log n)$ bits, that is, only information about a constant number of nodes is allowed.
- Except for the temporary storage of packets before forwarding, a node is not allowed to maintain any information.

Geographic routing is particularly interesting, as it operates without any routing tables whatsoever. Furthermore, once the position of the destination is known, all operations are strictly local, that is, every node is required to keep track only of its direct neighbors. These two factors – absence of necessity to keep routing tables up to date and independence of remotely occurring topology changes – are among the foremost reasons why geographic routing is exceptionally suitable for operation in ad hoc networks. Furthermore, in a sense, geographic routing can be considered a lean version of source routing appropriate for dynamic networks: While in source routing the complete hop-by-hop route to be followed by the message is specified by the source, in geographic routing the source simply addresses the message with the position of the destination. As the destination can generally be expected to move slowly compared to the frequency of topology changes between the source and the destination, it makes sense to keep track of the position of the destination instead of maintaining network topology information up to date; if the destination does not move too fast, the message is delivered regardless of possible topology changes among intermediate nodes.

The cost bounds presented in this entry are achieved on *unit disk graphs*. A unit disk graph is defined as follows:

Definition 2 (Unit Disk Graph) Let $V \subset \mathbb{R}^2$ be a set of points in the 2-dimensional plane. The graph with edges between all nodes with distance at most 1 is called the unit disk graph of V.

Unit disk graphs are often employed to model wireless ad hoc networks.

The routing algorithms considered in this entry operate on planar graphs, graphs that contain no two intersecting edges. There exist strictly local algorithms constructing such planar graphs given a unit disk graph. The edges of planar graphs partition the Euclidean plane into contiguous areas, so-called faces. The algorithms cited in this entry are based on these faces.

Key Results

The first geographic routing algorithm shown to always reach the destination was Face Routing introduced in [14].

Theorem 1 *If the source and the destination are connected, Face Routing executed on an arbitrary planar graph always finds a path to the destination. It thereby takes at most $O(n)$ steps, where n is the total number of nodes in the network.*

There exists however a geographic routing algorithm whose cost is bounded not only with respect to the total number of nodes, but in relation to the *shortest path* between the source and the destination: The GOAFR$^+$ algorithm [15, 16, 18, 24] (pronounced as "gopher-plus") combines *greedy routing* – where every intermediate node relays the message to be routed to its neighbor located nearest to the destination – with face routing. Together with the locally computable *Gabriel Graph* planarization technique, the effort expended by the GOAFR$^+$ algorithm is bounded as follows:

Theorem 2 *Let c be the cost of an optimal path from s to t in a given unit disk graph. GOAFR$^+$ reaches t with cost $O(c^2)$ if s and t are connected. If s and t are not connected, GOAFR$^+$ reports so to the source.*

On the other hand it can be shown that – on certain worst-case graphs – no geographic routing algorithm operating in compliance with the above definition can perform asymptotically better than GOAFR$^+$:

Theorem 3 *There exist graphs where any deterministic (randomized) geographic ad hoc routing algorithm has (expected) cost $\Omega(c^2)$.*

This leads to the following conclusion:

Theorem 4 *The cost expended by GOAFR$^+$ to reach the destination on a unit disk graph is asymptotically optimal.*

In addition, it has been shown that the GOAFR$^+$ algorithm is not only guaranteed to have low worst-case cost but that it also performs well in average-case networks with nodes randomly placed in the plane [15, 24].

Applications

By its strictly local nature geographic routing is particularly well suited for application in potentially highly dynamic wireless ad hoc networks. However, also its employment in dynamic networks in general is conceivable.

Open Problems

A number of problems related to geographic routing remain open. This is true above all with respect to the dissemination within the network of information about the destination position and on the other hand in the context of node mobility as well as network dynamics. Various approaches to these problems have been described in [7] as well as in chapters 11 and 12 of [24]. More generally, taking geographic routing one step further towards its application in practical wireless ad hoc networks [12, 13] is a field yet largely open. A more specific open problem is finally posed by the question whether geographic routing can be adapted to networks with nodes embedded in three-dimensional space.

Experimental Results

First experiences with geographic and in particular face routing in practical networks have

been made [12, 13]. More specifically, problems in connection with graph planarization that can occur in practice were observed, documented, and tackled.

Problem Definition

The central problem of private data analysis is to extract meaningful information from a statistical database without revealing too much about any particular individual represented in the database. Here, by a *statistical database*, we mean a multiset $D \in \mathcal{X}^n$ of n rows from the *data universe* $\mathcal{X}$. The notation $|D| \triangleq n$ denotes the *size* of the database. Each row represents the information belonging to a single individual. The universe $\mathcal{X}$ depends on the domain. A natural example to keep in mind is $\mathcal{X} = \{0,1\}^d$, i.e., each row of the database gives the values of d binary attributes for some individual.

Differential privacy formalizes the notion that an adversary should not learn too much about any individual as a result of a private computation. The formal definition follows.

Definition 1 ([8]) A randomized algorithm $\mathcal{A}$ satisfies (ε, δ)-differential privacy if for any two databases D and D' that differ in at most a single row (i.e., $|D \triangle D'| \leq 1$), and any measurable event S in the range of $\mathcal{A}$,

$$\Pr[\mathcal{A}(D) \in S] \leq e^{\varepsilon} \Pr[\mathcal{A}(D') \in S] + \delta.$$

Above, probabilities are taken over the internal coin tosses of $\mathcal{A}$.

Differential privacy guarantees to a data owner that allowing her data to be used for analysis does not risk much more than she would if she did not allow her data to be used.

In the sequel, we shall call databases D and D' that differ in a single row *neighboring databases*, denoted $D \sim D'$. Usually, the parameter ε is set to be a small constant so that $e^{\varepsilon} \approx 1 + \varepsilon$, and δ is set to be no bigger than n^{-2} or even $n^{-\omega(1)}$. The case of $\delta = 0$ often requires different techniques from the case $\delta > 0$; as is common in the literature, we shall call the two cases *pure differential privacy* and *approximate differential privacy*.

Query Release

In the query release problem, we are given a set $\mathcal{Q}$ of queries, where each $q \in \mathcal{Q}$ is a function $q : \mathcal{X}^n \to \mathbb{R}$. Our goal is to design a differentially private algorithm $\mathcal{A}$ which takes as input a database D and outputs a list of answers to the queries in $\mathcal{Q}$. We shall call such an algorithm a *(query answering) mechanism*. Here, we treat the important special case of query release for sets of *linear queries*. A linear query q is specified by a function $q : \mathcal{X} \to [-1, 1]$, and, slightly abusing notation, we define the value of the query as $q(D) \triangleq \sum_{x \in D} q(e)$. When $q : \mathcal{X} \to \{0,1\}$ is a predicate, $q(D)$ is a *counting query*: it simply counts the number of rows of D that satisfy the predicate.

It is easy to see that a differentially private algorithm (with any reasonable choice of ε and δ) cannot answer a nontrivial set of queries exactly. For this reason, we need to have a measure of error, and here we introduce the two most commonly used ones: average and worst-case error. Assume that on an input database D and a set of

linear queries $\mathcal{Q}$, the algorithm $\mathcal{A}$ gives answer $\tilde{q}^{\mathcal{A}}(D)$ for query $q \in \mathcal{Q}$. The *average error*of $\mathcal{A}$ on the query set $\mathcal{Q}$ for databases of size at most n is equal to

$$\mathrm{err}_{\mathrm{avg}}(\mathcal{A}, \mathcal{Q}, n) \triangleq \max_{D:|D|\leq n} \sqrt{\frac{1}{|\mathcal{Q}|}\mathbb{E}\left[\sum_{q\in\mathcal{Q}} |\tilde{q}^{\mathcal{A}}(D) - q(D)|^2\right]}.$$

The *worst-case error* is equal to

$$\mathrm{err}_{\mathrm{wc}}(\mathcal{A}, \mathcal{Q}, n) \triangleq \max_{D:|D|\leq n} \mathbb{E} \max_{q\in\mathcal{Q}} |\tilde{q}^{\mathcal{A}}(D) - q(D)|.$$

In both definitions above, expectations are taken over the coin throws of $\mathcal{A}$. We also define $\mathrm{err}_{\mathrm{avg}}(\mathcal{A}, \mathcal{Q}) = \sup_n \mathrm{err}_{\mathrm{avg}}(\mathcal{A}, \mathcal{Q}, n)$, and respectively $\mathrm{err}_{\mathrm{wc}}(\mathcal{A}, \mathcal{Q}) = \sup_n \mathrm{err}_{\mathrm{wc}}(\mathcal{A}, \mathcal{Q}, n)$, to be the maximum error over all database sizes. The objective in the query release problem is to *minimize error subject to privacy constraints*.

Marginal Queries

An important class of counting queries are the *marginal queries*. A k-way marginal query $\mathrm{mar}_{S,\alpha} : \{0,1\}^d \to \{0,1\}$ is specified by a subset of attributes $S \subseteq \{1, \ldots, d\}$ of size k and a vector $\alpha \in \{0,1\}^S$. The query evaluates to 1 on those rows that agree with α on all attributes in S, i.e., $\mathrm{mar}_{S,\alpha}(\chi) = \bigwedge_{i\in S} \chi_i = \alpha_i$ for any $\chi \in \{0,1\}^d$. Recall that, using the notation we introduced above, this implies that $\mathrm{mar}_{S,\alpha}(D)$ counts the number of rows in the database D that agree with α on S. Marginal queries capture contingency tables in statistics and OLAP cubes in databases. They are widely used in the sciences and are released by a number of official agencies.

Matrix Notation

It will be convenient to encode the query release problem for linear queries using matrix notation. A common and very useful representation of a database $D \in \mathcal{X}^n$ is the *histogram representation*: the histogram of D is a vector $x \in \mathbb{P}^{\mathcal{X}}$ ($\mathbb{P}$ is the set of nonnegative integers) such that for any $\chi \in \mathcal{X}$, x_χ is equal to the number of copies of χ in D. Notice that $\|x\|_1 = n$ and also that if x and x' are, respectively, the histograms of two neighboring databases D and D', then $\|x - x'\|_1 \leq 1$ (here $\|x\|_1 = \sum_\chi |x_\chi|$ is the standard ℓ_1 norm). Linear queries are a linear transformation of x. More concretely, let us define the *query matrix* $A \in [-1,1]^{\mathcal{Q}\times\mathcal{X}}$ associated with a set of linear queries $\mathcal{Q}$ by $a_{q,\chi} = q(\chi)$. Then it is easy to see that the vector Ax gives the answers to the queries $\mathcal{Q}$ on a database D with histogram x.

Key Results

A central object of study in geometric approaches to the query release problem is a convex body associated with a set of linear queries. Before introducing some of the main results and algorithms, we define this body.

The Sensitivity Polytope

Let A be the query matrix for some set of queries $\mathcal{Q}$, and let x and x' be the histograms of two neighboring databases, respectively, D and D'. Above, we observed that $D \sim D'$ implies that $\|x - x\|_1 \leq 1$. Let us use the notation $B_1^{\mathcal{X}} \triangleq \{x : \|x\|_1 \leq 1\}$ for the unit ball of the ℓ_1 norm in $\mathbb{R}^{\mathcal{X}}$. Then, $Ax - Ax' \in K_{\mathcal{Q}}$, where

$$K_{\mathcal{Q}} \triangleq \{Ax : \|x\|_1 \leq 1\} = A \cdot B_1^{\mathcal{X}}$$

is the *sensitivity polytope* associated with $\mathcal{Q}$. In other words, the sensitivity polytope is the smallest convex body such that $Ax' \in Ax + K_{\mathcal{Q}}$ for any histogram x and any histogram x' of a neighboring database. In this sense, $K_{\mathcal{Q}}$ describes how the answers to the queries $\mathcal{Q}$ can change between neighboring databases, which motivates the terminology. Informally, a differentially private algorithm must "hide" where in $Ax + K_{\mathcal{Q}}$ the true query answers are.

Another very useful property of the sensitivity polytope is that the vector Ax of query answers for any database of size at most n is contained in $n \cdot K_{\mathcal{Q}} = \{Ax : \|x\|_1 \leq n\}$.

Geometrically, $K_{\mathcal{Q}}$ is a convex polytope in $\mathbb{R}^{\mathcal{Q}}$, centrally symmetric around 0, i.e., $K_{\mathcal{Q}} = -K_{\mathcal{Q}}$. It is the convex hull of the points $\{\pm a_\chi : \chi \in \mathcal{X}\}$, where a_χ is the column of A indexed by the universe element χ, i.e., $a_\chi = (q(\chi))_{q \in \mathcal{Q}}$.

The sensitivity polytope was introduced by Hardt and Talwar [12]. The name was suggested by Li Zhang.

The Generalized Gaussian Mechanism

We mentioned informally that a differentially private mechanism must hide where in $Ax + K_{\mathcal{Q}}$ the true query answers lie. A simple formalization of this intuition is the Gaussian Mechanism, which we present here in a generalized geometric variant.

Recall that an *ellipsoid* in $\mathbb{R}^m$ is an affine transformation $F \cdot B_2^m + y$ of the unit Euclidean ball $B_2^m \triangleq \{x \in \mathbb{R}^m : \|x\|_2 \leq 1\}$ ($\|x\|_2$ is the usual Euclidean, i.e., ℓ_2 norm). In this article, we will only consider centrally symmetric ellipsoids, i.e., ellipsoids of the form $E = F \cdot B_2^m$.

Algorithm 1: Generalized Gaussian Mechanism $\mathcal{A}_E$

Input: *(Public)* Query set $\mathcal{Q}$; ellipsoid $E = F \cdot B_2^{\mathcal{Q}}$ such that $K_{\mathcal{Q}} \subseteq E$.
Input: *(Private)* Database D.
Sample a vector $g \sim N(0, c_{\varepsilon,\delta}^2)^{\mathcal{Q}}$, where $c_{\varepsilon,\delta} = \frac{0.5\sqrt{\varepsilon} + \sqrt{2\ln(1/\delta)}}{\varepsilon}$;
Compute the query matrix A and the histogram x for the database D;
Output: Vector of query answers $Ax + Fg$.

The *generalized Gaussian mechanism* $\mathcal{A}_E$ is shown as Algorithm 1. The notation $g \sim N(0, c_{\varepsilon,\delta}^2)^{\mathcal{Q}}$ means that each coordinate of g is an independent Gaussian random variable with mean 0 and variance $c_{\varepsilon,\delta}^2$. In the special case, when the ellipsoid E is just the Euclidean ball $\Delta_2 \cdot B_2^{\mathcal{Q}}$, with radius equal to the diameter $\Delta_2 \triangleq \max_{y \in K_{\mathcal{Q}}} \|y\|_2$ of $K_{\mathcal{Q}}$, $\mathcal{A}_E$ is the well-known Gaussian mechanism, whose privacy was analyzed in [6–8]. The diameter Δ_2 is also known as the ℓ_2-*sensitivity* of $\mathcal{Q}$ and for linear queries is always upper bounded by $\sqrt{|\mathcal{Q}|}$. The privacy of the generalized version is an easy corollary of the privacy of the standard Gaussian mechanism (see [16] for a proof).

Theorem 1 ([6–8, 16]) *For any ellipsoid E containing $K_{\mathcal{Q}}$, $\mathcal{A}_E$ satisfies (ε, δ)-differential privacy.*

It is not hard to analyze the error of the mechanism $\mathcal{A}_E$. Let $E = F \cdot B_2^{\mathcal{Q}}$, and recall the Hilbert-Schmidt norm $\|F\|_{HS} = \sqrt{\mathrm{tr}(FF^\intercal)}$ and the 1-to-2 norm $\|F^\intercal\|_{1\to 2}$ which is equal to the largest ℓ_2 norm of any row of F. Geometrically, $\|F\|_{HS}$ is equal to the square root of the sum of squared major axis lengths of E, and $\|F^\intercal\|_{1\to 2}$ is equal to the largest ℓ_∞ norm of any point in E. We have the error bounds

$$\mathrm{err}_{\mathrm{avg}}(\mathcal{A}, \mathcal{Q}) = O(c_{\varepsilon,\delta}) \cdot \frac{1}{\sqrt{|\mathcal{Q}|}} \|F\|_{HS};$$

$$\mathrm{err}_{\mathrm{wc}}(\mathcal{A}, \mathcal{Q}) = O(c_{\varepsilon,\delta} \sqrt{\log |\mathcal{Q}|}) \cdot \|F^\intercal\|_{1\to 2}.$$

Surprisingly, for any query set $\mathcal{Q}$, there exists an ellipsoid E such that the generalized Gaussian noise mechanism $\mathcal{A}_E$ is nearly optimal *among all differentially private mechanisms* for $\mathcal{Q}$. In order to formulate the result, let us define $\mathrm{opt}_{\mathrm{avg}}^{\varepsilon,\delta}(\mathcal{Q})$ (respectively, $\mathrm{opt}_{\mathrm{wc}}^{\varepsilon,\delta}(\mathcal{Q})$) to be the infimum of $\mathrm{err}_{\mathrm{avg}}(\mathcal{A}, \mathcal{Q})$ (respectively, $\mathrm{err}_{\mathrm{wc}}(\mathcal{A}, \mathcal{Q})$) over all (ε, δ)-differentially private mechanisms $\mathcal{A}$.

Theorem 2 ([16]) *Let $E = F \cdot B_2^{\mathcal{Q}}$ be the ellipsoid that minimizes $\|F\|_{HS}$ over all ellipsoids E containing $K_{\mathcal{Q}}$. Then*

$$\mathrm{err}_{\mathrm{avg}}(\mathcal{A}_E, \mathcal{Q}) = O(\log |\mathcal{Q}| \sqrt{\log 1/\delta}) \cdot \mathrm{opt}_{\mathrm{avg}}^{\varepsilon,\delta}(\mathcal{Q}).$$

If $E = F \cdot B_2^{\mathcal{Q}}$ minimizes $\|F^\intercal\|_{1\to 2}$ subject to $K_{\mathcal{Q}} \subseteq E$, then

$$\mathrm{err}_{\mathrm{wc}}(\mathcal{A}_E, \mathcal{Q}) = O((\log |\mathcal{Q}|)^{3/2} \sqrt{\log 1/\delta}) \cdot \mathrm{opt}_{\mathrm{wc}}^{\varepsilon,\delta}(\mathcal{Q}).$$

Minimizing $\|F\|_{HS}$ or $\|F^\intercal\|_{1\to 2}$ subject to $K_{\mathcal{Q}} \subseteq F \cdot B_2^{\mathcal{Q}}$ is a convex minimization problem.

An optimal solution can be approximated to within any prescribed degree of accuracy in time polynomial in $|\mathcal{Q}|$ and $|\mathcal{X}|$ via the ellipsoid algorithm. In fact, more efficient solutions are available: both problems can be formulated as semidefinite programs and solved via interior point methods, or one can also use the Plotkin-Shmoys-Tardos framework [1, 17]. Algorithm $\mathcal{A}_E$ also runs in time polynomial in $n, |\mathcal{Q}|, |\mathcal{X}|$, since it only needs to compute the true query answers and sample $|\mathcal{Q}|$ many Gaussian random variables. Thus, Theorem 2 gives an efficient approximation to the optimal differentially private mechanism for any set of linear queries.

The near-optimal mechanisms of Theorem 2 are closely related to the matrix mechanism [13]. The matrix mechanism, given a set of queries $\mathcal{Q}$ with query matrix A, solves an optimization problem to find a strategy matrix M, then computes answers $\tilde{y}$ to the queries Mx using the standard Gaussian mechanism, and outputs $AM^{-1}\tilde{y}$. The generalized Gaussian mechanism $\mathcal{A}_E$ instantiated with ellipsoid $E = F \cdot B_2^{\mathcal{Q}}$ is equivalent to the matrix mechanism with strategy matrix $F^{-1}A$.

The proof of optimality for the generalized Gaussian mechanism is related to a fundamental geometric fact: if all ellipsoids containing a convex body are "large," then the body itself must be "large." In particular, if the sum of squared major axis lengths of any ellipsoid containing $K_{\mathcal{Q}}$ is large, then $K_{\mathcal{Q}}$ must contain a simplex of proportionally large volume. Moreover, this simplex is the convex hull of a subset of the contact points of $K_{\mathcal{Q}}$ with the optimal ellipsoid. Since the contact points must be vertices of $K_{\mathcal{Q}}$, and all vertices of $K_{\mathcal{Q}}$ are either columns of the query matrix A or their negations, this guarantees the existence of a submatrix of A with large determinant. Determinants of submatrices in turn bound $\mathrm{opt}_{\mathrm{avg}}^{\varepsilon,\delta}(\mathcal{Q})$ from below (this is a consequence of a connection between combinatorial discrepancy and privacy [15], and the determinant lower bound on discrepancy [14]). This phenomenon is related to the Restricted Invertibility Principle of Bourgain and Tzafriri [4] and was established for the closely related minimum volume ellipsoid by Vershynin [18].

The Gaussian noise mechanism can only provide approximate privacy guarantees: when $\delta = 0$, the noise variance scaling factor $c_{\varepsilon,\delta}$ is unbounded. The case of pure privacy requires different techniques. Nevertheless, $(\varepsilon, 0)$-differentially private algorithms with efficiency and optimality guarantees analogous to these in Theorem 2 are known [2,12]. They use a more complicated noise distribution. In the important special case when $K_{\mathcal{Q}}$ is "well rounded" (technically, when $K_{\mathcal{Q}}$ is isotropic), the noise vector is sampled uniformly from $r \cdot K_{\mathcal{Q}}$, where r is a Γ-distributed random variable. Optimality is established conditional on the Hyperplane Conjecture [12] or unconditionally using Klartag's proof of an isomorphic version of the conjecture [2].

The Projection Mechanism

Despite the near-optimality guarantees, the generalized Gaussian mechanism has some drawbacks that can limit its applicability. One issue is that in some natural scenarios, the universe size $|\mathcal{X}|$ can be huge, and running time linear in $|\mathcal{X}|$ is impractical. Another is that its error is sometimes larger even than the database size, making the query answers unusable. We shall see that a simple modification of the Gaussian mechanism, based on an idea from statistics, goes a long way towards addressing these issues.

It is known that there exist sets of linear queries $\mathcal{Q}$ for which $\mathrm{opt}_{\mathrm{avg}}^{\varepsilon,\delta}(\mathcal{Q}) = \Omega(\sqrt{|\mathcal{Q}|})$ for any small enough constant ε and δ [6, 9]. However, this lower bound only holds for large databases, and algorithms with significantly better error guarantees are known when $n = o(|\mathcal{Q}|)$ [3, 10, 11]. We now know that there are (ε, δ)-differentially private algorithms that answer any set $\mathcal{Q}$ of linear queries on any database $D \in \mathcal{X}^n$ with average error at most

$$O\left(\frac{\sqrt{n}(\log|\mathcal{X}|)^{1/4}(\log 1/\delta)^{1/4}}{\sqrt{\varepsilon}}\right). \quad (1)$$

Moreover, for k-way marginal queries, this much error is necessary, up to factors logarithmic in n and $|\mathcal{Q}|$ [5]. Here, we describe a simple geometric algorithm from [16] that achieves this error bound for any $\mathcal{Q}$.

We know that for any set of queries $\mathcal{Q}$ and a database of size n, the true query answers are between 0 and n. Therefore, it is always safe to take the noisy answers $\tilde{y}$ output by the Gaussian mechanism and truncate them inside the interval $[0, n]$. However, we can do better by using knowledge of the query set $\mathcal{Q}$. For any database D of size n, the true query answers $y = Ax$ lie in $n \cdot K_{\mathcal{Q}}$. This suggests a regression approach: find the vector of answers $\hat{y} \in n \cdot K_{\mathcal{Q}}$ which is closest to the noisy output $\tilde{y}$ from the Gaussian mechanism. This is the main insight used in the projection mechanism (Algorithm 2).

Algorithm 2: Projection Mechanism $\mathcal{A}_{\text{proj}}$

Input: *(Public)* Query set $\mathcal{Q}$;
Input: *(Private)* Database $D \in \mathcal{X}^n$.
Compute a noisy vector of query answers $\tilde{y}$ with $\mathcal{A}_E$ for $E = \sqrt{|\mathcal{Q}|} \cdot B_2^{\mathcal{Q}}$.
Compute a projection $\hat{y}$ of $\tilde{y}$ onto $n \cdot K_{\mathcal{Q}}$:
$\hat{y} \triangleq \arg\min_{\hat{y} \in n \cdot K_{\mathcal{Q}}} \|\tilde{y} - \hat{y}\|_2$.
Output: Vector of answers $\hat{y}$.

The fact that the projection mechanism is (ε, δ)-differentially private is immediate, because its only interaction with the database is via the (ε, δ)-differentially private Gaussian mechanism, and post-processing cannot break differential privacy.

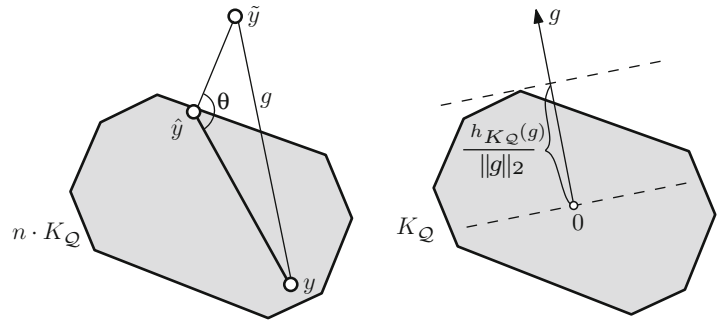
The projection step in $\mathcal{A}_{\text{proj}}$ reduces the noise significantly when $n = o(|\mathcal{Q}|/\varepsilon)$. Intuitively, in this case, $n \cdot K_{\mathcal{Q}}$ is small enough so that projection cancels a significant portion of the noise. Let us sketch the analysis. Let $y = Ax$ be the true query answers and $g = \tilde{y} - y$ the Gaussian noise vector. A simple geometric argument shows that $\|y - \hat{y}\|_2^2 \le 2|\langle y - \hat{y}, g\rangle|$: the main observation is that in the triangle formed by y, $\tilde{y}$, and $\hat{y}$, the angle at $\hat{y}$ is an obtuse or right angle; see Fig. 1. Since $\hat{y} \in n \cdot K_{\mathcal{Q}}$, there exists some histogram vector $\hat{x}$ with $\|\hat{x}\|_1 \le n$ such that $\hat{y} = A\hat{x}$. We can rewrite the inner product $\langle y - \hat{y}, g\rangle$ as $\langle x - \hat{x}, A^{\mathsf{T}} g\rangle$. Now, we apply Hölder's inequality and get

$$\begin{aligned} \mathbb{E}_g \|y - \hat{y}\|_2^2 &\le 2\mathbb{E}_g |\langle x - \hat{x}, A^{\mathsf{T}} g\rangle| \\ &\le 2\mathbb{E}_g \|x - \hat{x}\|_1 \|A^{\mathsf{T}} g\|_\infty \\ &\le 4n\mathbb{E}_g \|A^{\mathsf{T}} g\|_\infty. \end{aligned} \tag{2}$$

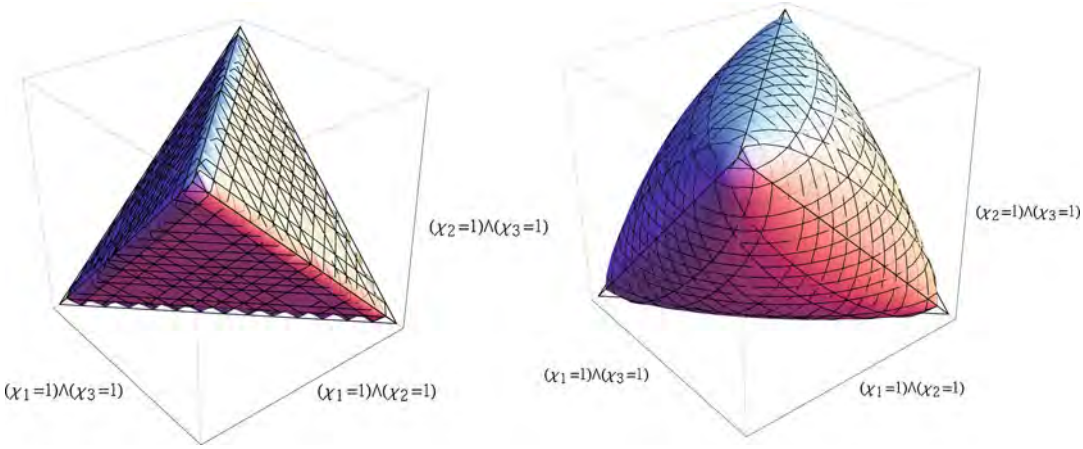
The term $\mathbb{E}_g \|A^{\mathsf{T}} g\|_\infty$ is the expected maximum of $|\mathcal{X}|$ Gaussian random variables, each with mean 0 and variance $c_{\varepsilon,\delta}^2 |\mathcal{Q}|^2$, and standard techniques give the bound $O(c_{\varepsilon,\delta} |\mathcal{Q}| \sqrt{\log |\mathcal{X}|})$. Plugging this into (2) shows that $\text{err}_{\text{avg}}(\mathcal{A}_{\text{proj}}, \mathcal{Q})$ is always bounded by (1). It is useful to note that $\|A^{\mathsf{T}} g\|_\infty$ is equal to $h_{K_{\mathcal{Q}}}(g) = \max_{y \in K_{\mathcal{Q}}} |\langle y, g\rangle|$, where $h_{K_{\mathcal{Q}}}$ is the *support function* of $K_{\mathcal{Q}}$. Geometrically, $h_{K_{\mathcal{Q}}}(g)$ is equal to half the width of $K_{\mathcal{Q}}$ in the direction of g, scaled by the Euclidean length of g (see Fig. 1). Thus, the average error of $\mathcal{A}_{\text{proj}}$ scales with the expected width of $n \cdot K_{\mathcal{Q}}$ in a random direction.

Running in Time Sublinear in $|\mathcal{X}|$

An important example when running time linear in $|\mathcal{X}|$ is impractical is marginal queries: the size of the universe is 2^d, which is prohibitive even for a moderate number of attributes. Notice, however, that in order to compute $\tilde{y}$ in Algorithm 2, we only need to compute the true query answers and add independent Gaussian noise to each. This can be done in time $O(n|\mathcal{Q}|)$. The computa-



Geometric Approaches to Answering Queries, Fig. 1 The projection mechanism $\mathcal{A}_{\text{proj}}$ on the *left*: the angle θ is necessarily obtuse or right. The figure on the *right* shows the value of the support function $h_{K_{\mathcal{Q}}}(g)$ is equal to $\frac{1}{2}\|g\|_2$ times the width of $K_{\mathcal{Q}}$ in the direction of g



Geometric Approaches to Answering Queries, Fig. 2 The sensitivity polytope for 2-way marginals on 3 attributes (*left*) and a spectrahedral relaxation of the polytope (*right*). A projection onto 3 of the 12 queries restricted to the positive orthant is shown

tionally expensive operation then is computing the projection $\tilde{y}$. This is a convex optimization problem, and can be solved using the ellipsoid algorithm, provided we have a separation oracle for $K_{\mathcal{Q}}$. (A more practical approach is to use the Frank-Wolfe algorithm which can be implemented efficiently as long as we can solve arbitrary linear programs with feasible region $K_{\mathcal{Q}}$.) For k-way marginals, after a linear transformation that doesn't significantly affect error, $K_{\mathcal{Q}}$ can be assumed to be the convex hull of $\{\pm\chi^{\otimes k} : \chi \in \{-1,1\}^d\}$, where $\chi^{\otimes k}$ is the k-fold tensor power of χ. Unfortunately, even for $k = 2$, separation for this convex body is NP-hard. Nevertheless, a small modification of the analysis of $\mathcal{A}_{\text{proj}}$ shows that the algorithm achieves asymptotically the same error bound if we project onto a convex body L such that $K_{\mathcal{Q}} \subseteq L$ and $\mathbb{E}_g h_L(g) \leq O(1) \cdot \mathbb{E}_g h_{K_{\mathcal{Q}}}(g)$. In other words, we need a convex L that relaxes $K_{\mathcal{Q}}$ but is not too much wider than $K_{\mathcal{Q}}$ in a random direction. If we can find such an L with an efficient separation oracle, we can implement $\mathcal{A}_{\text{proj}}$ in time polynomial in $\mathcal{Q}$ and n while only increasing the error by a constant factor. For 2-way marginals, an appropriate relaxation can be derived from Grothendieck's inequality and is formulated using semidefinite programming. The sensitivity polytope $K_{\mathcal{Q}}$ and the relaxation L are shown for 2-way marginals on $\{0,1\}^3$ in Fig. 2. Finding a relaxation L for k-way marginals with efficient separation and mean width bound $\mathbb{E}_g h_L(g) \leq O(1) \cdot \mathbb{E}_g h_{K_{\mathcal{Q}}}(g)$ is an open problem for $k \geq 3$.

Optimal Error for Small Databases

We can refine the optimal error $\text{opt}^{\varepsilon,\delta}_{\text{avg}}(\mathcal{Q})$ to a curve $\text{opt}^{\varepsilon,\delta}_{\text{avg}}(\mathcal{Q}, n)$, where $\text{opt}^{\varepsilon,\delta}_{\text{avg}}(\mathcal{Q}, n)$ is the infimum of $\text{err}_{\text{avg}}(\mathcal{A}, \mathcal{Q}, n)$ over all (ε, δ)-differentially private algorithms $\mathcal{A}$. There exists an algorithm that, for any database of size at most n and any query set $\mathcal{Q}$, has an average error only a polylogarithmic (in $|\mathcal{Q}|$, $|\mathcal{X}|$, and $1/\delta$) factor larger than $\text{opt}^{\varepsilon,\delta}_{\text{avg}}(\mathcal{Q}, n)$ [16]. The algorithm is similar to $\mathcal{A}_{\text{proj}}$. However, the noise distribution used is the optimal one from Theorem 2. The post-processing step is also slightly more complicated, but the key step is again noise reduction via projection onto a convex body. The running time is polynomial in $n, |\mathcal{Q}|, |\mathcal{X}|$. Giving analogous guarantees for worst-case error remains open.

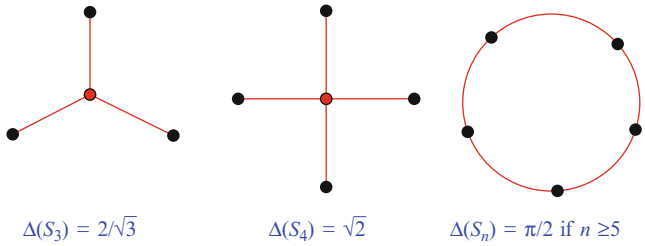
Problem Definition

Urban street systems can be modeled by *plane geometric networks* $G = (V, E)$ whose edges $e \in E$ are piecewise smooth curves that connect the vertices $v \in V \subset \mathbb{R}^2$. Edges do not intersect, except at common endpoints in V. Since streets are lined with houses, the quality of such a network can be measured by the length of the connections



Geometric Dilation of Geometric Networks, Fig. 1 Minimum dilation embeddings of regular point sets

it provides between two arbitrary points p and q on G.

Let $\xi_G(p,q)$ denote a shortest path from p to q in G. Then

$$\delta(p,q) := \frac{|\xi_G(p,q)|}{|pq|} \tag{1}$$

is the detour one encounters when using network G, in order to get from p to q, instead of walking straight. Here, $|\ .\ |$ denotes the Euclidean length. The *geometric dilation of network* G is defined by

$$\delta(G) := \sup_{p \neq q \in G} \delta(p,q). \tag{2}$$

This definition differs from the notion of stretch factor (or spanning ratio) used in the context of spanners; see the monographs by Eppstein [6] or Narasimhan and Smid [11]. In the latter, only the paths between the vertices $p, q \in V$ are considered, whereas the geometric dilation involves all points on the edges as well. As a consequence, the stretch factor of a triangle T equals 1, but its geometric dilation is given by $\delta(T) = \sqrt{2/(1-\cos\alpha)} \geq 2$, where $\alpha \leq 60°$ is the most acute angle of T.

Presented with a finite set S of points in the plane, one would like to find a finite geometric network containing S whose geometric dilation is as small as possible. The value of

$$\Delta(S) := \inf\{\delta(G); G \text{ finite plane geometric network containing } S\}$$

is called the *geometric dilation of point set S*. The problem is in computing, or bounding, $\Delta(S)$ for a given set S.

Key Results

Theorem 1 ([4]) *Let S_n denote the set of corners of a regular n-gon. Then, $\Delta(S_3) = 2/\sqrt{3}, \Delta(S_4) = \sqrt{2}$, and $\Delta(S_n) = \pi/2$ for all $n \geq 5$.*

The networks realizing these minimum values are shown in Fig. 1. The proof of minimality uses the following two lemmata that may be interesting in their own right. Lemma 1 was independently obtained by Aronov et al. [1].

Lemma 1 *Let T be a tree containing S_n. Then $\delta(T) \geq n/\pi$.*

Lemma 2 follows from a result of Gromov's [7]. It can more easily be proven by applying Cauchy's surface area formula; see [4].

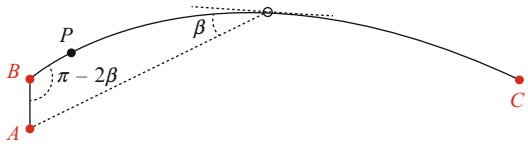
Lemma 2 *Let C denote a simple closed curve in the plane. Then $\delta(C) \geq \pi/2$.*

Clearly, Lemma 2 is tight for the circle. The next lemma implies that the circle is the only closed curve attaining the minimum geometric dilation of $\pi/2$.

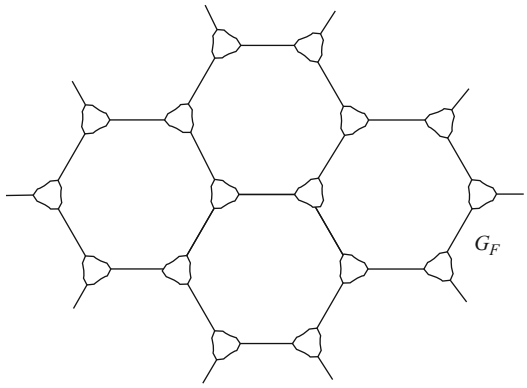
Lemma 3 ([3]) *Let C be a simple closed curve of geometric dilation $< \pi/2 + \epsilon(\delta)$. Then C is contained in an annulus of width δ.*

For points in general position, computing their geometric dilation seems quite complicated. Only for sets $S = \{A, B, C\}$ of size three is the solution completely known.

Theorem 2 ([5]) *The plane geometric network of minimum geometric dilation containing three given points $\{A, B, C\}$ is either a line segment, or a Steiner tree as depicted in Fig. 1, or a simple path consisting of two line segments and one segment of an exponential spiral; see Fig. 2.*



Geometric Dilation of Geometric Networks, Fig. 2 The minimum dilation embedding of points A, B, and C



Geometric Dilation of Geometric Networks, Fig. 3 A network of geometric dilation ≈1,6778

The optimum path shown in Fig. 2 contains a degree two Steiner vertex, P, situated at distance $|AB|$ from B. The path runs straight between A, B and B, P. From P to C, it follows an exponential spiral centered at A.

The next results provide upper and lower bounds to $\Delta(S)$.

Theorem 3 ([4]) *For each finite point set S, the estimate $\Delta(S) < 1.678$ holds.*

To prove this general upper bound, one can replace each vertex of the hexagonal tiling of $\mathbb{R}^2$ with a certain closed Zindler curve (by definition, all point pairs bisecting the perimeter of a Zindler curve have identical distance). This results in a network G_F of geometric dilation ≈1.6778; see Fig. 3. Given a finite point set S, one applies a slight deformation to a scaled version of G_F, such that all points of S lie on a finite part, G, of the deformed net. By Dirichlet's result on simultaneous approximation of real numbers by rationals, a deformation small as compared to the cell size is sufficient, so that the dilation is not affected. See [8] for the history and properties of Zindler curves.

Theorem 4 ([3]) *There exists a finite point set S such that $\Delta(S) > (1 + 10^{-11})\pi/2$.*

Theorem 4 holds for the set S of 19×19 vertices of the integer grid. Roughly, if S were contained in a geometric network G of dilation close to $\pi/2$, the boundaries of the faces of G must be contained in small annuli, by Lemma 3. To the inner and outer circles of these annuli, one can now apply a result by Kuperberg et al. [9] stating that an enlargement, by a certain factor, of a packing of disks of radius ≤ 1 cannot cover a square of size 4.

Applications

The geometric dilation has applications in the theory of knots; see, e.g., Kusner and Sullivan [10] and Denne and Sullivan [2]. With respect to urban planning, the above results highlight principal dilation bounds for connecting given sites with plane geometric networks.

Open Problems

For practical applications, one would welcome upper bounds to the weight (= total edge length) of a geometric network, in addition to upper bounds on its geometric dilation. Some theoretical questions require further investigation, too. Is $\Delta(S)$ always attained by a finite network? How to compute, or approximate, $\Delta(S)$ for a given finite set S? What is the precise value of $\sup\{\Delta(S); S \text{finite}\}$?

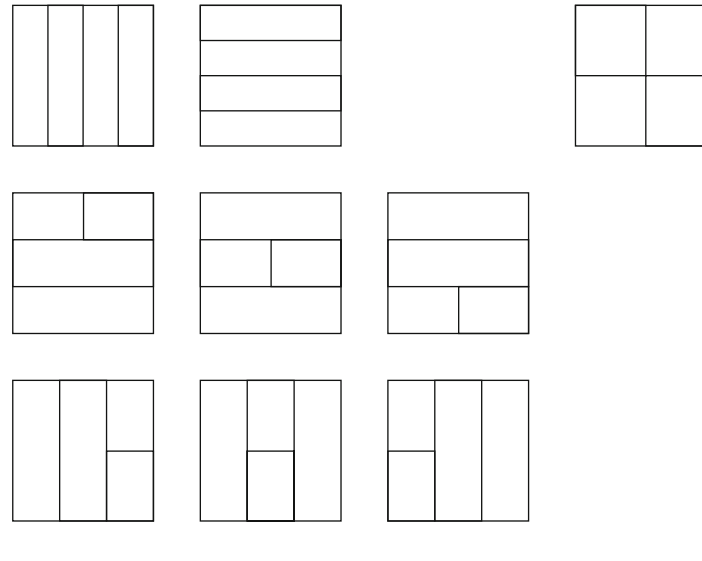
Problem Definition

Enumerating objects with the given property is one of basic problems in mathematics. We review some geometric objects enumeration problems and algorithms to solve them.

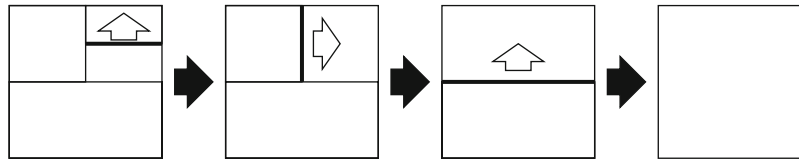
A graph is *planar* if it can be embedded in the plane so that no two edges intersect geometrically except at a vertex to which they are both incident. A *plane* graph is a planar graph with a fixed planar embedding. A plane graph divides the plane into connected regions called *faces*. The unbounded face is called the outer face, and other faces are called inner faces.

A plane graph is a *floor plan* if each face (including the outer face) is a rectangle. A *based* floor plan is a floor plan with one designated line on the contour of the outer face. The designated line is called the *base* line and we always draw the base line as the lowermost horizontal line of the drawing. The 25 based floor plans having 4 inner faces are shown in Fig. 1. Given an integer f the problem of *floor plan enumeration* asks for generating all floor plans with exactly f inner faces.

A plane graph is a *plane triangulation* if each inner face has exactly three edges on its contour. A *based* plane triangulation is a plane triangulation with one designated edge on the contour of the outer face. The designated edge is called the *base* edge. Triangulations are important model for 3D modeling. A graph is biconnected if removing any vertex always results in a connected graph. A graph is triconnected if removing any two vertices always results in a connected graph. Given two integers n and r, the problem of *biconnected plane triangulation enumeration* asks for generating all biconnected



Geometric Object Enumeration, Fig. 1 The 25 based floor plans having 4 inner faces



Geometric Object Enumeration, Fig. 2 The sequence

Geometric Object Enumeration, Fig. 3 The tree F_4

plane triangulations with exactly n vertices including exactly r vertices on the outer face. Given two integers n and r, the problem of *triconnected plane triangulation enumeration* asks for generating all triconnected plane triangulations with exactly n vertices including exactly r vertices on the outer face.

Key Results

Enumeration of All Floor Plans

Using *reverse search method* [1], one can enumerate all based floor plans with f inner faces in $O(1)$ time for each [3]. We sketch the method in [3].

Let S_f be the set of all based floor plans with $f > 1$ inner faces. Let R be a based floor plan in S_f and F a face of R having the upper right corner of R. We have two cases. If R has a vertical line segment with upper end at the lower left corner of F, then by continually shrinking R to the uppermost horizontal line of R with preserving the width of F and enlarging the faces below R, we can have a based floor plan with one less inner face. If R has no vertical line segment with the upper end at the lower left corner of F, then R has a horizontal line segment with the right end at the lower left corner of F, and then by continually shrinking R to the rightmost vertical line of R with preserving the height of F and enlarging the faces locating the left of R, we can have a base floor plan with one less inner face. Repeating this results in the sequence of based floor plans which always ends with the based floor plan with one inner face. See an example in Fig. 2. If we merge the sequence of all R in S_f, then we have the tree T_f in which every R in S_f appears as a leaf in T_f. See Fig. 3.

The reverse search method efficiently traverses the tree (without storing the tree in the memory) and output each based floor plan in S_f at each corresponding leaf. Thus, we can efficiently enumerate all based floor plans in S_f. The algorithm enumerates all based floor plans in S_f in $O(1)$ time for each.

Enumeration of Triangulations

Similarly, using *reverse search method* [1], given two integers n and r, one can enumerate all based biconnected triangulations having exactly n vertices including exactly r vertices on the outer face in $O(1)$ time for each [2], all based triconnected triangulations having exactly n vertices including exactly r vertices on the outer face in $O(1)$ time for each [3], and all triconnected (non-based) plane triangulation having exactly n vertices including exactly r vertices on the outer face in $O(r^2 n)$ time for each [3]. Also one can enumerate all based triangulation having exactly n vertices with exactly three vertices on the outer face in $O(1)$ time for each [3].

Computational geometry; Continuous Dijkstra method; Shortest path; Shortest path map; Visibility graph

Years and Authors of Summarized Original Work

1996; Mitchell
1999; Hershberger, Suri

Problem Definition

Finding the shortest path between a source and a destination is a natural optimization problem with many applications. Perhaps the oldest variant of the problem is the geometric shortest path problem, in which the domain is physical space: the problem is relevant to human travelers, migrating animals, and even physical phenomena like wave propagation. The key feature that distinguishes the geometric shortest path problem from the corresponding problem in graphs or other discrete spaces is the unbounded number of paths in a multidimensional space. To solve the problem efficiently, one must use the "shortness" criterion to limit the search.

In computational geometry, physical space is modeled abstractly as the union of some number of constant-complexity primitive elements. The traditional formulation of the shortest path problem considers paths in a domain bounded by linear elements – line segments in two dimensions, triangles in three dimensions, and $(d-1)$-dimensional simplices in $d > 3$. Canny and Reif showed that the three-dimensional shortest path problem is NP-complete [2], so this article will focus on the two-dimensional problem.

We consider paths in a free space P bounded by h polygons – one outer boundary and $(h-1)$ obstacles – with a total of n vertices. The free space is closed, so paths may touch the boundary. The source and destination of the shortest path are points s and t inside or on the boundary of P. The goal of the shortest path problem is to find the shortest path from s to t inside P, denoted by $\pi(s,t)$, as efficiently as possible, where running time and memory use are expressed as functions of n and h. The length of $\pi(s,t)$ is denoted by $dist(s,t)$; in some applications, it may be desirable to compute $dist(s,t)$ without finding $\pi(s,t)$ explicitly.

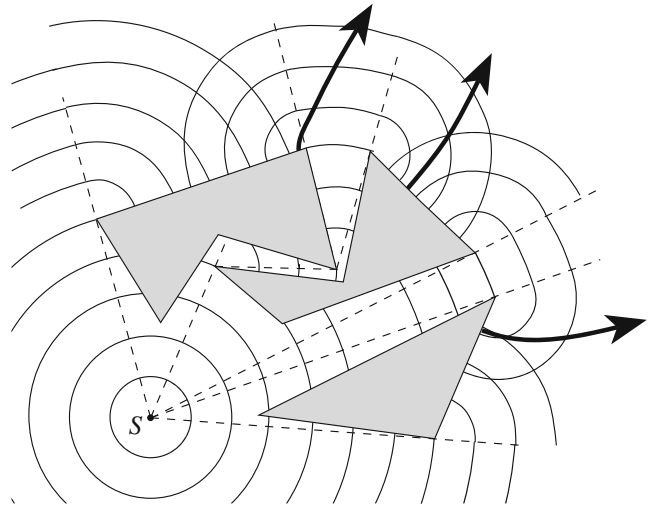
Key Results

Visibility Graph Algorithms

Early approaches to the two-dimensional shortest path problem exploited the *visibility graph* to reduce the continuous shortest path problem to a discrete graph problem [1, 12, 18]. The visibility graph is a graph whose nodes are s, t, and the vertices of P and whose edges (u,v) connect vertex pairs such that the line segment $\overline{uv}$ is contained in P. It is convenient and customary to identify the edges of the abstract visibility graph with the line segments they represent. The visibility graph is important because the edges of the shortest path $\pi(s,t)$ are a subset of the visibility graph edges. This is easy to understand intuitively, because of subpath optimality – for any two points $a, b \in \pi(s,t)$, the subpath of $\pi(s,t)$ between a and b is also the shortest path between a and b. In particular, if $\overline{ab}$ is contained in P, then $\pi(s,t)$ coincides with $\overline{ab}$ between a and b, and the distance $dist(a,b)$ is equal to $|ab|$, the length of the segment $\overline{ab}$. If $\pi(s,t)$ has a bend anywhere except at a vertex of P, an infinitesimal subpath near the bend can be shortened by a straight shortcut, implying that $\pi(s,t)$ is *not* the shortest path. Hence every segment of $\pi(s,t)$ is an edge of the visibility graph.

This observation leads directly to an algorithm for computing shortest paths: compute the visibility graph of P and then run Dijkstra's algorithm to find the shortest path from s to t in the visibility graph. The visibility graph can be constructed in $O(n \log n + m)$ time, where m is the number of edges, using an algorithm of Ghosh and Mount [7]. Dijkstra's algorithm takes $O(n \log n + m)$ time on a graph with n nodes and m edges [4], so this is the running time of the straightforward visibility graph solution to the shortest path problem. This algorithm can be quadratic in the worst case, since m, the number of visibility graph edges, can be as large as $\Theta(n^2)$.

The running time can be improved somewhat by noting that only a subset of the visibility graph edges can belong to a shortest path. In particular, any shortest path must turn toward the boundary of P at any path vertex. This limits the edges to common tangents of the polygons of P. We omit



Geometric Shortest Paths in the Plane, Fig. 1
The spreading wavefront

the details, but note that if s and t are known, the common tangent restriction limits the number of visibility graph edges that may belong to $\pi(s,t)$ to $O(n+h^2)$ [11]. These useful edges can be computed in $O(n\log n+h^2)$ time [17], and so the shortest path can be computed in the same time bound by applying Dijkstra's algorithm to the subgraph [11].

Continuous Dijkstra Algorithms

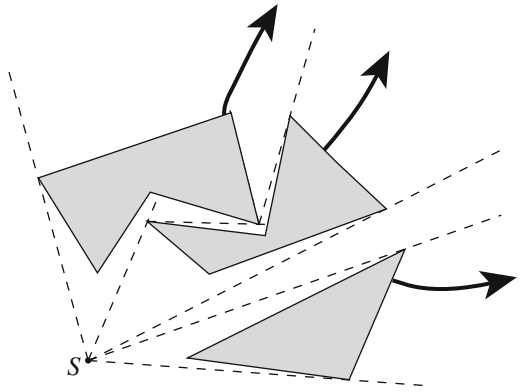
Visibility graph approaches to finding the shortest path run in quadratic time in the worst case, since h may be $\Theta(n)$. This led Mitchell to propose an alternative approach called the *continuous Dijkstra method* [15]. Imagine a wavefront that spreads at unit speed inside P, starting from s. The wavefront at time τ is the set of points in P whose geodesic (shortest path) distance from s is exactly τ. Said another way, the shortest path distance from s to a point $p \in P$ is equal to the time at which the wavefront reaches p.

The wavefront at time τ is a union of paths and cycles bounding the region whose geodesic distance from s is at most τ. Each path or cycle is a sequence of circular arc *wavelets*, each centered on a vertex v that is its *root*. The radius of the wavelet is $\tau - dist(s,v)$, with $dist(s,v) < \tau$. As τ increases, the combinatorial structure of the wavefront changes at discrete event times when the wavefront hits the free space boundary, collides with itself, or eliminates wavelets squeezed between neighboring wavelets. See Fig. 1. The continuous Dijkstra method simulates the spread of this wavefront, computing the shortest path distance to every point of the free space in the process.

Mitchell used the continuous Dijkstra method to compute shortest paths under the L_1 metric in $O(n\log n)$ time [15]. He later extended the approach to compute L_2 (Euclidean) shortest paths in $O(n^{5/3+\epsilon})$ time, for ϵ arbitrarily small [16]. Hershberger and Suri gave an alternative implementation of the continuous Dijkstra scheme, using different data structures, that computes Euclidean shortest paths in $O(n\log n)$ time [9]. The next two subsections discuss these algorithms in more detail.

Continuous Dijkstra with Sector Propagation Queries

If p is a point in P, $\pi(s,p)$ is a shortest path from s to p, and the *predecessor* of p is the vertex of $\pi(s,p)$ adjacent to (immediately preceding) p in the path. If a point is reached by multiple shortest paths, it has multiple predecessors. The *shortest path map* is a linear-complexity partition of P into regions such that every point inside a region has the same predecessor. See Fig. 2. The *root* of each region is the predecessor of all points in the region. The edges of the shortest path map are polygon edges and *bisectors* (curves with two distinct predecessors, namely, the roots of the regions separated by the bisector).



Geometric Shortest Paths in the Plane, Fig. 2 The shortest path map for the wavefront in Fig. 1

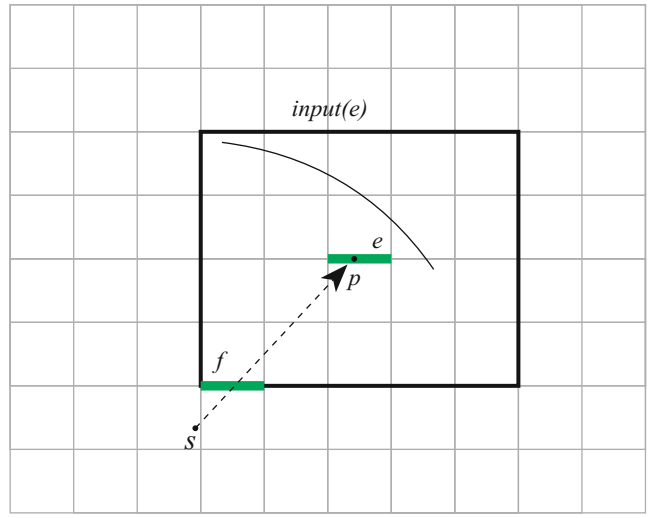
Mitchell's shortest path algorithm simulates the spread of the wavefront inside the shortest path map. This may seem a bit peculiar, since the shortest path map is not known until the shortest paths have been computed. The trick is that the algorithm builds the shortest path map as it runs, and it propagates a *pseudo-wavefront* inside its current model of the shortest path map at each step. The true wavefront is a subset of the pseudo-wavefront. This pseudo-wavefront is locally correct – each wavelet's motion is determined by its neighbors in the pseudo-wavefront and the shortest path map known so far – but it may overrun itself. When an overrun is detected, the algorithm revises its model of the shortest path map in the neighborhood of the overrun.

To be more specific, each wavelet w is a circular arc centered at a root vertex $r(w)$. The endpoints of w move along left and right *tracks* $\alpha(w)$ and $\beta(w)$. Each track is either a straight line segment (a polygon edge or an extension of a visibility edge) or a bisector determined by w and the left/right neighbor wavefront $L(w)$ or $R(w)$. For example, if $r = r(w)$ and $r' = r(L(w))$, the left bisector is the set of points x such that $dist(s, r) + |rx| = dist(s, r') + |r'x|$; consequently, the bisector is a hyperbolic arc. For every wavelet w, the algorithm computes a next event, which is the next value of τ where w reaches an endpoint of one of its tracks, the left and right tracks collide, or w hits a polygon vertex between its left and right tracks. (Collisions with polygon edges or other wavefront arcs are *not* detected.) The events for all wavelets are placed in a global priority queue and processed in order of increasing τ values.

When the algorithm processes an event, it updates the wavelets involved and their events in the priority queue. Processing wavelet collisions with a polygon vertex v is the most complicated case: To detect possible previous collisions with polygon edges, the algorithm performs a ray shooting query from $r(w)$ toward v [8]. If the ray hits an edge, the algorithm traces the edge through the current shortest path map regions and updates the corresponding wavelets. If v is reached for the first time by w, then the algorithm updates the wavefront with a new wavelet rooted at v. If vertex v was previously reached by another wavelet, then there are previously undiscovered bisectors between w and the other wavelet. The algorithm traces these bisectors through its local shortest path map model and carves off portions that are reached by a shorter path following another route. Processing other events (track vertices and track collisions) is similar.

Mitchell shows that even though vertices may be reached more than once by different wavelets, and portions of the shortest path map are carved off and discarded when they are discovered to be invalid, no vertex is reached more than $O(1)$ times, and the total shortest path map complexity, even including discarded portions, is $O(n)$. The most costly part of the algorithm is finding the first polygon vertex hit by each wavelet. All the rest of the algorithm – ray shooting, priority queue, bisector tracing, and maintaining the shortest path map structure – can be done in $O(n \log n)$ total time.

The complexity of Mitchell's algorithm is dominated by *wavelet dragging queries*, which find the first obstacle vertex hit by a wavelet w between the left and right tracks $\alpha(w)$ and $\beta(w)$. Mitchell phrases this as a ten-dimensional optimization problem dependent on the position and distance from s for the root of w and its neighbors in the wavefront, plus the start time τ. Although Euclidean distances are square roots of quadratics (by Pythagoras), Mitchell is able,



Geometric Shortest Paths in the Plane, Fig. 3 The well-covering region for edge e is bounded by $input(e)$

by squaring, substitution, and simplification, to convert the distance minimization problem into a linear optimization range query over a constant-size polyhedron in $\Re^5$. (The objects in the range query are n 5-dimensional points, images of the polygon vertices.) There are $O(n)$ such queries to be performed. Using known bounds and balancing preprocessing against query time, the $O(n)$ queries can be answered in $O(n^{5/3+\epsilon})$ time and space [3, 13, 14]. All other parts of the algorithm take near-linear time, so the total time for Mitchell's algorithm to find the Euclidean shortest path map is $O(n^{5/3+\epsilon})$ [16].

Continuous Dijkstra in a Conforming Subdivision

The challenge of implementing the continuous Dijkstra paradigm is that detecting and processing wavefront events in strict temporal order is difficult to do efficiently, but processing events out of order may lead to incorrect results or to processing too many invalid events. Mitchell addresses the challenge by detecting only one subclass of events in temporal order (wavelet contacts with polygon vertices) and repairing errors in the shortest path map structure as they are discovered. Hershberger and Suri achieve a better time bound (optimal $O(n \log n)$) by processing events in an even more relaxed order [9]. The key to their approach is a subdivision of the free space in which spatial locality is used to bound the temporal inaccuracy of wavefront event processing.

As a simple example, consider a wavefront propagating across an obstacle-free plane that has been subdivided into a grid of unit squares. Each edge e of the grid lies at the center of a 4×5 rectangle of squares. The distance from e to each of the 18 edges on the rectangle boundary is at least 2. If the wavefront source is outside the rectangle, then the first wavelet that reaches any point $p \in e$ must pass through the rectangle boundary at least two time units before it reaches p. By the triangle inequality, an edge of length δ is completely covered by the wavefront within time δ of the time the wavefront first hits it. It follows that if the shortest path to $p \in e$ passes through an edge f on the rectangle boundary, edge f is completely covered by the wavefront at least one time unit before the wavefront reaches p. See Fig. 3.

The algorithm propagates the wavefront from edge to edge in the grid. For each edge e, let $input(e)$ be the edges on the boundary of the 4×5 rectangle around e. The algorithm computes a *cover time* for e, denoted $cover(e)$, that is an upper bound on the time when the wavefront completely covers e. If $fvc(e)$ is the time at which the wavefront first contacts a vertex of e, and $|e|$ is the length of e, then $cover(e)$ is defined to be $fvc(e) + |e|$. For each edge e, $cover(e)$ is

determined by a wavefront passing through $f \in input(e)$, and $cover(f) < cover(e)$.

The propagation algorithm processes edges in order of cover time, computing the wavefront at e by combining the wavefronts from edges $f \in input(e)$ with $cover(f) < cover(e)$. The combination algorithm is linear in the number of features of the shortest path map that lie inside the rectangle for e. The algorithm computes a one-dimensional representation of the intersection of the shortest path map with each edge of the grid; each bisector that has an event (an arc endpoint) within the input region of an edge e is flagged in the wavefront representation for e. To turn the one-dimensional wavefront representation at edges into a two-dimensional representation of the shortest path map, the algorithm combines the wavefronts of the edges on each cell's boundary to compute the shortest path map inside the cell. (The algorithm computes additively weighted Voronoi diagrams [6] for the wavelet roots whose bisectors have events (endpoints) in the cell, plus compact representations of the groups of bisectors that have no endpoints in the cell.)

The key feature of the grid subdivision is *well-covering property*: each edge e is surrounded by a region that is the union of $O(1)$ cells, and the distance from e to the region boundary is relatively large. In particular, if f is an edge on the boundary, $dist(e, f) \geq 2 \cdot \max(|e|, |f|)$. This property allows the algorithm to perform *spatial* (not temporal) wavefront propagation at discrete cover times. Hershberger and Suri show how to extend the well-covering property to a special *conforming subdivision* of free space made up of $O(n)$ constant-complexity cells. The wavefront propagation algorithm carries over from the grid to the conforming subdivision of free space with only a few changes to handle the obstacle vertices. As on the grid, the number of propagation steps and data structure changes is $O(n)$. Including the overhead of a priority queue and data structure updates (full persistence is needed [5]) increases the time and space by a factor of $O(\log n)$, so the overall algorithm runs in $O(n \log n)$ time and space.

Extensions

Hershberger and Suri's algorithm supports multiple wavefront sources, including line-segment sources. Hence the algorithm can be used to compute geodesic Voronoi diagrams, including Voronoi diagrams whose sites are points, segments, polygons, or combinations of all these.

Since the publication of Hershberger and Suri's optimal-time algorithm for shortest paths among polygonal obstacles, their result has been extended to other two-dimensional domains. Schreiber showed how to find shortest paths on the surface of a convex polyhedron in $O(n \log n)$ time [20]. His algorithm decomposes the surface into cells and then propagates wavefronts between cell edges similarly to Hershberger and Suri's algorithm. Schreiber extended his algorithm for polyhedra to work for polygonal terrains as well, assuming that the maximum gradient of the terrain is bounded by a constant [19]. More recently, Hershberger, Suri, and Yıldız [10] extended the algorithm for polygonal obstacles [9] to find shortest paths in a free space bounded by curved obstacle edges. The conforming subdivision for the free space is very similar to that for polygonal obstacles; the chief difficulty is computing the positions of bisector events (intersections). Bisectors for polygonal obstacles are hyperbolic arcs, but they are much more complicated curves for curved obstacles. The algorithm of [10] approximates the bisector events using primitive tangent-finding operations on individual obstacle curves, with the result that the algorithm's running time is $O(n \log(n/\epsilon))$, where ϵ is the relative error of the computed path length.

Problem Definition

Consider a set S of n points in d-dimensional Euclidean space. A network on S can be modeled as an undirected graph G with vertex set S of size n and an edge set E where every edge (u, v) has a weight. A geometric (Euclidean) network is a network where the weight of the edge (u, v) is the Euclidean distance $|uv|$ between its end points. Given a real number $t > 1$, we say that G is a *t-spanner* for S, if for each pair of points $u, v \in S$, there exists a path in G of weight at most t times the Euclidean distance between u and v. The minimum t such that G is a t-spanner for S is called the stretch factor, or dilation, of G. For a detailed description of many constructions

of t-spanners, see the book by Narasimhan and Smid [30]. The problem considered is the construction of t-spanners given a set S of n points in $\mathcal{R}^d$ and a positive real value $t > 1$, where d is a constant. The aim is to compute a good t-spanner for S with respect to the following quality measures:

size: the number of edges in the graph
degree: the maximum number of edges incident on a vertex
weight: the sum of the edge weights
spanner diameter: the smallest integer k such that for any pair of vertices u and v in S, there is a path in the graph of length at most $t \cdot |uv|$ between u and v containing at most k edges
fault tolerance: the resilience of the graph to edge, vertex, or region failures

Thus, good t-spanners require large fault tolerance and small size, degree, weight, and spanner diameter. Additionally, the time required to compute such spanners must be as small as possible.

Key Results

This section contains descriptions of several known approaches for constructing a t-spanner of a set of points in Euclidean space. We also present descriptions of the construction of fault-tolerant spanners, spanners among polygonal obstacles, and, finally, a short note on dynamic and kinetic spanners.

Spanners of Points in Euclidean Space

The most well-known classes of t-spanner networks for points in Euclidean space include Θ-graphs, WSPD graphs, and greedy spanners. In the following sections, the main idea of each of these classes is given, together with the known bounds on the quality measures.

The Θ-Graph

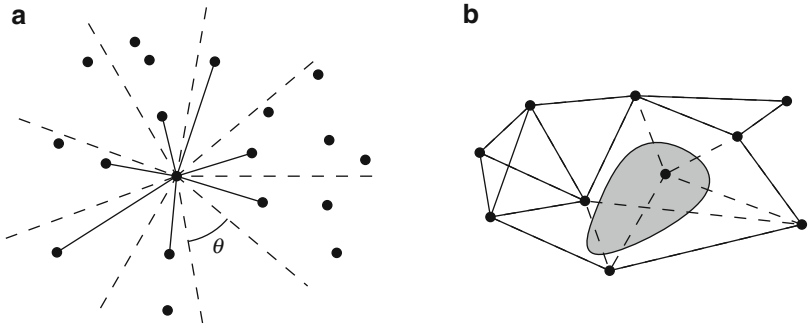
The Θ-graph was discovered independently by Clarkson and Keil in the late 1980s. The general idea is to process each point $p \in S$ independently as follows: partition $\mathcal{R}^d$ into k simplicial cones of angular diameter at most θ and apex at p, where $k = O(1/\theta^{d-1})$. For each nonempty cone C, an edge is added between p and the point in C whose orthogonal projection onto some fixed ray in C emanating from p is closest to p; see Fig. 1a. The resulting graph is called the Θ-graph on S. The following result is due to Arya et al. [9].

Theorem 1 *The Θ-graph is a t-spanner of S for $t = \frac{1}{\cos\theta - \sin\theta}$ with $O\left(\frac{n}{\theta^{d-1}}\right)$ edges and can be computed in $O\left(\frac{n}{\theta^{d-1}} \log^{d-1} n\right)$ time using $O\left(\frac{n}{\theta^{d-1}} + n \log^{d-2} n\right)$ space.*

The following variants of the Θ-graph also give bounds on the degree, spanner diameter, and weight.

Skip-List Spanners

The idea is to generalize skip lists and apply them to the construction of spanners. Construct a



Geometric Spanners, Fig. 1 (**a**) Illustrating the Θ-graph and (**b**) a graph with a region fault

sequence of h subsets, $S_1, \ldots, S_h$, where $S_1 = S$ and S_i is constructed from S_{i-1} as follows (reminiscent of the levels in a skip list). For each point in S_{i-1}, flip a fair coin. The set S_i is the set of all points of S_{i-1} whose coin flip produced heads. The construction stops if $S_i = \emptyset$. For each subset, a Θ-graph is constructed. The union of the graphs is the skip-list spanner of S with dilation t, having $O\left(\frac{n}{\theta^{d-1}}\right)$ edges and $O(\log n)$ spanner diameter with high probability [9].

Gap Greedy

A set of directed edges is said to satisfy the *gap* property if the sources of any two distinct edges in the set are separated by a distance that is at least proportional to the length of the shorter of the two edges. Arya and Smid [6] proposed an algorithm that uses the gap property to decide whether or not an edge should be added to the t-spanner graph. Using the gap property, the constructed spanner can be shown to have degree $O(1/\theta^{d-1})$ and weight $O(\log n \cdot \mathrm{wt}(\mathrm{MST}(S)))$, where $\mathrm{wt}(\mathrm{MST}(S))$ is the weight of the minimum spanning tree of S.

The WSPD Graph

The well-separated pair decomposition (WSPD) was developed by Callahan and Kosaraju [12]. The construction of a t-spanner using the well-separated pair decomposition is done by first constructing a WSPD of S with respect to a separation constant $s = \frac{4(t+1)}{(t-1)}$. Initially set the spanner graph $G = (S, \emptyset)$ and add edges iteratively as follows. For each well-separated pair $\{A, B\}$ in the decomposition, an edge (a, b) is added to the graph, where a and b are arbitrary points in A and B, respectively. The resulting graph is called the WSPD graph on S.

Theorem 2 *The WSPD graph is a t-spanner for S with $O(s^d \cdot n)$ edges and can be constructed in time $O(s^d n + n \log n)$, where $s = 4(t+1)/(t-1)$.*

There are modifications that can be made to obtain bounded spanner diameter or bounded degree.

Bounded spanner diameter: Arya, Mount, and Smid [7] showed how to modify the construction algorithm such that the spanner diameter of the graph is bounded by $2 \log n$. Instead of selecting an arbitrary point in each well-separated set, their algorithm carefully chooses a representative point for each set.

Bounded degree: A single point v can be part of many well-separated pairs, and each of these pairs may generate an edge with an end point at v. Arya et al. [8] suggested an algorithm that retains only the shortest edge for each cone direction, thus combining the Θ-graph approach with the WSPD graph. By adding a postprocessing step that handles all high-degree vertices, a t-spanner of degree $O\left(\frac{1}{(t-1)^{2d-1}}\right)$ is obtained.

The Greedy Spanner

The greedy algorithm was first presented in 1989 by Bern, and since then, the greedy algorithm has been subject to considerable research. The graph constructed using the greedy algorithm is called a Greedy spanner, and the general idea is that the algorithm iteratively builds a graph G. The edges in the complete graph are processed in order of increasing edge length. Testing an edge (u, v) entails a shortest path query in the partial spanner graph G. If the shortest path in G between u and v is at most $t \cdot |uv|$, then the edge (u, v) is discarded; otherwise, it is added to the partial spanner graph G.

Das, Narasimhan, and Salowe [22] proved that the Greedy spanner fulfills the so-called *leapfrog property*. A set of undirected edges E is said to satisfy the t-leapfrog property, if for every $k \geq 2$, and for every possible sequence $\{(p_1, q_1), \ldots, (p_k, q_k)\}$ of pairwise distinct edges of E,

$$t \cdot |p_1 q_1| < \sum_{i=2}^{k} |p_i q_i| + t \cdot \left(\sum_{i=1}^{k-1} |q_i p_{i+1}| + |p_k q_1| \right).$$

Using the leapfrog property, it has been shown that the total edge weight of the graph is within a constant factor of the weight of a minimum spanning tree of S.

Using Dijkstra's shortest-path algorithm, the greedy spanner can be constructed in $O(n^3 \log n)$ time. Bose et al. [10] improved the time to $O(n^2 \log n)$, while using $O(n^2)$ space. Alewijnse et al. [4] improved the space bound to $O(n)$, while slightly increasing the time bound to $O(n^2 \log^2 n)$.

Das and Narasimhan [21] observed that an approximation of the greedy spanner can be constructed while maintaining the leapfrog property. This observation allowed for faster construction algorithms.

Theorem 3 ([27]) *The greedy spanner is a t-spanner of S with $O\left(\frac{n}{(t-1)^d} \log(\frac{1}{t-1})\right)$ edges, maximum degree $O\left(\frac{1}{(t-1)^d} \log(\frac{1}{t-1})\right)$, and weight $O\left(\frac{1}{(t-1)^{2d}} \cdot \mathrm{wt}(\mathrm{MST}(S))\right)$ and can be computed in time $O\left(\frac{n}{(t-1)^{2d}} \log n\right)$.*

The Transformation Technique

Chandra et al. [16, 17] introduced a transformation technique for general metrics that transforms an algorithm for constructing spanners with small stretch factor and size into an algorithm for constructing spanners with the same asymptotic stretch factor and size, but with the additional feature of small weight. Elkin and Solomon [24] refined their approach to develop a transformation technique that achieved the following: It takes an algorithm for constructing spanners with small stretch factor, small size, small degree, and small spanner diameter and transforms it into an algorithm for constructing spanners with a small increase in stretch factor, size, degree, and spanner diameter, but that also has small weight and running time.

Using the transformation technique allowed Elkin and Solomon to prove the following theorem.

Theorem 4 ([24]) *For any set of n points in Euclidean space of any constant dimension d, any $\epsilon > 0$, and any parameter $\rho \geq 2$, there exists a $(1+\epsilon)$-spanner with $O(n)$ edges, degree $O(\rho)$, spanner diameter $O(\log_\rho n + \alpha(\rho))$, andweight $O(\rho \cdot \log_\rho n \cdot \mathrm{wt}(\mathrm{MST}))$, which can be constructed in time $O(n \log n)$.*

Given the lower bounds proved by Chan and Gupta [13] and Dinitz et al. [23], these results represent optimal tradeoffs in the entire range of the parameter ρ.

Fault-Tolerant Spanners

The concept of fault-tolerant spanners was first introduced by Levcopoulos et al. [28] in 1998: After one or more vertices or edges fail, the spanner should retain its good properties. In particular, there should still be a short path between any two vertices in what remains of the spanner after the fault. Czumaj and Zhao [19] showed that a greedy approach produces a k-vertex (or k-edge) fault-tolerant geometric t-spanner with degree $O(k)$ and total weight $O(k^2 \cdot \mathrm{wt}(\mathrm{MST}(S)))$; these bounds are asymptotically optimal. Chan et al. [15] used a "standard net-tree with cross-edge framework" developed by [14, 26] to design an algorithm that produces a k-vertex (or k-edge) fault-tolerant geometric $(1+\epsilon)$-spanner with degree $O(k^2)$, diameter $O(\log n)$, and total weight $O(k^2 \log n \cdot \mathrm{wt}(\mathrm{MST}(S)))$. Such a spanner can be constructed in $O(n \log n + k^2 n)$ time.

For geometric spanners, it is natural to consider *region faults*, i.e., faults that destroy all vertices and edges intersecting some geometric fault region. For a fault region F, let $G \ominus F$ be the part of G that remains after the points from S inside F and all edges that intersect F have been removed from the graph; see Fig. 1b. Abam et al. [2] showed how to construct region-fault tolerant t-spanners of size $O(n \log n)$ that are fault tolerant to any convex region fault. If one is allowed to use Steiner points, then a linear size t-spanner can be achieved.

Spanners Among Obstacles

The visibility graph of a set of pairwise non-intersecting polygons is a graph of intervisible locations. Each polygonal vertex is a vertex in the graph and each edge represents a visible

connection between them, that is, if two vertices can see each other, an edge is drawn between them. This graph is useful since it contains the shortest obstacle avoiding path between any pair of vertices.

Das [20] showed that a t-spanner of the visibility graph of a point set in the Euclidean plane can be constructed by using the Θ-graph approach followed by a pruning step. The obtained graph has linear size and constant degree.

Dynamic and Kinetic Spanners

Arya et al. [9] designed a data structure of size $O(n \log^d n)$ that maintains the skip-list spanner, described in section "The Θ-Graph," in $O(\log^d n \log\log n)$ expected amortized time per insertion and deletion in the model of random updates.

Gao et al. [26] showed how to maintain a t-spanner of size $O\left(\frac{n}{(t-1)^d}\right)$ and maximum degree $O\left(\frac{1}{(t-2)^d}\log\alpha\right)$, in time $O\left(\frac{\log\alpha}{(t-1)^d}\right)$ per insertion and deletion, where α denotes the aspect ratio of S, i.e., the ratio of the maximum pairwise distance to the minimum pairwise distance. The idea is to use an hierarchical structure T with $O(\log\alpha)$ levels, where each level contains a set of centers (subset of S). Each vertex v on level i in T is connected by an edge to all other vertices on level i within distance $O\left(\frac{2^i}{t-1}\right)$ of v. The resulting graph is a t-spanner of S and it can be maintained as stated above. The approach can be generalized to the kinetic case so that the total number of events in maintaining the spanner is $O(n^2 \log n)$ under pseudo-algebraic motion. Each event can be updated in $O\left(\frac{\log\alpha}{(t-1)^d}\right)$ time.

The problem of maintaining a spanner under insertions and deletions of points was settled by Gottlieb and Roditty [5]: For every set of n points in a metric space of bounded doubling dimension, there exists a $(1+\epsilon)$-spanner whose maximum degree is $O(1)$ and that can be maintained under insertions and deletions of points, in $O(\log n)$ time per operation.

Recently several papers have considered the kinetic version of the spanner construction problem. Abam et al. [1, 3] gave the first data structures for maintaining the Θ-graph, which was later improved by Rahmati et al. [32]. Assuming the trajectories of the points can be described by polynomials whose degrees are at most a constant s, the data structure uses $O(n \log^d n)$ space and handles $O(n^2)$ events with a total cost of $O\left(n\lambda_{2s+2}(n)\log^{d+1} n\right)$, where $\lambda_{2s+2}(n)$ is the maximum length of Davenport-Schinzel sequences of order $2s+2$ on n symbols. The kinetic data structure is compact, efficient, responsive (in an amortized sense), and local.

Applications

The construction of sparse spanners has been shown to have numerous application areas such as metric space searching [31], which includes query by content in multimedia objects, text retrieval, pattern recognition, and function approximation. Another example is broadcasting in communication networks [29]. Several well-known theoretical results also use the construction of t-spanners as a building block, for example, Rao and Smith [33] made a breakthrough by showing an optimal $O(n \log n)$-time approximation scheme for the well-known Euclidean *traveling salesperson problem*, using t-spanners (or banyans). Similarly, Czumaj and Lingas [18] showed approximation schemes for minimum-cost multi-connectivity problems in geometric networks.

