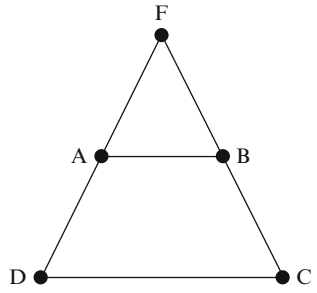
The Steiner tree problem was proposed by Gauss in 1835 as a generalization of the Fermat problem. Given three points A, B, and C in the Euclidean plane, Fermat studied the problem of finding a point S to minimize $|SA| + |SB| + |SC|$. He determined that when all three inner angles of triangle ABC are less than 120°, the optimal S should be at the position that $\angle ASB = \angle BSC = \angle CSA = 120°$.

The generalization of the Fermat problem has two directions:

1. Given n points in the Euclidean plane, find a point S to minimize the total distance from S to n given points. This is still called the Fermat problem.
2. Given n points in the Euclidean plane, find the shortest network interconnecting all given points.

Gauss found the second generalization through communication with Schumacher. On March 19, 1836, Schumacher wrote a letter to Gauss and mentioned a paradox about Fermat's problem: Consider a convex quadrilateral $ABCD$. It is known that the solution of Fermat's problem for four points A, B, C, and D is the intersection E of diagonals AC and BD. Suppose extending DA and CB can obtain an intersection F. Now, move A and B to F. Then E will also be moved to F. However, when the angle at F is less than 120°, the point F cannot be the solution of Fermat's problem for three given points F, D, and C. What happens? (Fig. 1.)

On March 21, 1836, Gauss wrote a letter replying to Schumacher in which he explained that the mistake of Schumacher's paradox occurs at the place where Fermat's problem for four points A, B, C, and D is changed to Fermat's problem for three points F, C, and D. When A and B are identical to F, the total distance from E to four points A, B, C, and D equals $2|EF| + |EC| + |ED|$, not $|EF| + |EC| + |ED|$. Thus,



Steiner Trees, Fig. 1 Convex quadrilateral $ABCD$, Fermat's problem

the point E may not be the solution of Fermat's problem for F, C, and D. More importantly, Gauss proposed a new problem. He said that it is more interesting to find the shortest network rather than a point. Gauss also presented several possible connections of the shortest network for four given points.

It was unfortunate that Gauss' letter was not seen by researchers of Steiner trees at an earlier stage. Especially, R. Courant and H. Robbins who in their popular book *What is mathematics?* (published in 1941) [6] called Gauss' problem the Steiner tree so that "Steiner tree" became a popular name for the problem.

The Steiner tree became an important research topic in mathematics and computer science due to its applications in telecommunication and computer networks. Starting with Gilbert and Pollak's work published in 1968, many publications on Steiner trees have been generated to solve various problems concerning it.

One well-known problem is the *Gilbert-Pollak conjecture* on the Steiner ratio, which is the least ratio of lengths between the Steiner minimum tree and the minimum spanning tree on the same set of given points. Gilbert and Pollak in 1968 conjectured that the Steiner ratio in the Euclidean plane is $\sqrt{3}/2$ which is achieved by three vertices of an equilateral triangle. A great deal of research effort has been put into the conjecture and it was finally proved by Du and Hwang [7].

Another important problem is called the *better approximation*. For a long time no approximation could be proved to have a performance ratio smaller than the inverse of the Steiner ratio. Zelikovsky [14] made the first breakthrough. He found a polynomial-time 11/6-approximation for NST which beats 1/2, the inverse of the Steiner ratio in the edge-weighted network. Later, Berman and Ramaiye [2] gave a polynomial-time 92/72-approximation for RST, and Du, Zhang, and Feng [8] closed the story by showing that in any metric space, there exists a polynomial-time approximation with a performance ratio better than the inverse of the Steiner ratio provided that for any set of a fixed number of points, the Steiner minimum tree is polynomial-time computable.

All the above better approximations came from the family of k-restricted Steiner trees. By improving some detail of construction, the constant performance ratio was decreasing, but the improvements were also becoming smaller. In 1996, Arora [1] made significant progress for EST and RST. He showed the existence of PTAS for EST and RST. Therefore, the theoretical researchers now pay more attention to NST. Bern and [3] showed that NST is MAX SNP-complete. This means that there exists a positive number r; computing the r-approximation for NST is NP-hard. The best-known performance for NST was given by Robin and Zelikovsky [12]. They also gave a very simple analysis to a well-known heuristic, the iterated 1-Steiner tree for pseudo-bipartite graphs.

Analysis of the iterated 1-Steiner tree is another long-standing open problem. Since Chang [4,5] proposed that the iterated 1-Steiner tree approximates the Steiner minimum tree in 1972, its performance has been claimed to be very good through computer experiments [10, 13], but no theoretical analysis supported this claim. Actually, both the k-restricted Steiner tree and the iterated 1-Steiner tree are obtained by greedy algorithms, but with different types of potential functions. For the iterated 1-Steiner tree, the potential function is non-submodular, but for the k-restricted Steiner tree, it is submodular; a property that holds for k-restricted Steiner trees may not hold for iterated 1-Steiner trees. Actually, the submodularity of potential function is very important in analysis of greedy approximations [11]. Du et al. [9] gave a correct analysis for the iterated 1-Steiner tree with a general technique to deal with non-submodular potential function.

Key Results

Consider input edge-weighted graph $G = (V, E)$ of NST. Assume that G is a complete graph and the edge weight satisfies the triangular inequality; otherwise, consider the complete graph on V with each edge (u, v) having a weight equal to the length of the shortest path between u and v in G. Given a set P of terminals, a *Steiner tree* is a

tree interconnecting all given terminals such that every leaf is a terminal.

In a Steiner tree, a terminal may have degree more than one. The Steiner tree can be decomposed, at those terminals with degree more than one, into smaller trees in which every terminal is a leaf. In such a decomposition, each resulting small tree is called a *full component*. The *size* of a full component is the number of terminals in it. A Steiner tree is *k-restricted* if every full component of it has a size at most k. The shortest k-restricted Steiner tree is also called the *k-restricted Steiner minimum tree*. Its length is denoted by $smt_k(P)$. Clearly, $smt_2(P)$ is the length of the minimum spanning tree on P, which is also denoted by $mst(P)$. Let $smt(P)$ denote the length of the Steiner minimum tree on P. If $smt_3(P)$ can be computed in polynomial time, then it is better than $mst(P)$ for an approximation of $smt(P)$. However, so far no polynomial-time approximation has been found for $smt_3(P)$. Therefore, Zelikovsky [14] used a greedy approximation of $smt_3(P)$ to approximate $smt(P)$. Actually, Chang [4, 5] used a similar greedy algorithm to compute an iterated 1-Steiner tree. Let $\mathcal{F}$ be a family of subgraphs of input edge-weighted graph G. For any connected subgraph H, denote by $mst(H)$ the length of the minimum spanning tree of H, and for any subgraph H, denote by $mst(H)$ the sum of $mst(H')$ for H' over all connected components of H. Define

$$gain(H) = mst(P) - mst(P : H) - mst(H),$$

where $mst(P : H)$ is the length of the minimum spanning tree interconnecting all unconnected terminals in P after every edge of H shrinks into a point.

Greedy Algorithm $H \leftarrow \emptyset$;
while P has not been interconnected by H **do** choose $F \in \mathcal{F}$ to maximize $gain(H \cup F)$;
output $mst(H)$.

When $\mathcal{F}$ consists of all full components of size at most three, this greedy algorithm gives the 3-restricted Steiner tree of Zelikovsky [14]. When $\mathcal{F}$ consists of all 3-stars and all edges where a 3-star is a tree with three leaves and a central vertex, this greedy algorithm produces the iterated 1-Steiner tree. An interesting fact pointed out by Du et al. [9] is that the function $gain(\cdot)$ is submodular over all full components of size at most three, but not submodular over all 3-stars and edges.

Let us consider a base set E and a function f from all subsets of E to real numbers. f is *submodular* if for any two subsets A, B of E,

$$f(A) + f(B) \geq f(A \cup B) + f(A \cap B).$$

For $x \in E$ and $A \subseteq E$, denote $\Delta_x f(A) = f(A \cup \{x\}) - f(A)$.

Lemma 1 *f is submodular if and only if for any $A \subset E$ and distinct $x, y \in E - A$,*

$$\Delta_x \Delta_y f(A) \leq 0. \tag{1}$$

Proof Suppose f is submodular. Set $B = A \cup \{x\}$ and $C = A \cup \{y\}$. Then $B \cup C = A \cup A \cup \{x, y\}$ and $B \cap C = A$. Therefore, one has

$$f(A \cup \{x, y\}) - f(A \cup \{x\}) - f(A \cup \{y\}) + f(A) \leq 0,$$

that is, (1) holds.

Conversely, suppose (1) holds for any $A \subset E$ and distinct $x, y \in E - A$. Consider two subsets A, B of E. If $A \subseteq B$ or $B \subseteq A$, it is trivial to have

$$f(A) + f(B) \geq f(A \cup B) + f(A \cap B).$$

Therefore, one may assume that $A \backslash B \neq \emptyset$ and $B \backslash A \neq \emptyset$. Write $A \backslash B = \{x_1, \ldots, x_k\}$ and $B \backslash A = \{y_1, \ldots, y_h\}$. Then

$$\begin{aligned} & f(A \cup B) - f(A) - f(B) + f(A \cap B) \\ &= \sum_{i=1}^{k} \sum_{j=1}^{h} \Delta_{x_i} \Delta_{y_j} f(A \cup \{x_1, \ldots, x_{i-1}\} \cup \{y_1, \ldots, y_{j-1}\}) \\ &\leq 0, \end{aligned}$$

where $\{x_1, \ldots x_{i-1}\} = \emptyset$ for $i = 1$ and $\{y_1, \ldots, y_{j-1}\} = \emptyset$ for $j = 1$. □

Lemma 2 *Define $f(H) = -mst(P : H)$. Then f is submodular over edge set E.*

Proof Note that for any two distinct edges x and y not in subgraph H,

$$\begin{aligned}
&\Delta_x \Delta f(H) \\
&\quad = -mst(P : H \cup x \cup y) + mst(P : H \cup x) \\
&\qquad + mst(P : H \cup y) - mst(P : H) \\
&\quad = (mst(P : H) - mst(P : H \cup x \cup y)) \\
&\qquad - (mst(P : H) - mst(P : H \cup x)) \\
&\qquad + (mst(P : H) - mst(P : H \cup y)).
\end{aligned}$$

Let T be a minimum spanning tree for unconnected terminals after every edge of H shrinks into a point. T contains a path P_x connecting two endpoints of x and also a path P_y connecting two endpoints of y. Let e_x (e_y) be a longest edge in P_x (P_y). Then

$$\begin{aligned}
mst(P : H) - mst(P : H \cup x) &= length(e_x), \\
mst(P : H) - mst(P : H \cup y) &= length(e_y).
\end{aligned}$$

$mst(P : H) - mst(P : H \cup x \cup y)$ can be computed as follows: Choose a longest edge $e\prime$ from $P_x \cup P_y$. Note that $T \cup x \cup y - e'$ contains a unique cycle Q. Choose a longest edge $e\prime\prime$ from $(P_x \cup P_y) \cap Q$. Then

$$mst(P : H) - mst(P : H \cup x \cup y) = length(e'')$$

Now, to show the submodularity of f, it suffices to prove

$$length(e_x) + length(e_y) \geq length(e'') \quad (2)$$

Case 1. $e_x P_x \cap P_y$ and $e_y P_x \cap P_y$. Without loss of generality, assume $length(e_x) \geq length(e_y)$. Then one may choose $e' = e_x$ so that $(P_x \cup P_y) \cap Q = P_y$. Hence, one can choose $e'' = e_y$. Therefore, the equality holds for (2).

Case 2. $e_x P_x \cap P_y$ and $e_y \in P_x \cap P_y$. Clearly, $length(e_x) \geq length(e_y)$. Hence, one may choose $e' = e_x$ so that $(P_x \cup P_y) \cap Q = P_y$. Hence, one can choose $e'' = e_y$. Therefore, the equality holds for (2).

Case 3. $e_x \in P_x \cap P_y$ and $e_y P_x \cap P_y$. Similar to Case 2.

Case 4. $e_x \in P_x \cap P_y$ and $e_y \in P_x \cap P_y$. In this case, $length(e_x) = length(e_y) = length(e')$. Hence, (2) holds. □

The following explains that the submodularity of $gain(\cdot)$ holds for a k-restricted Steiner tree.

Theorem 1 *Let ε be the set of all full components of a Steiner tree. Then $gain(\cdot)$ as a function on the power set of ε is submodular.*

Proof Note that for any $\mathcal{H} \subset \mathcal{E}$ and $x, y \in \mathcal{E} - \mathcal{H}$,

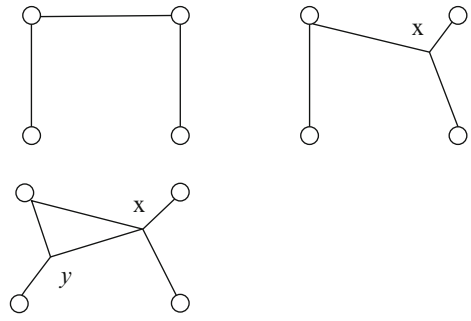
$$\Delta_x \Delta_y mst(H) = 0,$$

where $H = \cup_{z \in \mathcal{H}} z$. Thus, this theorem follows from Lemma 2.

Let $\mathcal{F}$ be the set of 3-stars and edges chosen in the greedy algorithm to produce an iterated 1-Steiner tree. Then $gain(\cdot)$ may not be submodular on $\mathcal{F}$. To see this fact, consider two 3-stars x and y in Fig. 2. Note that $gain(x \cup y) > gain(x), gain(y) \leq 0$, and $gain(\emptyset) = 0$. One has

$$gain(x \cup y) - gain(x) - gain(y) + gain(\emptyset) > 0.$$

□



Steiner Trees, Fig. 2 An example for the proof of Theorem 1

Applications

The Steiner tree problem is a classic NP-hard problem with many applications in the design of computer circuits, long-distance telephone lines, multicast routing in communication networks, etc. There exist many heuristics of the greedy type for Steiner trees in the literature. Most of them have a good performance in computer experiments, without support from theoretical analysis. The approach given in this work may apply to them.

Open Problems

It is still open whether computing the 3-restricted Steiner minimum tree is NP-hard or not. For $k \geq 4$, it is known that computing the k-restricted Steiner minimum tree is NP-hard.

Problem Definition

This problem deals with packing a maximum reward set of items into a knapsack of given capacity, when the item sizes are random. The input is a collection of n items, where each item $i \in [n] := \{1, \ldots, n\}$ has reward $r_i \geq 0$ and

size $S_i \geq 0$, and a knapsack capacity $B \geq 0$. In the *stochastic knapsack* problem, all rewards are deterministic but the sizes are random. The random variables S_is are independent with known, arbitrary distributions. The actual size of an item is known only when it is placed into the knapsack. The objective is to add items sequentially (one by one) into the knapsack so as to maximize the expected reward of the items that fit into the knapsack. As usual, a subset T of items is said to fit into the knapsack if the total size $\sum_{i \in T} S_i$ is at most the knapsack capacity B.

A feasible solution (or policy) to the stochastic knapsack problem is represented by a decision tree. Nodes in this decision tree denote the current "state" of the solution (i.e., previously added items and the residual knapsack capacity) as well as the new item to place into the knapsack at this state. Branches in the decision tree denote the random size instantiations of items placed into the knapsack. Such solutions are called *adaptive policies*, to emphasize the fact that the items being placed may depend on previously observed outcomes. More formally, an adaptive policy is given by a mapping $\pi : 2^{[n]} \times [0, B] \to [n]$, where $\pi(T, C)$ denotes the next item to place into the knapsack when some subset $T \subseteq [n]$ of items has already been added, and $C = B - \sum_{i \in T} S_i$ is the residual knapsack capacity. The policy ends when the knapsack overflows (i.e., the total size of items added exceeds the knapsack capacity); we use the convention that no reward is obtained from the last overflowing item.

Notice that an arbitrary adaptive policy may require exponential space to even store. This motivates a special class of solutions, called *nonadaptive policies*. A nonadaptive policy is just specified by a fixed ordering of the n items, and the solution adds items into the knapsack in that order (irrespective of the actual size instantiations) until the knapsack overflows. Again, there is no reward obtained from the last overflowing item. While it may be easier to obtain a good nonadaptive policy, the obvious drawback is that nonadaptive policies may perform much worse than adaptive policies. The benefit of being adaptive is quantified by a measure called the *adaptivity gap*, which is the maximum ratio (over all instances) of the expected reward of an optimal adaptive policy to the expected reward of an optimal nonadaptive policy.

In both the adaptive and nonadaptive settings, the stochastic knapsack problem is at least NP-hard, since it generalizes the deterministic knapsack problem. Moreover, certain questions regarding adaptive policies are PSPACE-hard [4].

Notation We assume that the item size distributions are given explicitly. For any item $i \in [n]$ define its effective reward $w_i = r_i \cdot \Pr[S_i \leq B]$ and its mean truncated size $\mu_i = \mathbb{E}[\min\{S_i, B\}]$. Note that the expected reward obtained by placing the single item i into the knapsack is exactly w_i.

Key Results

Dean, Goemans, and Vondrák introduced the stochastic knapsack problem and the notion of adaptivity gaps. They proved the following.

Theorem 1 ([4]) *There is a polynomial time algorithm for the stochastic knapsack problem that computes a nonadaptive policy having expected reward at least $\frac{1}{4}$ that of an optimal adaptive policy.*

As a consequence, the adaptivity gap of the stochastic knapsack problem is also upper bounded by four. Dean, Goemans, and Vondrák [4] also showed an instance of stochastic knapsack that lower bounds the adaptivity gap by $\frac{5}{4}$.

The algorithm in Theorem 1 uses a natural greedy approach. It outputs the better of the following two nonadaptive policies:

- Place the single item $i^* = \arg\max_{i \in [n]} w_i$.
- Place items in nonincreasing order of w_i / μ_i.

In terms of adaptive policies, Bhalgat, Goel, and Khanna proved the following.

Theorem 2 ([2, 3]) *For any constant $\epsilon > 0$, there is polynomial time algorithm for the stochastic knapsack problem that computes an*

adaptive policy having expected reward at least $\frac{1}{2+\epsilon}$ *that of an optimal adaptive policy.*

The algorithm in Theorem 2 relies on an intricate transformation of general size distributions to certain canonical distributions and an algorithm for computing a near-optimal adaptive policy under canonical size distributions.

Extensions

Several variants of the stochastic knapsack problem have been studied, and good algorithms have been obtained for them.

Correlated Stochastic Knapsack

This is a generalization of the stochastic knapsack problem, where each item's reward is also random and possibly correlated with its size. The distributions across items are still independent: so the correlations are only between the size and reward of a single item. Gupta, Krishnaswamy, Molinaro, and Ravi [6] gave an algorithm for this problem that computes a nonadaptive policy having expected reward within factor 8 of the optimal adaptive policy. Recently, Ma [8] gave an algorithm that for any constant $\epsilon > 0$ computes an adaptive policy having expected reward within factor $2 + \epsilon$ of the optimal adaptive policy; this algorithm requires item sizes and the capacity B to be specified in unary.