Open Problems

A few open problems are mentioned below:

1. Determine if there exists a fault-tolerant t-spanner of linear size for convex region faults.
2. Can the k-vertex fault-tolerant spanner be computed in $O(n \log n + kn)$ time?

Experimental Results

The problem of constructing spanners has received considerable attention from a theoretical perspective but not much attention from a practical or experimental perspective. Navarro and Paredes [31] presented four heuristics for point sets in high-dimensional space ($d = 20$) and showed by empirical methods that the running time was $O(n^{2.24})$ and the number of edges in the produced graphs was $O(n^{1.13})$. Farshi and Gudmundsson [25] performed a thorough comparison of the construction algorithms discussed in section "Spanners of Points in Euclidean Space." The results showed that the spanner produced by the original greedy algorithm is superior compared to the graphs produced by the other approaches discussed in section "Spanners of Points in Euclidean Space" when it comes to number of edges, maximum degree, and weight. However, the greedy algorithm requires $O(n^2 \log n)$ time [10] and uses quadratic space, which restricted experiments in [25] to instances containing at most 13,000 points. Alewijnse et al. [4] showed how to reduce the space usage to linear only paying an additional $O(\log n)$ factor in the running time. In their experiments, they could handle more than a million points. In a follow-up paper, Bouts et al. [11] gave further experimental improvements.

Problem Definition

Given a graph G in which every edge has a nonnegative capacity, the goal of the minimum-cut problem is to find a subset of edges of G with minimum total capacity whose deletion disconnects G. The closely related minimum (s,t)-cut problem further requires two specific vertices s and t to be separated by the deleted edges. Minimum cuts and their generalizations play a central role in divide-and-conquer and network optimization algorithms.

The fastest algorithms known for computing minimum cuts in arbitrary graphs run in roughly $O(mn)$ time for graphs with n vertices

and m edges. However, even faster algorithms are known for graphs with additional topological structure. This entry sketches algorithms to compute minimum cuts in near-linear time when the input graph can be drawn on a surface with bounded genus – informally, a sphere with a bounded number of handles.

Problem 1 (Minimum (s,t)-Cut)
INPUT: *An undirected graph $G = (V, E)$ embedded on an orientable surface of genus g, a nonnegative capacity function $c: E \to \mathbb{R}$, and two vertices s and t.* OUTPUT: *A minimum-capacity (s, t)-cut in G.*

Problem 2 (Global Minimum Cut)
INPUT: *An undirected graph $G = (V, E)$ embedded on an orientable surface of genus g and a nonnegative capacity function $c: E \to \mathbb{R}$.* OUTPUT: *A minimum-capacity cut in G.*

Key Results

Topological Background

A surface is a compact space in which each point has a neighborhood homeomorphic to either the plane or a closed half plane. Points with half-plane neighborhoods comprise the boundary of the surface, which is the union of disjoint simple cycles. The genus is the maximum number of disjoint simple cycles whose deletion leaves the surface connected. A surface is orientable if it does not contain a MÃbius band. An embedding is a drawing of a graph on a surface, with vertices drawn as distinct points and edges as simple interior-disjoint paths, whose complement is a collection of disjoint open disks called the faces of the embedding.

An even subgraph of G is a subgraph in which every vertex has even degree; each component of an even subgraph is Eulerian. Two even subgraphs of an embedded graph G are $\mathbb{Z}_2$-homologous, or in the same $\mathbb{Z}_2$-homology class, if their symmetric difference is the boundary of a subset of the surface. If G is embedded on a surface of genus g with $b > 0$ boundary cycles, the even subgraphs of G fall into 2^{2g+b-1} $\mathbb{Z}_2$-homology classes. An even subgraph of G is $\mathbb{Z}_2$-minimal if it has minimum total cost within its $\mathbb{Z}_2$-homology class. Each component of a $\mathbb{Z}_2$-minimal even subgraph is itself $\mathbb{Z}_2$-minimal.

Every embedded graph G has a dual graph G^*, embedded on the same surface, whose vertices correspond to faces of G and whose edges correspond to pairs of faces that share an edge in G. The cost of a dual edge in G^* is the capacity of the corresponding primal edge in G.

Duality maps cut to certain sets of cycles and vice versa. For example, the minimum-capacity (s, t)-cut in any planar graph G is dual to the minimum-cost cycle in G^* that separates the dual faces s^* and t^*. If we remove s^* and t^* from the sphere, the dual of the minimum cut is the shortest generating cycle of the resulting annulus [11, 15]. More generally, let X denote the set of edges that cross some minimum (s, t)-cut in an embedded graph G, and let X^* denote the corresponding subgraph of the dual graph G^*. Then X^* is a minimum-cost even subgraph of G^* that separates s^* and t^*. If we remove s^* and t^* from the surface, X^* becomes a $\mathbb{Z}_2$-minimal subgraph homologous with the boundary of s^*.

Crossing Sequences

Our first algorithm [6] reduces computing a minimum (s, t)-cut in a graph embedded on a genus-g surface to $g^{O(g)}$ instances of the planar minimum-cut problem.

The algorithm begins by constructing a collection A of $2g + 1$ paths in G^*, called a greedy system of arcs, with three important properties. First, the endpoints of each path are incident to the boundary faces s^* and t^*. Second, each path is composed of two shortest paths plus at most one additional edge. Finally, the complement $\Sigma \setminus A$ of the paths is a topological open disk. A greedy system of arcs can be computed in $O(gn)$ time [5, 9].

We regard each component of X^* as a closed walk, and we enumerate all possible sequences of crossings between the components of X^* with the arcs in A. The components of any $\mathbb{Z}_2$-minimal even subgraph cross any shortest path, and there-

fore any arc in A, at most $O(g)$ times. It follows that we need to consider at most $g^{O(g)}$ crossing sequences, each of length at most $O(g^2)$. Following Kutz [13], the shortest closed walk with a given crossing sequence is the shortest generating cycle in an annulus obtained by gluing together $O(g^2)$ copies of the disk $\Sigma \setminus A$, which can be computed in $O(g^2 n \log\log n)$ time using the planar minimum-cut algorithm of Italiano et al. [12]. The overall running time of this algorithm is $g^{O(g)} n \log\log n$.

Surprisingly, a reduction from MAXCUT implies that finding the minimum-cost even subgraph in an arbitrary $\mathbb{Z}_2$-homology class is NP-hard. Different reductions imply that it is NP-hard to find the minimum-cost *closed walk* [5] or *simple cycle* [2] in a given $\mathbb{Z}_2$-homology class.

$\mathbb{Z}_2$-Homology Cover

Our second algorithm [9] finds the minimum-cost closed walks in G^* in every $\mathbb{Z}_2$-homology class by searching a certain covering space and then assembles X^* from these closed walks via dynamic programming.

As in our first algorithm, we first compute a greedy system of arcs A. The homology class of any cycle γ is determined by the parity of the number of crossings of γ with each arc in A. Each arc $\alpha_i \in A$ appears as two paths α_i^+ and α_i^- on the boundary of the disk $D = \Sigma \setminus A$.

We then construct a new surface $\overline{\Sigma}$, called the $\mathbb{Z}_2$-*homology cover* of Σ, by gluing together several copies of D as follows. We associate each homology class $h \in \mathbb{Z}_2^{2g+1}$ with a vector of $2g+1$ bits. Let $h \wedge i$ denote the bit vector obtained from h by flipping its ith bit. For each bit vector h, we construct a copy D_h of D; let $\alpha_{i,h}^+$ and $\alpha_{i,h}^-$ denote the copies of α_i^+ and α_i^- on the boundary of D_h. Finally, we construct $\overline{\Sigma}$ by identifying the paths $\alpha_{i,h}^+$ and $\alpha_{i,h\wedge i}^-$ for each homology class h and index i.

This construction also yields a graph $\overline{G}$ embedded in $\overline{\Sigma}$, with 2^{2g+1} vertices v_h and edges e_h for each vertex v and edge e of G^*. Each edge e_h of $\overline{G}$ inherits the cost of the corresponding edge e in G^*. Any walk in $\overline{G}$ projects to a walk in G^* by dropping subscripts; in particular, any walk in $\overline{G}$ from v_0 to v_h projects to a closed walk in G^* with homology class h that starts and ends at vertex v. Conversely, the *shortest* closed walk in G^* in any homology class h is the projection of the *shortest* path from v_0 to v_h, for some vertex v.

Any cycle in any nontrivial homology class crosses some path α_i, an odd number of times, and therefore at least once. To find all such cycles for each index i, we slice $\overline{G}$ along the lifted path $\alpha_{i,0}$ to obtain a new boundary cycle, and then compute the shortest path from each vertex v_0 on this cycle to every other vertex v_h in $2^{O(g)} n \log n$ time, using an algorithm of Chambers et al. [3]. Altogether, we find the shortest closed walk in every $\mathbb{Z}_2$-homology class in $2^{O(g)} n \log n$ time. The dual minimum cut X^* can then be built from these $\mathbb{Z}_2$-minimal cycles in $2^{O(g)}$ additional time via dynamic programming.

Global Minimum Cuts

Our final result generalizes the recent $O(n \log\log n)$-time algorithm for planar graphs by Lacki and Sankowski [14], which in turn relies on the $O(n \log\log n)$-time algorithm for planar minimum (s,t)-cuts of Italiano et al. [12].

The global minimum cut X in a surface graph G is dual to the minimum-cost nonempty separating subgraph of the dual graph G^*. In particular, if G is planar, X is dual to the shortest nonempty cycle in G^*. There are two cases to consider: either X^* is a simple contractible cycle, or it isn't. We describe two algorithms, one of which is guaranteed to return the minimum-cost separating subgraph.

To handle the contractible cycle case, we first slice the surface Σ to make it planar, first along the shortest non-separating cycle α in G^*, which we compute in $g^{O(g)} n \log\log n$ time using a variant of our crossing sequence algorithm, and then along a greedy system of arcs A connecting the resulting boundary cycles. Call the resulting planar graph D; each edge of $\alpha \cup A$ appears as two edges on the boundary of D. Let e^+ and e^- be edges on the boundary of D corresponding to some edge e of α. Using the planar algorithm of Lacki and Sankowski [14], we find the shortest cycle γ^+ in $D \setminus e^+$ and the shortest cycle γ^- in $D \setminus e^-$. The shorter of these two cycles projects to a closed walk γ in the original dual graph G^*.

Results of Cabello [2] imply that if γ is a simple cycle, it is the shortest contractible simple cycle in G^*; otherwise, X^* is not a simple cycle.

Our second algorithm begins by enumerating all $2^{O(g)}$ $\mathbb{Z}_2$-minimal even subgraphs in G^* in $g^{O(g)}n \log\log n$ time, using our crossing sequence algorithm. Our algorithm marks the faces on either side of an arbitrary edge of each $\mathbb{Z}_2$-minimal even subgraphs in G^*. If X^* is not a simple contractible cycle, then some pair of marked faces must be separated by X^*. In other words, in $g^{O(g)}n \log\log n$ time, we identify a set T of $2^{O(g)}$ vertices of G, at least two of which are separated by the global minimum cut. Thus, if we fix an arbitrary source vertex s and compute the minimum (s,t)-cut for each vertex $t \in T$ in $g^{O(g)}n \log\log n$ time, the smallest such cut is the global minimum cut X.

Open Problems

Extending these algorithms to *directed* surface graphs remains an interesting open problem; currently the only effective approach known is to compute a maximum (s,t)-flow and apply the maxflow-mincut theorem. The recent algorithm of Borradaile and Klein [1] computes maximum flows in directed *planar* graphs in $O(n \log n)$ time. For higher-genus graphs, Chambers et al. [7] describes maximum-flow algorithms that run in $g^{O(g)}n^{3/2}$ time for arbitrary capacities and in $O(g^8 n \log^2 n \log^2 C)$ for integer capacities that sum to C.

Another open problem is reducing the dependencies on the genus from exponential to polynomial. Even though there are near-quadratic algorithms to compute minimum cuts, the only known approach to achieving near-linear time for bounded-genus graphs with weighted edges is to solve an NP-hard problem.

Finally, it is natural to ask whether minimum cuts can be computed quickly in other minor-closed families of graphs, for which embeddings on to bounded-genus surfaces may not exist. Such results already exist for one-crossing-minor-free families [4] and in particular, graphs of bounded treewidth [10].

Problem Definition

Global routing is a key step in VLSI physical design after floor planning and placement. Its main goal is to reduce the overall routing complexity and guide the detailed router by planning the approximate routing path of each net. The commonly used objectives during global routing include minimizing total wirelength, mitigating routing congestion, or meeting routing resource constraints. If timing critical paths are known, they can also be put in the design objectives during global routing, along with other metrics such as manufacturability and noise.

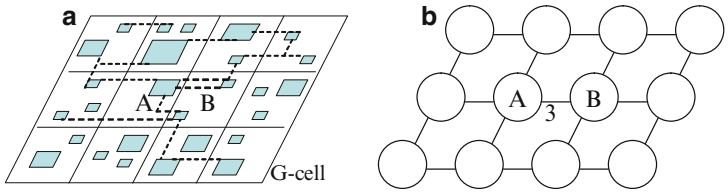
The global routing problem can be formulated using graph models. For a given netlist graph $G(C, N)$, vertices C represent pins on placed objects such as standard cells or IP blocks, and edges N represent nets connecting the pins. The routing resources on a chip can be modeled in another graph $G(V, E)$ by dividing the entire global routing region into a set of smaller regions, so-called global routing cells (G-cells), where $v \in V$ represents a G-cell and $e \in E$ represents the boundary between two adjacent G-cells with a given routing capacity (c_e). Figure 1 shows how the chip can be abstracted into a 2-dimensional global routing graph. Such abstraction can be easily extended to 3-dimensional global routing graph to perform layer assignment (e.g., [15]). Since all standard cells and IP blocks are placed before the global routing stage (e.g., C can be mapped into V), the goal of global routing is to find G-cell to G-cell paths for N while trying to meet certain objectives such as routability optimization and wirelength minimization.

A straightforward mathematical optimization for global routing can be formulated as a 0-1 integer linear programming (ILP). Let R_i be a set of Steiner trees on G for net $n_i \in N$, and $x_{i,j}$ be the binary variable to indicate whether $r_{i,j} \in R_i$ is selected as the routing solution. Then an example ILP formulation can be written as follows:

The above formulation minimizes the total routing capacity utilization under the maximum routing capacity constraint for each edge $e \in E$. In fact, minimizing the total routing capacity is equivalent to minimizing total wirelength, because a unit wirelength in the global routing utilizes one routing resource (i.e., crossing the boundary between two adjacent G-cells). Other objectives/constraints can include timing optimization, noise reduction [10, 14], or manufacturability (e.g., CMP) [8].

Key Results

The straightforward formulation using ILP, e.g., as in Fig. 2, is NP-complete which cannot be solved efficiently for modern VLSI designs. One common technique to solve ILP is to use linear



Global Routing, Fig. 1 Graph model for global routing. (**a**) Real circuit with G-cells. (**b**) Global routing graph

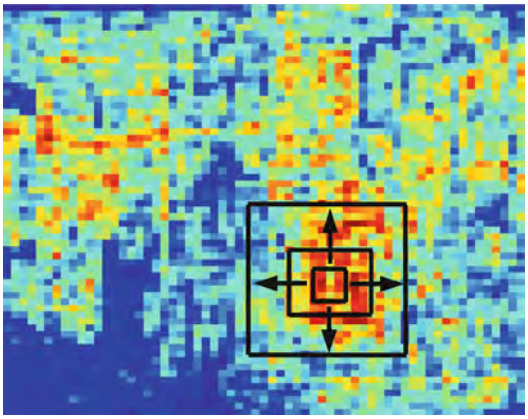
$$\mathbf{min}: \sum_{e \in E} u_e$$

$$\mathbf{s.t}: \sum_{r_{i,j} \in R_i} x_{i,j} = 1, \forall n_i \in N$$

$$u_e = \sum_{(i,j):e \in r_{i,j}} x_{i,j}, \forall e \in E$$

$$u_e \leq c_e, \forall e \in E$$

Global Routing, Fig. 2 An example of global routing formulation using ILP



Global Routing, Fig. 3 Box expansion for Progressive ILP during BoxRouter

programming relaxation where the binary variables are made continuous, $x_{i,j} \in [0, 1]$, and that can be solved in polynomial time. Once a linear programming solution is obtained, rounding technique is used to find the binary solution. Another technique is a hierarchical divide-and-conquer scheme to limit the complexity, which solves many independent subproblems of similar sizes. These approaches may suffer from large amount of rounding errors or lack of interactions between subproblems, resulting in poor quality.

BoxRouter [1, 6] proposed a new approach to divide the entire routing region into a set of synergistic subregions. The key idea in BoxRouter is the progressive ILP based on the routing box expansion, which pushes congestion outward progressively from the highly congested region. Unlike conventional hierarchical divide-and-conquer approach, BoxRouter solves a sequence of ILP problems where an early problem is a subset of a later problem. BoxRouter progressively applies box expansion to build a sequence of ILP problems starting from the most congested region which is obtained through a very fast pre-routing stage. Figure 3 illustrates the concept of box expansion.

The advantage of BoxRouter over conventional approach is that each problem synergically reflects the decisions made so far by taking the previous solutions as constraints, in order to enhance congestion distribution and shorten the wirelength. In that sense, the first ILP problem has the largest flexibility which motivates the box expansion originating from the most congested region. Even though the last box can cover the whole design, the effective ILP size remains tractable in BoxRouter, as ILP is only performed on the wires between two subsequent boxes.

Compared with the formulation in Fig. 2 which directly minimizes the total wirelength, progressive ILP in BoxRouter maximizes the completion rate (e.g., minimizing unrouted nets) which can be more important and practical than minimizing total wirelength as shown in Fig. 4. Wirelength minimization in BoxRouter is indirectly achieved by allowing only the minimum rectilinear Steiner trees for each binary variable (i.e., $x_{i,j}$) and being augmented with the post-maze routing step. Such change in the objective function provides higher computation efficiency: it is found that the BoxRouter formulation can be solved significantly faster

$$\max : \sum x_{i,j}$$

$$\text{s.t} : \sum_{r_{i,j} \in R_i} x_{i,j} \leq 1, \forall n_i \in N$$

$$\sum_{(i,j):e \in r_{i,h}} x_{i,j} \leq c_e, \forall e \in E$$

Global Routing, Fig. 4 Global routing formulation in BoxRouter for minimal unrouted nets

than the traditional formulations due to its simple and well-exploited knapsack structure [7].

In case some nets remain unrouted after each ILP problem either due to insufficient routing resources inside a box or a limited number of Steiner graphs for each net, BoxRouter applies adaptive maze routing which penalizes using routing resources outside the current box, in order to reserve them for subsequence problems. Based on the new ILP techniques, BoxRouter has obtained much better results than previous state-of-the-art global routers [4, 9] and motivated many further studies in global routing (e.g., [5, 11–13, 15]) and global routing contests at ISPD 2007 and ISPD 2008 [2, 3].

2007; Bhalgat, Hariharan, Kavitha, Panigrahi

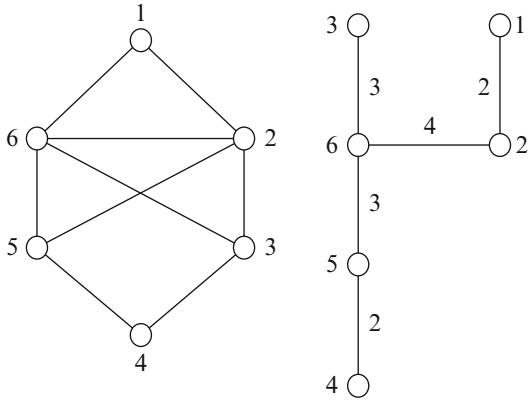
Problem Definition

Let $G = (V, E)$ be an undirected graph with $|V| = n$ and $|E| = m$. The edge connectivity of two vertices $s, t \in V$, denoted by $\lambda(s, t)$, is defined as the size of the smallest cut that separates s and t; such a cut is called a minimum $s - t$ cut. Clearly, one can represent the $\lambda(s, t)$ values for all pairs of vertices s and t in a table of size $O(n^2)$. However, for reasons of efficiency, one would like to represent all the $\lambda(s, t)$ values in a more succinct manner. *Gomory-Hu trees* (also known as *cut trees*) offer one such succinct representation of linear (i.e., $O(n)$) space and constant (i.e., $O(1)$) lookup time. It has the additional advantage that apart from representing all the $\lambda(s, t)$ values, it also contains structural information from which a minimum $s - t$ cut can be retrieved easily for any pair of vertices s and t.

Formally, a Gomory-Hu tree $T = (V, F)$ of an undirected graph $G = (V, E)$ is a weighted undirected tree defined on the vertices of the graph such that the following properties are satisfied:

- For any pair of vertices $s, t \in V, \lambda(s, t)$ is equal to the minimum weight on an edge in the unique path connecting s to t in T. Call this edge $e(s, t)$. If there are multiple edges with the minimum weight on the s to t path in T, any one of these edges is designated as $e(s, t)$.
- For any pair of vertices s and t, the bipartition of vertices into components produced by removing $e(s, t)$ (if there are multiple candidates for $e(s, t)$, this property holds for each candidate edge) from T corresponds to a minimum $s - t$ cut in the original graph G.

To understand this definition better, consider the following example. Figure 1 shows an undirected graph and a corresponding Gomory-Hu tree. Focus on a pair of vertices, for instance, 3 and 5.



Gomory-Hu Trees, Fig. 1 An undirected graph (*left*) and a corresponding Gomory-Hu tree (*right*)

Clearly, the edge (6,5) of weight 3 is a minimum-weight edge on the 3 to 5 path in the Gomory-Hu tree. It is easy to see that $\lambda(3, 5) = 3$ in the original graph. Moreover, removing edge (6,5) in the Gomory-Hu tree produces the vertex bipartition ({1,2,3,6},{4,5}), which is a cut of size 3 in the original graph.

It is not immediate that such Gomory-Hu trees exist for all undirected graphs. In a classical result in 1961, Gomory and Hu [8] showed that not only do such trees exist for all undirected graphs but that they can also be computed using $n - 1$ minimum s-t cut (or equivalently maximum s-t flow) computations. In fact, a graph can have multiple Gomory-Hu trees.

All previous algorithms for constructing Gomory-Hu trees for undirected graphs used maximum-flow subroutines. Gomory and Hu gave an algorithm to compute a cut tree T using $n - 1$ maximum-flow computations and graph contractions. Gusfield [9] proposed an algorithm that does not use graph contractions; all $n - 1$ maximum-flow computations are performed on the input graph. Goldberg and Tsioutsiouliklis [7] did an experimental study of the algorithms due to Gomory and Hu and due to Gusfield for the cut tree problem and described efficient implementations of these algorithms. Examples were shown by Benczúr [1] that cut trees do not exist for directed graphs.

Any maximum-flow-based approach for constructing a Gomory-Hu tree would have a running

time of $(n-1)$ times the time for computing a single maximum flow. Till now, faster algorithms for Gomory-Hu trees were by-products of faster algorithms for computing a maximum flow. The current fastest $\tilde{O}(m+n\lambda(s,t))$ (polylog n factors ignored in $\tilde{O}$ notation) maximum-flow algorithm, due to Karger and Levine [11], yields the current best expected running time of $\tilde{O}(n^3)$ for Gomory-Hu tree construction on simple unweighted graphs with n vertices. Bhalgat et al. [2] improved this time complexity to $\tilde{O}(mn)$. Note that both Karger and Levine's algorithm and Bhalgat et al.'s algorithm are randomized Las Vegas algorithms. The fastest deterministic algorithm for the Gomory-Hu tree construction problem is a by-product of Goldberg and Rao's maximum-flow algorithm [6] and has a running time of $\tilde{O}(nm^{1/2}\min(m, n^{3/2}))$.

Since the publication of the results of Bhalgat et al. [2], it has been observed that the maximum-flow subroutine of Karger and Levine [11] can also be used to obtain an $\tilde{O}(mn)$ time Las Vegas algorithm for constructing the Gomory-Hu tree of an unweighted graph. However, this algorithm does not yield partial Gomory-Hu trees which are defined below. For planar undirected graphs, Borradaile et al. [3] gave an $\tilde{O}(mn)$ time algorithm for constructing a Gomory-Hu tree.

It is important to note that in spite of the tremendous recent progress in approximate maximum s-t flow (or approximate minimum s-t cut) computation, this does not immediately translate to an improved algorithm for approximate Gomory-Hu tree construction. This is because of two reasons: first, the property of uncrossability of minimum s-t cuts used by Gomory and Hu in their minimum s-t cut based cut tree construction algorithm does not hold for approximate minimum s-t cuts, and second, the errors introduced in individual minimum s-t cut computation can add up to create large errors in the Gomory-Hu tree.

Key Results

Bhalgat et al. [2] considered the problem of designing an efficient algorithm for constructing a Gomory-Hu tree on unweighted undirected graphs. The main theorem shown in this entry is the following.

Theorem 1 *Let $G = (V, E)$ be a simple unweighted graph with m edges and n vertices. Then a Gomory-Hu tree for G can be built in expected time $\tilde{O}(mn)$.*

Their algorithm is always faster by a factor of $\tilde{\Omega}(n^{2/9})$ (polylog n factors ignored in $\tilde{\Omega}$ notation) compared to the previous best algorithm.

Instead of using maximum-flow subroutines, they use a Steiner connectivity algorithm. The *Steiner connectivity* of a set of vertices S (called the *Steiner set*) in an undirected graph is the minimum size of a cut which splits S into two parts; such a cut is called a *minimum Steiner cut*. Generalizing a tree-packing algorithm given by Gabow [5] for finding the edge connectivity of a graph, Cole and Hariharan [4] gave an algorithm for finding the Steiner connectivity k of a set of vertices in either undirected or directed Eulerian unweighted graphs in $\tilde{O}(mk^2)$ time. (For undirected graphs, their algorithm runs a little faster in time $\tilde{O}(m + nk^3)$.) Bhalgat et al. improved this result and gave the following theorem.

Theorem 2 *In an undirected or directed Eulerian unweighted graph, the Steiner connectivity k of a set of vertices can be determined in time $\tilde{O}(mk)$.*

The algorithm in [4] was used by Hariharan et al. [10] to design an algorithm with expected running time $\tilde{O}(m + nk^3)$ to compute a *partial* Gomory-Hu tree for representing the $\lambda(s,t)$ values for all pairs of vertices s, t that satisfied $\lambda(s,t) \leq k$. Replacing the algorithm in [4] by the new algorithm for computing Steiner connectivity yields an algorithm to compute a partial Gomory-Hu tree in expected running time $\tilde{O}(m+nk^2)$. Bhalgat et al. showed that using a more detailed analysis, this result can be improved to give the following theorem.

Theorem 3 *The partial Gomory-Hu tree of an undirected unweighted graph to represent all $\lambda(s,t)$ values not exceeding k can be constructed in expected time $\tilde{O}(mk)$.*

Since $\lambda(s,t) < n$ for all s,t vertex pairs in an unweighted (and simple) graph, setting k to n in Theorem 3 implies Theorem 1.

Applications

Gomory-Hu trees have many applications in multiterminal network flows and are an important data structure in graph connectivity literature.

Open Problems

The problem of derandomizing the algorithm due to Bhalgat et al. [2] to produce an $\tilde{O}(mn)$ time deterministic algorithm for constructing Gomory-Hu trees for unweighted undirected graphs remains open. The other main challenge is to extend the results in [2] to weighted graphs.

Experimental Results

Goldberg and Tsioutsiouliklis [7] did an extensive experimental study of the cut tree algorithms due to Gomory and Hu [8] and that due to Gusfield [9]. They showed how to efficiently implement these algorithms and also introduced and evaluated heuristics for speeding up the algorithms. Their general observation was that while Gusfield's algorithm is faster in many situations, Gomory and Hu's algorithm is more robust. For more detailed results of their experiments, refer to [7].

No experimental results are reported for the algorithm due to Bhalgat et al. [2].

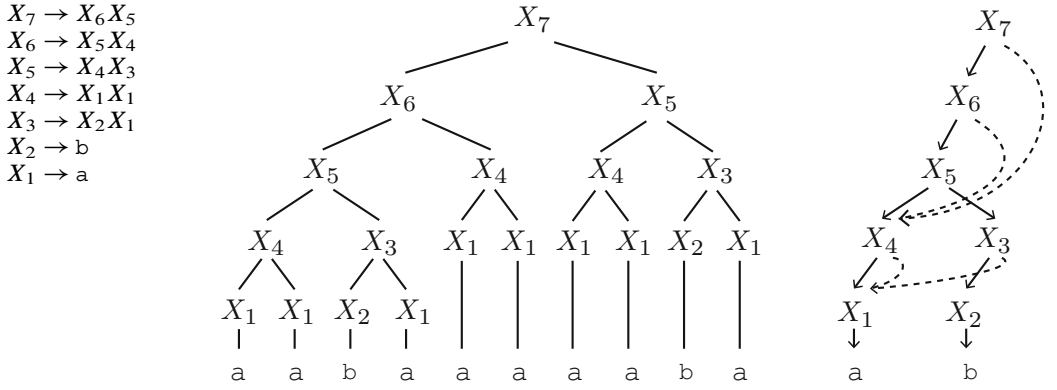
Problem Definition

Given an input string S, the grammar-based compression problem is to find a small



Grammar Compression, Fig. 1 (*Left*) an SLP G that represents string aabaaaaaba, where the variable X_7 is the start symbol. (*Center*) derivation tree of G. (*Right*) an ordered DAG corresponding to G, where the *solid* and *dashed edges* respectively correspond to the first and second child of each node

description of S that is based on a deterministic context-free grammar that generates a language consisting only of S. We will call such a context-free grammar, a grammar that represents S.

Generally, grammar-based compression can be divided into two phases [8], the *grammar transform* phase, where a context-free grammar G that represents string S is computed, and the *grammar encoding* phase, where an encoding for G is computed. Kieffer and Yang [8] showed that if a grammar transform is *irreducible*, namely, if the resulting grammar that represents S satisfies the following three conditions: (1) distinct variables derive different strings, (2) every variable other than the start symbol is used more than once (rule utility), and (3) all pairs of symbols have at most one nonoverlapping occurrence in the right-hand side of production rules (di-gram uniqueness); then, the grammar-based code using a zero order arithmetic code for encoding the grammar is universal.

Grammar-based compression algorithms differ mostly by how they perform the grammar transform, which can be stated as the following problem.

Problem 1 (Smallest Grammar Problem) Given an input string S of length N, output the smallest context-free grammar that represents S.

Here, the *size* of the grammar is defined as the total length of the right-hand side of the production rules in the grammar. Often, grammars are considered to be in the Chomsky normal form, in which case the grammar is called a *straight line program* (SLP) [7], i.e., the right-hand side of each production rule is either a terminal character or a pair of variables. Note that any grammar of size n can be converted into an SLP of size $O(n)$. Figure 1 shows an example of an SLP that represents string aabaaaaaba. A grammar representing a string can be considered as an ordered directed acyclic graph. Another important feature is that grammars allow for exponential compression, that is, the size of a grammar that represents a string of length N can be as small as $O(\log N)$.

Grammar-based compression is known to be especially suitable for compressing *highly repetitive strings*, for example, multiple whole genomes, where, although each individual string may not be easily compressible, the ensemble of strings is very compressible since each string is very similar to each other. Also, due to its ease of manipulation, grammar-based representation of strings is a frequently used model for *compressed string processing*, where the aim is to efficiently process compressed strings without explicit decompression. Such an approach allows for theoretical and practical speedups compared to a naive decompress-then-process approach.

Key Results

Hardness

The smallest grammar problem is known to be NP-hard [21]. The approximation ratio of a grammar-based algorithm A is defined as $\max_{S \in \Sigma^*} \frac{|G_S^{\mathrm{A}}|}{|G_S^{\mathrm{opt}}|}$, where $|G_S^{\mathrm{A}}|$ is the size of the grammar that represents string S produced by A and $|G_S^{\mathrm{opt}}|$ is the size of the smallest grammar that represents string S. Charikar et al. [3] showed that there is no polynomial-time algorithm for the smallest grammar problem with approximation ratio less than $\frac{8,569}{8,568}$, unless $P = NP$. Furthermore, they show that for a given set $\{k_1, \ldots, k_m\}$ of positive integers, the smallest grammar for string $\mathtt{a}^{k_1}\mathtt{b}\mathtt{a}^{k_2}\mathtt{b}\cdots\mathtt{b}\mathtt{a}^{k_m}$ is within a constant factor of the smallest number of multiplications required to compute $x^{k_1}, \ldots, x^{k_m}$, given a real number x. This is a well-studied problem known as the addition chain problem, whose best-known approximation algorithm has an approximation ratio of $O(\frac{\log N}{\log \log N})$ [23]. Thus, achieving $o(\frac{\log N}{\log \log N})$ approximation for the smallest grammar problem may be difficult.

Algorithms for Finding Small Grammars

Heuristics

Below, we give brief descriptions of several grammar-based compression algorithms based on simple greedy heuristics for which approximation ratios have been analyzed [3] (see Table 1).

- LZ78 [24] can be considered as constructing a grammar. Recall that each LZ78 factor of length at least two consists of a previous factor and a letter and can be expressed as a production rule of a grammar.
- SEQUITUR [15] processes the string in an online manner and adds a new character of the string to the right-hand side of the production rule of the start symbol, which is initially empty. For each new character, the algorithm updates the grammar, adding or removing production rules and replacing corresponding symbols in the grammar so that the di-gram uniqueness and rule utility properties are satisfied. The algorithm can be implemented to run in expected linear time. The grammar produced by SEQUITUR is not necessarily irreducible, and thus a revised version called SEQUENTIAL was proposed in [8].
- RE-PAIR [11] greedily and recursively replaces the most frequent di-gram in the string with a new symbol until no di-gram occurs more than once. Each such replacement corresponds to a new production rule in the final grammar. The algorithm can be implemented to run in linear time.
- LONGEST MATCH [8] greedily and recursively replaces the longest substring that has more than one nonoverlapping occurrence. The algorithm can be implemented to run in linear time by carefully maintaining a structure based on the suffix tree, through the course of the algorithm [10, 14].
- GREEDY [1] (originally called OFF-LINE, but coined in [3]) greedily and recursively replaces substrings that give the highest compression (with several variations in its definition). The algorithm can be implemented to run in $O(N \log N)$ time for each production rule, utilizing a data structure called minimal augmented suffix trees, which augments the suffix tree in order to consider the total number of nonoverlapping occurrences of a given substring.
- BISECTION [9] recursively partitions the string S into strings L and R of lengths 2^i and $N - 2^i$, where $i = \lceil \log N \rceil - 1$, each time forming a production rule $X_S \rightarrow X_L X_R$. A new production rule is created only for each distinct substring, and the rule is shared for identical substrings. The algorithm can be viewed as fixing the shape of the derivation tree and then computing the smallest grammar whose derivation tree is of the given shape.

Approximation Algorithms

Rytter [16] and Charikar et al. [3] independently and almost simultaneously developed linear time

Grammar Compression, Table 1 Known upper and lower bounds on approximation ratios for the simple heuristic algorithms (Taken from [3] with corrections)

Algorithm	Upper bound	Lower bound
LZ78 [24]	$O((N/\log N)^{2/3})$	$\Omega(N^{2/3}/\log N)$
RE-PAIR [11]		$\Omega(\sqrt{\log N})$
LONGEST MATCH [8]		$\Omega(\log\log N)$
GREEDY [1]		$(5\log 3)/(3\log 5) > 1.137\ldots$
SEQUENTIAL [8]	$O((N/\log N)^{3/4})$	$\Omega(N^{1/3})$
BISECTION [9]	$O((N/\log N)^{1/2})$	$\Omega(N^{1/2}/\log N)$

Grammar Compression, Table 2 Approximation algorithms for the smallest grammar problem. N is the size of the input string, and n is the size of the output grammar

Algorithm	Approximation ratio	Working space	Running time
Charikar et al. [3]	$O(\log(N/G_S^{\text{opt}}))$	$O(N)$	$O(N)$
Rytter [16]			
LEVELWISE-REPAIR [18]			
Jeż [5]			
Jeż [6]			
LCA [19]	$O((\log N)\log G_S^{\text{opt}})$	$O(n)$	$O(N)$ expected
LCA* [20]	$O((\log^* N)\log N)$	$O(n)$	$O(N\log^* N)$ expected
OLCA [12]	$O(\log^2 N)$	$O(n)$	$O(N)$ expected
FOLCA [13]	$O(\log^2 N)$	$2n\log n(1+o(1))+2n$ bits	$O(N\log N)$

algorithms which achieve the currently best approximation ratio of $O(\log(N/G_S^{\text{opt}}))$, essentially relying on the same two key ideas: the LZ77 factorization and balanced binary grammars. Below, we briefly describe the approach by Rytter to obtain an $O(\log N)$ approximation algorithm.

The string is processed from left to right, and the LZ77 factorization of the string helps to reuse, as much as possible, the grammar of previously occurring substrings. For string S, let $S = f_1 \ldots f_z$ be the LZ77 factorization of S. The algorithm sequentially processes each LZ factor f_i, maintaining a grammar G_i for $f_1 \ldots f_i$. Recall that by definition, each factor f_i of length at least 2 occurs in $f_1 \ldots f_{i-1}$. Therefore, there exists a sequence of $O(h_{i-1})$ variables of grammar G_{i-1} whose concatenation represents f_i, where h_{i-1} is the height of the derivation tree of G_{i-1}. Using this sequence of variables, a grammar for f_i is constructed, which is then subsequently appended to G_{i-1} to finally construct G_i.

A balanced binary grammar is a grammar in which the shape of the derivation tree resembles a balanced binary tree. Rytter proposed AVL (height balanced) grammars, where the height of sibling sub-trees differ by at most one. By restricting the grammar to AVL grammars, the height of the grammar is bounded by $O(\log N)$, and the above operations can be performed in $O(\log N)$ time for each LZ77 factor, by adding $O(\log N)$ new variables and using techniques resembling those of binary balanced search trees for re-balancing the tree. The resulting time complexity as well as the size of the grammar is $O(z\log N)$.

Finally, an important observation is that the size of the LZ77 factorization of a string S is a lower bound on the size of any grammar G that represents S.

Theorem 1 ([3, 16]) *For string S, let $S = f_1 \ldots f_z$ be the LZ77 factorization of S. Then, for any grammar G that represents S, $z \le |G|$.*

Thus, the total size of the grammar is $O(G_S^{\text{opt}} \log N)$, achieving an $O(\log N)$ approximation ratio. Instead of AVL grammars, Charikar et al. use α balanced (length balanced) grammars, where the ratio between the lengths of sibling sub-trees is between $\frac{\alpha}{1-\alpha}$ and $\frac{1-\alpha}{\alpha}$ for some constant $0 < \alpha \leq \frac{1}{2}$, but the remaining arguments are similar.

Several other linear time algorithms that achieve $O(\log(N/G_S^{\text{opt}}))$ approximation have been proposed [5, 6, 18]. These algorithms resemble RE-PAIR in that they basically replace di-grams in the string with a new symbol in a bottom-up fashion but with specific mechanisms to choose the di-grams so that a good approximation ratio is achieved.

LCA and its variants [12, 13, 19, 20] are approximation algorithms shown to be among the most scalable and practical. The approximation ratios are slightly weaker, but the algorithm can be made to run in an online manner and to use small space (see Table 2). Although seemingly proposed independently, the core idea of LCA is essentially the same as LCP [17] which constructs a grammar based on a technique called *locally consistent parsing*. The parsing is a partitioning of the string that can be computed using only local characteristics and guarantees that for any two occurrences of a given substring, the partitioning in the substring will be almost identical with exceptions in a sufficiently short prefix and suffix of the substring. This allows the production rules of the grammar to be more or less the same for repeated substrings, thus bounding the approximation ratio.

Decompression

The string that a grammar represents can be recovered in linear time by a simple depth-first left-to-right traversal on the grammar. Given an SLP G of size n that represents a string S of length N, G can be preprocessed in $O(n)$ time and space so that each variable holds the length of the string it derives. Using this information, it is possible to access $S[i]$ for any $1 \leq i \leq N$ in $O(h)$ time, where h is the height of the SLP, by simply traversing down the production rules starting from the start symbol until reaching a terminal character corresponding to $S[i]$. Balanced SLPs have height $O(\log N)$ and, therefore, allow access to any position of S in $O(\log N)$ time. For any grammar G, G can be preprocessed in $O(n)$ time and space, so that an arbitrary substring of length l of S can be obtained in $O(l + \log N)$ time [2]. Also, G can be preprocessed in $O(n)$ time and space so that the prefix or suffix of any length l for any variable in G can be obtained in $O(l)$ time [4]. On the other hand, it has been shown that using any data structure of size polynomial in n, the time for retrieving a character at an arbitrary position is at least $(\log N)^{1-\epsilon}$ for any constant $\epsilon > 0$ [22].

Problem Definition

The *graph bandwidth problem* concerns producing a linear ordering of the vertices of a graph $G = (V, E)$ so as to minimize the maximum

"stretch" of any edge in the ordering. Formally, let $n = |V|$, and consider any one-to-one mapping $\pi : V \to \{1, 2, \ldots, n\}$. The *bandwidth* of this ordering is $\mathsf{bw}_\pi(G) = \max_{\{u,v\}\in E} |\pi(u) - \pi(v)|$. The *bandwidth of G* is given by the bandwidth of the best possible ordering: $\mathsf{bw}(G) = \min_\pi \mathsf{bw}_\pi(G)$.

The original motivation for this problem lies in the preprocessing of sparse symmetric square matrices. Let A be such an $n \times n$ matrix, and consider the problem of finding a permutation matrix P such that the non-zero entries of $P^{\mathrm{T}}AP$ all lie in as narrow a band as possible about the diagonal. This problem is equivalent to minimizing the bandwidth of the graph G whose vertex set is $\{1, 2, \ldots, n\}$ and which has an edge $\{u, v\}$ precisely when $A_{u,v} \neq 0$.

In lieu of this fact, one tries to efficiently compute a linear ordering π for which $\mathsf{bw}_\pi(G) \leq A \cdot \mathsf{bw}(G)$, with the *approximation factor* A is as small as possible. There is even evidence that achieving any value $A = O(1)$ is NP-hard [18]. Much of the difficulty of the bandwidth problem is due to the objective function being a maximum over all edges of the graph. This makes divide-and-conquer approaches ineffective for graph bandwidth, whereas they often succeed for related problems like Minimum Linear Arrangement [6] (here the objective is to minimize $\sum_{\{u,v\}\in E} |\pi(u) - \pi(v)|$). Instead, a more global algorithm is required. To this end, a good lower bound on the value of $\mathsf{bw}(G)$ has to be initially discussed.

The Local Density

For any pair of vertices $u, v \in V$, let $d(u, v)$ to be the shortest path distance between u and v in the graph G. Then, define $B(v, r) = \{u \in V : d(u, v) \leq r\}$ as the *ball of radius r* about a vertex $v \in V$. Finally, the *local density of G* is defined by $D(G) = \max_{v\in V, r\geq 1} |B(v, r)|/(2r)$. It is not difficult to see that $\mathsf{bw}(G) \geq D(G)$. Although it was conjectured that an upper bound of the form $\mathsf{bw}(G) \leq \mathrm{poly}(\log n) \cdot D(G)$ holds, it was not proven until the seminal work of Feige [7].

Key Results

Feige proved the following.

Theorem 1 *There is an efficient algorithm that, given a graph $G = (V, E)$ as input, produces a linear ordering $\pi: V \to \{1, 2, \ldots, n\}$ for which $\mathsf{bw}_\pi(G) \leq O\left((\log n)^3 \sqrt{\log n \log\log n}\right) \cdot D(G)$. In particular, this provides a $\mathrm{poly}(\log n)$-approximation algorithm for the bandwidth problem in general graphs.*

Feige's algorithmic framework can be described quite simply as follows.

1. Compute a representation $f: V \to \mathbb{R}^n$ of G in Euclidean space.
2. Let $u_1, u_2, \ldots, u_n$ be independent $N(0, 1)$. ($N(0; 1)$ denotes a standard normal random variable with mean 0 and variance 1.) random variables, and for each vertex $v \in V$, compute $h(v) = \sum_{i=1}^n u_i f_i(v)$, where $f_i(v)$ is the ith coordinate of the vector $f(v)$.
3. Sort the vertices by the value $h(v)$, breaking ties arbitrarily, and output the induced linear ordering.

An equivalent characterization of steps (2) and (3) is to choose a uniformly random vector $\mathbf{a} \in S^{n-1}$ from the $(n-1)$-dimensional sphere $S^{n-1} \subseteq \mathbb{R}^n$ and output the linear ordering induced by the values $h(v) = \langle \mathbf{a}, f(v) \rangle$, where $\langle \cdot, \cdot \rangle$ denotes the usual inner product on $\mathbb{R}^n$. In other words, the algorithm first computes a map $f: V \to \mathbb{R}^n$, projects the images of the vertices onto a randomly oriented line, and then outputs the induced ordering; step (2) is the standard way that such a random projection is implemented.

Volume-Respecting Embeddings

The only step left unspecified is (1); the function f has to somehow preserve the structure of the graph G in order for the algorithm to output a low-bandwidth ordering. The inspiration for the existence of such an f comes from the field of *low-distortion metric embeddings* (see,

e.g., [2, 14]). Feige introduced a generalization of low-distortion embeddings to mappings called *volume respecting embeddings*. Roughly, the map f should be non-expansive, in the sense that $\|f(u) - f(v)\| \leq 1$ for every edge $\{u, v\} \in E$, and should satisfy the following property: For any set of k vertices $v_1, \ldots, v_k$, the $(k-1)$-dimensional volume of the convex hull of the points $f(v_1), \ldots, f(v_k)$ should be as large as possible. The proper value of k is chosen to optimize the performance of the algorithm. Refer to [7, 10, 11] for precise definitions on volume-respecting embeddings, and a detailed discussion of their construction. Feige showed that a modification of Bourgain's embedding [2] yields a mapping $f: V \to \mathbb{R}^n$ which is good enough to obtain the results of Theorem 1.

The requirement $\|f(u) - f(v)\| \leq 1$ for every edge $\{u, v\}$ is natural since $f(u)$ and $f(v)$ need to have similar projections onto the random direction $\mathbf{a}$; intuitively, this suggests that u and v will not be mapped too far apart in the induced linear ordering. But even if $|h(u) - h(v)|$ is small, it may be that many vertices project between $h(u)$ and $h(v)$, causing u and v to incur a large stretch. To prevent this, the images of the vertices should be sufficiently "spread out," which corresponds to the volume requirement on the convex hull of the images.

Applications

As was mentioned previously, the graph bandwidth problem has applications to preprocessing sparse symmetric matrices. Minimizing the bandwidth of matrices helps in improving the efficiency of certain linear algebraic algorithms like Gaussian elimination; see [3, 8, 17]. Follow-up work has shown that Feige's techniques can be applied to VLSI layout problems [19].

Open Problems

First, state the *bandwidth conjecture* (see, e.g., [13]).

Conjecture: For any n-node graph $G = (V, E)$, one has $\mathsf{bw}(G) = O(\log n) \cdot D(G)$.

The conjecture is interesting and unresolved even in the special case when G is a tree (see [9] for the best results for trees). The best-known bound in the general case follows from [7, 10], and is of the form $\mathsf{bw}(G) = O(\log n)^{3.5} \cdot D(G)$. It is known that the conjectured upper bound is best possible, even for trees [4]. One suspects that these combinatorial studies will lead to improved approximation algorithms.

However, the best approximation algorithms, which achieve ratio $O((\log n)^3 (\log \log n)^{1/4})$, are not based on the local density bound. Instead, they are a hybrid of a semi-definite programming approach of [1, 5] with the arguments of Feige, and the volume-respecting embeddings constructed in [12, 16]. Determining the approximability of graph bandwidth is an outstanding open problem, and likely requires improving both the upper and lower bounds.

Problem Definition

An independent set in an undirected graph $G = (V, E)$ is a set of vertices that induce a subgraph which does not contain any edges. The size of the maximum independent set in G is denoted by $\alpha(G)$. For an integer k, a k-coloring of G is a function $\sigma : V \to [1 \dots k]$ which assigns colors to the vertices of G. A valid k-coloring of G is a coloring in which each color class is an independent set. The chromatic number $\chi(G)$ of G is the smallest k for which there exists a valid k-coloring of G. Finding $\chi(G)$ is a fundamental NP-hard problem. Hence, when limited to polynomial time algorithms, one turns to the question of estimating the value of $\chi(G)$ or to the closely related problem of *approximate coloring*.

Problem 1 (Approximate coloring)
INPUT: Undirected graph $G = (V, E)$.
OUTPUT: A valid coloring of G with $r \cdot \chi(G)$ colors, for some approximation ratio $r \geq 1$.
OBJECTIVE: Minimize r.

Let G be a graph of size n. The approximate coloring of G can be solved efficiently within an approximation ratio of $r = O\left(\frac{n(\log\log n)^2}{\log^3 n}\right)$ [12]. This holds also for the approximation of $\alpha(G)$ [8]. These results may seem rather weak; however, it is NP-hard to approximate $\alpha(G)$ and $\chi(G)$ within a ratio of $n^{1-\varepsilon}$ for any constant $\varepsilon > 0$ [9, 14, 23]. Under stronger complexity assumptions, there is some constant $0 < \delta < 1$ such that neither problem can be approximated within a ratio of $n/2^{\log^\delta n}$ [19,23]. This entry will concentrate on the problem of coloring graphs G for which $\chi(G)$ is *small*. As will be seen, in this case the approximation ratio achievable significantly improves.

Vector Coloring of Graphs

The algorithms achieving the best ratios for approximate coloring when $\chi(G)$ is small are all based on the idea of *vector coloring*, introduced by Karger, Motwani, and Sudan [17]. (Vector coloring as presented in [17] is closely related to the Lovász θ function [21]. This connection will be discussed shortly.)

Definition 1 A vector k-coloring of a graph is an assignment of unit vectors to its vertices, such that for every edge, the inner product of the vectors assigned to its endpoints is at most (in the sense that it can only be more negative) $-1/(k-1)$.

The *vector chromatic number* $\overrightarrow{\chi}(G)$ of G is the smallest k for which there exists a vector k-coloring of G. The vector chromatic number can be formulated as follows:

$$\begin{aligned} \overrightarrow{\chi}(G)\ \text{Minimize}\quad & k \\ \text{subject to:}\quad & \langle v_i, v_j\rangle \le -\tfrac{1}{k-1} \quad \forall (i,j)\in E \\ & \langle v_i, v_i\rangle = 1 \qquad\quad \forall i \in V \end{aligned}$$

Here, assume that $V = [1,\ldots,n]$ and that the vectors $\{v_i\}_{i=1}^n$ are in R^n. Every k-colorable graph is also vector k-colorable. This can be seen by identifying each color class with one vertex of a perfect $(k-1)$-dimensional simplex centered at the origin. Moreover, unlike the chromatic number, a vector k-coloring (when it exists) can be found in polynomial time using semidefinite programming (up to an arbitrarily small error in the inner products).

Claim 1 (Complexity of vector coloring [17]) Let $\varepsilon > 0$. If a graph G has a vector k-coloring, then a vector $(k+\varepsilon)$-coloring of the graph can be constructed in time polynomial in n and $\log(1/\varepsilon)$.

One can strengthen Definition 1 to obtain a different notion of vector coloring and the vector chromatic number:

$$\begin{aligned} \overrightarrow{\chi}_2(G)\ \text{Minimize}\quad & k \\ \text{subject to:}\quad & \langle v_i, v_j\rangle = -\tfrac{1}{k-1} \quad \forall (i,j)\in E \\ & \langle v_i, v_i\rangle = 1 \qquad\quad \forall i \in V \end{aligned}$$

$$\begin{aligned} \overrightarrow{\chi}_3(G)\ \text{Minimize}\quad & k \\ \text{subject to:}\quad & \langle v_i, v_j\rangle = -\tfrac{1}{k-1} \quad \forall (i,j)\in E \\ & \langle v_i, v_j\rangle \ge -\tfrac{1}{k-1} \quad \forall i,j \in V \\ & \langle v_i, v_i\rangle = 1 \qquad\quad \forall i \in V \end{aligned}$$

The function $\overrightarrow{\chi}_2(G)$ is referred to as the *strict* vector chromatic number of G and is equal to the Lovász θ function on $\bar{G}$ [17,21], where $\bar{G}$ is the *complement* graph of G. The function $\overrightarrow{\chi}_3(G)$ is referred to as the *strong* vector chromatic number. An analog to Claim 1 holds for both $\overrightarrow{\chi}_2(G)$ and $\overrightarrow{\chi}_3(G)$. Let $\omega(G)$ denote the size of the maximum clique in G; it holds that $\omega(G) \le \overrightarrow{\chi}(G) \le \overrightarrow{\chi}_2(G) \le \overrightarrow{\chi}_3(G) \le \chi(G)$.

Key Results

In what follows, assume that G has n vertices and maximal degree Δ. The $\tilde{O}(\cdot)$ and $\tilde{\Omega}(\cdot)$ notation are used to suppress polylogarithmic factors. We now state the key result of Karger, Motwani, and Sudan [17]:

Theorem 1 ([17]) *If $\overrightarrow{\chi}(G) = k$, then G can be colored in polynomial time using $\min\{\tilde{O}(\Delta^{1-2/k}), \tilde{O}(n^{1-3/(k+1)})\}$ colors.*

As mentioned above, the use of vector coloring in the context of approximate coloring was initiated in [17]. Roughly speaking, once given a vector coloring of G, the heart of the algorithm in [17] finds a large independent set in G. In a nutshell, this independent set corresponds to a set of vectors in the vector coloring which are *close* to one another (and thus by definition cannot share an edge). Combining this with the ideas of Wigderson [22] mentioned below yields Theorem 1.

We proceed to describe related work. The first two theorems below appeared prior to the work of Karger, Motwani, and Sudan [17].

Theorem 2 ([22]) *If $\chi(G) = k$, then G can be colored in polynomial time using $O(k\,n^{1-1/(k-1)})$ colors.*

Theorem 3 ([1]) *If $\chi(G) = 3$, then G can be colored in polynomial time using $\tilde{O}(n^{3/8})$ colors. If $\chi(G) = k \geq 4$ then G can be colored in polynomial time using at most $\tilde{O}(n^{1-1/(k-3/2)})$ colors.*

Combining the techniques of [17] and [1], the following results were obtained for graphs G with $\chi(G) = 3, 4$ (these results were also extended for higher values of $\chi(G)$).

Theorem 4 ([2]) *If $\chi(G) = 3$, then G can be colored in polynomial time using $\tilde{O}(n^{3/14})$ colors.*

Theorem 5 ([13]) *If $\chi(G) = 4$, then G can be colored in polynomial time using $\tilde{O}(n^{7/19})$ colors.*

The currently best known result for coloring a 3-colorable graph is presented in [16]. The algorithm of [16] combines enhanced notions of vector coloring presented in [5] with the combinatorial coloring techniques of [15].

Theorem 6 ([16]) *If $\chi(G) = 3$, then G can be colored in polynomial time using $O(n^{0.19996})$ colors.*

To put the above theorems in perspective, it is NP-hard to color a 3-colorable graph G with 4 colors [11, 18] and a k-colorable graph (for sufficiently large k) with $k^{\frac{\log k}{25}}$ colors [19]. Under stronger complexity assumptions (related to the unique games conjecture [20]) for any constant k, it is hard to color a k-colorable graph with any constant number of colors [6]. The wide gap between these hardness results and the approximation ratios presented in this section has been a major initiative in the study of approximate coloring.

Finally, the limitations of vector coloring are addressed. Namely, are there graphs for which $\overrightarrow{\chi}(G)$ is a poor estimate of $\chi(G)$? One would expect the answer to be "yes" as estimating $\chi(G)$ beyond a factor of $n^{1-\varepsilon}$ is a hard problem. As will be stated below, this is indeed the case (even when $\overrightarrow{\chi}(G)$ is small). Some of the results that follow are stated in terms of the maximum independent set $\alpha(G)$ in G. As $\chi(G) \geq n/\alpha(G)$, these results imply a lower bound on $\chi(G)$. Theorem 7 (i) states that the original analysis of [17] is essentially tight. Theorem 7 (ii) presents bounds for the case of $\overrightarrow{\chi}(G) = 3$. Theorem 7 (iii) and Theorem 8 present graphs G in which there is an extremely large gap between $\chi(G)$ and the relaxations $\overrightarrow{\chi}(G)$ and $\overrightarrow{\chi}_2(G)$.

Theorem 7 ([10]) *(i) For every constant $\varepsilon > 0$ and constant $k > 2$, there are infinitely many graphs G with $\overrightarrow{\chi}(G) = k$ and $\alpha(G) \leq n/\Delta^{1-\frac{2}{k}-\varepsilon}$ (here $\Delta > n^{\delta}$ for some constant $\delta > 0$). (ii) There are infinitely many graphs G with $\overrightarrow{\chi}(G) = 3$ and $\alpha(G) \leq n^{0.843}$. (iii) For some constant c, there are infinitely many graphs G with $\overrightarrow{\chi}(G) = O(\frac{\log n}{\log\log n})$ and $\alpha(G) \leq \log^c n$.*

Theorem 8 ([7]) *For some constant c, there are infinitely many graphs G with $\overrightarrow{\chi}_2(G) \leq 2^{\sqrt{\log n}}$ and $\chi(G) \geq n/2^{c\sqrt{\log n}}$.*

Vector colorings, including the Lovász θ function and its variants, have been extensively studied in the context of approximation algorithms for problems other than Problem 1. These include approximating $\alpha(G)$, approximating the minimum vertex cover problem, and combinatorial optimization in the context of random graphs.

Applications

Besides its theoretical significance, graph coloring has several concrete applications (see, e.g., [3,4]).

Open Problems

By far the major open problem in the context of approximate coloring addresses the wide gap between what is known to be hard and what can be obtained in polynomial time. The case of constant $\chi(G)$ is especially intriguing, as the best known upper bounds (on the approximation ratio) are polynomial while the lower bounds are of constant nature. Regarding the vector coloring paradigm, a majority of the results stated in section "Key Results" use the weakest from of vector coloring $\overrightarrow{\chi}(G)$ in their proof, while stronger relaxations may also be considered. It

would be very interesting to improve upon the algorithmic results stated above using stronger relaxations, as would a matching analysis of the limitations of these relaxations.

Problem Definition

An undirected graph is said to be k-connected (specifically, k-vertex-connected) if the removal of any set of $k-1$ or fewer vertices (with their incident edges) does not disconnect G. Analogously, it is k-edge-connected if the removal of any set of $k-1$ edges does not disconnect

G. Menger's theorem states that a k-vertex-connected graph has at least k openly vertex-disjoint paths connecting every pair of vertices. For k-edge-connected graphs there are k edge-disjoint paths connecting every pair of vertices. The connectivity of a graph is the largest value of k for which it is k-connected. Finding the connectivity of a graph, and finding k disjoint paths between a given pair of vertices can be found using algorithms for maximum flow. An edge is said to be *critical* in a k-connected graph if upon its removal the graph is no longer k-connected.

The problem of finding a minimum-cardinality k-vertex-connected (k-edge-connected) subgraph that spans all vertices of a given graph is called k-VCSS (k-ECSS) and is known to be nondeterministic polynomial-time hard for $k \geq 2$. We review some results in finding approximately minimum solutions to k-VCSS and k-ECSS. We focus primarily on simple graphs. A simple approximation algorithm is one that considers the edges in some order and removes edges that are not critical. It thus outputs a k-connected subgraph in which all edges are critical and it can be shown that it is a 2-approximation algorithm (that outputs a solution with at most kn edges in an n-vertex graph, and since each vertex has to have degree at least k, we can claim that $kn/2$ edges are necessary).

Approximation algorithms that do better than the simple algorithm mentioned above can be classified into two categories: depth first search (DFS) based, and matching based.

Key Results

Lower Bounds for k-Connected Spanning Subgraphs

Each node of a k-connected graph has at least k edges incident to it. Therefore, the sum of the degrees of all its nodes is at least kn, where n is the number of its nodes. Since each edge is counted twice in this degree-sum, the cardinality of its edges is at least $kn/2$. This is called the *degree lower bound*. Expanding on this idea yields a stronger lower bound on the cardinality of a k-connected spanning subgraph of a given graph. Let D_k be a subgraph in which the degree of each node is at least k. Unlike a k-connected subgraph, D_k has no connectivity constraints. The counting argument above shows that any D_k has at least $kn/2$ edges. A minimum cardinality D_k can be computed in polynomial time by reducing the problem to matching, and it is called the *matching lower bound*.

DFS-Based Approaches

The following natural algorithm finds a 3/2 approximation for 2-ECSS. Root the tree at some node r and run DFS. All edges of the graph are now either tree edges or back edges. Process the DFS tree in postorder. For each subtree, if the removal of the edge from its root to its parent separates the graph into two components, then add a farthest-back edge from this subtree, whose other end is closest to r. It can be shown that the number of back edges added by the algorithm is at most half the size of *Opt*.

This algorithm has been generalized to solve the 2-VCSS problem with the same approximation ratio, by adding carefully chosen back edges that allow the deletion of tree edges. Wherever it is unable to delete a tree edge, it adds a vertex to an independent set I. In the final analysis, the number of edges used is less than $n + |I|$. Since *Opt* is at least $\max(n, 2|I|)$, it obtains a 3/2-approximation ratio.

The algorithm can also be extended to the k-ECSS problem by repeating these ideas $k/2$ times, augmenting the connectivity by 2 in each round. It has been shown that this algorithm achieves a performance of about 1.61.

Matching-Based Approaches

Several approximation algorithms for k-ECSS and k-VCSS problems have used a minimum cardinality D_k as a starting solution, which is then augmented with additional edges to satisfy the connectivity constraints. This approach yields better ratios than the DFS-based approaches.

$1 + \frac{1}{k}$ Algorithm for k-VCSS
Find a minimum cardinality D_{k-1}. Add just enough additional edges to it to make the subgraph k-connected. In this step, it is ensured that the edges added are critical. It is known by a theorem of Mader that in a k-connected graph, a cycle of critical edges contains at least one node of degree k. Since the edges added by the algorithm in the second step are all critical, there can be no cycle induced by these edges because the degree of all the nodes on such a cycle would be at least $k + 1$. Therefore, at most $n - 1$ edges are added in this step. The number of edges added in the first step, in the minimum D_{k-1} is at most $Opt - n/2$. The total number of edges in the solution thus computed is at most $(1 + 1/k)$ times the number of edges in an optimal k-VCSS.

$1 + \frac{2}{k+1}$ Algorithm for k-ECSS
Mader's theorem about cycles induced by critical edges is valid only for vertex connectivity and not edge connectivity, Therefore, a different algorithm is proposed for k-ECSS in graphs that are k-edge-connected, but not k-connected. This algorithm finds a minimum cardinality D_k and augments it with a minimal set of edges to make the subgraph k-edge-connected. The number of edges added in the last step is at most $\frac{k}{k+1}(n-1)$. Since the number of edges added in the first step is at most Opt, the total number of edges is at most $(1 + \frac{2}{k+1})Opt$.

Better Algorithms for Small k
For $k \in \{2, 3\}$, better algorithms have been obtained by implementing the abovementioned algorithms carefully, deleting unnecessary edges, and by getting better lower bounds. For $k = 2$, a 4/3 approximation can be obtained by generating a path/cycle cover from a minimum cardinality D_2 and 2-connecting them one at a time to a "core" component. Small cycles/paths allow an edge to be deleted when they are 2-connected to the core, which allows a simple amortized analysis. This method also generalizes to the 3-ECSS problem, yielding a 4/3 ratio.

Hybrid approaches have been proposed which use the path/cycle cover to generate a specific DFS tree of the original graph and then 2-connect the tree, trying to delete edges wherever possible. The best ratios achieved using this approach are 5/4 for 2-ECSS, 9/7 for 2-VCSS, and 5/4 for 2-VCSS in 3-connected graphs.

Applications

Network design is one of the main application areas for this work. This involves the construction of low-cost highly connected networks.

Recommended Reading

For additional information on DFS, matchings and path/cycle covers, see [3]. Fast 2-approximation algorithms for k-ECSS and k-VCSS were studied by Nagamochi and Ibaraki [13]. DFS-based algorithms for 2-connectivity were introduced by Khuller and Vishkin [11]. They obtained 3/2 for 2-ECSS, 5/3 for 2-VCSS, and 2 for weighted k-ECSS. The ratio for 2-VCSS was improved to 3/2 by Garg et al. [6], 4/3 by Vempala and Vetta [14], and 9/7 by Gubbala and Raghavachari [7]. Khuller and Raghavachari [10] gave an algorithm for k-ECSS, which was later improved by Gabow [4], who showed that the algorithm obtains a ratio of about 1.61. Cheriyan et al. [2] studied the k-VCSS problem with edge weights and designed an $O(\log k)$ approximation algorithm in graphs with at least $6k^2$ vertices.

The matching-based algorithms were introduced by Cheriyan and Thurimella [1]. They proposed algorithms with ratios of $1 + \frac{1}{k}$ for k-VCSS, $1 + \frac{2}{k+1}$ for k-ECSS, $1 + \frac{1}{k}$ for k-VCSS in directed graphs, and $1 + \frac{4}{\sqrt{k}}$ for k-ECSS in directed graphs. Vempala and Vetta [14] obtained a ratio of 4/3 for 2-VCSS. The ratios were further improved by Krysta and Kumar [12], who introduced the hybrid approach, which was used to derive a 5/4 algorithm by Jothi et al. [9]. A 3/2-approximation algorithm for 3-ECSS has been proposed by Gabow [5] that works on

multigraphs, whereas the earlier algorithm of Cheriyan and Thurimella gets the same ratio in simple graphs only. This ratio has been improved to 4/3 by Gubbala and Raghavachari [8].

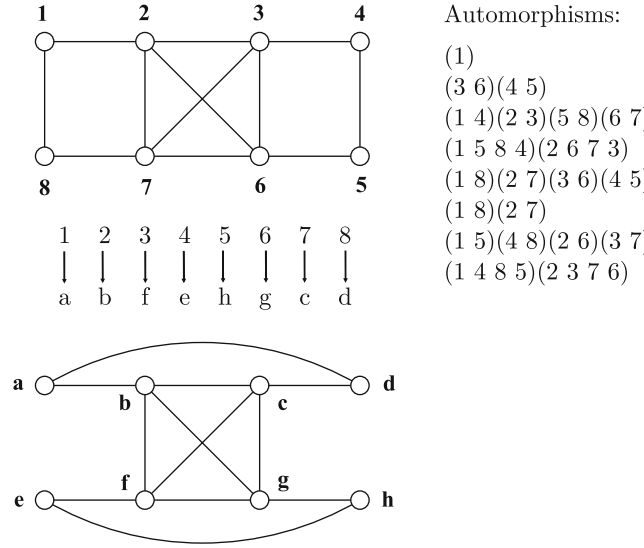
Problem Definition

The problem of determining isomorphism of two combinatorial structures is a ubiquitous one, with applications in many areas. The paradigm case of concern in this chapter is isomorphism of two graphs. In this case, an isomorphism consists of a bijection between the vertex sets of the graphs which induces a bijection between the edge sets of the graphs. One can also take the second graph to be a copy of the first, so that isomorphisms map a graph onto themselves. Such isomorphisms are called *automorphisms* or, less formally, *symmetries*. The set of all automorphisms forms a group under function composition called the *automorphism group*. Computing the automorphism group is a problem rather similar to that of determining isomorphisms.

Graph isomorphism is closely related to many other types of isomorphism of combinatorial structures. In the section entitled "Applications", several examples are given.

Formal Description

A *graph* is a pair $G = (V, E)$ of finite sets, with E being a set of 2-tuples (v, w) of elements of V. The elements of V are called *vertices* (also *points*, *nodes*), while the elements of E are called



Graph Isomorphism, Fig. 1 Example of an isomorphism and an automorphism group

directed edges (also *arcs*). A complementary pair $(v, w), (w, v)$ of directed edges $(v \neq w)$ will be called an *undirected edge* and denoted $\{v, w\}$. A directed edge of the form (v, v) will also be considered an undirected edge, called a *loop* (also *self-loop*). The word "edges" without qualification will indicate undirected edges, directed edges, or both.

Given two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, an *isomorphism* from G_1 to G_2 is a bijection from V_1 to V_2 such that the induced action on E_1 is a bijection onto E_2. If $G_1 = G_2$, then the isomorphism is an *automorphism* of G_1. The set of all *automorphisms* of G_1 is a group under function composition, called the *automorphism group* of G_1, and denoted Aut (G_1).

In Fig. 1 two isomorphic graphs are shown, together with an isomorphism between them and the automorphism group of the first.

Canonical Labeling

Practical applications of graph isomorphism testing do not usually involve individual pairs of graphs. More commonly, one must decide whether a certain graph is isomorphic to any of a collection of graphs (the database lookup problem) or one has a collection of graphs and needs to identify the isomorphism classes in it (the graph sorting problem). Such applications are not well served by an algorithm that can only test graphs in pairs.

An alternative is a *canonical labeling* algorithm. The essential idea is that in each isomorphism class there is a unique, *canonical* graph which the algorithm can find, given as input any graph in the isomorphism class. The canonical graph might be, for example, the least graph in the isomorphism class according to some ordering (such as lexicographic) of the graphs in the class. Practical algorithms usually compute a canonical form designed for efficiency rather than ease of description.

Key Results

The graphisomorphism problem plays a key role in modern complexity theory. It is not known to be solvable in polynomial time, nor to be NP-complete, nor is it known to be in the class co-NP. See [3, 8] for details. Polynomial-time algorithms are known for many special classes, notably graphs with bounded genus, bounded degree, bounded tree-width, and bounded eigenvalue multiplicity. The fastest theoretical algorithm for general graphs requires $\exp(n^{1/2+o(1)})$ time [1], but it is not known to be practical.

In this entry, the focus is on the program `nauty`, which is generally regarded as the most successful for practical use. McKay wrote the first version of `nauty` in 1976 and described its method of operation in [5]. It is known [7] to have exponential worst-case time, but in practice the worst case is rarely encountered.

The input to `nauty` is a graph with colored vertices. Two outputs are produced. The first is a set of generators for the color-preserving automorphism group. Though it is rarely necessary, the full group can also be developed element by element. The second, optional, output is a canonical graph. The canonical graph has the following property: two input graphs with the same number of vertices of each color have the same canonical graph if and only if they are isomorphic by a color-preserving isomorphism.

Two graph data structures are supported: a packed adjacency matrix suitable for small dense graphs and a linked list suitable for large sparse graphs.

Applications

As mentioned, `nauty` can handle graphs with colored vertices. In this section, it is described how several other types of isomorphism problems can be solved by mapping them onto a problem for vertex-colored graphs.

Isomorphism of Edge-Colored Graphs

An isomorphism of two graphs, each with both vertices and edges colored, is defined in the obvious way. An example of such a graph appears at the left of Fig. 2.

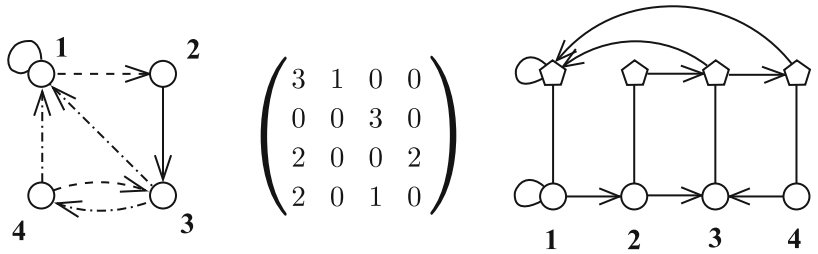
In the center of the figure the colors are identified with the integers $1, 2, 3$. At the right of the figure an equivalent vertex-colored graph is shown. In this case there are two layers, each with its own color. Edges of color 1 are represented as an edge in the first (lowest) layer, edges of color 2 are represented as an edge in the second layer, and edges of color 3 are represented as edges in both layers. It is now easy to see that the automorphism group of the new graph (specifically, its action on the first layer) is the automorphism group of the original graph. Moreover, the order in which a canonical labeling of the new graph labels the vertices of the first layer can be taken to be a canonical labeling of the original graph.

More generally, if the edge colors are integers in $\{1, 2, \ldots, 2^d - 1\}$, there are d layers, and the binary expansion of each color number dictates which layers contain edges. The vertical threads (each corresponding to one vertex of the original graph) can be connected using either paths or cliques. If the original graph has n vertices and k colors, the new graph has $O(n \log k)$ vertices. This can be improved to $O(n\sqrt{\log k})$ vertices by also using edges that are not horizontal.

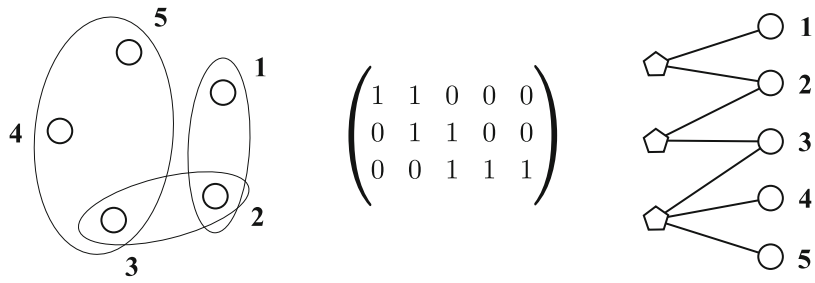
Isomorphism of Hypergraphs and Designs

A *hypergraph* is similar to an undirected graph except that the edges can be vertex sets of any size, not just of size 2. Such a structure is also called a *design*.

On the left of Fig. 3 there is a hypergraph with five vertices, two edges of size 2, and one edge of size 3. On the right is an equivalent vertex-colored graph. The vertices on the left, colored with one color, represent the hypergraph edges, while the edges on the right, colored with a



Graph Isomorphism, Fig. 2 Graph isomorphism with colored edges



Graph Isomorphism, Fig. 3 Hypergraph/design isomorphism as graph isomorphism

different color, represent the hypergraph vertices. The edges of the graph indicate the hypergraph incidence (containment) relationship.

The edge-vertex incidence matrix appears in the center of the figure. This can be any binary matrix at all, which correctly suggests that the problem under consideration is just that of determining the 0–1 matrix equivalence under independent permutation of the rows and columns. By combining this idea with the previous construction, such an equivalence relation on the set of matrices with arbitrary entries can be handled.

Other Examples

For several applications to equivalence operations such as isotopy, important for Latin squares and quasigroups, see [6].

Another important type of equivalence relates matrices over $\{-1, +1\}$. As well as permuting rows and columns, it allows multiplication of rows and columns by -1. A method of converting this *Hadamard equivalence* problem to a graph isomorphism problem is given in [4].

Experimental Results

`Nauty` gives a choice of sparse and dense data structures, and some special code for difficult graph classes. For the following timing examples, the best of the various options are used for a single CPU of a 2.4 GHz Intel Core-duo processor.

1. Random graph with 10,000 vertices, $p = \frac{1}{2}$: 0.014 s for group only, 0.4 s for canonical labeling as well.
2. Random cubic graph with 100,000 vertices: 8 s.
3. 1-skeleton of 20-dimensional cube (1,048,576 vertices, group size 2.5×10^{24}): 92 s.
4. 3-dimensional mesh of size 50 (125,000 vertices): 0.7 s.
5. 1027-vertex strongly regular graph from random Steiner triple system: 0.6 s.

Examples of more difficult graphs can be found in the `nauty` documentation.

URL to Code

The source code of `nauty` is available at http://cs.anu.edu.au/~bdm/nauty/. Another implementation of the automorphism group portion of nauty, highly optimized for large sparse graphs, is available as `saucy` [2]. `Nauty` is also incorporated into a number of general-purpose packages, including GAP, Magma, and MuPad.

Problem Definition

The basic problem we consider is testing whether an undirected graph G on n nodes $\{v_1, \ldots, v_n\}$ is connected. We consider this problem in the following two related models:

1. **Dynamic Graph Stream Model:** The graph G is defined by a sequence of edge insertions and deletions; the edges of G are the set of edges that have been inserted but not subsequently deleted. An algorithm for analyzing G may only read the input sequence from left to right and has limited working memory. If the available memory was $O(n^2)$ bits, then the algorithm could maintain the exact set of edges that have been inserted but not deleted. The primary objective in designing an algorithm in the stream model is to reduce the amount of memory required. Ideally, the time to process each element of the stream and the post-processing time should be small but ensuring this is typically a secondary objective.
2. **Simultaneous Communication Model:** We consider the n rows of the adjacency matrix of G to be partitioned between n players $P_1, \ldots, P_n$ where P_i receives the ith row of the matrix. This means that the existence of any edge is known by exactly two players. An additional player Q wants to evaluate a property of G, and to facilitate this, each player P_i simultaneously sends a message m_i to Q such that Q may evaluate the property given the messages $m_1, m_2, \ldots, m_n$. With n-bit messages from each player, Q could learn the entire graph and the problem would be uninteresting. The objective is to minimize the number of bits sent by each player. Note that the P_i players may not communicate to each other and that each message m_i must be constructed given only the ith row of the adjacency matrix and possibly a set of random bits that is known to all the players.

If there were no edge deletions in the data stream setting, it would be simple to determine whether G was connected using $O(n \log n)$ memory since it is possible to maintain the connected components of the graph; whenever an edge is added, we merge the connected components containing the endpoints of this edge. This algorithm is optimal in terms of space [19]. Such an approach does not extend if edges may also be deleted since it is unclear how the connected components should be updated when an edge is deleted within a connected component.

To illustrate the challenge in the simultaneous communication model, suppose G is connected but $G \setminus \{e\}$ is disconnected for some edge e. The player Q can only learn about the existence of the edge $e = \{v_i, v_j\}$ from either player P_i or player

P_j, but since both of these players have limited knowledge of the graph, neither will realize the important role this edge plays in determining the connectivity of the graph.

Linear Sketches

For both models the best known algorithms are based on random linear projections, aka *linear sketches*. If we denote the n rows of the adjacency matrix by $\mathbf{x}_1, \ldots, \mathbf{x}_n \in \{0,1\}^n$, then the linear sketches of the graph are $\mathcal{A}_1(\mathbf{x}_1), \ldots, \mathcal{A}_n(\mathbf{x}_n)$ where each $\mathcal{A}_i \in \mathbb{R}^{d \times n}$ is a random matrix chosen according to a specific distribution. Note that the matrices $\mathcal{A}_1, \ldots, \mathcal{A}_n$ need not be chosen independently.

In the simultaneous communication model, the message from player P_i is $m_i = \mathcal{A}_i(\mathbf{x}_i)$, and, assuming that the entries of $\mathcal{A}_i$ have polynomial precision, each of these messages requires $O(d \operatorname{polylog} n)$ bits. In the dynamic graph stream model, the algorithm constructs each $\mathcal{A}_i(\mathbf{x}_i)$ using $O(nd \operatorname{polylog} n)$ bits of space. Note that each $\mathcal{A}_i(\mathbf{x}_i)$ can be constructed incrementally using the following update rules:

on the insertion of $\{v_i, v_j\}$:	$\mathcal{A}_i(\mathbf{x}_i) \leftarrow \mathcal{A}_i(\mathbf{x}_i) + \mathcal{A}_i(\mathbf{e}_j)$
on the deletion of $\{v_i, v_j\}$:	$\mathcal{A}_i(\mathbf{x}_i) \leftarrow \mathcal{A}_i(\mathbf{x}_i) - \mathcal{A}_i(\mathbf{e}_j)$
on the insertion/deletion of $\{v_j, v_k\}$ for $i \notin \{j,k\}$:	$\mathcal{A}_i(\mathbf{x}_i) \leftarrow \mathcal{A}_i(\mathbf{x}_i)$

where $\mathbf{e}_j$ is the characteristic vector of the set $\{j\}$. Hence, we have transformed the problem of designing an efficient algorithm into finding the minimum d such that there exists a distribution of matrices $\mathcal{A}_1, \ldots, \mathcal{A}_n \in \mathbb{R}^{d \times n}$ such that for any graph G, we can determine (with high probability) whether G is connected given $\mathcal{A}_1(\mathbf{x}_1), \ldots, \mathcal{A}_n(\mathbf{x}_n)$.

Key Results

The algorithm for connectivity that we present in this entry, and much of the subsequent work on graph sketching, fits the following template. First, we consider a basic "non-sketch" algorithm for the graph problem in question. Second, we design sketches $\mathcal{A}_i$ such that it is possible to emulate the steps of the basic algorithm given only the projections $\mathcal{A}_i(\mathbf{x}_i) \in \mathbb{R}^d$ where $d = O(\operatorname{polylog} n)$.

Connectivity

Basic Non-sketch Algorithm

We pick an incident edge for each node arbitrarily and collapse the resulting connected components into a set of "supernodes." In each subsequent round of the algorithm, we pick an edge from each supernode to another supernode (if one exists) and collapse the connected components into new supernodes. It can be shown that this process terminates after $O(\log n)$ rounds and that the set of edges picked during the different rounds include a spanning forest of the graph. From this we can deduce whether the graph is connected.

Designing the Sketches

There are two main steps required in constructing the sketches for the connectivity algorithm:

An Alternative Graph Representation. Rather than consider the rows of the adjacency matrix $\mathbf{x}_i$, it will be convenient to consider an alternative representation $\mathbf{a}_i \in \{-1,0,1\}^{\binom{n}{2}}$ with entries indexed by pairs

$$\mathbf{a}_i[\{j,k\}] = \begin{cases} 1 & \text{if } i = j < k \text{ and } \{v_j, v_k\} \in E \\ -1 & \text{if } j < k = i \text{ and } \{v_j, v_k\} \in E \\ 0 & \text{otherwise} \end{cases}$$

These vectors have the useful property that for any subset of nodes $\{v_i\}_{i \in S}$, the non-zero en-

tries of $\sum_{i \in S} \mathbf{a}_i$ correspond exactly to the edges across the cut $(S, V \setminus S)$.

For example, consider the graph on nodes $\{v_1, v_2, v_3, v_4\}$ with edges $\{v_1, v_2\}$, $\{v_2, v_3\}$, $\{v_3, v_4\}$, and $\{v_1, v_4\}$. Then

$$\begin{aligned} \mathbf{a}_1 &= (\ 1\ \ 0\ \ 1\ \ 0\ \ 0\ \ 0) \\ \mathbf{a}_2 &= (-1\ \ 0\ \ 0\ \ 1\ \ 0\ \ 0) \\ \mathbf{a}_3 &= (\ 0\ \ 0\ \ 0\ -1\ \ 0\ \ 1) \\ \mathbf{a}_4 &= (\ 0\ \ 0\ -1\ \ 0\ \ 0\ -1) \end{aligned}$$

where the entries correspond to the pairs $\{1, 2\}$, $\{1, 3\}$, $\{1, 4\}$, $\{2, 3\}$, $\{2, 4\}$, $\{3, 4\}$ in that order. Note that the nonzero entries of

$$\mathbf{a}_1 + \mathbf{a}_2 = (\ 0\ \ 0\ \ 1\ \ 1\ \ 0\ \ 0)$$

correspond to $\{1, 4\}$ and $\{2, 3\}$ which are exactly the edges across the cut $(S, V \setminus S)$ for $S = \{v_1, v_2\}$.

ℓ_0-Sampling via Linear Sketches. ℓ_0-sampling is a technique that has found numerous applications in data stream processing. We appeal to a result by Jowhari et al. [12] that shows the existence of a distribution over matrices $\mathcal{M} \in \mathbb{R}^{\text{polylog}(n) \times \text{poly}(n)}$ such that for any nonzero vector $\mathbf{z} \in \mathbb{R}^{\text{poly}(n)}$, the index of some nonzero entry of $\mathbf{z}$ can be reconstructed with high probability given $\mathcal{M}(\mathbf{z}) \in \mathbb{R}^{\text{polylog}(n)}$. Note that we do not get to choose which entry is reconstructed.

Emulation Basic Algorithm via Sketches

Let $\mathcal{M}_1, \ldots, \mathcal{M}_r$ be $r = O(\log n)$ independent sketch matrices for ℓ_0-sampling. Given $\mathcal{M}_j(\mathbf{a}_i)$ for all $j \in [r]$ and $i \in [n]$, we can emulate the basic algorithm as follows:

1. Given $\mathcal{M}_1(\mathbf{a}_1), \mathcal{M}_1(\mathbf{a}_2), \ldots, \mathcal{M}_1(\mathbf{a}_n)$, we may emulate the first round of the algorithm since from each $\mathcal{M}_1(\mathbf{a}_i)$ we may reconstruct a nonzero entry of $\mathbf{a}_i$, and these nonzero entries correspond to edges incident to v_i.
2. To emulate round $j > 1$ of the algorithm, suppose S is one of the connected components already constructed. Then, given

$$\sum_{i \in S} \mathcal{M}_j(\mathbf{a}_i) = \mathcal{M}_j\left(\sum_{i \in S} \mathbf{a}_i\right)$$

we may reconstruct a nonzero entry of $\sum_{i \in S} \mathbf{a}_i$ which corresponds to an edge across the cut $(S, V \setminus S)$.

Extensions and Further Work

Subsequent work has extended the above results significantly. If d is increased to $O(k \operatorname{polylog} n)$ then, it is possible to test whether every cut has at least k edges [1]. With $d = O(\epsilon^{-2} \operatorname{polylog} n)$, it is possible to construct graph sparsifiers that can be used to estimate the size of *every* cut up to a $(1 + \epsilon)$ factor [2] along with spectral properties such as the eigenvalues of the graph [14]. With $d = O(\epsilon^{-1} k \operatorname{polylog} n)$, it is possible to distinguish graphs which are not k-vertex connected from those that are at least $(1 + \epsilon)k$-vertex connected [11]. Some of the above results have also been extended to hypergraphs [11]. The algorithm presented in this entry can be implemented with $O(\operatorname{polylog} n)$ update time in the dynamic graph stream model, but a connectivity query may take $\Omega(n)$ time. This was addressed in subsequent work by Kapron et al. [15].

More generally, solving graph problems via linear sketches has become a very active area of research [1–8, 10, 11, 13, 14, 16, 17]. Other problems that have been considered include approximating the densest subgraph [6, 9, 18], maximum matching [5, 7, 8, 16], vertex cover and hitting set [8], correlation clustering [4], and estimating the number of triangles [17].

Keywords

Technique for analysis of greedy approximation

Problem Definition

Consider a graph $G = (V, E)$. A subset C of V is called a *dominating set* if every vertex is either in C or adjacent to a vertex in C. If, furthermore, the subgraph induced by C is connected, then C is called a *connected dominating set*.

Given a connected graph G, find a connecting dominating set of minimum cardinality. This problem is denoted by MCDS and is NP-hard. Its optimal solution is called a *minimum*

connected dominating set. The following is a greedy approximation with potential function f.

Greedy Algorithm A:
$C \leftarrow \emptyset$;
while $f(C) > 2$**do**
choose a vertex x to maximize $f(C) - f(C \cup \{x\})$ and
$C \leftarrow C \cup \{x\}$; output C.

Here, f is defined as $f(C) = p(C) + q(C)$ where $p(C)$ is the number of connected components of subgraph induced by C and $q(C)$ is the number of connected components of subgraph with vertex set V and edge set $\{(u, v) \in E \mid u \in C \text{ or v} \in \text{C}\}$. f has an important property that C is a connected dominating set if and only if $f(C) = 2$.

If C is a connected dominating set, then $p(C) = q(C) = 1$, and hence $f(C) = 2$. Conversely, suppose $f(C \cup \{x\}) = 2$. Since $p(C) \geq 1$ and $q(C) \geq 1$, one has $p(C) = q(C) = 1$ which implies that C is a connected dominating set. f has another property, for G with at least three vertices, that if $f(C) > 2$, then there exists $x \in V$ such that $f(C) - f(C \cup \{x\}) > 0$. In fact, for $C = \emptyset$, since G is a connected graph with at least three vertices, there must exist a vertex x with degree at least two, and for such a vertex x, $f(C \cup \{x\}) < f(C)$. For $C \neq \emptyset$, consider a connected component of the subgraph induced by C. Let B denote its vertex set which is a subset of C. For every vertex y adjacent to B, if y is adjacent to a vertex not adjacent to B and not in C, then $p(C \cup \{y\}) < p(C)$ and $q(C \cup \{y\}) \leq q(C)$; if y is adjacent to a vertex in $C - B$, then $p(C \cup \{y\}) \leq p(C)$ and $q(C \cup \{y\}) < q(C)$.

Now, look at a possible analysis for the above greedy algorithm: Let $x_1, \ldots, X_g$ be vertices chosen by the greedy algorithm in the ordering of their appearance in the algorithm. Denote $C_i = \{x_1, \ldots, x_i\}$. Let $C^* = \{y_1, \ldots, y_{opt}\}$ be a minimum connected dominating set. Since adding C^* to C_i will reduce the potential function value from $f(C_i)$ to 2, the value of f reduced by a vertex in C^* would be $(f(C_i) - 2)/opt$ in average. By the greedy rule for choosing $x_i + 1$, one has

$$f(C_i) - f(C_{i+1}) \geq \frac{f(C_i) - 2}{opt}.$$

Hence,

$$\begin{aligned} f(C_{i+1}) - 2 &\leq (f(C_i) - 2)\left(1 - \tfrac{1}{opt}\right) \\ &\leq (f(\emptyset) - 2)\left(1 - \tfrac{1}{opt}\right)^{i+1} \\ &= (n-2)\left(1 - \tfrac{1}{opt}\right)^{i+1}, \end{aligned}$$

where $n = |V|$. Note that $1 - 1/opt \leq \mathrm{e}^{-1/opt}$. Hence,

$$f(C_i) - 2 \leq (n-2)\mathrm{e}^{-i/opt}.$$

Choose i such that $f(C_i) \geq opt + 2 > f(C_{i+1})$. Then

$$opt \leq (n-2)\,\mathrm{e}^{-i/opt}$$

and

$$g - i \leq opt.$$

Therefore,

$$g \leq opt + i \leq opt\left(1 + \ln\frac{n-2}{opt}\right).$$

Is this analysis correct? The answer is NO. Why? How could one give a correct analysis? This entry will answer those questions and introduce a new general technique, analysis of greedy approximation with nonsubmodular potential function.

Key Results

The Role of Submodularity

Consider a set X and a function f defined on the power set 2^X, i.e., the family of all subsets of X. f is said to be *submodular* if for any two subsets A and B in 2^X,

$$f(A) + f(B) \geq f(A \cap B) + f(A \cup B).$$

For example, consider a connected graph G. Let X be the vertex set of G. The function $-q(C)$

defined in the last section is submodular. To see this, first mention a property of submodular functions.

A submodular function f is *normalized* if $f(\emptyset) = 0$. Every submodular function f can be normalized by setting $g(A) = f(A) - f(\emptyset)$. A function f is *monotone increasing* if $f(A) \leq f(B)$ for $A \subset B$. Denote $\Delta_x f(A) = f(A \cup \{x\}) - f(A)$.

Lemma 1 *A function $f : 2^X \to R$ is submodular if and only if $\Delta_x f(A) \leq \Delta_x f(B)$ for any $x \in X - B$ and $A \subseteq B$. Moreover, f is monotone increasing if and only if $\Delta_x f(A) \leq \Delta_x f(B)$ for any $x \in B$ and $A \subseteq B$.*

Proof If f is submodular, then for $x \in X - B$ and $A \subseteq B$, one has

$$\begin{aligned} & f(A \cup \{x\}) + f(B) \\ & \quad \geq f((A \cup \{x\}) \cup B) + f(A \cup \{x\}) \cap B) \\ & \quad = f(B \cup \{x\}) + f(A), \end{aligned}$$

that is,

$$\Delta_x f(A) \geq \Delta_x f(B). \tag{1}$$

Conversely, suppose (1) holds for any $x \in B$ and $A \subseteq B$. Let C and D be two sets and $C/D = \{x_1, \ldots, x_k\}$. Then

$$\begin{aligned} f(C \cup D) - f(D) & = \sum_{i=1}^{k} \Delta_{x_i} f(D \cup \{x_1, \ldots, x_{i-1}) \\ & \leq \sum_{i=1}^{k} \Delta_{x_i} f((C \cap D) \cup \{x_1, \ldots, x_{i-1}) \\ & = f(C) - f(C \cap D). \end{aligned}$$

If f is monotone increasing, then for $A \subseteq B$, $f(A) \leq f(B)$. Hence, for $x \in B$,

$$\Delta) x f(A) \geq 0 = \Delta_x f(B).$$

Conversely, if $\Delta_x f(A) \geq \Delta_x f(B)$ for any $x \in B$ and $A \subseteq B$, then for any x and A, $\Delta_x f(A) \geq \Delta_x f(A \cup \{x\}) = 0$, that is, $f(A) \leq f(A \cup \{x\})$. Let $B - A = \{x_1, \ldots, x_k\}$. Then

$$\begin{aligned} f(A) & \leq f(A \cup \{x_1\}) \\ & \leq f(A \cup \{x_1, x_2\}) \leq \cdots \leq f(B). \end{aligned}$$

Next, the submodularity of $-q(A)$ is studied. □

Lemma 2 *If $A \subset B$, then $\Delta_y q(A) \geq \Delta_y q(B)$.*

Proof Note that each connected component of graph $(V, D(B))$ is constituted by one or more connected components of graph $(V, D(A))$ since $A \subset B$. Thus, the number of connected components of $(V, D(B))$ dominated by y is no more than the number of connected components of $(V, D(A))$ dominated by y. Therefore, the lemma holds.

The relationship between submodular functions and greedy algorithms has been established for a long time [2].

Let f be a normalized, monotone increasing, submodular integer function. Consider the minimization problem

$$\begin{aligned} \min \quad & c(A) \\ \text{subject to } & A \in \mathcal{C}_f. \end{aligned}$$

where c is a nonnegative cost function defined on 2^X and $\mathcal{C}_f = \{C \,\mathrm{mid}\, f(C \cup \{x\}) - f(C) = 0 \text{ for all } x \in X\}$. The following is a greedy algorithm to produce approximation solution for this problem. □

Greedy Algorithm B

input submodular function f and cost function c;
$A \leftarrow \emptyset$;
while there exists $x \in E$ such that $\Delta_x f(A) > 0$
do select a vertex x that maximizes $\Delta_x f(A)/c(x)$ and set
$A \leftarrow A \cup \{x\}$;
return A.

The following two results are well known.

Theorem 1 *If f is a normalized, monotone increasing, submodular integer function, then Greedy Algorithm B produces an approximation solution within a factor of $H(\gamma)$ from optimal, where $\gamma = max_{x \in E} f(\{x\})$.*

Theorem 2 *Let f be a normalized, monotone increasing, submodular function and c a nonnegative cost function. If in Greedy Algorithm B,*

selected x always satisfies $\Delta_x f(A_{i-1})/c(x) \geq 1$, then it produces an approximation solution within a factor of $1 + \ln(f^*/opt)$ from optimal for the above minimization problem where $f^* = f(A^*)$ and $opt = c(A^*)$ for optimal solution A^*.

Now, come back to the analysis of Greedy Algorithm A for the MCDS. It looks like that the submodularity of f is not used. Actually, the submodularity was implicitly used in the following statement:

"Since adding C^* to C_i will reduce the potential function value from $f(C_i)$ to 2, the value of f reduced by a vertex in C^* would be $(f(C_i - 2)/opt$ in average. By the greedy rule for choosing $x_i + 1$, one has

$$f(C_i) - f(C_{i+1}) \geq \frac{f(C_i) - 2}{opt}."$$

To see this, write this argument more carefully.

Let $C^* = \{y_1, \ldots, y_{opt}\}$ and denote $C_j^* = \{y_1, \ldots, y_j\}$. Then

$$\begin{aligned} f(C_i) - 2 &= f(C_i) - f(C_i \cup C^*) \\ &= \sum_{j=1}^{opt} [f(C_i \cup C_{j-1}^*) - f(C_i \cup C_j^*)] \end{aligned}$$

where $C_0^* = \emptyset$. By the greedy rule for choosing $x_i + 1$, one has

$$f(C_i) - f(C_{i+1}) \geq f(C_i) - f(C_i \cup \{y_j\})$$

for $j = 1, \ldots, opt$. Therefore, it needs to have

$$\begin{aligned} -\Delta_{y_j} f(C_i) &= f(C_i) - f(C_i \cup \{y_j\}) \\ &\geq f(C_i \cup C_{j-1}^*) - f(C_i \cup C_j^*) \\ &= -\Delta_{y_j} f(C_i \cup C_{j-1}^*) \end{aligned} \tag{2}$$

in order to have

$$f(C_i) - f(C_{i+1}) \geq \frac{f(C_i) - 2}{opt}.$$

Equation (2) asks the submodularity of $-f$. Unfortunately, $-f$ is not submodular. A counterexample can be found in [2]. This is why the analysis of Greedy Algorithm A in section "Problem Definition" is incorrect.

Giving Up Submodularity

Giving up submodularity is a challenge task since it is open for a long time. But, it is possible based on the following observation on (2) by Du et al. [1]: **The submodularity of $-f$ is applied to increment of a vertex y_j belonging to optimal solution C^*.**

Since the ordering of y_j's is flexible, one may arrange it to make $\Delta_{yj} f(C_i) - \Delta_{yj} f(C_i \cup C_{j-1}^*)$ under control. This is a successful idea for the MCDS.

Lemma 3 *Let y_j's be ordered in the way that for any $j = 1, \ldots, opt$, $\{y_1, \ldots, y_j\}$ induces a connected subgraph. Then*

$$\Delta_{y_j} f(C_i) - \Delta_{y_j} f(C_i \cup C_{j-1}^*) \leq 1.$$

Proof Since all $y_1, \ldots, y_{j-1}$ are connected, y_j can dominate at most one additional connected component in the subgraph induced by $C_{i-1} \cup C_{j-1}^*$ than in the subgraph induced by $c_i - 1$. Hence,

$$\Delta_{y_j} p(C_i) - \Delta_{y_j} f(C_i \cup C_{j-1}^*) \leq 1.$$

Moreover, since $-q$ is submodular,

$$\Delta_{y_j} q(C_i) - \Delta_{y_j} q(C_i \cup C_{j-1}^*) \leq 0.$$

Therefore,

$$\Delta_{y_j} f(C_i) - \Delta_{y_j} f(C_i \cup C_{j-1}^*) \leq 1.$$

Now, one can give a correct analysis for the greedy algorithm for the MCDS [3].

By Lemma 3,

$$f(C_i) - f(C_{i+1}) \geq \frac{f(C_i) - 2}{opt} - 1.$$

Hence,

$$
\begin{aligned}
f(C_{i+1}) - 2 - opt &\\
&\le (f(C_i) - 2 + opt)\left(1 - \tfrac{1}{opt}\right)\\
&\le (f(\emptyset) - 2 - opt)\left(1 - \tfrac{1}{opt}\right)^{i+1}\\
&= (n - 2 - opt)\left(1 - \tfrac{1}{opt}\right)^{i+1},
\end{aligned}
$$

where $n = |V|$. Note that $1 - 1/opt \le \mathrm{e}^{-1/opt}$. Hence,

$$f(C_i) - 2 - opt \le (n-2)\mathrm{e}^{-i/opt}.$$

Choose i such that $f(C_i) \ge 2 \cdot opt + 2 > f(C_{i+1})$. Then

$$opt \le (n-2)\mathrm{e}^{-i/opt}$$

and

$$g - i \le 2 \cdot opt.$$

Therefore,

$$g \le 2 \cdot opt + i \le opt\left(2 + \ln\frac{n-2}{opt}\right) \le opt(2 + \ln\delta)$$

where δ is the maximum degree of input graph G. □

Applications

The technique introduced in the previous section has many applications, including analysis of iterated 1-Steiner trees for minimum Steiner tree problem and analysis of greedy approximations for optimization problems in optical networks [3] and wireless networks [2].

Open Problems

Can one show the performance ratio $1 + H(\delta)$ for Greedy Algorithm B for the MCDS? The answer is unknown. More generally, it is unknown how to get a clean generalization of Theorem 1.

Dominating set; Greedy algorithm; Hitting set; Minimizing a linear function subject to a submodular constraint; Set cover

Years and Authors of Summarized Original Work

1974–1979; Chvátal, Johnson, Lovász, Stein

Problem Definition

Given a collection $\mathcal{S}$ of sets over a universe U, a *set cover* $C \subseteq \mathcal{S}$ is a subcollection of the

sets whose union is U. The *set-cover problem* is, given $\mathcal{S}$, to find a minimum-cardinality set cover. In the *weighted set-cover problem*, for each set $s \in \mathcal{S}$, a weight $w_s \geq 0$ is also specified, and the goal is to find a set-cover C of minimum total weight $\sum_{S \in C} w_S$.

Weighted set cover is a special case of *minimizing a linear function subject to a submodular constraint*, defined as follows. Given a collection $\mathcal{S}$ of objects, for each object s a nonnegative weight w_s, and a nondecreasing submodular function $f : 2^{\mathcal{S}} \to \mathbb{R}$, the goal is to find a subcollection $C \subseteq \mathcal{S}$ such that $f(C) = f(\mathcal{S})$ minimizing $\sum_{s \in C} w_s$. (Taking $f(C) = |\cup_{s \in C} s|$ gives weighted set cover.)

Key Results

The *greedy algorithm* for weighted set cover builds a cover by repeatedly choosing a set s that minimizes the weight w_s divided by the number of elements in s not yet covered by chosen sets. It stops and returns the chosen sets when they form a cover:

Let H_k denote $\sum_{i=1}^{k} 1/i \approx \ln k$, where k is the largest set size.

greedy-set-cover(S, w)
1. Initialize $C \leftarrow \emptyset$. Define $f(C) \doteq |\cup_{s \in C} s|$.
2. Repeat until $f(C) = f(S)$:
3. Choose $s \in S$ minimizing the price per element $w_s/[f(C \cup \{s\}) - f(C)]$.
4. Let $C \leftarrow C \cup \{s\}$.
5. Return C.

Theorem 1 *The greedy algorithm returns a set cover of weight at most H_k times the minimum weight of any cover.*

Proof When the greedy algorithm chooses a set s, imagine that it charges the price per element for that iteration to each element newly covered by s. Then, the total weight of the sets chosen by the algorithm equals the total amount charged, and each element is charged once.

Consider any set $s = \{x_k, x_{k-1}, \ldots, x_1\}$ in the optimal set cover C^*. Without loss of generality, suppose that the greedy algorithm covers the elements of s in the order given: $x_k, x_{k-1}, \ldots, x_1$. At the start of the iteration in which the algorithm covers element x_i of s, at least i elements of s remain uncovered. Thus, if the greedy algorithm were to choose s in that iteration, it would pay a cost per element of at most w_s / i. Thus, in this iteration, the greedy algorithm pays at most w_s / i per element covered. Thus, it charges element x_i at most w_s / i to be covered. Summing over i, the total amount charged to elements in s is at most $w_s H_k$. Summing over $s \in C^*$ and noting that every element is in some set in C^*, the total amount charged to elements overall is at most $\sum_{s \in C^*} W_s H_k = H_k \mathrm{OPT}$. □

The theorem was shown first for the unweighted case (each $w_s = 1$) by Johnson [5], Lovász [8], and Stein [13] and then extended to the weighted case by Chvátal [2].

Since then a few refinements and improvements have been shown, including the following:

Theorem 2 *Let $\mathcal{S}$ be a set system over a universe with n elements and weights $w_s \leq 1$. The total weight of the cover C returned by the greedy algorithm is at most $[1 + \ln(n/OPT)]\,OPT + 1$ (compare to [12]).*

Proof Assume without loss of generality that the algorithm covers the elements in order $x_n, x_{n-1}, \ldots, x_1$. At the start of the iteration in which the algorithm covers x_i, there are at least i elements left to cover, and all of them could be covered using multiple sets of total cost OPT. Thus, there is some set that covers not-yet-covered elements at a cost of at most OPT/i per element.

Recall the charging scheme from the previous proof. By the preceding observation, element x_i is charged at most OPT/i. Thus, the total charge to elements $x_n, \ldots, x_i$ is at most $(H_n - H_{i-1})\mathrm{OPT}$. Using the assumption that each $w_s \leq 1$, the charge to each of the remaining elements is at most 1 per element. Thus, the total charge to all elements is at most $i - 1 + (H_n -$

H_{i-1})OPT. Taking $i = 1 + \lceil \text{OPT} \rceil$, the total charge is at most $\lceil \text{OPT} \rceil + (H_n - H_{\lceil \text{OPT} \rceil})\text{OPT} \leq 1 + \text{OPT}(1 + \ln(n/\text{OPT}))$. □

Each of the above proofs implicitly constructs a linear-programming primal-dual pair to show the approximation ratio. The same approximation ratios can be shown with respect to any fractional optimum (solution to the fractional set-cover linear program).

Other Results

The greedy algorithm has been shown to have an approximation ratio of $\ln n - \ln \ln n + O(1)$ [11]. For the special case of set systems whose duals have finite Vapnik-Chervonenkis (VC) dimension, other algorithms have substantially better approximation ratio [1]. Constant-factor approximation algorithms are known for geometric variants of the closely related k-median and facility location problems.

The greedy algorithm generalizes naturally to many problems. For example, for minimizing a linear function subject to a submodular constraint (defined above), the natural extension of the greedy algorithm gives an H_k -approximate solution, where $k = \max_{s \in \mathcal{S}} f(\{s\}) - f(\emptyset)$, assuming f is integer valued [10].

The set-cover problem generalizes to allow each element x to require an arbitrary number r_x of sets containing it to be in the cover. This generalization admits a polynomial-time $O(\log n)$-approximation algorithm [7].

The special case when each element belongs to at most r sets has a simple r-approximation algorithm ([15] § 15.2). When the sets have uniform weights ($w_s = 1$), the algorithm reduces to the following: select any maximal collection of elements, no two of which are contained in the same set; return all sets that contain a selected element.

The variant "Max k-coverage" asks for a set collection of total weight at most k covering as many of the elements as possible. This variant has a $(1 - 1/e)$-approximation algorithm ([15] Problem 2.18) (see [6] for sets with nonuniform weights).

For a general discussion of greedy methods for approximate combinatorial optimization, see ([4] Ch. 4).

Finally, under likely complexity-theoretic assumptions, the ln n approximation ratio is essentially the best possible for any polynomial-time algorithm [3,9].

Applications

Set cover and its generalizations and variants are fundamental problems with numerous applications. Examples include:

- Selecting a small number of nodes in a network to store a file so that all nodes have a nearby copy
- Selecting a small number of sentences to be uttered to tune all features in a speech-recognition model [14]
- Selecting a small number of telescope snapshots to be taken to capture light from all galaxies in the night sky
- Finding a short string having each string in a given set as a contiguous sub-string

Stochastic order relations between Erdös–Rényi random graph model and random intersection graphs; Threshold for appearance of Hamilton cycles in random intersection graphs

Years and Authors of Summarized Original Work

2005; Efthymiou, Spirakis

Problem Definition

E. Marczewski proved that every graph can be represented by a list of sets where each vertex corresponds to a set and the edges to nonempty intersections of sets. It is natural to ask what sort of graphs would be most likely to arise if the list of sets is generated randomly.

Consider the model of random graphs where each vertex chooses randomly from a universal set the members of its corresponding set, each independently of the others. The probability space that is created is the space of random intersection graphs, $G_{n,m,p}$, where n is the number of vertices, m is the cardinality of a universal set of elements and p is the probability for each vertex to choose an element of the universal set. The model of random intersection graphs was first introduced by M. Karońsky, E. Scheinerman, and K. Singer-Cohen in [4]. A rigorous definition of the model of random intersection graphs follows:

Definition 1 Let n, m be positive integers and $0 \leq p \leq 1$. The random intersection graph $G_{n,m,p}$ is a probability space over the set of graphs on the vertex set $\{1, \ldots, n\}$ where each vertex is assigned a random subset from a fixed set of m elements. An edge arises between two vertices when their sets have at least a common element. Each random subset assigned to a vertex is determined by

$$\mathbf{Pr}\,[\text{vertex } i \text{ chooses element } j] = p$$

with these events mutually independent.

A common question for a graph is whether it has a cycle, a set of edges that form a path so that the

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

first and the last vertex is the same, that visits *all* the vertices of the graph exactly once. We call this kind of cycle the *Hamilton cycle* and the graph that contains such a cycle is called a *Hamiltonian graph*.

Definition 2 Consider an undirected graph $G = (V, E)$ where V is the set of vertices and E the set of edges. This graph contains a Hamilton cycle if and only if there is a simple cycle that contains each vertex in V.

Consider an instance of $G_{n,m,p}$, for specific values of its parameters n, m, and p, what is the probability of that instance to be Hamiltonian? Taking the parameter p, of the model, to be a function of n and m, in [2], a threshold function $P(n, m)$ has been found for the graph property "Contains a Hamilton cycle"; i.e., a function $P(n, m)$ is derived such that

if $p(n, m) \ll P(n, m)$

$$\lim_{n,m\to\infty} \mathbf{Pr}\left[G_{n,m,p} \text{Contains Hamilton cycle}\right] = 0$$

if $p(n, m) \gg P(n, m)$

$$\lim_{n,m\to\infty} \mathbf{Pr}\left[G_{n,m,p} \text{Contains Hamilton cycle}\right] = 1$$

When a graph property, such as "Contains a Hamilton cycle," holds with probability that tends to 1 (or 0) as n, m tend to infinity, then it is said that this property holds (does not hold), "almost surely" or "almost certainly."

If in $G_{n,m,p}$ the parameter m is very small compared to n, the model is not particularly interesting and when m is exceedingly large (compared to n) the behavior of $G_{n,m,p}$ is essentially the same as the Erdös–Rényi model of random graphs (see [3]). If someone takes $m = \lceil n^\alpha \rceil$, for fixed real $\alpha > 0$, then there is some deviation from the standard models, while allowing for a natural progression from sparse to dense graphs. Thus, the parameter m is assumed to be of the form $m = \lceil n^\alpha \rceil$ for some fixed positive real α.

The proof of existence of a Hamilton cycle in $G_{n,m,p}$ is mainly based on the establishment of a *stochastic order relation* between the model $G_{n,m,p}$ and the Erdös–Rényi random graph model $G_{n,\hat{p}}$.

Definition 3 Let n be a positive integer, $0 \le \hat{p} \le 1$. The random graph $G(n, \hat{p})$ is a probability space over the set of graphs on the vertex set $\{1, \ldots, n\}$ determined by

$$\mathbf{Pr}[i, j] = \hat{p}$$

with these events mutually independent.

The stochastic order relation between the two models of random graphs is established in the sense that if $\mathcal{A}$ is an increasing graph property, then it holds that

$$\mathbf{Pr}\left[G_{n,\hat{p}} \in \mathcal{A}\right] \le \mathbf{Pr}\left[G_{n,m,p} \in \mathcal{A}\right]$$

where $\hat{p} = f(p)$. A graph property $\mathcal{A}$ is increasing if and only if given that $\mathcal{A}$ holds for a graph $G(V, E)$ then $\mathcal{A}$ holds for any $G(V, E')$: $E' \supseteq E$.

Key Results

Theorem 1 *Let $m = \lceil n^\alpha \rceil$, where α is a fixed real positive, and C_1, C_2 be sufficiently large constants. If*

$$p \ge C_1 \frac{\log n}{m} \quad \text{for} \quad 0 < \alpha < 1 \quad \text{or}$$

$$p \ge C_2 \sqrt{\frac{\log n}{nm}} \quad \text{for} \quad \alpha > 1$$

then almost all $G_{n,m,p}$ are Hamiltonian. Our bounds are asymptotically tight.

Note that the theorem above says nothing when $m = n$, i.e., $\alpha = 1$.

Applications

The Erdös–Rényi model of random graphs, $G_{n,p}$, is exhaustively studied in computer science because it provides a framework for studying

practical problems such as "reliable network computing" or it provides a "typical instance" of a graph and thus it is used for average case analysis of graph algorithms. However, the simplicity of $G_{n,p}$ means it is not able to capture satisfactorily many practical problems in computer science. Basically, this is because of the fact that in many problems independent edge-events are not well justified. For example, consider a graph whose vertices represent a set of objects that either are placed or move in a specific geographical region, and the edges are radio communication links. In such a graph, we expect that, any two vertices u, w are more likely to be adjacent to each other, than any other, arbitrary, pair of vertices, if both are adjecent to a third vertex v. Even epidemiological phenomena (like the spread of disease) tend to be more accurately captured by this proximity-sensitive random intersection graph model. Other applications may include oblivious resource sharing in a distributive setting, interaction of mobile agents traversing the web etc.

The model of random intersection graphs $G_{n,m,p}$ was first introduced by M. Karońsky, E. Scheinerman, and K. Singer-Cohen in [4] where they explored the evolution of random intersection graphs by studying the thresholds for the appearance and disappearance of small induced subgraphs. Also, J.A. Fill, E.R. Scheinerman, andK. Singer Cohen in [3] proved an equivalence theorem relating the evolution of $G_{n,m,p}$ and $G_{n,p}$, in particular they proved that when $m = n^{\alpha}$ where $\alpha > 6$, the total variation distance between the graph random variables has limit 0. S. Nikoletseas, C. Raptopoulos, and P. Spirakis in [8] studied the existence and the efficient algorithmic construction of close to optimal independent sets in random intersection graphs. D. Stark in [11] studied the degree of the vertices of the random intersection graphs. However, after [2], Spirakis and Raptopoulos, in [10], provide algorithms that construct Hamilton cycles in instances of $G_{n,m,p}$, for p above the Hamiltonicity threshold. Finally, Nikoletseas et al. in [7] study the mixing time and cover time as the parameter p of the model varies.

Open Problems

As in many other random structures, e.g., $G_{n,p}$ and random formulae, properties of random intersection graphs also appear to have threshold behavior. So far threshold behavior has been studied for the induced subgraph appearance and hamiltonicity.

Other fields of research for random intersection graphs may include the study of connectivity behavior, of the model i.e., the path formation, the formation of giant components. Additionally, a very interesting research question is how cover and mixing times vary with the parameter p, of the model.

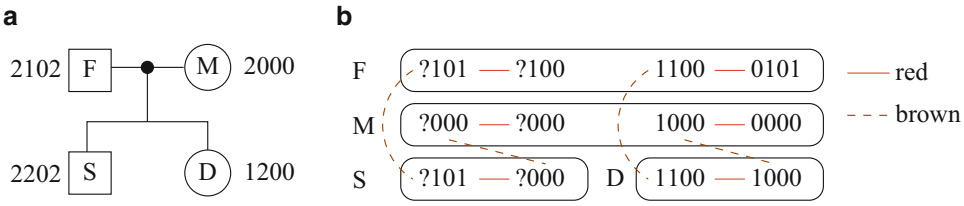
Problem Definition

In many diploid organisms like humans, chromosomes come in pairs. Genetic variation occurs in some "positions" along the chromosomes. These genetic variations are commonly modelled in the form of *single nucleotide polymorphisms* (SNPs) [5], which are the nucleotide sites where more than one nucleotide can occur. A *haplotype* is the sequence of linked SNP genetic markers (small segments of DNA) on a single chromosome. However, experiments often yield *genotypes*, which is a blend of the two haplotypes of the chromosome pair. It is more useful to have information on the haplotypes, thus giving rise to the computational problem of inferring haplotypes from genotypes.

The physical position of a marker on a chromosome is called a *locus* and its state is called an *allele*. SNP are often *biallelic*, i.e., the allele can take on two different states, corresponding to two different nucleotides. In the language of computer science, the allele of a biallelic SNP can be denoted by 0 and 1, and a haplotype with m loci is represented as a length-m string in $\{0,1\}^m$ and a genotype as a length-m string in $\{0,1,2\}^m$. Consider a haplotype pair $\langle h_1, h_2\rangle$ and a corresponding genotype g. For each locus, if both haplotypes show a 0, then the genotype must also be 0, and if both haplotypes show a 1, the genotype must also be 1. These loci are called *homozygous*. If however one of the haplotypes shows a 0 and the other a 1, the genotype shows a 2 and the locus is called *heterozygous*. This is called *SNP consistency*. For example, considering a single individual, the genotype $g = 012212$ has four SNP-consistent haplotype pairs: $\{\langle 01\underline{1}1\underline{1}1, 01\underline{0}0\underline{1}0\rangle, \langle 01\underline{1}1\underline{1}0, 01\underline{0}0\underline{1}1\rangle, \langle 01\underline{1}0\underline{1}1, 01\underline{0}1\underline{1}0\rangle, \langle 01\underline{1}0\underline{1}0, 01\underline{0}1\underline{1}1\rangle\}$. In general, if a genotype has s heterozygous loci, it can have 2^{s-1} SNP-consistent haplotype solutions.

Haplotypes are passed down from an individual to its descendants. *Mendelian consistency* requires that, in the absence of *recombinations* or mutations, each child inherits one haplotype from one of the two haplotypes of the father and inherits the other haplotype from the mother similarly. This gives us more information to infer haplotypes when we are given a *pedigree*. The computational problem is therefore, given a pedigree with n individuals where each individual is associated with a genotype of length m, find an assignment of a pair of haplotypes to each individual such that SNP consistency



Haplotype Inference on Pedigrees Without Recombinations, Fig. 1 (**a**) Example of a pedigree with four nodes. (**b**) The graph G with 12 vertices, 6 *red edges*, and 4 *brown edges*. Each vector is a vertex in G. Vector pairs enclosed by *rounded rectangles* belong to the same individual

and Mendelian consistency are obeyed for each individual. In rare cases (especially for humans) [3], the pedigree may contain *mating loops*: a mating loop is formed when, for example, there is a marriage between descendants of a common ancestor.

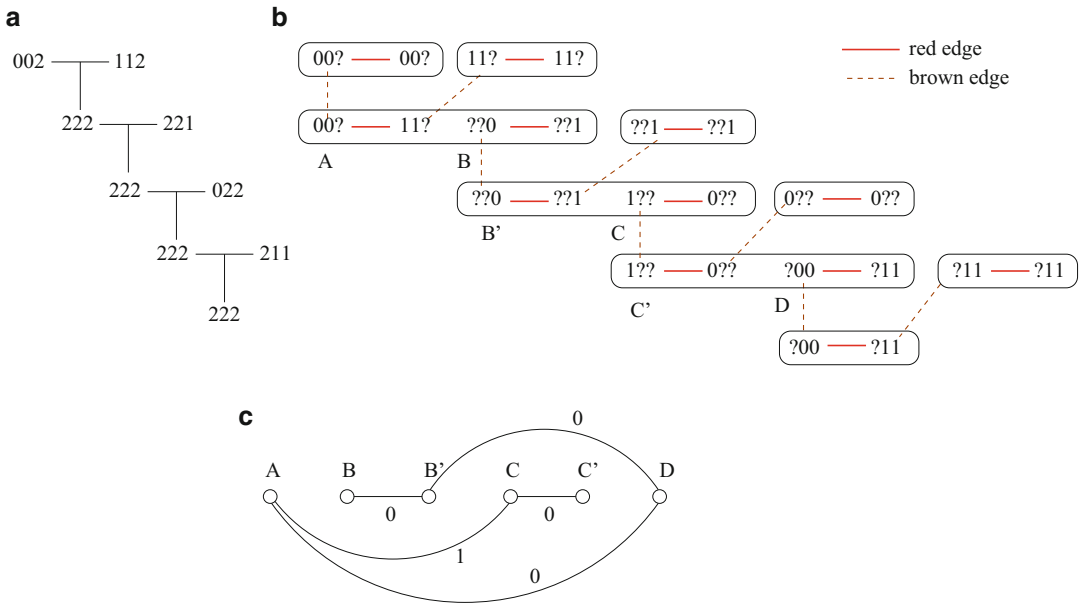
As a simple example, consider the pedigree in Fig. 1a for a family of four individuals and their genotypes. Due to SNP consistency, mother M's haplotypes must be $\langle 0000, 1000 \rangle$ (the order does not matter). Similarly, daughter D's haplotypes must be $\langle 1000, 1100 \rangle$. Now we apply Mendelian consistency to deduce that D must obtain the 1000 haplotype from M since neither of father F's haplotypes can be 1000 (considering locus 2). Therefore, D obtains 1100 from F, and F's haplotypes must be $\langle 0101, 1100 \rangle$. With F's and M's haplotypes known, the only solution for the haplotypes of son S that is consistent with his genotype 2202 is $\langle 0101, 1000 \rangle$.

Key Results

While this kind of deduction might appear to be enough to resolve all haplotype values, it is not the case. As we will shortly see, there are "long-distance" constraints that need to be considered. These constraints can be represented by a system of linear equations in GF(2) and solved using Gaussian elimination. This gives a $O(m^3n^3)$ time algorithm [3]. Subsequent papers try to capture or solve the constraints more economically. The time complexity was improved in [6] to $O(mn^2 + n^3 \log^2 n \log\log n)$ by eliminating redundant equations and using low-stretch spanning trees. A different approach was used in [1], representing the constraints by the parity of edge labels of some auxiliary graphs and finding solutions of these constraints using graph traversal without (directly) solving a system of linear equations. This gives a linear $O(mn)$ time algorithm, although it only works for the case with no mating loops and only produces one particular solution even when the pedigree admits more than one solution. Later algorithms include [4] which returns the full set of solutions in optimal time (again without mating loops) and [2] which can handle mating loops and runs in $O(kmn + k^2m)$ time where k is the number of mating loops.

In the following we sketch the idea behind the linear time algorithm in [1]. Each individual only has a pair of haplotypes, but the algorithm first produces a number of vector pairs for each individual, one vector pair for each trio (a father-mother-child triplet) that this individual belongs to. Each vector pair represents the information about the two haplotypes of this individual that can be derived by considering this trio only. These vector pairs will eventually be "unified" to become a single pair.

For the pedigree in Fig. 1a, the algorithm first produces the graph G in Fig. 1b, which has two connected components for the two trios F-M-S and F-M-D. The rule for enforcing SNP consistency (Mendelian consistency) is that the unresolved loci values, i.e., the ? values, must be different (same) at opposite ends of a red (brown) edge. There is only one way to unify the vector pairs of F consistently (due to locus 4): ?101 must correspond to 0101. We add an edge between these two vectors to represent the fact that they should be identical. Then all ? values



Haplotype Inference on Pedigrees Without Recombinations, Fig. 2 An example showing how constraints are represented by labeled edges in another graph. (**a**) The pedigree. (**b**) The local graph G. (**c**) The parity constraint graph J. Three constraints are added

can be resolved by traversing the now-connected graph and applying the aforementioned rules for enforcing consistency.

However, consider another pedigree in Fig. 2a. The previous steps can only produce Fig. 2b, which has four connected components and unresolved loci. We need to decide for A and B whether $A = 00?$ should connect to $B = ??0$ or its complement ??1 and similarly for B' and C, etc. Observe that a path between A and C must go through an odd number of red edges since locus 1 changes from 0 to 1. To capture this type of long-distance constraints, we construct a *parity constraint graph* J where the edge labels represent the parity constraints; see Fig. 2c. In effect, J represents a set of linear equations in GF(2); in Fig. 2c, the equations are $x_{AB}+x_{B'C} = 1, x_{B'C}+x_{C'D} = 0$, and $x_{AB}+x_{B'C}+x_{C'D} = 0$.

Finally, we can traverse J along the unique path between any two nodes; the parity of this path tells us how to merge the vector pairs in G. For example, the parity between A and B should be 0, indicating 00? in A should connect to ??0 in B (so both become 000), while the parity between B' and C is 1, so B' and C should be 000 and 111, respectively.

DNF; function representation; NP-hardness of learning; PAC learning; Proper learning; representation-based hardness

Years and Authors of Summarized Original Work

1988; Pitt, Valiant

Problem Definition

The work of Pitt and Valiant [18] deals with learning Boolean functions in the Probably Approximately Correct (PAC) learning model introduced by Valiant [19]. A learning algorithm in Valiant's original model is given random examples of a function $f : \{0,1\}^n \to \{0,1\}$ from a representation class $\mathcal{F}$ and produces a hypothesis $h \in \mathcal{F}$ that closely approximates f. Here, a *representation class* is a set of functions and a language for describing the functions in the set. The authors give examples of natural representation classes that are NP-hard to learn in this model, whereas they can be learned if the learning algorithm is allowed to produce hypotheses from a richer representation class $\mathcal{H}$. Such an algorithm is said to learn $\mathcal{F}$ by $\mathcal{H}$; learning $\mathcal{F}$ by $\mathcal{F}$ is called *proper* learning.

The results of Pitt and Valiant were the first to demonstrate that the choice of representation of hypotheses can have a dramatic impact on the computational complexity of a learning problem. Their specific reductions from NP-hard problems are the basis of several other follow-up works on the hardness of proper learning [1,3,7].

Notation

Learning in the PAC model is based on the assumption that the unknown function (or *concept*) belongs to a certain class of concepts $\mathcal{C}$. In order to discuss algorithms that learn and output functions, one needs to define how these functions are represented. Informally, a representation for a concept class $\mathcal{C}$ is a way to describe concepts from $\mathcal{C}$ that defines a procedure to evaluate a concept in $\mathcal{C}$ on any input. For example, one can represent a conjunction of input variables by listing the variables in the conjunction. More formally, a representation class can be defined as follows.

Definition 1 A *representation class* $\mathcal{F}$ is a pair $(L, \mathcal{R})$ where

- L is a language over some fixed finite alphabet (e.g., $\{0,1\}$);
- $\mathcal{R}$ is an algorithm that for $\sigma \in L$, on input $(\sigma, 1^n)$ returns a Boolean circuit over $\{0,1\}^n$.

In the context of efficient learning, only efficient representations are considered, or, representations for which $\mathcal{R}$ is a polynomial-time algorithm. The concept class represented by $\mathcal{F}$ is the set of functions over $\{0,1\}^n$ defined by the circuits in $\{\mathcal{R}(\sigma, 1^n) \mid \sigma \in L\}$. For a Boolean function f, "$f \in \mathcal{F}$" means that f belongs to the concept class represented by $\mathcal{F}$ and that there is a $\sigma \in L$ whose associated Boolean circuit computes f. For most of the representations discussed in the context of learning, it is straightforward to construct a language L and the corresponding translating function $\mathcal{R}$, and therefore, they are not specified explicitly.

Associated with each representation is the complexity of describing a Boolean function using this representation. More formally, for a Boolean function $f \in \mathcal{C}$, $\mathcal{F}\text{-}\mathtt{size}(f)$ is the length of the shortest way to represent f using $\mathcal{F}$, or $\min\{|\sigma| \mid \sigma \in L, \mathcal{R}(\sigma, 1^n) \equiv f\}$.

We consider Valiant's PAC model of learning [19], as generalized by Pitt and Valiant [18].

In this model, for a function f and a distribution $\mathcal{D}$ over X, an *example oracle* $\mathrm{EX}(f, \mathcal{D})$ is an oracle that, when invoked, returns an example $\langle x, f(x)\rangle$, where x is chosen randomly with respect to $\mathcal{D}$, independently of any previous examples. For $\epsilon \geq 0$, we say that function g ϵ-approximates a function f with respect to distribution $\mathcal{D}$ if $\mathbf{Pr}_{\mathcal{D}}[f(x) \neq g(x)] \leq \epsilon$.

Definition 2 A representation class $\mathcal{F}$ is *PAC learnable* by representation class $\mathcal{H}$ if there exists an algorithm that for every $\epsilon > 0$, $\delta > 0$, n, $f \in \mathcal{F}$, and distribution $\mathcal{D}$ over X, given ϵ, δ, and access to $\mathrm{EX}(f, \mathcal{D})$, runs in time polynomial in $n, s = \mathcal{F}\text{-}\mathtt{size}(c), 1/\epsilon$ and $1/\delta$, and outputs, with probability at least $1-\delta$, a hypothesis $h \in \mathcal{H}$ that ϵ-approximates f.

A DNF expression is defined as an OR of ANDs of literals, where a *literal* is a possibly negated input variable. We refer to the ANDs of a DNF formula as its *terms*. Let $\mathsf{DNF}(k)$ denote the representation class of k-term DNF expressions. Similarly, a CNF expression is an OR of ANDs of literals. Let k-CNF denote the representation class of CNF expressions with each AND having at most k literals.

For a real-valued vector $c \in \mathbb{R}^n$ and $\theta \in \mathbb{R}$, a *linear threshold function* (also called a *halfspace*) $T_{c,\theta}(x)$ is the function that equals 1 if and only if $\sum_{i \leq n} c_i x_i \geq \theta$. The representation class of Boolean threshold functions consists of all linear threshold functions with $c \in \{0,1\}^n$ and θ an integer.

Key Results

Theorem 1 ([18]) *For every $k \geq 2$, the representation class of $\mathsf{DNF}(k)$ is not properly learnable unless $\mathsf{RP} = \mathsf{NP}$.*

More specifically, Pitt and Valiant show that learning $\mathsf{DNF}(k)$ by $\mathsf{DNF}(\ell)$ is at least as hard as coloring a k-colorable graph using ℓ colors. For the case $k = 2$, they obtain the result by reducing from Set Splitting (see [9] for details on the problems). Theorem 1 is in sharp contrast with the fact that $\mathsf{DNF}(k)$ is learnable by k-CNF [19].

Theorem 2 ([18]) *The representation class of Boolean threshold functions is not properly learnable unless $\mathsf{RP} = \mathsf{NP}$.*

This result is obtained via a reduction from the NP-complete Zero-One Integer Programming problem (see [9] (p.245) for details on the problem). The result is contrasted by the fact that general linear thresholds are properly learnable [4].

These results show that using a specific representation of hypotheses forces the learning algorithm to solve a combinatorial problem that can be NP-hard. In most machine learning applications it is not important which representation of hypotheses is used as long as the value of the unknown function is predicted correctly. Therefore, learning in the PAC model is now defined without any restrictions on the output hypothesis (other than it being efficiently evaluatable). Hardness results in this setting are usually based on cryptographic assumptions (cf. [15]).

Hardness results for proper learning based on assumption $\mathsf{NP} \neq \mathsf{RP}$ are now known for several other representation classes and for other variants and extensions of the PAC learning model. Blum and Rivest show that for any $k \geq 3$, unions of k halfspaces are not properly learnable [3]. Hancock et al. prove that decision trees (cf. [16] for the definition of this representation) are not learnable by decision trees of somewhat larger size [11]. This result was strengthened by Alekhnovich et al. who also proved that intersections of two halfspaces are not learnable by intersections of k halfspaces for any constant k, general DNF expressions are not learnable by unions of halfspaces (and in particular are not properly learnable) and *k-juntas* are not properly learnable [1]. Further, DNF expressions remain NP-hard to learn properly even if *membership queries*, or the ability to query the unknown function at any point, are allowed [7]. Khot and Saket show that the problem of learning intersections of two halfspaces remains NP-hard even if a hypothesis with any constant error smaller than $1/2$ is required [17]. No efficient algorithms or hardness results are known for any of the above learning problems if no restriction is placed on the representation of hypotheses.

The choice of representation is important even in powerful learning models. Feldman proved that n^c-term DNF are not properly learnable for any constant c even when the distribution of examples is assumed to be uniform and membership queries are available [7]. This contrasts with Jackson's celebrated algorithm for learning DNF in this setting [13], which is not proper.

In the *agnostic learning* model of Haussler [12] and Kearns et al. [14], even the representation classes of conjunctions, decision lists, halfspaces, and parity functions are NP-hard to learn properly (cf. [2, 6, 8, 10] and references therein). Here again the status of these problems in the representation-independent setting is largely unknown.

Applications

A large number of practical algorithms use representations for which hardness results are known (most notably decision trees, halfspaces, and neural networks). Hardness of learning $\mathcal{F}$ by $\mathcal{H}$ implies that an algorithm that uses $\mathcal{H}$ to represent its hypotheses will not be able to learn $\mathcal{F}$ in the PAC sense. Therefore such hardness results elucidate the limitations of algorithms used in practice. In particular, the reduction from an NP-hard problem used to prove the hardness of learning $\mathcal{F}$ by $\mathcal{H}$ can be used to generate hard instances of the learning problem.

Open Problems

A number of problems related to proper learning in the PAC model and its extensions are open. Almost all hardness of proper learning results are for learning with respect to unrestricted distributions. For most of the problems mentioned in section "Key Results" it is unknown whether the result is true if the distribution is restricted to belong to some natural class of distributions (e.g., product distributions). It is unknown whether decision trees are learnable properly in the PAC model or in the PAC model with membership queries. This question is open even in the PAC model restricted to the uniform distribution only. Note that decision trees are learnable (non-properly) if membership queries are available [5] and are learnable properly in time $O(n^{\log s})$, where s is the number of leaves in the decision tree [1].

An even more interesting direction of research would be to obtain hardness results for learning by richer representation classes, such as AC^0 circuits, classes of neural networks and, ultimately, unrestricted circuits.

Harmonic Algorithm for Online Bin Packing

Leah Epstein
Department of Mathematics, University of Haifa, Haifa, Israel

Keywords

Bin packing; Bounded space algorithms; Competitive ratio

Years and Authors of Summarized Original Work

1985; Lee, Lee

Problem Definition

One of the goals of the design of the harmonic algorithm (or class of algorithms) was to provide an online algorithm for the classic bin packing problem that performs well with respect to the asymptotic competitive ratio, which is the standard measure for online algorithms for bin packing type problems. The competitive ratio for a given input is the ratio between the costs of the algorithm and of an optimal off-line solution. The asymptotic competitive ratio is the worst-case competitive ratio of inputs for which the optimal cost is sufficiently large. In the *online* (standard) bin packing problem, items of rational sizes in $(0, 1]$ are presented one by one. The algorithm must pack each item into a bin before the following item is presented. The total size of items packed into a bin cannot exceed 1, and the goal is to use the minimum number of bins, where a bin is used if at least one item was packed into it. All items must be packed, and the supply of bins is unlimited.

When an algorithm acts on an input, it can decide to *close* some of its bins and never use them again. A bin is called *closed* in such a case, while otherwise a used bin (which already has at least one item) is called *open*. The motivation for closing bins is to obtain fast running times per item (so that the algorithm will pack it into a bin selected out of a small number of options). Simple algorithms such as First Fit (FF), Best Fit (BF), and Worst Fit (WF) have worst-case running times of $O(\log N)$ per item, where N is the number of items at the time of assignment of the new item. On the other hand, the simple algorithm Next Fit (NF), which keeps at most of open bin and closes it when a new item cannot be packed there (before it uses a new bin for the new item), has a worst-case running time of $O(1)$ per item. Algorithms that keep a constant number of open bins are called *bounded space*. In many practical applications, this property is desirable, since the number of candidate bins for a new item is small and it does not increase with the input size.

Algorithm HARM_k (for an integer $k \geq 3$) was defined by Lee and Lee [7]. The fundamental and natural idea of "harmonic-based" algorithms is classify each item by size first (for online algorithms, the classification of an item must be done immediately upon arrival) and then pack it according to its class (instead of letting the exact size influence packing decisions). For the classifi-

cation of items, HARM_k splits the interval $(0, 1]$ into subintervals. There are $k-1$ subintervals of the form $(\frac{1}{i+1}, \frac{1}{i}]$ for $i = 1, \ldots, k-1$ and one final subinterval $(0, \frac{1}{k}]$. Each bin will contain only items from one subinterval (type). Every type is packed independently into its own bins using NF. Thus, there are at most $k-1$ open bins at each time (since for items of sizes above $\frac{1}{2}$, two items cannot share a bin, and any bin can be closed once it receives an item). Moreover, for $i < k$, as the items of type i have sizes no larger than $\frac{1}{i}$ but larger than $\frac{1}{i+1}$, every closed bin of this type will have exactly i items. For type k, a closed bin will contain at least k items, but it may contain many more items. This defines a class of algorithms (containing one algorithm for any $k \geq 3$). The term *the harmonic algorithm* (or simply HARM) refers to HARM_k for a sufficiently large value of k, and its asymptotic competitive ratio is the infimum value that can be achieved as the asymptotic competitive ratio of any algorithm of this class.

Key Results

It was shown in paper [7] that for k tending to infinity, the asymptotic ratio of HARM is a sum of series denoted by Π_∞ (see below), and it is equal to approximately 1.69103. Moreover, this is the best possible asymptotic competitive ratio of any online bounded space algorithm for standard bin packing.

The crucial item sizes are of the form $\frac{1}{\ell} + \varepsilon$, where $\varepsilon > 0$ is small and ℓ is an integer. These are items of type $\ell - 1$, and bins consisting of such items contain $\ell - 1$ items (except for the last bin used for this type that may contain a smaller number of items). However, a bin (of an off-line solution) that already contains an item of size $\frac{1}{2} + \varepsilon_1$ and an item of size $\frac{1}{3} + \varepsilon_2$ (for some small $\varepsilon_1, \varepsilon_2 > 0$) cannot contain also an item whose size is slightly above $\frac{1}{4}$. The largest item of this form would be slightly larger than $\frac{1}{7}$. Thus, the following sequence was defined [7]. Let $\pi_1 = 1$ and, for $j > 1$, $\pi_j = \pi_{j-1}(\pi_{j-1} + 1)$ (note that $\pi_{j'}$ is divisible by any π_j for $j < j'$). It turns out that the crucial item sizes are just above $\frac{1}{\pi_j + 1}$. The series $\sum_{j=1}^{\infty} \frac{1}{\pi_j}$ give the asymptotic competitive ratio of the HARM, Π_∞. For a long time the best lower bound on the asymptotic competitive ratio of (unbounded space) online algorithms was the one by van Vliet [8, 13], proved using this sequence (but the current best lower bound was proved using another set of inputs [1]).

In order to prove the upper bound Π_∞ on the competitive ratio, weights were used [12]. In this case weights are defined (for a specific value of k) quite easily such that all bins (except for the bins that remain open when the algorithm terminates) have total weights of at least 1. The weight of an item of type $i < k$ is $\frac{1}{i}$. The bins of type k are almost full for sufficiently large values of k (a bin can be closed only if the total size of its items exceeds $1 - \frac{1}{k}$). Assigning such an item a weight that is $\frac{k}{k-1}$ times its size will allow one to show that all bins except for a constant number of bins (at most $k-1$ bins) have total weights of at least 1. It is possible to show that the total weight of any packed bin is sufficiently close to Π_∞ for large values of k. As both HARM_k and an optimal solution pack the same items, the competitive ratio is implied. To show the upper bound on the total weight of any packed bin, it is required to show that the worst-case bin contains exactly one item of size just above $\frac{1}{\pi_j + 1}$ for $\pi_j \leq k - 1$ (and the remaining space can only contain items of type k). Roughly speaking, this holds as once it was proved that the bin contains the largest such items, the largest possible additional weight can be obtained only by adding the next such item.

Proving that no better bounded space algorithms exist can be done as follows. Let j' be a fixed integer. Let N be a large integer and consider a sequence containing N items of each size $\frac{1}{\pi_j} + \delta$ for a sufficiently small $\delta > 0$, for any $j = j', j' - 1, \cdots, 1$. If δ is chosen appropriately, we have $\sum_{j=1}^{j'} \frac{1}{\pi_j + 1} + j'\delta < 1$, so the items can be packed (off-line) into N bins. However, if items are presented in this order (sorted by nondecreasing size), after all items of one size have been presented, only a constant number of bins can receive larger items, and

thus the items of each size are packed almost independently.

Related Results

The space of a bounded space algorithm is the number of open bins that it can have. The space of NF is 1, while the space of harmonic algorithms increases with k. A bounded space algorithm with space 2 and the same asymptotic competitive ratio as FF and BF have been designed [3] (for comparison, $HARM_3$ has an asymptotic competitive ratio of $\frac{7}{4}$). A modification where smaller space is used to obtain the same competitive ratios of harmonic algorithms (or alternatively, smaller competitive ratios were obtained using the same space) was designed by Woeginger [15]. Thus, there exists another sequence of bounded space algorithms, with an increasing sequence of open bins, where their sequence of competitive ratios tends to Π_∞ such that the space required for every competitive ratio is much smaller than that of [7].

One drawback of the model above is that an off-line algorithm can rearrange the items and does not have to process them as a sequence. The variant where it must process them in the same order as an online algorithm was studied as well [2]. Algorithms that are based on partitioning into classes and have smaller asymptotic competitive ratios (but they are obviously not bounded space) were designed [7, 9, 11].

Generalizations have been studied too, in particular, bounded space bin packing with cardinality constraints (where an item cannot receive more than t items for a fixed integer $t \geq 2$) [5], parametric bin packing (where there is an upper bound strictly smaller than 1 on item sizes) [14], bin packing with rejection (where an item i has a rejection penalty r_i associated with it, and it can be either packed, or rejected for the cost r_i) [6], variable-sized bin packing (where bins of multiple sizes are available for packing) [10], and bin packing with resource augmentation (where the online algorithm can use bins of size $b > 1$ for a fixed rational number b, while an off-line algorithm still uses bins of size 1) [4]. In this last variant, the sequences of critical item sizes were redefined as a function of b, while variable-sized bin packing required a more careful partition into intervals.

Problem Definition

The general idea of *hierarchical* self-assembly (a.k.a., *multiple tile* [2], *polyomino* [8, 10], *two-handed* [3, 5, 6]) is to model self-assembly of tiles in which attachment of two multi-tile assemblies is allowed, as opposed to all attachments being that of a single tile onto a larger assembly. Several problems concern comparing hierarchical self-assembly to its single-tile-attachment variant (called the "seeded" model of self-assembly), so we define both models here. The model of hierarchical self-assembly was first defined (in a slightly different form that restricted the size of assemblies that could attach) by Aggarwal, Cheng, Goldwasser, Kao, Moisset de Espanes, and Schweller [2]. Several generalizations of the model exist that incorporated staged mixing of test tubes, "dissolvable" tiles, active signaling across tiles, etc., but here we restrict attention to the model closest to the seeded model of Winfree [9], different from that model only in the absence of a seed and the ability of two large assemblies to attach.

Definitions

A *tile type* is a unit square with four sides, each consisting of a *glue label* (often represented as a finite string) and a nonnegative integer *strength*. We assume a finite set T of tile types, but an infinite number of copies of each tile type, each copy referred to as a *tile*. An *assembly* is a positioning of tiles on the integer lattice $\mathbb{Z}^2$, i.e., a partial function $\alpha : \mathbb{Z}^2 \dashrightarrow T$. We write $|\alpha|$ to denote $|\text{dom } \alpha|$. Write $\alpha \sqsubseteq \beta$ to denote that α is a *subassembly* of β, which means that $\text{dom } \alpha \subseteq \text{dom } \beta$ and $\alpha(p) = \beta(p)$ for all points $p \in \text{dom } \alpha$. We abuse notation and take a tile type t to be equivalent to the single-tile assembly containing only t (at the origin if not otherwise specified). Two adjacent tiles in an assembly *interact* if the glue labels on their abutting sides are equal and have positive strength. Each assembly induces a *binding graph*, a grid graph whose vertices are tiles, with an edge between two tiles if they interact. The assembly is τ*-stable* if every cut of its binding graph has strength at least τ, where the weight of an edge is the strength of the glue it represents. That is, the assembly is stable if at least energy τ is required to separate the assembly into two parts.

We now define both the seeded and hierarchical variants of the tile assembly model. A *seeded tile system* is a triple $\mathcal{T} = (T, \sigma, \tau)$, where T is a finite set of tile types, $\sigma : \mathbb{Z}^2 \dashrightarrow T$ is a finite, τ-stable *seed assembly*, and τ is the *temperature*. If $\mathcal{T}$ has a single seed tile $s \in T$ (i.e., $\sigma(0, 0) = s$ for some $s \in T$ and is undefined elsewhere), then we write $\mathcal{T} = (T, s, \tau)$. Let $|\mathcal{T}|$ denote $|T|$. An assembly α is *producible* if either $\alpha = \sigma$ or if β is a producible assembly and α can be obtained from β by the stable binding of a single tile. In this case, write $\beta \to_1 \alpha$ (α is producible from β by the attachment of one tile), and write $\beta \to \alpha$ if $\beta \to_1^* \alpha$ (α is producible from β by the attachment of zero or more tiles). An assembly is *terminal* if no tile can be τ-stably attached to it.

A *hierarchical tile system* is a pair $\mathcal{T} = (T, \tau)$, where T is a finite set of tile types and $\tau \in \mathbb{N}$

is the temperature. An assembly is *producible* if either it is a single tile from T or it is the τ-stable result of translating two producible assemblies without overlap. Therefore, if an assembly α is producible, then it is produced via an *assembly tree*, a full binary tree whose root is labeled with α, whose $|\alpha|$ leaves are labeled with tile types, and each internal node is a producible assembly formed by the stable attachment of its two child assemblies. An assembly α is *terminal* if for every producible assembly β, α and β cannot be τ-stably attached. If α can grow into β by the attachment of zero or more assemblies, then we write $\alpha \to \beta$.

In either model, let $\mathcal{A}[\mathcal{T}]$ be the set of producible assemblies of $\mathcal{T}$, and let $\mathcal{A}_{\square}[\mathcal{T}] \subseteq \mathcal{A}[\mathcal{T}]$ be the set of producible, terminal assemblies of $\mathcal{T}$. A TAS $\mathcal{T}$ is *directed* (a.k.a., *deterministic*, *confluent*) if $|\mathcal{A}_{\square}[\mathcal{T}]| = 1$. If $\mathcal{T}$ is directed with unique producible terminal assembly α, we say that $\mathcal{T}$ *uniquely produces* α. It is easy to check that in the seeded aTAM, $\mathcal{T}$ uniquely produces α if and only if every producible assembly $\beta \sqsubseteq \alpha$. In the hierarchical model, a similar condition holds, although it is more complex since hierarchical assemblies, unlike seeded assemblies, do not have a "canonical translation" defined by the seed position. $\mathcal{T}$ uniquely produces α if and only if for every producible assembly β, there is a translation β' of β such that $\beta' \sqsubseteq \alpha$. In particular, if there is a producible assembly $\beta \neq \alpha$ such that dom α = dom β, then α is not uniquely produced. Since dom β = dom α, every nonzero translation of β has some tiled position outside of dom α, whence no such translation can be a subassembly of α, implying α is not uniquely produced.

Power of Hierarchical Assembly Compared to Seeded

One sense in which we can conclude that one model of computation M is at least as powerful as another model of computation M' is to show that any machine defined by M' can be "simulated efficiently" by a machine defined by M. In self-assembly, there is a natural definition of what it means for one tile system $\mathcal{S}$ to "simulate" another $\mathcal{T}$. We now discuss intuitively how to define such a notion. There are several intricacies to the full formal definition that are discussed in further detail in [3,5].

First, we require that there is a constant $k \in \mathbb{Z}^+$ (the "resolution loss") such that each tile type t in $\mathcal{T}$ is "represented" by one or more $k \times k$ blocks β of tiles in $\mathcal{S}$. In this case, we write $r(\beta) = t$, where $\beta : \{1, \ldots, k\}^2 \dashrightarrow S$ and S is the tile set of $\mathcal{S}$. Then β represents a $k \times k$ block of such tiles, possibly with empty positions at points $\mathbf{x}$ where $\beta(\mathbf{x})$ is undefined. We call such a $k \times k$ block in $\mathcal{S}$ a "macrotile." We can extend r to a function R that, given an assembly $\alpha_{\mathcal{S}}$ partitioned into $k \times k$ macrotiles, outputs an assembly $\alpha_{\mathcal{T}}$ of $\mathcal{T}$ such that, for each macrotile β of $\alpha_{\mathcal{S}}$, $r(\beta) = t$, where t is the tile type at the corresponding position in $\alpha_{\mathcal{T}}$.

Given such a representation function R indicating how to interpret assemblies of $\mathcal{S}$ as representing assemblies of $\mathcal{T}$, we now define what it means to say that $\mathcal{S}$ *simulates* $\mathcal{T}$. For each producible assembly $\alpha_{\mathcal{T}}$ of $\mathcal{T}$, there is a producible assembly $\alpha_{\mathcal{S}}$ of $\mathcal{S}$ such that $R(\alpha_{\mathcal{S}}) = \mathcal{T}$, and furthermore, for every producible assembly $\alpha_{\mathcal{S}}$, if $R(\alpha_{\mathcal{S}}) = \mathcal{T}$, then $\mathcal{T}$ is producible in $\mathcal{T}$. Finally, we require that R respects the "single attachment" dynamics of $\mathcal{T}$: there is a single tile that can be attached to $\alpha_{\mathcal{T}}$ to result in $\alpha'_{\mathcal{T}}$ if and only if there is some sequence of attachments to $\alpha_{\mathcal{S}}$ that results in assembly $\alpha'_{\mathcal{S}}$ such that $R(\alpha'_{\mathcal{S}}) = \alpha'_{\mathcal{T}}$.

With such an idea in mind, we can ask, "Is the hierarchical model at least as powerful as the seeded model?"

Problem 1 For every seeded tile system $\mathcal{T}$, design a hierarchical tile system $\mathcal{S}$ that simulates $\mathcal{T}$.

Another interpretation of a solution to Problem 1 is that, to the extent that the hierarchical model is more realistic than the seeded model by incorporating the reality that tiles may aggregate even in the absence of a seed, such a solution shows how to enforce seeded growth even in such an unfriendly environment that permits non-seeded growth.

Assembly Time

We now define time complexity for hierarchical systems (this definition first appeared in [4],

where it is explained in more detail). We treat each assembly as a single molecule. If two assemblies α and β can attach to create an assembly γ, then we model this as a chemical reaction $\alpha + \beta \to \gamma$, in which the rate constant is assumed to be equal for all reactions (and normalized to 1). In particular, if α and β can be attached in two different ways, this is modeled as two different reactions, even if both result in the same assembly.

At an intuitive level, the model we define can be explained as follows. We imagine dumping all tiles into solution at once, and at the same time, we grab one particular tile and dip it into the solution as well, pulling it out of the solution when it has assembled into a terminal assembly. Under the seeded model, the tile we grab will be a seed, assumed to be the only copy in solution (thus requiring that it appears only once in any terminal assembly). In the seeded model, no reactions occur other than the attachment of individual tiles to the assembly we are holding. In the hierarchical model, other reactions are allowed to occur in the background (we model this using the standard mass-action model of chemical kinetics [7]), but only those reactions with the assembly we are holding move it "closer" to completion. The other background reactions merely change concentrations of other assemblies (although these indirectly affect the time it will take our chosen assembly to complete, by changing the rate of reactions with our chosen assembly).

More formally, let $\mathcal{T} = (T, \tau)$ be a hierarchical TAS, and let $\rho : T \to [0, 1]$ be a concentrations function, giving the *initial* concentration of each tile type (we require that $\sum_{t \in T} \rho(t) = 1$, a condition known as the "finite density constraint"). Let $\mathbb{R}^+ = [0, \infty)$, and let $t \in \mathbb{R}^+$. For $\alpha \in \mathcal{A}[\mathcal{T}]$, let $[\alpha]_\rho(t)$ (abbreviated $[\alpha](t)$ when ρ is clear from context) denote the concentration of α at time t with respect to initial concentrations ρ, defined as follows. Given two assemblies α and β that can attach to form γ, we model this event as a chemical reaction $R : \alpha + \beta \to \gamma$. Say that a reaction $\alpha + \beta \to \gamma$ is *symmetric* if $\alpha = \beta$. Define the *propensity* (a.k.a., *reaction rate*) of R at time $t \in \mathbb{R}^+$ to be $\rho_R(t) = [\alpha](t) \cdot [\beta](t)$ if R is not symmetric and $\rho_R(t) = \frac{1}{2} \cdot [\alpha](t)^2$ if R is symmetric.

If α is consumed in reactions $\alpha + \beta_1 \to \gamma_1, \ldots, \alpha + \beta_n \to \gamma_n$ and produced in asymmetric reactions $\beta'_1 + \gamma'_1 \to \alpha, \ldots, \beta'_m + \gamma'_m \to \alpha$ and symmetric reactions $\beta''_1 + \beta''_1 \to \alpha, \ldots, \beta''_p + \beta''_p \to \alpha$, then the concentration $[\alpha](t)$ of α at time t is described by the differential equation:

$$\frac{d[\alpha](t)}{dt} = \sum_{i=1}^{m} [\beta'_i](t) \cdot [\gamma'_i](t) + \sum_{i=1}^{p} \frac{1}{2} \cdot [\beta''_i](t)^2 - \sum_{i=1}^{n} [\alpha](t) \cdot [\beta_i](t), \tag{1}$$

with boundary conditions $[\alpha](0) = \rho(r)$ if α is an assembly consisting of a single tile r and $[\alpha](0) = 0$ otherwise. In other words, the propensities of the various reactions involving α determine its rate of change, negatively if α is consumed and positively if α is produced.

This completes the definition of the dynamic evolution of concentrations of producible assemblies; it remains to define the time complexity of assembling a terminal assembly. Although we have distinguished between seeded and hierarchical systems, for the purpose of defining a model of time complexity in hierarchical systems and comparing them to the seeded system time complexity model of [1], it is convenient to introduce a seedlike "timekeeper tile" into the hierarchical system, in order to stochastically analyze the growth of this tile when it reacts in a solution that is itself evolving according to the continuous model described above. The seed does not have the purpose of nucleating growth but is introduced merely to focus attention on a single molecule that has not yet assembled anything, in order to ask how long it will take to assemble

into a terminal assembly. The choice of which tile type to pick will be a parameter of the definition, so that a system may have different assembly times depending on the choice of timekeeper tile.

Fix a copy of a tile type s to designate as a "timekeeper seed." The assembly of s into some terminal assembly $\hat{\alpha}$ is described as a time-dependent continuous-time Markov process in which each state represents a producible assembly containing s, and the initial state is the size-1 assembly with only s. For each state α representing a producible assembly with s at the origin, and for each pair of producible assemblies β, γ such that $\alpha + \beta \to \gamma$ (with the translation assumed to happen only to β so that α stays "fixed" in position), there is a transition in the Markov process from state α to state γ with transition rate $[\beta](t)$.

We define $\mathbf{T}_{\mathcal{T},\rho,s}$ to be the random variable representing the time taken for the copy of s to assemble into a terminal assembly via some sequence of reactions as defined above. We define the time complexity of a directed hierarchical TAS $\mathcal{T}$ with concentrations ρ and timekeeper s to be $\mathsf{T}(\mathcal{T}, \rho, s) = \mathrm{E}\left[\mathbf{T}_{\mathcal{T},\rho,s}\right]$.

For a shape $S \subset \mathbb{Z}^2$ (finite and connected), define the *diameter* of S to be $\mathrm{diam}(S) = \max_{\mathbf{u},\mathbf{v}\in S} \|\mathbf{u}-\mathbf{v}\|_1$, where $\|\mathbf{w}\|_1$ is the L_1 norm of $\mathbf{w}$.

Problem 2 Design a hierarchical tile system $\mathcal{T} = (T, \tau)$ such that every producible terminal assembly $\hat{\alpha}$ has the same shape S, and for some $s \in T$ and concentrations function $\rho : T \to [0, 1]$, $\mathsf{T}(\mathcal{T}, \rho, s) = o(\mathrm{diam}(S))$.

It is provably impossible to achieve this with the seeded model [1, 4], since all assemblies in that model require expected time at least proportional to their diameter.