Budgeted Multi-armed Bandit

The input to this problem consists of a bound B and n "arms" (each arm is a Markov chain with rewards at its states and a specified starting state). A feasible policy consists of B steps. In each step, the policy can select one arm $i \in [n]$: upon selecting arm i, it gets the reward at the current state of arm i and the arm transitions to its next state according to its Markov chain. The objective is to maximize the expected total reward over B steps of the policy. Again, we are interested in adaptive policies, whose actions may depend on past outcomes. Guha and Munagala [5] introduced this problem and gave a $(2 + \epsilon)$-approximation algorithm, under the assumption that the rewards of each arm satisfy a "Martingale" condition (which is natural in many settings). Gupta, Krishnaswamy, Molinaro, and Ravi [6] gave the first constant-factor approximation algorithm for this problem without the Martingale reward assumption. The constant factor in the latter result was improved to 6.75 by Ma [8].

Stochastic Orienteering

This problem is defined on a finite metric space (V, d) with vertex set V and distance function $d : V \times V \to \mathbb{R}_+$ that satisfies (i) symmetry $d(u, v) = d(v, u)$ for all $u, v \in V$ and (ii) triangle inequality $d(u, w) \leq d(u, v) + d(v, w)$ for all $u, v, w \in V$. The distances between vertices denote travel times. Each vertex $i \in V$ corresponds to a job having deterministic reward $r_i \geq 0$ and random processing time $S_i \geq 0$. The random variables S_is are independent with known, arbitrary distributions. Given a start-vertex $\rho \in V$ and bound B, the goal is to compute a policy, which describes a (possibly adaptive) path originating from ρ that visits vertices and runs the respective jobs. The actual processing time of a job is known only when it completes. The policy ends when the total time (for travel plus processing) exceeds B. The objective is to maximize the expected total reward; there is no reward obtained from a partially completed job (which may occur at the end of the policy). As before, an optimal policy may be adaptive and choose the next job to run based on previously observed outcomes. Gupta, Krishnaswamy, Nagarajan, and Ravi [7] gave an $O(\log \log B)$-approximation algorithm for the stochastic orienteering problem; this result requires the bound B, distances, and processing times to be integer valued. As a corollary, [7] also upper bounded the adaptivity gap by $O(\log \log B)$. Recently, Bansal and Nagarajan [1] gave an $\Omega\left(\sqrt{\log \log B}\right)$ lower bound on the adaptivity gap.

Applications

The stochastic knapsack problem and its variants model various applications in advertising, logistics, medical diagnosis, and robotics.

Open Problems

It is not known if the stochastic knapsack problem is any harder to approximate than the usual (deterministic) knapsack problem. In particular, is there a PTAS for stochastic knapsack? Determining a tight bound on its adaptivity gap is also an interesting open question.

Stochastic Scheduling

Jay Sethuraman
Industrial Engineering and Operations Research, Columbia University, New York, NY, USA

Keywords

Queueing; Sequencing

Years and Authors of Summarized Original Work

2001; Glazebrook, Nino-Mora

Problem Definition

Scheduling is concerned with the allocation of scarce resources (such as machines or servers) to competing activities (such as jobs or customers) over time. The distinguishing feature of a *stochastic* scheduling problem is that some of the relevant data are modeled as *random variables*, whose distributions are known, but whose actual realizations are not. Stochastic scheduling problems inherit several characteristics of their deterministic counterparts. In particular, there are virtually an unlimited number of problem types depending on the machine environment (single machine, parallel machines, job shops, flow shops), processing characteristics (preemptive versus nonpreemptive, batch scheduling versus allowing jobs to arrive "over time," due dates, deadlines), and objectives (makespan, weighted completion time, weighted flow time, weighted tardiness). Furthermore, stochastic scheduling models have some new, interesting features (or difficulties!):

- The scheduler may be able to make inferences about the remaining processing time of a job by using information about its elapsed processing time; whether the scheduler is allowed to make use of this information or not is a question for the modeler.
- Many scheduling algorithms make decisions by comparing the processing times of jobs. If jobs have deterministic processing times, this poses no problems as there is only one way to compare them. If the processing times are random variables, comparing processing times is a subtle issue. There are many ways to compare pairs of random variables, and some are only *partial* orders. Thus, any algorithm that operates by comparing processing times must now specify the particular ordering used to

compare random variables (and to determine what to do if two random variables are not comparable under the specified ordering).

These considerations lead to the notion of a scheduling *policy*, which specifies how the scarce resources have to be allocated to the competing activities as a function of the *state* of the system at any point in time. The state of the system includes information such as prior job completions, the elapsed time of jobs currently in service, the realizations of the random release dates and due dates (if any), and any other information that can be inferred based on the history observed so far. A policy that is allowed to make use of all this information is said to be *dynamic*, whereas a policy that is not allowed to use any state information is *static*.

Given any policy, the objective function for a stochastic scheduling model operating under that policy is typically a random variable. Thus, comparison of two policies entails the comparison of the associated random variables, so the *sense* in which these random variables are compared must be specified. A common approach is to find a solution that optimizes the *expected value* of the objective function (which has the advantage that it is a total ordering); less commonly, other orderings such as the stochastic ordering or the likelihood ratio ordering are used.

Key Results

Consider a single machine that processes n jobs, with the (random) processing time of job i given by a distribution $F_i(\cdot)$ whose mean is p_i. The Weighted Shortest Expected Processing Time first (WSEPT) rule sequences the jobs in decreasing order of w_i / p_i. Smith [13] proved that the WSEPT rule minimizes the sum of weighted completion times when the processing times are deterministic. Rothkopf [11] generalized this result and proved the following:

Theorem 1 *The WSEPT rule minimizes the expected sum of the weighted completion times in the class of all nonpreemptive dynamic policies (and hence also in the class of all nonpreemptive static policies).*

If preemption is allowed, the WSEPT rule is not optimal. Nevertheless, Sevcik [12] showed how to assign an "index" to each job at each point in time such that scheduling a job with the largest index at each point in time is optimal. Such policies are called index policies and have been investigated extensively because they are (relatively) simple to implement and analyze. Often, the optimality of index policies can be proved under some assumptions on the processing time distributions. For instance, Weber, Varaiya, and Walrand [14] proved the following result for scheduling n jobs on m identical parallel machines:

Theorem 2 *The SEPT rule minimizes the expected sum of completion times in the class of all nonpreemptive dynamic polices, if the processing time distributions of the jobs are stochastically ordered.*

For the same problem but with the makespan objective, Bruno, Downey, and Frederickson [3] proved the optimality of the Longest Expected Processing Time first rule provided all the jobs have exponentially distributed processing times.

One of the most significant achievements in stochastic scheduling is the proof of optimality of index policies for the multiarmed bandit problem and its many variants, due originally to Gittins and Jones [5, 6]. In an instance of the bandit problem, there are N projects, each of which is in any one of a possibly finite number of states. At each (discrete) time, any one of the projects can be attempted, resulting in a random reward; the attempted project undergoes a (Markovian) state transition, whereas the other projects remain frozen and do not change state. The goal of the decision maker is to determine an optimal way to attempt the projects so as to maximize the total discounted reward. Of course one can solve this problem as a large, stochastic dynamic program, but such an approach does not reveal any structure and is moreover computationally impractical

except for very small problems. (Also, if the state space of any project is countable or infinite, it is not clear how one can solve the resulting DP exactly!) The remarkable result of Gittins and Jones [6] is the optimality of index policies: to each state of each project, one can associate an index so that attempting a project with the largest index at any point in time is optimal. The original proof of Gittins and Jones [6] has subsequently been simplified by many authors; moreover, several alternative proofs based on different techniques have appeared, leading to a much better understanding of the class of problems for which index policies are optimal [2, 4, 5, 10, 17].

While index policies are easy to implement and analyze, they are often not optimal in many problems. It is therefore natural to investigate the gap between an optimal index policy (or a natural heuristic) and an optimal policy. For example, the WSEPT rule is a natural heuristic for the problem of scheduling jobs on identical parallel machines to minimize the expected sum of the weighted completion times. However, the WSEPT rule is not necessarily optimal. Weiss [16] showed that, under mild and reasonable assumptions, the expected number of times that the WSEPT rule differs from the optimal decision is bounded above by a *constant*, independent of the number of jobs. Thus, the WSEPT rule is asymptotically optimal. As another example of a similar result, Whittle [18] generalized the multiarmed bandit model to allow for state transitions in projects that are *not* activated, giving rise to the "restless bandit" model. For this model, Whittle [18] proposed an index policy whose asymptotic optimality was established by Weber and Weiss [15].

A number of stochastic scheduling models allow for jobs to arrive over time according to a stochastic process. A commonly used model in this setting is that of a multiclass queueing network. Multiclass queueing networks serve as useful models for problems in which several types of *activities* compete for a limited number of shared *resources*. They generalize deterministic job-shop problems in two ways: jobs arrive *over time* and each job has a *random* processing time at each stage. The optimal control problem in a multiclass queueing network is to find an optimal allocation of the available resources to activities over time. Not surprisingly, index policies are optimal only for restricted versions of this general model. An important example is scheduling a multiclass single-server system with feedback: there are N types of jobs; type i jobs arrive according to a Poisson process with rate λ_i, require service according to a service-time distribution $F_i(\cdot)$ with mean processing time s_i, and incur holding costs at rate c_i per unit time. A type i job after undergoing processing becomes a type j job with probability p_{ij} or exits the system with probability $1-\sum_j p_{ij}$ isn't in document. The objective is to find a scheduling policy that minimizes the expected holding cost rate in steady state. Klimov [9] proved the optimality of index policies for this model, as well as for the objective in which the total discounted holding cost is to be minimized. While the optimality result does not hold when there are many parallel machines, Glazebrook and Niño-Mora [7] showed that this rule is asymptotically optimal. For more general models, the prevailing approach is to use approximations such as fluid approximations [1] or diffusion approximations [8].

Applications

Stochastic scheduling models are applicable in many settings, most prominently in computer and communication networks, call centers, logistics and transportation, and manufacturing systems [4, 10].

Problem Definition

Given a *pattern string* $P = p_1 p_2 \dots p_m$ and a *text string* $T = t_1 t_2 \dots t_n$, both being sequences over an alphabet Σ of size σ, the *exact string-matching (ESM)* problem is to find one or, more generally, all the text positions where P occurs in T, that is, compute the set $\{j \mid 1 \le j \le n-m+1 \text{ and } P = t_j t_{j+1} \dots t_{j+m-1}\}$.

Both worst- and average-case complexities are considered. For the latter one assumes that pattern and text are randomly generated by choosing each character uniformly and independently from Σ. For simplicity and practicality the assumption $m = o(n)$ is made in this entry.

Key Results

Most algorithms that solve the ESM problem proceed in two steps: a preprocessing phase of the pattern P followed by a searching phase over the

text T. The preprocessing phase serves to collect information on the pattern in order to speed up the searching phase.

The searching phase of string-matching algorithms works as follows: they first align the left ends of the pattern and the text, then compare the aligned symbols of the text and the pattern – this specific work is called an attempt or a scan – and after a whole match of the pattern or after a mismatch, they shift the pattern to the right. They repeat the same procedure again until the right end of the pattern goes beyond the right end of the text. The scanning part can be viewed as operating on the text through a window, which size is most often the length of the pattern. This processing manner is called the scan and shift mechanism. Different scanning strategies of the window lead to algorithms having specific properties and advantages.

The brute force algorithm for the ESM problem consists in checking if P occurs at each position j on T, with $1 \leq j \leq n - m + 1$. It does not need any preprocessing phase. It runs in quadratic time $O(mn)$ with constant extra space and performs $O(n)$ character comparisons on average. This is to be compared with the following bounds.

Theorem 1 (Cole et al. [6]) *The minimum number of character comparisons to solve the ESM problem in the worst case is* $n + \frac{9}{4m}(n - m)$, *and there exists an algorithm performing at most* $n + \frac{8}{3(m+1)}(n-m)$ *character comparisons in the worst case.*

Theorem 2 (Yao [26]) *The ESM problem needs* $\Omega\left(\frac{\log_\sigma m}{m} \times n\right)$ *time in expectation.*

Online Text Parsing

The first linear ESM algorithm appears in the 1970s. The preprocessing phase consists in computing the periods of the pattern prefixes, or equivalently the length of the longest border for all the prefixes of the pattern. A border of a string is both a prefix and a suffix of it distinct from the string itself. Let $next[i]$ be the length of the longest border of $p_1 \dots p_{i-1}$. Consider an attempt at position j, when the pattern $p_1 \dots p_m$ is aligned with the segment $t_j \dots t_{j+m-1}$ of the text. Assume that the first mismatch (during a left to right scan) occurs between symbols p_i and t_{i+j} for $1 \leq i \leq m$. Then, $p_1 \dots p_{i-1} = t_j \dots t_{i+j-1} = u$ and $a = p_i \neq t_{i+j} = b$. A prefix v of the pattern may match a suffix of the portion u of the text. By the definition of table *next*, a shift that aligns $p_{next[i]}$ with t_{i+j} cannot miss any occurrence of P in T, and thus backtracking in the text is not necessary. There exist two variants [18, 19], depending on whether $p_{next[i]}$ has to be different from p_i or not. The second is slightly more efficient.

Theorem 3 (Knuth, Morris, and Pratt [18]) *The text searching can be done in time* $O(n)$ *and space* $O(m)$. *Preprocessing the pattern can be done in time* $O(m)$.

The search can also be realized using an implementation with successor by default of the deterministic automaton $\mathcal{D}(P)$ recognizing the language $\Sigma^* P$. The size of the implementation is $O(m)$ independent of the alphabet size, due to the fact that $\mathcal{D}(P)$ possesses $m + 1$ states, m forward arcs, and at most m backward arcs. Using the automaton for searching a text leads to an algorithm having an efficient delay (maximum time for processing a character of the text).

Theorem 4 (Hancart [15]) *Searching for the pattern* P *can be done with a delay of* $O(min\{\sigma, \log_2 m)\})$ *letter comparisons.*

Note that for most algorithms the pattern preprocessing is not necessarily done before the text parsing, as it can be performed on the fly during the parsing.

Algorithms Sublinear on the Average

The Boyer-Moore algorithm [3] is among the most efficient ESM algorithms. A simplified version of it, or the entire algorithm, is often implemented in text editors for the search and substitute commands.

The algorithm scans the characters of the window from right to left beginning with its rightmost symbol. In case of a mismatch (or a complete match of the pattern), it uses two precomputed functions to shift the pattern to the right.

These two shift functions are called the *bad-character shift* and the *good-suffix shift*. They are based on the following observations. Assume that a mismatch occurs between character $p_i = a$ of the pattern and character $t_{i+j} = b$ of the text during an attempt at position j. Then, $p_{i+1} \dots p_m = t_{i+j+1} \dots t_{j+m} = u$ and $p_i \neq t_{i+j}$. The good-suffix shift consists in aligning the segment $t_{i+j+1} \dots t_{j+m}$ with its rightmost occurrence in P that is preceded by a character different from p_i. Another variant called the *best-suffix shift* consists in aligning the segment $t_{i+j} \dots t_{j+m}$ with its rightmost occurrence in P. Both variants can be computed in time and space $O(m)$ independent of the alphabet size. If there exists no such segment, the shift consists in aligning the longest suffix v of $t_{i+j+1} \dots t_{j+m}$ with a matching prefix of x. The bad-character shift consists in aligning the text character t_{i+j} with its rightmost occurrence in $p_1 \dots p_{m-1}$. If t_{i+j} does not appear in the pattern, no occurrence of P in T can overlap the symbol t_{i+j}, then the left end of the pattern is aligned with the character at position $i + j + 1$. The search can then be done in $O(n/m)$ in the best case.

Theorem 5 (Cole [5]) *During the search for a nonperiodic pattern P of length m (such that the length of the longest border of P is less than $m/2$) in a text T of length n, the Boyer-Moore algorithm performs at most $3n$ comparisons between letters of P and of T.*

In practice, when scanning the window from right to left during an attempt, it is sometimes more efficient to only use the bad-character shift. This was first done by the Horspool algorithm [16]. Other practical efficient algorithms are the Quick Search by Sunday [24] and the Tuned Boyer-Moore by Hume and Sunday [17].

Yao's bound can be reached using an indexing structure giving access to all the factors of the reverse pattern. This is done by the Reverse Factor algorithm also called BDM (for Backward Dawg Matching).

Theorem 6 (Crochemore et al. [9]) *The search can be done in optimal expected time $O\left(\frac{\log_\sigma m}{m} \times n\right)$ using the suffix automaton or the suffix tree of the reverse pattern.*

A factor oracle can be used instead of an index structure. A factor oracle is an automaton simpler than the suffix automaton that may recognize some additional strings of length smaller than m. The only string of length m accepted by the factor oracle of a string w of length m is w itself. Then it can be used for solving the ESM problem. This is done by the Backward Oracle Matching (BOM) algorithm of Allauzen, Crochemore, and Raffinot [1]. Its behavior in practice is similar to the one of the BDM algorithm.

Time-Space Optimal Algorithms

Algorithms of this type run in linear time (for both preprocessing and searching) and need only constant space in addition to the inputs.

Theorem 7 (Galil and Seiferas [13]) *The search can be done optimally in time $O(n)$ and constant extra space.*

After Galil and Seiferas' first solution, other solutions are by Crochemore-Perrin [8] and Rytter [22]. These algorithms rely on a partition of the pattern in two parts; they first search for the right part of the pattern from left to right, and then, if no mismatch occurs, they search for the left part. The partition can be the perfect factorization [13], the critical factorization [8], or based on the lexicographically maximum suffix of the pattern [22]. Another solution by Crochemore [7] is a variant of KMP [18]: it computes lower bounds of pattern prefixes periods on the fly and requires no preprocessing.

Bit-Parallel Solution

It is possible to use the bit-parallelism technique for ESM.

Theorem 8 (Baeza-Yates and Gonnet [2]; Wu and Manber [25]) *If the length m of the string P is smaller than the number of bits of a machine word, the preprocessing phase can be done in time and space $O(\sigma)$ and the searching phase in time $O(n)$.*

It is even possible to use this bit-parallelism technique to simulate the BDM algorithm. This is realized by the BNDM (Backward Nondeterministic Dawg Matching) algorithm [20].

There exists another method that uses the bit-parallelism technique that is optimal on the average. It considers sparse q-grams and thus avoids to scan a lot of text positions. It is due to Fredriksson and Grabowski [12].

Applications

The methods that are described here apply to the treatment of the natural language, of genetic and musical sequences, the problems of safety related to data flows like virus detection, and the management of the textual databases, to quote only some immediate applications.

Open Problems

There remain only a few open problems on this question. It is still unknown if it is possible to design an average optimal time constant space string-matching algorithm. The exact size of the Boyer-Moore automaton is still unknown [3]. The Boyer-Moore automaton was first introduced by Knuth [18]. Its states encode all the possible situations when searching the pattern with the Boyer-Moore algorithm and remember every text character already matched in the window.

Experimental Results

The book of G. Navarro and M. Raffinot [21] is a good introduction and presents an experimental map of ESM algorithms for different alphabet sizes and pattern lengths. Basically, the Shift-Or algorithm is efficient for small alphabets and short patterns, the BNDM algorithm is efficient for medium-sized alphabets and medium-length patterns, the Horspool algorithm is efficient for large alphabets, and the BOM algorithm is efficient for long patterns. The article of S. Faro and T. Lecroq [11] updates the experimental map with the most recent results.

URLs to Code and Data Sets

The site monge.univ-mlv.fr/~lecroq/string presents a large number of ESM algorithms (see also [4]). Each algorithm is implemented in C code and a Java applet is given. The site www.dmi.unict.it/~faro/smart presents SMART, a string-matching research tool, which contains the C code of a great number of exact string-matching algorithms and some corpora (natural language, musical, biological, and random texts). The user can easily plug its own algorithm to compare it against some selected algorithms.

Cross-References

- Approximate String Matching is the version where errors are permitted;
- Multiple String Matching is the version where a finite set of patterns is searched for in a text;
- Regular Expression Matching is the more complex case where P can be a regular expression;
- Suffix Trees and Arrays refers to the case where the text is preprocessed.

Further information can be found in the three following books: [10, 14] and [23].

String Sorting

Rolf Fagerberg
Department of Mathematics and Computer Science, University of Southern Denmark, Odense, Denmark

Keywords

Sorting of multidimensional keys; Vector sorting

Years and Authors of Summarized Original Work

1997; Bentley, Sedgewick

Problem Definition

The problem is to sort a set of strings into lexicographical order. More formally: A *string* over an *alphabet* Σ is a finite sequence $x_1x_2x_3\ldots x_k$ where $x_i \in \Sigma$ for $i = 1,\ldots,k$. The x_is are called the *characters* of the string, and k is the *length* of the string. If the alphabet Σ is ordered, the *lexicographical order* on the set of strings over Σ is defined by declaring a string $x = x_1x_2x_3\ldots x_k$ smaller than a string $y = y_1y_2y_3\ldots y_l$ if either there exists a $j \geq 1$ such that $x_i = y_i$ for $1 \leq i < j$ and $x_j < y_j$ or if $k < l$ and $x_i = y_i$ for $1 \leq i \leq k$. Given a set S of strings over some ordered alphabet, the problem is to sort S according to lexicographical order.

The input to the string sorting problem consists of an array of pointers to the strings to be sorted. The output is a permutation of the array of pointers, such that traversing the array will point to the strings in nondecreasing lexicographical order.

The complexity of string sorting depends on the alphabet as well as the machine model. The main solution [15] described in this entry works for alphabets of unbounded size (i. e., comparisons are the only operations on characters of Σ) and can be implemented on a pointer

machine. See below for more information on the asymptotic complexity of string sorting in various settings.

Key Results

This section is structured as follows: first, the key result appearing in the title of this entry [15] is described; then an overview of other relevant results in the area of string sorting is given.

The string sorting algorithm proposed by Bentley and Sedgewick in 1997 [15] is called three-way radix quicksort [5]. It works for unbounded alphabets, for which it achieves optimal performance.

Theorem 1 *The algorithm three-way radix quicksort sorts K strings of total length N in time $O(K \log K + N)$.*

This time complexity is optimal, which follows by considering strings of the form `bbb...bx`, where all xs are different: Sorting the strings can be no faster than sorting the xs, and all `b`s must be read (else an adversary could change one unread `b` to `a` or `c`, making the returned order incorrect). A more precise version of the bounds above (upper as well as lower) is $K \log K + D$, where D is the sum of the lengths of the *distinguishing prefixes* of the strings. The distinguishing prefix d_s of a string s in a set S is the shortest prefix of s which is not a prefix of another string in S (or is s itself, if s is a prefix of another string). Clearly, $K \leq D \leq N$.

The three-way radix quicksort of Bentley and Sedgewick is not the first algorithm to achieve this complexity; however, it is a very simple and elegant way of doing it. As demonstrated in [3, 15], it is also very fast in practice. Although various elements of the algorithm had been noted earlier, their practical usefulness for string sorting was overlooked until the work in [15].

Three-way radix quicksort is shown in pseudocode in Fig. 1 (adapted from [5]), where S is a list of strings to be sorted and d is an integer. To sort S, an initial call SORT(S, 1) is made. The value s_d denotes the dth character of the string s, and + denotes concatenation. The presentation in Fig. 1 assumes that all strings end in a special end-of-string (EOS) character (such as the null character in C). In an actual implementation, S will be an array of pointers to strings, and the sort will be in-place (using an in-place method from standard quicksort for three-way partitioning of the array into segments holding $S_<$, $S_=$, and $S_>$), rendering concatenation superfluous.

```
SORT(S, d)
  IF |S| ≤ 1:
    RETURN
  Choose a partitioning character v ∈ {s_d | s ∈ S}
  S< = {s ∈ S | s_d < v}
  S= = {s ∈ S | s_d = v}
  S> = {s ∈ S | s_d > v}
  SORT(S<, d)
  IF v ≠ EOS:
    SORT(S=, d + 1)
  SORT(S>, d)
  S = S< + S= + S>
```

String Sorting, Fig. 1 Three-way radix quicksort (assuming each string ends in a special EOS character)

Correctness follows from the following invariant being maintained by the algorithm: At the start of a call SORT(S, d), all strings in S agree on the first $d - 1$ characters.

Time complexity depends on how the partitioning character v is chosen. One particular choice is the median of all the dth characters (including doublets) of the strings in S. Partitioning and median finding can be done in time $O(|S|)$, which is $O(1)$ time per string partitioned. Hence, the total running time of the algorithm is the sum over all strings of the number of partitionings they take part in. For each string, let a partitioning be of type I if the string ends up in $S_<$ or $S_>$ and of type II if it ends up in $S_=$. For a string s, type II can only occur $|d_s|$ times and type I can only occur $\log K$ times. Hence, the running time is $O(K \log K + D)$.

Like for standard quicksort, median finding impairs the constant factors of the algorithm, and more practical choices of partitioning character include selecting a random element among all the dth characters of the strings in S and selecting the median of three elements in this set. The worst-case bound is lost, but the result is a fast, randomized algorithm.

Note that the ternary recursion tree of three-way radix quicksort is equivalent to a trie over the input strings where each trie node is implemented by a binary search tree whose node elements are the child edges (in the trie) of the trie node. In more detail, a node in a binary tree contains the character of a trie edge and a pointer to the root of the binary tree implementing the corresponding trie child. The search keys in a binary tree are the characters in its nodes. This trie implementation is named ternary search trees in [15]. In the recursion tree of three-way radix quicksort, an edge representing a recursive call on $S_<$ or $S_>$ corresponds to a tree edge inside a binary tree implementing a trie node, and an edge representing a recursive call on $S_=$ corresponds to a trie edge.

For the version of the algorithm where the partitioning character v is chosen as the median of all the dth characters, it is not hard to see that the binary trees representing the trie nodes become weighted trees. These are binary trees in which each element x has an associated weight w_x, and searches for x take $O(\log W/w_x)$, where $W = \Sigma_x w_x$ is the sum of all weights in the binary tree. Here, the weight of a binary tree node storing character x is the number of strings which in the trie reside below the corresponding trie edge. As shown in [13], in such a trie implementation, searching for a string P among K stored strings takes time $O(\log K + |P|)$, which is optimal for unbounded (i.e., comparison-based) alphabets. Hence, by the correspondence between the recursion trees of three-way radix quicksort and ternary search trees, three-way radix quicksort may additionally be viewed as a construction algorithm for an efficient dictionary structure for strings.

Other key results in the area of string sorting are now described. The classic string sorting algorithm is radixsort, which assumes a constant-sized alphabet. The least-significant-digit-first variant is easy to implement and runs in $O(N + l|\Sigma|)$ time, where l is the length of the longest string. The most-significant-digit-first variant is more complicated to implement but has a better running time of $O(D + d|\Sigma|)$, where D is the sum of the lengths of the distinguishing prefixes and d is the longest distinguishing prefix. McIlroy et al. [12] discusses in depth efficient implementations of radixsort.

If the alphabet consists of integers, then on a word-RAM the complexity of string sorting is essentially determined by the complexity of integer sorting. More precisely, the time (when allowing randomization) for sorting strings is $\Theta(\text{Sort}_{\text{Int}}(K) + N)$, where $\text{Sort}_{\text{Int}}(K)$ is the time to sort K integers [2], which currently is known to be $O(K\sqrt{\log\log K})$ [11].

Returning to comparison-based model, the papers [8, 10] give generic methods for turning any data structure over one-dimensional keys into a data structure over strings. Using finger search trees, this gives an adaptive sorting method for strings which uses $O(N + K\log(F/K))$ time, where F is the number of inversions among the strings to be sorted.

Concerning space complexity, it has been shown [9] that string sorting can still be done in $O(K\log K + N)$ time using only $O(1)$ space besides the strings themselves. However, this assumes that all strings have equal lengths.

All algorithms so far are designed to work in internal memory, where CPU time is assumed to be the dominating factor. For external memory computation, a more relevant cost measure is the number of I/Os performed, as captured by the I/O model [1], which models a two-level memory hierarchy with an infinite outer memory, an inner memory of size M, and transfer (I/Os) between the two levels taking place in blocks of size B. For external memory, upper bounds

were first given in [4], along with matching lower bounds in restricted I/O models. For a comparison-based model where strings may only be moved in blocks of size B (hence, characters may not be moved individually), it is shown in [4] that string sorting takes $\Theta(N_1/B \log_{M/B}(N_1/B) + K_2 \log_{M/B} K_2 + N/B)$ I/Os, where N_1 is the total length of strings shorter than B characters, K_2 is the number of strings of at least B characters, and N is the total number of characters. This bound is equal to the sum of the I/O costs of sorting the characters of the short strings, sorting B characters from each of the long strings, and scanning all strings. In the same paper, slightly better bounds in a model where characters may be moved individually in internal memory are given, as well as some upper bounds for non-comparison-based string sorting. Further bounds (using randomization) for non-comparison-based string sorting have been given, with I/O bounds of $O(K/B \log_{M/B}(K/M) \log\log_{M/B}(K/M) + N/B)$ [7] and $O(K/B(\log_{M/B}(N/M))^2 \log_2 K + N/B)$ (Ferragina, personal communication).

Returning to internal memory, it may also there be the case that memory hierarchy effects are the determining factor for the running time of algorithms but now due to cache faults rather than disk I/Os. Heuristic algorithms (i.e., algorithms without good worst-case bounds), aiming at minimizing cache faults for internal memory string sorting, have been developed. Of these, the burstsort line of algorithms [16] performs particularly well in experiments.

Applications

Data sets consisting partly or entirely of string data are very common: Most database applications have strings as one of the data types used, and in some areas, such as bioinformatics, Web retrieval, and word processing, string data is predominant. Additionally, strings form a general and fundamental data model, containing, e.g., integers and multidimensional data as special cases. Since sorting is arguably among the most important data processing tasks in any domain, string sorting is a general and important problem with wide practical applications.

Open Problems

As appears from the bounds discussed above, the asymptotic complexity of the string sorting problem is known for comparison-based alphabets. For integer alphabets on the word-RAM, the problem is almost closed in the sense that it is equivalent to integer sorting, for which the gap left between the known bounds and the trivial linear lower bound is small.

In external memory, the situation is less settled. As noted in [4], a natural upper bound to hope for in a comparison-based setting is to meet the lower bound of $\Theta(K/B \log_{M/B} K/M + N/B)$ I/Os, which is the sorting bound for K single characters plus the complexity of scanning the input. The currently known upper bounds only get close to this when leaving the comparison-based setting and allowing randomization.

Experimental Results

In [15], experimental comparison of two implementations (one simple and one tuned) of three-way radix quicksort with a tuned quicksort [6] and a tuned radixsort [12] showed the simple implementation to always outperform the quicksort implementation and the tuned implementation to be competitive with the radixsort implementation.

In [3], experimental comparison among existing and new radixsort implementations (including the one used in [15]), as well as tuned quicksort and tuned three-way radix quicksort, was performed. This study confirms the picture of three-way radix quicksort as very competitive, always being one of the fastest algorithms, and arguably the most robust across various input distributions.

Problem Definition

Let $G = (V, E)$ be a directed graph. For an arc $(u, v) \in E$, u is said to *dominate* v, and v is said to *absorb* u. Vertex u is also called a *dominator* of v, and vertex v is called an *absorber* of u. A vertex set $D \subseteq V$ is a *dominating set* (DS) of G if every vertex in $V \setminus D$ has a dominator in D; it is an *absorbing set* (AS) of G if every vertex in $V \setminus D$ has an absorber in D. A directed graph G is *strongly connected* if for any pair of ordered vertices $u, v \in V$, there is a directed path in G from u to v. The "Minimum Strongly Connected Dominating and Absorbing Set" problem (MSCDAS) is to find a vertex set D such that D is both a dominating set and an absorbing set of G and the subgraph of G induced by D is strongly connected.

Disk graph is a geometric graph which is of particular interest in the study of MSCDAS, since disk graph is a model of heterogeneous wireless sensor network, and as one can see in the application part, MSCDAS plays an important role in wireless sensor network. In a *disk graph*, every vertex u corresponds to a sensor on the plane equipped with an omnidirectional antenna of transmission radius $r(u)$. Another sensor v can correctly decode the message sent by u if and only if v is in the disk centered at u with radius $r(u)$. Hence, there is an arc (u, v) in the disk graph if and only if $\|uv\| \leq r(u)$, where $\|\cdot\|$ is the Euclidean distance between u and v. In particular, if all sensors are equipped with the same transmission radius, then the disk graph degenerates to an undirected graph called *unit disk graph*.

Key Results

Hardness Results

In a general digraph, the MSCDAS problem cannot be approximated within a factor of $(1-\varepsilon)\ln n$ for any real number $\varepsilon > 0$, where n is the number of vertices in the digraph. Even in disk graph, MSCDAS is still NP-hard. These hardness results follow from the fact that their undirected counterparts have these hardness results [1, 5].

MSCDAS in General Digraph

Li et al. [8] gave a $(3H(n-1)-1)$-approximation for MSCDAS, where $H(\gamma) = \sum_{i=1}^{\gamma} 1/i$ is the harmonic number.

The algorithm is based on the following observation. For a vertex u in a digraph G, a spanning *in-arborescence* (resp. *out-arborescence*) rooted at u is a spanning sub-digraph of G in which every vertex except u has in-degree (resp. out-degree) exactly one and vertex u has in-degree (resp. out-degree) zero. For a spanning arborescence T of G, denote by $\text{int}(T)$ the set of internal vertices of T. For any vertex u, suppose T^{in} and T^{out} are spanning in-arborescence and spanning out-arborescence of G rooted at u, respectively. Then $\text{int}(T^{\text{in}}) \cup \text{int}(T^{\text{out}})$ is an SCDAS of G.

Define the problem "Spanning Arborescence with Fewest Internal Vertices" (SAFIV) as follows: given a digraph G and a vertex u, find a spanning arborescence T rooted at u such that $|\text{int}(T)|$ is as small as possible. By the above observation, if SAFIV has a ρ-approximation, then MSCDAS has a 2ρ-approximation. Li et al. gave a $(1.5H(n-1)-0.5)$-approximation for SAFIV, and thus the approximation ratio $(3H(n-1)-1)$ for MSCDAS follows.

The approximation algorithm for SAFIV uses the idea in [6, 7] which study the problem of "Minimum Node-Weighted Steiner Tree" (MNWST). The idea is to iteratively merge smaller arborescences greedily (a vertex is a trivial arborescence) until finally one gets one arborescence including all vertices which is rooted at the given vertex. It was pointed out in [8] that using the method in [6], the approximation ratio for SAFIV can be further reduced to $1.35\ln n$. Since SAFIV is at least as hard as the minimum

connected dominating set problem, it cannot be approximated within factor $(1-\varepsilon)\ln n$. Any progress narrowing the gap between $\ln n$ and $1.35\ln n$ would be interesting.

MSCDAS in Disk Graph

Making use of geometric properties, can the approximation ratio for MSCDAS be better in a disk graph? The answer is yes. Du et al. [2] were the first to give a constant approximation in this setting. Their idea was further explored by Park et al. [11] to output an SCDAS with size at most $9.6(k+1/2)^2\text{opt}+14.8(k+1/2)^2$, where opt is the size of an optimal solution and $k = r_{\max}/r_{\min}$, the ratio between the maximum radius and the minimum radius. The core in their work is an algorithm for SAFIV, which first colors all vertices white and then, by growing a search tree step by step, turns the colors to either black, blue, or gray. The set of black vertices forms a dominating set, and the set of blue vertices connects these black vertices into an out-arborescence. In fact, black vertices are mutually independent, where two vertices u and v are said to be *independent* if either uv or vu is not an arc. Two independent vertices have distance greater than $r_{\min}$. Such a property guarantees an upper bound for the number of black vertices. Furthermore, the structure of a search tree guarantees that the number of blues vertices is no larger than that of black vertices. Then, the desired approximation ratio follows. It should be noted that if $r_{\max}/r_{\min}$ is unbounded, then the approximation ratio is not a constant.

Without a bounded assumption on $r_{\max}/r_{\min}$, Xu and Li [12] showed that a $(2+\varepsilon)$-approximation exists for MDAS, which is a combination of a PTAS for MDS and a PTAS for MAS. In fact, the PTAS for MAS is a special case of the "Geometric Hitting Set" problem studied in [10], and the PTAS for MDS is a variation for the MDS problem in an undirected graph studied in [4]. Both PTASs are obtained through a local search method. The analysis is based on the separator theorem for planar graphs [3, 9]. Zhang et al. [13] also obtained approximation ratio $(2+\varepsilon)$ using the same method. Based on such a DAS, adding Steiner nodes to connect, Zhang et al. showed that a $(4+3\ln(2+\varepsilon)\text{opt}+\varepsilon)$-approximation exists for MSCDAS. When the optimal value opt is substantially smaller than n, this is an improvement on ratio $3H(n-1)-1$ for disk graphs.

Applications

One application of MSCDAS is the communication in wireless sensor network (WSN). In a WSN, information is distributed among sensors by multi-hop transmissions. If all sensors transmit messages in a flooding manner, then a lot of energy is wasted, and large amount of interference is created. To alleviate such problems, it is desirable that only a small fraction of sensors participate in the transmission, while information can still be successfully shared. An SCDAS can serve for this purpose. Suppose D is an SCDAS of directed graph G (the topology of the WSN). If there is a message at source sensor u to be sent to destination sensor v, then the message can be first sent from u to its absorber; since $G[D]$ is strongly connected, it can be successfully relayed to the dominator of v and then sent to v.

Open Problems

It is still open whether there exists a constant approximation algorithm for MSCDAS in disk graph.

Problem Definition

A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$, where Σ is a fixed, finite alphabet. The second component is called the *parameter* of the problem. The central notion in parameterized complexity is the notion of *fixed-parameter tractability (FPT)*. A parameterized problem L is called FPT if it can be determined in time $f(k) \cdot n^c$ whether or not $(x,k) \in L$, where $n = |(x,k)|$, f is a computable function depending only on k, and c is a constant independent of n and k. The complexity class containing all fixed-parameter tractable problems is called FPT.