Key Results

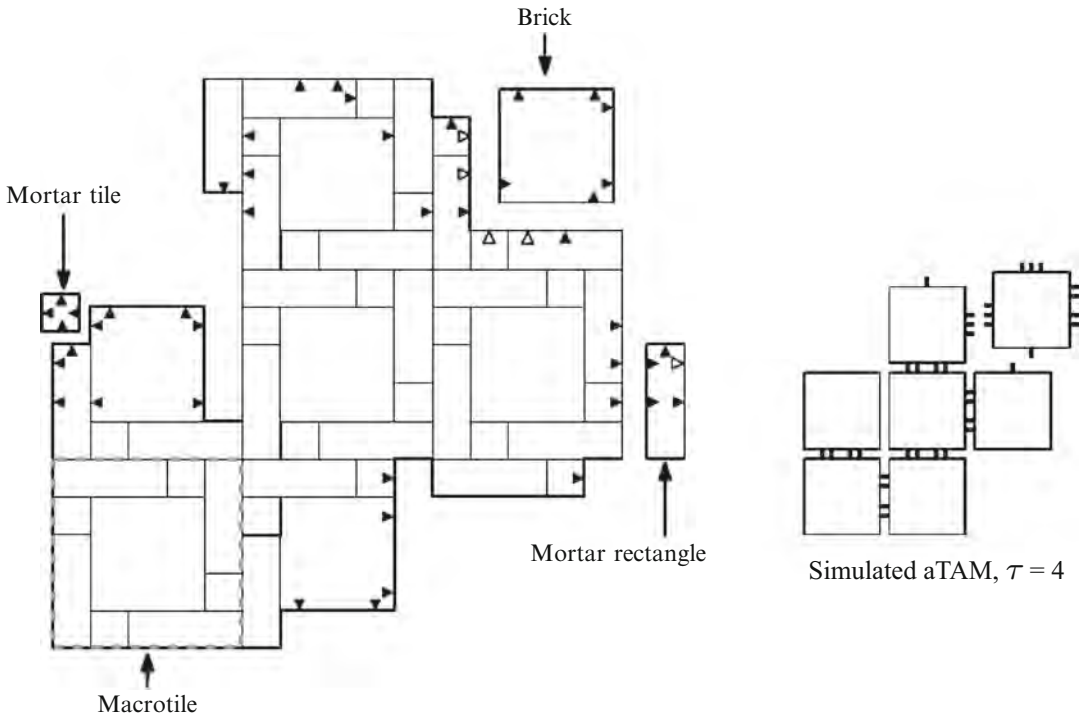
Power of Hierarchical Assembly Compared to Seeded

Cannon, Demaine, Demaine, Eisenstat, Patitz, Schweller, Summers, and Winslow [3] showed a solution to Problem 1. (They also showed several other ways in which the hierarchical model is more powerful than the seeded model, but we restrict attention to simulation here.) For the most part, temperature 2 seeded systems are as powerful as those at higher temperatures, but the simulation results of [3] hold for higher temperatures as well. In particular, they showed that every seeded temperature ≥ 4 tile system $\mathcal{T}$ can be simulated by a hierarchical temperature 4 tile system (as well as showing it is possible for temperature τ hierarchical tile systems to simulate temperature τ seeded tile systems for $\tau \in \{2, 3\}$, using similar logic to the higher-temperature construction). The definition of simulation has a parameter k indicating the resolution loss of the simulation. In fact, the simulation described in [3] requires only resolution loss $k = 5$.

Figure 1 shows an example of $\mathcal{S}$ simulating $\mathcal{T}$. The construction enforces the "simulation of dynamics" constraint that if and only if a single tile can attach in $\mathcal{T}$, and then a 5×5 macrotile representing it in $\mathcal{S}$ can assemble. It is critical that each tile type in $\mathcal{T}$ is represented by *more than one* type of macrotile in $\mathcal{S}$: each different type of macrotile represents a different subset of sides that can cooperate to allow the tile to bind. To achieve this, each macrotile consists of a central "brick" (itself a 3×3 block composed of 9 unique tile types with held together with strength-4 glues) surrounded by "mortar" (forming a ring around the central brick). Figure 1 shows "mortar rectangles" but, similarly to the brick, these are just 3×1 assemblies of 3 individual tile types with strength-4 glues. The logic of the system is such that if a brick B designed for a subset of cooperating sides $C \subseteq \{\mathsf{N}, \mathsf{S}, \mathsf{E}, \mathsf{W}\}$, then only if the mortar for all sides in C is present can B attach. Its attachment is required to fill in the remaining mortar representing the other sides in $\{\mathsf{N}, \mathsf{S}, \mathsf{E}, \mathsf{W}\} \setminus C$ that may not be present. Finally, those tiles enable the assembly of mortar in *adjacent* 5×5 blocks, to be ready for possible cooperation to bind bricks in those blocks.

Assembly Time

Chen and Doty [4] showed a solution to Problem 2, by proving that for infinitely many $n \in \mathbb{N}$, there is a (non-directed) hierarchical TAS



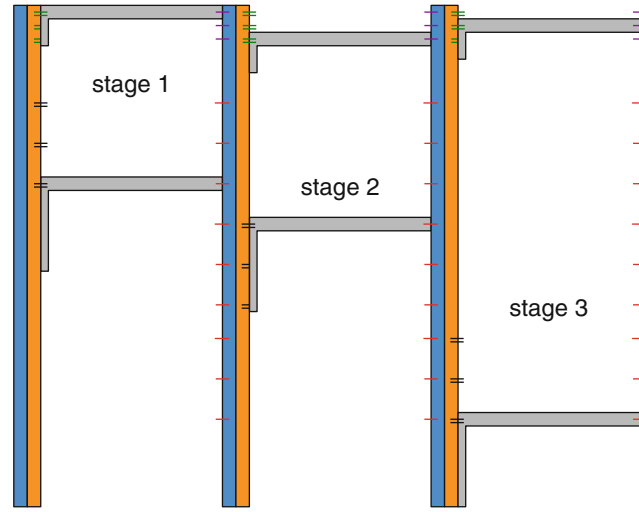
Hierarchical Self-Assembly, Fig. 1 Simulation of a seeded tile system $\mathcal{T}$ of temperature ≥ 4 by a hierarchical tile system $\mathcal{S}$ of temperature 4 (Figure taken from [3]). *Filled arrows* represent glues of strength 2, and *unfilled arrows* represent glues of strength 1. In the seeded tile system, the number of *dashes* on the side of a tile represent its strength

$\mathcal{T} = (T, 2)$ that strictly self-assembles an $n \times n'$ rectangle S, where $n' = o(n)$ (hence $\text{diam}(S) = \Theta(n)$), such that $|T| = O(\log n)$ and there is a tile type $s \in T$ and concentrations function $\rho : T \to [0, 1]$ such that $\mathsf{T}(\mathcal{T}, \rho, s) = O(n^{4/5} \log n)$.

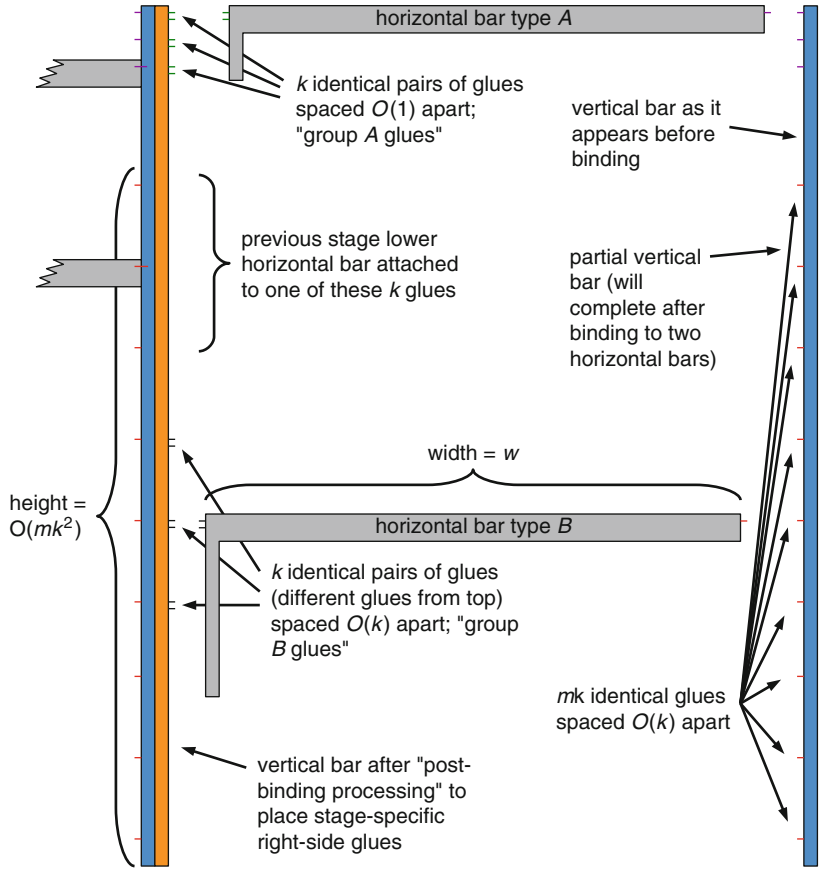
The construction consists of $m = n^{1/5}$ stages shown in Fig. 2, where each stage consists of the attachment of two "horizontal bars" to a single "vertical bar" as shown in Fig. 3. The vertical bar of the next stage then attaches to the right of the two horizontal bars, which cooperate to allow the binding because they each have a single strength 1 glue. All vertical bars are identical when they attach, but attachment triggers the growth of some tiles (shown in orange in Figs. 2 and 3) that make the attachment sites on the right side different from their locations in the previous stage, which is how the stages "count down" from m to 1.

The bars themselves are assembled in a "standard" way that requires time linear in the diameter of the bar, which is $w = n^{4/5}$ for a horizontal bar and $mk^2 = n^{3/5}$ (where k is a parameter that we set to be $n^{1/5}$) for a vertical bar. The speedup comes from the fact that each horizontal bar can attach to one of k different binding sites on a vertical bar, so the expected time for this to happen is factor k lower than if there were only a single binding site. The vertical "arm" on the left of each horizontal bar has the purpose of preventing any other horizontal bars from binding near it. Each stage also requires filler tiles to fill in the gap regions, but the time required for this is negligible compared to the time for all vertical and horizontal bars to attach.

Note that this construction is not directed: although every producible terminal assembly has the shape of an $n \times n'$ rectangle, there are many such terminal assemblies. Chen and Doty [4] also showed that for a class of directed systems called "partial order tile systems," no solution to Problem 2 exists: provably any such tile system



Hierarchical Self-Assembly, Fig. 2 High-level overview of interaction of "vertical bars" and "horizontal bars" to create the rectangle in the solution to Problem 2 that assembles in time sublinear in its diameter. Filler tiles fill in the empty regions. If glues overlap two regions then represent a formed bond. If glues overlap one region but not another, they are glues from the former region but are mismatched (and thus "covered and protected") by the latter region



Hierarchical Self-Assembly, Fig. 3 "Vertical bars" for the construction of a fast-assembling square, and their interaction with horizontal bars, as shown for a single stage of Fig. 2. "Type B" horizontal bars have a longer vertical arm than "Type A" since the glues they must block are farther apart

assembling a shape of diameter d requires expected time $\Omega(d)$.

Open Problems

It is known [2] that the tile complexity of assembling an $n \times k$ rectangle in the seeded aTAM, if $k < \frac{\log n}{\log\log n - \log\log\log n}$, is asymptotically lower bounded by $\Omega\left(\frac{n^{1/k}}{k}\right)$ and upper bounded by $O(n^{1/k})$. For the hierarchical model, the upper bound holds as well [2], but the strongest known lower bound is the information-theoretic $\Omega\left(\frac{\log n}{\log\log n}\right)$.

Question 1 What is the tile complexity of assembling an $n \times k$ rectangle in the hierarchical model, when $k < \frac{\log n}{\log\log n - \log\log\log n}$?

Problem Definition

Many algorithmic problems on spatial data can be solved efficiently if a suitable decomposition of the ambient space is available. Two desirable properties of the decomposition are that its cells have a nice shape – convex and/or of constant complexity – and that each cell intersects only a few objects from the given data set. Another desirable property is that the decomposition is hierarchical, meaning that the space is partitioned in a recursive manner. Popular hierarchical space decompositions include quadtrees and binary space partitions.

When the objects in the given data set are nonpoint objects, they can be fragmented by the partitioning process. This fragmentation has a negative impact on the storage requirements of the decomposition and on the efficiency of algorithms operating on it. Hence, it is desirable to minimize fragmentation. In this chapter, we describe methods to construct linear-size compressed quadtrees and binary space partitions for so-called low-density sets. To simplify the presentation, we describe the constructions in the plane. We use S to denote the set of n objects for which we want to construct a space decomposition and assume for simplicity that the objects in S are disjoint, convex, and of nonzero area.

Binary Space Partitions

A *binary space partition* for a set S of n objects in the plane is a recursive decomposition of the plane by lines, typically such that each cell in the final decomposition intersects only a few objects from S. The tree structure modeling this decomposition is called a *binary space partition tree*, or BSP *tree* for short – see Fig. 1 for an illustration. Thus, a BSP tree $\mathcal{T}$ for S can be defined as follows.

- If a predefined stopping criterion is met – often this is when $|S|$ is sufficiently small – then $\mathcal{T}$ consists of a single leaf where the set S is stored.
- Otherwise the root node v of $\mathcal{T}$ stores a suitably chosen *splitting line* ℓ. Let ℓ^- and ℓ^+ denote the half-planes lying to the left and to the right of ℓ, respectively (or, if ℓ is horizontal, below and above ℓ).
  - The left subtree of v is a BSP tree for $S^- := \{o \cap \ell^- : o \in S\}$, the set of object fragments lying in the half-plane ℓ^-.
  - The right subtree of v is a BSP tree for $S^+ := \{o \cap \ell^+ : o \in S\}$, the set of object fragments lying in the half-plane ℓ^+.

The *size* of a BSP tree is the total number of object fragments stored in the tree.

Compressed Quadtrees

Let $U = [0, 1]^2$ be the unit square. We say that a square $\sigma \subseteq U$ is a *canonical square* if there is an integer $k \geqslant 0$ such that σ is a cell of the regular subdivision of U into $2^k \times 2^k$ squares. A *donut* is the set-theoretic difference $\sigma_{\text{out}} \setminus \sigma_{\text{in}}$ of a canonical square σ_{out} and a canonical square $\sigma_{\text{in}} \subset \sigma_{\text{out}}$. A *compressed quadtree* $\mathcal{T}$ for a set P of points inside a canonical square σ defined as follows; see also Fig. 2 (middle).

- If a predefined stopping criterion is met – usually this is when $|P|$ is sufficiently small – then $\mathcal{T}$ consists of a single leaf storing the set P.
- If the stopping criterion is not met, then $\mathcal{T}$ is defined as follows. Let σ_{NE} denote the northeast quadrant of σ and let $P_{\text{NE}} := P \cap \sigma_{\text{NE}}$. Define σ_{SE}, σ_{SW}, σ_{NW} and P_{SE}, P_{SW}, P_{NW} similarly for the other three quadrants. (Here we should make sure that points on the boundary between quadrants are assigned to quadrants in a consistent manner.) Now $\mathcal{T}$ consists of a root node v with four or two children, depending on how many of the sets P_{NE}, P_{SE}, P_{SW}, P_{NW} are nonempty:
  - If at least two of the sets P_{NE}, P_{SE}, P_{SW}, P_{NW} are nonempty, then v has four children v_{NE}, v_{SE}, v_{SW}, v_{NW}. The child v_{NE} is the root of a compressed quadtree for the set P_{NE} inside the square σ_{NW}; the other three children are defined similarly for the point sets inside the other quadrants.
  - If only one of P_{NE}, P_{SE}, P_{SW}, P_{NW} is nonempty, then v has two children v_{in} and v_{out}. The child v_{in} is the root of a

Hierarchical Space Decompositions for Low-Density Scenes, Fig. 2 Construction of a compressed quadtree for a set of disks: take the bounding-box vertices (*left*), construct a compressed quadtree for the vertices (*middle*), and put the disks back in (*right*)

compressed quadtree for P inside σ_{in}, where σ_{in} is the smallest canonical square containing all points from P. The other child is a leaf corresponding to the donut $\sigma \setminus \sigma_{\text{in}}$.

A compressed quadtree for a set of n points has size $O(n)$.

Above we defined compressed quadtrees for point sets. In this chapter, we are interested in compressed quadtrees for nonpoint objects. These are defined similarly: each internal node corresponds to a canonical square, and each leaf is a canonical square or a donut. This time donuts need not be empty, but may intersect objects (although not too many). The right picture in Fig. 2 shows a compressed quadtree for a set of disks. The *size* of a compressed quadtree for a set of nonpoint objects is defined as the total number of object fragments stored in the tree. Because nonpoint objects may be split into fragments during the subdivision process, a compressed quadtree for nonpoint objects is not guaranteed to have linear size.

Low-Density Scenes

The main question we are interested in is the following: given a set S of n objects, can we construct a compressed quadtree or BSP tree with $O(n)$ leaves such that each leaf region intersects $O(1)$ objects? In general, the answer to this question is no. For compressed quadtrees, this can be seen by considering a set S of slanted parallel segments that are very close

together. A linear-size BSP tree cannot be guaranteed either: there are sets of n disjoint segments in the plane for which any BSP tree has size $\Omega(n \log n / \log\log n)$ [7]. In $\mathbb{R}^3$ the situation is even worse: there are sets of n disjoint triangles for which any BSP tree has size $\Omega(n^2)$ [5]. (Both bounds are tight: there are algorithms that guarantee a BSP tree of size $O(n \log n / \log\log n)$ in the plane [8] and of size $O(n^2)$ in $\mathbb{R}^3$ [6].) Fortunately, in practice, the objects for which we want to construct a space decomposition are often distributed nicely, which allows us to construct much smaller decompositions than for the worst-case examples mentioned above. To formalize this, we define the concept of *density* of a set of objects in $\mathbb{R}^d$.

Definition 1 The *density* of a set S of objects in $\mathbb{R}^d$, denoted density(S), is defined as the smallest number λ such that the following holds: any ball $b \subset \mathbb{R}^d$ intersects at most λ objects $o \in S$ such that $\text{diam}(o) \geqslant \text{diam}(b)$, where diam$(\cdot)$ denotes the diameter of an object.

As illustrated in Fig. 3(i), a set of n parallel segments can have density n if the segments are very close together. In most practical situations, however, the input objects are distributed nicely and the density will be small. For many classes of objects, one can even prove that the density is $O(1)$. For example, a set of disjoint disks in the plane has density at most 5. More generally, any set of disjoint objects that are *fat* – examples of fat objects are disks, squares, triangles whose minimum angle is lower bounded – has density $O(1)$ [3]. The main question now is: Is low density sufficient to guarantee a hierarchical space decomposition of linear size? The answer is yes, and constructing the space decomposition is surprisingly easy.

Key Results

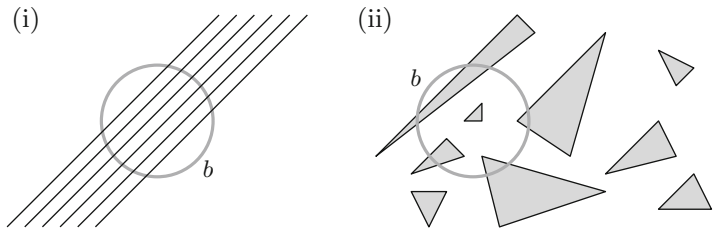
The construction of space decompositions for low-density sets is based on the following lemma. In the lemma, the square σ is considered to be open, that is, σ does not include its boundary. Let bb(o) denote the axis-aligned bounding box of an object o.

Lemma 1 *Let S be a set of n objects in the plane and let B_S denote the set of $4n$ vertices of the bounding boxes* bb(o) *of the objects $o \in S$. Let σ be any square region in the plane. Then the number of objects in S intersecting σ is at most $k + 4\lambda$, where k is the number of bounding-box vertices inside σ and $\lambda :=$* density(S).

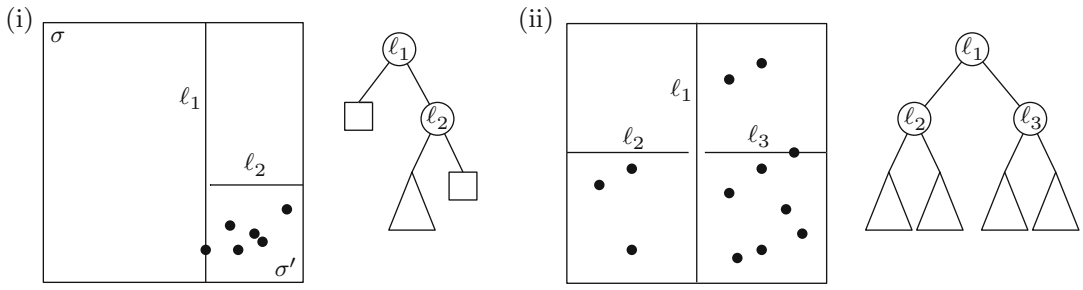
With Lemma 1 in hand, it is surprisingly simple to construct BSP trees or compressed quadtrees of small size for any given set S whose density is small.

Binary Space Partitions

For BSP trees we proceed as follows. Let B_S be the set of vertices of the bounding boxes of the objects in S. In a generic step in the recursive construction of $\mathcal{T}$, we are given a square σ and the set of points $B_S(\sigma) := B_S \cap \sigma$. Initially σ is a square containing all points of B_S. When $B_S = \emptyset$, then $\mathcal{T}$ consists of a single leaf and the



Hierarchical Space Decompositions for Low-Density Scenes, Fig. 3 (**i**) The ball b intersects all n segments and the segments have diameter larger than diam(b), so the density of the set of segments is n. (**ii**) Any ball b, no matter where it is placed or what its size is, intersects at most three triangles with diameter at least diam(b), so the density of the set of triangles is 3



Hierarchical Space Decompositions for Low-Density Scenes, Fig. 4 Two cases in the construction of the BSP tree

recursion ends; otherwise we proceed as follows. Let σ_{NE}, σ_{SE}, σ_{SW}, and σ_{NW} denote the four quadrants of σ. We now have two cases, illustrated in Fig. 4.

Case (i): all points in $B_S(\sigma)$ lie in the same quadrant. Let σ' be the smallest square sharing a corner with σ and containing all points from $B_S(\sigma)$ in its interior or on its boundary. Split σ into three regions using a vertical and a horizontal splitting line such that σ' is one of those regions; see Fig. 4(i). Recursively construct a BSP tree for the square σ' with respect to the set $B_S(\sigma')$ of points lying in the interior of σ'.

Case (ii): not all points in $B_S(\sigma)$ lie in the same quadrant. Split σ into four quadrants using a vertical and two horizontal splitting lines; see Fig. 4(ii). Recursively construct a BSP tree for each quadrant with respect to the points lying in its interior.

The construction produces a subdivision of the initial square into $O(n)$ leaf regions, which are squares or rectangles and which do not contain points from B_S in their interior. Using Lemma 1, one can argue that each leaf region intersects $O(\lambda)$ objects.

Compressed Quadtrees

The construction of a compressed quadtree for a low-density set S is also based on the set B_S of bounding-box vertices: we construct a compressed quadtree for B_S, where we stop the recursive construction when a square contains bounding-box vertices from at most one object in S or when all bounding-box vertices inside the square coincide. Figure 2 illustrates the process. The resulting compressed quadtree has $O(n)$ leaf regions, which are canonical squares or donuts. Again using Lemma 1, one can argue that each leaf region intersects $O(\lambda)$ objects.

Improvements and Generalizations

The constructions above guarantee that each region in the space decomposition is intersected by $O(\lambda)$ objects and that the number of regions is $O(n)$. Hence, the total number of the object fragments is $O(\lambda n)$. The main idea behind the introduction of the density λ is that in practice λ is often a small constant. Nevertheless, it is (at least from a theoretical point of view) desirable to get rid of the dependency on λ in the number of fragments. This is possible by reducing the number of regions in the decomposition to (n/λ). To this end, we allow leaf regions to contain up to $O(\lambda)$ bounding-box vertices. Note that Lemma 1 implies that a square with $O(\lambda)$ bounding-box vertices inside intersects $O(\lambda)$ objects. If implemented correctly, this idea leads to decompositions with $O(n/\lambda)$ regions each of which intersects $O(\lambda)$ objects, both for binary space partitions [2, Section 12.5] and for compressed quadtrees [4]. The results can also be generalized to higher dimensions, giving the following theorem.

Theorem 1 *Let S be a set of n objects in $\mathbb{R}^d$ and let $\lambda :=$ density(S). There is a binary space partition for S consisting of $O(n/\lambda)$ leaf regions, each intersecting $O(\lambda)$ objects. Similarly, there is a compressed quadtree with $O(n/\lambda)$ leaf regions, each intersecting $O(\lambda)$ objects.*

High Performance Algorithm Engineering for Large-Scale Problems

David A. Bader
College of Computing, Georgia Institute of Technology, Atlanta, GA, USA

Keywords

Experimental algorithmics

Years and Authors of Summarized Original Work

2005; Bader

Problem Definition

Algorithm engineering refers to the process required to transform a pencil-and-paper algorithm into a robust, efficient, well tested, and easily usable implementation. Thus it encompasses a number of topics, from modeling cache behavior to the principles of good software engineering; its main focus, however, is experimentation. In that sense, it may be viewed as a recent outgrowth of *Experimental Algorithmics* [14], which is specifically devoted to the development of methods, tools, and practices for assessing and refining algorithms through experimentation. The *ACM Journal of Experimental Algorithmics (JEA)*, at URL www.jea.acm.org, is devoted to this area.

High-performance algorithm engineering [2] focuses on one of the many facets of algorithm engineering: speed. The high-performance aspect does not immediately imply parallelism; in fact, in any highly parallel task, most of the impact of high-performance algorithm engineering tends to come from refining the serial part of the code.

The term *algorithm engineering* was first used with specificity in 1997, with the organization of the first *Workshop on Algorithm Engineering (WAE 97)*. Since then, this workshop has taken place every summer in Europe. The 1998 *Workshop on Algorithms and Experiments (ALEX98)* was held in Italy and provided a discussion forum for researchers and practitioners interested in the design, analyzes and experimental testing of exact and heuristic algorithms. A sibling workshop was started in the Unites States in 1999, the *Workshop on Algorithm Engineering and Experiments (ALENEX99)*, which has taken place every winter, colocated with the *ACM/SIAM Symposium on Discrete Algorithms (SODA)*.

Key Results

Parallel computing has two closely related main uses. First, with more memory and storage resources than available on a single workstation, a parallel computer can solve correspondingly larger instances of the same problems. This

increase in size can translate into running higher-fidelity simulations, handling higher volumes of information in data-intensive applications, and answering larger numbers of queries and datamining requests in corporate databases. Secondly, with more processors and larger aggregate memory subsystems than available on a single workstation, a parallel computer can often solve problems faster. This increase in speed can also translate into all of the advantages listed above, but perhaps its crucial advantage is in turnaround time. When the computation is part of a real-time system, such as weather forecasting, financial investment decision-making, or tracking and guidance systems, turnaround time is obviously the critical issue. A less obvious benefit of shortened turnaround time is higher-quality work: when a computational experiment takes less than an hour, the researcher can afford the luxury of exploration – running several different scenarios in order to gain a better understanding of the phenomena being studied.

In algorithm engineering, the aim is to present repeatable results through experiments that apply to a broader class of computers than the specific make of computer system used during the experiment. For sequential computing, empirical results are often fairly machine-independent. While machine characteristics such as word size, cache and main memory sizes, and processor and bus speeds differ, comparisons across different uniprocessor machines show the same trends. In particular, the number of memory accesses and processor operations remains fairly constant (or within a small constant factor). In high-performance algorithm engineering with parallel computers, on the other hand, this portability is usually absent: each machine and environment is its own special case. One obvious reason is major differences in hardware that affect the balance of communication and computation costs – a true shared-memory machine exhibits very different behavior from that of a cluster based on commodity networks.

Another reason is that the communication libraries and parallel programming environments (e.g., MPI [12], OpenMP [16], and High-Performance Fortran [10]), as well as the parallel algorithm packages (e.g., fast Fourier transforms using FFTW [6] or parallelized linear algebra routines in ScaLAPACK [4]), often exhibit differing performance on different types of parallel platforms. When multiple library packages exist for the same task, a user may observe different running times for each library version even on the same platform. Thus a running-time analysis should clearly separate the time spent in the user code from that spent in various library calls. Indeed, if particular library calls contribute significantly to the running time, the number of such calls and running time for each call should be recorded and used in the analysis, thereby helping library developers focus on the most cost-effective improvements. For example, in a simple message-passing program, one can characterize the work done by keeping track of sequential work, communication volume, and number of communications. A more general program using the collective communication routines of MPI could also count the number of calls to these routines. Several packages are available to instrument MPI codes in order to capture such data (e.g., MPICH's nupshot [8], Pablo [17], and Vampir [15]). The SKaMPI benchmark [18] allows running-time predictions based on such measurements even if the target machine is not available for program development. SKaMPI was designed for robustness, accuracy, portability, and efficiency; For example, SKaMPI adaptively controls how often measurements are repeated, adaptively refines message-length and step-width at "interesting" points, recovers from crashes, and automatically generates reports.

Applications

The following are several examples of algorithm engineering studies for high-performance and parallelcomputing.

1. Bader's prior publications (see [2] and http://www.cc.gatech.edu/~bader) contain many empirical studies of parallel algorithms for

combinatorial problems like sorting, selection, graph algorithms, and image processing.

2. In a recent demonstration of the power of high-performance algorithm engineering, a million-fold speed-up was achieved through a combination of a 2,000-fold speedup in the serial execution of the code and a 512-fold speedup due to parallelism (a speed-up, however, that will scale to any number of processors) [13]. (In a further demonstration of algorithm engineering, additional refinements in the search and bounding strategies have added another speedup to the serial part of about 1,000, for an overall speedup in excess of 2 billion)
3. JáJá and Helman conducted empirical studies for prefix computations, sorting, and list-ranking, on symmetric multiprocessors. The sorting research (see [9]) extends Vitter's external Parallel Disk Model to the internal memory hierarchy of SMPs and uses this new computational model to analyze a general-purpose sample sort that operates efficiently in shared-memory. The performance evaluation uses nine well-defined benchmarks. The benchmarks include input distributions commonly used for sorting benchmarks (such as keys selected uniformly and at random), but also benchmarks designed to challenge the implementation through load imbalance and memory contention and to circumvent algorithmic design choices based on specific input properties (such as data distribution, presence of duplicate keys, pre-sorted inputs, etc.).
4. In [3] Blelloch et al. compare through analysis and implementation three sorting algorithms on the Thinking Machines CM-2. Despite the use of an outdated (and no longer available) platform, this paper is a gem and should be required reading for every parallel algorithm designer. In one of the first studies of its kind, the authors estimate running times of four of the machine's primitives, then analyze the steps of the three sorting algorithms in terms of these parameters. The experimental studies of the performance are normalized to provide clear comparison of how the algorithms scale with input size on a $32K$-processor CM-2.
5. Vitter et al. provide the canonical theoretic foundation for I/O-intensive experimental algorithmics using external parallel disks (e.g., see [1, 19, 20]). Examples from sorting, FFT, permuting, and matrix transposition problems are used to demonstrate the parallel disk model.
6. Juurlink and Wijshoff [11] perform one of the first detailed experimental accounts on the preciseness of several parallel computation models on five parallel platforms. The authors discuss the predictive capabilities of the models, compare the models to find out which allows for the design of the most efficient parallel algorithms, and experimentally compare the performance of algorithms designed with the model versus those designed with machine-specific characteristics in mind. The authors derive model parameters for each platform, analyses for a variety of algorithms (matrix multiplication, bitonic sort, sample sort, all-pairs shortest path), and detailed performance comparisons.
7. The LogP model of Culler et al. [5] provides a realistic model for designing parallel algorithms for message-passing platforms. Its use is demonstrated for a number of problems, including sorting.
8. Several research groups have performed extensive algorithm engineering for high-performance numerical computing. One of the most prominent efforts is that led by Dongarra for ScaLAPACK [4], a scalable linear algebra library for parallel computers. ScaLAPACK encapsulates much of the high-performance algorithm engineering with significant impact to its users who require efficient parallel versions of matrix–matrix linear algebra routines. New approaches for automatically tuning the sequential library (e.g., LAPACK) are now available as the ATLAS package [21].

Open Problems

All of the tools and techniques developed over the last several years for algorithm engineering are applicable to high-performance algorithm engineering. However, many of these tools need

further refinement. For example, cache-efficient programming is a key to performance but it is not yet well understood, mainly because of complex machine-dependent issues like limited associativity, virtual address translation, and increasingly deep hierarchies of high-performance machines. A key question is whether one can find simple models as a basis for algorithm development. For example, cache-oblivious algorithms [7] are efficient at all levels of the memory hierarchy in theory, but so far only few work well in practice. As another example, profiling a running program offers serious challenges in a serial environment (any profiling tool affects the behavior of what is being observed), but these challenges pale in comparison with those arising in a parallel or distributed environment (for instance, measuring communication bottlenecks may require hardware assistance from the network switches or at least reprogramming them, which is sure to affect their behavior). Designing efficient and portable algorithms for commodity multicore and manycore processors is an open challenge.

Problem Definition

The framework of Holant problems is intended to capture a class of sum-of-product computations in a more refined way than counting CSP problems and is inspired by Valiant's holographic algorithms [12] (also cf. entry ▸ Holographic Algorithms). A constraint function f, or *signature*, is a mapping from $[\kappa]^n$ to $\mathbb{C}$, representing a local contribution to a global sum. Here, $[\kappa]$ is a finite domain set, and n is the arity of f. The range is usually taken to be $\mathbb{C}$, but it can be replaced by any commutative semiring. A Holant problem Holant($\mathcal{F}$) is parameterized by a set of constraint functions $\mathcal{F}$. We usually focus on the Boolean domain, namely, $\kappa = 2$. For consideration of models of computation, we restrict function values to be complex algebraic numbers.

We allow multigraphs, namely, graphs with self-loops and parallel edges. A *signature grid* $\Omega = (G, \pi)$ of Holant($\mathcal{F}$) consists of a graph $G = (V, E)$, where π assigns each vertex $v \in V$ and its incident edges with some $f_v \in \mathcal{F}$ and its input variables. We say Ω is a *planar signature grid* if G is planar. The Holant problem on instance Ω is to evaluate

$$\text{Holant}(\Omega; \mathcal{F}) = \sum_{\sigma} \prod_{v \in V} f_v(\sigma \mid_{E(v)}),$$

a sum over all edge labelings $\sigma : E \to [\kappa]$, where $E(v)$ denotes the incident edges of v and $\sigma \mid_{E(v)}$ denotes the restriction of σ to $E(v)$. This is also known as the partition function in the statistical physics literature.

Formally, a set of signatures $\mathcal{F}$ defines the following Holant problem:

Name Holant($\mathcal{F}$)
Instance A *signature grid* $\Omega = (G, \pi)$
Output Holant($\Omega; \mathcal{F}$)

The problem Pl-Holant($\mathcal{F}$) is defined similarly using a planar signature grid.

A function f_v can be represented by listing its values in lexicographical order as in a truth table, which is a vector in $\mathbb{C}^{\kappa^{\deg(v)}}$ or as a tensor in $(\mathbb{C}^{\kappa})^{\otimes \deg(v)}$. Special focus has been put on *symmetric* signatures, which are functions invariant under any permutation of the input. An example is the EQUALITY signature $=_n$ of arity n. A Boolean symmetric function f of arity n can be listed as $[f_0, f_1, \ldots, f_n]$, where f_w is the function value of f when the input has Hamming

weight w. Using this notation, an EQUALITY signature is $[1, 0, \ldots, 0, 1]$. Another example is the EXACTONE signature $[0, 1, 0, \ldots, 0]$. Clearly, the Holant problem defined by this signature counts the number of perfect matchings.

The set $\mathcal{F}$ is allowed to be an infinite set. For Holant($\mathcal{F}$) to be tractable, the problem must be computable in polynomial time even when the description of the signatures in the input Ω is included in the input size. In contrast, we say Holant($\mathcal{F}$) is #P-hard if there exists a finite subset of $\mathcal{F}$ for which the problem is #P-hard.

The Holant framework is a generalization and refinement of both counting graph homomorphisms and counting constraint satisfaction problems (see entry ▸Complexity Dichotomies for Counting Graph Homomorphisms for more details and results).

Key Results

The Holant problem was introduced by Cai, Lu, and Xia [3], which also contains a dichotomy of Holant* for symmetric Boolean complex functions. The notation Holant* means that all unary functions are assumed to be available. This restriction is later weakened to only allow two constant functions that pin a variable to 0 or 1. This framework is called Holant^c. In [5], a dichotomy of Holant^c is obtained. The need to assume some freely available functions is finally avoided in [10]. In this paper, Huang and Lu proved a dichotomy for Holant but with the caveat that the functions must be real weighted. This result was later improved by Cai, Guo, and Williams [6], who proved a dichotomy for Holant parameterized by any set of symmetric Boolean complex functions.

We will give some necessary definitions and then state the dichotomy from [6]. First are several tractable families of functions over the Boolean domain.

Definition 1 A signature f of arity n is *degenerate* if there exist unary signatures $u_j \in \mathbb{C}^2$ $(1 \le j \le n)$ such that $f = u_1 \otimes \cdots \otimes u_n$. A symmetric degenerate signature has the form $u^{\otimes n}$.

Definition 2 A k-ary function $f(x_1, \ldots, x_k)$ is of *affine* type if it has the form

$$\lambda \chi_{Ax=0} \cdot \sqrt{-1}^{\sum_{j=1}^{n} \langle \alpha_j, x \rangle},$$

where $\lambda \in \mathbb{C}$, $x = (x_1, x_2, \ldots, x_k, 1)^{\mathrm{T}}$, A is a matrix over $\mathbb{F}_2$, α_j is a vector over $\mathbb{F}_2$, and χ is a 0–1 indicator function such that $\chi_{Ax=0}$ is 1 iff $Ax = 0$. Note that the dot product $\langle \alpha_j, x \rangle$ is calculated over $\mathbb{F}_2$, while the summation $\sum_{j=1}^{n}$ on the exponent of $i = \sqrt{-1}$ is evaluated as a sum mod 4 of 0–1 terms. We use $\mathscr{A}$ to denote the set of all affine-type functions.

An alternative but equivalent form for an affine-type function is $\lambda \chi_{Ax=0} \cdot \sqrt{-1}^{Q(x_1, x_2, \ldots, x_k)}$ where $Q(\cdot)$ is a quadratic form with integer coefficients that are even for every cross term.

Definition 3 A function is of *product type* if it can be expressed as a product of unary functions, binary equality functions ($[1, 0, 1]$), and binary disequality functions ($[0, 1, 0]$), each applied to some of its variables. We use $\mathscr{P}$ to denote the set of product-type functions.

Definition 4 A function f is called *vanishing* if the value Holant($\Omega; \{f\}$) is 0 for every signature grid Ω. We use $\mathscr{V}$ to denote the set of vanishing functions.

For vanishing signatures, we need some more definitions.

Definition 5 An arity n symmetric signature of the form $f = [f_0, f_1, \ldots, f_n]$ is in $\mathscr{R}_t^+$ for a nonnegative integer $t \ge 0$ if $t > n$ or for any $0 \le k \le n - t$, $f_k, \ldots, f_{k+t}$ satisfy the recurrence relation

$$\binom{t}{t} i^t f_{k+t} + \binom{t}{t-1} i^{t-1} f_{k+t-1} + \cdots + \binom{t}{0} i^0 f_k = 0. \quad (1)$$

We define $\mathscr{R}_t^-$ similarly but with $-i$ in place of i in (1).

With $\mathscr{R}_t^{\pm}$, one can define the recurrence degree of a function f.

Definition 6 For a nonzero symmetric signature f of arity n, it is of *positive* (resp. *negative*) *recurrence degree* $t \le n$, denoted by $\mathrm{rd}^+(f) = t$ (resp. $\mathrm{rd}^-(f) = t$), if and only if $f \in \mathscr{R}_{t+1}^+ - \mathscr{R}_t^+$ (resp. $f \in \mathscr{R}_{t+1}^- - \mathscr{R}_t^-$). If f is the all-zero signature, we define $\mathrm{rd}^+(f) = \mathrm{rd}^-(f) = -1$.

In [6], it is shown that $f \in \mathscr{V}$ if and only if for either $\sigma = +$ or $-$, we have $2\mathrm{rd}^\sigma(f) < \mathrm{arity}(f)$. Accordingly, we split the set $\mathscr{V}$ of vanishing signatures in two.

Definition 7 We define $\mathscr{V}^\sigma$ for $\sigma \in \{+, -\}$ as

$$\mathscr{V}^\sigma = \{f \mid 2\mathrm{rd}^\sigma(f) < \mathrm{arity}(f)\}.$$

To state the dichotomy, we also need the notion of $\mathcal{F}$-transformable. For a matrix $T \in \mathbb{C}^{2\times 2}$, and a signature set $\mathcal{F}$, define $T\mathcal{F} = \{g \mid \exists f \in \mathcal{F}$ of arity n, $g = T^{\otimes n} f\}$. Here, we view the signatures as column vectors. Let $=_2$ be the equality function of arity 2.

Definition 8 A signature set $\mathcal{F}'$ is $\mathcal{F}$-transformable if there exists a non-singular matrix $T \in \mathbb{C}^{2\times 2}$ such that $\mathcal{F}' \subseteq T\mathcal{F}$ and $(=_2)T^{\otimes 2} \in \mathcal{F}$.

If a set of functions $\mathcal{F}'$ is $\mathcal{F}$-transformable and $\mathcal{F}$ is a tractable set, then Holant($\mathcal{F}'$) is tractable as well.

The dichotomy of Holant problems over symmetric Boolean complex functions is stated as follows.

Theorem 1 ([6]) *Let $\mathcal{F}$ be any set of symmetric, complex-valued signatures in Boolean variables. Then,* Holant($\mathcal{F}$) *is #P-hard unless $\mathcal{F}$ satisfies one of the following conditions, in which case the problem is in P:*

1. *All nondegenerate signatures in $\mathcal{F}$ are of arity at most 2;*
2. *$\mathcal{F}$ is $\mathscr{A}$-transformable;*
3. *$\mathcal{F}$ is $\mathscr{P}$-transformable;*
4. *$\mathcal{F} \subseteq \mathscr{V}^\sigma \cup \{f \in \mathscr{R}_2^\sigma \mid \mathrm{arity}(f) = 2\}$ for some $\sigma \in \{+, -\}$;*
5. *All nondegenerate signatures in $\mathcal{F}$ are in $\mathscr{R}_2^\sigma$ for some $\sigma \in \{+, -\}$.*

Theorem 1 is about Holant problems parameterized by symmetric Boolean complex functions over general graphs. Holant problems are studied in other settings as well. For planar graphs, [2] contains a dichotomy for Holant^c with real symmetric functions. There are signature sets that are #P-hard over general graphs but tractable over planar graphs. The algorithms for such sets are due to Valiant's holographic algorithms and the theory of matchgates [1, 12].

Another generalization looks at a broader range of functions. One may consider asymmetric functions as in [4], which contains a dichotomy for Holant* problems defined by asymmetric Boolean complex functions. One can also consider functions of larger domain size. For domain size 3, [7] contains a dichotomy for a single arity 3 symmetric complex function in the Holant* setting. For any constant domain size, [8] contains a dichotomy for a single arity 3 complex weighted function that satisfies a strong symmetry property.

One can consider constraint functions with a range other than $\mathbb{C}$. Replacing $\mathbb{C}$ by some finite field $\mathbb{F}_p$ for some prime p defines counting problems modulo p. The case $p = 2$ is called parity Holant problems. It is of special interest because computing the permanent modulo 2 is tractable, which implies a family of tractable matchgate functions even over general graphs. For parity Holant problems, a complete dichotomy for symmetric functions is obtained by Guo, Lu, and Valiant [9].

Open Problems

Unlike the progress in the general graph setting, the strongest known dichotomy results for planar Holant problems are rather limited. These planar dichotomies showed that newly tractable problems over planar graphs are captured by holographic algorithms with matchgates, but with restrictions like symmetric functions or regular graphs. The theory of holographic algorithms

with matchgates can be applied to planar graphs and asymmetric signatures. A true test of its power would be to obtain an asymmetric complex weighted dichotomy of planar Holant problems. The situation is similarly limited for higher domain sizes, where things seem considerably more complicated. A reasonable first step in this direction would be to consider some restricted (yet still powerful) family of functions.

Despite the success for $\mathbb{F}_2$, little is known about the complexity of Holant problems over other finite fields or semirings. As Valiant showed in [11], counting problems modulo some finite modulus include some interesting and surprising phenomena. It deserves further research.

Problem Definition

Holographic algorithm, introduced by L. Valiant [11], is an algorithm design technique rather than a single algorithm for a particular problem. In essence, these algorithms are reductions to the FKT algorithm [7–9] to count the number of perfect matchings in a planar graph in polynomial time. Computation in these algorithms is expressed and interpreted through a choice of linear basis vectors in an exponential "holographic" mix, and then it is carried out by the FKT method via the Holant Theorem. This methodology has

produced polynomial time algorithms for a variety of problems ranging from restrictive versions of satisfiability, vertex cover, to other graph problems such as edge orientation and node/edge deletion. No polynomial time algorithms were known for these problems, and some minor variations are known to be NP-hard (or even #P-hard).

Let $G = (V, E, W)$ be a weighted undirected planar graph, where V, E, and W are sets of vertices, edges, and edge weights, respectively. A matchgate is a tuple (G, X) where $X \subseteq V$ is a set of external nodes on the outer face. A matchgate is considered a generator or a recognizer matchgate when the external nodes are considered output or input nodes, respectively. They differ mainly in the way they are transformed. The external nodes are ordered clockwise on the external face. Γ is called an odd (resp. even) matchgate if it has an odd (resp. even) number of nodes.

Each matchgate is assigned a *signature* tensor. A generator Γ with m output nodes is assigned a contravariant tensor $\mathbf{G} \in V_0^m$ of type $\binom{m}{0}$, where V_0^m is the tensor space spanned by the m-fold tensor products of the standard basis $\mathbf{b} = [\mathbf{b}_0, \mathbf{b}_1] = \left[\binom{1}{0}, \binom{0}{1}\right]$. The tensor $\mathbf{G}$ under the standard basis $\mathbf{b}$ has the form

$$\sum G^{i_1 i_2 \ldots i_m} \mathbf{b}_{i_1} \otimes \mathbf{b}_{i_2} \otimes \cdots \otimes \mathbf{b}_{i_m},$$

where

$$G^{i_1 i_2 \ldots i_m} = \text{PerfMatch}(G - Z).$$

Here Z is the subset of the output nodes of Γ having the characteristic sequence $\chi_Z = i_1 i_2 \ldots i_m \in \{0,1\}^m$, $\text{PerfMatch}(G - Z) = \sum_M \prod_{(i,j)\in M} w_{ij}$ is a sum over all perfect matchings M in the graph $G - Z$ obtained from G by removing Z and its incident edges, and w_{ij} is the weight of the edge (i, j). Similarly a recognizer Γ' with underlying graph G' having m input nodes is assigned a covariant tensor $\mathbf{R} \in V_m^0$ of type $\binom{0}{m}$. This tensor under the standard (dual) basis $\mathbf{b}^*$ has the form

$$\sum R_{i_1 i_2 \ldots i_m} \mathbf{b}^{i_1} \otimes \mathbf{b}^{i_2} \otimes \cdots \otimes \mathbf{b}^{i_m},$$

where

$$R_{i_1 i_2 \ldots i_m} = \text{PerfMatch}(G' - Z),$$

and Z is the subset of the input nodes of Γ' having the characteristic sequence $\chi_Z = i_1 i_2 \ldots i_m$.

As a contravariant tensor, $\mathbf{G}$ transforms as follows. Under a basis transformation $\boldsymbol{\beta}_j = \sum_i \mathbf{b}_i t_j^i$,

$$(G')^{j_1 j_2 \cdots j_m} = \sum G^{i_1 i_2 \ldots i_m} \tilde{t}_{i_1}^{j_1} \tilde{t}_{i_2}^{j_2} \cdots \tilde{t}_{i_m}^{j_m},$$

where $(\tilde{t}_i^j)$ is the inverse matrix of (t_j^i). Similarly, $\mathbf{R}$ transforms as a covariant tensor, namely,

$$(R')_{j_1 j_2 \ldots j_m} = \sum R_{i_1 i_2 \ldots i_m} t_{j_1}^{i_1} t_{j_2}^{i_2} \cdots t_{j_m}^{i_m}.$$

A signature is *symmetric* if each entry only depends on the Hamming weight of the index $i_1 i_2 \ldots i_m$. This notion is invariant under a basis transformation. A symmetric signature is denoted by $[\sigma_0, \sigma_1, \ldots, \sigma_m]$, where σ_i denotes the value of a signature entry whose Hamming weight of its index is i.

A *matchgrid* $\Omega = (A, B, C)$ is a weighted planar graph consisting of a disjoint union of: a set of g generators $A = (A_1, \ldots, A_g)$, a set of r recognizers $B = (B_1, \ldots, B_r)$, and a set of f connecting edges $C = (C_1, \ldots, C_f)$, where each C_i edge has weight 1 and joins an output node of a generator with an input node of a recognizer, so that every input and output node in every constituent matchgate has exactly one such incident connecting edge.

Let $\mathbf{G} = \bigotimes_{i=1}^{g} \mathbf{G}(A_i)$ be the tensor product of all the generator signatures, and let $\mathbf{R} = \bigotimes_{j=1}^{r} \mathbf{R}(B_j)$ be the tensor product of all the recognizer signatures. Then Holant_Ω is defined to be the contraction of the two product tensors, under some basis $\boldsymbol{\beta}$, where the corresponding indices match up according to the f connecting edges C_k:

$$\text{Holant}_{\Omega} = \langle \mathbf{R}, \mathbf{G} \rangle = \sum_{x \in \boldsymbol{\beta}^{\otimes f}} \left\{ [\Pi_{1 \le i \le g} \mathbf{G}(A_i, x|_{A_i})] \cdot [\Pi_{1 \le j \le r} \mathbf{R}(B_j, x^*|_{B_j})] \right\}. \quad (1)$$

If we write the covariant tensor $\mathbf{R}$ as a row vector of dimension 2^f, write the contravariant tensor $\mathbf{G}$ as a column vector of dimension 2^f, both indexed by some common ordering of the connecting edges, then Holant_{Ω} is just the dot product of these two vectors. Valiant's beautiful Holant Theorem is as follows:

Theorem 1 (Valiant) *For any matchgrid Ω over any basis $\boldsymbol{\beta}$, let G be its underlying weighted graph, then*

$$\text{Holant}_{\Omega} = \text{PerfMatch}(G).$$

The FKT algorithm can compute the perfect matching polynomial $\text{PerfMatch}(G)$ for a planar graph in polynomial time. This gives a polynomial time algorithm to compute Holant_{Ω}.

Key Results

To design a holographic algorithm for a given problem, the creative part is to formalize the given problem as a Holant problem. The theory of holographic algorithms is trying to answer the second question: given a Holant problem, can we find a basis transformation so that all the signatures in the Holant problem can be realized by some matchgates on that basis? More formally, we want to solve the following simultaneous realizability problem (SRP).

Definition 1 Simultaneous Realizability Problem (SRP):

Input: A set of constraint functions for generators and recognizers.

Output: A common basis under which these functions can be simultaneously realized by matchgate signatures, if any exists; "NO" if they are not simultaneously realizable.

The theory of matchgates and holographic algorithms provides a systematic understanding of which constraint functions can be realized by matchgates, the structure for the bases, and finally solve the simultaneous realizability problem.

Matchgate Identities

There is a set of algebraic identities [1, 6] which completely characterizes signatures directly realizable without basis transformation by matchgates for any number of inputs and outputs. These identities are derived from Grassmann-Plücker identities for Pfaffians.

Patterns α, β are m-bit strings, i.e., $\alpha, \beta \in \{0,1\}^m$. A position vector $P = \{p_i\}, i \in [l]$ is a subsequence of $\{1, 2, \ldots, m\}$, i.e., $p_i \in [m]$ and $p_1 < p_2 < \cdots < p_l$. We also use p to denote the m-bit string, whose $(p_1, p_2, \ldots, p_l)$-th bits are 1 and others are 0. Let $e_i \in \{0,1\}^m$ be the pattern with 1 in the i-th bit and 0 elsewhere. Let $\alpha, \beta \in \{0,1\}^m$ be any pattern, and let $P = \{p_i\} = \alpha + \beta$, $i \in [l]$ be their bit-wise XOR as a position vector. Then, we have the following identity:

$$\sum_{i=1}^{l} (-1)^i G^{\alpha + e_{p_i}} G^{\beta + e_{p_i}} = 0. \quad (2)$$

A tensor $\mathbf{G} = (G^{i_1, \ldots, i_m})$ is realizable as the signature, without basis transformation, of some planar matchgate iff it satisfies the matchgate identities (2) for all α and β.

Basis Collapse

When we consider basis transformations for holographic algorithms, we mainly focus on

invertible transformations, and these are bases of dimension 2. However, in a paper called "accidental algorithm" [10], Valiant showed that a basis of dimension 4 can be used to solve in P an interesting (restrictive SAT) counting problem mod 7. In a later paper [4], we have shown, among other things, that for this particular problem, this use of bases of size 2 is unnecessary. Then, in a sequence of two papers [2, 3], we completely resolve the problem of the power of higher dimensional bases. We prove that 2-dimensional bases are universal for holographic algorithms in the Boolean domain.

Theorem 2 (Basis Collapse Theorem) *Any holographic algorithm on a basis of any dimension which employs at least one nondegenerate generator can be efficiently transformed to a holographic algorithm in a basis of dimension 2. More precisely, if generators $G_1, G_2, \ldots, G_s$ and recognizers $R_1, R_2, \ldots, R_t$ are simultaneously realizable on a basis T of any dimension, and not all generators are degenerate, then all the generators and recognizers are simultaneously realizable in a basis $\hat{T}$ of dimension 2.*

From Art to Science

Based on the characterization for matchgate signatures and basis transformations, we can solve the simultaneous realizability problem [5]. In order to investigate the realizability of signatures, it is useful to introduce a basis manifold $\mathcal{M}$, which is defined to be the set of all possible bases modulo an equivalence relation. One can characterize in terms of $\mathcal{M}$ all realizable symmetric signatures under basis transformations. This structural understanding gives: (i) a uniform account of all the previous successes of holographic algorithms using symmetric signatures [10, 11]; (ii) generalizations to solve other problems, when this is possible; and (iii) a proof when this is not possible.

Applications

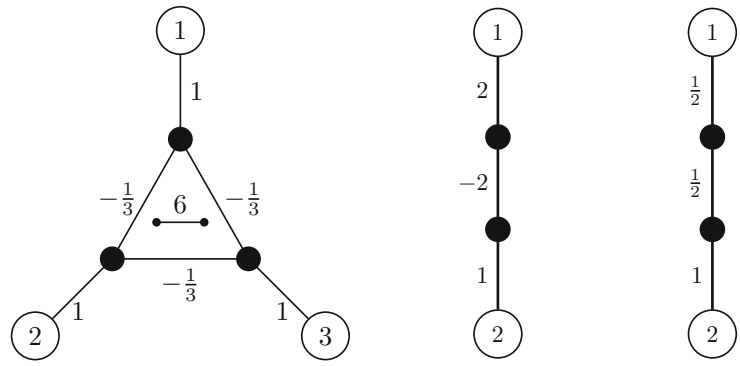
In this section, we list a few problems which can be solved by holographic algorithms.

#PL-3-NAE-ICE

INPUT: A planar graph $G = (V, E)$ of maximum degree 3.

OUTPUT: The number of orientations such that no node has all incident edges directed toward it or all incident edges directed away from it.

Hence, #PL-3-NAE-ICE counts the number of no-sink-no-source orientations. A node of degree one will preclude such an orientation. We assume every node has degree 2 or 3. To solve this problem by a holographic algorithm with matchgates, we design a signature grid based on G as follows: We attach to each node of degree 3 a generator with signature $[0, 1, 1, 0]$. This represents a NOT-ALL-EQUAL or NAE gate of arity 3. For any node of degree 2, we use a generator with the binary NAE (i.e., a binary DISEQUALITY) signature $(\neq_2) = [0, 1, 0]$. For each edge in E, we use a recognizer with signature $(\neq_2)$, which stands for an orientation from one node to the other. (To express such a problem, it is completely arbitrary



Holographic Algorithms, Fig. 1 Some matchgates used in #PL-3-NAE-ICE

to label one side as generators and the other side as recognizers.) From the given planar graph G, we obtain a signature grid Ω, where the underlying graph G' is the edge-vertex incidence graph of G. By definition, Holant_Ω is an exponential sum where each term is a product of appropriate entries of the signatures. Each term is indexed by a 0–1 assignment on all edges of G'; it has a value of 0 or 1, and it has a value of 1 iff it corresponds to an orientation of G such that at every vertex of G the local NAE constraint is satisfied. Therefore, Holant_Ω is precisely the number of valid orientations required by #PL-3-NAE-ICE.

Note that the signature $[0, 1, 1, 0]$ is not the signature of any matchgate. A simple reason for this is that a matchgate signature, being defined in terms of perfect matchings, cannot have nonzero values for inputs of both odd and even Hamming weights.

However, under a holographic transformation using $H = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$,

$$H^{\otimes 3}[0, 1, 1, 0] = H^{\otimes 3}\left\{\begin{bmatrix}1\\1\end{bmatrix}^{\otimes 3} - \begin{bmatrix}1\\0\end{bmatrix}^{\otimes 3} - \begin{bmatrix}0\\1\end{bmatrix}^{\otimes 3}\right\} = [6, 0, -2, 0],$$

$$H^{\otimes 2}[0, 1, 0] = H^{\otimes 2}\left\{\begin{bmatrix}1\\1\end{bmatrix}^{\otimes 2} - \begin{bmatrix}1\\0\end{bmatrix}^{\otimes 2} - \begin{bmatrix}0\\1\end{bmatrix}^{\otimes 2}\right\} = [2, 0, -2],$$

and

$$[0, 1, 0](H^{-1})^{\otimes 2} = \frac{1}{2}[1, 0, -1].$$

These signatures are all realizable as matchgate signatures by verifying all the matchgate identities. More concretely, we can exhibit the requisite three matchgates in Fig. 1.

Hence, #PL-3-NAE-ICE is precisely the following Holant problem on planar graphs:

$$\text{Holant}([0, 1, 0] \mid [0, 1, 0], [0, 1, 1, 0])$$
$$\equiv_T \text{Holant}(\tfrac{1}{2}[1, 0, -1] \mid [2, 0, -2], [6, 0, -2, 0]).$$

Now we may replace each signature $\frac{1}{2}[1, 0, -1]$, $[2, 0, -2]$, and $[6, 0, -2, 0]$ in Ω by their corresponding matchgates, and then we can compute Holant_Ω in polynomial time by Kasteleyn's algorithm.

The next problem is a satisfiability problem.

#PL-3-NAE-SAT

INPUT: A planar formula Φ consisting of a conjunction of NAE clauses each of size 3.

OUTPUT: The number of satisfying assignments of Φ.

This is a variant of 3SAT. A Boolean formula is planar if it can be represented by a planar graph where vertices represent variables and clauses, and there is an edge iff the variable or its negation appears in that clause. The SAT problem is when the gate for each clause is the Boolean OR. When SAT is restricted to planar formulae, it is still NP-complete, and its corresponding counting problem is #P-complete. Moreover, for many connectives other than NAE (e.g., EXACTLY ONE), the unrestricted or the planar decision problems are still NP-complete, and the corresponding counting problems are #P-complete.

We design a signature grid as follows: To each NAE clause, we assign a generator with signature $[0, 1, 1, 0]$. To each Boolean variable, we assign a generator with signature $(=_k)$ where k is the number of clauses the variable appears, either negated or unnegated. Further, if a variable occurrence is negated, we have a recognizer $[0, 1, 0]$ along the edge that joins the variable generator and the NAE generator, and if the variable occurrence is unnegated, then we use a recognizer $[1, 0, 1]$ instead. Under a holographic transformation using H, $(=_k)$ is transformed to

$$H^{\otimes k}\left\{\begin{bmatrix}1\\0\end{bmatrix}^{\otimes k}+\begin{bmatrix}0\\1\end{bmatrix}^{\otimes k}\right\}=\begin{bmatrix}1\\1\end{bmatrix}^{\otimes k}+\begin{bmatrix}1\\-1\end{bmatrix}^{\otimes k}$$
$$=2[1,0,1,0,\ldots].$$

It can be verified that all the signatures used satisfy all matchgate identities and thus can be realized by matchgates under the holographic transformation.

Problem Definition

An instance I of the *Hospitals/Residents problem* (HR) [6, 7, 18] involves a set $R = \{r_1, \ldots, r_n\}$ of *residents* and a set $H = \{h_1, \ldots, h_m\}$ of *hospitals*. Each hospital $h_j \in H$ has a positive integral *capacity*, denoted by c_j. Also, each resident $r_i \in R$ has a *preference list* in which he ranks in strict order a subset of H. A pair $(r_i, h_j) \in R \times H$ is said to be *acceptable* if h_j appears in r_i's preference list; in this case r_i is said to *find* h_j *acceptable*. Similarly each hospital $h_j \in H$ has a preference list in which it ranks in strict order those residents who find h_j acceptable. Given any three agents $x, y, z \in R \cup H$, x is said to *prefer* y to z if x finds each of y and z acceptable, and y precedes z on x's preference list. Let $C = \sum_{h_j \in H} c_j$.

Let A denote the set of acceptable pairs in I, and let $L = |A|$. An *assignment* M is a subset of A. If $(r_i, h_j) \in M$, r_i is said to be *assigned to* h_j, and h_j is *assigned* r_i. For each $q \in R \cup H$, the set of assignees of q in M is denoted by $M(q)$. If $r_i \in R$ and $M(r_i) = \emptyset$, r_i is said to be *unassigned*; otherwise r_i is *assigned*. Similarly, any hospital $h_j \in H$ is *under-subscribed*, *full*, or *over-subscribed* according as $|M(h_j)|$ is less than, equal to, or greater than c_j, respectively.

A *matching* M is an assignment such that $|M(r_i)| \leq 1$ for each $r_i \in R$ and $|M(h_j)| \leq c_j$ for each $h_j \in H$ (i.e., no resident is assigned to an unacceptable hospital, each resident is assigned to at most one hospital, and no hospital is over-subscribed). For notational convenience, given a matching M and a resident $r_i \in R$ such

that $M(r_i) \neq \emptyset$, where there is no ambiguity, the notation $M(r_i)$ is also used to refer to the single member of $M(r_i)$.

A pair $(r_i, h_j) \in A \backslash M$ *blocks* a matching M or is a *blocking pair* for M, if the following conditions are satisfied relative to M:

1. r_i is unassigned or prefers h_j to $M(r_i)$;
2. h_j is under-subscribed or prefers r_i to at least one member of $M(h_j)$ (or both).

A matching M is said to be *stable* if it admits no blocking pair. Given an instance I of HR, the problem is to find a stable matching in I.

Key Results

HR was first defined by Gale and Shapley [6] under the name "College Admissions Problem." In their seminal paper, the authors' primary consideration is the classical *Stable Marriage problem* (SM; see Entries ▸ Stable Marriage and ▸ Optimal Stable Marriage), which is a special case of HR in which $n = m$, $A = R \times H$, and $c_j = 1$ for all $h_j \in H$ – in this case, the residents and hospitals are more commonly referred to as the *men* and *women*, respectively. Gale and Shapley showed that every instance I of HR admits at least one stable matching. Their proof of this result is constructive, i.e., an algorithm for finding a stable matching in I is described. This algorithm has become known as the *Gale/Shapley algorithm*.

An extended version of the Gale/Shapley algorithm for HR is shown in Fig. 1. The algorithm involves a sequence of *apply* and *delete* operations. At each iteration of the while loop, some unassigned resident r_i with a nonempty preference list applies to the first hospital h_j on his list and becomes provisionally assigned to h_j (this assignment could subsequently be broken). If h_j becomes over-subscribed as a result of this assignment, then h_j rejects its worst assigned resident r_k. Next, if h_j is full (irrespective of whether h_j was over-subscribed earlier in the same loop iteration), then for each resident r_l that h_j finds less desirable than its worst assigned resident r_k, the algorithm *deletes the pair* (r_l, h_j), which comprises deleting h_j from r_l's preference list and vice versa.

Given that the above algorithm involves residents applying to hospitals, it has become known as the *Resident-oriented* Gale/Shapley algorithm, or RGS algorithm for short [7, Section 1.6.3]. The RGS algorithm terminates with a stable matching, given an instance of HR [6] [7, Theorem 1.6.2]. Using a suitable choice of data structures (extending those described in [7, Section 1.2.3]), the RGS algorithm can be implemented to run in $O(L)$ time. This algorithm produces the unique stable matching that is simultaneously best possible for all residents [6] [7, Theorem 1.6.2]. These observations may be summarized as follows:

Theorem 1 *Given an instance of HR, the RGS algorithm constructs, in $O(L)$ time, the unique stable matching in which each assigned resident obtains the best hospital that he could obtain in any stable matching, while each unassigned resident is unassigned in every stable matching.*

A counterpart of the RGS algorithm, known as the *Hospital-oriented Gale/Shapley algorithm*, or HGS algorithm for short [7, Section 1.6.2], gives the unique stable matching that similarly satisfies an optimality property for the hospitals [7, Theorem 1.6.1].

Although there may be many stable matchings for a given instance I of HR, some key structural properties hold regarding unassigned residents and under-subscribed hospitals with respect to all stable matchings in I, as follows.

Theorem 2 *For a given instance of HR:*

- *The same residents are assigned in all stable matchings;*
- *Each hospital is assigned the same number of residents in all stable matchings;*
- *Any hospital that is under-subscribed in one stable matching is assigned exactly the same set of residents in all stable matchings.*

These results are collectively known as the "Rural Hospitals Theorem" (see [7, Section 1.6.4] for further details). Furthermore, the set of stable matchings in I forms a distributive lattice under a natural dominance relation [7, Section 1.6.5].

```
M := ∅;
while (some resident r_i is unassigned and r_i has a nonempty list) {
    h_j := first hospital on r_i's list;
    /* r_i applies to h_j */
    M := M ∪ {(r_i, h_j)};
    if (h_j is over-subscribed) {
        r_k := worst resident in M(h_j) according to h_j's list;
        M := M\{(r_k, h_j)};
    }
    if (h_j is full) {
        r_k := worst resident in M(h_j) according to h_j's list;
        for (each successor r_l of r_k on h_j's list)
            delete the pair (r_l, h_j);
    }
}
```

Hospitals/Residents Problem, Fig. 1 Gale/Shapley algorithm for HR

Applications

Practical applications of HR are widespread, most notably arising in the context of centralized automated matching schemes that assign applicants to posts (e.g., medical students to hospitals, school leavers to universities, and primary school pupils to secondary schools). Perhaps the largest and best-known example of such a scheme is the National Resident Matching Program (NRMP) in the USA [8], which annually assigns around 31,000 graduating medical students (known as residents) to their first hospital posts, taking into account the preferences of residents over hospitals and vice versa and the hospital capacities. Counterparts of the NRMP are in existence in other countries, including Canada [9] and Japan [10]. These matching schemes essentially employ extensions of the RGS algorithm for HR.

Centralized matching schemes based largely on HR also occur in other practical contexts, such as school placement in New York [1], university faculty recruitment in France [3], and university admission in Spain [16]. Further applications are described in [15, Section 1.3.7].

Indeed, the Nobel Prize in Economic Sciences was awarded in 2012 to Alvin Roth and Lloyd Shapley, partly for their theoretical work on HR and its variants [6, 18] and partly for their contribution to the widespread deployment of algorithms for HR in practical settings such as junior doctor allocation as noted above.

Extensions of HR

One key extension of HR that has considerable practical importance arises when an instance may involve a set of *couples*, each of which submits a joint preference list over pairs of hospitals (typically in order that the members of the couple can be located geographically close to one another). The extension of HR in which couples may be involved is denoted by HRC; the stability definition in HRC is a natural extension of that in HR (see [15, Section 5.3] for a formal definition of HRC). It is known that an instance of HRC need not admit a stable matching (see [4]). Moreover, the problem of deciding whether an HRC instance admits a stable matching is NP-complete [17].

HR may be regarded as a many-one generalization of SM. A further generalization of SM is to a many-many stable matching problem, in which both residents and hospitals may be multiply assigned subject to capacity constraints. In this case, residents and hospitals are more commonly referred to as *workers* and *firms*, respectively. There are two basic variations of the many-many stable matching problem according to whether workers rank (i) individual acceptable

firms in order of preference and vice versa or (ii) acceptable *subsets* of firms in order of preference and vice versa. Previous work relating to both models is surveyed in [15, Section 5.4].

Other variants of HR may be obtained if preference lists include ties. This extension is again important from a practical perspective, since it may be unrealistic to expect a popular hospital to rank a large number of applicants in strict order, particularly if it is indifferent among groups of applicants. The extension of HR in which preference lists may include ties is denoted by HRT. In this context three natural stability definitions arise, the so-called *weak stability*, *strong stability*, and *super-stability* (see [15, Section 1.3.5] for formal definitions of these concepts). Given an instance I of HRT, it is known that weakly stable matchings may have different sizes, and the problem of finding a maximum cardinality weakly stable matching is NP-hard (see entry ▸ Stable Marriage with Ties and Incomplete Lists for further details). On the other hand, in contrast to the case for weak stability, a super-stable matching in I need not exist, though there is an $O(L)$ algorithm to find such a matching if one does [11]. Analogous results hold in the case of strong stability – in this case, an $O(L^2)$ algorithm [13] was improved by an $O(CL)$ algorithm [14] and extended to the many-many case [5]. Furthermore, counterparts of the Rural Hospitals Theorem hold for HRT under each of the super-stability and strong stability criteria [11, 19].

A further generalization of HR arises when each hospital may be split into several departments, where each department has a capacity, and residents rank individual departments in order of preference. This variant is modeled by the *Student-Project Allocation problem* [15, Section 5.5]. Finally, the *Hospitals/Residents problem under Social Stability* [2] is an extension of HR in which an instance is augmented by a *social network graph* G (a bipartite graph whose vertices correspond to residents and hospitals and whose edges form a subset of A) such that a blocking pair must additionally satisfy the property that it forms an edge of G. Edges in G correspond to resident–hospital pairs that are acquainted with one another and therefore more likely to block a matching in practice.

Open Problems

As noted in Section "Applications," ties in the hospitals' preference lists may arise naturally in practical applications. In an HRT instance, weak stability is the most commonly-studied stability criterion, due to the guaranteed existence of such a matching. Attempting to match as many residents as possible motivates the search for large weakly stable matchings. Several approximation algorithms for finding a maximum cardinality weakly stable matching have been formulated (see ▸ Stable Marriage with Ties and Incomplete Lists and [15, Section 3.2.6] for further details). It remains open to find tighter upper and lower bounds for the approximability of this problem.

Problem Definition

The Hospitals/Residents (**HR**) problem is the many-to-one version of the stable marriage problem introduced by Gale and Shapley. In this problem, a bipartite graph $G = (\mathcal{R} \cup \mathcal{H}, E)$ is given. Each vertex in $\mathcal{H}$ represents a hospital and each vertex in $\mathcal{R}$ a resident. Each vertex has a preference over its neighboring vertices. Each hospital h has an upper quota $u(h)$ specifying the maximum number of residents it can take in a matching. The goal is to find a stable matching while respecting the upper quotas of the hospitals.

The original **HR** has been well studied in the past decades. A recent trend is to assume that each hospital h also comes with a lower quota $l(h)$. In this context, it is required (if possible) that a matching satisfies both the upper and the lower quotas of each hospital. The introduction

of such lower quotas is to enforce some policy in hiring or to make the outcome more fair. It is well-known that hospitals in some rural areas suffer from the shortage of doctors.

With the lower quotas, the definition of stability in **HR** and the objective of the problem depend on the applications. Below we summarize three variants that have been considered in the literature.

Minimizing the Number of Blocking Pairs

In this variant, a matching M is feasible if, for each hospital h, $l(h) \leq |M(h)| \leq u(h)$. Given a feasible matching, a resident r and a hospital h form a blocking pair if the following condition holds. (i) $(r,h) \in E \backslash M$, (ii) r is unassigned in M or r prefers h to his assignment $M(r)$, and (iii) $|M(h)| < u(h)$ or h prefers r to one of its assigned residents. A matching is stable if the number of blocking pairs is 0. It is straightforward to check whether a stable matching exists. We assume that the given instance has no stable matching and the objective is to find a matching with the minimum number of blocking pairs. We call this problem **Min-BP HR**. An alternative objective is to minimize the number of residents that are part of a blocking pair in a matching. We call this problem **Min-BR HR**.

HR with the Option of Closing a Hospital

The following variation of **HR** is motivated by the higher education system in Hungary. Instead of requiring all hospitals to have enough residents to meet their lower quotas, it is allowed that a hospital be closed as long as there is not too much demand for it.

Precisely, in this variant, a matching M is feasible if, for each hospital h, $|M(h)| = 0$ or $l(h) \leq |M(h)| \leq u(h)$. In the former case, a hospital is closed; in the latter case, a hospital is opened. Given a feasible matching M, it is stable if

1. There is no opened hospital h and resident r so that (i) $(h,r) \in E \backslash M$, (ii) r is unassigned in M or r prefers h to his assignment $M(r)$, and (iii) $|M(h)| < u(h)$ or h prefers r to one of its assigned residents;
2. There is no closed hospital h and a set $R \subseteq \mathcal{R}$ of residents so that (i) $|R| \geq |l(h)|$, (ii) for each $r \in R$, $(r,h) \in E \backslash M$, and (iii) each resident $r \in R$ is either unassigned or prefers h to his assigned hospital $M(r)$.

With the above definition of stability, we refer to the question of the existence of a stable matching as **HR woCH**.

Classified HR

Motivated by the practice in academic hiring, Huang introduced a more generalized variant of **HR**. In this variant, a hospital h has a classification $h_{\mathcal{C}}$ over its neighboring residents. Each class $C \in h_{\mathcal{C}}$ comes with a upper quota $u(C)$ and a lower quota $l(C)$. A matching M is feasible if, for each hospital h and for each of its classes $c \in h_{\mathcal{C}}$, $l(C) \leq |M(h)| \leq u(C)$. A feasible matching M is stable if the following condition holds: there is no hospital h such that

1. There exists a resident r so that $(r,h) \in E \backslash M$, and r is either unassigned in M or r prefers h to his assignment $M(r)$;
2. For every class $C \in h_{\mathcal{C}}$, $l(C) \leq |M(h) \cup \{r\}| \leq u(C)$, or there exists another resident $r' \in M(h)$ so that h prefers r to r' and for every class $C \in h_{\mathcal{C}}$, $l(C) \leq |M(h) \cup \{r\} \backslash \{r'\}| \leq u(C)$.

With the above definition of stability, we refer to the question of the existence of a stable matching as **CHR**.

Key Results

For the first variant where the objective is to minimize the number of blocking pairs, Hamada et al. showed the following tight results.

Theorem 1 ([3]) *For any positive constant $\epsilon > 0$, there is no polynomial-time $(|\mathcal{R}| + |\mathcal{H}|)^{1-\epsilon}$-approximation algorithm for **Min-BP HR** unless P=NP. This holds true even if the given bipartite graph is complete and all upper quotas are 1 and all lower quotas are 0 or 1.*

Theorem 2 ([3]) *There is a polynomial-time* $(|\mathcal{R}| + |\mathcal{H}|)$*-approximation algorithm for* ***Min-BP HR****.*

In the case that the objective is to minimize the number of residents involved in blocking pairs, Hamada et al. showed the following.

Theorem 3 ([3]) ***Min-BR HR*** *is NP-hard. This holds true even if the given bipartite graph is complete and all hospitals have the same preference over the residents.*

Theorem 4 ([3]) *There is a polynomial-time* $\sqrt{|\mathcal{R}|}$*-approximation algorithm for* ***Min-BR HR****.*

For the second variant, where a hospital is allowed to be closed, Biró et al. showed the following.

Theorem 5 ([1]) *The problem* ***HR woCH*** *is NP-complete. This holds true even if all upper quotas are at most 3.*

For the last variant where each hospital is allowed to classify the neighboring residents and sets the upper and lower quotas for each of its classes, Huang showed that if all classifications of the hospitals are laminar families, the problem is in P. Fleiner and Kamiyama later proved the same result by a significantly simpler matroid-based technique.

Theorem 6 ([2,4]) *In* ***CHR****, if all classifications of the hospitals are laminar families, then one find a stable matching or detect its absence in the given instance in* $O(nm)$ *time, where* $n = |\mathcal{R} \cup \mathcal{H}|$ *and* $m = |E|$*.*

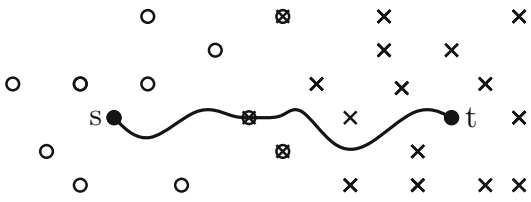
Problem Definition

Given a directed graph $G = (V, A)$ (with $n = |V|$ and $m = |A|$) with a length function $\ell : A \to \mathbf{R}^+$ and a pair of vertices s, t, a *distance oracle* returns the distance $\text{dist}(s, t)$ from s to t. A *labeling algorithm* [18] implements distance oracles in two stages. The *preprocessing* stage computes a *label* for each vertex of the input graph. Then, given s and t, the *query* stage computes $\text{dist}(s, t)$ using only the labels of s and t; the query does not explicitly use G and ℓ.

Hub labeling (HL) (or 2-hop labeling) is a special kind of labeling algorithm. The label $L(v)$ of a vertex v consists of two parts: the *forward label* $L_f(v)$ is a collection of vertices w with their distances $\text{dist}(v, w)$ from v, while the



Hub Labeling (2-Hop Labeling), Fig. 1 Example of a hub labeling. The hubs of s are *circles*; the hubs of t are *crosses* (Taken from [3])

backward label $L_b(v)$ is a collection of vertices u with their distances $\text{dist}(u, v)$ to v. (If the graph is undirected, a single label per vertex suffices.) The vertices in v's label are the *hubs* of v. The labels must obey the *cover property*: for any two vertices s and t, the set $L_f(s) \cap L_b(t)$ must contain at least one hub that is on the shortest $s - t$ path. Given the labels, HL queries are straightforward: to find $\text{dist}(s, t)$, simply find the hub $x \in L_f(s) \cap L_b(t)$ that minimizes $\text{dist}(s, x) + \text{dist}(x, t)$ (see Fig. 1 for an example). If the hubs in each label are sorted by ID, queries consist of a simple linear sweep over the labels, as in mergesort.

The size of a forward (backward) label, $|L_f(v)|$ ($|L_b(v)|$), is the number of hubs it contains. The *size of a labeling* L is the sum of the average label sizes, $(L_f(v) + L_b(v))/2$, over all vertices. The memory footprint of the algorithm is proportional to the size of the labeling, while query times are determined by the maximum label size. Queries themselves are trivial; the hard part is an efficient implementation of a preprocessing algorithm that, given G and ℓ, computes a small hub labeling.

Key Results

We describe an approximation algorithm for finding labelings of size within $O(\log n)$ of the optimal [9], as well as its generalization to other objectives, including the maximum label size [6]. Although polynomial, these approximation algorithms do not scale to large networks. For more practical alternatives, we discuss *hierarchical hub labelings* (HHLs), a subclass of HL. We show that HHLs are closely related to vertex orderings and present efficient algorithms for computing the minimal HHL for a given ordering, as well as heuristics for finding vertex orderings that lead to small labels. In particular, the RXL algorithm uses sampling to efficiently approximate a greedy vertex order, leading to empirically small labels. RXL can handle large problems from several application domains. We then discuss representations of hub labels that allow various trade-offs between space and query time.