While in the definition of class FPT, we are happy with any computable function f, from application perspective it is often desirable to have the asymptotic growth of f as slow as possible. Take as an example an FPT problem VERTEX COVER which has been subjected to intense scrutiny with progressively faster algorithms designed for it. Let us remind that in the VERTEX COVER problem, we are asked if an n vertex graph G contains a vertex cover of size k or in other words a set of vertices S such that every edge of G has at least one endpoint in S. Starting from a k^k algorithm of Buss and Goldsmith in 1993, there have been algorithms with $f(k) \in \{2^k, 1.324718^k, 1.29175^k, 1.2906^k, 1.271^k, 1.2738^k\}$. The current fastest algorithm for VERTEX COVER runs in time $1.2738^k n^{\mathcal{O}(1)}$ (see the entry ▸ Vertex Cover Search Trees from this book). The ever-decreasing running time leads to the following natural question: can VERTEX COVER admit a *subexponential* time algorithm? That is, can it have an algorithm with running time $2^{o(k)n^{\mathcal{O}(1)}}$? The negative answer to this question would imply that $P \neq NP$. However, using a stronger assumption in complexity theory, namely, exponential time hypothesis (ETH) (see the entry ▸ Exponential Lower Bounds for k-SAT Algorithms in this book), one can show that if ETH holds, then the answer to our question is NO. Moreover, subject to ETH, there are no subexponential algorithms for many other natural *NP*-complete problems. Thus, another natural question arises:

is it true that every *NP*-complete problem cannot be solved in subexponential time? Interestingly, the answer to this question is again NO, and there are examples in the literature of such problems. Coming back to our example of VERTEX COVER problem, if we restrict the input graph to be planar, the problem remains *NP*-complete, but the brute-force algorithm problem can be sped up even more. That is, VERTEX COVER on planar graphs can be solved in time $2^{O(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$, by *a subexponential algorithm*. We refer to more parameterized subexponential algorithms on planar graphs to the ▸ Bidimensionality in this book.

Until recently, the only subexponential algorithms were known for "geometric" graph problems, that is, problems on planar graphs or graphs excluding some fixed graph as minors. In 2009, Alon, Lokshtanov, and Saurabh [1] obtained the first parameterized subexponential algorithm for a natural "nongeometric" problem. This result has acted as catalyst for the discovery of new subexponential time algorithms. In this article, we give a short overview of these algorithms.

Key Results

FAST

In the FEEDBACK ARC SET IN TOURNAMENTS (FAST) problem, we are given an n-vertex tournament T and a positive integer k; the question is whether one can make T into a directed acyclic graph by deleting at most k arcs.

FAST
Input: A tournament $T = (V, E)$ and a nonnegative integer k.
Parameter: k.
Question: Is there $F \subseteq E$, $|F| \leq k$, such that diraph $H = (V, E \setminus F)$ is acyclic?

Alon, Lokshtanov, and Saurabh in [1] obtained a parameterized subexponential algorithm for FAST.

Theorem 1 ([1]) *FAST is solvable in time* $2^{\sqrt{k}\log k} n^{\mathcal{O}(1)}$.

The theorem is proved by making use of a novel randomized technique called *Chromatic Coding*. It appeared that subexponential algorithms exist for several other problems on tournaments (see entry ▸ Computing Cutwidth and Pathwidth of Semi-complete Digraphs in this book).

Fill-In

The next "nongeometric" problem for which a subexponential algorithm was found happened to be the classical MINIMUM FILL-IN problem.

A graph is *chordal* (or triangulated) if every cycle of length at least four contains a chord, i.e., an edge between nonadjacent vertices of the cycle. The MINIMUM FILL-IN problem (also known as MINIMUM TRIANGULATION and CHORDAL GRAPH COMPLETION) is to decide if a given graph G can be transformed into a chordal graph by adding at most k edges.

MINIMUM FILL-IN
Input: A graph $G = (V, E)$ and a nonnegative integer k.
Parameter: k.
Question: Is there $F \subseteq [V]^2$, $|F| \leq k$, such that graph $H = (V, E \cup F)$ is chordal?

Theorem 2 ([6]) MINIMUM FILL-IN *is solvable in time* $2^{\sqrt{k}\log k} n^{\mathcal{O}(1)}$.

The proof of the theorem is based on a combinatorial bound estimating the number of specific objects in the graph, namely, potential maximal cliques.

Completion to Graph Classes

Since discoveries of subexponential algorithms for FAST and MINIMUM FILL-IN, it appeared that several other graph modification problems admit subexponential algorithms. In particular, it was shown that problems of completion to a certain subclass of chordal graphs like trivially perfect, threshold [4], split [7], proper interval [2], and interval graphs [3] admit parameterized subexponential algorithms.

On the other hand, it has been shown that for a number of other graph classes, like cographs, completion to these classes of graphs cannot be done in parameterized subexponential time unless the exponential time hypothesis (ETH) fails [4].

Open Problems

The most natural open question about the given subexponential algorithms is the question about lower bounds. As a concrete example, an algorithm for FAST with running time bound $2^{o(\sqrt{k})}n^{\mathcal{O}(1)}$ would actually be a $2^{o(n)}$ time algorithm which inclines us to suspect that $2^{\mathcal{O}(\sqrt{k})}$ is the best possible dependency on k in the running time for this problem. Unfortunately, there is a big gap here between what we suspect and what we can prove, even assuming ETH. The only tight bound on parameterized subexponential algorithms for graph modification problems we are aware of is the p-CLUSTERING problem [5].

Problem Definition

Bin packing is a classical problem in combinatorial optimization. Given a collection of n items with different sizes, the objective is to pack the items into a minimum number of uniform capacity bins. More formally, the input of the bin packing problem is described by a set of n items $I = \{1, \ldots, n\}$ and a size function $s : I \to [0, 1]$. The output is a packing of the items into bins $B_1, \ldots, B_k \subseteq I$ such that $s(B_j) \leq 1$ for $j = 1, \ldots, k$, where the notation $s(B)$ denotes $\sum_{i \in B} s_i$ for any $B \subseteq I$. The objective is to minimize the number bins used in the packing.

The SUBSET-SUM algorithm is an intuitively appealing greedy heuristic for the bin packing problem: Starting from the empty packing, the algorithm repeatedly finds a subset B of yet-unpacked items maximizing $s(B)$ subject to $s(B) \leq 1$, adds B to the packing, and iterates. Each iteration requires that we solve an instance of the *knapsack* problem. In practice, instead of finding the optimal solution, one can use an fully polynomial time approximation scheme (FPRAS) to compute a $(1 - \epsilon)$-approximate solution [6].

This note is concerned with the worst-case asymptotic performance of the SUBSET-SUM algorithm. For a given instance $s : I \to [0, 1]$, we use $\mathrm{OPT}(s)$ to denote the number of bins used in an optimal packing of s and $\mathrm{SS}(s)$ to denote the number of bins used by the SUBSET-SUM algorithm. Then for a given class $\mathcal{C}$ of instances, we define the worst-case asymptotic approximation ratio of SUBSET-SUM as

$$R_{\mathrm{SS}}^{\infty}(\mathcal{C}) = \lim_{k \to \infty} \sup_{\substack{s \in \mathcal{C} \\ \mathrm{OPT}(s) = k}} \frac{\mathrm{SS}(s)}{\mathrm{OPT}(s)}. \qquad (1)$$

Finally, we use R_{SS}^{∞} to denote the ratio for general instances of the problem.

Key Results

Lower Bound on R_{SS}^{∞}

Graham [4] provided a family of instance exhibiting an approximation ratio that tends to $\sum_{i=1}^{\infty} \frac{1}{2^i - 1} \approx 1.6067$.

Theorem 1 (Graham [4]) $R_{\mathrm{SS}}^{\infty} \geq \sum_{i=1}^{\infty} \frac{1}{2^i - 1} \approx 1.6067$.

Proof Consider the following instance parameterized by two positive integers r and N. For each $j = 1, \ldots, r$, we create N items of size $2^{-i} + \delta$, where $\delta = 2^{-2r}$. Let us denote this instance with s. Provided that $2^i - 1$ divides N for all $i = 1, \ldots, r$, it is not hard to see that SUBSET-SUM first packs the smallest items into $N/(2^r - 1)$ bins, then it packs the second-smallest items into $N/(2^{r-1} - 1)$ bins, and so on, until it packs the largest items into N bins. On the other hand, the optimal solution uses just N bins by packing one item of each size class per bin. Therefore,

$$\frac{\mathrm{SS}(s)}{\mathrm{OPT}(s)} = \sum_{i=1}^{r} \frac{1}{2^i - 1}, \qquad (2)$$

which quickly approaches 1.6067 as r grows. □

Upper Bound on R_{SS}^{∞}

A trivial upper bound on R_{SS}^{∞} is 2. This follows from the fact only the last bin can be less than half full. Caprara and Pferschy [1] gave the first nontrivial upper bound, by showing that R_{SS}^{∞} is at most $4/3 + \ln 4 \approx 1.6210$. Interestingly, Graham [4] had conjectured that the true value of R_{SS}^{∞} should match his lower bound. This conjecture was finally proven by Epstein et al. [2].

Theorem 2 (Epstein et al. [3]) $R_{\mathrm{SS}}^{\infty} \leq \sum_{i=1}^{\infty} \frac{1}{2^i - 1} \approx 1.6067$.

The proof of this result uses *weighting functions* and a *factor revealing mathematical program*. Here we only sketch the high level idea of the approach. Let B be one of the bins opened by SUBSET-SUM. For every item $i \in B$ we define

$$w_i = \begin{cases} \frac{s_i}{s(B)} & \text{if } 1 - s_{\min} \leq s(B), \\ s_i & \text{otherwise,} \end{cases} \qquad (3)$$

S

where $s_{\min}$ is the size of the smallest yet-unpacked item just before opening B.

The weights are used to charge the cost of the packing computed by SUBSET-SUM to an optimal packing. The following lemma allows us to bound the performance of the algorithm provided we can show that the sum of the weights is comparable to the cost of the SUBSET-SUM packing and that no bin in the optimal solution is charged too much.

Lemma 1 *Let $\mathcal{O}$ be an optimal solution and $\mathcal{B}$ be the solution computed* SUBSET-SUM. *If there is a weighting function w such that $w(O) \leq \rho$ for all $O \in \mathcal{O}$ and $|\mathcal{B}| \leq w(I) + \delta$, then $|\mathcal{B}| \leq \rho|\mathcal{O}| + \delta$.*

Proof Because $\mathcal{O}$ is a packing $\sum_{O \in \mathcal{O}} w(O) = w(I)$, therefore,

$$|\mathcal{B}| \leq w(I) + \delta = \sum_{O \in \mathcal{O}} w(O) + \delta \leq \rho|\mathcal{O}| + \delta. \quad \square$$

The key contribution of Epstein et al. [3] was bounding the parameters ρ and δ associated with the weighting function (3). Bounding δ is a relatively straightforward exercise. Bounding ρ is more involved and requires analytically solving a mathematical program. Here we only state their bounds.

Lemma 2 (Epstein et al. [3]) *Let $\mathcal{B}$ be the* SUBSET-SUM *packing and let w be the weighting function* (3) *for $\mathcal{B}$. Then*

1. $|\mathcal{B}| \leq w(I) + 1$,
2. $w(B) \leq \sum_{i=1}^{\infty} \frac{1}{2^i - 1}$ *for all* $B \subseteq I$ *such that* $s(B) \leq 1$.

Theorem 2 follows immediately from Lemmas 1 and 2.

Parametric Case

As it is the case with most bin packing heuristics, the performance of SUBSET-SUM improves when the items are small relative to the capacity of the bin. In a *parametric analysis* of a heuristic, we restrict our attention to instances where the maximum item size is bounded. More formally, for every real $\alpha \in (0, 1]$, we define $\mathcal{C}_\alpha$ to be the class of instances s such that $\max_{i \in I} s_i \leq \alpha$.

Theorem 3 (Epstein et al. [3]) *For every integer $t \geq 1$ and $\alpha \in (\frac{1}{t+1}, \frac{1}{t}]$, we have $R_{\mathrm{SS}}^{\infty}(\mathcal{C}_\alpha) = 1 + \sum_{i=1}^{\infty} \frac{1}{(t+1)2^i - 1}$.*

Notice that this is a strict generalization of Theorems 1 and 2, which only cover the case $\alpha = 1$.

Applications

There is an interesting connection between the performance of the SUBSET-SUM algorithm and the quality of equilibria of a game-theoretic version of bin packing. Let us associate a game with each instance $s : I \to [0, 1]$ of the bin packing problem. The set of players in this game is I, the set of items. Each player can decide in which bin it wants to be packed; this is the player's strategy space. For each bin B chosen in this uncoordinated fashion, if $s(B) > 1$ then the players in B are charged ∞; otherwise, player $i \in B$ is charged $\frac{s_i}{s(B)}$. These payments enforce that a strategy profile is a valid packing if and only if the payments are finite. Furthermore, if the payments are finite, the sum of these payments equals the number of bins in the packing.

A strategy profile is said to be a Nash Equilibrium (NE) if there is no player that can switch bins to decrease its payment. The *price of anarchy* of the bin packing game is the asymptotic worst-case ratio between the number of bins used by an NE and the number of bins in an optimal packing. A packing is said to be a Strong Nash Equilibrium (SNE) if no coalition of players can switch bins to decrease the sum of their payments. The *strong price of anarchy* of the bin packing game is the asymptotic worst-case ratio between the number of bins used by an SNE and the number of bins by an optimal packing.

Theorem 4 (Epstein and Kleiman [2]) *The strong price of anarchy for the bin packing game is exactly R_{SS}^{∞}.*

Notice that every SNE is an NE, since we can think of an NE as requiring that there are no "coalitions" of size 1. Therefore, Theorem 4 establishes a lower bound on the price of anarchy for the bin packing game. However, not every NE is an SNE. In fact, it is known that the price of anarchy for the bin packing game is strictly worse than its strong price of anarchy [2, 3].

Experimental Results

Gupta and Ho [5] performed an experimental evaluation of SUBSET-SUM. (Gupta and Ho call the algorithm *minimum bin slack* because they formulate each iteration as trying to minimize the slack (unused space) of the bin, which is equivalent to maximizing the bin's usage.) The instances used in the evaluation were randomly generated by selecting the item sizes uniformly at random from different numerical ranges. They compared the performance of SUBSET-SUM to two well-known heuristics: FIRST-FIT-DECREASING and BEST-FIT-DECREASING. They observed that SUBSET-SUM performed better on average without incurring a significant computational overhead.

Substring Parsimony

Mathieu Blanchette
Department of Computer Science, McGill University, Montreal, QC, Canada

Years and Authors of Summarized Original Work

2001; Blanchette, Schwikowski, Tompa

Problem Definition

The Substring Parsimony Problem, introduced by Blanchette et al. [1] in the context of motif discovery in biological sequences, can be described in a more general framework:
Input:

- A discrete space $\mathcal{S}$ on which an integral distance d is defined (i.e., $d(x, y) \in \mathbb{N}\ \forall x, y \in \mathcal{S}$).
- A rooted binary tree $T = (V, E)$ with n leaves. Vertices are labeled $\{1, 2, \ldots, n, \ldots, |V|\}$, where the leaves are vertices $\{1, 2, \ldots, n\}$.
- Finite sets $S_1, S_2, \ldots, S_n$, where set $S_i \subseteq \mathcal{S}$ is assigned to leaf i, for all $i = 1 \ldots n$.
- A non-negative integer t

Output: All solutions of the form $(x_1, x_2, \ldots, x_n, \ldots, x_{|V|})$ such that:

- $x_i \in \mathcal{S}$ for all $i = 1 \ldots |V|$

- $x_i \in S_i$ for all $i = 1 \ldots n$
- $\sum_{(u,v)\in E} d(x_u, x_v) \leq t$

The problem thus consists of choosing one element x_i from each set S_i such that the Steiner distance of the set of points is at most t. This is done on a Steiner tree T of fixed topology. The case where $|S_i| = 1$ for all $i = 1 \ldots n$ is a standard Steiner tree problem on a fixed tree topology (see [11]). It is known as the Maximum Parsimony Problem and its complexity depends on the space $\mathcal{S}$.

Key Results

The substring parsimony problem can be solved using a dynamic programming algorithm. Let $u \in V$ and $s \in \mathcal{S}$. Let $W_u[s]$ be the score of the best solution that can be obtained for the subtree rooted at node u, under the constraint that node u is labeled with s, i.e.,

$$W_u[s] = \min_{\substack{x_1,\ldots,x_{|V|}\in\mathcal{S} \\ x_u = s}} \sum_{\substack{(i,j)\in E \\ i,j\in \text{subtree}(u)}} d(x_i, x_j).$$

Let v be a child of u, and let $X_{(u,v)}[s]$ be the score of the best solution that can be obtained for the subtree consisting of node u together with the subtree rooted at its child v, under the constraint that node u is labeled with s:

$$X_{(u,v)}[s] = \min_{\substack{x_1,\ldots,x_{|V|}\in\mathcal{S} \\ x_u = s}} \sum_{\substack{(i,j)\in E \\ i,j\in \text{subtree}(v)\cup\{(u,v)\}}} d(x_i, x_j).$$

Then, we have:

$$W_u[s] = \begin{cases} 0 & \text{if } u \text{ is a leaf and } s \in S_u \\ +\infty & \text{if } u \text{ is a leaf and } s \notin S_u \\ \sum_{v\in \text{children}(u)} X_{(u,v)}[s] & \text{if } u \text{ is not a leaf} \end{cases}$$

and

$$X_{(u,v)}[s] = \min_{y'\in\mathcal{S}} W_u[s'] + d(s, s').$$

Tables W and X can thus be computed using a dynamic programming algorithm, proceeding in a post-order traversal of the tree. Solutions can then be recovered by tracing the computation back for all s such that $W_{\text{root}}[s] \leq t$. Note that the same solution may be recovered more than once in this process.

A straight-forward implementation of this dynamic programming algorithm would run in time $O(n \cdot |\mathcal{S}|^2 \cdot \gamma(\mathcal{S}))$, where $\gamma(\mathcal{S})$ is the time needed to compute the distance between any two points in $\mathcal{S}$. Let $N_a(\mathcal{S})$ be the maximum number of a-neighbors a point in $\mathcal{S}$ can have, i.e., $N_a(\mathcal{S}) = \max_{x\in\mathcal{S}} |\{y \in \mathcal{S} : d(x, y) = a\}|$. Blanchette et al. [3] showed how to use a modified breadth-first search of the space $\mathcal{S}$ to compute each table $X_{(u,v)}$ in time $O(|\mathcal{S}| \cdot N_1(\mathcal{S}))$, thus reducing the total time complexity to $O(n \cdot |\mathcal{S}| \cdot N_1(\mathcal{S}))$. Since only solutions with a score of at most t are of interest, the complexity can be further reduced by only computing those table entries which will yield a score of at most t. This results in an algorithm whose running time is $O(n \cdot M \cdot N_{\lfloor t/2 \rfloor}(\mathcal{S}) \cdot N_1(\mathcal{S}))$ where $M = \max_{i=1\ldots n} |S_i|$.

The problem has been mostly studied in the context of biological sequence analysis, where $\mathcal{S} = \{A, C, G, T\}^k$, for some small k ($k = 5, \ldots, 20$ are typical values). The distance d is the Hamming distance, and a phylogenetic tree T is given. The case where $|S_i| = 1$ for all $i = 1 \ldots n$ is known as the Maximum Parsimony Problem and can be solved in time $O(n \cdot k)$ using Fitch's algorithm [9] or Sankoff's algorithm [12]. In the more general version, a long DNA sequence P_u of length L is assigned to each leaf u. The set S_u is defined as the set of all k-substrings of P_u. In this case, $M = L - k + 1 \in O(L)$, and $N_a \in O(\min(4^k, (3k)^a))$, resulting in a complexity of $O(n \cdot L \cdot 3k \cdot \min(4^k, (3k)^{\lfloor d/2 \rfloor}))$. Notice that for a fixed k and d, the algorithm is linear over the whole sequence. The problem was independently shown to be NP-hard by Blanchette et al. [3] and by Elias [7].

Applications

Most applications are found in computational biology, although the algorithm can be applied to a wide variety of domains. The algorithm

for the substring parsimony problem has been implemented in a software package called FootPrinter [5] and applied to the detection of transcription factor binding sites in orthologous DNA regulatory sequences through a method called phylogenetic footprinting [4]. Other applications include the search for conserved RNA secondary structure motifs in orthologous RNA sequences [2]. Variants of the problem have been defined to identify motifs regulating alternative splicing [13]. Blanchette et al. [3] study a relaxation of the problem where one does not require that a substring be chosen from each of the input sequences, but instead asks that substrings be chosen from a sufficiently large subset of the input sequence. Fang and Blanchette [8] formulate another variant of the problem where substring choices are constrained to respect a partial order relation defined by a set of local multiple sequence alignments.

Open Problems

Optimizations taking advantage of the specific structure of the space $\mathcal{S}$ may yield more efficient algorithms in certain cases. Many important variations could be considered. First, the case where the tree topology is not given needs to be considered, although the resulting problems would usually be NP-hard even when $|S_i| = 1$. Another important variation is one where the phylogenetic relationships between trees is not given by a tree but rather by a phylogenetic network [10]. Finally, randomized algorithms similar to those proposed by Buhler et al. [6] may yield important and practical improvements.

Problem Definition

A basic building block for compressed data structures for texts and functions is the representation of a permutation of the integers $\{1, \ldots, n\}$, denoted by $[1 \ldots n]$. A permutation π is trivially representable in $n\lceil \lg n \rceil$ bits which is within $O(n)$ bits of the information theoretic bound of $\lg(n!)$, but instances from restricted classes of permutations can be represented using much less space.

We are interested in encodings of permutations that can efficiently access them. Given a permutation π over $[1 \ldots n]$, an integer k and an integer $i \in [1 \ldots n]$, data structures on permutations aim to support the following operators as fast as possible, using as little additional space as possible:

- $\pi(i)$: application of the permutation to i,
- $\pi^{-1}(i)$: application of the inverse permutation to i,
- $\pi^{(k)}(i)$: $\pi()$ iteratively applied k times starting with value i (e.g., $\pi^{(2)}(i) = \pi(\pi(i))$).

Key Results

We distinguish between two types of solutions: the succinct index and two succinct data structures for permutations introduced by Munro et al. [1], and the various compressed data structures proposed later [2–4].

Succinct Data Structures

Munro et al. [1] studied the problem of succinctly representing a permutation to support operators on it quickly. They give several solutions, described below.

"Shortcut" Index Supporting $\pi()$ and $\pi^{-1}()$

Given an integer parameter t, the operators $\pi()$ and $\pi^{-1}()$ can be supported by simply writing down π in an array of n words of $\lceil \lg n \rceil$ bits each, plus an auxiliary array S of at most n/t back pointers called shortcuts: in each cycle of length at least t, every t-th element has a pointer t steps back. Then, $\pi(i)$ is simply the i-th value in the primary structure, and $\pi^{-1}(i)$ is found by moving forward until a back pointer is found and then continuing to follow the cycle to the location that contains the value i.

The trick is in the encoding of the locations of the back pointers: this is done with a simple bit vector B of length n, in which a 1 indicates that a back pointer is associated with a given location. B is augmented using $o(n)$ additional bits so that the number of 1's up to a given position and the position of the r-th 1 can be found in constant time (i.e., using the rank and select operators on binary strings [5]). This gives the location of the appropriate back pointer in the auxiliary array S. As there are back pointers every t elements in the cycle, finding the predecessor requires $O(t)$ memory accesses.

Theorem 1 *For any strictly positive integer n and any permutation π on $[1 \ldots n]$ which can be decomposed into δ cycles of respective sizes $c_1, \ldots, c_\delta$, there is a representation of π using within $(\sum_{i \in [1 \ldots \delta]} \lfloor \frac{c_i}{t} \rfloor) \lg n + 2n + o(n) \subseteq \frac{n \lg n}{t} + 2n + o(n)$ bits to support the operator $\pi()$ in constant time and the operator $\pi^{-1}()$ in time within $O(t)$.*

Interestingly enough, Munro et al. [1] did not notice that their construction is actually an index and that the raw encoding can be replaced by any data structure supporting the operator $\pi()$, including the compressed ones later described [4].

"Cycle" Data Structure Supporting $\pi^k()$

For arbitrary i and k, $\pi^k()$ is supported by writing the cycles of π together with a bit vector B marking the beginning of each cycle. Observe that the cycle representation itself is a permutation in "standard form"; call it σ. The first task is to find i in the representation: it is in position $\sigma^{-1}(i)$. The segment of the representation containing i is found through the rank and select operators on B. Then $\pi^k(i)$ is determined by taking k modulo the cycle length, moving that number of steps around the cycle starting at the position of i, and applying $\sigma()$ to obtain the value to return.

Other than the support of the operators on σ, all operators are performed in constant time; hence the asymptotic supporting time of $\pi^k()$ depends on the supporting time in which the data structure chosen to represent σ supports the operators $\sigma()$ and $\sigma^{-1}()$. Munro et al. [1] proposed the following, using a raw encoding of σ with a shortcut index to support $\sigma^{-1}()$:

Theorem 2 *For any strictly positive integer n and any permutation π on $[1 \dots n]$, there is a representation of π using at most $(1+\varepsilon)n \lg n + O(n)$ bits to support the operator $\pi^k()$ in time within $O(1/\varepsilon)$, for any ε less than 1 and for any arbitrary value of k.*

Under a restricted model of pointer machine, this technique is optimal: using $O(n)$ extra bits (i.e., $O(n/\log n)$ extra words), time within $\Omega(\log n)$ is necessary to support both $\pi()$ and $\pi^{-1}()$.

"Benes Network" Data Structure Supporting $\pi^k()$

Any permutation can be implemented by a communication network composed of switches: this is called a Benes Network and uses even less space under the RAM model than the solutions described in the previous sections. Sparsely adding pointers accelerates the support of $\pi^k()$ to time within $O(\frac{\log n}{\log \log n})$.

Theorem 3 *For any strictly positive integer n and any permutation π on $[1 \dots n]$, there is a representation of π using at most $\lceil \lg(n!) \rceil + O(n)$ bits to support the operator $\pi^k()$ in time within $O(\log n / \log \log n)$.*

This representation uses space within an additive term within $O(n)$ of the optimal, both on average and in the worst case over all permutations over $[1 \dots n]$.

Compressed Data Structures

Any comparison-based sorting algorithm yields an encoding for permutations, and any adaptive sorting algorithm in the comparison model yields a compression scheme for permutations. Supporting operators on such compressed permutation in less time than required to decompress the whole of it requires some more work:

Runs

Barbay and Navarro [2] described how to segment a partition into $\texttt{nRuns}$ *runs* composed of consecutive positions forming already sorted blocks and how to merge those via a wavelet tree. This yields a data structure compressing a permutation within space optimal over all permutations with $\texttt{nRuns}$ runs of sizes given by the vector $\texttt{vRuns}$. This data structure supports the operators $\pi()$ and $\pi^{-1}()$ in sublinear time within $O(1 + \log \texttt{nRuns})$, with the average supporting time within $O(1 + \mathcal{H}(\texttt{vRuns}))$, which decreases with the entropy of the partition of the permutation into runs. Here, the *entropy* of a sequence of positive integers $X = \langle n_1, n_2, \dots, n_r \rangle$ adding up to n is $\mathcal{H}(X) = \sum_{i=1}^{r} \frac{n_i}{n} \lg \frac{n}{n_i}$.

Theorem 4 *For any strictly positive integer n and any permutation π on $[1 \dots n]$ which can be decomposed into $\texttt{nRuns}$ runs of sizes $\texttt{vRuns} = (r_1, \dots, r_{\texttt{nRuns}})$, there is a representation of π using at most $n\mathcal{H}(\texttt{vRuns}) + O(\texttt{nRuns} \log n) + o(n)$ bits to support the computation of $\pi(i)$ and $\pi^{-1}(i)$ in time within $O(1 + \log \texttt{nRuns})$ in the worst case over $i \in [1 \dots n]$ and in*

time within $O(1 + \mathcal{H}(\texttt{vRuns}))$ *on average when* $i \in [1 \ldots n]$ *is uniformly distributed. This compressed data structure can be computed in time within* $O(n(1 + \mathcal{H}(\texttt{vRuns})))$*, which is worst-case optimal in the comparison model over all such permutations decomposed into* nRuns *runs of sizes given by the vector* vRuns.

The partitioning takes only $n - 1$ comparisons, and the construction of the compressed data structure itself is an adaptive sorting algorithm improving over previous results [6,7].

Heads of Strict Runs

A two-level partition of the permutation yields further compression [2]. The first level partitions the permutation into *strict ascending runs* (maximal ranges of positions satisfying $\pi(i + k) = \pi(i) + k$). The second level partitions the *heads* (first position) of those strict runs into conventional ascending runs. This is analogous to the notion of blocks described by Moffat and Petersson [7] for multisets.

Theorem 5 *For any strictly positive integer* n *and any permutation* π *on* $[1 \ldots n]$ *which can be decomposed into* nBlock *strict runs and into* $\texttt{nRuns} \leq \texttt{nBlock}$ *monotone runs, let* vHRuns *be the vector formed by the* nRuns *monotone run lengths in the permutation of strict run heads. Then, there is a representation of* π *using at most* $\texttt{nBlock}\mathcal{H}(\texttt{vHRuns})) + O(\texttt{nBlock} \log \frac{n}{\texttt{nBlock}}) + o(n)$ *bits to support the operator* $\pi()$ *and* $\pi^{-1}()$ *in time within* $O(1 + \log \texttt{nBlock})$*. This compressed data structure can be computed in time within* $O(n(1 + \log \texttt{nBlock}))$.

Shuffled Subsequences

The preorder measures seen so far have considered runs which group contiguous positions in π: this does not need to be always the case. A permutation π over $[1 \ldots n]$ can be decomposed in n comparisons into a minimal number nSUS of *Shuffled Up Sequences*, defined as a set of, not necessarily consecutive, subsequences of increasing numbers that have to be removed from π in order to reduce it to the empty sequence [8]. Then those subsequences can be merged using the same techniques as above, which yields a new adaptive sorting algorithm and a new compressed data structure [2]. An optimal partition of a permutation π over $[1 \ldots n]$ into a minimal number nSMS of *Shuffled Monotone Sequences*, sequences of not necessarily consecutive subsequences of increasing or decreasing numbers, is NP-hard to compute [9], but if such a permutation is given, the same technique applies [10].

LRM Subsequences

LRM trees partition a sequence of values into consecutive sorted blocks and express the relative position of the first element of each block within a previous block. Such a tree can be computed in $2(n - 1)$ comparisons within the array and overall linear time, through an algorithm similar to that of Cartesian Trees [11]. The interest of LRM trees in the context of adaptive sorting and permutation compression is that the values are increasing in each root-to-leaf branch: they form a partition of the array into subsequences of increasing values. Barbay et al. [3] described how to compute the partition of the LRM tree of minimal size-vector entropy, which yields a compressed data structure asymptotically smaller than $\mathcal{H}(\texttt{vRuns})$-adaptive sorting, smaller in practice than $\mathcal{H}(\texttt{vSUS})$-adaptive sorting, as well as a faster adaptive sorting algorithm.

Number of Inversions

The preorder measure nInv counts the number of pairs (i, j) of positions $1 \leq i < j \leq n$ in a permutation π over $[1 \ldots n]$ such that $\pi(i) > \pi(j)$. Its value is exactly the number of comparisons performed by the algorithm `Insertion Sort`, between n and n^2 for a permutation over $[1 \ldots n]$. A variant of `Insertion Sort`, named `Local Insertion Sort`, sorts π in $n(1 + \lceil \lg(\texttt{nInv}/n) \rceil)$ comparisons [6,7].

Simply encoding the n values $(\pi(i) - i)_{i \in [1 \ldots n]}$ using the γ' code from Elias [12], and indexing the positions of the beginning of each code by a compressed bit vector, yields a compressed data structure supporting the operator $\pi()$ in constant time. The resulting data structure uses space within $n(1 + 2 \lg \frac{\texttt{nInv}}{n}) + o(n)$ bits. Support for

the operator $\pi^{-1}()$ can be added in two distinct ways, either encoding both π and π^{-1} using this technique within $2n(1 + 2\lg \frac{\texttt{nInv}}{n}) + o(n)$ bits, which supports both operators $\pi()$ and $\pi^{-1}()$ in constant time, or adding support for the operator $\pi^{-1}()$ using Munro et al.'s shortcut succinct index for permutations [1] described previously.

Removing Elements

The preorder measure `nRem` counts the minimum number of elements that must be removed from a permutation so that what remains is already sorted. Its exact value is n minus the length of the *Longest Increasing Subsequence*, which can be computed in time within $O(n \log n)$. Alternatively, the value of `nRem` can be approximated within a constant factor of 2 in $2(n - 1)$ comparisons. Partitioning π into the removed elements and the remaining ones through a bit vector of n bits, representing the order of the `2nRem` elements in a wavelet tree (using any of the data structures described above), and representing the merging of both into n bits yield a compressed data structure using space within $2n + 2\texttt{nRem}\lg(n/\texttt{nRem}) + o(n)$ bits and supporting the operators $\pi()$ and $\pi^{-1}()$ in sublinear time, within $O(1 + \log(\texttt{nRem} + 1))$.

Applications

Integer Functions

Munro et al. [1] extended the results on permutations to arbitrary functions from $[1 \ldots n]$ to $[1 \ldots n]$. Again $f^k(i)$ indicates the function iterated k times starting at i: if k is nonnegative, this is straightforward. The case in which k is negative is more complicated as the image is a (possibly empty) multiset over $[1 \ldots n]$.

Whereas π is a set of cycles, f can be viewed as a set of cycles in which each node is the root of a tree. Starting at any node (element of $[1 \ldots n]$), the evaluation moves one step along a branch of the tree, or one step along a cycle. Moving k steps in a positive direction is straightforward, and one moves up a tree and perhaps around a cycle. When k is negative, one must determine all nodes at distance k from the starting location, i, in the direction toward the leaves of the trees. The key technical issue is to run across succinct tree representations picking off all nodes at the appropriate levels. Using a raw encoding of the permutation mapping integers to the nodes, and Munro et al.'s shortcut succinct index [1] to support the operations on it, yields the following result:

Theorem 6 *For any fixed ε, $n > 0$ and $f : [1 \ldots n] \to [1 \ldots n]$, there is a representation of f using $(1 + \varepsilon)n \lg n + O(1)$ bits of space to compute $f^k(i)$ in time within $O(1 + |f^k(i)|)$, for any integer k and for any integer $i \in [1 \ldots n]$.*

Open Problems

Other Measures of Disorder

Moffat and Petersson [7] list many measures of preorder and adaptive sorting techniques. Each measure explored above yields a compressed data structure for permutations supporting the operators $\pi()$ and $\pi^{-1}()$ in sublinear time. Each adaptive sorting algorithm in the comparison model yields a compression scheme for permutations, but the encoding thus defined does not necessarily support the simple application of the permutation to a single element without decompressing the whole permutation nor the application of the inverse permutation. More work is required in order to decide whether there are compressed data structures for permutations, supporting the operators $\pi()$ and $\pi^{-1}()$ in sublinear time and using space proportional to the other preorder measures [6, 7] (e.g., `Reg`, `Exc`, `Block`, and `Enc`).

Sorting and Encoding Multisets

Munro and Spira [13] showed how to sort multisets through `MergeSort`, `Insertion Sort`, and `Heap Sort`, adapting them with counters to sort in time within $O(n(1 + \mathcal{H}(\langle m_1, \ldots, m_r \rangle)))$ where m_i is the number of occurrences of i in the multiset (note that this is orthogonal to the results described in this chapter that depend on the distribution of the lengths of monotone runs).

It seems easy to combine both approaches (e.g., on `MergeSort` in a single algorithm using both runs and counters), yet quite hard to *analyze* the complexity of the resulting algorithm and compressed data structure. The difficulty measure must depend not only on both the entropy of the partition into runs and the entropy of the partition of the values of the elements but also on the interaction of those partitions.

Compressed Data Structures Supporting $\pi^k()$

In Munro et al.'s "cycle" data structure [1] for supporting the operator $\pi^k()$ (Theorem 2), the raw encoding of the permutation σ representing the cycles of π can be replaced by any compressed data structure such as those described here, with the warning that the compressibility of σ depends not only on π but also on the order in which its cycles are placed in σ. The question if there is a compressed data structure supporting the operator $\pi^k()$ which takes advantage of this order is open.

Keywords

Succinct balanced parentheses

Years and Authors of Summarized Original Work

2001; Munro, Raman

Problem Definition

This problem is to design succinct representation of balanced parentheses in a manner in which a number of "natural" queries can be supported quickly, and use it to represent trees and graphs succinctly. The problem of succinctly representing balanced parentheses was initially proposed by Jacobson [6] in 1989, when he proposed *succinct data structures*, i.e., data structures that occupy space close to the information-theoretic

lower bound to represent them, while supporting efficient navigational operations. Succinct data structures provide solutions to manipulate large data in modern applications. The work of Munro and Raman [8] provides an optimal solution to the problem of balanced parentheses representation under the word RAM model, based on which they design succinct trees and graphs.

Balanced Parentheses

Given a balanced parenthesis sequence of length $2n$, where there are n opening parentheses and n closing parentheses, consider the following operations:

- `findclose`(i) (`findopen`(i)), the matching closing (opening) parenthesis for the opening (closing) parenthesis at position i;
- `excess`(i), the number of opening parentheses minus the number of closing parentheses in the sequence up to (and including) position i;
- `enclose`(i), the closest enclosing (matching parenthesis) pair of a given matching parenthesis pair whose opening parenthesis is at position i.