General Hub Labelings

The time and space efficiency of the distance oracles we discuss depend on the label size. If labels are big, HL is impractical. Gavoille et al. [15] show that there exist graphs for which general labelings must have size $\tilde{\Theta}(n^2)$. For planar graphs, they give an $\tilde{\Omega}(n^{4/3})$ lower and $\tilde{O}(n^{3/2})$ upper bound. They also show that graphs with k-separators have hub labelings of size $\tilde{O}(nk)$. Abraham et al. [1] show that graphs with small highway dimension (which they conjecture include road networks) have small hub labelings.

Given a particular graph, computing a labeling with the smallest size is NP-hard. Cohen et al. [9] developed an $O(\log n)$-approximation algorithm for the problem. Next we discuss this *general HL* (GHL) algorithm.

A *partial labeling* is a labeling that does not necessarily satisfy the cover property. Given a partial labeling $L = (L_f, L_b)$, we say that a vertex pair $[u, w]$ is *covered* if $L_f(u) \cap L_b(w)$ contains a vertex on a shortest path from u to w and *uncovered* otherwise. GHL maintains a partial labeling L (initially empty) and the corresponding set U of uncovered vertex pairs. Each iteration of the algorithm selects a vertex v and two subsets $X', Y' \subseteq V$, adds $(v, \text{dist}(x, v))$ to $L_f(x)$ for all $x \in X'$, and adds $(y, \text{dist}(v, y))$ to $L_b(y)$ for all $y \in Y'$. Then, GHL deletes from U the set $U(v, X', Y')$ of vertex pairs that become covered by this augmentation. Among all $v \in V$ and $X', Y' \subseteq V$, the triple (v, X', Y') picked in each iteration is one that maximizes $|U(v, X', Y')|/(|X'| + |Y'|)$, i.e., the ratio of the number of paths covered over the increase in label size.

Cohen et al.'s efficient implementation of GHL uses the notion of *center graphs*. Given a set U of vertex pairs and a vertex v, the center graph $G_v = (X, Y, A_v)$ is a bipartite graph with $X = Y = V$ such that an arc $(u, w) \in A_v$ if $[u, w] \in U$ and some shortest path from u to w in G go through v. If U is the set of uncovered vertex pairs, then, for a fixed vertex v, maximizing $|U(v, X', Y')|/(|X'| + |Y'|)$ over all $X', Y' \subseteq V$ is (by definition) the same as finding the vertex induced-subgraph of G_v with maximum *density* (defined as its number of arcs divided by its number of vertices). This *maximum density subgraph* (MDS) problem can be solved in polynomial time using parametric flows (see e.g., [14]). To maximize the ratio over all triples (v, X', Y'), GHL solves an MDS problem for center graphs G_v and picks the densest of the n resulting subgraphs. It then adds the corresponding vertex v^* to the labels of the vertices given by the sides of the MDS. Arcs corresponding to newly covered pairs are removed from center graphs between iterations.

Cohen et al. show that GHL is a special case of the greedy set cover algorithm [8] and thus gives an $O(\log n)$-optimal labeling. They also show that the same guarantee holds if one uses a constant-factor approximation to the MDS. We refer to a k approximation of MDS as a k-AMDS. Using a linear-time 2-AMDS algorithm by Kortsarz and Peleg [17], each GHL iteration is dominated by n AMDS computations on graphs with $O(n^2)$ arcs. Since each iteration increases the size of the labeling, the number of iterations is at most $O(n^2)$. The total running time of GHL is thus $O(n^5)$.

Delling et al. [11] improve the time bound for GHL to $O(n^3 \log n)$ using *eager* and *lazy* evaluation. Intuitively, eager evaluation finds an AMDS G' of G such that deleting G' reduces the MDS value of G by a constant factor. More precisely, given a graph G, an upper bound μ on the MDS value of G and a parameter $\alpha > 1$, *α-eager evaluation* attempts to find a (2α)-AMDS G' of G such that the MDS value of G with the arcs of G' deleted is at most μ/α. If the evaluation fails to find such G', the MDS value of G is at most μ/α. *Lazy evaluation* was introduced by Cohen et al. [9] to speed up their implementation of GHL and refined by Stengel et al. [20]. It is based on the observation that the MDS value of a center graph does not increase as the algorithm adds vertices to labels and removes arcs from center graphs.

The eager-lazy algorithm maintains upper bounds on the center subgraph densities μ_v computed in previous iterations. These values are computed during initialization and updated in a lazy fashion as follows. In each iteration, the algorithm picks the maximum μ_v and applies α-eager evaluation to G_v. If the evaluation succeeds, the labels are updated. Regardless of whether the evaluation succeeds or not, μ_v/α is a valid upper bound on the density of G_v at the end of the iteration. This can be used to show that each vertex is selected by $O(n \log n)$ iterations, each taking $O(n^2)$ time.

Babenko et al. [6] generalize the definition of a labeling size as follows. Suppose vertex IDs are $1, 2, \ldots, n$. Define a $(2n)$-dimensional vector $\mathcal{L}$ by $\mathcal{L}_{2i-1} = |L_f(i)|$ and $\mathcal{L}_{2i} = |L_b(i)|$. The p-norm of $\mathcal{L}$ is defined as $\|\mathcal{L}\|_p = (\sum_{i=0}^{2n-1} \mathcal{L}_i^p)^{1/p}$, where p is a natural number and $\|\mathcal{L}\|_\infty = \max \mathcal{L}_i$. Note that $\|\mathcal{L}\|_1/2$ is the total size of the labeling and $\|\mathcal{L}\|_\infty$ is the maximum label size. Babenko et al. [6] generalize the algorithm of Cohen et al. to obtain an $O(\log n)$-approximation algorithm for this more general problem in $O(n^5)$ time. Delling et al. [11] show that the eager-lazy approach yields an $O(\log n)$-approximation algorithm running in time $O(n^3 \log n \min(p, \log n))$.

Hierarchical Hub Labelings

Even with the performance improvements mentioned above, GHL requires too much time and space to work on large networks. To overcome this problem, one may use heuristics that have no known theoretical guarantees on the label size but produce small labels for large instances from a wide variety of domains. The most successful current heuristics use a restricted class of labelings called *hierarchical hub labeling* (HHL) [4]. Hierarchical labels have the cover property and implement exact distance oracles.

Given a labeling, let $v \lesssim w$ if w is a hub of $L(v)$. HL is *hierarchical* if $\lesssim$ is a partial order. (Intuitively, $v \lesssim w$ if w is "more important" than v.) We say that an HHL *respects* a given (total) order on the vertices if the partial order $\lesssim$ induced by the HHL is consistent with the order.

Consider an order defined by a permutation *rank*, with $rank(v) < rank(w)$ if v appears before (is less important than) w. The *canonical labeling* L for *rank* is defined as follows [4]. Vertex v belongs to $L_f(u)$ if and only if there exists w such that v is the highest-ranked vertex that hits $[u, w]$. Similarly, v belongs to $L_b(w)$ if and only if there exists u such that v is the highest-ranked vertex that hits $[u, w]$.

Abraham et al. [4] prove that the canonical labeling for a given vertex order *rank* is the minimum-sized labeling that respects *rank*. This suggests a two-stage approach for finding a small hierarchical hub labeling: first, find a "good" vertex order, and then compute its corresponding canonical labeling. We first discuss the latter step and then the former.

From Orderings to Labelings

We first consider how, given an order *rank*, one can compute the canonical hierarchical labeling L that respects *rank*.

The straightforward way is to just apply the definition: for every pair $[u, w]$ of vertices, find the maximum-ranked vertex on any shortest u–w path, and then add it to $L_f(u)$ and $L_b(w)$. Although polynomial, this algorithm is too slow in practice.

A faster (but still natural) algorithm is as follows [4]. Start with an empty (partial) labeling L, and process vertices from the most to least important. When processing v, for every uncovered pair $[u, w]$ that v covers, add v to $L_f(u)$ and $L_b(w)$. (In other words, add v to the labels of all end points of arcs in the center graph G_v.) Abraham et al. [4] show how to implement this in $O(mn \log n)$ time and $\Theta(n^2)$ space, which is still impractical for large instances.

When labels are not too large, a much more efficient solution is the *pruned labeling* (PL) algorithm by Akiba et al. [5]. Starting from empty labels, PL also processes vertices from the most to least important, with the iteration that processes vertex v, adding v to all relevant labels. The crucial observation is that, when processing v, one only needs to look at uncovered pairs containing v itself; if $[u, v]$ is not covered, PL adds v to $L_f(u)$; if $[v, w]$ is not covered, it adds v to $L_b(w)$. This is enough because of the subpath optimality property of the shortest paths.

To process v efficiently, PL runs two pruned Dijkstra searches [13] from v. The first search works on the forward graph (out of v) as follows. Before scanning a vertex w (with distance label $d(w)$ within the Dijkstra search), it computes a v–w distance estimate q by performing an HL query with the current partial labels. (If the labels do not intersect, set $q = \infty$.) If $q \leq d(w)$, the $[v, w]$ pair is already covered by previous hubs, so PL prunes the search (ignores w). Otherwise (if $q > d(w)$), PL adds $(v, \text{dist}(v, w))$ to $L_b(w)$ and scans w as usual. The second Dijkstra search uses the reverse graph and is pruned similarly; it adds $(v, \text{dist}(w, v))$ to $L_f(w)$ for all scanned vertices w. Note that the number of Dijkstra scans equals the size of the labeling. Since each visited vertex requires an HL query using partial labels, the running time can be quadratic in the average label size. It is easy to see that PL produces canonical labelings.

The final algorithm we discuss, due to Abraham et al. [4], computes a hierarchical hub labeling from a vertex ordering recursively. Its basic building block is the *shortcut operation* (see e.g., [16]). To shortcut a vertex v, the operation deletes v from the graph and adds arcs to ensure that the distances between the remaining vertices remain unchanged. For every pair consisting of an incoming arc (u, v) and an outgoing arc (v, w), the algorithm checks if $(u, v) \cdot (v, w)$ is the only shortest u–w path (by running a partial Dijkstra search from u or w) and, if so, adds a new arc (u, w) with length $\ell(u, w) = \ell(u, v) + \ell(v, w)$.

The recursive algorithm computes one label at a time, from the bottom up (from the least to the most important vertex). It starts by shortcutting the least important vertex v from G to get a graph

G' (same as G, but without v and its incident arcs and with the added shortcuts). It then recursively finds a labeling for G', which gives correct distances (in G) for all pairs of vertices not containing v. Then, the algorithm computes the label of v from the labels of its neighbors. We describe how to compute $L_f(v)$; $L_b(v)$ is computed similarly. The crucial observation is that any nontrivial shortest path starting at v must go through one of its neighbors. Accordingly, we initialize $L_f(v)$ with entry $(v, 0)$ (to cover the trivial path from v to itself), and then, for every neighbor w of v in G and every entry $(x, \text{dist}(w, x)) \in L_f(w)$, add $(x, \ell(v, w) + \text{dist}(w, x))$ to $L_f(v)$. If x already is a hub of v, we only keep the smallest entry for x. Finally, we prune from $L_f(v)$ the entries $(x, \ell(v, w) + \text{dist}(w, x))$ for which $\ell(v, w) + \text{dist}(w, x) > \text{dist}(v, x)$. (This can happen if the shortest path from v to x through another neighbor w' of v is shorter than the one through w.) Note that $\text{dist}(v, x)$ can be computed using the labels of v and x. In general, the shortcut operation can make the graph dense, limiting the efficiency of the bottom-up approach. On some network classes, such as road networks, the graph remains sparse and the approach scales to large problems.

Vertex Ordering Heuristics

As mentioned above, the size of the labeling is determined by the ordering. The most natural approach to capture the notion of importance is attributed to Abraham et al. [4], whose *greedy ordering algorithm* obtains good orderings on a wide class of problems. It orders vertices from the most to least important using a greedy selection rule. In each iteration, it selects as the next most important hub the vertex v that hits the most vertex pairs not covered by previously selected vertices.

When the shortest paths are unique, this can be implemented relatively efficiently. The algorithm maintains (initially full) the shortest-path trees from each vertex in the graph. The tree T_s rooted at s implicitly represents all shortest paths starting at s. The total number of descendants of a vertex v (in aggregate over all trees) is exactly the number of paths it covers. Once such a vertex v is picked as the next hub, we restore this invariant for the remaining paths by removing all of v's descendants (including v itself) from all trees. Abraham et al. [4] show how the entire greedy order can be found in $O(nm \log n)$ time. An alternative algorithm (in the same spirit) works even if the shortest paths are not unique, but takes $O(n^3)$ time [12].

The *weighted greedy ordering algorithm* is similar but selects v so as to maximize the ratio of the number of uncovered paths that v covers to the increase in the label size if v is selected next. This gives slightly better results and can be implemented in the same time bounds as the greedy ordering algorithm [4, 12]. Although faster than GHL, none of these greedy variants scale to large graphs.

To cope with this problem, Delling et al. [12] developed RXL (Robust eXact Labeling), which can be seen as a sampling version of the greedy ordering algorithm. In each iteration, RXL finds a vertex v that *approximately* maximizes the number of pairs covered. Rather than maintaining n shortest-path trees, RXL maintains shortest-path trees from a small number of roots picked uniformly at random. It estimates the coverage of v based on how many descendants it has in these trees. To reduce the bias in this estimation, the algorithm discards outliers before taking the average number of descendants. Moreover, as the original trees shrink (because some of its subtrees become covered), new subtrees (from other roots) are added. These new trees are not full, however; they are pruned from the start (using PL), ensuring the total space (and time) usage remains under control.

For certain graph classes, simpler ordering techniques can be used. Akiba et al. [5] show that ordering by degree works well on a subclass of complex networks. Abraham et al. [2,4] show that the order induced by the contraction hierarchies (CH) algorithm [16] works well on road networks and other sparse inputs. CH order vertices from the bottom up: using only local information, it determines the least important vertex, shortcuts it, and repeats the process in the remaining graph. The most relevant signals to estimate the importance of v are the arc difference (of number

of arcs removed and added if v were shortcut) and how many neighbors of v have already been shortcut.

Label Representation and Queries

Given a source s and a target t, one can compute the minimum of $\text{dist}(s,v) + \text{dist}(v,t)$ over all $v \in L_f(s) \cap L_b(t)$ in $O(|L_f(s)| + |L_f(t)|)$ time. If vertex labels are represented as arrays sorted by hub IDs, one can compute $L_f(s) \cap L_b(t)$ by a coordinated sweep of the corresponding arrays, as in mergesort. This is very cache efficient and works well when the two labels have similar sizes.

In some applications, label sizes can be very different. Assuming (without loss of generality) that $|L_f(s)| \ll |L_f(t)|$, one can compute $L_f(s) \cap L_b(t)$ in time $O(|L_f(s)| + \log(|L_b(t)|))$ by performing a binary search for each hub $v \in L_f(s)$ to determine if v is in $L_b(t)$. In fact, this *set intersection problem* can be solved even faster, in $O(\min(|L_f(s)|, |L_b(t)|))$ time [19].

As each label can be stored in a contiguous memory block, HL queries are well suited for an external memory (or even distributed) implementations, including relational databases [3] or key-value stores. In such cases, query times depend on the time to fetch two blocks of data.

For in-memory implementations of HL, storage may be a bottleneck. One can trade space for time using label compression, which interprets each label as a tree and stores common subtrees only once; this reduces space consumption by an order of magnitude, but queries become much less cache efficient [10, 12]. Another technique to reduce the space consumption is to store vertices and a constant number of their neighbors as superhubs in the labels [5]; on unweighted and undirected graphs, distances from a vertex v to all elements of a superhub can be represented compactly in difference form. This works well on some social and communication networks [5].

HL has efficient extensions to problems beyond point-to-point shortest paths, including one-to-many and via-point queries. These are important for applications in road networks, such as finding the closest points of interest, ride sharing, and path prediction [3].

Experimental Results

Even for very small (constant) sample sizes, the labels produced by RXL are typically no more than about 10 % bigger [12] than those produced by the full greedy hierarchical algorithms, which in turn are not much worse than those produced by GHL [11]. Scalability is much different, however. In a few hours in a modern CPU, GHL can only handle graphs with about 10,000 vertices [11]; for the greedy hierarchical algorithms, the practical limit is about 100,000 [4]. In contrast, as long as labels remain small, RXL scales to problems with millions of vertices [12] from a wide variety of graph classes, including meshes, grids, random geometric graphs (sensor networks), road networks, social networks, collaboration networks, and web graphs. For example, for a web graph with 18.5 million vertices and almost 300 million arcs, one can find labels with fewer than 300 hubs on average in about half a day [12]; queries then take less than 2 µs.

For some graph classes, other methods have faster preprocessing. For continental road networks with tens of millions of vertices, a hybrid approach combining weighted greedy (for the top few thousand vertices) with the CH order (for all other vertices) provides the best trade-off between preprocessing times and label size [2, 4]. On a benchmark data set representing Western Europe (about 18 million vertices, 42.5 million arcs), it takes roughly an hour to compute labels with about 70 hubs on average, leading to average query times of about 0.5 µs, roughly the time of ten random memory accesses. With additional improvements, one can further reduce query times (but not the label sizes) by half [2], making it the fastest algorithm for this application [7]. For some unweighted and undirected complex (social, communication, and collaboration) networks, simply sorting vertices by degree [5] produces labels that are not much bigger than those computed by a more sophisticated ordering technique.

Overall, RXL is the most robust method. For all instances tested in the literature, its preprocessing is never much slower than any other methods (and often much faster), and query times

are similar. In particular, CH-based ordering is too costly for large complex networks (as contraction tends to create dense graphs), and the degree-based order leads to prohibitively large labels for road networks and web graphs.

Problem Definition

A sequence of n positive weights or frequencies is given, $\langle w_i > 0 \mid 0 \le i < n \rangle$, together with an output radix r, with $r = 2$ in the case of binary output strings.

Objective To determine a sequence of integral codeword lengths $\langle \ell_i \mid 0 \le i < n \rangle$ such that: (a) $\sum_{i=0}^{n-1} r^{-\ell_i} \le 1$, and (b) $C = \sum_{i=0}^{n-1} \ell_i \cdot w_i$ is minimized. Any sequence of codeword lengths $\langle \ell_i \rangle$ that satisfies these two properties describes a *minimum-redundancy code* for the weights $\langle w_i \rangle$. Once a set of minimum-redundancy codeword lengths $\langle \ell_i \rangle$ has been identified, a prefix-free r-ary code in which symbol i is assigned a codeword of length ℓ_i can always be constructed.

Constraints

1. **Long messages.** In one application, each weight w_i is the frequency of symbol i in a message M of length $m = |M| = \sum_{i=0}^{n-1} w_i$, and C is the number of symbols required by a compressed representation of M. In this application it is usual to assume that $m \gg n$.
2. **Entropy-based limit.** Define $W = \sum_{i=0}^{n-1} w_i$ to be the sum of the weights and $p_i = w_i / W$ to be the corresponding probability of symbol i. Define $H_0 = -\sum_{i=0}^{n-1} (p_i \log_2 p_i)$ to be the zero-order entropy of the distribution. Then when $r = 2$, $\lceil n H_0 \rceil \le C \le n \lceil \log_2 n \rceil$.

Key Results

A minimum-redundancy code can be identified in $O(n)$ time if the weights w_i are nondecreasing and in $O(n \log n)$ time if the weights must be sorted first.

Example Weights

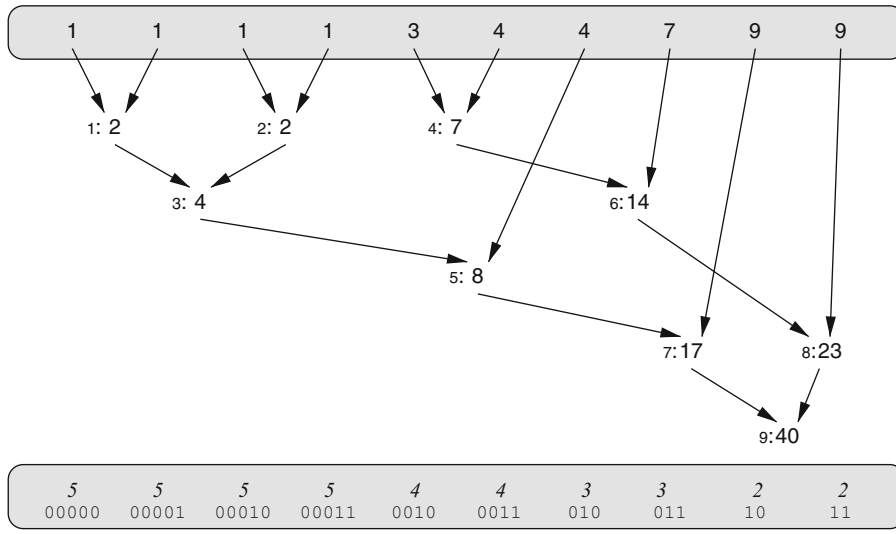
The $n = 10$ weights $\langle 1, 1, 1, 1, 3, 4, 4, 7, 9, 9 \rangle$ with $W = 40$ are used as an example.

Huffman's Algorithm

In 1952 David Huffman [3] described a process for calculating minimum-redundancy codes, developed in response to a term-paper challenge set the year before by his MIT class instructor, Robert Fano, a problem that Fano and his collaborator Claude Shannon had already tackled unsuccessfully [7]. In his solution Huffman created a classic algorithm that is taught to most undergraduate computing students as part of algorithms classes. Initially the sequence of input weights $\langle w_i \rangle$ is regarded as being the leaves of a tree, with no internal nodes, and each leaf the root of its own subtree. The two subtrees (whether singleton leaves or internal nodes) with the smallest root nodes are then combined by making both of them children of a new parent, with an assigned weight calculated as the sum of the two original nodes. The pool of subtrees decreases by one at each cycle of this process; after $n-1$ iterations a total of $n-1$ internal nodes has been added, and all of the original nodes must be leaves in a single tree and descendants of that tree's root node.

Figure 1 shows an example of codeword length computation, with the original weights across the top. Each iteration takes the two least-weight elements (leaf or internal) and combines them to make a new internal node; note that the internal nodes are created in nondecreasing weight order. Once the Huffman tree has been constructed, the sequence $\langle \ell_i \rangle$ can be read from it, by computing the depth of each corresponding leaf node. In Fig. 1, for example, one of the elements of weight 4 is at depth three in the tree, and one is at depth four from the root, hence $\ell_5 = 4$ and $\ell_6 = 3$. A set of codewords can be assigned at the same time as the depths are being computed; one possible assignment of codewords that satisfies the computed sequence $\langle \ell_i \rangle$ is shown in the second row in the lower box. Decoding throughput is considerably faster if codewords are assigned systematically based on codeword length in the manner shown, rather than by strictly following the edge labeling of the Huffman tree from which the codeword lengths were extracted [6].

Because ties can occur and can be broken arbitrarily, different codes are also possible. The sequence $\langle \ell_i \rangle = \langle 6, 6, 6, 6, 4, 3, 3, 3, 2, 2 \rangle$ has the same cost of $C = 117$ bits as the one shown



Huffman Coding, Fig. 1 Example of (binary) codeword lengths calculated using Huffman's algorithm, showing the order in which internal nodes are formed, and their weights. The input weights in the top section are used to compute the corresponding codeword lengths in the bottom box. A valid assignment of prefix-free codewords is also shown

in the figure. For the example weights, $H_0 = 2.8853$ bits per symbol, providing a lower bound of $\lceil 115.41 \rceil = 116$ bits on the total cost C for the input weights. In this case, the minimum-redundancy codes listed are just 1 bit inferior to the entropy-based lower limit.

Implementing Huffman's Algorithm

Huffman's algorithm is often used in algorithms textbooks as an example of a process that requires a dynamic priority queue. If a heap is used, for example, the n initial and $n-2$ subsequent insert operations, take a total of $O(n \log n)$ time, as do the $2(n-1)$ extract-min operations.

A simpler approach is to first sort the n weights into increasing order and then apply an $O(n)$-time algorithm due to van Leeuwen [10]. Two sorted lists are maintained: a static one of original weights, representing the leaves of the Huffman tree, and a dynamic queue of internal nodes that is initially empty, to which new internal nodes are appended as they are created. Each iteration compares front-of-list elements from the two lists and combines the two that have the least weight and then adds the new internal node at the tail of the queue. The algorithm stops when the queue contains only one node; it is the last item that was added and is the root of the Huffman tree.

If the input weights are provided in an array $w_i = A[i \mid 0 \le i < n]$ of sorted integers, that array can be processed in situ into an output array $\ell_i = A[i]$ in $O(n)$ time by van Leeuwen's technique using an implementation described by Moffat and Katajainen [5]. Each array element takes on values that are, variously, input weight, internal node weight, parent pointer, and then, finally, codeword length. Algorithm 1 is taken from Moffat and Katajainen [5] and describes this process in detail. There are three phases of operation. In the first phase, in steps 2–2, leaf weights in $A[leaf \ldots n-1]$ are combined with a queue of internal node weights in $A[root \ldots next-1]$ to form a list of parent pointers in $A[0 \ldots root-1]$. At the end of this phase, $A[0 \ldots n-3]$ is a list of parents, $A[n-2]$ is the sum of the weights, and $A[n-1]$ is unused.

In phase 2 (steps 12–3), the set of parent pointers of internal nodes is converted to a set of internal node depths. This mapping is done by processing the tree from the root down, making the depth of each node one greater than the depth of its parent.

Algorithm 1 Compute Huffman codeword lengths

```
 0: function calc_huff_lens(A, n)                    ▷ Input: A[i − 1] ≤ A[i] for 0 < i < n
 1:     // Phase 1
 2:     set leaf ← 0 and root ← 0
 3:     for next ← 0 to n − 2 do
 4:         if leaf ≥ n or (root < next and A[root] < A[leaf]) then
 5:             set A[next] ← A[root] and A[root] ← next and root ← root + 1   ▷ Use internal node
 6:         else
 7:             set A[next] ← A[leaf] and leaf ← leaf + 1                      ▷ Use leaf node
 8:         end if
 9:         repeat steps 1–8, but adding to A[next] rather than assigning to it   ▷ Find second child
10:     end for
11:     // Phase 2
12:     set A[n − 2] ← 0
13:     for next ← n − 3 downto 0 do
14:         set A[next] ← A[A[next]] + 1                   ▷ Compute depths of internal nodes
15:     end for
16:     // Phase 3
17:     set avail ← 1 and used ← 0 and depth ← 0 and root ← n − 2 and next ← n − 1
18:     while avail > 0 do
19:         while root ≥ 0 and A[root] = depth do
                                          ▷ Count internal nodes used at depth depth
20:             set used ← used + 1 and root ← root − 1
21:         end while
22:         while avail > used do          ▷ Assign as leaves any nodes that are not internal
23:             set A[next] ← d and next ← next − 1 and avail ← avail − 1
24:         end while
25:         set avail ← 2 · used and depth ← depth + 1 and used ← 0        ▷ Move to next depth
26:     end while
27:     return A                ▷ Output: A[i] is the length ℓ_i of the i th codeword
28: end function
```

Phase 3 (steps 17–4) then processes those internal node depths and converts them to a list of leaf depths. At each depth, some total number *avail* of nodes exist, being twice the number of internal nodes at the previous depth. Some number *used* of those are internal nodes; the balance must thus be leaf nodes at this depth and can be assigned as codeword lengths. Initially there is one node available at $depth = 0$, representing the root of the whole Huffman tree. Table 1 shows several snapshots of the Moffat and Katajainen code construction process when applied to the example sequence of weights.

Nonbinary Output Alphabets

The example Huffman tree developed in Fig. 1 and the process shown in Algorithm 1 assume that the output alphabet is binary. Huffman noted in his original paper that for r-ary alphabets all that is required is to add additional dummy symbols of weight zero, so as to bring the total number of symbols to be one more than a multiple of $(r - 1)$. Each merging step then combines r leaf or internal nodes to form a new root node and decreases the number of items by $r - 1$.

Dynamic Huffman Coding

Another assumption made by the processes described so far is that the symbol weights are known in advance and that the code that is computed can be *static*. This assumption can be satisfied, for example, by making a first pass over the message that is to be encoded. In a *dynamic* coding system, symbols must be coded on the fly, as soon as they are received by the encoder. To achieve this, the code must be adaptive, so that it can be altered after each symbol. Vitter [11] summarizes earlier work by Gallager [2], Knuth [4], and Cormack and Horspool [1] and describes a mechanism in which the total encoding cost, including the cost of keeping the code tree up to date, is

Huffman Coding, Table 1 Sequence of values computed by Algorithm 1 for the example weights. The first row shows the initial state of the array, with $A[i] = w_i$. Values "-2-" indicate parent pointers of internal nodes that have already been merged; italic values "*7*" indicate weights of internal nodes before being merged; values "(4)" indicate depths of internal nodes; bold values "**5**" indicate depths of leaves; and values "–" are unused

	i									
	0	1	2	3	4	5	6	7	8	9
Initial arrangement, $A[i] = w_i$	1	1	1	1	3	4	4	7	9	9
Phase 1, $root = 3, next = 5, leaf = 7$	-2-	-2-	-4-	*7*	*8*	–	–	7	9	9
Phase 1, finished, $root = 8$	-2-	-2-	-4-	-5-	-6-	-7-	-8-	-8-	*40*	–
Phase 2, $next = 4$	-2-	-2-	-4-	-5-	-6-	(2)	(1)	(1)	(0)	–
Phase 2, finished	(4)	(4)	(3)	(3)	(2)	(2)	(1)	(1)	(0)	–
Phase 3, $next = 5, avail = 4$	(4)	(4)	(3)	(3)	(2)	(2)	**3**	**3**	**2**	**2**
Final arrangement, $A[i] = \ell_i$	**5**	**5**	**5**	**5**	**4**	**4**	**3**	**3**	**2**	**2**

$O(1)$ per output bit. Turpin and Moffat [9] describe an alternative approximate algorithm that reduces the time required by a constant factor, by collecting the frequency updates into batches and allowing controlled inefficiency in the length of the coded output sequence. Their "GEO" Coding method is faster than dynamic Huffman Coding and also faster than dynamic Arithmetic Coding, which is comparable in speed to dynamic Huffman Coding, but uses less space for the dynamic frequency-counting data structure.

Applications

Minimum-redundancy codes have widespread use in data compression systems. The sequences of weights are usually conditioned according to a *model*, rather than taken as plain symbol frequency counts in the source message. The use of multiple conditioning contexts, and hence multiple codes, one per context, allows improved compression when symbols are not independent in the message, as is the case in natural language data. However, when the contexts are sufficiently specific that highly biased probability distributions arise, Arithmetic Coding will yield superior compression effectiveness.

Turpin and Moffat [8] consider several ancillary components of Huffman Coding, including methods for transmitting the description of the code to the decoder.

Definition

The input/output model (I/O model) [1] views the computer as consisting of a *processor*, *internal memory* (RAM), and *external memory* (disk). See Fig. 1. The internal memory is of limited size, large enough to hold M data items. The external memory is of conceptually unlimited size and is divided into *blocks* of B consecutive data items. All computation has to happen on data in internal memory. Data is brought into internal memory and written back to external memory using *I/O operations* (I/Os), which are performed explicitly by the algorithm. Each such operation reads or writes one block of data from or to external memory. The complexity of an algorithm in this model is the number of I/Os it performs.

The *parallel disk model* (PDM) [15] is an extension of the I/O model that allows the external memory to consist of $D \geq 1$ parallel disks. See Fig. 2. In this model, a single I/O operation is capable of reading or writing up to D independent blocks, as long as each of them is stored on a different disk.

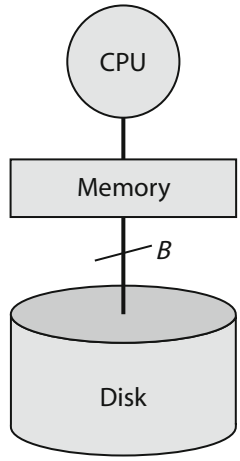
The *parallel external memory* (PEM) [5] model is a simple multiprocessor extension of the I/O model. See Fig. 3. It consists of P processing units, each having a private cache of size M. Data exchange between the processors takes place via a shared main memory of conceptually unlimited size: in a parallel I/O operation, each processor can transfer one block of size B between its private cache and the shared memory.

The relationship between the PEM model and the very popular MapReduce framework is discussed in [8]. A survey of realistic computer models can be found in [2].

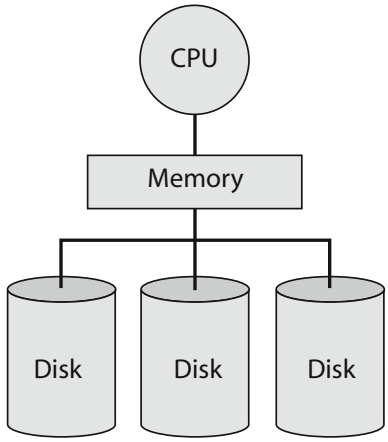
Key Results

A few complexity bounds are of importance to virtually every I/O-efficient algorithm or data structure. The *searching bound* of $\Theta(\log_B n)$ I/Os, which can be achieved using a Btree [6], is

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4



I/O-Model, Fig. 1 The I/O model



I/O-Model, Fig. 2 The parallel disk model

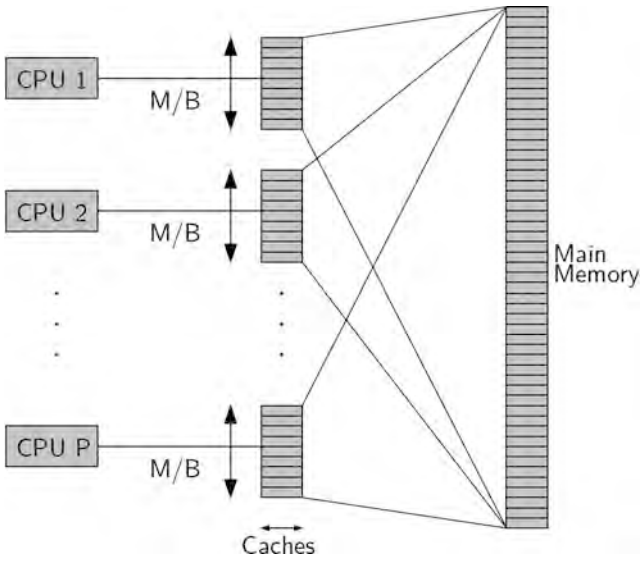
the cost of searching for an element in an ordered collection of n elements using comparisons only. It is thus the equivalent of the $\Theta(\log n)$ searching bound in internal memory.

Scanning a list of n consecutive data items obviously takes $\lceil n/B \rceil$ I/Os. This *scanning bound* is usually referred to as a "linear number of I/Os" because it is the equivalent of the $O(n)$ time bound required to do the same in internal memory. The respective PDM and PEM bounds are $\lceil n/DB \rceil$ and $\lceil n/PB \rceil$.

The *sorting bound* of $\text{sort}(n) = \Theta((n/B)\log_{M/B}(n/B))$ I/Os denotes the cost of sorting n elements using comparisons only. It is thus the equivalent of the $\Theta(n \log n)$ sorting bound in internal memory. In the PDM and PEM model, the sorting bound becomes $\Theta((n/DB)\log_{M/B}(n/B))$ and $\Theta((n/PB)\log_{M/B}(n/B))$, respectively. The sorting bound can be achieved using a range of sorting algorithms, including external merge sort [1, 5, 10] and distribution sort [1,5,9].

Arguably, the most interesting bound is the *permutation bound*, that is, the cost of rearranging n elements in a given order, which is $\Theta(\min(\text{sort}(n), n))$ [1] or, in the PDM, $\Theta(\min(\text{sort}(n), n/D))$ [15]. For all practical purposes, this is the same as the sorting bound. Note the contrast to internal memory where, up to constant factors, permuting has the same cost as a linear scan. Since almost all nontrivial algorithmic problems include a permutation problem, this implies that only exceptionally simple problems can be solved in $O(\text{scan}(n))$ I/Os; most problems have an $\Omega(\text{perm}(n))$, that is, essentially an $\Omega(\text{sort}(n))$ lower bound. Therefore, while internal-memory algorithms aiming for linear time have to carefully avoid the use of sorting as a tool, external-memory algorithms can sort without fear of significantly exceeding the lower bound. This makes the design of I/O-optimal algorithms potentially easier than the design of optimal internal-memory algorithms. It is, however, counterbalanced by the fact that, unlike in internal memory, the sorting bound is *not* equal to n times the searching bound, which implies that algorithms based on querying a tree-based search structure $O(n)$ times usually do not translate into I/O-efficient algorithms. *Buffer trees* [4] achieve an amortized search bound of $O((1/B)\log_{M/B}(N/B))$ I/Os but can be used only if the entire update and query sequence is known in advance and thus provide only a limited solution to this problem.

Apart from these fundamental results, there exist a wide range of interesting techniques, particularly for solving geometric and graph problems. For surveys, refer to [3, 14]. Also, many I/O-efficient algorithms have been derived from fast and work-efficient *parallel* algorithms; see the book entry on external-memory list ranking for a well-known example of this technique.



I/O-Model, Fig. 3 The PEM model

Applications

Modern computers are equipped with memory hierarchies consisting of several levels of cache memory, main memory (RAM), and disk(s). Access latencies increase with the distance from the processor, as do the sizes of the memory levels. To amortize these increasing access latencies, data are transferred between different levels of cache in blocks of consecutive data items. As a result, the cost of a memory access depends on the level in the memory hierarchy currently holding the data item – the difference in access latency between L1 cache and disk is about 10^6 – and the cost of a sequence of accesses to data items stored at the same level depends on the number of blocks over which these items are distributed.

Traditionally, algorithms were designed to minimize the number of computation steps; the access locality necessary to solve a problem using few data transfers between memory levels was largely ignored. Hence, the designed algorithms work well on data sets of moderate size but do not take noticeable advantage of cache memory and usually break down completely in out-of-core computations. Since the difference in access latencies is largest between main memory and disk, the I/O model focuses on minimizing this I/O bottleneck. This two-level view of the memory hierarchy keeps the model simple and useful for analyzing sophisticated algorithms while providing a good prediction of their practical performance. The picture is slightly more complex for flash memory-based solid state disks, which have recently become quite popular (also due to their *energy* efficiency [7]): not only do they internally use different block sizes for reading and writing, but their (reading) latency is also significantly smaller compared to traditional hard disks. Nevertheless, the latency gap of solid state disks compared to main memory remains large, and optimized device controllers or translation layers manage to hide the read/write discrepancy in most practical settings. Thus, the I/O model still provides reasonable estimates on flash memory, but extended models with different block sizes and access costs for reading and writing are more accurate.

Much effort has been made already to translate provably I/O-efficient algorithms into highly efficient implementations. Examples include TPIE [12] and STXXL [11], two libraries that aim to provide highly optimized and powerful primitives for the implementation of I/O-efficient algorithms. In particular, TPIE has been used to realize a number of geometric and GIS applications, whereas STXXL has served as a basis for the implementation of various graph algorithms.

In spite of these efforts, a significant gap between the theory and practice of I/O-efficient algorithms remains (see next section).

Open Problems

There are a substantial number of open problems in the area of I/O-efficient algorithms. The most important ones concern graph and geometric problems.

Traditional graph algorithms usually apply a well-organized graph traversal such as depth-first search or breadth-first search to gain information about the structure of the graph and then use this information to solve the problem at hand. For massive sparse graphs, no I/O-efficient depth-first search algorithm is known, and for breadth-first search and shortest paths, only limited progress has been made on undirected graphs. Some recent results concern dynamic and approximation variants or all-pairs shortest paths problems. For directed graphs, even such simple problems as deciding whether there exists a directed path between two vertices are currently still open. The main research focus in this area is therefore to either develop (or disprove the existence of) I/O-efficient general traversal algorithms or to continue the current strategy of devising graph algorithms that depart from traditional traversal-based approaches.

Techniques for solving geometric problems I/O efficiently are much better understood than is the case for graph algorithms, at least in two dimensions. Nevertheless, there are a few important frontiers that remain. Despite new results on some range reporting problems in three and higher dimensions, arguably the most important frontier is the development of I/O-efficient algorithms and data structures for higher-dimensional geometric problems. Motivated by database applications, results on specialized range searching variants (such as coloured and top-K range searching) have begun to appear in the literature. Little work has been done in the past on solving proximity problems, which pose another frontier currently being explored. Motivated by the need for such structures in a range of application areas and in particular in geographic information systems, there has been some recent focus on the development of multifunctional data structures, that is, structures that can answer different types of queries efficiently. This is in contrast to most existing structures, which are carefully tuned to efficiently support *one* particular type of query.

We also face a significant lack of external-memory lower bounds. Classic results concern permuting and sorting (see [14] for an overview), and more recent results concentrate on I/O-efficient data structure problems such as dynamic membership [13]. The optimality of many basic external-memory algorithms, however, is completely open. For instance, it is unclear whether sparse graph traversal (and hence probably a large number of advanced graph problems) will ever be solvable in an I/O-efficient manner.

For both I/O-efficient graph algorithms and computational geometry, there is still a substantial gap between the obtained theoretical results and what is known to be practical, even though quite some *algorithm engineering* work has been done during the last decade. Thus, if I/O-efficient algorithms in these areas are to have more practical impact, increased efforts are needed to bridge this gap by developing practically I/O-efficient algorithms that are still *provably* efficient.

Problem Definition

DIMACS Implementation Challenges (http://dimacs.rutgers.edu/Challenges/) are scientific events devoted to assessing the practical performance of algorithms in experimental settings, fostering effective technology transfer and establishing common benchmarks for fundamental computing problems. They are organized by DIMACS, the Center for Discrete Mathematics and Theoretical Computer Science. One of the main goals of DIMACS Implementation Challenges is to address questions of determining realistic algorithm performance where worst case analysis is overly pessimistic and probabilistic models are too unrealistic: experimentation can provide guides to realistic algorithm performance where analysis fails. Experimentation also brings

algorithmic questions closer to the original problems that motivated theoretical work. It also tests many assumptions about implementation methods and data structures. It provides an opportunity to develop and test problem instances, instance generators, and other methods of testing and comparing performance of algorithms. And it is a step in technology transfer by providing leading edge implementations of algorithms for others to adapt.

The first Challenge was held in 1990–1991 and was devoted to *Network flows and Matching*. Other addressed problems included: *Maximum Clique, Graph Coloring, and Satisfiability* (1992–1993), *Parallel Algorithms for Combinatorial Problems* (1993–1994), *Fragment Assembly and Genome Rearrangements* (1994–1995), *Priority Queues, Dictionaries, and Multi-Dimensional Point Sets* (1995–1996), *Near Neighbor Searches* (1998–1999), *Semidefinite and Related Optimization Problems* (1999–2000), and *The Traveling Salesman Problem* (2000–2001).

This entry addresses the goals and the results of the *9th DIMACS Implementation Challenge*, held in 2005–2006 and focused on *Shortest Path* problems.

The 9th DIMACS Implementation Challenge: The Shortest Path Problem

Shortest path problems are among the most fundamental combinatorial optimization problems with many applications, both direct and as subroutines in other combinatorial optimization algorithms. Algorithms for these problems have been studied since the 1950s and still remain an active area of research.

One goal of this Challenge was to create a reproducible picture of the state of the art in the area of shortest path algorithms, identifying a standard set of benchmark instances and generators, as well as benchmark implementations of well-known shortest path algorithms. Another goal was to enable current researchers to compare their codes with each other, in hopes of identifying the more effective of the recent algorithmic innovations that have been proposed.

Challenge participants studied the following variants of the shortest paths problem:

- *Point to point shortest paths* [4, 5, 6, 9, 10, 11, 14]: the problem consists of answering multiple online queries about the shortest paths between pairs of vertices and/or their lengths. The most efficient solutions for this problem preprocess the graph to create a data structure that facilitates answering queries quickly.
- *External-memory shortest paths* [2]: the problem consists of finding shortest paths in a graph whose size is too large to fit in internal memory. The problem actually addressed in the Challenge was single-source shortest paths in undirected graphs with unit edge weights.
- *Parallel shortest paths* [8, 12]: the problem consists of computing shortest paths using multiple processors, with the goal of achieving good speedups over traditional sequential implementations. The problem actually addressed in the Challenge was single-source shortest paths.
- *K-shortest paths* [13, 15]: the problem consists of ranking paths between a pair of vertices by non decreasing order of their length.
- *Regular-language constrained shortest paths:* [3] the problem consists of a generalization of shortest path problems where paths must satisfy certain constraints specified by a regular language. The problems studied in the context of the Challenge were single-source and point-to-point shortest paths, with applications ranging from transportation science to databases.

The Challenge culminated in a Workshop held at the DIMACS Center at Rutgers University, Piscataway, New Jersey on November 13–14, 2006. Papers presented at the conference are available at the URL: http://www.dis.uniroma1.it/~challenge9/papers.shtml. Selected contributions are expected to appear in a book published by the American Mathematical Society in the DIMACS Book Series.

Key Results

The main results of the 9th DIMACS Implementation Challenge include:

- Definition of common file formats for several variants of the shortest path problem, both static and dynamic. These include an extension of the famous DIMACS graph file format used by several algorithmic software libraries. Formats are described at the URL: http://www.dis.uniroma1.it/~challenge9/formats.shtml.
- Definition of a common set of core input instances for evaluating shortest path algorithms.
- Definition of benchmark codes for shortest path problems.
- Experimental evaluation of state-of-the-art implementations of shortest path codes on the core input families.
- A discussion of directions for further research in the area of shortest paths, identifying problems critical in real-world applications for which efficient solutions still remain unknown.

The chief information venue about the 9th DIMACS Implementation Challenge is the website http://www.dis.uniroma1.it/~challenge9.

Applications

Shortest path problems arise naturally in a remarkable number of applications. A limited list includes transportation planning, network optimization, packet routing, image segmentation, speech recognition, document formatting, robotics, compilers, traffic information systems, and dataflow analysis. It also appears as a subproblem of several other combinatorial optimization problems such as network flows. A comprehensive discussion of applications of shortest path problems appears in [1].

Open Problems

There are several open questions related to shortest path problems, both theoretical and practical. One of the most prominent discussed at the 9th DIMACS Challenge Workshop is modeling traffic fluctuations in point-to-point shortest paths. The current fastest implementations preprocess the input graph to answer point-to-point queries efficiently, and this operation may take hours on graphs arising in large-scale road map navigation systems. A change in the traffic conditions may require rescanning the whole graph several times. Currently, no efficient technique is known for updating the preprocessing information without rebuilding it from scratch. This would have a major impact on the performance of routing software.

Data Sets

The collection of benchmark inputs of the 9th DIMACS Implementation Challenge includes both synthetic and real-world data. All graphs are strongly connected. Synthetic graphs include random graphs, grids, graphs embedded on a torus, and graphs with small-world properties. Real-world inputs consist of graphs representing the road networks of Europe and USA. Europe graphs are provided by courtesy of the PTV company, Karlsruhe, Germany, subject to signing a (no-cost) license agreement. They include the road networks of 17 European countries: AUT, BEL, CHE, CZE, DEU, DNK, ESP, FIN, FRA, GBR, IRL, ITA, LUX, NDL, NOR, PRT, SWE, with a total of about 19 million nodes and 23 million edges. USA graphs are derived from the *UA Census 2000 TIGER/Line Files* produced by the Geography Division of the US Census Bureau, Washington, DC. The TIGER/Line collection is available at: http://www.census.gov/geo/www/tiger/tigerua/ua_tgr2k.html. The Challenge USA core family contains a graph representing the full USA road system with about 24 million nodes and 58 million edges, plus 11 subgraphs obtained by cutting it along different bounding boxes as shown in Table 1. Graphs in the collection include also node coordinates and are given in DIMACS format.

The benchmark input package also features query generators for the single-source and point-to-point shortest path problems. For the single-source version, sources are randomly chosen. For the point-to-point problem, both random and

local queries are considered. Local queries of the form (s, t) are generated by randomly picking t among the nodes with rank in $[2^i, 2^{i+1})$ in the ordering in which nodes are scanned by Dijkstra's algorithm with source s, for any parameter i. Clearly, the smaller i is, the closer nodes s and t are in the graph. Local queries are important to test how the algorithms' performance is affected by the distance between query endpoints.

Experimental Results

One of the main goals of the Challenge was to compare different techniques and algorithmic approaches. The most popular topic was the point-to-point shortest path problem, studied by six research groups in the context of the Challenge. For this problem, participants were additionally invited to join a competition aimed at assessing the performance and the robustness of different implementations. The competition consisted of preprocessing a version of the full USA graph of Table 1 with unit edge lengths and answering a sequence of 1,000 random distance queries. The details were announced on the first day of the workshop and the results were due on the second day. To compare experimental results by different participants on different platforms, each participant ran a Dijkstra benchmark code [7] on the USA graph to do machine calibration. The final ranking was made by considering each query time divided by the time required by the benchmark code on the same platform (benchmark ratio). Other performance measures taken into account were space usage and the average number of nodes scanned by query operations.

Six point-to-point implementations were run successfully on the USA graph defined for the competition. Among them, the fastest query time was achieved by the *HH-based transit* code [14]. Results are reported in Table 2. Codes *RE* and *REAL*(16, 1) [9] were not eligible for the competition, but used by the organizers as a proof that the problem is feasible. Some other codes were not able to deal with the size of the full USA graph, or incurred runtime errors.

Experimental results for other variants of the shortest paths problem are described in the papers presented at the Challenge Workshop.

Years and Authors of Summarized Original Work

2002; Johnson, McGeoch

Problem Definition

The Eighth DIMACS Implementation Challenge, sponsored by DIMACS, the Center for Discrete Mathematics and Theoretical Computer Science, concerned heuristics for the symmetric Traveling Salesman Problem. The Challenge began in June 2000 and was organized by David S. Johnson, Lyle A. McGeoch, Fred Glover and César Rego. It explored the state-of-the-art in the area of TSP heuristics, with researchers testing a wide range of implementations on a common (and diverse) set of input instances. The Challenge remained ongoing in 2007, with new results still being accepted by the organizers and posted on the Challenge website: www.research.att.com/~dsj/chtsp. A summary of the submissions through 2002 appeared in a book chapter by Johnson and McGeoch [5].

Participants tested their heuristics on four types of instances, chosen to test the robustness and scalability of different approaches:

1. The 34 instances that have at least 1000 cities in TSPLIB, the instance library maintained by Gerd Reinelt.
2. A set of 26 instances consisting of points uniformly distributed in the unit square, with sizes ranging from 1000 to 10,000,000 cities.
3. A set of 23 randomly generated clustered instances, with sizes ranging from 1000 to 316,000 cities.
4. A set of 7 instances based on random distance matrices, with sizes ranging from 1000 to 10,000 cities.

The TSPLIB instances and generators for the random instances are available on the Challenge website. In addition, the website contains a collection of instances for the asymmetric TSP problem.

For each instance upon which a heuristic was tested, the implementers reported the machine used, the tour length produced, the user time, and (if possible) memory usage. Some heuristics could not be applied to all of the instances, either because the heuristics were inherently geometric or because the instances were too large. To help facilitate timing comparisons between heuristics tested on different machines, participants ran a benchmark heuristic (provided by the organizers) on instances of different sizes. The benchmark times could then be used to normalize, at least approximately, the observed running times of the participants' heuristics.

The quality of a tour was computed from a submitted tour length in two ways: as a ratio over the optimal tour length for the instance (if known), and as a ratio over the Held-Karp (HK) lower bound for the instance. The Concorde optimization package of Applegate et al. [1] was able to find the optimum for 58 of the instances in reasonable time. Concorde was used in a second way to compute the HK lower bound for all but the three largest instances. A third algorithm, based on Lagrangian relaxation, was used to compute an approximate HK bound, a lower bound on true HK bound, for the remaining instances. The Challenge website reports on each of these three algorithms, presenting running times and a comparison of the bounds obtained for each instance.

The Challenge website permits a variety of reports to be created:

1. For each heuristic, tables can be generated with results for each instance, including tour length, tour quality, and raw and normalized running times.

2. For each instance, a table can be produced showing the tour quality and normalized running time of each heuristic.
3. For each pair of heuristics, tables and graphs can be produced that compare tour quality and running time for instances of different type and size.

Heuristics for which results were submitted to the Challenge fell into several broad categories:

Heuristics designed for speed. These heuristics – all of which target geometric instances – have running times within a small multiple of the time needed to read the input instance. Examples include the strip and spacefilling-curve heuristics. The speed requirement affects tour quality dramatically. Two of these algorithms produced tours with 14 % of the HK lower bound for a particular TSPLIB instance, but none came within 25 % on the other 89 instances.

Tour construction heuristics. These heuristics construct tours in various ways, without seeking to find improvements once a single tour passing through all cities is found. Some are simple, such as the nearest-neighbor and greedy heuristics, while others are more complex, such as the famous Christofides heuristic. These heuristics offer a number of options in trading time for tour quality, and several produce tours within 15 % of the HK lower bound on most instances in reasonable time. The best of them, a variant of Christofides, produces tours within 8 % on uniform instances but is much more time-consuming than the other algorithms.

Simple local improvement heuristics. These include the well-known two-opt and three-opt heuristics and variants of them. These heuristics outperform tour construction heuristics in terms of tour quality on most types of instances. For example, 3-opt gets within about 3 % of the HK lower bound on most uniform instances. The submissions in this category explored various implementation choices that affect the time-quality tradeoff.

Lin-Kernighan and its variants. These heuristics extend the local search neighborhood used in 3-opt. Lin-Kernighan can produce high-quality tours (for example, within 2 % of the HK lower bound on uniform instances) in reasonable time. One variant, due to Helsgaun [3], obtains tours within 1 % on a wide variety of instances, although the running time can be substantial.

Repeated local search heuristics. These heuristics are based on repeated executions of a heuristic such as Lin-Kernighan, with random kicks applied to the tour after a local optimum is found. These algorithms can yield high-quality tours at increased running time.

Heuristics that begin with repeated local search. One example is the tour-merge heuristic [2], which runs repeated local search multiple times, builds a graph containing edges found in the best tours, and does exhaustive search within the resulting graph. This approach yields the best known tours for some of the instances in the Challenge.

The submissions to the Challenge demonstrated the remarkable effectiveness of heuristics for the traveling salesman problem. They also showed that implementation details, such a choice of data structure or whether to approximate aspects of the computation, can affect running time and/or solution quality greatly. Results for a given heuristic also varied enormously depending on the type of instance to which it is applied.

Implementing Shared Registers in Asynchronous Message-Passing Systems

Eric Ruppert
Department of Computer Science and Engineering, York University, Toronto, ON, Canada

Keywords

Emulation; Simulation

Years and Authors of Summarized Original Work

1995; Attiya, Bar-Noy, Dolev

Problem Definition

A distributed system is composed of a collection of n processes which communicate with one another. Two means of interprocess communication have been heavily studied. *Message-passing systems* model computer networks where each process can send information over message channels to other processes. In *shared-memory systems*, processes communicate less directly by accessing information in shared data structures. Distributed algorithms are often easier to design for shared-memory systems because of their similarity to single-process system architectures. However, many real distributed systems are constructed as message-passing systems. Thus, a key problem in distributed computing is the implementation of shared memory in message-passing systems. Such implementations are also called simulations or emulations of shared memory.

The most fundamental type of shared data structure to implement is a *(read-write) register*, which stores a value, taken from some domain D. It is initially assigned a value from D and can be accessed by two kinds of operations, read and write(v), where $v \in D$. A register may be either *single-writer*, meaning only one process is allowed to write it, or *multi-writer*, meaning any process may write to it. Similarly, it may be either *single-reader* or *multi-reader*. Attiya and Welch [4] give a survey of how to build multi-writer, multi-reader registers from single-writer, single-reader ones.

If reads and writes are performed one at a time, they have the following effects: a read returns the value stored in the register to the invoking process, and a write(v) changes the value stored in the register to v and returns an acknowledgment, indicating that the operation is complete. When many processes apply operations concurrently, there are several ways to specify a register's behavior [14]. A single-writer register is *regular* if each read returns either the argument of the write that completed most recently before the read began or the argument of some write operation that runs concurrently with the read. (If there is no write that completes before the read begins, the read may return either the initial value of the register or the value of a concurrent write operation.) A register is *atomic* (see ▸ Linearizability) if each operation appears to take place instantaneously. More precisely, for any concurrent execution, there is a total order of the operations such that each read returns the value written by the last write that precedes it in the order (or the initial value of the register, if there is no such write).

Moreover, this total order must be consistent with the temporal order of operations: if one operation finishes before another one begins, the former must precede the latter in the total order. Atomicity is a stronger condition than regularity, but it is possible to implement atomic registers from regular ones with some complexity overhead [12].

This article describes the problem of implementing registers in an asynchronous message-passing system in which processes may experience crash failures. Each process can send a message, containing a finite string, to any other process. To make the descriptions of algorithms more uniform, it is often assumed that processes can send messages to themselves. All messages are eventually delivered. In the algorithms described below, senders wait for an acknowledgment of each message before sending the next message, so it is not necessary to assume that the message channels are first-in-first-out. The system is totally asynchronous: there is no bound on the time required for a message to be delivered to its recipient or for a process to perform a step of local computation. A process that fails by crashing stops executing its code, but other processes cannot distinguish between a process that has crashed and one that is running very slowly. (Failures of message channels [3] and more malicious kinds of process failures [15] have also been studied.)

A *t-resilient* register implementation provides programmes to be executed by processes to simulate read and write operations. These programmes can include any standard control structures and accesses to a process's local memory, as well as instructions to send a message to another process and to read the process's buffer, where incoming messages are stored. The implementation should also specify how the processes' local variables are initialized to reflect any initial value of the implemented register. In the case of a single-writer register, only one process may execute the write programme. A process may invoke the read and write programmes repeatedly, but it must wait for one invocation to complete before starting the next one. In any such execution where at most t processes crash, each of a process's invocations of the read or write programme should eventually terminate. Each read operation returns a result from the set D, and these results should satisfy regularity or atomicity.

Relevant measures of algorithm complexity include the number of messages transmitted in the system to perform an operation, the number of bits per message, and the amount of local memory required at each process. One measure of time complexity is the time needed to perform an operation, under the optimistic assumption that the time to deliver messages is bounded by Δ and local computation is instantaneous (although algorithms must work correctly even without these assumptions).

Key Results

Implementing a Regular Register

One of the core ideas for implementing shared registers in message-passing systems is a construction that implements a regular single-writer multi-reader register. It was introduced by Attiya, Bar-Noy and Dolev [3] and made more explicit by Attiya [2]. A write(v) sends the value v to all processes and waits until a majority of the processes ($\lfloor \frac{n}{2} \rfloor + 1$, including the writer itself) return an acknowledgment. A reader sends a request to all processes for their latest values. When it has received responses from a majority of processes, it picks the most recently written value among them. If a write completes before a read begins, at least one process that answers the reader has received the write's value prior to sending its response to the reader. This is because any two sets that each contain a majority of the processes must overlap. The time required by operations when delivery times are bounded is 2Δ.

This algorithm requires the reader to determine which of the values it receives is most recent. It does this using *timestamps* attached to the values. If the writer uses increasing integers as timestamps, the messages grow without bound as

the algorithm runs. Using the bounded timestamp scheme of Israeli and Li [13] instead yields the following theorem.

Theorem 1 (Attiya [2]) *There is an* $\lceil \frac{n-2}{2} \rceil$*-resilient implementation of a regular single-writer, multi-reader register in a message-passing system of n processes. The implementation uses* $\Theta(n)$ *messages per operation, with* $\Theta(n^3)$ *bits per message. The writer uses* $\Theta(n^4)$ *bits of local memory and each reader uses* $\Theta(n^3)$ *bits.*

Theorem 1 is optimal in terms of fault-tolerance. If $\lceil \frac{n}{2} \rceil$ processes can crash, the network can be partitioned into two halves of size $\lfloor \frac{n}{2} \rfloor$, with messages between the two halves delayed indefinitely. A write must terminate before any evidence of the write is propagated to the half not containing the writer, and then a read performed by a process in that half cannot return an up-to-date value. For $t \geq \lceil \frac{n}{2} \rceil$, registers can be implemented in a message-passing system only if some degree of synchrony is present in the system. The exact amount of synchrony required was studied by Delporte-Gallet et al. [6].

Theorem 1 is within a constant factor of the optimal number of messages per operation. Evidence of each write must be transmitted to at least $\lceil \frac{n}{2} \rceil - 1$ processes, requiring $\Omega(n)$ messages; otherwise this evidence could be obliterated by crashes. A write must terminate even if only $\lfloor \frac{n}{2} \rfloor + 1$ processes (including the writer) have received information about the value written, since the rest of the processes could have crashed. Thus, a read must receive information from at least $\lceil \frac{n}{2} \rceil$ processes (including itself) to ensure that it is aware of the most recent write operation.

A t-resilient implementation, for $t < \lceil \frac{n}{2} \rceil$, that uses $\Theta(t)$ messages per operation is obtained by the following adaptation. A set of $2t + 1$ processes is preselected to be data storage servers. Writes send information to the servers, and wait for $t + 1$ acknowledgments. Reads wait for responses from $t + 1$ of the servers and choose the one with the latest timestamp.

Implementing an Atomic Register

Attiya, Bar-Noy and Dolev [3] gave a construction of an atomic register in which readers forward the value they return to all processes and wait for an acknowledgment from a majority. This is done to ensure that a read does not return an older value than another read that precedes it. Using unbounded integer timestamps, this algorithm uses $\Theta(n)$ messages per operation. The time needed per operation when delivery times are bounded is 2Δ for writes and 4Δ for reads. However, their technique of bounding the timestamps increases the number of messages per operation to $\Theta(n^2)$ (and the time per operation to 12Δ). A better implementation of atomic registers with bounded message size is given by Attiya [2]. It uses the regular registers of Theorem 1 to implement atomic registers using the "handshaking" construction of Haldar and Vidyasankar [12], yielding the following result.

Theorem 2 (Attiya [2]) *There is an* $\lceil \frac{n-2}{2} \rceil$*-resilient implementation of an atomic single-writer, multi-reader register in a message-passing system of n processes. The implementation uses* $\Theta(n)$ *messages per operation, with* $\Theta(n^3)$ *bits per message. The writer uses* $\Theta(n^5)$ *bits of local memory and each reader uses* $\Theta(n^4)$ *bits.*

Since atomic registers are regular, this algorithm is optimal in terms of fault-tolerance and within a constant factor of optimal in terms of the number of messages. The time used when delivery times are bounded is at most 14Δ for writes and 18Δ for reads.

Applications

Any distributed algorithm that uses shared registers can be adapted to run in a message-passing system using the implementations described above. This approach yielded new or improved message-passing solutions for a number of problems, including randomized consensus [1], multi-writer registers [4], and snapshot objects ▸ Distributed Snapshots. The

reverse simulation is also possible, using a straightforward implementation of message channels by single-writer, single-reader registers. Thus, the two asynchronous models are equivalent, in terms of the set of problems that they can solve, assuming only a minority of processes crash. However there is some complexity overhead in using the simulations.

If a shared-memory algorithm is implemented in a message-passing system using the algorithms described here, processes must continue to operate even when the algorithm terminates, to help other processes execute their reads and writes. This cannot be avoided: if each process must stop taking steps when its algorithm terminates, there are some problems solvable with shared registers that are not solvable in the message-passing model [5].

Using a majority of processes to "validate" each read and write operation is an example of a quorum system, originally introduced for replicated data by Gifford [10]. In general, a quorum system is a collection of sets of processes, called quorums, such that every two quorums intersect. Quorum systems can also be designed to implement shared registers in other models of message-passing systems, including dynamic networks and systems with malicious failures. For examples, see [7, 9, 11, 15].

Open Problems

Although the algorithms described here are optimal in terms of fault-tolerance and message complexity, it is not known if the number of bits used in messages and local memory is optimal. The exact time needed to do reads and writes when messages are delivered within time Δ is also a topic of ongoing research. (See, for example, [8].) As mentioned above, the simulation of shared registers can be used to implement shared-memory algorithms in message-passing systems. However, because the simulation introduces considerable overhead, it is possible that some of those problems could be solved more efficiently by algorithms designed specifically for message-passing systems.

Problem Definition

Ensuring truthful evaluation of alternatives in human activities has always been an important issue throughout history. In sports, in particular, such an issue is vital and practice of the fair-play principle has been consistently put forward as a matter of foremost priority. In addition to relying on the code of ethics and professional responsibility of players and coaches, the design of game rules is an important measure in enforcing fair play.

Ranking alternatives through pairwise comparisons (or competitions) is the most common approach in sports tournaments. Its goal is to find out the "true" ordering among alternatives through complete or partial pairwise competitions [1, 3–7]. Such studies have been mainly based on the assumption that all the players play truthfully, i.e., with their maximal effort. It is, however, possible that some players form a coalition and cheat for group benefit. An interesting example can be found in [2].

Problem Description

The work of Chen, Deng, and Liu [2] considers the problem of choosing m winners out of n candidates.

Suppose a tournament is held among n players $P_n = \{p_1, \ldots p_n\}$ and m winners are expected to be selected by a selection protocol. Here a protocol $f_{n,m}$ is a predefined function (which will become clear later) to choose winners through pairwise competitions, with the intention of finding m players of highest capacity. When the tournament starts, a distinct ID in $N_n = \{1, 2, \ldots n\}$ is assigned to each player in P_n by a randomly picked indexing function $I : P_n \to N_n$. Then a match is played between each pair of players. The competition outcomes will form a graph G, whose vertex set is N_n and edges represent the results of all the matches. Finally, the graph will be treated as the input to $f_{n,m}$, and it will output a set of m winners. Now it should be clear that $f_{n,m}$ maps every possible tournament graph G to a subset (of cardinality m) of N_n.

Suppose there exists a group of bad players who play dishonestly, i.e., they might lose a match on purpose to gain overall benefit for the whole group, while the rest of the players always play truthfully, i.e., they try their best to win matches. The group of bad players gains benefit if they are able to have more winning positions than that according to the true ranking. Given knowledge of the selection protocol $f_{n,m}$, the indexing function I, and the true ranking of all players, the bad players try to find a cheating strategy that can fool the protocol and gain benefit.

The problem is discussed under two models in which the characterizations of bad players are

different. Under the *collective incentive compatible model*, bad players are willing to sacrifice themselves to win group benefit, while the ones under the *alliance incentive compatible model* only cooperate if their individual interests are well maintained in the cheating strategy.

The goal is to find an "ideal" protocol, under which players or groups of players maximize their benefits only by strictly following the fair-play principle, i.e., always play with maximal effort.

Formal Definitions

When the tournament begins, an indexing function I is randomly picked, which assigns ID $I(p) \in N_n$ to each player $p \in P_n$. Then a match is played between each pair of players, and the results are represented as a directed graph G. Finally, G is fed into the predefined selection protocol $f_{n,m}$, to produce a set of m winners $I^{-1}(W)$, where $W = f_{n,m}(G) \subset N_n$.

Notations

An indexing function I for a tournament attended by n players $P_n = \{p_1, p_2, \ldots p_n\}$ is a one-to-one correspondence from P_n to the set of IDs: $N_n = \{1, 2, \ldots n\}$. A ranking function R is a one-to-one correspondence from P_n to $\{1, 2, \ldots n\}$. $R(p)$ represents the underlying true ranking of player p among the n players. The smaller, the stronger.

A tournament graph of size n is a directed graph $G = (N_n, E)$ such that for all $i \neq j \in N_n$, either $ij \in E$ (player with ID i beats player with ID jn) or $ji \in E_n$. Let K_n denote the set of all such graphs. A selection protocol $f_{n,m}$, which chooses m winners out of n candidates, is a function from K_n to $\{S \subset N_n \text{ and } |S| = m\}$.

A tournament T_n among players P_n is a pair $T_n = (R, B)$ where R is a ranking function from P_n to N_n and $B \subset P_n$ is the group of bad players.

Definition 1 (Benefit) Given a protocol $f_{n,m}$, a tournament $T_n = (R, B)$, an indexing function I, and a tournament graph $G \in K_n$, the benefit of the group of bad players is

$$\text{Ben}(f_{n,m}, T_n, I, G) = |\{i \in f_{n,m}(G),\ I^{-1}(i) \in B\}| - |\{p \in B, R(p) \leq m\}|.$$

Given knowledge of $f_{n,m}$, T_n, and I, not every $G \in K_n$ is a feasible strategy for B: the group of bad players. First, it depends on the tournament $T_n = (R, B)$, e.g., a player $p_b \in B$ cannot win a player $p_g \notin B$ if $R(p_b) > R(p_g)$. Second, it depends on the property of bad players which is specified by the model considered. Tournament graphs, which are recognized as feasible strategies, are characterized below, for each model. The key difference is that a bad player in the alliance incentive compatible model is not willing to sacrifice his/her own winning position, while a player in the other model fights for group benefit at all costs.

Definition 2 (Feasible Strategy) Given $f_{n,m}$, $T_n = (R, B)$, and I, graph $G \in K_n$ is *c-feasible* if

1. For every two players $p_i, p_j \notin B$, if $R(p_i) < R(p_j)$, then $I(p_i)I(p_j) \in E$;
2. For all $p_g \notin B$ and $p_b \in B$, if $R(p_g) < R(p_b)$, then edge $I(p_g)I(p_b) \in E$.

Graph $G \in K_n$ is *a-feasible* if it is c-feasible and also satisfies

1. For every bad player $p \in B$, if $R(p) \leq m$, then $I(p) \in f_{n,m}(G)$.

A cheating strategy is then a feasible tournament graph G that can be employed by the group of bad players to gain positive benefit.

Definition 3 (Cheating Strategy) Given $f_{n,m}$, $T_n = (R, B)$, and I, a cheating strategy for the group of bad players under the collective incentive compatible (alliance incentive compatible) model is a graph $G \in K_n$ which is c-feasible (a-feasible) and satisfies $\text{Ben}(f_{n,m}, T_n, I, G) > 0$.

The following two problems are studied in [2]: (**1**) Is there a protocol $f_{n,m}$ such that for

all T_n and I no cheating strategy exists under the collective incentive compatible model? (**2**) Is there a protocol $f_{n,m}$ such that for all T_n and I, no cheating strategy exists under the alliance incentive compatible model?

Key Results

Definition 4 For all integers n and m such that $2 \leq m \leq n-2$, a tournament graph $G_{n,m} = (N_n, E) \in K_n$, which consists of three parts T_1, T_2, and T_3, is defined as follows:

1. $T_1 = \{1, 2, \ldots .m-2\}$.

For all $i < j \in T_1$, edge $ij \in E$;

2. $T_2 = \{m-1, m, m+1\}$.

$(m-1)m, m(m+1), (m+1)(m-1) \in E$;

3. $T_3 = \{m+2, m+3, \ldots n\}$.

For all $i < j \in T_3$, edge $ij \in E$;

4. For all $i' \in T_i$ and $j' \in T_j$ such that $i < j$, edge $i'j' \in E$.

Theorem 1 *Under the collective incentive compatible model , for every selection protocol $f_{n,m}$ with $2 \leq m \leq n-2$, if $T_n = (R, B)$ satisfies (**1**) at least one bad player ranks as high as $m-1$, (2) the ones ranked $m+1$ and $m+2$ are both bad players, and (**3**) the one ranked m is a good player, then there always exists an indexing function I such that $G_{n,m}$ is a cheating strategy.*

Theorem 2 *Under the alliance incentive compatible model , if $n - m \geq 3$, then there exists a selection protocol $f_{n,m}$ [2] such that for every tournament T_n, indexing function I, and a-feasible strategy $G \in K_n$, $\text{Ben}(f_{n,m}, T_n, I, G) \leq 0$.*

Applications

The result shows that if players are willing to sacrifice themselves, no protocol is able to prevent malicious coalitions from obtaining undeserved benefits.

The result may have potential applications in the design of output truthful mechanisms.

Open Problems

Under the collective incentive compatible model, the work of Chen, Deng, and Liu indicates that cheating strategies are available in at least 1/8 of tournaments, assuming the probability for each player to be in the bad group is 1/2. Could this bound be improved? Or could one find a good selection protocol in the sense that the number of tournaments with cheating strategies is close to this bound? On the other hand, although no ideal protocol exists in this model, does there exist any randomized protocol, under which the probability of having cheating strategies is negligible?

Existence and efficient construction of independent sets of vertices in general random intersection graphs

Years and Authors of Summarized Original Work

2004; Nikoletseas, Raptopoulos, Spirakis

Problem Definition

This problem is concerned with the efficient construction of an independent set of vertices (i.e., a set of vertices with no edges between them) with maximum cardinality, when the input is an instance of the uniform random intersection graphs model. This model was introduced by Karoński, Sheinerman, and Singer-Cohen in [4] and Singer-Cohen in [10] and it is defined as follows

Definition 1 (Uniform random intersection graph) Consider a universe $M=\{1,2,\ldots,m\}$ of elements and a set of vertices $V=\{v_1,v_2,\ldots,v_n\}$. If one assigns independently to each vertex v_j, $j=1,2,\ldots,n$, a subset S_{v_j} of M by choosing each element independently with probability p and puts an edge between two vertices v_{j_1}, v_{j_2} if and only if $S_{v_{j_1}} \cap S_{v_{j_2}} \neq \emptyset$, then the resulting graph is an instance of the uniform random intersection graph $G_{n,m,p}$.

The universe M is sometimes called *label set* and its elements *labels*. Also, denote by L_l, for $l \in M$, the set of vertices that have chosen label l.

Because of the dependence of edges, this model can abstract more accurately (than the Bernoulli random graphs model $G_{n,p}$ that assumes independence of edges) many real-life applications. Furthermore, Fill, Sheinerman, and Singer-Cohen show in [3] that for some ranges of the parameters n, m, p $(m=n^{\alpha}, \alpha>6)$, the spaces $G_{n,m,p}$ and $G_{n,\hat{p}}$ are equivalent in the sense that the total variation distance between the graph random variables has limit 0. The work of Nikoletseas, Raptopoulos, and Spirakis [7] introduces two new models, namely the *general random intersection graphs model* $G_{n,m,\vec{p}}$, $\vec{p}=[p_1,p_2,\ldots,p_m]$ and the *regular random intersection graphs model* $G_{n,m,\lambda}$, $\lambda>0$ that use a different way to randomly assign labels to vertices, but the edge appearance rule remains the same. The $G_{n,m,\vec{p}}$ model is a generalization of the uniform model where each label $i \in M$ is chosen independently with probability p_i, whereas in the $G_{n,m,\lambda}$ model each vertex chooses a random subset of M with exactly λ labels.

The authors in [7] first consider the existence of independent sets of vertices of a given cardinality in general random intersection graphs and provide exact formulae for the mean and variance of the number of independent sets of vertices of cardinality k. Furthermore, they present and analyze three polynomial time (on the number of labels m and the number of vertices n) algorithms for constructing large independent sets of vertices when the input is an instance of the $G_{n,m,p}$ model. To the best knowledge of the

entry authors, this work is the first to consider algorithmic issues for these models of random graphs.

Key Results

The following theorems concern the existence of independent sets of vertices of cardinality k in general random intersection graphs. The proof of Theorem 1 uses the linearity of expectation of sums of random variables.

Theorem 1 *Let $X^{(k)}$ denote the number of independent sets of size k in a random intersection graph $G(n, m, \vec{p})$, where $\vec{p} = [p_1, p_2, \ldots, p_m]$. Then*

$$E\left[X^{(k)}\right] = \binom{n}{k} \prod_{i=1}^{m} \left((1-p_i)^k + k p_i (1-p_i)^{k-1}\right).$$

Theorem 2 *Let $X^{(k)}$ denote the number of independent sets of size k in a random intersection graph $G(n, m, \vec{p})$, where $\vec{p} = [p_1, p_2, \ldots, p_m]$. Then*

$$\mathrm{Var}\left(X^{(k)}\right) = \sum_{s=1}^{k} \binom{n}{2k-s} \binom{2k-s}{s} \left(\gamma(k,s) \frac{E\left[X^{(k)}\right]}{\binom{n}{k}} - \frac{E^2\left[X^{(k)}\right]}{\binom{n}{k}^2}\right)$$

where $E\left[X^{(k)}\right]$ is the mean number of independent sets of size k and

$$\gamma(k,s) = \prod_{i=1}^{m} \left((1-p_i)^{k-s} + (k-s) p_i (1-p_i)^{k-s-1} \left(1 - \frac{s p_i}{1+(k-1)p_i}\right)\right).$$

Theorem 2 is proved by first writing the variance as the sum of covariances and then applying a vertex contraction technique that merges several vertices into one supervertex with similar probabilistic behavior in order to compute the covariances. By using the second moment method (see [1]) one can derive thresholds for the existence of independent sets of size k.

One of the three algorithms that were proposed in [7] is presented below. The algorithm starts with V (i.e., the set of vertices of the graph) as its "candidate" independent set. In every subsequent step it chooses a label and removes from the current candidate independent set all vertices having that label in their assigned label set except for one. Because of the edge appearance rule, this ensures that after doing this for every label in M, the final candidate independent set will contain only vertices that do not have edges between them and so it will be indeed an independent set.

Algorithm:
Input: A random intersection graph $G_{n,m,p}$.
Output: An independent set of vertices A_m.

1. set $A_0 := V$; set $L := M$;
2. **for** $i = 1$ **to** m **do**
3. **begin**
4. select a random label $l_i \in L$; set $L := L - \{l_i\}$;
5. set $D_i := \{v \in A_{i-1} : l_i \in S_v\}$;
6. **if** $(|D_i| \geq 1)$ **then** select a random vertex $u \in D_i$ and set $D_i := D_i - \{u\}$;
7. set $A_i := A_{i-1} - D_i$;
8. **end**
9. **output** A_m;

The following theorem concerns the cardinality of the independent set produced by the algorithm. The analysis of the algorithm uses Wald's equation (see [9]) for sums of a random number of random variables to calculate the mean value of $|A_m|$, and also Chernoff bounds (see e.g., [6]) for concentration around the mean.

Theorem 3 *For the case $mp = \alpha \log n$, for some constant $\alpha > 1$ and $m \geq n$, and for some constant $\beta > 0$, the following hold with high probability:*

1. *If $np \to \infty$ then $|A_m| \geq (1-\beta)\frac{n}{\log n}$.*
2. *If $np \to b$ where $b > 0$ is a constant then $|A_m| \geq (1-\beta)n(1-\mathrm{e}^{-b})$.*
3. *If $np \to 0$ then $|A_m| \geq (1-\beta)n$.*

The above theorem shows that the algorithm manages to construct a quite large independent set with high probability.

Applications

First of all, note that (as proved in [5]) any graph can be transformed into an intersection graph. Thus, the random intersection graphs models can be very general. Furthermore, for some ranges of the parameters n, m, p ($m = n^{\alpha}, \alpha > 6$) the spaces $G_{n,m,p}$ and $G_{n,p}$ are equivalent (as proved by Fill, Sheinerman, and Singer-Cohen in [3], showing that in this range the total variation distance between the graph random variables has limit 0).

Second, random intersection graphs (and in particular the general intersection graphs model of [7]) may model real-life applications more accurately (compared to the $G_{n,p}$ case). In particular, such graphs can model resource allocation in networks, e.g., when network nodes (abstracted by vertices) access shared resources (abstracted by labels): the intersection graph is in fact the conflict graph of such resource allocation problems.

Other Related Work

In their work [4] Karoński et al. consider the problem of the emergence of graphs with a constant number of vertices as induced subgraphs of $G_{n,m,p}$ graphs. By observing that the $G_{n,m,p}$ model generates graphs via clique covers (for example the sets $L_l, l \in M$ constitute an obvious clique cover) they devise a natural way to use them together with the first and second moment methods in order to find thresholds for the appearance of any fixed graph H as an induced subgraph of $G_{n,m,p}$ for various values of the parameters n, m and p.

The connectivity threshold for $G_{n,m,p}$ was considered by Singer-Cohen in [10]. She studies the case $m = n^{\alpha}, \alpha > 0$ and distinguishes two cases according to the value of α. For the case $\alpha > 1$, the results look similar to the $G_{n,p}$ graphs, as the mean number of edges at the connectivity thresholds are (roughly) the same. On the other hand, for $\alpha \leq 1$ we get denser graphs in the $G_{n,m,p}$ model. Besides connectivity, [10] examines also the size of the largest clique in uniform random intersection graphs for certain values of n, m and p.

The existence of Hamilton cycles in $G_{n,m,p}$ graphs was considered by Efthymiou and Spirakis in [2]. The authors use coupling arguments to show that the threshold of appearance of Hamilton cycles is quite close to the connectivity threshold of $G_{n,m,p}$. Efficient probabilistic algorithms for finding Hamilton cycles in uniform random intersection graphs were presented by Raptopoulos and Spirakis in [8]. The analysis of those algorithms verify that they perform well w.h.p. even for values of p that are close to the connectivity threshold of $G_{n,m,p}$. Furthermore, in the same work, an expected polynomial algorithm for finding Hamilton cycles in $G_{n,m,p}$ graphs with constant p is given.

In [11] Stark gives approximations of the distribution of the degree of a fixed vertex in the $G_{n,m,p}$ model. More specifically, by applying a sieve method, the author provides an exact formula for the probability generating function of the degree of some fixed vertex and then analyzes this formula for different values of the parameters n, m and p.

Open Problems

A number of problems related to random intersection graphs remain open. Nearly all the algorithms proposed so far concerning constructing large independent sets and finding Hamilton cycles in random intersection graphs are greedy. An interesting and important line of research would be to find more sophisticated algorithms for these problems that outperform the greedy ones. Also, all these algorithms were presented and analyzed in the uniform random intersection graphs model. Very little is known about how the same algorithms would perform when their input was an instance of the general or even the regular random intersection graph models.

Of course, many classical problems concerning random graphs have not yet been studied.

One such example is the size of the minimum dominating set (i.e., a set of vertices that has the property that all vertices of the graph either belong to this set or are connected to it) in a random intersection graph. Also, what is the degree sequence of $G_{n,m,p}$ graphs? Note that this is very different from the problem addressed in [11].

Finally, notice that none of the results presented in the bibliography for general or uniform random intersection graphs carries over immediately to regular random intersection graphs. Of course, for some values of n, m, p and λ, certain graph properties shown for $G_{n,m,p}$ could also be proved for $G_{n,m,\lambda}$ by showing concentration of the number of labels chosen by any vertex via Chernoff bounds. Other than that, the fixed sizes of the sets assigned to each vertex impose more dependencies to the model.

Problem Definition

Consider a text $S[1 \ldots n]$ over a finite alphabet Σ. The problem is to build an index for S such that for any query pattern $P[1 \ldots m]$ and any integer $k \geq 0$, all locations in S that match P with at most k errors can be reported efficiently. If the error is measured in terms of the Hamming distance

(number of character substitutions), the problem is called k-mismatch problem. If the error is measured in terms of the edit distance (number of character substitutions, insertions, or deletions), the problem is called k-difference problem. The two problems are formally defined as follows.

Problem 1 (k-mismatch problem) Consider a text $S[1 \ldots n]$ over a finite alphabet Σ. For any pattern P and threshold k, position i is an occurrence of P if the Hamming distance between P and $S[i \ldots i']$ is less than k for some i'. The k-mismatch problem asks for an index I for S such that, for any pattern P, all occurrences of P in S can be reported efficiently.

Problem 2 (k-difference problem) Consider a text $S[1 \ldots n]$ over a finite alphabet Σ. For any pattern P and threshold k, position i is an occurrence of P if the edit distance between P and $S[i \ldots i']$ is less than k for some i'. The k-difference problem asks for an index I for S such that, for any pattern P, all occurrences of P in S can be reported efficiently.

These two problems are also called indexed inexact pattern matching problem or indexed pattern searching problem based on Hamming distance or edit distance.

The major concern of these two problems is how to achieve efficient pattern searching without using a large amount of space for storing the index.

Key Results

For indexed k-mismatch or k-difference string matching, a naive solution either requires an index of size $\Omega(n^k)$ or supports the query using $\Omega(m^k)$ time. The first non-trival solution is by Cole et al. [10]. They modify suffix tree to give an $O(n \log^k n)$-word index that supports k-difference query using $O(m + \text{occ} + \frac{1}{k!}(c \log n)^k \log\log n)$ time. After that, a number of indexes are proposed that support k-mismatch/k-difference pattern query for any $k > 0$. All these indexes are created by augmenting the suffix tree and its variants.

Tables 1 and 2 summarize the related results in the literature for $k = 1$ and $k \geq 2$. Below, the current best results are briefly summarized.

	$O((2\lvert\Sigma\rvert)^{k-1} m^{k-1} \log n \log\log n + \text{occ})$	[6]
$O(n \sqrt{\log n} \log \lvert\Sigma\rvert)$ bits	$O((\lvert\Sigma\rvert m)^k (k + \log\log n) + \text{occ})$	[14]
$O(n \log \lvert\Sigma\rvert)$ bits	$O((\lvert\Sigma\rvert m)^k \max(k, \log^2 n) + \text{occ} \log n)$	[13]
	$O(((\lvert\Sigma\rvert m)^k (k + \log\log n) + \text{occ}) \log^\epsilon n)$	[14]
	$O(m + (k^3 3^k \text{occ} + (c \log n)^{k^2+2k} \log\log n) \log^\epsilon n)$	[5]

Inexact Matching When $k = 1$

For 1-mismatch and 1-difference approximate matching problem, the theorems below give the current best solutions. Both algorithms try to handle long and short patterns separately. Short patterns of size polylog(n) can be handled using index of size O(polylog(n)) space by brute force. Long patterns can be handled with the help of some augmented suffix tree.

When the index is of size $O(n \log \lvert\Sigma\rvert)$ bits, the next theorem is the current best result.

Theorem 1 (Chan, Lam, Sung, Tam, and Wong [5]) *Given an index of size $O(n \log \lvert\Sigma\rvert)$ bits, 1-mismatch or 1-difference query can be supported in $O(m + (\text{occ} + \lvert\Sigma\rvert \log^4 n \log\log n) \log^\epsilon n)$ time where ϵ is any positive constant smaller than or equal to 1.*

When we allow a bit more space, Belazzougui can further reduce the query time, as shown in the following theorem.

Theorem 2 (Belazzougui [3]) *Given an index of size $O(n \log^\epsilon n \log \lvert\Sigma\rvert)$ bits (or $O(n \log\log n \log \lvert\Sigma\rvert)$ bits, respectively), 1-mismatch/1-difference lookup can be supported in $O(\lvert\Sigma\rvert m + \text{occ})$ (or $O((\lvert\Sigma\rvert m + \text{occ}) \log\log n)$, respectively) time.*

Inexact Matching When $k \geq 2$

For k-mismatch and k-difference approximate matching problem where $k \geq 2$, existing solutions are all based on the so-called k-error suffix trees and its variants (following the idea of Cole et al.).

Some current solutions create indexes whose sizes depend on k. Theorems 3–6 summarize the current best results in this direction.

Theorem 3 (Maas and Nowak [15]) *Given an index of size $O(\lvert\Sigma\rvert^k n \log^k n)$ words, k-mismatch/k-difference lookup can be supported in $O(m + \text{occ})$ expected time.*

Theorem 4 (Maas and Nowak [15]) *Consider a uniformly and independently generated text of length n. There exists an index of size $O(\lvert\Sigma\rvert^k n \log^k n)$ words on average such that an k-mismatch/k-difference lookup query can be supported in $O(m + \text{occ})$ worst-case time.*

Theorem 5 (Chan, Lam, Sung, Tam, and Wong [5]) *Given an index of size* $O(n \log^{k-h+1} n)$ *words where* $h \leq k$, *k-mismatch lookup can be supported in* $O(m + \text{occ} + c^{k^2} \log^{\max\{kh,k+h\}} n \log\log n)$ *time where c is a positive constant. For k-difference lookup, the term* occ *becomes* $k^3 3^k \text{occ}$.

Theorem 6 (Chan, Lam, Sung, Tam, and Wong [6]) *Given an index of size* $O(n \log^{k-1} n)$ *words, k-mismatch/k-difference lookup can be supported in* $O(m + \text{occ} + \log^k n \log\log n)$ *time.*

Theorems 7–12 summarize the current best results when the index size is independent of k.

Theorem 7 (Chan, Lam, Sung, Tam, and Wong [5]) *Given an index of size* $O(n)$ *words, k-mismatch lookup can be supported in* $O(m + \text{occ} + (c \log n)^{k(k+1)} \log\log n)$ *time where c is a positive constant. For k-difference lookup, the term* occ *becomes* $k^3 3^k \text{occ}$.

Theorem 8 (Chan, Lam, Sung, Tam, and Wong [5]) *Given an index of size* $O(n \log|\Sigma|)$ *bits, k-mismatch lookup can be supported in* $O(m + (\text{occ} + (c \log n)^{k(k+2)} \log\log n) \log^{\epsilon} n)$ *time where c is a positive constant and* ϵ *is any positive constant smaller than or equal to* 1. *For k-difference lookup, the term* occ *becomes* $k^3 3^k \text{occ}$.

Theorem 9 (Lam, Sung, and Wong [14]) *Given an index of size* $O(n \sqrt{\log n} \log|\Sigma|)$ *bits, k-mismatch/k-difference lookup can be supported in* $O((|\Sigma|m)^k (k + \log\log n) + \text{occ})$ *time.*

Theorem 10 (Lam, Sung, and Wong [14]) *Given an index of size* $O(n \log|\Sigma|)$ *bits, k-mismatch/k-difference lookup can be supported in* $O(((|\Sigma|m)^k (k + \log\log n) + \text{occ}) \log^{\epsilon} n)$ *time where* ϵ *is any positive constant smaller than or equal to* 1.

Theorem 11 (Chan, Lam, Sung, Tam, and Wong [6]) *Given an index of size* $O(n)$ *words, k-mismatch/k-difference lookup can be supported in* $O((2|\Sigma|)^{k-1} m^{k-1} \log n \log\log n + \text{occ})$ *time.*

Theorem 12 (Tsur [19]) *Given an index of size* $O(n^{1+\epsilon})$ *words, k-mismatch/k-difference lookup can be supported in* $O(m + \text{occ} + \log\log n)$ *time.*

Practically Fast Inexact Matching

In addition, there are indexes which are efficient in practice for small k/m but give no worst-case complexity guarantees. Those methods are based on filtration. The basic idea is to partition the pattern into short segments and locate those short segments in the text allowing zero or a small number of errors. Those short segments help to identify candidate regions for the occurrences of the pattern. Finally, by verifying those candidate regions, all occurrences of the pattern are recovered. See [18] for a summary of those results. One of the best results based on filtration is stated in the following theorem.

Theorem 13 (Myers [16] and Navarro and Baeza-Yates [17]) *If* $k/m < 1 - O(1/\sqrt{|\Sigma|})$, *k-mismatch/k-difference search can be supported in* $O(n^{\epsilon})$ *expected time, where* ϵ *is a positive constant smaller than* 1, *with an index of size* $O(n)$ *words.*

Other methods with good performance on average include [11] and [12].

All the above approaches either try to index the strings with errors or are based on filtering. There are also solutions which use radically different approaches. For instance, there are solutions which transform approximate string searching into range queries in metric space [7].

Applications

Due to the advance in both the Internet and biological technologies, enormous text data is accumulated. For example, 60G genomic sequence data are currently available in GenBank. The data size is expected to grow exponentially.

To handle the huge data size, indexing techniques are vital to speed up the pattern matching queries. Moreover, exact pattern matching is no longer sufficient for both the Internet and bio-

logical data. For example, biological data usually contains a lot of differences due to experimental errors and due to mutation and evolution. Therefore, approximate pattern matching becomes more appropriate. This gives the motivation for developing indexing techniques that allow pattern matching with errors.

Open Problems

The complexity for indexed approximate matching is still not fully understood. A number of questions are still open. For instance, there are two open questions: (1) Given a fixed index size of $O(n)$ words, what is the best time complexity of a k-mismatch/k-difference query? (2) Fixed the k-mismatch/k-difference query time to be $O(m + \text{occ})$, what is the best space complexity of the index?

Problem Definition

Regular expressions (REs) provide an expressive and powerful formalism for capturing the structure of messages, events, and documents. Consequently, they have been used extensively in the specification of a number of languages for important application domains, including the XPath pattern language for XML documents [6] and the policy language of the *Border Gateway Protocol* (BGP) for propagating routing information between autonomous systems in the Internet [12]. Many of these applications have to manage large databases of RE specifications and need to provide an effective matching mechanism that, given an input string, quickly identifies all the REs in the database that match it. This RE retrieval problem is therefore important for a variety of software components in the middleware and networking infrastructure of the Internet.

The RE retrieval problem can be stated as follows: Given a large set S of REs over an alphabet Σ, where each RE $r \in S$ defines a regular language $L(r)$, construct a data structure on S that efficiently answers the following query: given an arbitrary input string $w \in \Sigma^*$, find the subset S_w of REs in S whose defined regular languages include the string w. More precisely, $r \in S_w$ iff $w \in L(r)$. Since S is a large, dynamic, disk-resident collection of REs, the data structure should be dynamic and provide efficient support of updates (insertions and deletions) to S. Note that this problem is the opposite of the more traditional RE search problem where $S \subseteq \Sigma^*$ is a collection of strings and the task is to efficiently find all strings in S that match an input regular expression.

Notations

An RE r over an alphabet Σ represents a subset of strings in σ^* (denoted by $L(r)$) that can be defined recursively as follows [9]: (1) the constants ϵ and $\emptyset$ are REs, where $L(\epsilon) = \{\epsilon\}$ and $L(\emptyset) = \emptyset$; (2) for any letter $a \in \sigma$, a is an RE where $L(a) = \{a\}$; (3) if r_1 and r_2 are REs, then their union, denoted by $r_1 + r_2$, is an RE where $L(r_1 + r_2) = L(r_1) \cup L(r_2)$; (4) if r_1 and r_2 are REs, then their concatenation, denoted by $r_1.r_2$, is an RE where $L(r_1.r_2) = \{s_1 s_2 \mid s_1 \in L(r_1), s_2 \in L(r_2)\}$; (5) if r is an RE, then its closure, denoted by r^*, is an RE where $L(r^*) = L(\epsilon) \cup L(r) \cup L(rr) \cup L(rrr) \cup \cdots$; and (6) if r is an RE, then a parenthesized r, denoted by (r), is an RE where $L((r)) = L(r)$. For example, if $\sigma = \{a, b, c\}$, then $(a + b).(a + b + c)^*.c$ is an RE representing the set of strings that begins with either a "a" or a "b" and ends with a "c." A string $s \in \sigma^*$ is said to match an RE r if $s \in L(r)$.

The language $L(r)$ defined by an RE r can be recognized by a *finite automaton (FA)* M that decides if an input string w is in $L(r)$ by reading each letter in w sequentially and updating its current state such that the outcome is determined by the final state reached by M after w has been processed [9]. Thus, M is an FA for r if the language accepted by M, denoted by $L(M)$, is equal to $L(r)$. An FA is classified as a *deterministic finite automaton* (DFA) if its current state is always updated to a single state; otherwise, it is a *nondeterministic finite automaton* (NFA) if its current state could refer to multiple possible states. The trade-off between a DFA and an NFA representations for an RE is that the latter is more space efficient, while the former is more time efficient for recognizing a matching string by checking a single path of state transitions. Let $|L(M)|$ denote the size of $L(M)$ and $|L_n(M)|$ denote the number of length-n strings in $L(M)$. Given a set $\mathcal{M}$ of finite automata, let $L(\mathcal{M})$ denote the language recognized by the automata in $\mathcal{M}$; i.e., $L(\mathcal{M}) = \bigcup_{M_i \in \mathcal{M}} L(M_i)$.

Key Results

The RE retrieval problem was first studied for a restricted class of REs in the context of content-based dissemination of XML documents using

XPath-based subscriptions (e.g., [1, 3, 7]), where each XPath expression is processed in terms of a collection of path expressions. While the XPath language [6] allows rich patterns with tree structure to be specified, the path expressions that it supports lack the full expressive power of REs (e.g., XPath does not permit the RE operators *, + and · to be arbitrarily nested in path expressions), and thus extending these XML-filtering techniques to handle general REs may not be straightforward. Further, all of the XPath-based methods are designed for indexing main-memory resident data. Another possible approach would be to coalesce the automata for all the REs into a single NFA and then use this structure to determine the collection of matching REs. It is unclear, however, if the performance of such an approach would be superior to a simple sequential scan over the database of REs; furthermore, it is not easy to see how such a scheme could be adapted for disk-resident RE data sets.

The first disk-based data structure that can handle the storage and retrieval of REs in their full generality is the *RE-tree* [4, 5]. Similar to the R-tree [8], an RE-tree is a dynamic, height-balanced, hierarchical index structure, where the leaf nodes contain data entries corresponding to the indexed REs, and the internal nodes contain "directory" entries that point to nodes at the next level of the index. Each leaf node entry is of the form (id, M), where id is the unique identifier of an RE r and M is a finite automaton representing r. Each internal node stores a collection of finite automata, and each node entry is of the form (M, ptr), where M is a finite automaton and ptr is a pointer to some node N (at the next level) such that the following *containment property* is satisfied: If $\mathcal{M}_N$ is the collection of automata contained in node N, then $L(\mathcal{M}_N) \subseteq L(M)$. The automaton M is referred to as the *bounding automaton* for $\mathcal{M}_N$. The containment property is key to improving the search performance of hierarchical index structures like RE-trees: if a query string w is not contained in $L(M)$, then it follows that $w \notin L(M_i)$ for all $M_i \in \mathcal{M}_N$. As a result, the entire subtree rooted at N can be pruned from the search space. Clearly, the closer $L(M)$ is to $L(\mathcal{M}_N)$, the more effective this search-space pruning will be.

In general, there are an infinite number of bounding automata for $\mathcal{M}_N$ with different degrees of precision from the least precise bounding automaton with $L(M) = \sigma^*$ to the most precise bounding automaton, referred to as the *minimal bounding automaton*, with $L(M) = L(\mathcal{M}_N)$. Since the storage space for an automaton is dependent on its complexity (in terms of the number of its states and transitions), there is a space-precision trade-off involved in the choice of a bounding automaton for each internal node entry. Thus, even though minimal bounding automata result in the best pruning due to their tightness, it may not be desirable (or even feasible) to always store minimal bounding automata in RE-trees since their space requirement can be too large (possibly exceeding the size of an index node), thus resulting in an index structure with a low fan-out. Therefore, to maintain a reasonable fan-out for RE-trees, a space constraint is imposed on the maximum number of states (denoted by α) permitted for each bounding automaton in internal RE-tree nodes. The automata stored in RE-tree nodes are, in general, NFAs with a minimum number of states. Also, for better space utilization, each individual RE-tree node is required to contain at least m entries. Thus, the RE-tree height is $O(\log_m(|S|))$.

RE-trees are conceptually similar to other hierarchical, spatial index structures, like the R-tree [8] that is designed for indexing a collection of multidimensional rectangles, where each internal entry is represented by a minimal bounding rectangle (MBR) that contains all the rectangles in the node pointed to by the entry. RE-tree search simply proceeds top-down along (possibly) multiple paths whose bounding automaton accepts the input string; RE-tree updates try to identify a "good" leaf node for insertion and can lead to node splits (or, node merges for deletions) that can propagate all the way up to the root. There is, however, a fundamental difference between the RE-tree and the R-tree in the indexed data types: regular languages typically represent *infinite* sets with no well-defined notion of spatial locality. This difference mandates the development of

novel algorithmic solutions for the core RE-tree operations. To optimize for search performance, the core RE-tree operations are designed to keep each bounding automaton M in every internal node to be as "tight" as possible. Thus, if M is the bounding automaton for $\mathcal{M}_N$, then $L(M)$ should be as close to $L(\mathcal{M}_N)$ as possible.

There are three core operations that need to be addressed in the RE-tree context: (P1) selection of an optimal insertion node, (P2) computing an optimal node split, and (P3) computing an optimal bounding automaton. The goal of (P1) is to choose an insertion path for a new RE that leads to "minimal expansion" in the bounding automaton of each internal node of the insertion path. Thus, given the collection of automata $\mathcal{M}(N)$ in an internal index node N and a new automaton M, an optimal $M_i \in \mathcal{M}(N)$ needs to be chosen to insert M such that $|L(M_i) \cap L(M)|$ is maximum. The goal of (P2), which arises when splitting a set of REs during an RE-tree node-split, is to identify a partitioning that results in the minimal amount of "covered area" in terms of the languages of the resulting partitions. More formally, given the collection of automata $\mathcal{M} = \{M_1, M_2, \ldots, M_k\}$ in an overflowed index node, find the optimal partition of $\mathcal{M}$ into two disjoint subsets $\mathcal{M}_1$ and $\mathcal{M}_2$ such that $|\mathcal{M}_1| \geq m$, $|\mathcal{M}_2| \geq m$, and $|L(\mathcal{M}_1)| + |L(\mathcal{M}_2)|$ is minimum. The goal of (P3), which arises during insertions, node-splits, or node-merges, is to identify a bounding automaton for a set of REs that does not cover too much "dead space." Thus, given a collection of automata $\mathcal{M}$, the goal is to find the optimal bounding automaton M such that the number of states of M is no more than α, $L(\mathcal{M}) \subseteq L(M)$ and $|L(M)|$ is minimum.

The objective of the above three operations is to maximize the pruning during search by keeping bounding automata tight. In (P1), the optimal automaton M_i selected (within an internal node) to accommodate a newly inserted automaton M is to maximize $|L(M_i) \cap L(M)|$. The set of automata $\mathcal{M}$ are split into two tight clusters in (P2), while in (P3), the most precise automaton (with no more than α states) is computed to cover the set of automata in $\mathcal{M}$. Note that (P3) is unique to RE-trees, while both (P1) and (P2) have their equivalents in R-trees. The heuristics solutions [2, 8] proposed for (P1) and (P2) in R-trees aim to minimize the number of visits to nodes that do not lead to any qualifying data entries. Although the minimal bounding automata in RE-trees (which correspond to regular languages) are very different from the MBRs in R-trees, the intuition behind minimizing the area of MBRs (total area or overlapping area) in R-trees should be effective for RE-trees as well. The counterpart for area in an RE-tree is $|L(M)|$, the size of the regular language for M. However, since a regular language is generally an infinite set, new measures need to be developed for the size of a regular language or for comparing the sizes of two regular languages.

One approach to compare the relative sizes of two regular languages is based on the following definition: for a pair of automata M_i and M_j, $L(M_i)$ is said to be larger than $L(M_j)$ if there exists a positive integer N such that for all $k \geq N$, $\sum_{l=1}^{k} |L_l(M_i)| \geq \sum_{l=1}^{k} |L_l(M_j)|$. Based on the above intuition, three increasingly sophisticated measures are proposed to capture the size of an infinite regular language. The *max-count measure* simply counts the number of strings in the language up to a certain size λ; i.e., $|L(M)| = \sum_{i=1}^{\lambda} |L_i(M)|$. This measure is useful for applications where the maximum length of all the REs to be indexed is known and is not too large so that λ can be set to some value slightly larger than the maximum length of the REs. A second more robust measure that is less sensitive to the λ parameter value is the *rate-of-growth measure* which is based on the intuition that a larger language grows at a faster rate than a smaller language. The size of a language is approximated by computing the rate of change of its size from one "window" of lengths to the next consecutive "window" of lengths: if λ is a length parameter that denote the start of the first window and θ is a window-size parameter, then $|L(M)| = \sum_{\lambda+\theta}^{\lambda+2\theta-1} |L_i(M)| / \sum_{\lambda}^{\lambda+\theta-1} |L_i(M)|$. As in the max-count measure, the parameters λ

and θ should be chosen to be slightly greater than the number of states of M to ensure that strings involving a substantial portion of paths, cycles, and accepting states are counted in each window. However, there are cases where the rate-of-growth measure also fails to capture the "larger than" relationship between regular languages [4]. To address some of the shortcomings of the first two metrics, a third information-theoretic measure is proposed that is based on Rissanen's minimum description length (MDL) principle [11]. The intuition is that if $L(M_i)$ is larger than $L(M_j)$, then the per-symbol cost of an MDL-based encoding of a random string in $L(M_i)$ using M_i is very likely to be higher than that of a string in $L(M_j)$ using M_j, where the per-symbol cost of encoding a string $w \in L(M)$ is the ratio of the cost of an MDL-based encoding of w using M to the length of w. More specifically, if $w = w_1.w_2.\ldots.w_n \in L(M)$ and $s_0, s_1, \ldots, s_n$ is the unique sequence of states visited by w in M, then the MDL-based encoding cost of w using M is given by $\sum_{i=0}^{n-1} \lceil \log_2(n_i) \rceil$, where each n_i denotes the number of transitions out of state s_i, and $\log_2(n_i)$ is the number of bits required to specify the transition out of state s_i. Thus, a reasonable measure for the size of a regular language $L(M)$ is the expected per-symbol cost of an MDL-based encoding for a random sample of strings in $L(M)$.

To utilize the above metrics for measuring $L(M)$, one common operation needed is the computation of $|L_n(M)|$, the number of length-n strings in $L(M)$. While $|L_n(M)|$ can be efficiently computed when M is a DFA, the problem becomes #P-complete when M is an NFA [10]. Two approaches were proposed to approximate $|L_n(M)|$ when N is an NFA [10]. The first approach is an unbiased estimator for $|L_n(M)|$, which can be efficiently computed but can have a very large standard deviation. The second approach is a more accurate randomized algorithm for approximating $|L_n(M)|$ but it is not very useful in practice due to its high time complexity of $O(n^{\log(n)})$. A more practical approximation algorithm with a time complexity of $O(n^2|M|^2 \min\{|\sigma|, |M|\})$ was proposed in [4].

The RE-tree operations (P1) and (P2) require frequent computations of $|L(M_i \cap M_j)|$ and $|L(M_i \cup M_j)|$ to be performed for pairs of automata M_i, M_j. These computations can adversely affect RE-tree performance since construction of the intersection and union automaton M can be expensive. Furthermore, since the final automaton M may have many more states than the two initial automata M_i and M_j, the cost of measuring $|L(M)|$ can be high. The performance of these computations can, however, be optimized by using sampling. Specifically, if the counts and samples for each $L(M_i)$ are available, then this information can be utilized to derive approximate counts and samples for $L(M_i \cap M_j)$ and $L(M_i \cup M_j)$ without incurring the overhead of constructing the automata $M_i \cap M_j$ and $M_i \cup M_j$ and counting their sizes. The sampling techniques used are based on the following results for approximating the sizes of and generating uniform samples of unions and intersections of arbitrary sets:

Theorem 1 (Chan, Garofalakis, Rastogi [4]) *Let r_1 and r_2 be uniform random samples of sets S_1 and S_2, respectively.*

1. $(|r_1 \cap S_2||S_1|)/|r_1|$ *is an unbiased estimator of the size of* $S_1 \cap S_2$.
2. $r_1 \cap S_2$ *is a uniform random sample of* $S_1 \cap S_2$ *with size* $|r_1 \cap S_2|$.
3. *If the sets S_1 and S_2 are disjoint, then a uniform random sample of $S_1 \cup S_2$ can be computed in $O(|r_1| + |r_2|)$ time. If S_1 and S_2 are not disjoint, then an approximate uniform random sample of $S_1 \cup S_2$ can be computed with the same time complexity.*

Applications

The RE retrieval problem also arises in the context of both XML document classification, which identifies matching DTDs for XML documents, as well as BGP routing, which assigns appropriate priorities to BGP advertisements based on their matching routing-system sequences.

Experimental Results

Experimental results with synthetic data sets [5] clearly demonstrate that the RE-tree index is significantly more effective than performing a sequential search for matching REs and, in a number of cases, outperforms sequential search by up to an order of magnitude.

Problem Definition

This entry is concerned with designing and building indexes of a two-dimensional matrix, which is basically the generalization of indexes of a string, the *suffix tree* [12] and the *suffix array* [11], to a two-dimensional matrix. This problem was first introduced by Gonnet [7]. Informally, a two-dimensional analog of the suffix tree is a

tree data structure storing all submatrices of an $n \times m$ matrix, $n \geq m$. The *submatrix tree* [2] is an incarnation of such indexes. Unfortunately, building such indexes requires $\Omega(nm^2)$ time [2]. Therefore, much of the attention paid has been restricted to square matrices and submatrices, the important special case in which much better results are available.

For square matrices, the *Lsuffix tree* and its array form, storing all *square submatrices* of an $n \times n$ matrix, have been proposed [3, 9, 10]. Moreover, the general framework for these index families is also introduced [4, 5]. Motivated by LZ1-type image compression [14], the online case, i.e., the matrix is given one row or column at a time, has been also considered. These data structures can be built in time close to n^2. Building these data structures is a nontrivial extension of the algorithms for the standard suffix tree and suffix array. Generally, a tree data structure and its array form of this type for square matrices are referred to as the *two-dimensional suffix tree* and the *two-dimensional suffix array*, which are the main concerns of this entry.

Notations

Let A be an $n \times n$ matrix with entries defined over a finite alphabet Σ. $A[i \ldots k, j \ldots l]$ denotes the submatrix of A with corners (i, j), (k, j), (i, l), and (k, l). When $i = k$ or $j = l$, one of the repeated indexes is omitted. For $1 \leq i, j \leq n$, the *suffix* $A(i, j)$ of A is the largest square submatrix of A that starts at position (i, j) in A. That is, $A(i, j) = A[i \ldots i + k, j \ldots j + k]$, where $k = n - \max(i, j)$. Let $\$_i$ be a special symbol not in Σ such that $\$_i$ is lexicographically smaller than any other character in Σ. Assume that $\$_i$ is lexicographically smaller than $\$_j$ for $i < j$. For notational convenience, assume that the last entries of the ith row and column are $\$_i$. It makes all suffixes distinct. See Fig. 1a, b for an example.

Let $L\sum = \bigcup_{i=1}^{\infty} \sum^{2i-1}$. The strings of $L\Sigma$ are referred to as *Lcharacters*, and each of them is considered as an atomic item. $L\Sigma$ is called the *alphabet of Lcharacters*. Two Lcharacters are equal if and only if they are equal as strings over Σ. Moreover, given two Lcharacters *La* and *Lb* of equal length, *La* is *lexicographically smaller than or equal to Lb* if and only if the string corresponding to *La* is lexicographically smaller than or equal to that corresponding to *Lb*. A *chunk* is the concatenation of Lcharacters with the following restriction: an Lcharacter in Σ^{2i-1} can precede only one in $\Sigma^{2(i+1)-1}$ and succeed only one in $\Sigma^{2(i-1)-1}$. An *Lstring* is a chunk such that the first Lcharacter is in Σ.

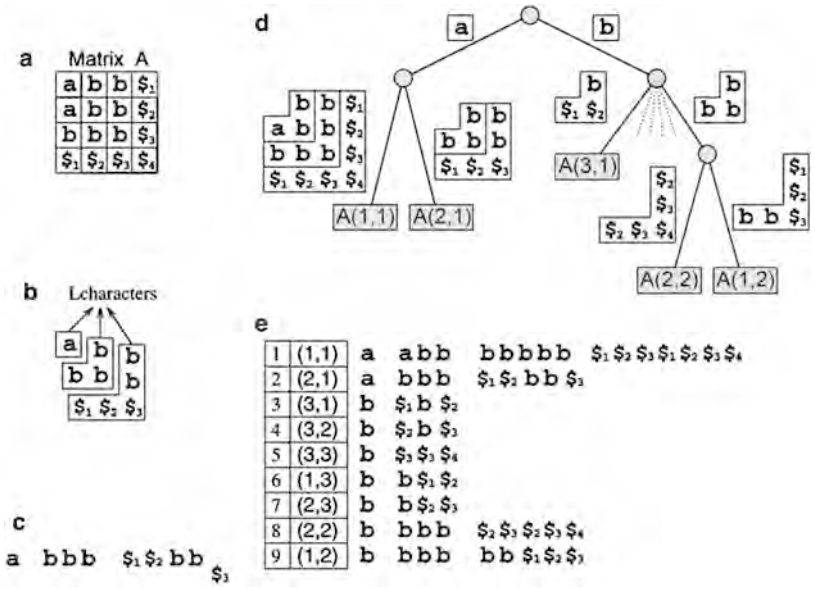
For dealing with matrices as strings, a linear representation of square matrices is needed. Given $A[1 \ldots n, 1 \ldots n]$, divide A into n Lshaped characters. Let $a(i)$ be the concatenation of row $A[i, 1 \ldots i - 1]$ and column $A[1 \ldots i, i]$. Then, $a(i)$ can be regarded as an Lcharacter. The linearized string of matrix A, called the Lstring of matrix A, is the concatenation of Lcharacters $a(1), \ldots, a(n)$. See Fig. 1c for an example. Slightly different linearizations have been used [9, 10, 13], but they are essentially the same in the aspect of two-dimensional functionality.

Two-Dimensional Suffix Trees

The suffix tree of matrix A is a compacted trie over the alphabet $L\Sigma$ that represents Lstrings corresponding to all suffixes of A. Formally, the *two-dimensional suffix tree* of matrix A is a rooted tree that satisfies the following conditions (see Fig. 1d for an example):

1. Each edge is labeled with a chunk.
2. There is no internal node of outdegree one.
3. Chunks assigned to sibling edges start with different Lcharacters, which are of the same length as strings in Σ^*.
4. The concatenation of the chunks labeling the edges on the path from the root to a leaf gives the Lstring of exactly one suffix of A, say $A(i, j)$. It is said that this leaf is associated with $A(i, j)$.
5. There is exactly one leaf associated with each suffix.

Conditions 4 and 5 mean that there is a one-to-one correspondence between the leaves of the tree and the suffixes of A (which are all distinct because $\$_i$ is unique).



Indexed Two-Dimensional String Matching, Fig. 1 (**a**) A matrix A, (**b**) the suffix $A(2,1)$ and Lcharacters composing $A(2,1)$, (**c**) the Lstring of $A(2,1)$, (**d**) the suffix tree of A, and (**e**) the suffix array of A (omitting the suffixes started with $\$_i$)

Problem 1 (Construction of 2D suffix tree)

INPUT: An $n \times n$ matrix A.

OUTPUT: A two-dimensional suffix tree storing all square submatrices of A.

Online Suffix Trees

Assume that A is read *online* in row major order (column major order can be considered similarly). Let $A_t = A[1 \ldots t, 1 \ldots n]$ and $row_t = A[t, 1 \ldots n]$. At time $t-1$, nothing but A_{t-1} is known about A. At time t, row_t is read and so A_t is known. After time t, the online suffix tree of A is storing all suffixes of A_t . Note that Condition 4 may not be satisfied during the online construction of the suffix tree. A leaf may be associated with more than one suffix, because the suffixes of A_t are not all distinct.

Problem 2 (Online construction of 2D suffix tree)

INPUT: A sequence of rows of $n \times n$ matrix A, $row_1, row_2, \ldots, row_n$.

OUTPUT: A two-dimensional suffix tree storing all square submatrices of A_t after reading row_t .

Two-Dimensional Suffix Arrays

The *two-dimensional suffix array* of matrix A is basically a sorted list of all Lstrings corresponding to suffixes of A. Formally, the kth element of the array has the start position (i, j) if and only if the Lstring of $A(i, j)$ is the kth smallest one among the Lstrings of all suffixes of A. See Fig. 1e for an example. The two-dimensional suffix array is also coupled with additional information tables, called *Llcp* and *Rlcp*, to enhance its performance like the standard suffix array. The two-dimensional suffix array can be constructed from the two-dimensional suffix tree in linear time.

Problem 3 (Construction of 2D suffix array)

INPUT: An $n \times n$ matrix A.

OUTPUT: The two-dimensional suffix array storing all square submatrices of A.

Submatrix Trees

The *submatrix tree* is a tree data structure storing all submatrices. This entry just gives a result on submatrix trees. See [2] for details.

Problem 4 (Construction of a submatrix tree)

INPUT: An $n \times m$ matrix B, $n \geq m$.
OUTPUT: The submatrix tree and its array form storing all submatrices of B.

Key Results

Theorem 1 (Kim et al. 2011 [10], Cole and Hariharan 2003 [1]) *Given an $n \times n$ matrix A over an integer alphabet, one can construct the two-dimensional suffix tree in $O(n^2)$ time.*

Kim and Park's result is a deterministic algorithm, while Cole and Hariharan's result is a randomized one. For an arbitrary alphabet, one needs first to sort it and then to apply the theorem above.

Theorem 2 (Na et al. 2007 [13]) *Given an $n \times n$ matrix A, one can construct online the two-dimensional suffix tree of A in $O(n^2 \log n)$ time.*

Theorem 3 (Kim et al. 2003 [9]) *Given an $n \times n$ matrix A, one can construct the two-dimensional suffix array of A in $O(n^2 \log n)$ time without constructing the two-dimensional suffix tree.*

Theorem 4 (Giancarlo 1993 [2]) *Given an $n \times m$ matrix B, one can construct the submatrix tree of B in $O(nm^2 log(nm))$ time.*

Applications

Two-dimensional indexes can be used for many pattern-matching problems of two-dimensional applications such as low-level image processing, image compression, visual data bases, and so on [3, 6]. Given an $n \times n$ text matrix and an $m \times m$ pattern matrix over an alphabet Σ, the *two-dimensional pattern retrieval problem*, which is a basic pattern-matching problem, is to find all occurrences of the pattern in the text. The two-dimensional suffix tree and array of the text can be queried in $O(m^2 \log |\Sigma| + occ)$ time and $O(m^2 + \log n + occ)$ time, respectively, where occ is the number of occurrences of the pattern in the text. This problem can be easily extended to a set of texts. These queries have the same procedure and performance as those of indexes for strings. Online construction of the two-dimensional suffix tree can be applied to LZ-1-type image compression [6].

Open Problems

The main open problems on two-dimensional indexes are to construct indexes in optimal time. The linear-time construction algorithm for two-dimensional suffix trees is already known [10]. The online construction algorithm due to [13] is optimal for unbounded alphabets, but not for integer or constant alphabets. Another open problem is to construct two-dimensional suffix arrays directly in linear time.

Experimental Results

An experiment that compares construction algorithms of two-dimensional suffix trees and suffix arrays was presented in [8]. Giancarlo's algorithm [2] and Kim et al.'s algorithm [8] were implemented for two-dimensional suffix trees and suffix arrays, respectively. Random matrices of sizes $200 \times 200 \sim 800 \times 800$ and alphabets of sizes 2, 4, 16 were used for input data. According to experimental results, the construction of two-dimensional suffix arrays is ten times faster and five times more space efficient than that of two-dimensional suffix trees.

Keywords

Induction; Learning from examples; Recursion theory

Years and Authors of Summarized Original Work

1983; Case, Smith

Problem Definition

The theory of inductive inference is concerned with the capabilities and limitations of machine learning. Here the learning machine, the concepts to be learned, as well as the hypothesis space are modeled in recursion theoretic terms, based on the framework of identification in the limit [1, 9, 15].

Formally, considering recursive functions (mapping natural numbers to natural numbers) as target concepts, a learner (inductive inference machine) is supposed to process, step by step, gradually growing initial segments of the graph of a target function. In each step, the learner outputs a program in some fixed programming system, where successful learning means that the sequence of programs returned in this process eventually stabilizes on some program actually computing the target function.

Case and Smith [3, 4] proposed several variants of this model in order to study the influence that certain constraints or relaxations may have on the capabilities of learners. Their models restrict (i) the number of mind changes (i.e., changes of output programs) a learner is allowed to make during the learning process and (ii) the number of errors the program eventually hypothesized may have when compared to the target function.

One major result of studying the corresponding effects is a hierarchy of inference types culminating in a model general enough to allow for the identification of the whole class of recursive functions by a single inductive inference machine.

Notation

The target concepts for learning in the model discussed below are recursive functions [14] mapping natural numbers to natural numbers. Such functions, as well as partial recursive functions in general, are considered as computable

in an arbitrary, but fixed Gödel numbering $\varphi = (\varphi_i)_{i\in\mathbb{N}}$. Here $\mathbb{N} = \{0, 1, 2, \ldots\}$ denotes the set of all natural numbers. $\varphi = (\varphi_i)_{i\in\mathbb{N}}$ is interpreted as a programming system, where the number $i \in \mathbb{N}$ is called a program for the partial recursive function φ_i.

Suppose f and g are partial recursive functions and $n \in \mathbb{N}$. Below $f =^n g$ is written if the set $\{x \in \mathbb{N} | f(x) \neq g(x)\}$ is of cardinality at most n. If the set $\{x \in \mathbb{N} | f(x) \neq g(x)\}$ is finite, this is denoted by $f =^* g$. One considers $*$ as a special symbol for which the $<$-relation is extended by $n < *$ for all $n \in \mathbb{N}$. For any recursive f and any $z \in \mathbb{N}$, let $f[z]$ denote $(z, (f(0), \ldots, f(z)))$ for short.

For further basic recursion theoretic notions, the reader is referred to [14].

Learning Models

Case and Smith [4] build their theory upon the fundamental model of identification in the limit [1, 9]. There a learner can be understood as an algorithmic device, called an inductive inference machine, which, given any "graph segment" $f[z]$ as its input, returns a program $i \in \mathbb{N}$. Such a learner M identifies a recursive function f in the limit, if there is some $j \in \mathbb{N}$ such that

$$\varphi_j = f \text{ and } M(f[z]) = j \text{ for all but finitely many } z \in \mathbb{N}.$$

A class of recursive functions is learnable in the limit, if there is an inductive inference machine identifying each function in the class in the limit. Identification in the limit is called EX-identification, since a program for f is termed an *ex*planation for f.

For instance, the class of all primitive recursive functions is EX-identifiable, whereas the class of all recursive functions is not [9].

The central question discussed by Case and Smith [4] is how the limitations of EX-learners are affected by posing certain requirements on the success criterion, concerning:

- Convergence criteria:
  - e.g., when restricting the number of permitted mind changes
  - e.g., when relaxing the constraints on syntactical convergence of the sequence of programs returned in the learning process
- Accuracy:
  - e.g., when relaxing the number of permitted anomalies in the programs returned eventually

Problem 1 In which way do modifications of EX-identification in terms of accuracy and convergence criteria affect the capabilities of the corresponding learners?

Problem 2 In particular, if inaccuracies are permitted, can EX-learners always refute inaccurate hypotheses?

Problem 3 How much relaxation of the model of EX-identification is needed to achieve learnability of the full class of recursive functions?

Key Results

Accuracy and Convergence Constraints

In order to systematically address these problems, Case and Smith [4] defined inference types reflecting restrictions and relaxations of EX-identification as follows.

Definition 1 Suppose S is a class of recursive functions and $m, n \in \mathbb{N} \cup \{*\}$. S is $\mathrm{EX}_n{}^m$-identifiable if there is an inductive inference machine M, such that for any function $f \in S$, there is some $j \in \mathbb{N}$ satisfying:

- $M(f[z]) = j$ for all but finitely many $z \in \mathbb{N}$.
- $j = mf$.
- The cardinality of the set $\{z \in \mathbb{N} | M(f[z]) \neq M(f[z+1])\}$ is at most n.

For intuition one may view n as an upper bound on the allowed number of "mind changes" and m as an upper bound on the allowed number of "anomalies."

$\mathrm{EX}_n{}^m$ denotes the set of all classes of recursive functions which are $\mathrm{EX}_n{}^m$-identifiable.

Definition 2 Suppose S is a class of recursive functions and $m \in \mathbb{N} \cup \{*\}$. S is BC^m-identifiable if there is an inductive inference machine M, which, for any function $f \in S$, satisfies:

- $\varphi_{M(f[z])} =^m f$ for all but finitely many $z \in \mathbb{N}$.

BC^m denotes the set of all classes of recursive functions which are BC^m-identifiable. BC is short for behaviorally correct; the difference to EX-learning is that convergence of the sequence of programs returned by the learner is defined only in terms of semantics, no longer in terms of syntax.

The Impact of Accuracy and Convergence Constraints

In general, each permission of mind changes or anomalies increases the capabilities of learners; however, mind changes cannot be traded in for anomalies or vice versa.

Theorem 1 *Let* $a, b, c, d \in \mathbb{N} \cup \{*\}$. *Then* $\mathrm{EX}_b{}^a \subseteq \mathrm{EX}_d{}^c$ *if and only if* $a \leq c$ *and* $b \leq d$.

Corollary 1 *For any* $m, n \in \mathbb{N}$, *the following inclusions hold.*

1. $\mathrm{EX}_n^m \subset \mathrm{EX}_n^{m+1} \subset \mathrm{EX}_n^*$.
2. $\mathrm{EX}_n^m \subset \mathrm{EX}_{n+1}^m \subset \mathrm{EX}_*^m$.

Theorem 2 *Let* $n \in \mathbb{N}$. *Then* $\mathrm{EX}_*^* \subset \mathrm{BC}^n \subset \mathrm{BC}^{n+1} \subset \mathrm{BC}^*$.

These results provide a solution to Problem 1.

Refutability

In particular, refutability demands (in the sense that every incorrect hypothesis should be refutable; see [13]) are not applicable in the theory of inductive inference; see Problem 2.

Formally, Case and Smith [4] consider refutability as a property guaranteed by Popperian machines, the latter being defined as follows:

Definition 3 Suppose M is an inductive inference machine M. M is Popperian if, on any input, M returns a program of a recursive function.

Results thereon include the following:

Theorem 3 *There is an EX-identifiable class S of recursive functions for which there is no Popperian inductive inference machine witnessing its EX-identifiability.*

Corollary 2 *There is an* EX^1*-identifiable class S of recursive functions for which there is no Popperian inductive inference machine witnessing its* EX^1*-identifiability.*

Additionally, in EX^1-identification, Popper's refutability principle cannot be applied even if it concerns only those hypotheses returned in the limit.

Learning All Recursive Functions

Since the results above yield a hierarchy of inference types with strictly growing collections of learnable classes, there is also an implicit answer to Problem 3: the class of recursive functions is neither in $\mathrm{EX}_n{}^m$ for any $m, n \in \mathbb{N} \cup \{*\}$ nor in BC^m for any $m \in \mathbb{N}$. In contrast to that, Case and Smith [4] prove:

Theorem 4 *The class of all recursive functions is in* BC^*.

Applications

The work of Case and Smith [4] has been of high impact in learning theory.

A consequence of the discussion of anomalies is that refutability principles in general do not hold for identification in the limit. This result has given rise to later studies on methods and techniques inductive inference machines might apply in order to discover their errors [7] and thus to further insights into the nature of inductive inference.

Concerning the study of mind change hierarchies, among others, their lifting to transfinite ordinal numbers [8] is a notable extension.

Moreover, the theory of learning as proposed by Case and Smith [4] has been applied for the development of the theory of identifying recursive [11] or recursively enumerable [10] languages.

Open Problems

Among the currently open problems in inductive inference, one key challenge is to find a reasonable notion of the complexity of learning problems (i.e., of classes of recursive functions) involving the run-time complexity of learners as well as the number of mind changes required to learn the functions in a class. In particular, special natural classes of functions should be analyzed in terms of such a complexity notion.

Though of course the hierarchies $\mathrm{EX}_0{}^m \subset \mathrm{EX}_1{}^m \subset \mathrm{EX}_2{}^m \subset \ldots$ for any $m \in \mathbb{N}$ reflect some increase of complexity in that sense, a corresponding complexity notion would not address the aspect of run-time complexity of learners. Different complexity notions have been introduced, such as the so-called intrinsic complexity [2, 6] (neglecting run-time complexity) and the "measure under the curve" [5] (respecting the number of examples required, but neglecting the number of mind changes). In particular, for learning deterministic finite automata, different notions of run-time complexity have been discussed [12].

However, the definition of a more capacious complexity notion remains an open issue.

Problem Definition

A social network is a graph of relationships and interactions within a set of individuals. Information can spread within a social network by "word-of-mouth" effects. In other words, information diffuses from individuals to individuals in a social network through the connections between them, and if some information is spread by some initial individuals, many individuals may believe in it due to information diffusion. A social network is denoted as G=(V, E, w), where V is a set of vertexes with size n, $E \subseteq V \times V$ is a set of edges with size m, and $w : E \to [0, 1]$ is the set of all $w(u, v)$ which is the weight of edge (u, v).

Independent Cascade (IC) and Linear Threshold (LT) Models

The IC and LT models [1] are two basic models of influence diffusion in social networks, and there are two vertex stages: *inactive* and *active*. The influence always starts from a set of a set S consists of seeds (initially active nodes). The time is divided into discrete steps $0, 1, 2, \ldots$ Denote S_i the set of active vertexes at step i ($S_0 = S$ and $S_{-1} = \emptyset$). In the IC model, influence propagates as follows: S_i is the union set of S_{i-1} and other vertexes activated by vertexes in $S_{i-1} \setminus S_{i-2}$ in step i. Each node u has only one chance to activate each of its neighbors v with probability $w(u, v)$ when u first becomes active. In the LT model, influence propagates as follows: at the beginning each vertex v picks a threshold θ_v uniformly at random from $[0, 1]$ which is the threshold of this vertex becoming active. In each step i, $S_i = S_{i-1} \cup \{v | \sum_{u \in S_{i-1}} w(u, v) \geq \theta_v\}$. Both IC and LT models stop at the step $t+1$ when the process reaches its maximum influence, i.e., $S_{t+1} = S_t$.

Problem 1: Influence Maximization Problem (InfMax) [1]

INPUT: *A social network $G = (V, E, w)$ and k, the number of seeds.*

OUTPUT: *The set S containing k seeds that maximizes the influence $\mathcal{I}(S)$.*

Price-Related Propagation (PR) Frame

Adding monetary factor into the propagation process of the IC and LT models makes this *price related (PR) propagation* frame. In the PR frame, only the individual who adopts a product propagates this product's influence, and the adoption depends on the relationship between the price offered and the individual's valuation about this product. In detail, every vertex u has three stages: *neutral*, *influenced*, and *active*. Vertex u being neutral means it has no idea or positive attitude about this product. When u becomes influenced, u holds a positive attitude to the product but u hasn't adopted this product yet. Only if u further turns into active stage, u adopts the product and propagates the influence by telling its network neighbors. The PR frame separates, holding a positive attitude and propagating influence, in which the two are the same in traditional IC and LT models. This separation comes from the fact that individuals in social networks are independent human beings who not only are influenced by the people around but also have their own judgements. If someone receives some information, surely he or she should first evaluate the information before spreading it.

The PR frame assumes that each individual u has a *valuation* for the product, which is the highest price this individual thinks the product is worth. The rule of judging whether an influenced individual turns into active is the following: only if u is *influenced* and its valuation is higher than the offered price, u will turn *active*, adopt this product, and propagate the influence. The PR frame is an extension to the IC and LT models; it contains the PR-I model based on the IC and the PR-L model based on the LT. The rules of an individual turning from *neutral* to *influenced* in PR-I and PR-L model are the same as the rules of an individual turning from *inactive* to *active* in IC and LT model, respectively. However in the PR frame the *influenced* individuals do not propagate influence, but only the *active* ones do, and an *influence* individual turns to *active* if and only if the offered price is lower than its valuation.

Pricing Strategies in the PR Frame

Since price is vitally significant in the PR frame, we design two strategies to determine the prices offered to the individuals. The first one is *binary pricing* (BYC), in which all chosen seeds are given free samples and all other individuals are charged the same price, and the second one is *panoramic pricing* (PAP), in which prices for individuals including seeds are unconstrained different values that can be any value if needed.

In the PR frame, choosing node u as a seed merely means turning u to *influenced*. However, in BYC, any seed u must further become *active* for each seed is offered a free sample, i.e., the offered price is 0 and no greater than the valuation. In PAP, on the other hand, a seed u may not be *active*.

Price plays a vital role on the influence and profit in the PR frame. High prices may bring high profit but it hinders the influence propagation, and to enlarge the influence, some sacrifice on profit is inevitable. Base on this observation, a parameter $\lambda \in [0, 1)$ is adopted to denote the decision maker's preference toward influence and profit, and the objective is the weighted sum of influence and profit, which we call balanced influence and profit (BIP).

Problem 2: Balanced Influence and Profit Maximization Problem (BIPMax) [2]

INPUT: *A social network $G = (V, E, w)$, the distribution of customer evaluation, and λ the decision maker's preference.*

OUTPUT: *The seed set S and the price $\boldsymbol{p}$ for all individuals that maximize the objective function $\mathcal{B}(S, \boldsymbol{p}) = \lambda \cdot \mathcal{I}(S, \boldsymbol{p}) + (1-\lambda) \cdot \mathcal{R}(S, \boldsymbol{p})$ where $\mathcal{I}(S, \boldsymbol{p})$ is the influence and $\mathcal{R}(S, \boldsymbol{p})$ is the profit.*

Key Results

Result 1: *InfMax under the IC and LT models is both NP-hard.* [1]

Result 2: *BIPMax under the PR-I and PR-L models is both NP-hard.* [2]

The above two results show the difficulties of solving InfMax and BIPMax, respectively. It can be seen that both of them are "hard" to solve. However, approximation algorithms may exist, and the following two properties are used to design and analyze algorithms. Suppose f is a set function on subsets of V.

Submodularity and Monotony

1. **Submodular function.** f is called *submodular* if for every $X \subseteq Y \subseteq V$ and $z \in V \setminus Y$, $f(X \cup \{z\}) - f(X) \geq f(Y \cup \{z\}) - f(Y)$.
2. **Monotone function.** f is called *monotone* if $f(X \cup \{z\}) \geq f(X)$ for any set $X \subset V$ and element $z \in V$.

Result 3: *Influence $\mathcal{I}(S)$ under both IC and LT models is submodular and monotone w.r.t. S.* [1]

Result 4: *BIP $\mathcal{B}(S, \boldsymbol{p})$ under both PR-I and PR-L models is submodular w.r.t. S, if the prices $\boldsymbol{p}$ are fixed and $p_i \geq c$, where p_i is the ith element of $\boldsymbol{p}$ and c is the manufacturing cost of the product.* [2]

Remark 1 $\mathcal{B}(S, \boldsymbol{p})$ under both PR-I and PR-L models is non-monotone w.r.t. S. [2]

Algorithm for InfMax

Nemhauser et al. in [3] showed that greedy hill-climbing algorithm has the approximation ratio with $1 - 1/e$ of maximizing a submodular and monotone set function f. The greedy algorithm of maximizing influence is presented in Algorithm 1: each time the vertex that brings the highest marginal influence will be picked as a new seed, until the desired number of seeds are picked. Hence, according to Result 3, Algorithm 1 has a constant performance ratio $1 - 1/e$ solving InfMax.

Note that computing actual influence as well as marginal influence is #P-hard [1]. To estimate the influence in a reasonable time, Monte Carlo simulation is usually adopted, generating a number of samples and calculating the average value of all samples.

Algorithm 1 Greedy algorithm

$S \leftarrow \emptyset$;
while $|S| < k$ **do**
  $u = \arg\max_{u \in V \setminus S} \{\mathcal{I}(S \cup \{u\}) - \mathcal{I}(S)\}$;
  $S \leftarrow S \cup u$;
end while
output S;

Algorithms for BIPMax

For a non-monotone submodular set function f, Feige et al. [4] devised a deterministic local-search $\frac{1}{3}$-approximation and a randomized $\frac{2}{5}$-approximation algorithm if f is nonnegative; therefore, if the prices $\boldsymbol{p}$ are preknown and fixed, the techniques in [4] may be ideal approximation algorithms. However, usually prices $\boldsymbol{p}$ are to be determined to achieve the maximum BIP, and general algorithms need careful consideration.

To give a better pricing method for BIPMax, both the manufacturing cost and local influence should be considered. The manufacturing cost is denoted by c. Individual v_i's evaluation is a random variable X_i whose cumulative distribution function (CDF) is denoted by F_i. (If v_i is *influenced* and being offered price q, then the probability that v_i turns *active* is $\text{Prob}(x_i \geq q) = 1 - F_i(q)$.) For v_i itself, if it is chosen as the only seed and offered price p, the expected profit solely from v_i is $(1-F_i(p))(p-c)$, what is more, the expected influence to other nodes solely from v_i is $(1-F_i(p))\cdot\mathcal{I}(v_i, \boldsymbol{p})$. However, $\mathcal{I}(v_i, \boldsymbol{p})$ depends on other nodes' prices; to ease the computation, the following simple one-hop estimation is adopted: $\sum_{\forall u|\text{ outneighbor of } v_i} w(v_i, u)/d^{\text{out}}(v_i)$, where $d^{\text{out}}(v_i)$ is the outdegree of v_i. Then the *optimal price* p_i' for v_i is calculated as follows:

$$\tilde{\mathcal{B}}_i(p) = \lambda(1 - F_i(p)) \sum \frac{w(v_i,u)}{d^{\text{out}}(v_i)} + (1-\lambda)(1-F_i(p))(p-c), \quad (1)$$

$$p_i' = \arg\min_{p \in [0,1]} \tilde{\mathcal{B}}_i(p). \quad (2)$$

Equation (1) considers both the manufacturing cost and the network structure; however, the price calculated by (2) is still myopic.

Determine the Seeds and Prices Under BYC

In BYC the prices can only be 0 or the full price; for a company this strategy takes the least implementation expense. *ABYC* is the algorithm for BYC. ABYC contains two stages: first offering every individual a same full price and second determining the seeds whom free samples are given to.

Equation (2) is not used in the first stage since the obtained p_i' may vary from v_i. Instead we calculate the *universal optimal price*: $p_U' = \arg\min_{p \in [0,1]} \sum_i^n \tilde{\mathcal{B}}_i(p)$.

Greedy is used in the second stage of determining seeds: every round for each non-seed vertex u we compute the marginal BIP of picking u as a seed, and choose the vertex that provides the highest marginal gain. When no marginal BIP gain can be bought by any vertex, ABYC stops.

Suppose the price vector $\boldsymbol{p} = (p_1, \ldots p_n)$; denote $(\boldsymbol{p}_{-i}, q)$ the vector obtained by altering p_i, the ith element of $\boldsymbol{p}$ to q, i.e., $(\boldsymbol{p}_{-i}, q) = (p_1, \ldots, p_{i-1}, q, p_{i+1}, \ldots, p_n)$.

Algorithm 2 ABYC: the algorithm for BYC

$S \leftarrow \emptyset$, $\boldsymbol{p} \leftarrow \boldsymbol{0}$;
for $\forall v_i \in V$ **do**
  $p_i \leftarrow p_U'$;
end for
while true **do**
  $u \leftarrow \arg\max_{v_i \in V \setminus S} \{\mathcal{B}(S \cup \{v_i\}, (\boldsymbol{p}_{-i}, 0)) - \mathcal{B}(S, \boldsymbol{p})\}$;
  if $\mathcal{B}(S \cup \{u\}, (\boldsymbol{p}_{-i}, 0)) - \mathcal{B}(S, \boldsymbol{p}) > 0$ **then**
    $S \leftarrow S \cup \{u\}$; $\boldsymbol{p} \leftarrow (\boldsymbol{p}_{-i}, 0)$;
  else *break*;
  end if
end while
output $(S, \boldsymbol{p})$;

Determine the Seeds and Prices Under PAP

BYC is easy to implement, however it is too simple and constrained, PAP is much freer where prices are assigned with no constraint. APAP is the algorithm for PAP, and like ABYC it also contains two stages. In the first stage, to obtain p_i' for every v_i (2) is adopted. In the second stage, the vertex with the maximum marginal BIP gain

is picked step by step until no positive gain is available.

The computation of the marginal BIP gain under PAP when adding v_i into the seed set S is much more complex comparing to BYC, since when choosing v_i as a new seed a new price may also be offered to it. Suppose the new price for v_i is q, then the marginal BIP gain of adding v_i is: $\mathcal{B}(S \cup \{v_i\}, (\boldsymbol{p}_{-i}, q)) - \mathcal{B}(S, \boldsymbol{p})$. Since $\mathcal{B}(S, \boldsymbol{p})$ is a constant w.r.t. q, $\mathcal{B}(S \cup \{v_i\}, (\boldsymbol{p}_{-i}, q))$ should be maximized. When offering price q to v_i, only two outcomes exist in the sample space, outcome ω_1 where v_i accepts the price and turns *active*, outcome ω_0 where v_i rejects the price, stays *influenced* and never spreads the influence. If ω_1 happens, the influence gain collected from v_i is 1 and the profit gain collected from v_i is $q - c$, suppose the influence from other nodes is I_1 and the profit from other nodes is R_1, then the BIP gain is $g_i(q) = \lambda(I_1 + 1) + (1-\lambda)(q - c + R_1)$, which is a linear function w.r.t. q. Else if ω_0 happens, the influence gain collected from v_i is 1 and the profit gain collected from v_i is 0, suppose the influence from other nodes is I_0 and the profit from other nodes is R_0, then the BIP gain is $h_i = \lambda(I_0 + 1) + (1 - \lambda)R_0$, a constant independent of q. $\text{Prob}(\omega_1) = 1 - F_i(q)$ and $\text{Prob}(\omega_0) = F_i(q)$. Hence the expected BIP is:

$$\delta_i(q) = g_i(q) \cdot (1 - F_i(q)) + h_i \cdot F_i(q) \quad (3)$$

Algorithm 3 APAP: the algorithm for PAP

$S \leftarrow \emptyset$, $\boldsymbol{p} \leftarrow \boldsymbol{0}$;
for $\forall v_i \in V$ **do**
  $p_i \leftarrow p_i' = \arg\min_{p \in [0,1]} \tilde{\mathcal{B}}_i(p)$;
end for
while true **do**
  for $\forall v_i \in V \setminus S$ **do**
    $p_i^* \leftarrow \arg\max_{q \in [0,1]} \delta_i(q)$;
  end for
  $u \leftarrow \arg\max_{v_i \in V \setminus S} \{\mathcal{B}(S \cup \{v_i\}, (\boldsymbol{p}_{-i}, p_i^*)) - \mathcal{B}(S, \boldsymbol{p})\}$;
  if $\mathcal{B}(S \cup \{u\}, (\boldsymbol{p}_{-i}, p_i^*)) - \mathcal{B}(S, \boldsymbol{p}) > 0$ **then**
    $S \leftarrow S \cup \{u\}$; $\boldsymbol{p} \leftarrow (\boldsymbol{p}_{-i}, p_i^*)$;
  else *break*;
  end if
end while
output $(S, \boldsymbol{p})$;

To calculate I_1 and R_1, set v_i turns active with probability 1 and run Monte Carlo simulations, and to calculate I_0 and R_0, set v_i turns active with probability 0 and run Monte Carlo simulations. After obtaining I_1, R_1, I_0, and R_0, p_i^* should be computed. If $\delta_i(q)$ is a closed form, then p_i^* is easy to calculate. However $\delta_i(q)$ may not be a close form. For example, if the valuation follows normal distribution, then F_i contains an integral term and $\delta_i(q)$ is not a closed form. In this case, *golden section search* [5] which works fast on finding the extremum of a strictly unimodal function can be used. This technique successively narrows the range inside which the extremum exists to find it. Even if $\delta_i(q)$ is not always unimodal, it is unimodel in subintervals of $[0, 1]$. To reduce error, divide the interval $[0, 1]$ into several small intervals with the same size and pick each small interval's midpoint as a sample q_t. The search starts with the interval that contains the sample $q_0 = \arg\max_t \delta_i(q_t)$ and stops when the interval that contains p^* is narrower than a predefined threshold.

Problem Definition

One of the fundamental problems in social network is influence maximization. Informally, if we can convince a small number of individuals in a social network to adopt a new product or innovation, and the target is to trigger a maximum further adoptions, then which set of individuals should we convince? Consider a social network as a graph $G(V, E)$ consisting of individuals (node set V) and relationships (edge set E); essentially influence maximization comes down to the problem of finding important nodes or structures in graphs.

Influence Diffusion

In order to address the influence maximization problem, first it is needed to understand the influence diffusion process in social networks. In other words, how does the influence propagate over time through a social network? Assume time is partitioned into discrete time slots, and then influence diffusion can be modeled as the process by which activations occur from neighbor to neighbor. In each time slot, all previously activated nodes remain active and others either remain inactive or be activated by their neighbors according to the activation constraints. The whole process runs in a finite number of time slots and stops at a time slot when no more activation occurs. Let S denote the set of initially activated nodes; we denote by $f(S)$ eventually the number of activations, and the target is to maximize $f(S)$ with a limited budget.

Problem (Influence Maximization)

INPUT: A graph $G(V, E)$ where V is the set of individuals and E is the set of relationships, an activation model f, and a limited budget number K.

OUTPUT: A set S of nodes where $S \subseteq V$ such that the final activations $f(S)$ is maximized and $|S| \leq K$.

Activation Models

The influence maximization problem was first proposed by Domingos et al. and Richardson

Influence Maximization, Fig. 1 Pseudo-code: Greedy algorithm

Greedy Algorithm

1: let $S \leftarrow \emptyset$ (S holds the selected nodes);
2: **while** $|S| \leq K$ **do**
3: find $v \in (V \setminus S)$ such that $f(S \cup \{v\})$ is maximized;
4: let $S \leftarrow S \cup \{v\}$;
5: **end while**

et al. in [4] and [8], respectively, in which the social networks are modeled as Markov random field. After that, Kempe et al. ([6] and [7]) further investigated this problem in two models: *Independent Cascade* proposed by Goldenberg et al. ([5] and [11]) and *Linear Threshold* proposed by Granovetter et al. and Schelling et al., respectively, in [9] and [10].

In the *Independent Cascade* model, the activations are independent among different individuals, i.e., each newly activated individual u will have a chance, in the next time slot, to activate his or her neighbors v with certain probability $p(u, v)$ which is independent with other activations. In the *Linear Threshold* model, the activation is based on a threshold manner; the influence from an individual u to another individual v is presented by a weight $w(i, j)$ and the individual v will be activated at the moment when the sum of weights he or she receives from previous activated neighbors exceeds the threshold $t(v)$. It is worthy to note that there are two ways to assign the thresholds to individuals: *random* and *deterministic*. In the random model, the thresholds are randomly selected at uniform during the time, while in the deterministic model, the thresholds are assigned to individuals at the beginning and fixed for all time slots. For the sake of simplicity, they are called *Random Linear Threshold* and *Deterministic Linear Threshold*, respectively.

Key Results

Greedy Algorithm

In [6], it has been found that the activation function f under the *Independent Cascade* model and the *Random Linear Threshold* model is sub-modular. Therefore, the natural greedy algorithm (Fig. 1), which selects the node with the maximum marginal gain repeatedly, achieves a $\left(1 - \frac{1}{e}\right)$-approximation solution. However, the problem of exactly calculating the activation function f in a general graph G under the *Independent Cascade* model or the *Random Linear Threshold* model, respectively, is #P-hard [1, 2], which indicates that the greedy algorithm is not a polynomial time algorithm for the two models. The time complexity directly follows the pseudo-code (Fig. 1). Assume there exists an oracle that can compute the activation function f in τ time, and then the greedy algorithm runs in $O(K|V|\tau)$ time.

In [13], it has been found that the problem of exactly calculating the activation function f given an arbitrary set S under the *Deterministic Linear Threshold* model can be solved in linear time in terms of the number of edges. Therefore, the greedy algorithm runs in $O(K|V||E|)$ time. However, it has no approximation guarantee under this model.

Inapproximation Results

Under the *Independent Cascade* model or the *Random Linear Threshold* model, it can be shown by doing a gap-preserving reduction from the Set Cover problem [3] that $\left(1 - \frac{1}{e}\right)$ is the best possible polynomial time approximation ratio for the influence maximization problem; assume NP $\not\subset$ DTIME $\left(n^{\log \log n}\right)$. Under the *Deterministic Linear Threshold* model, it has been shown that there is no polynomial time $n^{1-\epsilon}$-approximation algorithm for the influence maximization problem unless P = NP where n is the number of nodes and $0 < \epsilon < 1$ [12].

Actually in the case that an individual can be activated after one of his or her neighbors

becomes active, the greedy algorithm achieves a polynomial time $\left(1-\frac{1}{e}\right)$-approximation solution, and even in the simple case that an individual can be activated when one or two of his or her neighbors become active, the influence maximization problem under the *Deterministic Linear Threshold* model is NP-hard to approximate.

Degree-Bounded Graphs

A graph $G(V, E)$ is a (d_1, d_2)-degree-bounded graph if every node in V has at most d_1 incoming edges and at most d_2 outgoing edges.

For the sake of simplicity, the influence maximization problem over such a degree-bounded graph is called (d_1, d_2)-influence maximization. In [13], it has been found that for any constant $\epsilon \in (0, 1)$, there is no polynomial time $n^{1-\epsilon}$-approximation algorithm for the $(2, 2)$-influence maximization problem under the *Deterministic Linear Threshold* model unless P = NP where n is the number of nodes, which indicates that the influence maximization problem under *Deterministic Linear Threshold* model is NP-hard to approximate to within any nontrivial factor, even if an individual can be activated when at least two of his or her neighbors become active.

Applications

Influence maximization would be of great interest for corporations, such as Facebook, LinkedIn, and Twitter, as well as individuals who desire to spread their products, ideas, etc. The solutions have a wide range of applications in various fields, such as product promotions where corporations want to distribute sample products among customers, political elections where candidates want to spread their popularity or political ideas among voters, and emergency situations where emergency news like sudden earthquake needs to spread to every resident in the community. In addition, the solutions may be also applicable in military defense where malicious information which has already propagated dynamically needs to be blocked.

Years and Authors of Summarized Original Work

2014; Kane, Tompa

Problem Definition

This problem is concerned with efficiently finding a set of documents that closely match a query within a large corpus of documents (i.e., a search engine). This is accomplished by producing an index offline to the query processing and then using the index to quickly answer the queries. The indexing stage involves splitting the dataset into tokens and then constructing an *inverted index* which maps from each token to the list of document identifiers of the documents that contain that token (a *postings list*). The query can then be executed by converting it to a set of query tokens, using the inverted index to find the corresponding postings lists, and *intersecting* the lists to find the documents contained in all the lists (conjunctive intersection or boolean AND). A subsequent ranking step is used to restrict the conjunctive intersection to a list of top-k results that best answer the query.

Objective

Produce an efficient system to answer queries, where efficiency is a space-time trade-off involving the storage of the inverted index (space) and the intersection of the lists (time). If the inverted index is stored on a slow medium, then efficiency might also include the size of the lists required to answer the query (transfer).

Design Choices

There are many degrees of freedom in designing such a system:

1. Creating a document to internal identifier mapping
2. Encoding of the inverted index mapping
3. Encoding of the postings lists
4. Using auxiliary structures in postings lists
5. Ordering of the internal identifiers in the postings lists
6. Order and method of executing the list intersection

Variants

For queries where the conjunctive intersection is too small, the intersection can be relaxed to find documents containing a weighted portion of the query tokens (see t-threashold or Weak-AND). The query lists can be intersected using any boolean operators, though the most commonly added is the boolean NOT operator which can be used to quickly reduce the number of conjunctive results. The query results can also be reduced by including token offset restrictions, such as ensuring tokens appear as a phrase or within some proximity. While many implementations interleave the conjunctive intersection with the calculation of the ranking, some also use ranking information to prune documents from the intersection or to terminate the query early when the correct results (or good enough results) have been found.

Key Results

Traditionally, inverted indexes were stored on disk, causing the reduction of transfer costs to be the dominant objective. Modern systems often store their inverted indexes in memory meaning that reducing overall index size is important and that implementation details of the intersection algorithms can produce significant performance

differences, thus leading to a more subtle space-time trade-off. In either case, the mapping portion of the inverted index (the dictionary or lexicon) can be implemented using a data structure such as a B-tree which is both fast and compact, so we do not examine dictionary implementations in the remainder of this article.

Multi-list Processing

Intersecting multiple lists can be implemented by intersecting the two smallest lists and then intersecting the result with the next smallest list iteratively, thus producing a *set versus set* (svs) or *term-at-a-time* (TAAT) approach. If the lists are in sorted order, then each step of the svs approach uses the *merge* algorithm, which takes each element in the smaller list M and finds it in the larger list N by executing a forward search and then reports any elements that are found. The M list could be encoded differently than the N list, and indeed, after the first svs step, it is the uncompressed result list of the previous step. The sequential processing and memory accesses of the svs approach allows the compiler and CPU to optimize the execution, making this approach extremely fast, even though temporary memory is required for intermediate result accumulators. If the lists are not sorted, then additional temporary memory must be used to intersect the lists using some equality-join algorithm.

Intersecting multiple lists can also be implemented by intersecting all the lists at the same time. If the lists are not in sorted order, using this approach may require a large amount of temporary space for the join structures and the accumulators. If the lists are sorted, then we call this a *document-at-a-time* (DAAT) approach, and it requires very little temporary space: just one pointer per list to keep track of its processing location. The order that the lists are intersected could be static, such as ascending term frequency order (as done with svs), or it could adapt to the processing. All of these non-svs approaches jump among the lists that are stored at different memory locations, so it is more difficult for the compiler and CPU to optimize the execution. In addition, the loop iterating over the lists for each result item and the complications when using different list encodings will slow down non-svs implementations. Despite these limitations, many of the optimizations for svs list intersection can be applied to implementations using non-svs approaches. For systems that return the top-ranked results, a small amount of additional memory is needed for a top-k heap to keep track of the best results. Instead of adding results that match all the terms into a simple array of results, they are added to the heap. At the end of query processing, the content of the heap is output in rank order to form the final top-k query results.

Uncompressed Lists

Storing the lists of document identifiers in an *uncompressed* format simply means using a sequential array of integers. For fast intersection, the integers in these lists are stored in order, thus avoiding join structures and allowing many methods of searching for a particular value in a list. As a result, there are many fast algorithms available for intersecting uncompressed integer lists, but the memory used to store the uncompressed lists is very large and probes into the list can produce wasted or inefficient memory access. All of these uncompressed intersection algorithms rely on random access into the lists, so they are inappropriate for compressed lists. We present only three of the best performing algorithms [2]:

Galloping svs (g-svs): Galloping forward search probes into the list to find a point past the desired value, where the probe distance doubles each time, then the desired location is found using binary search within the last two probe points.

Galloping swapping svs (g-swsvs): In the previous galloping svs algorithm, values from the smaller list are found in the larger list. Galloping swapping svs, however, finds values from the list with the smaller number of remaining integers in the other list, thus potentially swapping the roles of the lists.

Sorted Baeza-Yates using adaptive binary forward search (ab-sBY): The Baeza-Yates algorithm is a divide and conquer approach that finds the median value of the smaller list in the

larger list, splits the lists, and recurses. Adding matching values at the end of the recursion produces a sorted result list. The adaptive binary forward search variant uses binary search within the recursed list boundaries, rather than using the original list boundaries.

Compressed Lists

There are a large variety of compression algorithms available for sorted integer lists. The lists are first converted into differences minus one (i.e., deltas or d-gaps) to get smaller values, but this removes the ability to randomly access elements in the list. Next, a variable length encoding is used to reduce the number of bits needed to store the values, often grouping multiple values together to allow word or byte alignment of the groups and faster bulk decoding. The most common list compression algorithms are *Variable byte (vbyte)*, *PForDelta (PFD)*, and *Simple9 (S9)*. Recent work has improved decoding, and delta restore speeds for many list compression algorithms using vectorization [7]. Additional gains are possible by changing delta encoding to act on groups of values, thus improving runtime at the expense of using more space. Another recent approach called quasi-succinct indexing [10] first acts on the values as monotone sequences and then incorporates some delta encoding more deeply in the compression algorithm.

List Indexes

List indexes, also known as skip structures or auxiliary indexes, can be included to jump over values in the postings lists and thus avoid decoding, or even accessing, portions of the lists. The desired jump points can be encoded inline with the lists, but they are better stored in a separate contiguous memory location without compression, allowing fast scanning through the jump points. These list index algorithms can be used with compressed lists by storing the deltas of the jump points, but the block-based structure causes complications if the jump point is not byte or word aligned, as well as block aligned. The actual list values that are found in the skip structures can either be maintained within the original compressed list (overlaid) preserving fast iteration through the list, or the values could be extracted (i.e., removed) from the original compressed lists, giving a space reduction but slower iteration through the list.

A simple list index algorithm ("skipper" [9]) groups by a fixed number of elements storing every X^{th} element in a separate array structure, where X is a constant, so we refer to it as skips(X). When intersecting lists, the skip structure is scanned linearly to find the appropriate jump point into the compressed structure, where the decoding can commence. Using variable length skips is possible, such as tuning the number of skipped values relative to the list size n, perhaps using a multiple of $\sqrt{n}$ or $\log(n)$.

Another type of list index algorithm ("lookup" [9]) groups by a fixed size document identifier range using the top-level bits of the value to index into an array storing the desired location in the encoded list, similar to a segment/offset scheme. Each list can pick the number of bits in order to produce reasonable jump sizes. We use D as the domain size and n as the list size, giving a list's density as $y = \frac{n}{D}$. If we assume randomized data and use the parameter B to tune the system, then by using $\left\lceil \log_2 \left(\frac{B}{y} \right) \right\rceil$ bottom level bits will leave between $\frac{B}{2}$ and B entries per segment in expectation. As a result, we call this algorithm segment(B).