Trees

There are essentially two forms of trees. An *ordinal tree* is a rooted tree in which the children of a node are ordered and specified by their ranks, while in a *cardinal tree* of degree k, each child of a node is identified by a unique number from the set $\{1, 2, \cdots, k\}$. An *binary tree* is a cardinal tree of degree 2. The information-theoretic lower bound of representing an ordinal tree or binary tree of n nodes is $2n - o(n)$ bits, as there are $\binom{2n}{n}/(n+1)$ different ordinal trees or binary trees.

Consider the following operations on ordinal trees (a node is referred to by its preorder number):

- `child`(x, i), the ith child of node x for $i \geq 1$;
- `child_rank`(x), the number of left siblings of node x;
- `depth`(x), the depth of x, i.e., the number of edges in the rooted path to node x;
- `parent`(x), the parent of node x;
- `nbdesc`(x), the number of descendants of node x;
- `height`(x), the height of the subtree rooted at node x;
- `LCA`(x, y), the lowest common ancestor of node x and node y.

On binary trees, the operations `parent`, `nbdesc` and the following operations are considered:

- `leftchild`(x) (`rightchild`(x)), the left (right) child of node x.

Graphs

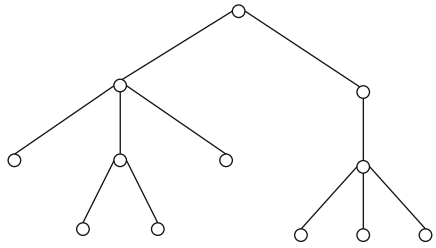
Consider an undirected graph G of n vertices and m edges. Bernhart and Kainen [1] introduced the concept of *page book embedding*. A *k-book embedding* of a graph is a topological embedding of it in a book of k pages that specifies the ordering of the vertices along the spine, and carries each edge into the interior of one page, such that the edges on a given page do not intersect. Thus, a graph with one page is an *outerplanar graph*. The *pagenumber* or *book thickness* [1] of a graph is the minimum number of pages that the graph can be embedded in. A very common type of graphs are planar graphs, and any planar graph can be embedded in at most four pages [15]. Consider the following operations on graphs:

- `adjacency`(x, y), whether vertices x and y are adjacent;
- `degree`(x), the degree of vertex x;
- `neighbors`(x), the neighbors of vertex x.

Key Results

All the results cited are under the word RAM model with word size $\Theta(\lg n)$ bits ($\lg n$ denotes $\lceil \log_2 n \rceil$), where n is the size of the problem considered.

Theorem 1 ([8]) *A sequence of balanced parentheses of length 2n can be represented using*



Balanced parentheses: ((( ) (( ) ( )) ( )) ((( ) ( ) ( ))))

Succinct Data Structures for Parentheses Matching, Fig. 1 An example of the balanced parenthesis sequence of a given ordinal tree

$2n + o(n)$ *bits to support the operations findclose, findopen, excess and enclose in constant time.*

There is a polymorphism between a balanced parenthesis sequence and an ordinal tree: when performing a depth-first traversal of the tree, output an opening parenthesis each time a node is visited, and a closing parenthesis immediately after all the descendants of a node are visited (see Fig. 1 for an example). The work of Munro and Raman proposes a succinct representation of ordinal trees using $2n + o(n)$ bits to support `depth`, `parent` and `nbdesc` in constant time, and `child`(x, i) in $O(i)$ time. Lu and Yeh have further extended this representation to support `child`, `child_rank`, `height` and `LCA` in constant time.

Theorem 2 ([8, 7]) *An ordinal tree of n nodes can be represented using* $2n + o(n)$ *bits to support the operations child, child_rank, parent, depth, nbdesc, height and LCA in constant time.*

A similar approach can be used to represent binary trees:

Theorem 3 ([8]) *A binary tree of n nodes can be represented using* $2n + o(n)$ *bits to support the operations leftchild, rightchild, parent and nbdesc in constant time.*

Finally, balanced parentheses can be used to represent graphs. To represent a one-page graph, the work of Munro and Raman proposes to list the vertices from left to right along the spine, and each node is represented by a pair of parentheses, followed by zero or more closing parentheses and then zero or more opening parentheses, where the number of closing (or opening) parentheses is equal to the number of adjacent vertices to its left (or right) along the spine (see Fig. 2 for an example). This representation can be applied to each page to represent a graph with pagenumber k.

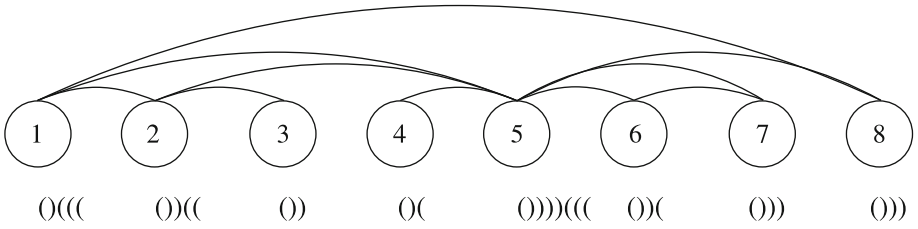
Theorem 4 ([8]) *An outerplanar graph of n vertices and m edges can be represented using* $2n + 2m + o(n + m)$ *bits to support operations adjacency and degree in constant time, and neighbors(x) in time proportional to the degree of x.*

Theorem 5 ([8]) *A graph of n vertices and m edges with pagenumber k can be represented using* $2kn + 2m + o(nk + m)$ *bits to support operations adjacency and degree in* $O(k)$ *time, and neighbors(x) in* $O(d(x) + k)$ *time where d(x) is the degree of x. In particular, a planar graph of n vertices and m nodes can be represented using* $8n + 2m + o(n)$ *bits to support operations adjacency and degree in constant time, and neighbors(x) in* $O(d(x))$ *time where d(x) is the degree of x.*

Applications

Succinct Representation of Suffix Trees

As a result of the growth of the textual data in databases and on the World Wide Web, and also applications in bioinformatics, various indexing techniques have been developed to facilitate pattern searching. Suffix trees [14] are a popular type of text indexes. A suffix tree is constructed over the suffixes of the text as a tree-based data structure, so that queries can be performed by searching the suffixes of the text. It takes $O(m)$ time to use a suffix tree to check whether an arbitrary pattern P of length m is a substring of a given text T of length n, and to count the number of the occurrences, occ, of P in T. $O(occ)$ additional time is required to list all the occurrences



Succinct Data Structures for Parentheses Matching, Fig. 2 An example of the balanced parenthesis sequence of a graph with one page

of P in T. However, a standard representation of a suffix tree requires somewhere between $4n \lg n$ and $6n \lg n$ bits, which is impractical for many applications.

By reducing the space cost of representing the tree structure of a suffix tree (using the work of Munro and Raman), Munro, Raman and Rao [9] have designed space-efficient suffix trees. Given a string of n characters over a fixed alphabet, they can represent a suffix tree using $n \lg n + O(n)$ bits to support the search of a pattern in $O(m + occ)$ time. To achieve this result, they have also extended the work of Munro and Raman to support various operations to retrieve the leaves of a given subtree in an ordinal tree. Based on similar ideas and by applying compressed suffix arrays [5], Sadakane [13] has proposed a different trade-off; his compressed suffix tree occupies $O(n \lg \sigma)$ bits, where σ is the size of the alphabet, and can support any algorithm on a suffix tree with a slight slowdown of a factor of polylog(n).

Succinct Representation of Functions

Munro and Rao [11] have considered the problem of succinctly representing a given function, $f : [n] \to [n]$, to support the computation of $f^k(i)$ for an arbitrary integer k. The straightforward representation of a function is to store the sequence $f(i)$, for $i = 0, 1, \ldots, n-1$. This takes $n \lg n$ bits, which is optimal. However, the computation of $f^k(i)$ takes $\Theta(k)$ time even in the easier case when k is positive. To address this problem, Munro and Rao [11] first extends the representation of balanced parenthesis to support the `next_excess`(i, k) operator, which returns the minimum j such that $j > i$ and `excess`$(j) = k$. They further use this operator to support the `level_anc`(x, i) operator on succinct ordinal trees, which returns the ith ancestor of node x for $i \geq 0$ (given a node x at depth d, its ith ancestor is the ancestor of x at depth $d - i$). Then, using succinct ordinal trees with the support for `level_anc`, they propose a succinct representation of functions using $(1 + \epsilon)n \lg n + O(1)$ bits for any fixed positive constant ϵ, to support $f^k(i)$ in constant time when $k > 0$, and $f^k(i)$ in $O(1 + |f^k(i)|)$ time when $k < 0$.

Multiple Parentheses and Graphs

Chuang et al. [3] have proposed to succinctly represent *multiple parentheses*, which is a string of $O(1)$ types of parentheses that may be unbalanced. They have extended the operations on balanced parentheses to multiple parentheses and designed a succinct representation. Based on the properties of canonical orderings for planar graphs, they have used multiple parentheses and the succinct ordinal trees to represent planar graphs. One of their main results is a succinct representation of planar graphs of n vertices and m edges in $2m + (5 + \epsilon)n + o(m + n)$ bits, for any constant $\epsilon > 0$, to support the operations supported on planar graphs in Theorem 5 in asymptotically the same amount of time. Chiang et al. [2] have further reduced the space cost to $2m + 3n + o(m + n)$ bits. In their paper, they have also shown how to support the operation `wrapped`(i), which returns the number of matching parenthesis pairs whose closest enclosing (matching parenthesis) pair is the pair whose opening parenthesis is at position i, in constant time on balanced parentheses. They

have used it to show how to support the operation `degree`(x), which returns the degree of node x (i.e., the number of its children), in constant time on succinct ordinal trees.

Open Problems

One open research area is to support more operations on succinct trees. For example, it is not known how to support the operation to convert a given node's rank in a preorder traversal into its rank in a level-order traversal.

Another open research area is to further reduce the space cost of succinct planar graphs. It is not known whether it is possible to further improve the encoding of Chiang et al. [2].

A third direction for future work is to design succinct representations of dynamic trees and graphs. There have been some preliminary results by Munro et al. [10] on succinctly representing dynamic binary trees, which have been further improved by Raman and Rao [12]. It may be possible to further improve these results, and there are other related dynamic data structures that do not have succinct representations.

Experimental Results

Geary et al. [4] have engineered the implementation of succinct ordinal trees based on balanced parentheses. They have performed experiments on large XML trees. Their implementation uses orders of magnitude less space than the standard pointed-based representation, while supporting tree traversal operations with only a slight slowdown.

Suffix Array Construction

Juha Kärkkäinen
Department of Computer Science, University of Helsinki, Helsinki, Finland

Keywords

Longest common prefix array; Suffix array; Suffix sorting; Text indexing

Years and Authors of Summarized Original Work

2006; Kärkkäinen, Sanders, Burkhardt

Problem Definition

The *suffix array* [4, 15] is the lexicographically sorted array of all the suffixes of a string. It is a popular text index structure with many applications. The subject of this entry is algorithms that construct the suffix array.

More precisely, the input to a suffix array construction algorithm is a *text string* $T = T[0 \ldots n) = t_0 t_1 \ldots t_{n-1}$, i.e., a sequence of n *characters* from an *alphabet* Σ. For $i \in [0 \ldots n]$, let S_i denote the *suffix* $T[i \ldots n) = t_i t_{i+1} \ldots t_{n-1}$. The output is the *suffix array* $SA[0 \ldots n]$ of T, a permutation of $[0 \ldots n]$ satisfying $S_{SA[0]} < S_{SA[1]} < \cdots < S_{SA[n]}$, where $<$ denotes the *lexicographical order* of strings.

Two specific models for the alphabet Σ are considered. An *ordered alphabet* is an arbitrary ordered set with constant time character comparisons. An *integer alphabet* is the integer range $[1 \ldots \sigma]$ for $\sigma = n^{\mathcal{O}(1)}$.

Many applications require that the suffix array is augmented with additional information, most commonly with the *longest common prefix* array $LCP[1 \ldots n]$. An entry $LCP[i]$ of the LCP array is the length of the longest common prefix of the suffixes $S_{SA[i]}$ and $S_{SA[i-1]}$. The *enhanced suffix array* [1] adds two more arrays to obtain a full range of text index functionalities.

There are other important text indexes, most notably suffix trees and compressed text indexes, covered in separate entries. Each of these indexes has their own construction algorithms, but they can also be constructed efficiently from each other. However, in this entry, the focus is on direct suffix array construction algorithms that do not rely on other text indexes.

Key Results

The naive approach to suffix array construction is to use a general sorting algorithm or an algorithm for sorting strings. However, any such algorithm has a worst-case time complexity $\Omega(n^2)$ because the total length of the suffixes is $\Omega(n^2)$.

The first efficient algorithms were based on the *doubling technique* of Karp, Miller, and Rosenberg [10]. The idea is to assign a *rank* to all substrings whose length is a power of two. The rank tells the lexicographic order of the substring among substrings of the same length. Given the ranks for substrings of length h, the ranks for substrings of length $2h$ can be computed using a radix sort step in linear time (doubling). The technique was first applied to suffix array construction by Manber and Myers [15]. The best practical algorithm based on the technique is by Larsson and Sadakane [14].

Theorem 1 (Manber and Myers [15]; Larsson and Sadakane [14]) *The suffix array can be constructed in $\mathcal{O}(n \log n)$ time, which is optimal for the ordered alphabet.*

Faster algorithms for the integer alphabet are based on a different technique, recursion. The basic procedure is as follows.

1. Sort a subset of the suffixes. This is done by constructing a shorter string, whose suffix array gives the order of the desired subset. The suffix array of the shorter string is constructed by recursion.
2. Extend the subset order to full order.

The technique first appeared in suffix tree construction [3], but 2003 saw the independent and simultaneous publication of three linear time suffix array construction algorithms based on the approach but not using suffix trees. Each of the three algorithms uses a different subset of suffixes requiring a different implementation of the second step.

Theorem 2 (Kärkkäinen, Sanders, and Burkhardt [8]; Kim et al. [12]; Ko and Aluru [13]) *The suffix array can be constructed in the optimal linear time for the integer alphabet.*

We will describe the algorithm of Kärkkäinen, Sanders, and Burkhardt [8] called DC3 in more detail. For $k \in \{0, 1, 2\}$, let $\mathcal{R}_k$ be the set of suffixes S_i such that $i \bmod 3 = k$. Let $\mathcal{R}_{12} = \mathcal{R}_1 \cup \mathcal{R}_2$ and define $\mathcal{R}_{01}$ and $\mathcal{R}_{02}$ symmetrically. For example, $\mathcal{R}_{12} = \{S_1, S_2, S_4, S_5, S_7, S_8, \dots\}$. The set $\mathcal{R}_{12}$ is the subset of suffixes sorted first. For $S_i \in \mathcal{R}_{12}$, let $\bar{S}_i$ be the lexicographical rank of S_i in $\mathcal{R}_{12}$. Given those lexicographical ranks, we can compare any two suffixes S_i and S_j in constant time using one of the following ways:

1. If $S_i, S_j \in \mathcal{R}_{12}$, compare the ranks $\bar{S}_i$ and $\bar{S}_j$.
2. If $S_i, S_j \in \mathcal{R}_{01}$, compare the pairs $\langle t_i, \bar{S}_{i+1}\rangle$ and $\langle t_j, \bar{S}_{j+1}\rangle$.
3. If $S_i, S_j \in \mathcal{R}_{02}$, compare the triples $\langle t_i, t_{i+1}, \bar{S}_{i+2}\rangle$ and $\langle t_j, t_{j+1}, \bar{S}_{j+2}\rangle$.

Furthermore, we can radix sort $\mathcal{R}_0$ in linear time by using $\langle t_i, \bar{S}_{i+1}\rangle$ to represent the suffix $S_i \in \mathcal{R}_0$. After this, we can merge $\mathcal{R}_0$ and $\mathcal{R}_{12}$, which takes linear time since we can compare suffixes in constant time.

We still need to describe how to sort $\mathcal{R}_{12}$. Let $\overline{t_i t_{i+1} t_{i+2}}$ be the lexicographical rank of the substring $t_i t_{i+1} t_{i+2}$ among all substrings of length three. Let

$$T_{12} = \overline{t_1 t_2 t_3}\ \overline{t_4 t_5 t_6}\ \overline{t_7 t_8 t_9} \dots \overline{t_2 t_3 t_4}\ \overline{t_5 t_6 t_7}\ \overline{t_8 t_9 t_{10}} \dots .$$

For example if $T =$ `yabbadabbado`, we have

$$T_{12} = \overline{\texttt{abb}}\ \overline{\texttt{ada}}\ \overline{\texttt{bba}}\ \overline{\texttt{do\$}}\ \overline{\texttt{bba}}\ \overline{\texttt{dab}}\ \overline{\texttt{bad}}\ \overline{\texttt{o\$\$}} = 12575648 ,$$

where \$ is a special padding symbol that does not appear in the text and is considered smaller than any normal character. Clearly, sorting the suffixes of T_{12} is equivalent to sorting the set $\mathcal{R}_{12}$. The suffixes of T_{12} are sorted by a recursive call to the algorithm itself. Since the recursive call is for a text of length at most $\lceil 2n/3 \rceil$ and everything outside the recursive call can be done in linear time, the total time complexity of DC3 is $\mathcal{O}(n)$.

The above algorithms and many other suffix array construction algorithms are surveyed in [18]. Worth mentioning among the more recent results are the linear time algorithms of Nong, Zhang, and Chan [17].

The $\Omega(n \log n)$ lower bound for the ordered alphabet mentioned in Theorem 1 comes from the sorting complexity of characters, since the initial characters of the sorted suffixes are the text characters in sorted order. Theorem 2 allows a generalization of this result. For any alphabet, one can first sort the characters of T, remove duplicates, assign a rank to each character, and construct a new string T' over the alphabet $[1 \dots n]$ by replacing the characters of T with their ranks. The suffix array of T' is exactly the same as the suffix array of T. Optimal algorithms for the integer alphabet then give the following result.

Theorem 3 *For any alphabet, the complexity of suffix array construction is the same as the complexity of sorting the characters of the string.*

The result extends to the related arrays.

Theorem 4 (Kasai et al. [11]; Abouelhoda, Kurtz, and Ohlebusch [1]) *The LCP array and the enhanced suffix array can be computed in linear time given the suffix array.*

One of the main advantages of suffix arrays over suffix trees is their smaller space requirement (by a constant factor), and a significant effort has been spent making construction algorithms space efficient, too. The best algorithms need very little extra space.

Theorem 5 (Kärkkäinen, Sanders, and Burkhardt [8]; Nong [16]) *For any* $v = \mathcal{O}(n^{2/3})$*, the suffix array can be constructed in* $\mathcal{O}(n(v + \log n))$ *time and* $\mathcal{O}(n/\sqrt{v})$ *extra space for the ordered alphabet and in* $\mathcal{O}(nv)$ *time and* $\mathcal{O}(n/\sqrt{v})$ *extra space or* $\mathcal{O}(n)$ *time and* $\mathcal{O}(\sigma)$ *extra space for the integer alphabet, where the extra space is the space needed in addition to the input (the string* T*) and the output (the suffix array).*

In the algorithm DC3 described above, all steps can be performed by sorting, prefix sums (assigning lexicographical ranks) and localized computation. This makes it straightforward to adapt to several parallel and hierarchical memory models of computation [8] including the following result for the standard external memory model.