Bitvectors

When using a compact domain of integers, as we are, the lists can instead be stored as bitvectors, where the bit number is the integer value and the bit is set if the integer is in the list. For runtime performance benefits, this mapping from the identifier to the bit location can be changed if it remains a one-to-one mapping and is applied to all bitvectors.

If all the lists are stored as bitvectors, conjunctive list intersection can be easily implemented by combining the bitvectors of the query terms using bitwise AND (bvand), with the final step converting the result to a list of integers (bvconvert). Note, except for the last step, the result of each step is a bitvector rather than an uncompressed result list. The bvconvert algorithm can

be implemented as a linear scan of the bits of each word, but using a logarithmic check is faster since the bitvectors being converted are typically sparse. Encoding all the lists as bitvectors gives good query runtime, but the space usage is very large since there are many tokens.

To alleviate the space costs of using bitvectors, the lists with density less than a parameter value F can be stored using normal delta compression, resulting in a hybrid bitvector algorithm [4]. This hybrid algorithm intersects the delta-compressed lists using merge and then intersects the remainder with the bitvectors by checking if the elements are contained in the first bitvector (bv-contains), repeating this for each bitvector in the query, with the final remaining values being the query result. Bitvectors are faster than other approaches for dense lists, so this hybrid algorithm is faster than non-bitvector algorithms. It can also be more compact than other compression schemes, because dense lists can be compactly stored as bitvectors. In addition, large overlaid skips can be used in the delta-compressed lists to improve query runtime.

In order to store more postings in the faster bitvector form, a semi-bitvector structure [5] encodes the front portion of a list as a bitvector and the rest using skips over delta compression. By skewing lists to have dense front portions, this approach can improve both space and runtime.

Other Approaches

Quasi-succinct indices [10] store list values in blocks with the lower bits of the values in an array and the higher bits as deltas using unary encoding combined with skips for fast access. This structure produces a good space-time trade-off when the number of higher-level bits is limited. The list intersection implementation can exploit the unary encoding of the higher-level bits by counting the number of ones in machine words to find values quickly. The resultant space-time performance is comparable to various skip-type implementations for conjunctive list intersection, though indexing speed may be slower.

The treap data structure combines the functionality of a binary tree and a binary heap. This treap data structure can implement list intersection [6] by storing each list as a treap where the list values are used as the tree order and the frequencies are used as the heap order. During list intersection, subtrees can be pruned from the processing if the frequency is too low to produce highly ranked results. In order to make this approach viable, low-frequency values are stored in separate lists using delta-compression with skips. This treap and frequency separated index structure can produce some space-time performance improvements compared to existing ranking-based search systems.

Wavelet trees can also be used to implement list intersection [8]. The postings lists are ordered by frequency, and each value is assigned a global location, so that each list can be represented by a range of global locations. A series of bit sequences represents a tree which starts with the frequency-ordered lists of the global locations and translates them into the actual document identifiers. Each level of the tree splits the document identifier domain ranges in half and encodes the edges of the tree using the bit sequences (left as 0 and right as 1). Multiple lists can be intersected by following the translation of their document ranges in this tree of bit sequences, only following the branch if it occurs in all of the list translations. After some careful optimization of the translation code, the wavelet tree data structure results in similar space usage, but faster query runtimes than some existing methods for conjunctive queries.

Ranking

Ranking algorithms are closely guarded trade secrets for large web search companies, so their details are not generally known. Many approaches, however, add term frequencies and/or postings offsets into the postings lists and combine this with corpus statistics to produce good results, as done in the standard BM25 approach. Unfortunately, information such as frequencies cannot be easily added to bitvector structures, thus limiting their use. Data and link analysis can also help by producing a global order, such as PageRank, which can be factored into the ranking function to improve results.

Reordering

Document identifiers in postings lists can be assigned to make the identifier deltas smaller and more compressible. As a first stage, they are assigned to form a compact domain of values, while a second stage renumbers these identifiers to optimize the system performance in a process referred to as document *reordering* [3]. Reordering can improve space usage by placing documents with similar terms close together in the ordering, thus reducing the size of the deltas, which can then be stored more compactly, among other benefits.

Applications

Intersecting inverted lists is at the heart of search engine query processing and top-k operators in databases.

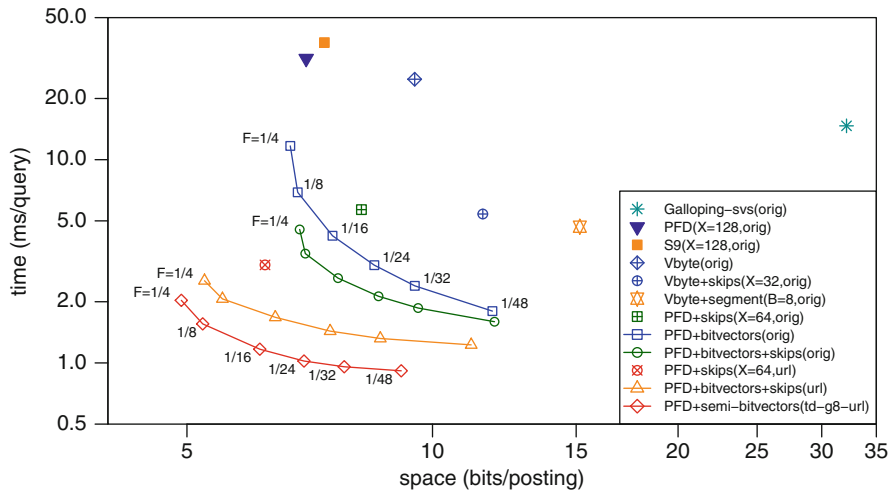
Open Problems

Going forward, main goal is to design list representations which are provably optimal in terms of space usage (entropy) together with algorithms that achieve the optimal trade-off between time and the space used by the given representation.

Experimental Results

Most published works involving intersections of inverted lists prove their results through experimentation. Following this approach, we show the relative performance of the described approaches using an in-memory conjunctive list intersection system that has document ordered postings lists without any ranking-based structures or processing. We run this system on the TREC GOV2 corpus and execute 5,000 of the associated queries. These experiments were executed on an AMD Phenom II X6 1090T 3.6 GHz Processor with 6 GB of memory running Ubuntu Linux 2.6.32-43-server. The code was compiled using the gcc 4.4.3 compiler with the -O3 command line parameter. Our results are presented in Fig. 1 using a space-time (log-log) plot. For the configurations considered, the block size of the encoding always equals the skip size, X, and the bitvector configurations all use $X = 256$.

With compressed lists alone, intersection is slow. On the other hand, uncompressed lists are much larger than compressed ones, but random access allows them to be fast. List indexes when combined with the compressed lists add some space, but their targeted access into the lists allows them to be even faster than the uncompressed algorithms. (For the list indexes, we present the fastest configurations we tested over the parameter ranges of X and B.)



Intersections of Inverted Lists, Fig. 1 Space vs. time (log-log) plot for various intersection algorithms

The performance of list indexes suggests that the benefits of knowing where to probe into the list (i.e., using skips rather than a probing search routine) outweigh the cost of decoding the data at that probe location. Using the hybrid bitvector approach is much faster and somewhat smaller than the other techniques. Adding large overlaid skips to the delta-compressed lists allows the bitvectors + skips algorithm to improve performance.

Reordering the documents to be in URL order gives significant space improvements. This ordering also improves query runtimes significantly, for all combinations of skips and/or bitvectors. Splitting the documents into eight groups by descending number of terms in document, reordering within the groups by URL ordering (td-g8-url), and using semi-bitvectors produce additional improvements in both space and runtime. This demonstration of the superior performance of bitvectors suggests that integrating them into ranking-based systems warrants closer examination.

URLs to Code and Datasets

Several standard datasets and query workloads are available from the Text REtreival Conference (TREC at http://trec.nist.gov). Many implementations of search engines are available in the open source community, including Wumpus (http://www.wumpus-search.org), Zettair (http://www.seg.rmit.edu.au/zettair/), and Lucene (http://lucene.apache.org).

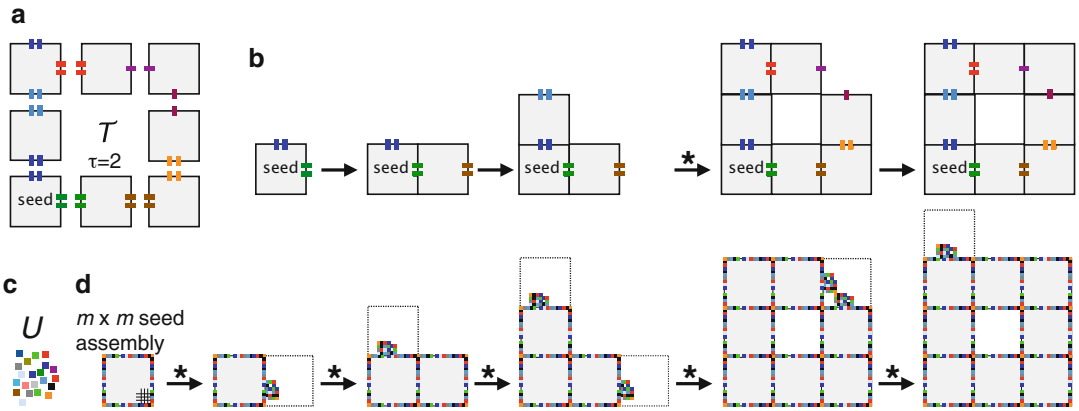
Problem Definition

Algorithmic self-assembly [11] is the idea that small self-assembling molecules can compute as they grow structures. It gives programmers a set of theoretical models in which to specify and design target structures while trying to optimize resources such as number of molecule types or even construction time. The abstract Tile Assembly Model [11] is one such model. An instance of the model is called a tile assembly system and is a triple $\mathcal{T} = (T, \sigma, \tau)$ consisting of a finite set T of square tiles, a seed assembly σ (one or more tiles stuck together), and a temperature $\tau \in \{1, 2, 3, \ldots\}$, as shown in Fig. 1a. Each side of a square tile has a glue (or color) g which in turn has a strength $s \in \{0, 1, 2, \ldots\}$. Growth occurs on the integer plane and begins from a seed assembly (or a seed tile) placed at the origin, as shown in Fig. 1b. A tile sticks to a partially formed assembly if it can be placed next to the assembly in such a way that enough of its glues match the glues of the adjacent tiles on the assembly and the sum of the matching glue strengths is at least the temperature. Growth proceeds one tile at a time, asynchronously and nondeterministically.

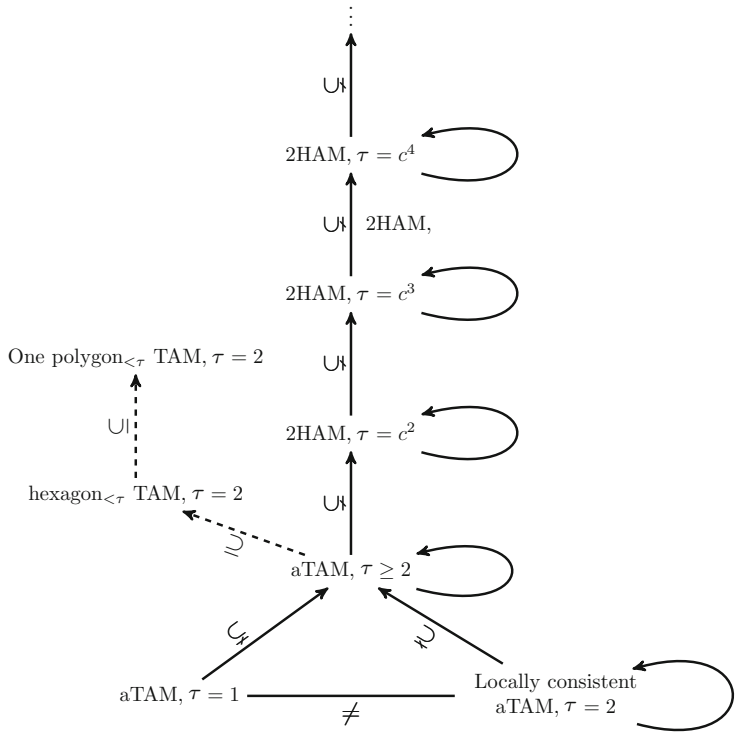
Here we discuss recent results and suggest open questions on intrinsic universality and simulation as a method to compare self-assembly models. Figure 2 gives an overview of these and other results. For more details, see [12].

Simulation and Intrinsic Universality

Intuitively, one self-assembly model simulates another if they grow the same structures, via the same dynamical growth processes, possibly with some spatial scaling. Let $\mathcal{S}$ and $\mathcal{T}$ be tile assembly systems of the abstract Tile Assembly Model described above. $\mathcal{S}$ is said to *simulate* $\mathcal{T}$ if the following conditions hold: (1) each tile of $\mathcal{T}$ is represented by one or more $m \times m$ blocks of tiles in $\mathcal{S}$ called *supertiles*, (2) the seed assembly



Intrinsic Universality in Self-Assembly, Fig. 1 An instance of the abstract Tile Assembly Model and an example showing simulation and intrinsic universality. (**a**) A tile assembly system $\mathcal{T}$ consists of a tile set, seed tile, and a temperature $\tau \in \mathbb{N}$. Colored glues on the tiles' sides have a natural number strength (shown here as 0, 1, or 2 colored tabs). (**b**) Growth begins from the seed with tiles sticking to the growing assembly if the sum of the strengths of the matching glues is at least τ. (**c**) An intrinsically universal tile set U. (**d**) When initialized with a seed assembly (which encodes $\mathcal{T}$) and at temperature 2, the intrinsically universal tile set simulates the dynamics of $\mathcal{T}$ with each tile placement in $\mathcal{T}$ being simulated by the growth of an $m \times m$ block of tiles. Single tile attachment is denoted by $\rightarrow$, and $\overset{*}{\rightarrow}$ denotes multiple tile attachments. Note that both systems have many other growth dynamics that are not shown



Intrinsic Universality in Self-Assembly, Fig. 2 Classes of tile assembly systems and their relationship with respect to simulation. There is an arrow from $\boldsymbol{B}$ to $\boldsymbol{A}$ if $\boldsymbol{A}$ contains $\boldsymbol{B}$ with respect to simulation: that is, for each tile assembly system $\mathcal{B} \in \boldsymbol{B}$, there is a tile assembly system $\mathcal{A}_{\mathcal{B}} \in \boldsymbol{A}$ that simulates $\mathcal{B}$. *Dashed arrows* denote containment, *solid arrows* denote strict containment, a self-loop denotes the existence of an intrinsically universal tile set for a class and its omission implies that the existence of such a tile set is an open problem. aTAM: abstract Tile Assembly Model (growth from a seed assembly by single tile addition in 2D), τ denotes "temperature." 2HAM: Two-Handed Tile Assembly Model (assemblies of tiles stick together in 2D). A 2HAM temperature hierarchy is shown for some $c \in \{2, 3, 4, \ldots\}$ and, in fact, for each such c the set of temperatures $\{c^i | i \in \{2, 3, \ldots\}\}$ gives an infinite hierarchy of classes of strictly increasing simulation power in the 2HAM

of $\mathcal{T}$ is represented by the *seed assembly* of $\mathcal{S}$ (one or more connected $m \times m$ supertiles), and (3) via supertile representation every sequence of tile placements in the simulated system $\mathcal{T}$ has a corresponding sequence of supertile placements in the simulator system $\mathcal{S}$, and vice versa. It is worth pointing out that although the intuitive idea of one assembly system simulating another is fairly simple, the formal definition of simulation [10] gets a little technical as the filling out of supertiles in the simulator is an asynchronous and nondeterministic distributed process with many supertiles growing independently and in parallel in the simulator system.

Key Results

The Abstract Tile Assembly Model Is Intrinsically Universal

A class of tile assembly systems C is said to be *intrinsically universal* if there exists a single set of tiles U that simulates any instance of C. For each such simulation, U should be appropriately initialized as an instance (i.e., a tile assembly system) of C itself. Figure 1d illustrates the concept. For example, the abstract Tile Assembly Model has been shown to be intrinsically universal [5]. Specifically, this means that there is a single set of tiles U that when appropriately initialized is

capable of simulating an arbitrary tile assembly system $\mathcal{T}$. To program such a simulation, tiles from $\mathcal{T}$ are represented as $m \times m$ supertiles (built from tiles in U), and the seed assembly of $\mathcal{T}$ is represented as a connected assembly $\sigma_{\mathcal{T}}$ of such supertiles. Furthermore, the entire tile assembly system $\mathcal{T}$ (a finite object) is itself encoded in the supertiles of $\sigma_{\mathcal{T}}$ of $\mathcal{U}$. Then if we watch all possible growth dynamics in both $\mathcal{T} = (T, \sigma, \tau)$ and $\mathcal{U} = (U, \sigma_{\mathcal{T}}, 2)$, we get that both systems produce the same set of assemblies via the same dynamics where we use a supertile representation function to map from supertiles over U to tiles from T. It is worth pointing out that in this particular construction [5], the simulating system is always (merely) at temperature $\tau = 2$ no matter how large the temperature ($\tau \geq 1$) of the simulated system.

This intrinsically universal tile set U has the ability to simulate both the geometry and growth order of any tile assembly system. Modulo spatial rescaling U represents the full power and expressivity of the entire abstract Tile Assembly Model.

Noncooperative Assembly Is Weaker than Cooperative Assembly

The temperature 1, or noncooperative, model is a restriction of the abstract Tile Assembly Model. Despite its esoteric name, it models a fundamental and ubiquitous form of growth: asynchronous growing and branching tips in Euclidian space where each new tile is added if it matches on at *least one side*. Separating the power of the noncooperative and cooperative models has presented significant challenge to the community.

Recently it has been shown that the noncooperative model is provably weaker than the full model [10] in that sense that it is not capable of *simulating* arbitrary tile assembly systems. This is the first fully general negative result about temperature 1 that does not assume restrictions on the model nor unproven hypotheses.

An interesting aspect of this result is that it holds for 3D noncooperative systems; they too cannot simulate arbitrary tile assembly systems. This seems quite shocking, given that 3D noncooperative systems are Turing-universal [1]! So in particular, 3D noncooperative systems can simulate 2D (or 3D) cooperative systems by simulating a Turing machine that in turn simulates the cooperative system, but this loose style of simulation ends up destroying the geometry and dynamics of tile assembly by encoding everything as "geometry-less" strings. Hence, Turing-universal algorithmic behavior in self-assembly does not imply the ability to simulate, in a direct geometric fashion, arbitrary algorithmic self-assembly processes.

One Tile to Rule Them All

As an example of a simulation result on a very different model of self-assembly, Demaine, Demaine, Fekete, Patitz, Schweller, Winslow, and Woods [4] describe a sequence of simulations that route from square tiles, to the intrinsically universal tile set, to hexagons (with strength $< \tau$, or weak, glues), to a *single* polygon that is translatable, rotatable, and flipable. Their fixed-sized polygon, when appropriately seeded, simulates any tile assembly system from the abstract Tile Assembly Model. They also show that with translation only (i.e., no rotation), such results are not possible with a small (size ≤ 3) seed (although with larger seeds, a single translation-only polyomino simulates the space-time diagram of a 1D cellular automaton). In the simpler setting of Wang plane tiling, they give an easy method to "compile" any tile set T (on the square or hexagonal lattice) to a single regular polygon that simulates exactly the tilings of T, except with tiny gaps between the polygons.

Two Hands

It has been shown that the two-handed, or hierarchical, model of self-assembly (where large assemblies of tiles may come together in a single step) is not intrinsically universal [3]. Specifically there is no tile set that, in the two-handed model, can simulate all two-handed systems for all temperatures. However, for each $\tau \in \{2, 3, 4, \ldots\}$, there is a tile set U_τ that is intrinsically universal for the class of two-handed systems that work at temperature τ. Also, there is an infinite hierarchy of classes of such systems with each level strictly more powerful than the one below. In fact there are an infinite set of such hierarchies, as

described in the caption of Fig. 2. These results give a formalization of the intuition that multiple long-range interactions are more powerful than fewer long-range interactions in the two-handed model.

Open Problems

Gaps in Fig. 2 (i.e., missing solid arrows and missing models) suggest a variety of open questions. Also, it remains as future work to further tease apart the power of restrictions of the abstract Tile Assembly Model, for example, it remains open whether 2D noncooperative systems are intrinsically universal for themselves.

It is an open question whether or not the hexagonal Tile Assembly Model [4], various polygonal Tile Assembly Models [4, 7], the Nubot model [13], and Signal-Passing Tile Assembly Model [6, 9] are intrinsically universal. Furthermore, simulation could be used to tease apart the power of subclasses of these models.

Gilbert et al. [7] investigate the computational power of various kinds of polygonal tile assembly systems, showing that regular polygon tiles with >6 sides simulate Turing machines. What is the relationship between tile geometry and simulation power? Do more sides give strictly more simulation power?

A desirable feature of a simulator is not only that it simulates all possible dynamics of some simulated system, but that the probability of a given dynamics is roughly equal in both the simulated system and the simulator. Is there an intrinsically universal tile set with that property? Here, the probability of seeing a given dynamics or assembly in a simulator should be close to that of the simulated system, where "close" means, say, within a factor proportional to the spatial scaling.

Does there exist a tile set U for the abstract Tile Assembly Model, such that for any (adversarially chosen) seed assembly σ, at temperature 2, this tile assembly system simulates some tile assembly system $\mathcal{T}$? Moreover, U should be able to simulate all such members $\mathcal{T}$ of some nontrivial class S. U is a tile set that can do one thing and nothing else: simulate tile assembly systems from the class S. This question about U is inspired by the factor simulation question in CA [2].

Many algorithmic tile assembly systems use cooperative self-assembly to simulate Turing machines in a "zig-zag" fashion, as do a number of experimentally implemented systems. Can the negative result of [10] be extended to show 2D temperature 1 abstract Tile Assembly Model systems do not simulate zig-zag tile assembly systems?

There are a number of future research directions for the two-handed, or hierarchical, self-assembly model. One open question [3, 8] asks whether or not temperature τ two-handed systems can simulate temperature $\tau - 1$ two-handed systems. Another direction involves finding which aspects of the model (e.g., mismatches, excess binding strength, geometric blocking) are required for intrinsic universality at a given temperature, to better understand the intricacies of this very powerful, but natural, model.

Of course, there are many other ways to compare the power of self-assembly models: shape and pattern building, tile complexity, time complexity, determinism versus nondeterminism, and randomized (coin-flipping) algorithms in self-assembly. It remains as important future work to find relationships between these notions on the one hand and intrinsic universality and simulation on the other hand. Can ideas from intrinsic universality be used to answer questions about these notions?

Motivation

The problem of coordinating the access to a shared medium is a central challenge in wireless networks. In order to solve this problem, a proper medium access control (MAC) protocol is needed. Ideally, such a protocol should not only be able to use the wireless medium as effectively as possible, but it should also be robust against a wide range of interference problems including jamming attacks. Interference problems from outside sources are usually ignored in theory but in practice it is important to take these into account, particularly because the ISM frequency band, which is the standard band used for wireless communication, is one of the most dirty frequency bands as it is affected by many devices like microwaves.

Problem Definition

We model inference from outside sources with the help of an adversary. In the most general model that we have published so far [9], our adversarial model is based on the most widely used model to capture interference problems, which is known as the SINR (signal-to-interference-and-noise ratio) model. In the SINR model, a message sent by node u is correctly received by node v if and only if $P_v(u)/(\mathcal{N} + \sum_{w \in S} P_v(w)) \geq \beta$ where $P_x(y)$ is the received power at node x of the signal transmitted by node y, $\mathcal{N}$ is the background noise, and S is the set of nodes $w \neq u$ that are transmitting at the same time as u. The threshold $\beta > 1$ depends on the desired rate, the modulation scheme, etc. When using the standard model for signal propagation, then this expression results in $(P(u)/d(u,v)^\alpha)/(\mathcal{N} + \sum_{w \in S}$

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

$P(w)/d(w,v)^\alpha) \geq \beta$ where $P(x)$ is the strength of the signal transmitted by x, $d(x,y)$ is the Euclidean distance between x and y, and α is the path-loss exponent. We assume that all nodes transmit with some fixed signal strength P and that $\alpha > 2 + \epsilon$ for some constant $\epsilon > 0$, which is usually the case in an outdoors environment.

In most theory papers on MAC protocols, the background noise $\mathcal{N}$ is either ignored (i.e., $\mathcal{N} = 0$) or assumed to behave like a Gaussian variable. This, however, is an oversimplification of the real world. There are many sources of interference producing a non-Gaussian noise such as electrical devices, temporary obstacles, coexisting networks, or jamming attacks. In order to capture a very broad range of noise phenomena, we model the background noise $\mathcal{N}$ (due to jamming or to environmental noise) with the aid of an adversary $\mathcal{ADV}$ that has a fixed energy budget within a certain time frame for each node v. More precisely, in our case, a message transmitted by a node u will be successfully received by node v if and only if

$$\frac{P/d(u,v)^\alpha}{\mathcal{ADV}(v) + \sum_{w \in S} P/d(w,v)^\alpha} \geq \beta, \quad (1)$$

where $\mathcal{ADV}(v)$ is the current noise level created by the adversary at node v. The goal is to design a MAC protocol that allows the nodes to successfully transmit messages under this model as long as this is in principle possible.

For the formal description and analysis, we assume a synchronized setting where time proceeds in synchronized time steps called *rounds*. In each round, a node u may either transmit a message or sense the channel, but it cannot do both. A node which is sensing the channel may either (i) sense an *idle* channel, (ii) sense a *busy* channel, or (iii) *receive* a packet. In order to distinguish between an idle and a busy channel, the nodes use a fixed noise threshold ϑ: if the measured signal power exceeds ϑ, the channel is considered busy, otherwise idle. Whether a message is successfully received is determined by the SINR rule described above. To leave some chance for the nodes to communicate, we restrict the adversary to be (B,T)-*bounded*: for each node v and time interval I of length T, a (B,T)-*bounded adversary* has an overall noise budget of $B \cdot T$ that it can use to increase the noise level at node v and that it can distribute among the time steps of I as it likes, depending on the current state of the nodes. This adversarial noise model is very general, since in addition to being adaptive, the adversary is allowed to make independent decisions on which nodes to jam at any point in time (provided that the adversary does not exceed its noise budget over a time window of size T).

Our goal is to design a *symmetric local-control* MAC protocol (i.e., there is no central authority controlling the nodes, and all the nodes are executing the same protocol) that has a constant competitive throughput against any (B,T)-bounded adversary as long as certain conditions (that are as general as possible) are met. In order to define what we mean by "competitive," we need some notation. The *transmission range* of a node v is defined as the disk with center v and radius r with $P/r^\alpha \geq \beta\vartheta$. Given a constant $\epsilon > 0$, a time step is called *potentially busy* at some node v if $\mathcal{ADV}(v) \geq (1-\epsilon)\vartheta$ (i.e., only a little bit of additional interference by the other nodes is needed so that v sees a busy channel). For a not potentially busy time step, it is still possible that a message sent by a node u within v's transmission range is successfully received by v. Therefore, as long as the adversary is forced to offer not potentially busy time steps due to its limited budget and every node has a least one other node in its transmission range, it is in principle possible for the nodes to successfully transmit messages. To investigate that formally, we use the following notation. For any time frame F and node v let $f_v(F)$ be the number of time steps in F that are not potentially busy at v and let $s_v(F)$ be the number of time steps in which v successfully receives a message. We call a protocol c-*competitive* for some time frame F if $\sum_{v \in V} s_v(F) \geq c \sum_{v \in V} f_v(F)$. An adversary is *uniform* if at any time step, $\mathcal{ADV}(v) = \mathcal{ADV}(w)$ for all nodes $v, w \in V$, which implies that $f_v(F) = f_w(F)$ for all nodes.

Key Results

We presented a MAC protocol called SADE which can achieve a c-competitive throughput where c only depends on ϵ and the path loss exponent α but not on the size of the network or other network parameters [9]. The intuition behind SADE is simple: each node v maintains a parameter p_v which specifies v's probability of accessing the channel at a given moment of time. That is, in each round, each node u decides to broadcast a message with probability p_v. (This is similar to classical random backoff mechanisms where the next transmission time t is chosen uniformly at random from an interval of size $1/p_v$.) The nodes adapt their p_v values over time in a multiplicative-increase multiplicative-decrease manner, i.e., the value is lowered in times when the channel is utilized (more specifically, we decrease p_v whenever a successful transmission occurs) or increased during times when the channel is idling. However, p_v will never exceed $\hat{p}$, for some sufficiently small constant $\hat{p} > 0$.

In addition to the probability value p_v, each node v maintains a time window estimate T_v and a counter c_v for T_v. The variable T_v is used to estimate the adversary's time window T: a good estimation of T can help the nodes recover from a situation where they experience high interference in the network. In times of high interference, T_v will be increased and the sending probability p_v will be decreased. Now we are ready to describe SADE in full detail.

Initially, every node v sets $T_v := 1$, $c_v := 1$, and $p_v := \hat{p}$. In order to distinguish between idle and busy rounds, each node uses a fixed noise threshold of ϑ.

The SADE protocol works in synchronized rounds. In every round, each node v decides with probability p_v to send a message. If it decides not to send a message, it checks the following two conditions:

- If v successfully receives a message, then $p_v := (1+\gamma)^{-1} p_v$.
- If v senses an idle channel (i.e., the total noise created by transmissions of other nodes and the adversary is less than ϑ), then $p_v := \min\{(1+\gamma)p_v, \hat{p}\}$, $T_v := \max\{1, T_v - 1\}$.

Afterward, v sets $c_v := c_v + 1$. If $c_v > T_v$ then it does the following – v sets $c_v := 1$ – and if there was no idle step among the past T_v rounds, then $p_v := (1+\gamma)^{-1} p_v$ and $T_v := T_v + 2$.

Given that $\gamma \in O(1/(\log T + \log\log n))$, one can show the following theorem, where n is the number of nodes and $N = \max\{n, T\}$.

Theorem 1 *When running* SADE *for at least* $\Omega((T \log N)/\epsilon + (\log N)^4/(\gamma\epsilon)^2)$ *time steps,* SADE *has a* $2^{-O((1/\epsilon)^{2/(\alpha-2)})}$*-competitive throughput for any* $((1-\epsilon)\vartheta, T)$*-bounded adversary as long as (a) the adversary is uniform and the transmission range of every node contains at least one node or (b) there are at least* $2/\epsilon$ *nodes within the transmission range of every node.*

SADE is an adaption of the MAC protocol described in [6] for Unit Disk Graphs that works in more realistic network scenarios considering physical interference. Variants of SADE have also been shown to be successful in other scenarios:

In [7] a variant called ANTIJAM is presented for a simpler wireless model but a more severe adversary called *reactive* adversary, which is an adversary that can base the jamming decision on the actions of the nodes in the current time step and not just the initial state of the system at the current time step. However, the adversary can only distinguish between the cases that at least one node is transmitting or no node is transmitting, i.e., it cannot determine whether a transmitted message is successfully received.

In [8] another variant called COMAC is presented for a simpler wireless model that can handle coexisting networks. Even if these networks cannot exchange any information and the number

of these networks is unknown, the protocol is shown to be competitive.

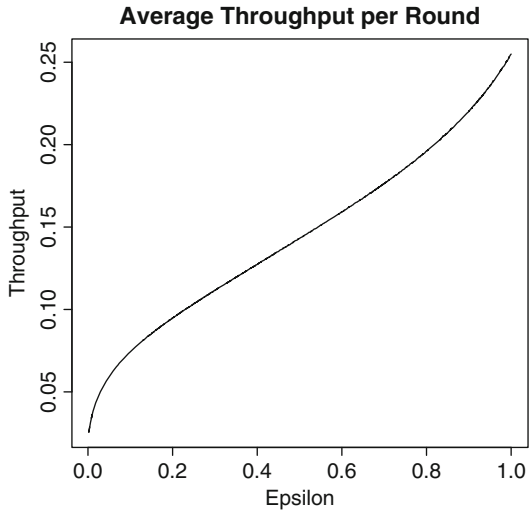
All of these results trace back to a first result in [1] for a very simple wireless model and the case of a single-hop wireless network.

Applications

Practical applications of our results are MAC protocols that are much more robust to outside interference and jamming than the existing protocols like 802.11. In fact, it is known that a much weaker jammer than the ones considered by us already suffices to dramatically reduce the throughput of the standard 802.11 MAC protocol [2].

Open Problems

So far, we have not considered the case of power control and multiple communication channels. Multiple communication channels have been covered in several other works (e.g., [3–5]) but under an adversary that is not as powerful as our adversary. Also, several of our bounds are not tight yet, so it remains to determine tight upper and lower bounds on the competitiveness of MAC protocols within our models.



Jamming-Resistant MAC Protocols for Wireless Networks, Fig. 1 The throughput with respect to varying ϵ

Experimental Results

We conducted various simulations to study the robustness of SADE. When varying ϵ, we found out that the worst-case bound of Theorem 1 may be too pessimistic in many scenarios, and the throughput depends to a lesser extent on the constant ϵ. To be more specific, our results suggest that the throughput depends only polynomially on ϵ (cf. the left-most image of Fig. 1), so more work is needed here.

Problem Definition

K-best enumeration problems are a type of combinatorial enumeration in which, rather than seeking a single best solution, the goal is to find a set of k solutions (for a given parameter value k) that are better than all other possible solutions. Many of these problems involve finding structures in a graph that can be represented by subsets of the graph's edges. In particular, the k shortest paths between two vertices s and t in a weighted network are a set of k distinct paths that are shorter than all other paths, and other problems such as the k smallest spanning trees of a graph or the k minimum weight matchings in a graph are defined in the same way.

Key Results

One of the earliest works in the area of k-best optimization was by Hoffman and Pavley [10] formulating the k-shortest path problem; their paper cites unpublished work by Bock, Kantner, and Hayes on the same problem. Later research by Lawler [12], Gabow [7], and Hamacher and Queyranne [8] described a general approach to k-best optimization, suitable for many of these problems, involving the hierarchical partitioning of the solution space into subproblems. One way

DOI 10.1007/978-1-4939-2864-4

of doing this is to view the optimal solution to a problem as a sequence of edges, and define one subproblem for each edge, consisting of the solutions that first deviate from the optimal solution at that edge. Continuing this subdivision recursively leads to a tree of subproblems, each having a worse solution value than its parent, such that each possible solution is the best solution for exactly one subproblem in the hierarchy. A best-first search of this tree allows the k-best solutions to be found. Alternatively, if both the first and second best solutions can be found, and differ from each other at an edge e, then one can form only two subproblems, one consisting of the solutions that include e and one consisting of the solutions that exclude e. Again, the subdivision continues recursively; each solution (except the global optimum) is the second-best solution for exactly one subproblem, allowing a best-first tree search to find the k-best solutions. An algorithm of Frederickson [6] solves this tree search problem in a number of steps proportional to k times the degree of the tree; each step involves finding the solution (or second-best solution) to a single subproblem.

Probably the most important and heavily studied of the k-best optimization problems is the problem of finding k shortest paths, first formulated by Hoffman and Pavley [10]. In the most basic version of this problem, the paths are allowed to have repeated vertices or edges (unless the input is acyclic, in which case repetitions are impossible). An algorithm of Eppstein [4] solves this version of the problem in the optimal time bound $O(m + n \log n + k)$, where m and n are the numbers of edges and vertices in the given graph; that is, after a preprocessing stage that is dominated by the time to use Dijkstra's algorithm to find a single shortest-path tree, the algorithm takes constant time per path. Eppstein's algorithm follows Hoffman and Pavley in representing a path by its sequence of *deviations*, the edges that do not belong to a tree T of shortest paths to the destination node. The deviation edges that can be reached by a path in T from a given node v are represented as a binary heap (ordered by how much additional length the deviation would cause) and these heaps are used to define a partition of the solution space into subproblems, consisting of the paths that follow a certain sequence of deviations followed by one more deviation from a specified heap. The best path in a subproblem is the one that chooses the deviation at the root of its heap, and the remaining paths can be partitioned into three sub-subproblems, two for the children of the root and one for the paths that use the root deviation but then continue with additional deviations. In this way, Eppstein constructs a tree of subproblems to which Frederickson's tree-searching method can be applied.

In a graph with cycles (or in an undirected graph which, when its edges are converted to directed edges, has many cycles), it is generally preferable to list only the k shortest simple (or loopless) paths, not allowing repetitions within a path. This variation of the k shortest paths problem was formulated by Clarke et al. [3]. Yen's algorithm [14] still remains the one with the best asymptotic time performance, $O(kn(m + n \log n))$; it is based on best-solution partitioning using Dijkstra's algorithm to find the best solution in each subproblem. A more recent algorithm of Hershberger et al. [9] is often faster, but is based on a heuristic that can sometimes fail, causing it to become no faster than Yen's algorithm. In the undirected case, it is possible to find the k shortest simple paths in time $O(k(m + n \log n))$ [11].

Gabow [7] introduced both the problem of finding the k minimum-weight spanning trees of an edge-weighted graph, and the technique of finding a binary hierarchical subdivision of the space of solutions, which he used to solve the problem. In any graph, the best and second-best spanning trees differ only by one edge swap (the removal of one edge from a tree and its replacement by a different edge that reconnects the two subtrees formed by the removal), a property that simplifies the search for a second-best tree as needed for Gabow's partitioning technique. The fastest known algorithms for the k-best spanning trees problem are based on Gabow's partitioning technique, together with dynamic graph data structures that keep track of the best swap in a network as that network undergoes a sequence of edge insertion and deletion operations. To use this technique, one initializes a fully-persistent best-swap data structure (one in

which each update creates a new version of the structure without modifying the existing versions, and in which updates may be applied to any version) and associates its initial version with the root of the subproblem tree. Then, whenever an algorithm for selecting the k best nodes of the subproblem tree generates a new node (a subproblem formed by including or excluding an edge from the allowed solutions) the parent node's version of the data structure is updated (by either increasing or decreasing the weight of the edge to force it to be included or excluded in all solutions) and the updated version of the data structure is associated with the child node. In this way, the data structure can be used to quickly find the second-best solution for each of the subproblems explored by the algorithm. Based on this method, the k-best spanning trees of a graph with n vertices and m edges can be found (in an implicit representation based on sequences of swaps rather than explicitly listing all edges in each tree) in time $O(\mathrm{MST}(m,n) + k \min(n,k)^{1/2})$ where $\mathrm{MST}(m,n)$ denotes the time for finding a single minimum spanning tree (linear time, if randomized algorithms are considered) [5].

After paths and spanning trees, probably the next most commonly studied k-best enumeration problem concerns matchings. The problem of finding the k minimum-weight perfect matchings in an edge-weighted graph was introduced by Murty [13]. A later algorithm by Chegireddy and Hamacher [1] solves the problem in time $O(kn^3)$ (where n is the number of vertices in the graph) using the technique of building a binary partition of the solution space. Other problems whose k-best solutions have been studied include the Chinese postman problem, the traveling salesman problem, spanning arborescences in a directed network, the matroid intersection problem, binary search trees and Huffman coding, chess strategies, integer flows, and network cuts.

For many NP-hard optimization problems, where even finding a single best solution is difficult, an approach that has proven very successful is *parameterized complexity*, in which one finds an integer parameter describing the input instance or its solution that is often much smaller than the input size, and designs algorithms whose running time is a fixed polynomial of the input size multiplied by a non-polynomial function of the parameter value. Chen et al. [2] extend this paradigm to k-best problems, showing that, for instance, many NP-hard k-best problems can be solved in polynomial time per solution for graphs of bounded treewidth.

Applications

The k shortest path problem has many applications. The most obvious of these are in the generation of alternative routes, in problems involving communication networks, transportation networks, or building evacuation planning. In bioinformatics, it has been applied to shortest-path formulations of dynamic programming algorithms for biological sequence alignment and also applied in the reconstruction of metabolic pathways, and reconstruction of gene regulation networks. The problem has been used frequently in natural language and speech processing, where a path in a network may represent a hypothesis for the correct decoding of an utterance or piece of writing. Other applications include motion tracking, genealogy, the design of power, communications, and transportation networks, timing analysis of circuits, and task scheduling.

The problem of finding the k-best spanning trees has been applied to point process intensity estimation, the analysis of metabolic pathways, image segmentation and classification, the reconstruction of pedigrees from genetic data, the parsing of natural-language text, and the analysis of electronic circuits.

Problem Definition

The theory of bidimensionality simultaneously provides subexponential time parameterized algorithms and efficient approximation schemes for a wide range of optimization problems on planar graphs and, more generally, on classes of graphs excluding a fixed graph H as a minor. It turns out that bidimensionality also provides *linear kernels* for a multitude of problems on these classes of graphs. The results stated here unify and generalize a number of kernelization results for problems on planar graphs and graphs of bounded genus; see [2] for a more thorough discussion.

Kernelization

Kernelization is a mathematical framework for the study of polynomial time preprocessing of instances of computationally hard problems. Let $\mathcal{G}$ be the set of all graphs. A *parameterized graph problem* is a subset Π of $\mathcal{G} \times \mathbb{N}$. An *instance* is a pair $(G,k) \in \mathcal{G} \times \mathbb{N}$. The instance (G,k) is a "yes"-instance of Π if $(G,k) \in \Pi$ and a "no"-instance otherwise. A *strict kernel with ck vertices* for a parameterized graph problem Π and constant $c > 0$ is an algorithm $\mathcal{A}$ with the following properties:

- $\mathcal{A}$ takes as input an instance (G,k), runs in polynomial time, and outputs another instance (G',k').
- (G',k') is a "yes"-instance of Π if and only if (G,k) is.
- $|V(G')| \leq c \cdot k$ and $k' \leq k$.

A *linear kernel* for a parameterized graph problem is a strict kernel with ck vertices for some constant c. We remark that our definition of a linear kernel is somewhat simplified compared to the classic definition [8], but that it is essentially equivalent. For a discussion of the definition of a kernel, we refer to the textbook of Cygan et al. [4].

Graph Classes

Bidimensionality theory primarily concerns itself with graph problems where the input graph is restricted to be in a specific *graph class*. A *graph class* $\mathcal{C}$ is simply a subset of the set $\mathcal{G}$ of all graphs. As an example, the set of all planar graphs is a graph class. Another example of a graph class is the set of all *apex* graphs. Here a graph H is *apex* if H contains a vertex v such that deleting v from H leaves a planar graph. Notice that every planar graph is apex.

A graph H is a *minor* of a graph G if H can be obtained from G by deleting vertices, deleting edges, or contracting edges. Here *contracting* the edge $\{u, v\}$ in G means identifying the vertices u and v and removing all self-loops and double edges. If H can be obtained from G just by contracting edges, then H is a *contraction* of G.

A graph class $\mathcal{C}$ is *minor closed* if every minor of a graph in $\mathcal{C}$ is also in $\mathcal{C}$. A graph class $\mathcal{C}$ is *minor-free* if $\mathcal{C}$ is minor closed and there exists a graph $H \notin \mathcal{C}$. A graph class $\mathcal{C}$ is *apex-minor-free* if $\mathcal{C}$ is minor closed and there exists an apex graph $H \notin \mathcal{C}$. Notice that $H \notin \mathcal{C}$ for a minor closed class $\mathcal{C}$ implies that H cannot be a minor of any graph $G \in \mathcal{C}$.

CMSO Logic

CMSO logic stands for *Counting Monadic Second Order* logic, a formal language to describe properties of graphs. A *CMSO-sentence* is a formula ψ with variables for single vertices, vertex sets, single edges and edge sets, existential and universal quantifiers ($\exists$ and $\forall$), logical connectives $\vee$, $\wedge$ and $\neg$, as well as the following operators:

- $v \in S$, where v is a vertex variable and S is a vertex set variable. The operator returns true if the vertex v is in the vertex set S. Similarly, CMSO has an operator $e \in X$ where e is an edge variable and X is an edge set variable.
- $v_1 = v_2$, where v_1 and v_2 are vertex variables. The operator returns true if v_1 and v_2 are the same vertex of G. There is also an operator $e_1 = e_2$ to check equality of two edge variables e_1 and e_2.
- $\mathbf{adj}(v_1, v_2)$ is defined for vertex variables v_1 and v_2 and returns true if v_1 and v_2 are adjacent in G.
- $\mathbf{inc}(v, e)$ is defined for a vertex variable v and edge variable e. $\mathbf{inc}(v, e)$ returns true if the edge e is incident to the vertex v in G, in other words, if v is one of the two endpoints of e.
- $\mathbf{card}_{p,q}(S)$ is defined for every pair of integers p, q, and vertex or edge set variable S. $\mathbf{card}_{p,q}(S)$ returns true if $|S| \equiv q \mod p$. For an example, $\mathbf{card}_{2,1}(S)$ returns true if $|S|$ is odd.

When we quantify a variable, we need to specify whether it is a vertex variable, edge variable, vertex set variable, or edge set variable. To specify that an existentially quantified variable x is a vertex variable we will write $\exists x \in V(G)$. We will use $\forall e \in E(G)$ to universally quantify edge variables and $\exists X \subseteq V(G)$ to existentially quantify vertex set variables. We will always use lower case letters for vertex and edge variables and upper case letters for vertex set and edge set variables.

A graph G on which the formula ψ is true is said to *model* ψ. The notation $G \models \psi$ means that G models ψ. As an example, consider the formula

$$\psi_1 = \forall v \in V(G)\ \forall x \in V(G)\ \forall y \in V(G)\ \forall z \in V(G) : \\ (x = y) \vee (x = z) \vee (y = z) \vee \neg\mathbf{adj}(v, x) \vee \neg\mathbf{adj}(v, y) \vee \neg\mathbf{adj}(v, z)$$

The formula ψ_1 states that for every four (not necessarily distinct) vertices v, x, y, and z, if x, y, and z are distinct, then v is not adjacent to all of $\{x, y, z\}$. In other words, a graph G models ϕ_1 if and only if the degree of every vertex G is at most 2. CMSO can be used to express many

graph properties, such as G having a Hamiltonian cycle, G being 3-colorable, or G being planar.

In CMSO, one can also write formulas where one uses *free variables*. These are variables that are used in the formula but never quantified with an $\exists$ or $\forall$ quantifier. As an example, consider the formula

$$\psi_{DS} = \forall u \in V(G)\, \exists v \in V(G) : (v \in S) \wedge (u = v \vee \mathbf{adj}(u, v))$$

The variable S is a free variable in ψ_{DS} because it is used in the formula, but is never quantified. It does not make sense to ask whether a graph G models ψ_{DS} because when we ask whether the vertex v is in S, the set S is not well defined. However, if the set $S \subseteq V(G)$ is provided together with the graph G, we can evaluate the formula ψ_{DS}. ψ_{DS} will be true for a graph G and set $S \subseteq V(G)$ if, for every vertex $u \in V(G)$, there exists a vertex $v \in V(G)$ such that v is in S and either $u = v$ or u and v are neighbors in G. In other words, the pair (G, S) models ψ_{DS} (written $(G, S) \models \psi_{DS}$) if and only if S is a dominating set in G (i.e., every vertex not in S has a neighbor in S).

CMSO-Optimization Problems

We are now in position to define the parameterized problems for which we will obtain kernelization results. For every CMSO formula ψ with a single free vertex set variable S, we define the following two problems:

ψ-CMSO-Min (Max):

INPUT: *Graph G and integer k.*
QUESTION: *Does there exist a vertex set $S \subseteq V(G)$ such that $(G, S) \models \psi$ and $|S| \leq k$ ($|S| \geq k$ for Max).*

Formally, ψ-CMSO-MIN (MAX) is a parameterized graph problem where the "yes" instances are exactly the pairs (G, k) such that there exists a vertex set S of size at most k (at least k) and $(G, S) \models \psi$. We will use the term *CMSO-optimization problems* to refer to ψ-CMSO-MIN (MAX) for some CMSO formula ψ.

Many well-studied and not so well-studied graph problems are CMSO-optimization problems. Examples include VERTEX COVER, DOMINATING SET, CYCLE PACKING, and the list goes on and on (see [2]). We encourage the interested reader to attempt to formulate the problems mentioned above as CMSO-optimization problems. We will be discussing CMSO-optimization problems *on planar graphs* and on minor-free classes of graphs.

Our results are for problems where the input graph is promised to belong to a certain graph class $\mathcal{C}$. We formalize this by encoding membership in $\mathcal{C}$ in the formula ψ. For an example, ψ_{DS}-CMSO-MIN is the well-studied DOMINATING SET problem. If we want to restrict the problem to planar graphs, we can make a new CMSO logic formula ψ_{planar} such that $G \models \psi_{\text{planar}}$ if and only if G is planar. We can now make a new formula

$$\psi'_{DS} = \psi_{DS} \wedge \psi_{\text{planar}}$$

and consider the problem ψ'_{DS}-CMSO-MIN. Here (G, k) is a "yes" instance if G has a dominating set S of size at most k *and* G is planar. Thus, this problem also forces us to check planarity of G, but this is polynomial time solvable and therefore not an issue with respect to kernelization. In a similar manner, one can restrict any CMSO-optimization problem to a graph class $\mathcal{C}$, as long as there exists a CMSO formula $\psi_{\mathcal{C}}$ such that $G \models \psi_{\mathcal{C}}$ if and only if $G \in \mathcal{C}$. Luckily, such a formula is known to exist for every minor-free class $\mathcal{C}$. We will say that a parameterized problem Π is a problem *on the graph class $\mathcal{C}$* if, for every "yes" instance (G, k) of Π, the graph G is in $\mathcal{C}$.

For any CMSO-MIN problem Π, we have that $(G, k) \in \Pi$ implies that $(G, k') \in \Pi$ for all $k' \geq k$. Similarly, for a CMSO-MAX problem Π, we have that $(G, k) \in \Pi$ implies that $(G, k') \in \Pi$ for all $k' \leq k$. Thus, the notion of "optimality" is well defined for CMSO-optimization problems. For the problem $\Pi = \psi$-CMSO-MIN, we define

$$OPT_{\Pi}(G) = \min\{k \,:\, (G, k) \in \Pi\}.$$

If no k such that $(G,k) \in \Pi$ exists, $OPT_\Pi(G)$ returns $+\infty$. Similarly, for the problem $\Pi = \psi$-CMSO-MAX,

$$OPT_\Pi(G) = \max\{k \ : \ (G,k) \in \Pi\}.$$

If no k such that $(G,k) \in \Pi$ exists, $OPT_\Pi(G)$ returns $-\infty$. We define $SOL_\Pi(G)$ to be a function that given as input a graph G returns a set S of size $OPT_\Pi(G)$ such that $(G,S) \models \psi$ and returns **null** if no such set S exists.

Bidimensionality

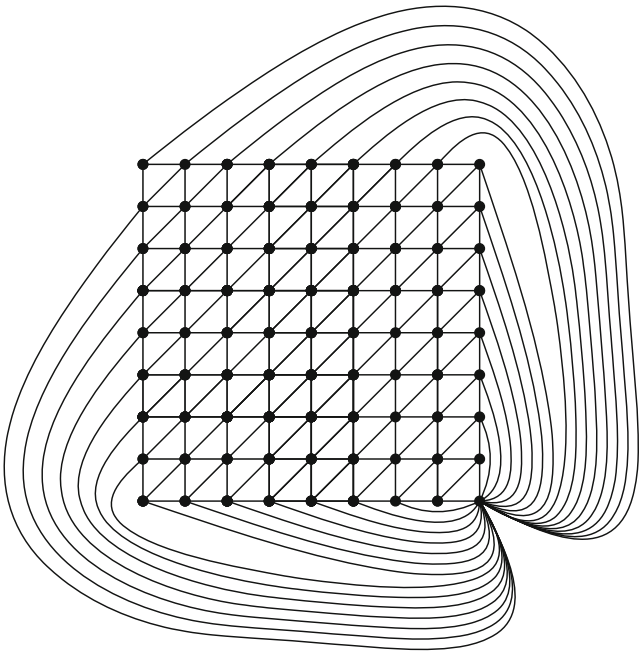
For many problems, it holds that contracting an edge cannot increase the size of the optimal solution. We will say that such problems are contraction closed. Formally, a CMSO-optimization problem Π is *contraction closed* if for any G and $uv \in E(G)$, $OPT_\Pi(G/uv) \leq OPT_\Pi(G)$. If contracting edges, deleting edges, and deleting vertices cannot increase the size of the optimal solution, we say that the problem is *minor closed*.

Informally, a problem is *bidimensional* if it is minor closed and the value of the optimum grows with both dimensions of a grid. In other words, on a $(k \times k)$-grid, the optimum should be approximately quadratic in k. To formally define bidimensional problems, we first need to define the $(k \times k)$-grid $\boxplus_k$, as well as the related graph Γ_k.

For a positive integer k, a $k \times k$ *grid*, denoted by $\boxplus_k$, is a graph with vertex set $\{(x,y) \ : \ x,y \in \{1,\ldots,k\}\}$. Thus, $\boxplus_k$ has exactly k^2 vertices. Two different vertices (x,y) and (x',y') are adjacent if and only if $|x-x'|+|y-y'| = 1$. For an integer $k > 0$, the graph Γ_k is obtained from the grid $\boxplus_k$ by adding in every grid cell the diagonal edge going up and to the right and making the bottom right vertex of the grid adjacent to all border vertices. The graph Γ_9 is shown in Fig. 1.

We are now ready to give the definition of bidimensional problems. A CMSO-optimization problem Π is *contraction-bidimensional* if it is contraction closed, and there exists a constant $c > 0$ such that $OPT_\Pi(\Gamma_k) \geq ck^2$. Similarly, Π is *minor-bidimensional* if it is minor closed, and there exists a constant $c > 0$ such that $OPT_\Pi(\boxplus_k) \geq ck^2$.

As an example, the DOMINATING SET problem is contraction-bidimensional. It is easy to verify that contracting an edge may not increase the size of the smallest dominating set of a graph G and that Γ_k does not have a dominating set of size smaller than $\frac{(k-2)^2}{7}$.



Kernelization, Bidimensionality and Kernels, Fig. 1 The graph Γ_9

Separability

Our kernelization algorithms work by recursively splitting the input instance by small separators. For this to work, the problem has to be somewhat well behaved in the following sense. Whenever a graph is split along a small separator into two independent sub-instances L and R, the size of the optimum solution for the graph $G[L]$ is relatively close to the size of the intersection between L and the optimum solution to the original graph G. We now proceed with a formal definition of what it means for a problem to be well behaved.

For a set $L \subseteq V(G)$, we define $\partial(L)$ to be the set of vertices in L with at least one neighbor outside L. A CMSO-optimization problem Π is *linear separable* if there exists a constant $c \geq 0$ such that for every set $L \subseteq V(G)$, we have

$$|SOL_\Pi(G) \cap L| - c \cdot |\partial(L)| \leq OPT_\Pi(G[L]) \leq |SOL_\Pi(G) \cap L| + c \cdot |\partial(L)|.$$

For a concrete example, we encourage the reader to consider the DOMINATING SET problem and to prove that for DOMINATING SET the inequalities above hold. The crux of the argument is to augment optimal solutions of G and $G[L]$ by adding all vertices in $\partial(L)$ to them.

Key Results

We can now state our main theorem.

Theorem 1 *Let Π be a separable CMSO-optimization problem on the graph class $\mathcal{C}$. Then, if Π is minor-bidimensional and $\mathcal{C}$ is minor-free, or if Π is contraction-bidimensional and $\mathcal{C}$ is apex-minor-free, Π admits a linear kernel.*

The significance of Theorem 1 is that it is, in general, quite easy to formulate graph problems as CMSO-optimization problems and prove that the considered problem is bidimensional and separable. If we are able to do this, Theorem 1 immediately implies that the problem admits a linear kernel on all minor-free graph classes, or on all apex-minor-free graph classes. As an example, the DOMINATING SET problem has been shown to have a linear kernel on planar graphs [1], and the proof of this fact is quite tricky. However, in our examples, we have shown that DOMINATING SET is a CMSO-MIN problem, that it is contraction-bidimensional, and that it is separable. Theorem 1 now implies that DOMINATING SET has a linear kernel not only on planar graphs but on all apex-minor-free classes of graphs! One can go through the motions and use Theorem 1 to give linear kernels for quite a few problems. We refer the reader to [9] for a non-exhaustive list.

We remark that the results stated here are generalizations of results obtained by Bodlaender et al. [2]. Theorem 1 is proved by combining "algebraic reduction rules" (fully developed by Bodlaender et al. [2]) with new graph decomposition theorems (proved in [9]). The definitions here differ slightly from the definitions in the original work [9] and appear here in the way they will appear in the journal version of [9].

Problem Definition

Let r be an integer, let $V = \{v_1, \ldots, v_n\}$ be a set of variables, each taking values -1 (TRUE) and 1 (FALSE), and let Φ be a set of Boolean functions, each involving at most r variables from V. In the problem MAX-r-CSP, we are given a collection $\mathcal{F}$ of m Boolean functions, each $f \in \mathcal{F}$ being a member of Φ and each with a positive integral weight. Our aim is to find a truth assignment that maximizes the total weight of satisfied functions from $\mathcal{F}$. We will denote the maximum by $\mathrm{sat}(\mathcal{F})$.

Let A be the average weight (over all truth assignments) of satisfied functions. Observe that A is a lower bound for $\mathrm{sat}(\mathcal{F})$. In fact, A is a tight lower bound, whenever the family Φ is closed under replacing each variable by its complement [1]. Thus, it is natural to parameterize MAX-r-CSP as follows (AA stands for *Above Average*).

MAX-r-CSP-AA

Instance: A collection $\mathcal{F}$ of m Boolean functions, each $f \in \mathcal{F}$ being a member of Φ, each with a positive integral weight, and a nonnegative integer k.
Parameter: k.
Question: $\mathrm{sat}(\mathcal{F}) \geq A + k$?

If Φ is the set of clauses with at most r literals, then we get a subproblem of MAX-r-CSP-AA, abbreviated MAX-r-SAT-AA, whose unparameterized version is simply MAX-r-SAT. Assign -1 or 1 to each variable in V randomly and uniformly. Since a clause c of an MAX-r-SAT-AA instance can be satisfied with probability $1 - 2^{r_c}$, where r_c is the number of literals in c, we have $A = \sum_{c \in \mathcal{F}} (1 - 2^{r_c})$. Clearly, A is a tight lower bound.

If Φ is the set S of equations $\prod_{i \in I_j} v_i = b_j$, $j = 1, \ldots, m$, where $v_i, b_j \in \{-1, 1\}$, b_js are constants, $|I_j| \leq r$, then we get a subproblem of MAX-r-CSP-AA, abbreviated MAX-r-LIN2-AA, whose unparameterized version is simply MAX-r-LIN2. Assign -1 or 1 to each variable in V randomly and uniformly. Since each equation of $\mathcal{F}$ can be satisfied with probability $1/2$, we have $A = W/2$, where W is the sum of the weights of equations in $\mathcal{F}$. For an assignment $v = v^0$ of values to the variables, let $\mathrm{sat}(S, v^0)$ denote the total weight of equations of S satisfied by the assignment. The difference $\mathrm{sat}(S, v^0) - W/2$ is called the *excess* of x^0. Let $\mathrm{sat}(S)$ be the maximum of $\mathrm{sat}(S, v^0)$ over all possible assignments v^0.

The following notion was introduced in [1]. Let Π and Π' be parameterized problems. A *bikernel* for Π is a polynomial-time algorithm that maps an instance (I,k) of Π to an instance (I',k') of Π' such that (i) $(I,k) \in \Pi$ if and only if $(I',k') \in \Pi'$ and (ii) $k' \leq g(k)$ and $|I'| \leq g(k)$ for some function g. The function $g(k)$ is called the *size* of the bikernel. It is known that a decidable problem is fixed-parameter tractable if and only if it admits a bikernel [1]. However, in general a bikernel can have an exponential size, in which case the bikernel may not be useful as a data reduction. A bikernel is called a *polynomial* bikernel if both $f(k)$ and $g(k)$ are polynomials in k.

When $\Pi = \Pi'$ we say that a bikernel for Π is simply a *kernel* of Π. A great deal of research has been devoted to decide whether a problem admits a polynomial kernel.

The following lemma of Alon et al. [1] shows that polynomial bikernels imply polynomial kernels.

Lemma 1 *Let Π, Π' be a pair of decidable parameterized problems such that the nonparameterized version of Π' is in NP and the nonparameterized version of Π is NP-complete. If there is a bikernelization from Π to Π' producing a bikernel of polynomial size, then Π has a polynomial-size kernel.*

Key Results

Following [2], for a Boolean function f of weight $w(f)$ and on $r(f) \leq r$ Boolean variables $v_{i_1}, \ldots, v_{i_{r(f)}}$, we introduce a polynomial $h_f(v)$, $v = (v_1, \ldots, v_n)$ as follows. Let $S_f \subseteq \{-1,1\}^{r(f)}$ denote the set of all satisfying assignments of f. Then

$$h_f(v) = w(f)2^{r-r(f)} \sum_{(a_1,\ldots,a_{r(f)}) \in S_f} \left[\prod_{j=1}^{r(f)} (1 + v_{i_j} a_j) - 1 \right].$$

Let $h(v) = \sum_{f \in \mathcal{F}} h_f(v)$. It is easy to see (cf. [1]) that the value of $h(v)$ at some v^0 is precisely $2^r(U - A)$, where U is the total weight of the functions satisfied by the truth assignment v^0. Thus, the answer to MAX-r-CSP-AA is YES if and only if there is a truth assignment v^0 such that $h(v^0) \geq k2^r$.

Algebraic simplification of $h(v)$ will lead us the following (Fourier expansion of $h(v)$, cf. [7]):

$$h(v) = \sum_{S \in \mathcal{F}} c_S \prod_{i \in S} v_i, \tag{1}$$

where $\mathcal{F} = \{\emptyset \neq S \subseteq \{1,2,\ldots,n\} : c_S \neq 0, |S| \leq r\}$. Thus, $|\mathcal{F}| \leq n^r$. The sum $\sum_{S \in \mathcal{F}} c_S \prod_{i \in S} v_i$ can be viewed as the excess of an instance of MAX-r-LIN2-AA, and, thus, we can reduce MAX-r-CSP-AA into MAX-r-LIN2-AA in polynomial time (since r is fixed, the algebraic simplification can be done in polynomial time and it does not matter whether the parameter of MAX-r-LIN2-AA is k or $k' = k2^r$). It is proved in [5] that MAX-r-LIN2-AA has a kernel with $O(k^2)$ variables and equations. This kernel is a bikernel from MAX-r-CSP-AA to MAX-r-LIN2-AA. Thus, by Lemma 1, we obtain the following theorem of Alon et al. [1].

Theorem 1 MAX-r-CSP-AA *admits a polynomial-size kernel.*

Applying a reduction from MAX-r-LIN2-AA to MAX-r-SAT-AA in which each monomial in (1) is replaced by 2^{r-1} clauses, Alon et al. [1] obtained the following:

Theorem 2 MAX-r-SAT-AA *admits a kernel with $O(k^2)$ clauses and variables.*

It is possible to improve this theorem with respect to the number of variables in the kernel. The following result was first obtained by Kim and Williams [6] (see also [3]).

Theorem 3 MAX-r-SAT-AA *admits a kernel with $O(k)$ variables.*

Crowston et al. [4] studied the following natural question: How parameterized complexity of MAX-r-SAT-AA changes when r is no longer

a constant, but a function $r(n)$ of n. They proved that MAX-$r(n)$-SAT-AA is para-NP-complete for any $r(n) \geq \lceil \log n \rceil$. They also proved that assuming the exponential time hypothesis, MAX-$r(n)$-SAT-AA is not even in XP for any integral $r(n) \geq \log\log n + \phi(n)$, where $\phi(n)$ is any real-valued unbounded strictly increasing computable function. This lower bound on $r(n)$ cannot be decreased much further as they proved that MAX-$r(n)$-SAT-AA is (i) in XP for any $r(n) \leq \log\log n - \log\log\log n$ and (ii) fixed-parameter tractable for any $r(n) \leq \log\log n - \log\log\log n - \phi(n)$, where $\phi(n)$ is any real-valued unbounded strictly increasing computable function. The proofs use some results on MAXLIN2-AA.

2009; Bodlaender, Downey, Fellows, Hermelin

Problem Definition

Research on kernelization is motivated in two ways. First, when solving a hard (e.g., NP-hard) problem in practice, a common approach is to first *preprocess* the instance at hand before running more time-consuming methods (like integer linear programming, branch and bound, etc.). The following is a natural question. Suppose we use polynomial time for this preprocessing phase: what can be predicted of the size of the instance resulting from preprocessing? The theory of kernelization gives us such predictions. A second motivation comes from the fact that a decidable parameterized problem belongs to the class FPT (i.e., is *fixed parameter tractable*,) if and only if the problem has kernelization algorithm.

A parameterized problem is a subset of $\Sigma^* \times \mathbf{N}$, for some finite set Σ. A *kernelization algorithm* (or, in short *kernel*) for a parameterized problem $Q \subseteq \Sigma^* \times \mathbf{N}$ is an algorithm A that receives as input a pair $(x,k) \in \Sigma^* \times \mathbf{N}$ and outputs a pair $(x',k') = A(x,k)$, such that:

- A uses time, polynomial in $|x| + k$.
- $(x,k) \in Q$, if and only if $(x',k') \in Q$.
- There are functions f, g, such that $|x'| \leq f(k)$ and $k' \leq g(k)$.

In the definition above, f and g give an upper bound on the size, respectively the parameter of the reduced instance. Many well-studied problems have kernels with $k' \leq k$. The running time of an exact algorithm that starts with a kernelization step usually is exponential in the size of the kernel (i.e., $f(k)$), and thus small kernels are desirable. A kernel is said to be *polynomial*, if f and g are bounded by a polynomial. Many well-known parameterized problems have a polynomial kernel, but there are also many for which such a polynomial kernel is not known.

Recent techniques allow us to show, under a complexity theoretic assumption, for some parameterized problems that they do not have a polynomial kernel. The central notion is that of *compositionality*; with the help of transformations and cross compositions, a larger set of problems can be handled.

Key Results

Compositionality

The basic building block of showing that problems do not have a polynomial kernel (assuming $NP \not\subseteq coNP/poly$) is the notion of compositionality. It comes in two types: or-composition and and-composition.

Definition 1 An *or-composition* for a parameterized problem $Q \subseteq \Sigma^* \times \mathbf{N}$ is an algorithm that:

- Receives as input a sequence of instances for Q with the same parameter $(s_1, k), (s_2, k), \ldots, (s_r, k)$
- Uses time, polynomial in $k + \sum_{i=1}^{r} |s_i|$
- Outputs one instance for Q, $(s', k') \in \Sigma^* \times \mathbf{N}$, such that:

  1. $(s', k') \in Q$, if and only if there is an i, $1 \leq i \leq r$, with $(s_i, k) \in Q$.
  2. k' is bounded by a polynomial in k.

The notion of *and-composition* is defined similarly, with the only difference that condition (1) above is replaced by

$(s', k') \in Q$, if and only if for all i, $1 \leq i \leq r$: $(s_i, k) \in Q$.

We define the *classic variant* of a parameterized problem $Q \subseteq \Sigma^* \times \mathbf{N}$ as the decision problem, denoted Q^c where we assume that the parameter is encoded in unary, or, equivalently, an instance (s, k) is assumed to have size $|s| + k$.

Combining results of three papers gives the following results.

Theorem 1 *Let $Q \subseteq \Sigma^* \times \mathbf{N}$ be a parameterized problem. Suppose that the classic variant of Q, Q^c is NP-hard. Assume that $NP \not\subseteq coNP/poly$.*

1. *(Bodlaender et al. [3], Fortnow and Santhanam [12]) If Q has an or-composition, then Q has no polynomial kernel.*
2. *(Bodlaender et al. [3], Drucker [11]) If Q has an and-composition, then Q has no polynomial kernel.*

The condition that $NP \not\subseteq coNP/poly$ is equivalent to $coNP \not\subseteq NP/poly$; if it does not hold, the polynomial time hierarchy collapses to the third level [19].

For many parameterized problems, one can establish (sometimes trivially, and sometimes with quite involved proofs) that they are or-compositional or and-compositional. Taking the disjoint union of instances often gives a trivial composition. A simple example is the LONG PATH problem; it gets as input a pair (G, k) with G an undirected graph and asks whether G has a simple path of length at least k.

Lemma 1 *If $NP \not\subseteq coNP/poly$, then* LONG PATH *has no kernel polynomial in k.*

Proof LONG PATH is well known to be NP-complete. Mapping $(G_1, k), \ldots, (G_r, k)$ to the pair (H, k) with H the disjoint union of $G_1, \ldots, G_r$ is an or-composition. So, the result follows directly as a corollary of Theorem 1. □

The TREEWIDTH problem gets as input a pair (G, k) and asks whether the treewidth of G is most k. As it is NP-hard to decide if the treewidth of a given graph G is at most a given

number k [1] and the treewidth of a graph is the maximum of its connected components, taking the disjoint union gives an and-composition for the TREEWIDTH problem and shows that TREEWIDTH has no polynomial kernel unless $NP \subseteq coNP/poly$. Similar proofs work for many more problems. Many problems can be seen to be and- or or-compositional and thus have no polynomial kernels under the assumption that $NP \not\subseteq coNP/poly$. See, e.g., [3,5,9,17].

Transformations

Several researchers observed independently (see [2,5,9]) that transformations can be used to show results for additional problems. The formalization is due to Bodlaender et al. [5].

Definition 2 A *polynomial parameter transformation* (*ppt*) from parameterized problem $Q \subseteq \Sigma^* \times \mathbf{N}$ to parameterized problem $R \subseteq \Sigma^* \times \mathbf{N}$ is an algorithm A that:

- Has as input an instance of Q, $(s,k) \in \Sigma^* \times \mathbf{N}$.
- Outputs an instance of R, $(s',k') \in \Sigma^* \times \mathbf{N}$.
- $(s,k) \in Q$ if and only if $(s',k') \in R$.
- A uses time polynomial in $|s| + k$.
- k' is bounded by a polynomial in k.

The differences with the well-known polynomial time or Karp reductions from NP-completeness theory are small: note in particular that it is required that the new value of the parameter is polynomially bounded in the old value of the parameter. The following theorem follows quite easily.

Theorem 2 (See [5,6]) *Let R have a polynomial kernel. If there is a ppt from Q to R, and a polynomial time reduction from R to the classic variant of Q, then Q has a polynomial kernel.*

This implies that if we have a ppt from Q to R, Q^c is NP-hard, $R^c \in NP$, then when Q has no polynomial kernel, R has no polynomial kernel.

Cross Composition

Bodlaender et al. [4] introduced the concept of *cross composition*. It gives a more powerful mechanism to show that some problems have no polynomial kernel, assuming $NP \not\subseteq coNP/poly$. We need first the definition of a polynomial equivalence relation.

Definition 3 A *polynomial equivalence relation* is an equivalence relation on Σ^* that can be decided in polynomial time and has for each n, a polynomial number of equivalence classes that contain strings of length at most n.

A typical example may be that strings represent graphs and two graphs are equivalent if and only if they have the same number of vertices and edges.

Definition 4 Let L be a language, R a polynomial equivalence relation, and Q a parameterized problem. An *OR cross composition* of L to Q (w.r.t. R) is an algorithm that:

- Gets as input a sequence of instances $s_1, \ldots, s_r$ of L that belong to the same equivalence class of R.
- Uses time, polynomial in $\sum_{i=1}^{r} |s_i|$.
- Outputs an instance (s',k) of Q.
- k is polynomial in $\max |s_i| + \log k$.
- $(s',k) \in Q$ if and only if there is an i with $s_i \in L$.

The definition for an AND cross composition is similar; the last condition is replaced by

$(s',k) \in Q$ if and only if for all i with $s_i \in L$.

Theorem 3 (Bodlaender et al. [4]) *If we have an OR cross composition, or an AND cross composition from an NP-hard language L into a parameterized problem Q, then Q does not have a polynomial kernel, unless $NP \subseteq coNP/poly$.*

The main differences with or-composition and and-composition are we do not need to start with a collection of instances from Q, but can use a collection of instances of any NP-hard language; the bound on the new value of k usually allows us to restrict to collections of at most 2^k instances, and with the polynomial equivalence relation, we can make assumptions on "similarities" between these instances.

For examples of OR cross compositions, and of AND cross compositions, see, e.g., [4, 8, 13, 17].

Other Models and Improvements

Different models of compressibility and stronger versions of the lower bound techniques have been studied, including more general models of compressibility (see [11] and [7]), the use of co-nondeterministic composition [18], weak composition [15], Turing kernelization [16], and a different measure for compressibility based on witness size of problems in NP [14].

Problems Without Kernels

Many parameterized problems are known to be hard for the complexity class $W[1]$. As decidable problems are known to have a kernel, if and only if they are fixed parameter tractable, it follows that $W[1]$-hard problems do not have a kernel, unless $W[1] = FPT$ (which would imply that the exponential time hypothesis does not hold). See, e.g., [10].

Problem Definition

Kernelization is the study of the power of polynomial-time instance simplification and preprocessing and relates more generally to questions of compact information representation. Given an instance x of a decision problem $\mathcal{P}$, with an associated *parameter* k (e.g., a bound on the solution size in x), a *polynomial kernelization* is an algorithm which in polynomial time produces an instance x' of $\mathcal{P}$, with parameter k', such that $x \in \mathcal{P}$ if and only if $x' \in \mathcal{P}$ and such that both $|x'|$ and k' are bounded by $p(k)$ for some $p(k) = \text{poly}(k)$. A *polynomial compression* is the variant where the output x' is an instance of a new problem $\mathcal{P}'$ (and may not have any associated parameter).

Matroid theory provides the tools for a very powerful framework for kernelization and more general information-preserving sparsification. As an example application, consider the following question. You are given a graph $G = (V, E)$ and two sets $S, T \subseteq V$ of terminal vertices, where potentially $|V| \gg |S|, |T|$. The task is to reduce G to a smaller graph $G' = (V', E')$, with $S, T \subseteq V'$ and $|V'|$ bounded by a function of $|S| + |T|$, such that for any sets $A \subseteq S$, $B \subseteq T$, the minimum (A, B)-cut in G' equals that in G. Here, all cuts are vertex cuts and may overlap A and B (i.e., the terminal vertices are also deletable). It is difficult to see how to do this without using both exponential time in $|S| + |T|$ (due to the large number of choices of A and B) and an exponential dependency of $|V'|$ on $|S|$ and $|T|$ (due to potentially having to include one min cut for every choice of A and B), yet using the appropriate tools from matroid theory, we can in polynomial time produce such a graph G' with $|V'| = O(|S| \cdot |T| \cdot \min(|S|, |T|))$. Call (G, S, T) a *terminal cut system*; we will revisit this example later.

The main power of the framework comes from two sources. The first is a class of matroids known as *gammoids*, which enable the representation of graph-cut properties as linear independence of vectors; the second is a tool known as the *representative sets lemma* (due to Lovász [4] via Marx [5]) applied to such a representation. To describe these closer, we need to review several definitions.

Background on Matroids

We provide only the bare essential definitions; for more, see Oxley [6]. Also see the relevant chapters of Schrijver [8] for a more computational perspective and Marx [5] for a concise, streamlined, and self-contained presentation of the issues most relevant to our concerns. For $s \in \mathbb{N}$, we let $[s]$ denote the set $\{1, \ldots, s\}$.

A *matroid* is a pair $M = (V, \mathcal{I})$ where V is a *ground set* and $\mathcal{I} \subseteq 2^V$ a collection of *independent sets*, subject to three axioms:

1. $\emptyset \in \mathcal{I}$.
2. If $B \in \mathcal{I}$ and $A \subseteq B$, then $A \in \mathcal{I}$.
3. If $A, B \in \mathcal{I}$ and $|A| < |B|$, then there exists some $b \in (B \setminus A)$ such that $A \cup \{b\} \in \mathcal{I}$.

All matroids we deal with will be finite (i.e., have finite ground sets). A set $S \subseteq V$ is *independent* in M if and only if $S \in \mathcal{I}$. A *basis* is a maximal independent set in M; observe that all bases of a matroid have the same cardinality. The *rank* of a set $X \subseteq V$ is the maximum cardinality of an independent set $S \subseteq X$; again, observe that this is well defined.

Linearly Represented Matroids

A prime example of a matroid is a *linear matroid*. Let A be a matrix over some field $\mathbb{F}$, and let V index the column set of A. Let $\mathcal{I}$ contain exactly those sets of columns of A that are linearly independent. Then $M = (V, \mathcal{I})$ defines a matroid, denoted $M(A)$, known as a linear matroid. For an arbitrary matroid M, if M is isomorphic to a linear matroid $M(A)$ (over a field $\mathbb{F}$), then M is *representable* (*over* $\mathbb{F}$), and the matrix A *represents* M. Observe that this is a compact representation, as $|\mathcal{I}|$ would in the general case be exponentially large, while the matrix A would normally have a coding size polynomial in $|V|$. In general, more powerful tools are available for linearly represented matroids than for arbitrary matroids (see, e.g., the MATROID MATCHING problem [8]). In particular, this holds for the representative sets lemma (see below).

Gammoids

The class of matroids central to our concern is the class of *gammoids*, first defined by Perfect [7]. Let $G = (V, E)$ be a (possibly directed) graph, $S \subseteq V$ a set of *source vertices*, and $T \subseteq V$ a set of *sink vertices* (where S and T may overlap). Let $X \subseteq T$ be independent if and only if there exists a collection of $|X|$ pairwise vertex-disjoint directed paths in G, each path starting in S and ending in X; we allow paths to have length zero (e.g., we allow a path from a vertex $x \in S \cap X$ to itself). This notion of independence defines a matroid on the ground set T, referred to as the *gammoid* defined by G, S, and T. By Menger's theorem, the rank of a set $X \subseteq T$ equals the cardinality of an (S, X)-min cut in G.

Gammoids are representable over any sufficiently large field [6], although only randomized procedures for computing a representation are known. An explicit randomized procedure was given in [2], computing a representation of the gammoid (G, S, T) in space (essentially) cubic in $|S| + |T|$. Hence, gammoids imply a polynomial-sized representation of terminal cut systems, as defined in the introduction. This has implications in kernelization [2], though it is not on its own the most useful form, since it is not a representation in terms of graphs.

Representative Sets

Let $M = (V, \mathcal{I})$ be a matroid, and X and Y independent sets in M. We say that Y *extends* X if $X \cup Y$ is independent and $X \cap Y = \emptyset$. The *representative sets lemma* states the following.

Lemma 1 ([4,5]) *Let $M = (V, \mathcal{I})$ be a linearly represented matroid of rank $r + s$, and let $\mathcal{S} = \{S_1, \ldots, S_m\}$ be a collection of independent sets, each of size s. In polynomial time, we can compute a set $\mathcal{S}^* \subseteq \mathcal{S}$ such that $|\mathcal{S}^*| \leq \binom{r+s}{s}$, and for any independent set X, there is a set $S \in \mathcal{S}$ that extends X if and only if there is a set $S' \in \mathcal{S}^*$ that extends X.*

We refer to $\mathcal{S}^*$ as a *representative set* for $\mathcal{S}$ in M. This result is due to Lovász [4], made algorithmic by Marx [5]; recently, Fomin et al. [1] improved the running time and gave algorithmic applications of the result. The power of the lemma is extended by several tools which construct new linearly represented matroids from existing ones; see Marx [5]. For a particularly useful case, for each $i \in [s]$ let $M_i = (V_i, \mathcal{I}_i)$ be a matroid, where each set V_i is a new copy of an original ground set V. Given a representation of these matroids over the same field $\mathbb{F}$, we can form a represented matroid $M = (V_1 \cup \ldots \cup V_s, \mathcal{I}_1 \times \ldots \times \mathcal{I}_s)$ as a *direct sum* of these matroids, where an independent set X in M is the union of an independent set X_i in M_i for each i. For an element $v \in V$, let $v(i)$ denote the copy of v in V_i. Then the set $\{v(1), \ldots, v(s)\}$ extends $X = X_1 \cup \ldots \cup X_s$ if and only if $\{v(i)\}$ extends X_i for each $i \in [s]$. In other words, we have constructed an *AND operation* for the notion of an extending set.

Closest Sets and Gammoids

We need one last piece of terminology. For a (possibly directed) graph $G = (V, E)$ and sets $A, X \subseteq V$, let $R_G(A, X)$ be the set of vertices reachable from A in $G \setminus X$. The set X is *closest to* A if there is no set X' such that $|X'| \leq |X|$ and X' separates X from A, i.e., $X \cap R_G(A, X') = \emptyset$. This is equivalent to X being the unique minimum (A, X)-vertex cut. For every pair of sets $A, B \subseteq V$, there is a unique minimum (A, B)-vertex cut closest to A, which can be computed in polynomial time. Finally, for sets S and X, the set X *pushed towards* S is the unique minimum (S, X)-vertex cut closest to S; this operation is well defined and has no effect if X is already closest to S. The following is central to our applications.

Lemma 2 *Let M be a gammoid defined from a graph $G = (V, E)$ and source set S. Let X be independent in M, and let X' be X pushed towards S. For any $v \in V$, the set $\{v\}$ extends X if and only if $v \in R_G(S, X')$.*

Key Results

The most powerful version of the terminal cut system result is the following.

Theorem 1 *Let $G = (V, E)$ be a (possibly directed) graph, and $X \subseteq V$ a set of vertices. In randomized polynomial time, we can find a set $Z \subseteq V$ of $|Z| = O(|X|^3)$ vertices such that for every partition $X = A \cup B \cup C \cup D$, the set Z contains a minimum (A, B)-vertex cut in the graph $G \setminus D$.*

There is also a variant for cutting into more than two parts, as follows.

Theorem 2 *Let $G = (V, E)$ be an undirected graph, and $X \subseteq V$ a set of vertices. In randomized polynomial time, we can find a set $Z \subseteq V$ of $|Z| = O(|X|^{s+1})$ vertices such that for every partition of X into at most s parts, the set Z contains a minimum solution to the corresponding multiway cut problem.*

We also have the following further kernelization results; see [3] for problem statements.

Theorem 3 *The following problems admit randomized polynomial kernels parameterized by the solution size*: ALMOST 2-SAT, VERTEX MULTICUT *with a constant number of cut requests, and* GROUP FEEDBACK VERTEX SET *with a constant-sized group.*

Applications

We now review the strategy behind kernelization usage of the representative sets lemma.

Representative Sets: Direct Usage

There have been various types of applications of the representative sets lemma in kernelization, from the more direct to the more subtle. We briefly review one more direct and one indirect. The most direct one is for reducing *constraint systems*. We illustrate with the DIGRAPH PAIR CUT problem (which is closely related to a central problem in kernelization [3]). Let $G = (V, E)$ be a digraph, with a source vertex $s \in V$, and let $\mathcal{P} \subseteq V^2$ be a set of pairs. The task is to find a set X of at most k vertices (with $s \notin X$) such that $R_G(s, X)$ does not contain any complete pair from $\mathcal{P}$. We show that it suffices to keep $O(k^2)$ of the pairs $\mathcal{P}$. For this, replace s by a set S of $k + 1$ copies of s, and let M be the gammoid of (G, S, V). By Lemma 2, if X is closest to S and $|X| \leq k$, then $\{u, v\} \subseteq R_G(s, X)$ if and only if both $\{u\}$ and $\{v\}$ extend X in M. Hence, using the direct sum construction, we can construct a representative set $\mathcal{P}^* \subseteq \mathcal{P}$ with $|\mathcal{P}^*| = O(k^2)$ such that for any set X closest to S, the set $R_G(s, X)$ contains a pair $\{u, v\} \in \mathcal{P}$ if and only if it contains a pair $\{u', v'\} \in \mathcal{P}^*$. Furthermore, for an arbitrary set X, pushing X towards S yields a set X' that can only be an improvement on X (i.e., the set of pairs in $R_G(s, X)$ shrinks); hence for any set X with $|X| \leq k$, either pushing X towards S yields a solution to the problem, or there is a pair in $\mathcal{P}^*$ witnessing that X is not a solution. Thus, the set $\mathcal{P}^*$ may be used to replace $\mathcal{P}$, taking the first step towards a kernel for the problem.

Indirect Usage

For more advanced applications, we "force" the lemma to reveal some set Z of special vertices in G, as follows. Let M be a linearly represented matroid, and let $\mathcal{S} = \{S(v) : v \in V\}$ be a collection of subsets of M of bounded size. Assume that we have shown that for every $z \in Z$, there is a carefully chosen set $X(z)$, such that $S(v)$ extends $X(z)$ if and only if $v = z$. Then, necessarily, the representative set $\mathcal{S}^*$ for $\mathcal{S}$ must contain $S(z)$ for every $z \in Z$, by letting $X = X(z)$ in the statement of the lemma. Furthermore, we do not need to provide the set $X(z)$ ahead of time, since the (possibly non-constructive) *existence* of such a set $X(z)$ is sufficient to force $S(z) \in \mathcal{S}^*$. Hence, the set $V^* = \{v \in V : S(v) \in \mathcal{S}^*\}$ must contain Z, among a polynomially bounded number of other vertices. The critical challenge, of course, is to construct the matroid M and sets $S(v)$ and $X(z)$ such that $S(z)$ indeed extends $X(z)$, while $S(v)$ fails to extend $X(z)$ for every $v \neq z$.

We illustrate the application to reducing terminal cut systems. Let $G = (V, E)$ be an undirected graph (the directed construction is similar), with $S, T \subseteq V$, and define a set of vertices Z where $z \in Z$ if and only if there are sets $A \subseteq S, B \subseteq T$ such that every minimum (A, B)-vertex cut contains z. We wish to learn Z. Let a *sink-only copy* of a vertex $v \in V$ be a copy v' of v with all edges oriented towards v'. Then the following follows from Lemma 2 and the definition of closest sets.

Lemma 3 *Let $A, B \subseteq V$, and let X be a minimum (A, B)-vertex cut. Then a vertex $v \in V$ is a member of every minimum (A, B)-vertex cut if and only if $\{v'\}$ extends X in both the gammoid (G, A, V) and the gammoid (G, B, V).*

Via a minor modification, we can replace the former gammoid by the gammoid (G, S, V) and the latter by (G, T, V) (for appropriate adjustments to the set X); we can then compute a set V^* of $O(|S| \cdot |T| \cdot k)$ vertices (where k is the size of an (S, T)-min cut) which contains Z. From this, we may compute the sought-after smaller graph G', by iteratively bypassing a single vertex $v \in V \setminus (S \cup T \cup V^*)$ and recomputing V^*, until $V^* \cup S \cup T = V$; observe that bypassing v does not change the size of any (A, B)-min cut. Theorem 1 follows by considering a modification of the graph G, and Theorem 2 follows by a generalization of the above, pushing into s different directions.

Further Applications

A polynomial kernel for MULTIWAY CUT (in the variants with only s terminals or with deletable terminals) essentially follows from the above, but the further kernelization applications in Theorem 3 require a few more steps. However, they follow a common pattern: First, we find an approximate solution X of size poly(k) to "bootstrap" the process; second, we use X to transform the problem into a more manageable form (e.g., for ALMOST 2-SAT, this manageable form is DIGRAPH PAIR CUT); and lastly, we use the above methods to kernelize the resulting problem. This pattern covers the problems listed in Theorem 3.

Finally, the above results have some implications beyond kernelization. In particular, the existence of the smaller graph G' computed for terminal cut systems, and correspondingly an implementation of a gammoid as a graph with poly$(|S| + |T|)$ vertices, was an open problem, solved in [3].

Problem Definition

In the problem MAX CUT, we are given a graph G with n vertices and m edges, and asked to find a bipartite subgraph of G with the maximum number of edges.

In 1973, Edwards [5] proved that if G is connected, then G contains a bipartite subgraph with at least $\frac{m}{2} + \frac{n-1}{4}$ edges, proving a conjecture of Erdős. This lower bound on the size of a bipartite subgraph is known as the *Edwards-Erdős bound*. The bound is tight – for example, it is an upper bound when G is a clique with odd number of vertices. Thus, it is natural to consider parameterized MAX CUT above this bound, as follows (AEE stands for *Above Edwards-Erdős*).

MAX CUT AEE

Instance: A connected graph G with n vertices and m edges, and a nonnegative integer k.
Parameter: k.
Question: Does G have a bipartite subgraph with at least $\frac{m}{2} + \frac{n-1}{4} + k$ edges?

Mahajan and Raman [6], in their first paper on above-guarantee parameterizations, asked whether this problem is fixed-parameter tractable. As such, the problem was one of the first open problems in above-guarantee parameterizations.

λ-Extendibility and the Poljak-Turzík Bound

In 1982, Poljak and Turzík [8] investigated extending the Edwards-Erdős bound to cases when the desired subgraph is something other than bipartite. To this end, they introduced the notion of λ-extendibility, which generalizes the notion of "bipartiteness." We will define the slightly stronger notion of *strong* λ-extendibility, introduced in [7], as later results use this stronger notion.

Recall that a *block* of a graph G is a maximal 2-connected subgraph of G. The blocks of a graph form a partition of its edges, and a vertex that appears in two or more blocks is a cut-vertex of the graph.

Definition 1 For a family of graphs Π and $0 \leq \lambda \leq 1$, we say Π is *s*trongly λ-extendible if the following conditions are satisfied:

1. If G is connected and $|G| = 1$ or 2, then $G \in \Pi$.
2. G is in Π if and only if each of its blocks is in Π.
3. For any real-valued positive weight function w on the edges of G, if $X \subseteq V(G)$ is such that $G[X]$ is connected and $G[X], G - X \in \Pi$, then G has a subgraph $H \in \Pi$ that uses all the edges of $G[X]$, all the edges of $G - X$, and at least a fraction λ (by weight) of the edges between X and $V(G) \setminus X$.

The definition of λ-extendibility given in [8] is the same as the above, except that the third condition is only required when $|X| = 2$. Clearly strong λ-extendibility implies λ-extendibility; it is an open question whether the converse holds.

The property of being bipartite is strongly λ-extendible for $\lambda = 1/2$. Other strongly λ-extendible properties include being acyclic for directed graphs ($\lambda = 1/2$) and being r-colorable ($\lambda = 1/r$).

Poljak and Turzík [8] extended Edwards' result by showing that for any connected graph G with n vertices and m edges, and any λ-extendible property Π, G contains a subgraph in Π with at least $\lambda m + \frac{1-\lambda}{2}(n-1)$ edges.

Thus, for any λ-extendible property Π, we can consider the following variation of MAX CUT AEE, for any λ-extendible Π (APT stands for *Above Poljak-Turzík*).

Π-SUBGRAPH APT

Instance: A connected graph G with n vertices and m edges, and a nonnegative integer k.
Parameter: k.
Question: Does G have a subgraph in Π with at least $\lambda m + \frac{1-\lambda}{2}(n-1) + k$ edges?

Key Results

We sketch a proof of the polynomial kernel result for MAX CUT AEE, first shown in [2] (although the method described here is slightly different to that in [2]).

For a connected graph G with n vertices and m edges, let $\beta(G)$ denote the maximum number of edges of a bipartite subgraph of G, let $\gamma(G) = \frac{m}{2} + \frac{n-1}{4}$, and let $\varepsilon(G) = \beta(G) - \gamma(G)$. Thus, for an instance (G, k), our aim is to determine whether $\varepsilon(G) \geq k$.

Now consider a connected graph G with a set X of three vertices such that $G' = G - X$ is connected and $G[X] = P_3$, the path with two edges. Note that $G[X]$ is bipartite. Let H' be a subgraph of G' with $\beta(G')$ edges. As bipartiteness is a $1/2$-extendible property, we can create a bipartite subgraph H of G using the edges of H', the edges of $G[X]$, and at least half of the edges between X and $G - X$. It follows that $\beta(G) \geq \beta(G') + \frac{|E(X,V(G)\setminus X)|}{2} + 2$. As $\gamma(G) = \gamma(G') + \frac{|E(X,V(G)\setminus X)|+2}{2} + \frac{3}{4}$, we have that $\varepsilon(G) = \beta(G) - \gamma(G) \geq \beta(G') - \gamma(G') + 2 - \frac{2}{2} - \frac{3}{4} = \varepsilon(G') + \frac{1}{4}$.

Consider a reduction rule in which, if there exists a set X as described above, we delete X from the graph. If we were able to apply such a reduction rule $4k$ times on a graph G, we would end up with a reduced graph G' such that G' is connected and $\varepsilon(G) \geq \varepsilon(G') + \frac{4k}{4} \geq 0 + k$, and therefore we would know that (G, k) is a YES-instance. Of course there may be many graphs for which such a set X cannot be found. However, we can adapt this idea as follows. Given a connected graph G, we recursively calculate a set of vertices $S(G)$ and a rational number $t(G)$ as follows:

- If G is a clique or G is empty, then set $S(G) = \emptyset$ and $t(G) = 0$.
- If G contains a set X such that $|X| = 3$, $G' = G - X$ is connected and $G[X] = P_3$, then set $S(G) = S(G') \cup X$ and set $t(G) = t(G') + \frac{1}{4}$.
- If G contains a cut-vertex v, then there exist non-empty sets of vertices X, Y such that $X \cap Y = \{v\}$, $G[X]$ and $G[Y]$ are connected, and all edges of G are in $G[X]$ or $G[Y]$. Then set $S(G) = S(G[X]) \cup S(G[Y])$ and set $t(G) = t(G[X]) + t(G[Y])$.

It can be shown that for a connected graph G, one of these cases will always hold, and so $S(G)$ and $t(G)$ are well defined. In the first case, we have that $\varepsilon(G) \geq 0$ by the Edwards-Erdős bound. In the second case, we have already shown that $\varepsilon(G) \geq \varepsilon(G') + \frac{1}{4}$. In the third case, we have that $\varepsilon(G) = \varepsilon(G[X]) + \varepsilon(G[Y])$ (note that the union of a bipartite subgraph of $G[X]$ and a bipartite subgraph of $G[Y]$ is a bipartite subgraph of G). It follows that $\varepsilon(G) \geq t(G)$. Note also that $|S(G)| \leq 12t(G)$. If we remove $S(G)$ from G, the resulting graph can be built by joining disjoint graphs at a single vertex, using only cliques as the initial graphs. Thus, $G - S(G)$ has the property

that each of its blocks is a clique. We call such a graph a *forest of cliques*.

We therefore get the following lemma.

Lemma 1 ([2]) *Given a connected graph G with n vertices and m edges, and an integer k, we can in polynomial time either decide that (G, k) is a* YES*-instance of* MAX CUT AEE*, or find a set S of at most $12k$ vertices such that $G - S$ is a forest of cliques.*

By guessing a partition of S and then using a dynamic programming algorithm based on the structure of $G - S$, we get a fixed-parameter algorithm.

Theorem 1 ([2]) MAX CUT AEE *can be solved in time $2^{O(k)} \cdot n^4$.*

Using the structure of $G - S$ and the fact that $|S| \leq 12k$, it is possible (using reduction rules) to show first that the number of blocks in $G - S$ must be bounded for any NO-instance, and then that the size of each block must be bounded (see [2]).

Thus, we get a polynomial kernel for MAX CUT AEE.

Theorem 2 ([2]) MAX CUT AEE *admits a kernel with $O(k^5)$ vertices.*

Crowston et al. [3] were later able to improve this to a kernel with $O(k^3)$ vertices.

Extensions to Π-SUBGRAPH APT

A similar approach can be used to show polynomial kernels for Π-SUBGRAPH APT, for other $1/2$-extendible properties. In particular, the property of being an acyclic directed graph is $1/2$-extendible, and therefore every directed graph with n vertices and m arcs has an acyclic subgraph with at least $\frac{m}{2} + \frac{n-1}{4}$ arcs. The problem of deciding whether there exists an acyclic subgraph with at least $\frac{m}{2} + \frac{n-1}{4} + k$ arcs is fixed-parameter tractable, and has a $O(k^2)$-vertex kernel [1].

The notion of a bipartite graph can be generalized in the following way. Consider a graph G with edges labeled either $+$ or $-$. Then we say G is *balanced* if there exists a partition V_1, V_2 of the vertices of G, such that all edges between V_1 and V_2 are labeled $-$ and all other edges are labeled $+$. (Note that if all edges of a graph are labeled $-$, then it is balanced if and only if it is bipartite.) The property of being a balanced graph is $1/2$-extendible, just as the property of being bipartite is. Therefore a graph with n vertices and m vertices, and all edges labeled $+$ or $-$, will have a balanced subgraph with at least $\frac{m}{2} + \frac{n-1}{4}$ edges. The problem of deciding whether there exists a balanced subgraph with at least $\frac{m}{2} + \frac{n-1}{4} + k$ edges is fixed-parameter tractable and has a $O(k^3)$-vertex kernel [3].

Mnich et al. [7] showed that Lemma 1 applies not just for MAX CUT AEE, but for Π-SUBGRAPH APT for any Π which is strongly λ-extendible for some λ (with the bound $12k$ replaced with $\frac{6k}{1-\lambda}$). Thus, Π-SUBGRAPH APT is fixed-parameter tractable as long as it is fixed-parameter tractable on graphs which are close to being a forest of cliques. Using this observation, Mnich et al. showed fixed-parameter tractability for a number of versions of Π-SUBGRAPH APT, including when Π is the family of acyclic directed graphs and when Π is the set of r-colorable graphs.

Crowston et al. [4] proved the existence of polynomial kernels for a wide range of strongly λ-extendible properties:

Theorem 3 ([4]) *Let $0 < \lambda < 1$, and let Π be a strongly λ-extendible property of (possibly oriented and/or labeled) graphs. Then Π-*SUBGRAPH APT *has a kernel on $O(k^2)$ vertices if Condition 1 or 2 holds, and a kernel on $O(k^3)$ vertices if only Condition 3 holds:*

1. *$\lambda \neq \frac{1}{2}$.*
2. *All orientations and labels (if applicable) of the graph K_3 belong to Π.*
3. *Π is a hereditary property of simple or oriented graphs.*

Open Problems

The Poljak-Turzík's bound extends to edge-weighted graphs. The weighted version is as follows: for a graph G with nonnegative real weights on the edges, and a λ-extendible family

of graphs Π, there exists a subgraph H of G such that $H \in \Pi$ and H has total weight $\lambda \cdot w(G) + \frac{1-\lambda}{2} \cdot MST(G)$, where $w(G)$ is the total weight of G and $MST(G)$ is the minimum weight of a spanning tree in G.

Thus, we can consider the weighted versions of MAX CUT AEE and Π-SUBGRAPH APT. It is known that a weighted equivalent of Lemma 1 holds (in which all edges in a block of $G-S$ have the same weight), and as a result, the integer-weighted version of MAX CUT AEE can be shown to be fixed-parameter tractable. However, nothing is known about kernelization results for these problems. In particular, it remains an open question whether the integer-weighted version of MAX CUT AEE has a polynomial kernel.

Problem Definition

The problem MAXLIN2 can be stated as follows. We are given a system of m equations in variables $x_1, \ldots, x_n$ where each equation is $\prod_{i \in I_j} x_i = b_j$, for some $I_j \subseteq \{1, 2, \ldots, n\}$ and $x_i, b_j \in \{-1, 1\}$ and $j = 1, \ldots, m$. Each equation is assigned a positive integral weight w_j. We are required to find an assignment of values to the variables in order to maximize the total weight of the satisfied equations. MAXLIN2 is a well-studied problem, which according to Håstad [8] "is as basic as satisfiability."

Note that one can think of MAXLIN2 as containing equations, $\sum_{i \in I_j} y_i = a_j$ over $\mathbb{F}_2$. This is equivalent to the previous definition by letting $y_i = 0$ if and only if $x_i = 1$ and letting $y_i = 1$ if and only if $x_i = -1$ (and $a_j = 1$ if and only if $b_j = -1$ and $a_j = 0$ if and only if $b_j = 1$). We will however use the original definition as this was the formulation used in [1].

Let W be the sum of the weights of all equations in an instance, S, of MAXLIN2 and let $\text{sat}(S)$ be the maximum total weight of equations that can be satisfied simultaneously. To see that $W/2$ is a tight lower bound on $\text{sat}(S)$, choose assignments to the variables independently and uniformly at random. Then $W/2$ is the expected weight of satisfied equations (as the probability of each equation being satisfied is $1/2$) and thus $W/2$ is a lower bound. It is not difficult to see that this bound is tight. For example, consider a system consisting of pairs of equations of the form $\prod_{i \in I} x_i = -1$, $\prod_{i \in I} x_i = 1$ of the same weight, for some nonempty sets $I \subseteq \{1, 2, \ldots, n\}$.

As MAXLIN2 is an NP-hard problem, we look for parameterized algorithms. We will give the basic definitions of fixed-parameter tractability (FPT) here and refer the reader to [4, 5] for more information. A *parameterized problem* is a subset $L \subseteq \Sigma^* \times \mathbb{N}$ over a finite alphabet Σ. L is *fixed-parameter tractable* (FPT, for short) if membership of an instance (x, k) in $\Sigma^* \times \mathbb{N}$ can be decided in time $f(k)|x|^{O(1)}$, where f is a function of the parameter k only.

If we set the parameter, k, of an instance, S, of MAXLIN2 to $\text{sat}(S)$, then it is easy to see that there exists an $O(f(k)|S|^c)$ algorithm, due to the fact that $k = \text{sat}(S) \geq W/2 \geq |S|/2$. Therefore, this parameter is not of interest (it is never small in practice), and a better parameter would be k, where we want to decide if $\text{sat}(S) \geq W/2 + k$. Parameterizing above tight lower bounds in this way was first introduced in 1997 in [11]. This leads us to define the following problem, where AA stands for *Above Average*.

MAXLIN2-AA

Instance: A system S of equations $\prod_{i \in I_j} x_i = b_j$, where $x_i, b_j \in \{-1, 1\}$, $j = 1, \ldots, m$ and where each equation is assigned a positive integral weight w_j and a nonnegative integer k.

Question: $\text{sat}(S) \geq W/2 + k$?

The above problem has also been widely studied when the number of variables in each equation is bounded by some constant, say r, which leads to the following problem.

MAX-r-LIN2-AA

Instance: A system S of equations $\prod_{i \in I_j} x_i = b_j$, where $x_i, b_j \in \{-1, 1\}$, $|I_j| \leq r$, $j = 1, \ldots, m$; equation j is assigned a positive integral weight w_j and a nonnegative integer k.

Question: $\text{sat}(S) \geq W/2 + k$?

Given a parameterized problem, Π, a *kernel* of Π is a polynomial-time algorithm that maps an instance (I, k) of Π to another instance, (I', k'), of Π such that (i) $(I, k) \in \Pi$ if and only if $(I', k') \in \Pi'$, (ii) $k' \leq f(k)$, and (iii) $|I'| \leq g(k)$ for some functions f and g. The function $g(k)$ is called the *size* of the kernel. It is well known that a problem is FPT if and only if it has a kernel.

A kernel is called a polynomial kernel if both $f(k)$ and $g(k)$ are polynomials in k. A great deal of research has been devoted to finding small-sized kernels and in particular to decide if a problem has a polynomial kernel.

We will show that both the problems stated above are FPT and in fact contain kernels with a polynomial number of variables. The number of equations may be non-polynomial, so these kernels are not real polynomial kernels. The above problems were investigated in a number of papers; see [1–3, 6].

Key Results

We will below outline the key results for both MaxLin2-AA and Max-r-Lin2-AA. See [1] for all the details not given here.

MaxLin2-AA

Recall that MaxLin2-AA considers a system S of equations $\prod_{i\in I_j} x_i = b_j$, where $x_i, b_j \in \{-1, 1\}$, $j = 1, \ldots, m$ and where each equation is assigned a positive integral weight w_j. Let $\mathcal{F}$ denote the m different sets I_j in the equations of S and let $b_{I_j} = b_j$ and $w_{I_j} = w_j$ for each $j = 1, 2, \ldots, m$.

Let $\varepsilon(x) = \sum_{I\in\mathcal{F}} w_I b_I \prod_{i\in I} x_i$ and note that $\varepsilon(x)$ is the difference between the total weight of satisfied and falsified equations. Crowston et al. [3] call $\varepsilon(x)$ the *excess* and the maximum possible value of $\varepsilon(x)$ the *maximum excess*.

Remark 1 Observe that the answer to MaxLin2-AA and Max-r-Lin2-AA is YES if and only if the maximum excess is at least $2k$.

Let A be the matrix over $\mathbb{F}_2$ corresponding to the set of equations in S, such that $a_{ji} = 1$ if $i \in I_j$ and 0, otherwise. Consider the following two reduction rules, where Rule 1 was introduced in [9] and Rule 2 in [6].

Reduction Rule 1 ([9]) *If we have, for a subset I of $\{1, 2, \ldots, n\}$, an equation $\prod_{i\in I} x_i = b'_I$ with weight w'_I, and an equation $\prod_{i\in I} x_i = b''_I$ with weight w''_I, then we replace this pair by one of these equations with weight $w'_I + w''_I$ if $b'_I = b''_I$ and, otherwise, by the equation whose weight is bigger, modifying its new weight to be the difference of the two old ones. If the resulting weight is 0, we delete the equation from the system.*

Reduction Rule 2 ([6]) *Let $t = \mathrm{rank}A$ and suppose columns $a^{i_1}, \ldots, a^{i_t}$ of A are linearly independent. Then delete all variables not in $\{x_{i_1}, \ldots, x_{i_t}\}$ from the equations of S.*

Lemma 1 ([6]) *Let S' be obtained from S by Rule 1 or 2. Then the maximum excess of S' is equal to the maximum excess of S. Moreover, S' can be obtained from S in time polynomial in n and m.*

If we cannot change a weighted system S using Rules 1 and 2, we call it *irreducible*. Let S be an irreducible system of MaxLin2-AA. Consider the following algorithm introduced in [3]. We assume that, in the beginning, no equation or variable in S is marked.

ALGORITHM $\mathcal{H}$
While the system S is nonempty, do the following:

1. Choose an equation $\prod_{i\in I} x_i = b$ and mark a variable x_l such that $l \in I$.
2. Mark this equation and delete it from the system.
3. Replace every equation $\prod_{i\in I'} x_i = b'$ in the system containing x_l by $\prod_{i\in I\Delta I'} x_i = bb'$, where $I\Delta I'$ is the symmetric difference of I and I' (the weight of the equation is unchanged).
4. Apply Reduction Rule 1 to the system.

The *maximum $\mathcal{H}$-excess* of S is the maximum possible total weight of equations marked by $\mathcal{H}$ for S taken over all possible choices in Step 1 of $\mathcal{H}$. The following lemma indicates the potential power of $\mathcal{H}$.

Lemma 2 ([3]) *Let S be an irreducible system. Then the maximum excess of S equals its maximum $\mathcal{H}$-excess.*

Theorem 1 ([1]) *There exists an $O(n^{2k}(nm)^{O(1)})$-time algorithm for* MaxLin2-AA$[k]$ *that returns an assignment of excess of at least $2k$ if one exists, and returns* NO *otherwise.*

In order to prove the above, the authors pick n equations $e_1, \ldots, e_n$ such that their rows in A are linearly independent. An assignment of excess at least $2k$ must either satisfy one of these equations or falsify them all. If they are all falsified, then the value of all variables is completely determined. Thus, by Lemma 2, algorithm $\mathcal{H}$ can mark one of these equations, implying a search tree of depth at most $2k$ and width at most k. This implies the desired time bound.

Theorem 2 below is proved using M-sum-free sets, which are defined as follows (see [3]). Let K and M be sets of vectors in $\mathbb{F}_2^n$ such that $K \subseteq M$. We say K is *M-sum-free* if no sum of two or more distinct vectors in K is equal to a vector in M.

Theorem 2 ([1]) *Let S be an irreducible system of* MaxLin2-AA$[k]$ *and let $k \geq 1$. If $2k \leq m \leq \min\{2^{n/(2k-1)} - 1, 2^n - 2\}$, then the maximum excess of S is at least $2k$. Moreover, we can find an assignment with excess of at least $2k$ in time $O(m^{O(1)})$.*

Using the above, we can solve the problem when $2k \leq m \leq 2^{n/(2k-1)} - 2$ and when $m \geq n^{2k} - 1$ (using Theorem 1). The case when $m < 2k$ immediately gives a kernel and the remaining case when $2^{n/(2k-1)} - 2 \leq m \leq n^{2k} - 2$ can be shown to imply that $n \in O(k^2 \log k)$, thereby giving us the main theorem and corollary of this section.

Theorem 3 ([1]) *The problem* MaxLin2-AA$[k]$ *has a kernel with at most $O(k^2 \log k)$ variables.*

Corollary 1 ([1]) *The problem* MaxLin2-AA$[k]$ *can be solved in time $2^{O(k \log k)}(nm)^{O(1)}$.*

Max-r-Lin2-AA

In [6] it was proved that the problem Max-r-Lin2-AA admits a kernel with at most $O(k^2)$ variables and equations (where r is treated as a constant). The bound on the number of variables can be improved and it was done by Crowston et al. [3] and Kim and Williams [10]. The best known improvement is by Crowston et al. [1].

Theorem 4 ([1]) *The problem* Max-r-Lin2-AA *admits a kernel with at most $(2k - 1)r$ variables.*

Both Theorem 4 and a slightly weaker analogous result of the results in [10] imply the following:

Lemma 3 ([1,10]) *There is an algorithm of runtime $2^{O(k)} + m^{O(1)}$ for* Max-r-Lin2-AA.

Kim and Williams [10] proved that the last result is best possible, in a sense, if the exponential time hypothesis holds.

Theorem 5 ([10]) *If* Max-3-Lin2-AA *can be solved in $O(2^{\epsilon k}2^{\epsilon m})$ time for every $\epsilon > 0$, then 3-SAT can be solved in $O(2^{\delta n})$ time for every $\delta > 0$, where n is the number of variables.*

Open Problems

The kernel for MaxLin2-AA contains at most $O(k^2 \log k)$ variables, but may contain an exponential number of equations. It would be of interest to decide if MaxLin2-AA admits a kernel that has at most a polynomial number of variables and equations.

Problem Definition

In parameterized complexity, each instance (I, k) of a problem comes with an additional parameter k which describes structural properties of the instance, for example, the maximum degree of an input graph. A problem is called *fixed-parameter tractable* if it can be solved in $f(k)\cdot\text{poly}(n)$ time, that is, the super-polynomial part of the running time depends only on k. Consequently, instances of the problem can be solved efficiently if k is small.

One way to show fixed-parameter tractability of a problem is the design of a polynomial-time data reduction algorithm that reduces any input instance (I, k) to one whose size is bounded in k. This idea is captured by the notion of kernelization.

Definition 1 Let (I, k) be an instance of a parameterized problem P, where $I \in \Sigma^*$ denotes the input instance and $k \in \mathbb{N}$ is a parameter. Problem P admits a *problem kernel* if there is a polynomial-time algorithm, called *problem kernelization*, that computes an instance (I', k') of the same problem P such that:

- (I, k) is a yes-instance if and only if (I', k') is a yes-instance, and
- $|I'| + k' \leq g(k)$

for a function g of k only.

Kernelization gives a performance guarantee for the effectiveness of data reduction: instances (I, k) with $|I| > g(k)$ are provably reduced to smaller instances. Thus, one aim in the design of kernelization algorithms is to make the function g as small as possible. In particular, one wants to obtain kernelizations where g is a polynomial function. These algorithms are called *polynomial problem kernelizations*.

For many parameterized problems, however, the existence of such a polynomial problem kernelization is considered to be unlikely (under a standard complexity-theoretic assumption) [4]. Consequently, alternative models of parameterized data reduction, for example Turing kernelization, have been proposed.

The concept of *partial kernelization* offers a further approach to obtain provably useful data reduction algorithms. Partial kernelizations do not aim for a decrease of the instance *size* but for a decrease of some *part* or *dimension* of the instance. For example, if the problem input is a binary matrix with m rows and n columns, the instance size is $\Theta(n \cdot m)$. A partial kernelization can now aim for reducing one dimension of the input, for example the number of rows n. Of course,

such a reduction is worthwhile only if we can algorithmically exploit the fact that the number of rows n is small. Hence, the aim is to reduce a dimension of the problem for which there are fixed-parameter algorithms. The dimension can thus be viewed as a secondary parameter.

Altogether, this idea is formalized as follows.

Definition 2 Let (I, k) be an instance of a parameterized problem P, where $I \in \Sigma^*$ denotes the input instance and k is a parameter. Let $d : \Sigma^* \to \mathbb{N}$ be a computable function such that P is fixed-parameter tractable with respect to $d(I)$. Problem P admits a *partial problem kernel* if there is a polynomial-time algorithm, called *partial problem kernelization*, that computes an instance (I', k') of the same problem such that:

- (I, k) is a yes-instance if and only if (I', k') is a yes-instance, and
- $d(I') + k' \leq g(k)$

for a computable function g.

Any parameterized problem P which has a partial kernel for some appropriate dimension d is fixed-parameter tractable with respect to k: First, one may reduce the original input instance (I, k) to the partial kernel (I', k'). In this partial kernel, we have $d(I') \leq g(k)$ and, since P can be solved in $f(d(I')) \cdot \text{poly}(n)$ time, it can thus be solved in $f(g(k)) \cdot \text{poly}(n)$ time.

Using partial problem kernelization instead of classic problem kernelization can be motivated by the following two arguments.

First, the function d in the partial problem kernelization gives us a different goal in the design of efficient data reduction rules. For instance, if the main parameter determining the hardness of a graph problem is the maximum degree, then an algorithm that produces instances whose maximum degree is $O(k)$ but whose size is unbounded might be more useful than an algorithm that produces instances whose size is $O(k^4)$ but the maximum degree is $\Omega(k^2)$.

Second, if the problem does not admit a polynomial-size problem kernel, then it might still admit a *partially polynomial kernel*, that is, a partial kernel in which $d(I') + k' \leq \text{poly}(k)$.

We now give two examples for applications of partial kernelizations.

Key Results

The partial kernelization concept was initially developed to obtain data reduction algorithms for consensus problems, where one is given a collection of combinatorial objects and one is asked to find one object that represents this collection [2].

In the KEMENY SCORE problem, these objects are permutations of a set U and the task is to find a permutation that is close to these permutations with respect to what is called *Kendall's Tau distance*, here denoted by τ. The formal definition of the (unparameterized) problem is as follows.

Input: A multiset $\mathcal{P}$ of permutations of a ground set U and an integer ℓ.
Question: Is there a permutation P such that $\sum_{P' \in \mathcal{P}} \tau(P, P') \leq \ell$?

The parameter k under consideration is the average distance between the input partitions, that is,

$$k := \sum_{\{P, P'\} \subseteq \mathcal{P}} \tau(P, P') / \binom{|\mathcal{P}|}{2}.$$

Observe that, since τ can be computed efficiently, KEMENY SCORE is fixed-parameter tractable with respect to $|U|$: try all possible permutations of U and choose the best one. Hence, if U is small, then the problem is easy. Furthermore, the number of input permutations is not such a crucial feature since KEMENY SCORE is already NP-hard for a constant number of permutations; the partial kernelization thus aims for a reduction of $|U|$ and ignores the—less important—number of input permutations.

This reduction is obtained by removing elements in U that are, compared to the other elements, in roughly the same position in many input permutations. The idea is based on a

generalization of the following observation: If some element u is the first element of at least $3|\mathcal{P}|/4$ input permutations, then this element is the first element of an optimal partition. Any instance containing such an element u can thus be reduced to an equivalent with one less element.

By removing such elements, one obtains a sub-instance of the original instance in which every element contributes a value of $16/3$ to the average distance k between the input permutations. This leads to the following result.

Theorem 1 ([3]) KEMENY SCORE *admits a partial kernel with* $|U| \leq 16/3k$.

Further partial kernelizations for consensus problems have been obtained for CONSENSUS CLUSTERING [2, 7] and SWAP MEDIAN PARTITION [2], the partial kernelization for KEMENY SCORE has been experimentally evaluated [3].

Another application of partial kernelization has been proposed for covering problems such as SET COVER [1].

Input: A family $\mathcal{S}$ of subsets of a ground set U.
Question: Is there a subfamily $\mathcal{S}' \subseteq \mathcal{S}$ of size at most ℓ such that every element in U is contained in at least one set of $\mathcal{S}'$?

If $\ell \geq |U|$, then SET COVER has a trivial solution. Thus, a natural parameter is the amount that can be saved compared to this trivial solution, that is, $k := |U| - \ell$. A polynomial problem kernelization for SET COVER parameterized by k is deemed unlikely, again under standard complexity-theoretic assumptions. There is, however, a partially polynomial problem kernel. The dimension d is the universe size $|U|$. SET COVER is fixed-parameter tractable with respect to $|U|$ as it can be solved in $f(|U|) \cdot \text{poly}(n)$ time, for example, by dynamic programming.

The idea behind the partial kernelization is to greedily compute a subfamily $\mathcal{T} \subseteq \mathcal{S}$ of size k. Then, it is observed that either this subfamily has a structure that can be used to efficiently compute a solution of the problem, or $|U| \leq 2k^2 - 2$, or there are elements in U whose removal yields an equivalent instance. Altogether this leads to the following.

Theorem 2 ([1]) SET COVER *admits a partial problem kernel with* $|U| \leq 2k^2 - 2$.

Open Problems

The notion of partial kernelization is quite recent. Hence, the main aim for the near future is to identify further useful applications of the technique. We list some problem areas that contain natural candidates for such applications. Problems that are defined on set families, such as SET COVER, have two obvious dimensions: the number m of sets in the set family and the size n of the universe. Matrix problems also have two obvious dimensions: the number m of rows and the number n of columns. For graph problems, useful dimensions could be identified by examining the so-called parameter hierarchy [6, 8]. Here, the idea is to find dimensions whose value can be much smaller than the number of vertices in the graph. If the size $|I|$ of the instance cannot be reduced to be smaller than $\text{poly}(k)$, then this might be still possible for the smaller dimension $d(I)$. A further interesting research direction could be to study the relationship between partial kernelization and other relaxed notions of kernelization such as Turing kernelization.

For some problems, the existence of partially polynomial kernels has been proven, but it is still unknown whether polynomial kernels exist. One such example is MAXLIN2-AA [5].

Keywords

Betweenness; Linear ordering; Parameterization above tight bound

Years and Authors of Summarized Original Work

2012; Gutin, van Iersel, Mnich, Yeo

Problem Definition

Let r be an integer and let V be a set of n variables. An *ordering* α is a bijection from V to $\{1, 2, \ldots, n\}$; a *constraint* is an ordered r-tuple $(v_1, v_2, \ldots, v_r)$ of distinct variables of V; α *satisfies* $(v_1, v_2, \ldots, v_r)$ if $\alpha(v_1) < \alpha(v_2) < \cdots < \alpha(v_r)$. An instance of MAX-$r$-LIN-ORDERING consists of a multiset $\mathcal{C}$ of constraints, and the objective is to find an ordering that satisfies the maximum number of constraints. Note that MAX-2-LIN ORDERING is equivalent to the problem of finding a maximum weight acyclic subgraph in an integer-weighted directed graph. Since the FEEDBACK ARC SET problem is NP-hard, MAX-2-LIN ORDERING is NP-hard, and thus MAX-r-LIN-ORDERING is NP-hard for each $r \geq 2$.

Let α be an ordering chosen randomly and uniformly from all orderings and let $c \in \mathcal{C}$ be a constraint. Then the probability that α satisfies c is $1/r!$. Thus the expected number of constraints in $\mathcal{C}$ satisfied by α equals $|\mathcal{C}|/r!$. This is a lower bound on the maximum number of constraints satisfied by an ordering, and, in fact, it is a tight lower bound. This allows us to consider the following parameterized problem (AA stands for *Above Average*).

MAX-r-LIN-ORDERING-AA

Instance: A multiset $\mathcal{C}$ of constraints and a nonnegative integer k.
Parameter: k.
Question: Is there an ordering satisfying at least $|\mathcal{C}|/r! + k$ constraints?

$(1, 2, \ldots, r)$ is the identity permutation of the symmetric group $\mathcal{S}_r$. We can extend MAX-r-LIN-ORDERING by considering an arbitrary subset of $\mathcal{S}_r$ rather than just $\{(1, 2, \ldots, r)\}$. Instead of describing the extension for each arity $r \geq 2$, we will do it only for $r = 3$, which is our main interest, and leave the general case to the reader.

Let $\Pi \subseteq \mathcal{S}_3 = \{(1,2,3), (1,3,2), (2,1,3), (2,3,1), (3,1,2), (3,2,1)\}$ be arbitrary. For an ordering $\alpha\colon V \to \{1, 2, \ldots, n\}$, a constraint $(v_1, v_2, v_3) \in \mathcal{C}$ is *Π-satisfied by α* if there is a permutation $\pi \in \Pi$ such that $\alpha(v_{\pi(1)}) < \alpha(v_{\pi(2)}) < \alpha(v_{\pi(3)})$. Given Π, the problem Π-CSP is the problem of deciding if there exists an ordering of V that Π-satisfies all the constraints. Every such problem is called a Permutation CSP of arity 3. We will consider the maximization version of these problems, denoted by MAX-Π-

Kernelization, Permutation CSPs Parameterized above Average, Table 1 Permutation CSPs of arity 3 (after symmetry considerations)

$\Pi \subseteq \mathcal{S}_3$	Name	Complexity
$\Pi_0 = \{(123)\}$	3-LIN-ORDERING	Polynomial
$\Pi_1 = \{(123), (132)\}$		Polynomial
$\Pi_2 = \{(123), (213), (231)\}$		Polynomial
$\Pi_3 = \{(132), (231), (312), (321)\}$		Polynomial
$\Pi_4 = \{(123), (231)\}$		NP-comp.
$\Pi_5 = \{(123), (321)\}$	BETWEENNESS	NP-comp.
$\Pi_6 = \{(123), (132), (231)\}$		NP-comp.
$\Pi_7 = \{(123), (231), (312)\}$	CIRCULAR ORDERING	NP-comp.
$\Pi_8 = \mathcal{S}_3 \setminus \{(123), (231)\}$		NP-comp.
$\Pi_9 = \mathcal{S}_3 \setminus \{(123), (321)\}$	NON-BETWEENNESS	NP-comp.
$\Pi_{10} = \mathcal{S}_3 \setminus \{(123)\}$		NP-comp.

CSP, parameterized above the average number of constraints satisfied by a random ordering of V (which can be shown to be a tight bound).

It is easy to see that there is only one distinct Π-CSP of arity 2. Guttmann and Maucher [5] showed that there are in fact only 13 distinct Π-CSPs of arity 3 up to symmetry, of which 11 are nontrivial. They are listed in Table 1 together with their complexity. Some of the problems listed in the table are well known and have special names. For example, the problem for $\Pi = \{(123), (321)\}$ is called the BETWEENNESS problem.

Gutin et al. [4] proved that all 11 nontrivial MAX-Π-CSP problems are NP-hard (even though four of the Π-CSP are polynomial).

Now observe that given a variable set V and a constraint multiset $\mathcal{C}$ over V, for a random ordering α of V, the probability of a constraint in $\mathcal{C}$ being Π-satisfied by α equals $\frac{|\Pi|}{6}$. Hence, the expected number of satisfied constraints from $\mathcal{C}$ is $\frac{|\Pi|}{6}|\mathcal{C}|$, and thus there is an ordering α of V satisfying at least $\frac{|\Pi|}{6}|\mathcal{C}|$ constraints (and this bound is tight). A derandomization argument leads to $\frac{|\Pi|}{6}$-approximation algorithms for the problems MAX-Π-CSP [1]. No better constant factor approximation is possible assuming the Unique Games Conjecture [1].

We will study the parameterization of MAX-Π-CSP above tight lower bound:

Π-ABOVE AVERAGE (Π-AA)

Instance: A finite set V of variables, a multiset $\mathcal{C}$ of ordered triples of distinct variables from V and a nonnegative integer k.

Parameter: k.

Question: Is there an ordering α of V such that at least $\frac{|\Pi|}{6}|\mathcal{C}| + k$ constraints of $\mathcal{C}$ are Π-satisfied by α?

Key Results

The following is a simple but important observation in [4] allowing one to reduce Π-AA to MAX-3-LIN-ORDERING-AA.

Proposition 1 *Let Π be a subset of $\mathcal{S}_3$ such that $\Pi \notin \{\emptyset, \mathcal{S}_3\}$. There is a polynomial time transformation f from Π-AA to* MAX-3-LIN-ORDERING-AA *such that an instance $(V, \mathcal{C}, k)$ of Π-AA is a Yes-instance if and only if $(V, \mathcal{C}', k) = f(V, \mathcal{C}, k)$ is a Yes-instance of* MAX-3-LIN-ORDERING-AA.

Using a nontrivial reduction from MAX-3-LIN-ORDERING-AA to a combination of MAX-2-LIN-ORDERING-AA and BETWEENNESS-AA and the facts that both problems admit kernels with quadratic numbers of variables and constraints (proved in [3] and [2], respectively),

Gutin et al. [4] showed that MAX-3-LIN-ORDERING-AA also admits a kernel with quadratic numbers of variables and constraints. Kim and Williams [6] partially improved this result by showing that MAX-3-LIN-ORDERING-AA admits a kernel with $O(k)$ variables.

The polynomial-size kernel result for MAX-3-LIN-ORDERING-AA and Proposition 1 imply the following (see [4] for details):

Theorem 1 ([4]) *Let Π be a subset of $\mathcal{S}_3$ such that $\Pi \notin \{\emptyset, \mathcal{S}_3\}$. The problem Π-AA admits a polynomial-size kernel with $O(k^2)$ variables.*

Open Problems

Similar to Proposition 1, it is easy to prove that, for each fixed r every Π-AA can be reduced to LIN-r-ORDERING-AA. Gutin et al. [4] conjectured that for each fixed r the problem MAX-r-LIN-ORDERING-AA is fixed-parameter tractable.

Problem Definition

Several combinatorial optimization problems on graphs involve identifying a subset of nodes S, of the smallest cardinality, such that the graph obtained after removing S satisfies certain properties. For example, the VERTEX COVER problem asks for a minimum-sized subset of vertices whose removal makes the graph edgeless, while the FEEDBACK VERTEX SET problem involves finding a minimum-sized subset of vertices whose removal makes the graph acyclic. The $\mathcal{F}$-DELETION problem is a generic formulation that encompasses several problems of this flavor.

Let $\mathcal{F}$ be a finite set of graphs. In the $\mathcal{F}$-DELETION problem, the input is an n-vertex graph G and an integer k, and the question is if

G has a subset S of at most k vertices, such that $G-S$ does not contain a graph from $\mathcal{F}$ as a minor. The optimization version of the problem seeks such a subset of the smallest possible size. The PLANAR $\mathcal{F}$-DELETION problem is the version of the problem where $\mathcal{F}$ contains at least one planar graph. The $\mathcal{F}$-DELETION problem was introduced by [3], who gave a non-constructive algorithm running in time $O(f(k) \cdot n^2)$ for some function $f(k)$. This result was improved by [1] to $O(f(k) \cdot n)$, for $f(k) = 2^{2^{O(k \log k)}}$.

For different choices of sets of forbidden minors $\mathcal{F}$, one can obtain various fundamental problems. For example, when $\mathcal{F} = \{K_2\}$, a complete graph on two vertices, this is the VERTEX COVER problem. When $\mathcal{F} = \{C_3\}$, a cycle on three vertices, this is the FEEDBACK VERTEX SET problem. The cases of $\mathcal{F}$ being $\{K_{2,3}, K_4\}$, $\{K_4\}$, $\{\theta_c\}$, and $\{K_3, T_2\}$, correspond to removing vertices to obtain an outerplanar graph, a series-parallel graph, a diamond graph, and a graph of pathwidth one, respectively.

Tools

Most algorithms for the PLANAR $\mathcal{F}$-DELETION problem appeal to the notion of *protrusions* in graphs. An r-protrusion in a graph G is a subgraph H of treewidth at most r such that the number of neighbors of H in $G - H$ is at most r. Intuitively, a protrusion H in a graph G may be thought of as subgraph of small treewidth which is cut off from the rest of the graph by a small separator.

Usually, as a means of preprocessing, protrusions are identified and *replaced* by smaller ones, while maintaining equivalence. The notion of graph replacement in this fashion originates in the work of [4]. The modern notion of protrusion reductions have been employed in various contexts [2, 5, 6, 12]. A widely used method for developing a protrusion replacement algorithm is via the notion of *finite-integer index*. Roughly speaking, this property ensures that graphs can be related under some appropriate notion of equivalence with respect to the problem, and that there are only finitely many equivalence classes. This allows us to identify the class that the protrusion belongs to and replace it with a canonical representative for that class.

Key Results

The algorithms proposed for PLANAR $\mathcal{F}$-DELETION usually have the following ingredients. First, the fact that $\mathcal{F}$ contains a planar graph implies that any YES-instance of the problem must admit a small subset of vertices whose removal leads to a graph of small treewidth. It turns out that such graphs admit a convenient structure from the perspective of the existence of protrusions. In particular, most of the graph can be decomposed into protrusions. From here, there are two distinct themes.

In the first approach, the protrusions are *replaced* by smaller, equivalent graphs. Subsequently, we have a graph that has no large protrusions. For such instances, it can be shown that if there is a solution, there is always one that is incident to a constant fraction of the edges in the graph, and this leads to a randomized algorithm by branching. Notably, the protrusion replacement can be performed by an algorithm that guarantees the removal of a constant fraction of vertices in every application. This helps in ensuring that the overall running time of the algorithm has a linear dependence on the size of the input. This algorithm is limited to the case when all graphs in $\mathcal{F}$ are connected, as is required in demonstrating finite-integer index.

Theorem 1 ([8]) *When every graph in $\mathcal{F}$ is connected, there is a randomized algorithm solving* PLANAR $\mathcal{F}$-DELETION *in time* $2^{O(k)} \cdot n$.

The second approach involves exploring the structure of the instance further. Here, an $O(k)$-sized subset of vertices is identified, with the key property that there is a solution that lives within it. The algorithm then proceeds to exhaustively branch on these vertices. This technique requires a different protrusion decomposition from the previous one. The overall algorithm is implemented using iterative compression. Since the protrusions are not replaced, this algorithm works for all instances of PLANAR $\mathcal{F}$-DELETION, with-

out any further assumptions on the family $\mathcal{F}$. While both approaches lead to algorithms that are single-exponential in k, the latter has a quadratic dependence on the size of the input.

Theorem 2 ([11]) PLANAR-$\mathcal{F}$-DELETION *can be solved in time* $2^{O(k)} \cdot n^2$.

In the context of approximation algorithms, the protrusion replacement is more intricate, because the notion of equivalence is now more demanding. The replacement should preserve not only the exact solutions, but also approximate ones. By appropriately adapting the machinery of replacements with lossless protrusion replacers, the problem admits the following approximation algorithm.

Theorem 3 ([8]) PLANAR $\mathcal{F}$-DELETION *admits a randomized constant ratio approximation algorithm.*

The PLANAR $\mathcal{F}$-DELETION problem also admits efficient preprocessing algorithms. Formally, a kernelization algorithm for the problem takes an instance (G, k) as input and outputs an equivalent instance (H, k') where the size of the output is bounded by a function of k. If the size of the output is bounded by a polynomial function of k, then it is called a polynomial kernel. The reader is referred to the survey [13] for a more detailed introduction to kernelization.

The technique of protrusion replacement was developed and used successfully for kernelization algorithms on sparse graphs [2,5]. These methods were also used for the special case of the PLANAR $\mathcal{F}$-DELETION problem when $\mathcal{F}$ is a graph with two vertices and constant number of parallel edges [6]. In the general setting of PLANAR $\mathcal{F}$-DELETION, kernelization involves anticipating protrusions, that is, identifying subgraphs that become protrusions after the removal of some vertices from an optimal solution. These "near-protrusions" are used to find irrelevant edges, i.e., an edge whose removal does not change the problem, leading to natural reduction rules. The process of finding an irrelevant edge appeals to the well-quasi-ordering of a certain class of graphs as a subroutine.

Theorem 4 ([8]) PLANAR $\mathcal{F}$-DELETION *admits a polynomial kernel.*

Applications

The algorithms for PLANAR $\mathcal{F}$-DELETION apply to any vertex deletion problem that can be described as hitting minor models of some fixed finite family that contains a planar graph.

For a finite set of graphs $\mathcal{F}$, let $\mathcal{G}_{\mathcal{F},k}$ be a class of graphs such that for every $G \in \mathcal{G}_{\mathcal{F},k}$ there is a subset of vertices S of size at most k such that $G \setminus S$ has no minor from $\mathcal{F}$. The following combinatorial result is a consequence of the kernelization algorithm for PLANAR $\mathcal{F}$-DELETION.

Theorem 5 ([8]) *For every set* $\mathcal{F}$ *that contains a planar graph, every minimal obstruction for* $\mathcal{G}_{\mathcal{F},k}$ *is of size polynomial in* k.

Kernelization algorithms on apex-free and H-minor-free graphs for all bidimensional problems from [5] can be implemented in linear time by employing faster protrusion reducers. This leads to randomized linear time, linear kernels for several problems.

In the framework for obtaining EPTAS on H-minor-free graphs in [7], the running time of approximation algorithms for many problems is $f(1/\varepsilon) \cdot n^{O(g(H))}$, where g is some function of H only. The only bottleneck for improving polynomial-time dependence is a constant factor approximation algorithm for TREEWIDTH η-DELETION. Using Theorem 3 instead, each EPTAS from [7] runs in time $O(f(1/\varepsilon) \cdot n^2)$. For the same reason, the PTAS algorithms for many problems on unit disk and map graphs from [9] become EPTAS algorithms.

Open Problems

An interesting direction for further research is to investigate PLANAR $\mathcal{F}$-DELETION when none of the graphs in $\mathcal{F}$ is planar. The most interesting case here is when $\mathcal{F} = \{K_5, K_{3,3}\}$, also known

as the VERTEX PLANARIZATION problem. The work in [10] demonstrates an algorithm with running time $2^{O(k \log k)}n$, which notably has a linear-time dependence on n. It remains open as to whether VERTEX PLANARIZATION can be solved in $2^{O(k)}n$ time. The question of polynomial kernels in the non-planar setting is also open, in particular, even the specific case of $\mathcal{F} = \{K_5\}$ is unresolved.

Problem Definition

The work of Dell and van Melkebeek [4] refines the framework for lower bounds for kernelization introduced by Bodlaender et al. [1] and Fortnow and Santhanam [6]. The main contribution is that their results yield a framework for proving polynomial lower bounds for kernelization rather than ruling out all polynomial kernels for a problem; this, for the first time, gives a technique for proving that some polynomial kernelizations are actually best possible, modulo reasonable complexity assumptions. A further important aspect is that, rather than studying kernelization directly, the authors give lower bounds for a far more general oracle communication protocol. In this way, they also obtain strong lower bounds for sparsification, lossy compression (in the sense of Harnik and Naor [7]), and probabilistically checkable proofs (PCPs).

To explain the connection between kernelization and oracle communication protocols, let us first recall the following. A *parameterized problem* is a language $\mathcal{Q} \subseteq \Sigma^* \times \mathbb{N}$; the second component k of instances $(x,k) \in \Sigma^* \times \mathbb{N}$ is called the *parameter*. A *kernelization for* $\mathcal{Q}$ *with size* $h\colon \mathbb{N} \to \mathbb{N}$ is an efficient algorithm that gets as input an instance $(x,k) \in \Sigma^* \times \mathbb{N}$ and returns an equivalent instance (x',k'), i.e., such that $(x,k) \in \mathcal{Q}$ if and only if $(x',k') \in \mathcal{Q}$, with $|x'|, k' \leq h(k)$. If $h(k)$ is polynomially bounded in k, then we also call it a polynomial kernelization.

One way to use a kernelization is to first simplify a given input instance and then solve the reduced instance by any (possibly brute-force) algorithm; together this yields an algorithm for solving the problem in question. If we abstract out the algorithm by saying that the answer for the reduced instance is given by an oracle, then we arrive at a special case of the following communication protocol.

Definition 1 (oracle communication protocol [4]) An *oracle communication protocol* for a language L is a communication protocol for two players. The first player is given the input x and has to run in time polynomial in the length of the input; the second player is computationally unbounded but is not given any part of x. At the end of the protocol, the first player should be able to decide whether $x \in L$. The cost of the protocol is the number of bits of communication from the first player to the second player.

As an example, if $\mathcal{Q}$ has a kernelization with size h, then instances (x,k) can be solved by a protocol of cost $h(k)$. It suffices that the first player can compute a reduced instance (x',k') and send it to the oracle who decides membership of (x',k') in $\mathcal{Q}$; this yields the desired answer for whether $(x,k) \in \mathcal{Q}$. Note that the communication protocol is far more general than kernelization because it makes no assumption about what exactly is sent (or in what encoding). More importantly, it also allows multiple rounds of communication, and the behavior of the oracle could also be active rather than just answering queries for the first player. Thus, the obtained lower bounds for oracle communication protocols are very robust, covering also relaxed forms of kernelization (like bikernels and compressions), and also yield the other mentioned applications.

Key Results

A central result in the work of Dell and van Melkebeek [4] (see also [5]) is the following lemma, called *complementary witness lemma*.

Lemma 1 (complementary witness lemma [4]) *Let L be a language and $t\colon \mathbb{N} \to \mathbb{N} \setminus \{0\}$ be polynomially bounded such that the problem of deciding whether at least one out of $t(s)$ inputs of length at most s belongs to L has an oracle communication protocol of cost $\mathcal{O}(t(s)\log t(s))$, where the first player can be conondeterministic. Then $L \in$ coNP/poly.*

A previous work of Fortnow and Santhanam [6] showed that an efficient algorithm for encoding any t instances $x_1, \ldots, x_t$ of size at most s into one instance y of size poly(s) such that $y \in L$ if and only if at least one x_i is in L implies $L \in$ coNP/poly. (We recall that this

settled the *OR-distillation conjecture* of Bodlaender et al. [1] and allowed their framework to rule out polynomial kernels under the assumption that NP $\not\subseteq$ coNP/poly.) Lemma 1 is obtained by a more detailed analysis of this result and requires an encoding of the OR of $t(s)$ instances into one instance of size $\mathcal{O}(t(s)\log t(s))$ rather than allowing only size poly(s) for all values of t. This focus on the number $t(s)$ of instances in relation to the maximum instance size s is the key for getting polynomial lower bounds for kernelization (and other applications). In this overview, we will not discuss the possibility of conondeterministic behavior of the first player, but the interested reader is directed to [9, 10] for applications thereof.

Before outlining further results of Dell and van Melkebeek [4], let us state a lemma that captures one way of employing the complementary witness lemma for polynomial lower bounds for kernelization. The lemma is already implicit in [4] and is given explicitly in follow-up work of Dell and Marx [3] (it can also be found in the current full version [5] of [4]). We recall that OR(L) refers to the language of all tuples $(x_1, \ldots, x_t)$ such that at least one x_i is contained in L.

Lemma 2 ([3, 5]) *Suppose that a parameterized problem Π has the following property for some constant c: For some* NP*-complete language L, there exists a polynomial-time mapping reduction from* OR(L) *to Π that maps an instance $(x_1, \ldots, x_t)$ of* OR(L) *in which each x_i has size at most s to an instance of Π with parameter $k \leq t^{1/c+o(1)} \cdot \text{poly}(s)$. Then Π does not have a communication protocol of cost $\mathcal{O}(k^{c-\epsilon})$ for any constant $\epsilon > 0$ unless* NP $\subseteq$ coNP/poly*, even when the first player is conondeterministic.*

Intuitively, Lemma 2 follows from Lemma 1 because if the reduction and communication protocol in Lemma 2 both exist (for all t), then we can choose $t(s)$ large enough (but polynomially bounded in s) such that for all s we get an oracle communication protocol of cost $\mathcal{O}(t(s))$ as required for Lemma 1. This implies $L \in$ coNP/poly and, hence, NP $\subseteq$ coNP/poly (since L is NP-complete). As discussed earlier, any kernelization yields an oracle communication protocol with cost equal to the kernel size and, thus, this bound carries over directly to kernelization.

Let us now state the further results of Dell and van Melkebeek [4] using the context of Lemma 2. The central result is the following theorem on lower bounds for vertex cover on d-uniform hypergraphs.

Theorem 1 ([4]) *Let $d \geq 2$ be an integer and ϵ a positive real. If* NP $\not\subseteq$ coNP/poly*, there is no protocol of cost $\mathcal{O}(n^{d-\epsilon})$ to decide whether a d-uniform hypergraph on n vertices has a vertex cover of at most k vertices, even when the first player is conondeterministic.*

To prove Theorem 1, Dell and van Melkebeek devise a reduction from OR(SAT) to CLIQUE on d-uniform hypergraphs parameterized by the number of vertices (fulfilling the assumption of Lemma 2 for $c = d$). This reduction relies on an intricate lemma, the *packing lemma*, that constructs a d-uniform hypergraph with t cliques on s vertices each, but having only about $\mathcal{O}(t^{1/d+o(1)} \cdot s)$ vertices and no further cliques of size s. In follow-up work, Dell and Marx [3] give a simpler proof for Theorem 1 without making use of the packing lemma, but use the lemma for another of their results.

Note that the stated bound for VERTEX COVER in d-uniform hypergraphs follows by complementation. Furthermore, since every nontrivial instance has $k \leq n$, this also rules out kernelization to size $\mathcal{O}(k^{d-\epsilon})$. The following lower bound for SATISFIABILITY is obtained by giving a reduction from VERTEX COVER on d-uniform hypergraphs with parameter n. In the reduction, hyperedges of size d are encoded by positive clauses on d variables (one per vertex), and an additional part of the formula (which requires $d \geq 3$) checks that at most k of these variables are set to true.

Theorem 2 ([4]) *Let $d \geq 3$ be an integer and ϵ a positive real. If* NP $\not\subseteq$ coNP/poly*, there is no*

protocol of cost $\mathcal{O}(n^{d-\epsilon})$ to decide whether an n-variable d-CNF formula is satisfiable, even when the first player is conondeterministic.

Finally, the following theorem proves that several known kernelizations for graph modification problems are already optimal. The theorem is proved by a reduction from VERTEX COVER (on graphs) with parameter k that is similar in spirit to the classical result of Lewis and Yannakakis on NP-completeness of the Π-VERTEX DELETION problem for nontrivial hereditary properties Π. Note that Theorem 3 requires that the property Π is not only hereditary, i.e., inherited by *induced* subgraphs, but inherited by *all subgraphs*.

Theorem 3 ([4]) *Let Π be a graph property that is inherited by subgraphs and is satisfied by infinitely many but not all graphs. Let ϵ be a positive real. If $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$, there is no protocol of cost $\mathcal{O}(k^{2-\epsilon})$ for deciding whether a graph satisfying Π can be obtained from a given graph by removing at most k vertices.*

As an example, the theorem implies that the FEEDBACK VERTEX SET problem does not admit a kernelization with size $\mathcal{O}(k^{2-\epsilon})$. This is in fact tight since a kernelization by Thomassé [12] achieves $\mathcal{O}(k^2)$ vertices and $\mathcal{O}(k^2)$ edges (cf. [4]); improving to $\mathcal{O}(k^{2-\epsilon})$ edges is ruled out since it would yield an encoding in size $\mathcal{O}(k^{2-\epsilon'})$. Similarly, the well-known kernelization for VERTEX COVER to $2k$ vertices is tight and cannot, in general, be expected to yield instances with less than the trivial $\mathcal{O}(k^2)$ edges.

Applications

Several authors have used the present approach to get polynomial lower bounds for kernelizations of certain parameterized problems; see, e.g., [2, 3, 8, 11]. Similarly, some results make use of conondeterminism [9, 10] and the more general setting of lower bounds for oracle communication protocols [11].

Open Problems

Regarding applications it would be interesting to have more lower bounds that use the full generality of the oracle communication protocols. Furthermore, it is an open problem to relax the assumption of $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$ to the minimal $\mathsf{P} \neq \mathsf{NP}$.

Problem Definition

This work undertakes a theoretical study of preprocessing for the NP-hard TREEWIDTH problem of finding a *tree decomposition* of width at most k for a given graph G. In other words, given G and $k \in \mathbb{N}$, the question is whether G has *treewidth* at most k. Several efficient reduction rules are known that provably preserve the correct answer, and experimental studies show significant size reductions [3, 5]. The present results study these and further newly introduced rules and obtain upper and lower bounds within the framework of *kernelization* from parameterized complexity.

The general interest in computing tree decompositions is motivated by the well-understood approach of using dynamic programming on tree decompositions that is known to allow fast algorithms on graphs of bounded treewidth (but with runtime exponential in the treewidth). A bottleneck for practical applications is the need for finding, as a first step, a sufficiently good tree decomposition; the best known exact algorithm due to Bodlaender [2] runs in time exponential in k^3 and is thus only of theoretical interest. This motivates the use of heuristics and preprocessing to find a reasonably good tree decomposition quickly.

Tree Decompositions and Treewidth

A *tree decomposition* for a graph $G = (V, E)$ consists of a tree $T = (N, F)$ and a family $\mathcal{X} := \{X_i \mid i \in N, X_i \subseteq V\}$. The sets X_i are also called *bags* and the vertices of T are usually referred to as *nodes* to avoid confusion with G; there is exactly one bag X_i associated with each node $i \in N$. The pair $(T, \mathcal{X})$ must fulfill the following three properties: (1) Every vertex of G is contained in at least one bag; (2) For each edge $\{u, v\} \in E$ there must be a bag X_i containing both u and v; (3) For each vertex v of G the set of nodes i of T with $v \in X_i$ induce a (connected) subtree of T. The *width of a tree decomposition* $(T, \mathcal{X})$ is equal to the size of the largest bag $X_i \in \mathcal{X}$ minus one. The *treewidth* of a graph G, denoted $\mathsf{tw}(G)$, is the smallest width taken over all tree decompositions of G.

Parameters

The framework of parameterized complexity allows the study of the TREEWIDTH problem with respect to different *parameters*. A parameter is simply an integer value associated with each problem instance. The *standard parameter* for an optimization problem like TREEWIDTH is the desired solution quality k and we denote this problem by TREEWIDTH(k). Apart from this, *structural parameters* are considered that capture structural aspects of G. For example, the work considers the behavior of TREEWIDTH when the input graph G has a small vertex cover S, i.e., such that deletion of $\ell = |S|$ vertices yields an independent set, with ℓ being used as the parameter. Similarly, several other parameters are discussed, foremost among them the feedback vertex set number and the vertex deletion distance to a single clique; the corresponding vertex sets are called *modulators*, e.g., a feedback vertex set is a modulator to a forest. We denote the arising parameterized problems by TREEWIDTH(vc), TREEWIDTH(fvs), and TREEWIDTH($\mathsf{vc}(\overline{G})$). To decouple the overhead of finding, e.g., a mini-

mum vertex cover for G, all these variants assume that an appropriate modulator is given along with the input and the obtained guarantees are in terms of the size of this modulator. Since all studied parameters can be efficiently approximated to within a constant factor of the optimum, not providing an (optimal) modulator gives only a constant-factor blowup in the obtained results.

Kernelization

A kernelization for a problem with parameter ℓ is an efficient algorithm that given an instance (x, ℓ) returns an equivalent instance (x', ℓ') of size and parameter value ℓ' bounded by some computable function of ℓ. If the bound is polynomial in ℓ then we have a *polynomial kernelization*. Specialized to, for example, TREEWIDTH(vc) a polynomial kernelization would have the following behavior: It gets as input an instance (G, S, k), asking whether the treewidth of G is at most k, where S is a vertex cover for G. In polynomial time it creates an instance (G', S', k') such that: (1) The size of the instance (G', S', k') and the parameter value $|S'|$ are bounded polynomially in k; (2) The set S' is a vertex cover of G'; (3) The graph G has treewidth at most k if and only if G' has treewidth at most k'.

Key Results

The kernelization lower bound framework of Bodlaender et al. [6] together with recent results of Drucker [9] is known to imply that TREEWIDTH(k) admits no polynomial kernelization unless NP $\subseteq$ coNP/poly and the polynomial hierarchy collapses. The present work takes a more detailed look at polynomial kernelization for TREEWIDTH with respect to structural parameters. The results are as follows.

Theorem 1 TREEWIDTH(vc) *i.e., parameterized by vertex cover number, admits a polynomial kernelization to an equivalent instance with* $\mathcal{O}((\mathsf{vc}(G))^3)$ *vertices.*

An interesting feature of this result is that it uses only three simple reduction rules that are well known and often used (cf. [5]). Two rules address so-called simplicial vertices, whose neighborhood is a clique, and a third rule inserts edges between certain pairs of vertices that have a large number of shared vertices. Analyzing these empirically successful rules with respect to the vertex cover number of the input graph yields a kernelization. A fact that nicely complements the observed experimental success.

Theorem 2 TREEWIDTH(fvs) *i.e., parameterized by feedback vertex set number, admits a polynomial kernelization to an equivalent instance with* $\mathcal{O}((\mathsf{fvs}(G))^4)$ *vertices.*

The feedback vertex set number of a graph is upper bounded by its vertex cover number, and forests have feedback vertex set number zero but arbitrarily large vertex cover number. Thus, for large families of input graphs, this second result is stronger. The result again builds on several known reduction rules (including the above ones), among others, for handling vertices that are *almost simplicial*, i.e., all but one neighboring vertex form a clique. On top of these, several new rules are added. One of them addresses a previously uncovered case of almost simplicial vertex removal, namely, when the vertex has degree exactly $k + 1$, where k is the desired treewidth bound. Furthermore, these reduction rules lead to a structure dubbed *clique-seeing paths*, which takes a series of fairly technical rules and analysis to reduce and bound. Altogether, this combination leads to the above result.

Theorem 3 TREEWIDTH($\mathsf{vc}(\overline{G})$) *i.e., parameterized by deletion distance to a single clique, admits no polynomial kernelization unless* NP $\subseteq$ coNP/poly *and the polynomial hierarchy collapses.*

The proof uses the notion of a *cross-composition* introduced by Bodlaender et al. [8], which builds directly on the kernelization lower bound framework of Bodlaender et al. [6] and Fortnow and Santhanam [10]. The cross-composition builds on the proof of NP-

completeness of TREEWIDTH by Arnborg et al. [1], which uses a Karp reduction from CUTWIDTH to TREEWIDTH. This construction is extended significantly to yield a cross-composition of CUTWIDTH ON SUBCUBIC GRAPHS (i.e., graphs of maximum degree three) into TREEWIDTH, which, roughly, requires an encoding of many CUTWIDTH instances into a single instance of TREEWIDTH with sufficiently small parameter.

Overall, together with previously known results, the obtained upper and lower bounds for TREEWIDTH cover a wide range of natural parameter choices (see the discussion in [7]). If $\mathcal{C}$ is any graph class that contains all cliques, then the vertex deletion distance of a graph G to $\mathcal{C}$ is upper bounded by $\mathsf{vc}(\overline{G})$. Thus, TREEWIDTH parameterized by distance to $\mathcal{C}$ does not admit a polynomial kernelization unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. This includes several well-studied classes like interval graphs, cographs, and perfect graphs. Since TREEWIDTH remains NP-hard on bipartite graphs, the result for parameterization by feedback vertex set number cannot be generalized to vertex deletion to a bipartite graph. It may, however, be possible to generalize this parameter to vertex deletion distance to an outerplanar graph, i.e., planar graphs having an embedding with all vertices appearing on the outer face. Since these graphs generalize forests, this value is upper bounded by the feedback vertex set number.

Theorem 4 WEIGHTED TREEWIDTH(vc) *i.e., parameterized by vertex cover number, admits no polynomial kernelization unless* $\mathsf{NP} \subseteq \mathsf{coNP/poly}$ *and the polynomial hierarchy collapses.*

In the WEIGHTED TREEWIDTH problem, each vertex comes with an integer weight, and the size of a bag in the tree decomposition is defined as the sum of the weights of its vertices. (To note, the present paper uses an extra deduction of one such that treewidth and weighted treewidth coincide for graphs with all vertices having weight one.) The result is proved by a cross-composition from TREEWIDTH (to WEIGHTED TREEWIDTH parameterized by vertex cover number) and complements the polynomial kernelization for the unweighted case. A key idea for the cross-composition is to use a result of Bodlaender and Möhring [4] on the behavior of treewidth under the join operation on graphs. This is combined with replacing all edges (in input graphs and join edges) by using a small number of newly introduced vertices of high weight.

Open Problems

A particular interesting case left open by existing results on polynomial kernelization for structural parameterizations of TREEWIDTH is the vertex deletion distance to outerplanar graphs.

Definition and Discussion

The basic definition of the field expresses kernelization as a Karp (many-one) self-reduction. Classical complexity and recursion theory offers quite a lot of alternative and more general notions of reducibilities. The most general notion, that of a Turing reduction, motivates the following definition:

Let (Q, κ) be a parameterized problem over a finite alphabet Σ.

- An *input-bounded oracle* for (Q, κ) is an oracle that, for any given input $x \in \Sigma^*$ of (Q, κ) and any bound t, first checks if $|x|, |\kappa(x)| \leq t$, and if this is certified, it decides in constant time whether the input x is a YES instance of (Q, κ).
- A *Turing kernelization (algorithm)* for (Q, κ) is an algorithm that, provided with access to some input-bounded oracle for (Q, κ), decides on input $x \in \Sigma^*$ in polynomial time whether x is a YES instance of (Q, κ) or not. During its computation, the algorithm can produce (polynomially many) oracle queries x' with bound $t = h(\kappa(x))$, where h is an arbitrary computable function. The function h is referred to as the *size* of the kernel.

If only one oracle access is permitted in a run of the algorithm, we basically get the classical notion of a (many-one or Karp) kernelization.

A more general definition was given in [4], allowing access to a different (auxiliary) problem (Q', κ'). As long as there is a computable reduction from Q' to Q, this does not make much of a difference, as we could translate the queries to Q' into queries of Q. Therefore, we prefer to use the definition given in [1].

Out-Branching: Showing the Difference

In [1], the first example of a natural problem is provided that admits a Turing kernel of polynomial size, but (most likely) no Karp kernel of polynomial size. We provide some details in the following.

Problem Definition

A subdigraph T of a digraph D is an *out-tree* if T is an oriented tree with only one vertex r of indegree zero (called the *root*). The vertices of T of outdegree zero are called *leaves*. If T is a spanning out-tree, i.e., $V(T) = V(D)$, then T is called an *out-branching* of D. The Directed Maximum Leaf Out-Branching problem is to find an out-branching in a given digraph with the maximum number of leaves. The parameterized version of the Directed Maximum Leaf Out-Branching problem is k-Leaf Out-Branching, where for a given digraph D and integer k, it is asked to decide whether D has an out-branching with at least k leaves. If we replace "out-branching" with "out-tree" in the definition of k-Leaf Out-Branching, we get a problem called k-Leaf

OUT-TREE. The parameterization κ is set to k in both problems. As the two problems are easily translatable into each other, we focus on k-LEAF OUT-BRANCHING as the digraph analogue of the well-known MAXIMUM LEAF SPANNING TREE problem.

Key Results

It is shown that the problem variant where an explicit root is given as additional input, called ROOTED k-LEAF OUT-BRANCHING, admits a polynomial Karp kernel. Alternatively, this variant can be seen as a special case of k-LEAF OUT-BRANCHING by adding one vertex of indegree zero and outdegree one, pointing to the designated root of the original graph. By making a call to this oracle for each of the vertices as potential roots, this provides a Turing kernelization of polynomial size for k-LEAF OUT-BRANCHING. This result is complemented by showing that k-LEAF OUT-TREE has no polynomial Karp kernel unless $coNP \subseteq NP/poly$.

We list the reduction rules leading to the polynomial-size kernel for the rooted version in the following.

Reachability Rule:If there exists a vertex u which is disconnected from the root r, then return NO.

Useless Arc Rule:If vertex u disconnects a vertex v from the root r, then remove the arc vu.

Bridge Rule:If an arc uv disconnects at least two vertices from the root r, contract the arc uv.

Avoidable Arc Rule:If a vertex set S, $|S| \leq 2$, disconnects a vertex v from the root r, $vw \in A(D)$ and $xw \in A(D)$ for all $x \in S$, then delete the arc vw.

Two Directional Path Rule:If there is a path $P = p_1 p_2 \ldots p_{l-1} p_l$ with $l = 7$ or $l = 8$ such that

- p_1 and $p_{\text{in}} \in \{p_{l-1}, p_l\}$ are the only vertices with in-arcs from the outside of P
- p_l and $p_{\text{out}} \in \{p_1, p_2\}$ are the only vertices with out-arcs to the outside of P
- The path P is the unique out-branching of $D[V(P)]$ rooted at p_1
- There is a path Q that is the unique out-branching of $D[V(P)]$ rooted at p_{in} and ending in p_{out}
- The vertex after p_{out} on P is not the same as the vertex after p_l on Q