Theorem 6 (Kärkkäinen, Sanders, and Burkhardt [8]) *The suffix array can be constructed in the optimal* $\mathcal{O}(\text{sort}(n))$ *I/Os in the standard external memory model, where* $\text{sort}(n)$ *is the I/O complexity of sorting n elements.*

The above algorithm can be modified to compute the LCP array too in the same I/O complexity [2, 7].

Applications

The suffix array is a simple and powerful text index structure with numerous applications; see [1] and Cross-References. The practical construction of many other text indexes usually starts with the suffix array construction. In particular, the Burrows–Wheeler transform, which is an important technique for text compression and the basis of many compressed text indexes, is easily computed from the suffix array.

Open Problems

Theoretically, the suffix array construction problem is essentially solved. The development of ever more efficient practical algorithms is still going on particularly for external memory and parallel computation. There is currently no external memory algorithm for computing the LCP array from the suffix array in $\mathcal{O}(\text{sort}(n))$ I/Os other than as a side effect of suffix array construction [6].

Experimental Results

Many papers on suffix array construction contain experimental results, but they are usually either out of date (e.g., [18]) or limited in scope (e.g., [16]). The most comprehensive comparison of algorithms is at https://code.google.com/p/libdivsufsort/wiki/SACA_Benchmarks. The best practical algorithms for large data are `divsufsort`, which is an $\mathcal{O}(n \log n)$ time algorithm combining several techniques, and `SAIS`, which is an implementation of the linear time algorithm by Gong, Zhang, and Chan [17] (see below for URLs to code). The comparison and the fastest implementation are by the same person, Yuta Mori, but the implementations are widely used and there are no substantial claims for other, faster algorithms.

There are also experiments for suffix array construction in external memory [2, 5] and for LCP array construction [2, 6, 9].

URLs to Code and Data Sets

The input to a suffix array construction algorithm is simply a text, so an abundance of data exists. Links to many text collections are provided at https://code.google.com/p/libdivsufsort/wiki/SACA_Benchmarks. Worth mentioning is also the Pizza&Chili site with its standard text corpus http://pizzachili.dcc.uchile.cl/texts.html and the repetitive text corpus http://pizzachili.dcc.uchile.cl/repcorpus.html.

Notable implementations of suffix array construction algorithms are available at https://code.google.com/p/libdivsufsort/, at https://sites.google.com/site/yuta256/sais, at http://panthema.net/2012/1119-eSAIS-Inducing-Suffix-and-LCP-Arrays-in-External-Memory/ [2], and at https://

www.cs.helsinki.fi/group/pads/SAscan.html [5]. The latter two work in external memory and provide (links to) LCP array construction too.

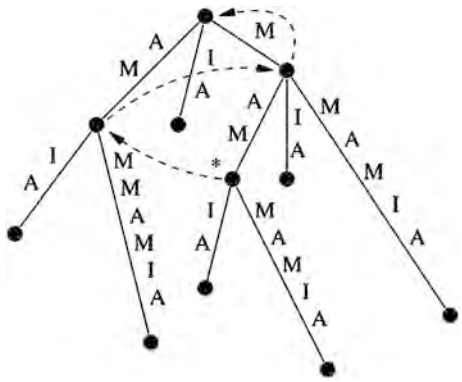
Problem Definition

The suffix tree is perhaps the best-known and most-studied data structure for string indexing with applications in many fields of sequence analysis. After its invention in the early 1970s, several approaches for the efficient construction of the suffix tree of a string have been developed for various models of computation. The most prominent of those that construct the suffix tree in main memory are summarized in this entry.

Notations

Given an alphabet Σ, a *trie* over Σ is a rooted tree whose edges are labeled with strings over Σ such that no two labels of edges leaving the same vertex start with the same symbol. A trie is *compacted* if all its internal vertices, except possibly the root, are branching. Given a finite string $S \in \Sigma^n$, the *suffix tree* of S, $T(S)$, is the compacted trie over Σ such that the concatenations of the edge labels along the paths from the root to the leaves are the suffixes of S. An example is given in Fig. 1.

The concatenation of the edge labels from the root to a vertex v of $T(S)$ is called the *path-label* of v, $P(v)$. For example, the path label of the vertex indicated by the asterisk in Fig. 1 is $P(*) = \text{MAM}$.



Suffix Tree Construction, Fig. 1 The suffix tree for the string $S = \text{MAMMAMIA}$. *Dashed arrows* denote suffix links that are employed by all efficient suffix tree construction algorithms

Constraints

The time complexity of constructing the suffix tree of a string S of length n depends on the size of the underlying alphabet Σ. It may be constant, it may be the alphabet of integers $\Sigma = \{1, 2, \ldots, n\}$, or it may be an arbitrary finite set whose elements can be compared in constant time. Note that the latter case reduces to the previous one if one maps the symbols of the alphabet to the set $\{1, \ldots, n\}$, though at the additional cost of sorting Σ.

Problem 1 (suffix tree construction)

INPUT: A finite string S of length n over an alphabet Σ.
OUTPUT: The suffix tree $T(S)$.

If one assumes that the outgoing edges at each vertex are lexicographically sorted, which is usually the case, the suffix tree allows retrieving the sorted order of S's characters in linear time. Therefore, suffix tree construction inherits the lower bounds from the problem complexity of sorting: $\Omega(n \log n)$ in the general alphabet case and $\Omega(n)$ for integer alphabets.

Key Results

Theorem 1 *The suffix tree of a string of length n can be represented in $O(n \log n)$ bits of space.*

This is easy to see since the number of leaves of $T(S)$ is at most n, and so is the number of internal vertices that, by definition, are all branching, as well as the number of edges. In order to see that each edge label can be stored in $O(\log n)$ bits of space, note that an edge label is always a substring of S. Hence it can be represented by a pair (l, r) consisting of *left pointer* l and *right pointer* r, if the label is $S[l, r]$.

Note that this space bound is not optimal since there are $|\Sigma|^n$ different strings and hence suffix trees, while $n \log n$ bits would allow to represent $n!$ different entities.

Theorem 2 *Suffix trees can be constructed in optimal time, in particular:*

1. For constant-size alphabet, the suffix tree $T(S)$ of a string S of length n can be constructed in $O(n)$ time [11–13]. For general alphabet, these algorithms require $O(n \log n)$ time.
2. For integer alphabet, the suffix tree of S can be constructed in $O(n)$ time [4,9].

Generally, there is a natural strategy to construct a suffix tree: Iteratively all suffixes are inserted into an initially empty structure. Such a strategy will immediately lead to a linear-time construction algorithm if each suffix can be inserted in constant time. Finding the correct position where to insert a suffix, however, is the main difficulty of suffix tree construction.

The first solution for this problem was given by Weiner in his seminal 1973 paper [13]. His algorithm inserts the suffixes from shortest to longest, and the insertion point is found in amortized constant time for constant-size alphabet, using rather a complicated amount of additional data structures. A simplified version of the algorithm was presented by Chen and Seiferas [3]. They give a cleaner presentation of the three types of links that are required in order to find the insertion points of suffixes efficiently, and their complexity proof is easier to follow. Since the suffix tree is constructed while reading the text from right to left, these two algorithms are sometimes called *anti-online* constructions.

A different algorithm was given in 1976 by McCreight [11]. In this algorithm the suffixes are inserted into the growing tree from longest to shortest. This simplifies the update procedure, and the additional data structure is limited to just one type of link: an internal vertex v with path label $P(v) = aw$ for some symbol $a \in \Sigma$ and string $w \in \Sigma^*$ has a *suffix link* to the vertex u with path label $P(u) = w$. In Fig. 1, suffix links are shown as dashed arrows. They often connect vertices above the insertion points of consecutively inserted suffixes, like the vertex with path-label "M" and the root, when inserting suffixes "MAMIA" and "AMIA" in the example of Fig. 1. This property allows reaching the next insertion point without having to search for it from the root of the tree, thus ensuring amortized constant time per suffix insertion. Note that since McCreight's algorithm treats the suffixes from longest to shortest and the intermediate structures are not suffix trees, the algorithm is not an online algorithm.

Another linear-time algorithm for constant-size alphabet is the online construction by Ukkonen [12]. It reads the text from left to right and updates the suffix tree in amortized constant time per added symbol. Again, the algorithm uses suffix links in order to quickly find the insertion points for the suffixes to be inserted. Moreover, since during a single update the edge labels of all leaf edges need to be extended by the new symbol, it requires a trick to extend all these labels in constant time: all the right pointers of the leaf edges refer to the same *end of string* value, which is just incremented.

An even stronger concept than online construction is *real-time* construction, where the worst-case (instead of amortized) time per symbol is considered. Amir et al. [1] present for general alphabet a suffix tree construction algorithm that requires $O(\log n)$ worst-case update time per every single input symbol when the text is read from right to left, and thus requires overall $O(n \log n)$ time, like the other algorithms for general alphabet mentioned so far. They achieve this goal using a binary search tree on the suffixes of the text, enhanced by additional pointers representing the lexicographic and the textual order of the suffixes, called *Balanced Indexing Structure*. This tree can be constructed in $O(\log\ n)$ worst-case time per added symbol and allows maintaining the suffix tree in the same time bound.

The first linear-time suffix tree construction algorithm for integer alphabets was given by Farach-Colton [4]. It uses the so-called *odd-even technique* that proceeds in three steps:

1. Recursively compute the compacted trie of all suffixes of S beginning at odd positions, called the *odd tree* T_o.
2. From T_o compute the *even tree* T_e, the compacted trie of the suffixes beginning at even positions in S.

3. Merge T_o and T_e into the whole suffix tree $T(S)$.

The basic idea of the first step is to encode pairs of characters as single characters. Since at most $n/2$ different such characters can occur, these can be radix-sorted and range-reduced to an alphabet of size $n/2$. Thus, the string S of length n over the integer alphabet $\Sigma = \{1, \ldots, n\}$ is translated in $O(n)$ time into a string S' of length $n/2$ over the integer alphabet $\Sigma' = \{1, \ldots, n/2\}$. Applying the algorithm recursively to this string yields the suffix tree of S'. After translating the edge labels from substrings of S' back to substrings of S, some vertices may exist with outgoing edges whose labels start with the same symbol, because two distinct symbols from Σ' may be pairs with the same first symbol from Σ. In such cases, by local modifications of edge labels or adding additional vertices, the trie property can be regained and the desired tree T_o is obtained.

In the second step, the odd tree T_o from the first step is used to generate the lexicographically sorted list (*lex-ordering* for short) of the suffixes starting at odd positions. Radix-sorting these with the characters at the preceding even positions as keys yields a lex-ordering of the even suffixes in linear time. Together with the longest common prefixes (lcps) of consecutive positions that can be computed in linear time from T_o using constant-time lowest common ancestor queries and the identity

$$\mathrm{lcp}(l_{2i}, l_{2j}) = \begin{cases} \mathrm{lcp}(l_{2i+1}, l_{2j+1}) + 1 & \text{if } S[2i] = S[2j] \\ 0 & \text{otherwise} \end{cases}$$

this ordering allows reconstructing the even tree T_e in linear time.

In the third step, the two tries T_o and T_e are merged into the suffix tree $T(S)$. Conceptually, this is a straightforward procedure: the two tries are traversed in parallel, and every part that is present in one or both of the two trees is inserted in the common structure. However, this procedure is simple only if edges are traversed character by character such that common and differing parts can be observed directly. Such a traversal would, however, require $O(n^2)$ time in the worst case, impeding the desired overall linear running time. Therefore, Farach-Colton suggests to use an oracle that tells for an edge of T_o and an edge of T_e the length of their common prefix.

However, the suggested oracle may overestimate this length, and that is why sometimes the tree generated must be corrected, called *unmerging*. The full details of the oracle and the unmerging procedure can be found in [4].

Overall, if $T(n)$ is the time it takes to build the suffix tree of a string $S \in \{1, \ldots, \mathrm{n}\}^n$, the first step takes $T(n/2) + O(n)$ time and the second and third steps take $O(n)$ time; thus the whole procedure takes $O(n)$ overall time on the RAM model.

Another linear-time construction of suffix trees for integer alphabets can be achieved via linear-time construction of suffix arrays together with longest common prefix tabulation, as described by Kärkkäinen and Sanders in [9].

All previously mentioned algorithms construct the suffix tree in main memory. However, since the data structure may become very large in practice, also methods for building the suffix tree in secondary memory have been studied. Possibly the simplest way is to first construct the suffix array A and the LCP array on disk, as described in the entry ▸ Suffix Array Construction. When this is done, it is only a small final step to construct the suffix tree [4]. The idea is to construct the tree in n phases from left to right, such that after phase i the suffix tree of the strings $A[1], \ldots, A[i]$ has been constructed. Simultaneously, an external-memory stack containing the nodes on the path leading from the root to $A[i]$ is maintained. In phase $i+1$, first, the leaf representing string $A[i+1]$ is created, and then all nodes are popped from the stack whose string length is strictly

greater than LCP[i]. Next, a new node with string depth LCP[i] is created (unless it already exists) whose parent is the top element of the stack and whose children are the last popped element and the new leaf. This new node and the new leaf are finally pushed on the stack. Keeping the two top pages of the stack in internal memory, the algorithm executes a total of $O(n)$ pop and push operations and therefore uses a total of $O(n/B)$ time, where B is the external memory block size.

Other more direct ways to construct the suffix tree on disk have also been developed, e.g., [14, 15].

In some applications the so-called *generalized* suffix tree of several strings is used, a dictionary obtained by constructing the suffix tree of the concatenation of the contained strings. An important question that arises in this context is that of dynamically updating the tree upon insertion and deletion of strings from the dictionary. More specifically, since edge labels are stored as pairs of pointers into the original string, when deleting a string from the dictionary, the corresponding pointers may become invalid and need to be updated. An algorithm to solve this problem in amortized linear time was given by Fiala and Greene [6], and a linear worst-case (and hence real-time) algorithm was given by Ferragina et al. [5].

Applications

The suffix tree supports many applications, most of them in optimal time and space, including exact string matching, set matching, longest common substring of two or more sequences, all-pairs suffix-prefix matching, repeat finding, and text compression. These and several other applications, many of them from bioinformatics, are given in [2] and [8].

Open Problems

Some theoretical questions regarding the expected size and branching structure of suffix trees under more complicated than i. i. d. sequence models are still open. Currently most of the research has moved toward more space-efficient data structures like suffix arrays and compressed string indices or the Burrows-Wheeler Transform.

Experimental Results

Suffix trees are infamous for their high memory requirements. The practical space consumption is between 9 and 11 times the size of the string to be indexed, even in the most space-efficient implementations known [7, 10]. Moreover, [7] also shows that suboptimal algorithms like the very simple quadratic-time *write-only top-down* (WOTD) algorithm can outperform optimal algorithms on many real-world instances in practice, if carefully engineered.

URLs to Code and Data Sets

Several sequence analysis libraries contain code for suffix tree construction. For example, Strmat (http://www.cs.ucdavis.edu/~gusfield/strmat.html) by Gusfield et al. contains implementations of Weiner's and Ukkonen's algorithm. An implementation of the WOTD algorithm by Kurtz can be found at (http://bibiserv.techfak.uni-bielefeld.de/wotd).

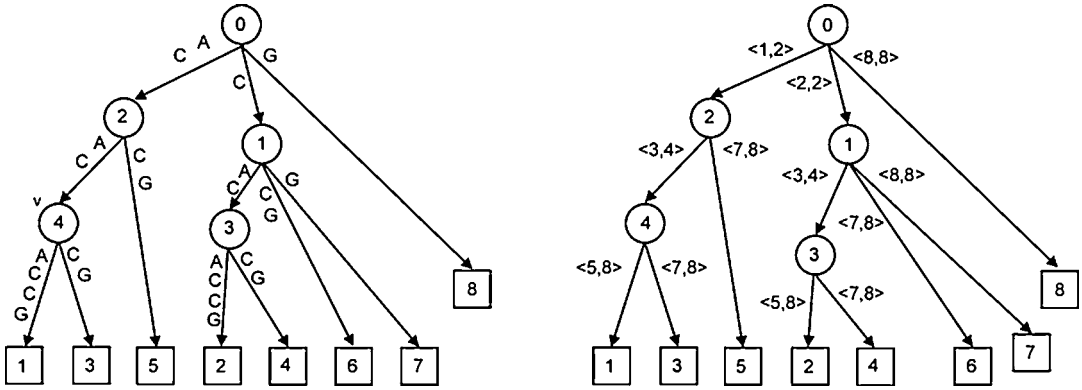
Problem Definition

The suffix tree is the ubiquitous data structure of combinatorial pattern matching myriad of situations – just to cite a few, searching, data compression and mining, and bioinformatics [7]. In these applications, the large data sets now available involve the use of numerous memory levels which constitute the storage medium of modern PCs: L1 and L2 caches, internal memory, multiple disks, and remote hosts over a network. The power of this memory organization is that it may be able to offer the expected access time of the fastest level (i.e., cache) while keeping the average cost per memory cell near the one of the cheapest level (i.e., disk), provided that data are properly *cached* and *delivered* to the requiring algorithms. Neglecting questions pertaining to the cost of memory references may even prevent the use of algorithms on large sets of input data. Engineering research is presently trying to improve the input/output subsystem to reduce the impact of these issues, but it is very well known [20] that the improvements achievable by means of a *proper arrangement of data* and a properly *structured algorithmic computation* abundantly surpass the best-expected technology advancements.

The Model of Computation

In order to reason about algorithms and data structures operating on hierarchical memories, it is necessary to introduce a *model of computation* that grasps the essence of real situations so that algorithms that are good in the model are also good in practice. The model considered here is the *external-memory model* [20], which received much attention because of its simplicity and reasonable accuracy. A computer is abstracted to consist of *two memory levels*: the internal memory of size M and the (unbounded) disk memory which operates by reading/writing data in blocks of size B (called *disk pages*). The performance of algorithms is then evaluated by counting (a) the number of disk accesses (I/Os), (b) the internal running time (CPU time), and (c) the number of disk pages occupied by the data structure or used by the algorithm as its working space. This simple model suggests, correctly, that a good external-memory algorithm should exploit both *spatial locality* and *temporal locality*. Of course, "I/O" and "two-level view" refer to any two levels



Suffix Tree Construction in Hierarchical Memory, Fig. 1 The suffix tree of $S = \texttt{ACACACCG}$ on the *left*, and its compact edge-encoding on the *right*. The endmarker # is not shown. Node v spells out the string *ACAC*. Each internal node stores the length of its associated string, and each leaf stores the starting position of its corresponding suffix

of the memory hierarchy with their parameters M and B properly set.

Notation

Let $S[1, n]$ be a string drawn from alphabet Σ, and consider the notation: S_i for the ith *suffix* of string S, $\texttt{lcp}(\alpha, \beta)$ for the *longest common prefix* between the two strings α and β, and $\texttt{lca}(u, v)$ for the *lowest common ancestor* between two nodes u and v in a tree.

The suffix tree of $S[1, n]$, denoted hereafter by $\mathcal{T}_S$, is a tree that stores all suffixes of $S\#$ in a compact form, where $\# \notin \Sigma$ is a special character (see Fig. 1). $\mathcal{T}_S$ consists of n leaves, numbered from 1 to n, and any root-to-leaf path spells out a suffix of $S\#$. The endmarker # guarantees that no suffix is the prefix of another suffix in $S\#$. Each internal node has at least two children and each edge is labeled with a nonempty substring of S. No two edges out of a node can begin with the same character, and sibling edges are ordered lexicographically according to that character. Edge labels are encoded with pairs of integers – say $S[x, y]$ is represented by the pair $\langle x, y \rangle$. As a result, all $\Theta(n^2)$ substrings of S can be represented in $O(n)$ optimal space by $\mathcal{T}_S$'s structure and edge encoding. Furthermore, the rightward scan of the suffix-tree leaves gives the ordered set of S's suffixes, also known as the *suffix array* of S [13]. Notice that the case of a large string collection $\Delta = \{S^1, S^2, \ldots, S^k\}$ *reduces to* the case of one long string $S = S^1 \#_1 S^2 \#_2 \cdots S^k \#_k$, where $\#_i \notin \Sigma$ are special symbols.

Numerous algorithms are known that build the suffix tree optimally in the RAM model (see [3] and references therein). However, most of them exhibit a marked absence of *locality of references* and thus elicit many I/Os when the size of the indexed string is too large to be fit into the internal memory of the computer. This is a serious problem because the slow performance of these algorithms can prevent the suffix tree being used even in medium-scale applications. This encyclopedia's entry surveys algorithmic solutions that deal efficiently with the *construction of suffix trees over large string collections* by executing an optimal number of I/Os. Since it is assumed that the edges leaving a node in $\mathcal{T}_S$ are lexicographically sorted, sorting is an obvious *lower bound* for building suffix trees (consider the suffix tree of a permutation!). The presented algorithms have sorting as their bottleneck, thus establishing that *the complexity of sorting and suffix tree construction match*.

Key Results

Designing a disk-efficient approach to suffix-tree construction has found efficient solutions only in the last few years [4]. The present section surveys

DIVIDE-AND-CONQUER ALGORITHM

(1) Construct the string $S'[j]$ = rank of $\langle S[2j], S[2j+1]\rangle$, and recursively compute $\mathcal{T}_{S'}$.
(2) Derive from $\mathcal{T}_{S'}$ the compacted trie $\mathcal{T}_O$ of all suffixes of S beginning at odd positions.
(3) Derive from $\mathcal{T}_O$ the compacted trie $\mathcal{T}_E$ of all suffixes of S beginning at even positions.
(4) Merge $\mathcal{T}_O$ and $\mathcal{T}_E$ into the whole suffix tree $\mathcal{T}_S$, as follows:
(4.1) Overmerge $\mathcal{T}_O$ and $\mathcal{T}_E$ into the tree $\mathcal{T}_M$.
(4.2) Partially unmerge $\mathcal{T}_M$ to get $\mathcal{T}_S$.

Suffix Tree Construction in Hierarchical Memory, Fig. 2 The algorithm that builds the suffix tree directly

SUFFIXARRAY-BASED ALGORITHM

(1) Construct the suffix array $\mathcal{A}_S$ and the array lcp_S of the string S.
(2) Initially set $\mathcal{T}_S$ as a single edge connecting the root to a leaf pointing to suffix $\mathcal{A}_S[1]$.
(2) For $i = 2,\ldots, n$:
(2.1) Create a new leaf ℓ_i that points to the suffix $\mathcal{A}_S[i]$.
(2.2) Walk up from ℓ_{i-1} until a node u_i is met whose string-length x_i is $\leq \text{lcp}_S[i]$.
(2.3) If $x_i = \text{lcp}_S[i]$, leaf ℓ_i is attached to u_i.
(2.4) If $x_i < \text{lcp}_S[i]$, create node u'_i with string-length x_i, attach it to u_i and leaf ℓ_i to u'_i;

Suffix Tree Construction in Hierarchical Memory, Fig. 3 The algorithm that builds the suffix tree passing through the suffix array

two theoretical approaches which achieve the best (optimal!) I/O-bounds in the worst case; the next section will discuss some practical solutions.

The first algorithm is based on a *Divide-and-Conquer* approach that allows us to reduce the construction process to external-memory sorting and few low-I/O primitives. It builds the suffix tree $\mathcal{T}_S$ by executing four (macro)steps, detailed in Fig. 2. It is not difficult to implement the first three steps in $\text{Sort}(n) = O(\frac{n}{B}\log_{M/B}\frac{n}{B})$ I/Os [20]. The last (merging) step is the most difficult one and its I/O-complexity bounds the cost of the overall approach. Farach-Colton et al. [3] propose an elegant merge for $\mathcal{T}_O$ and $\mathcal{T}_E$: substep (4.1) temporarily relaxes the requirement of getting $\mathcal{T}_S$ in one shot, and thus it blindly (over)merges the paths of $\mathcal{T}_O$ and $\mathcal{T}_E$ by comparing edges only via their first characters; then substep (4.2) refixes $\mathcal{T}_M$ by detecting and undoing in an I/O-efficient manner the (over)merged paths. Note that the time and I/O-complexity of this algorithm follow a nice recursive relation: $T(n) = T(n/2) + O(\text{Sort}(n))$.

Theorem 1 (Farach-Colton et al. [5]) *Given an arbitrary string $S[1,n]$, its suffix tree can be constructed in $O(\text{Sort}(n))$ I/Os, $O(n\log n)$ time and using $O(n/B)$ disk pages.*

The second algorithm [10] is deceptively simple, elegant, and I/O optimal and applies successfully to the construction of other indexing data structures, like the string Btree [5]. The key idea is to derive $\mathcal{T}_S$ from the suffix array $\mathcal{A}_S$ and from the *lcp* array, which stores the longest-common-prefix length of adjacent suffixes in $\mathcal{A}_S$. Its pseudocode is given in Fig. 3. Note that step (1) may deploy any external-memory algorithm for suffix array construction: used here is the elegant and optimal *Skew* algorithm of [9] which takes $O(\text{Sort}(n))$ I/Os. Step (2) takes a total of $O(n/B)$ I/Os by using a stack that stores the nodes on the current rightmost path of $\mathcal{T}_S$ in reversed order, i.e., leaf ℓ_i is on top. Walking upward, splitting edges or attaching nodes in $\mathcal{T}_S$ boils down to popping/pushing nodes from this stack. As a result, the time and I/O-complexity of this algorithm follow the recursive relation: $T(n) = T(2n/3) + O(\text{Sort}(n))$.

Theorem 2 (Kärkkäinen and Sanders 2003, see [10]) *Given an arbitrary string $S[1,n]$, its suffix tree can be constructed in $O(Sort(n))$ I/Os, $O(n \log n)$ time and using $O(n/B)$ disk pages.*

It is not evident which one of these two algorithms is better in practice [10]. The first one exploits a recursion with parameter 1/2 but incurs a large space overhead because of the management of the tree topology; the second one is more space efficient and easier to implement, but exploits a recursion with parameter 2/3.

Applications

The reader is referred to [4] and [7] for a long list of applications of large suffix trees and to [6, 18] for practical implementations.

Open Problems

The recent theoretical and practical achievements mean the idea that "suffix trees are not practical except when the text size to handle is so small that the suffix tree fits in internal memory" is no longer the case [15]. Given a suffix tree, it is known now (see, e.g., [4, 11]) how to map it onto a disk-memory system in order to allow I/O-efficient traversals for subsequent pattern searches. A fortiori, suffix-tree storage, and construction are challenging problems that need further investigation.

Space optimization is closely related to time optimization in a disk-memory system, so the design of *succinct* suffix-tree implementations is a key issue in order to scale to gigabytes of data in reasonable time. This topic is an active area of theoretical research with many fascinating solutions (see, e.g., [16] and the many papers that followed it), which need further exploration in the practical setting.

It is theoretically challenging to design a suffix-tree construction algorithm that takes optimal I/Os and space proportional to the *entropy* of the indexed string. The more compressible is the string, the lighter should be the space requirement of this algorithm. Some results are known [8, 11, 12], but both issues of compression and I/Os have been tackled jointly only recently [6], but more results are foreseen.

Experimental Results

The interest in building large suffix trees arose in the last few years because of the recent advances in sequencing technology, which have allowed the rapid accumulation of DNA and protein data. Some recent papers [1, 2, 9, 17, 18] proposed new practical algorithms that allow us to scale to Gbps/hours. Surprisingly enough, these algorithms are based on *disk-inefficient* schemes, but they properly select the insertion order of the suffixes and exploit carefully the internal memory as a buffer, so that their performance does not suffers significantly from the theoretical I/O-bottleneck.

In [9] the authors propose an *incremental* algorithm, called *PrePar*, which performs multiple passes over the string S and constructs the suffix tree for a *subrange* of suffixes at each pass. For a user-defined parameter q, a suffix subrange is defined as the set of suffixes prefixed by the same q-long string. Suffix subranges induce subtrees of $\mathcal{T}_S$ which can thus be built independently and evicted from internal memory as they are completed. The experiments reported in [9] successfully index 286 Mbps using 2 Gb internal memory.

In [2] the authors propose an improved version of *PrePar*, called *DynaCluster*, that deploys a *dynamic* technique to identify suffix subranges. Unlike *Prepar*, *DynaCluster* does not scan over and over the string S, but it starts from the q-based subranges and then splits them recursively in a DFS-manner if their size is larger than a fixed threshold τ. Splitting is implemented by looking at the next q characters of the suffixes in the subrange. This clustering and lazy-DFS visit of $\mathcal{T}_S$ significantly reduce the number of I/Os incurred by the frequent edge-splitting operations that occur during the suffix-tree construction process and allow it to cope efficiently with skew data.

As a result, *DynaCluster* constructs suffix trees for 200 Mbps with only 16 Mb internal memory.

In [17] authors improved the space requirement and the buffering efficiency, thus being able to construct a suffix tree of 3 Gbps in 30 h, whereas [1] improved the I/O behavior of RAM-algorithms for online suffix-tree construction, by devising a novel low-overhead buffering policy. More recently [14] introduced a new technique, called Elastic Range (ERA), which partitions the tree construction process horizontally and vertically and minimizes I/Os by dynamically adjusting the horizontal partitions independently for each vertical partition, based on the evolving shape of the tree and the available internal memory. This technique is specialized to work also for shared-memory and shared-disk multi-core systems and for parallel shared-nothing architectures. ERA indexes the entire human genome in 19 min on a commodity desktop PC. For comparison, the fastest existing method needs 15 min using 1024 CPUs on an IBM BluGene supercomputer.

Finally [19] observed that increasing memory sizes of current commodity PCs and servers enhance the impact of in-memory tasks on performance. So it is imperative nowadays to reassess the performance of in-memory algorithms and to propose new algorithms that incorporate the characteristics of modern hardware architectures, such as multilevel memory hierarchy and chip multiprocessors (CMPs). Starting from these premises the authors proposed cache-conscious suffix-tree construction algorithms that are tailored to CMP architectures, using novel sample-based cache-partitioning techniques that improved cache performance and exploited on-chip parallelism of CMPs thus achieving satisfactory speedups with increasing number of cores.

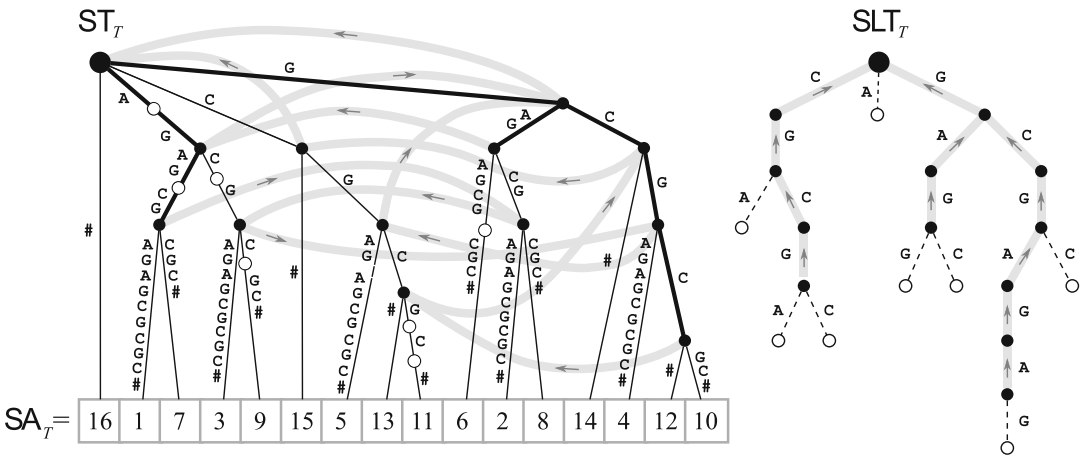
The suffix tree is one of the oldest full-text inverted indexes and one of the most persistent subjects of study in the theory of algorithms. With extensions and refinements, including succinct and compressed variants that provide some of its expressive power in smaller space, it constitutes a fundamental conceptual tool in the design of string algorithms. The companion structure represented by the suffix array is as powerful as the suffix tree in many applications, but it requires significantly less space. The uses of these data structures are so numerous that it is difficult to account for all of them, while even more are being discovered. Salient applications include searching for a pattern in a text in time proportional to the size of the pattern, various computations on regularities such as repeats and palindromes within a text, statistical tables of substring occurrences, data compression by textual substitution, as well as ancillary yet fundamental tasks in string searching with errors, and more.

Problem Definition

It is well known that searching among n keys in an unsorted table takes optimal linear time. When multiple searches are expected, however, it becomes worth to sort the table once and for all, whereby each subsequent search will require only logarithmic time. It is similarly possible to build an inverted index on a long text so that the search for any query string will take time proportional to the length of the query rather than that of the text. It turns out that the data structures built for this purpose support many more applications, which are the topic of this entry.

Formally, let T be a string of length n on alphabet $\Sigma = [1 \dots \sigma]$, let $\underline{T}$ be its reverse, and let $\# \notin \Sigma$ be a shorthand for zero. To simplify the exposition, we assume throughout that σ is a constant. The *suffix tree* $\mathsf{ST}_T = (\perp, V, E)$ of T is a tree rooted at node $\perp \in V$ with set of nodes V and set of labeled edges E (Fig. 1, left). Edge labels are pointers to substrings of $T\#$: we denote by $\ell(e)$, and equivalently by $\ell(u, v)$, the label of edge $e = (u, v) \in E$, and we denote by $\ell(v)$ the string $\ell(\perp, v_1) \cdot \ell(v_1, v_2) \cdot \dots \cdot \ell(v_{k-1}, v)$, where $\perp, v_1, v_2, \dots, v_{k-1}, v$ is a path in ST_T. We say that node v has *string depth* $|\ell(v)|$. Let $v \in V$ be an internal node, and let $w_1, w_2, \dots, w_k$ be its children: then, $2 \leq k \leq \sigma + 1$, and labels $\ell(v, w_1), \ell(v, w_2), \dots, \ell(v, w_k)$ start with distinct characters. The children of v are ordered lexicographically according to the labels of edges $(v, w_1), (v, w_2), \dots, (v, w_k)$. There is a bijection between the leaves of ST_T and the suffixes of $T\#$, so every leaf is annotated with the starting position of its corresponding suffix. Moreover, if leaf $v \in V$ is associated with the suffix that



Suffix Trees and Arrays, Fig. 1 Relationship between the suffix tree, the suffix array (*left*), and the suffix-link tree (*right*) of string $T = \texttt{AGAGCGAGAGCGCGC\#}$. *Thin black lines*, edges of ST_T; *thick gray lines*, suffix links; *thin dashed lines*, implicit Weiner links; *thick black lines*, the subtree of ST_T induced by maximal repeats. *Black dots*, nodes of ST_T; *large black dot*, $\perp$; *white dots*, destinations of implicit Weiner links. *Squares*, leaves of ST_T and cells of SA_T; numbers, starting position of each suffix in T. For clarity, implicit Weiner links are not overlaid to ST_T, and suffix links from the leaves of ST_T are not drawn

starts at position i, then $\ell(v) = T[i \ldots n]\#$. Since ST_T has exactly $n + 1$ leaves and every internal node has at least two children, there are at most n internal nodes; thus, ST_T takes $O(n)$ space. We drop the subscript from ST whenever the underlying string is clear from the context.

A substring W of $T\#$ is called *right maximal* if both Wa and Wb occur in T, with $\{a, b\} \subseteq \Sigma \cup \{\#\}$ and $a \neq b$. Clearly a substring W is right maximal iff $W = \ell(v)$ for some $v \in V$. Moreover, assume that $\ell(v) = aW$ for some $v \in V$, $a \in \Sigma$, and $W \in \Sigma^*$. Since aW is right maximal, string W is right maximal as well; therefore, there is a node $w \in V$ with $\ell(w) = W$. Thus, the set of labels $\{\ell(v) : v \in V\}$ enjoys the *suffix closure* property, in the sense that if a string W belongs to the set so does every one of its suffixes. We say that there is a *suffix link from v to w labeled by a*, and we write $\texttt{suffixLink}(v) = w$. Clearly, if v is a leaf, then $\texttt{suffixLink}(v)$ is either a leaf or $\perp$. The graph induced by V and by suffix links is a trie rooted at $\perp$: such trie is called the *suffix-link tree* SLT_T of string T (Fig. 1, right). Inverting the direction of all suffix links yields the so-called *explicit Weiner links*. Given a node v and a symbol $a \in \Sigma$, it might happen that string $a\ell(v)$ does occur in T but that it is not the label of any node in V: all such left extensions of nodes in V that end in the middle of an edge of ST are called *implicit Weiner links*. A node in V can have more than one outgoing Weiner link, and all such Weiner links have different labels. The number of suffix links (or, equivalently, of explicit Weiner links) is upper-bounded by $2n-2$, and the same bound holds for the number of implicit Weiner links: in some applications, we thus assume that ST is augmented with unary nodes that correspond to all the destinations of implicit Weiner links. A substring W of $T\#$ is called *left maximal* if both aW and bW occur in $T\#$, with $\{a, b\} \subseteq \Sigma \cup \{\#\}$ and $a \neq b$, where $T\#$ is interpreted as a circular string. A string that is both left and right maximal is called *maximal repeat*. The set of all left-maximal strings enjoys the *prefix closure* property; therefore, there is a bijection between the maximal repeats and the nodes that lie in some paths of ST that start from the root (Fig. 1, left).

The *suffix array* $\mathsf{SA}_T[1 \ldots n + 1]$ of string T is the permutation of $[1 \ldots n + 1]$ such that $\mathsf{SA}_T[k] = i$ iff suffix $T[i \ldots n]\#$ has position k in the list of all suffixes of $T\#$ taken in lexicographic order. In this case, we say that suffix $T[i \ldots n]\#$ has *lexicographic rank k*. Clearly

$\mathsf{SA}_T[1] = n + 1$. The *inverse suffix array* of string T is an array $R_T[1 \ldots n + 1]$ such that $R_T[\mathsf{SA}[i]] = i$ for all $i \in [1 \ldots n + 1]$. A substring W of $T\#$ corresponds to a unique, contiguous *interval* (i_W, j_W) of SA_T, which contains all the suffixes of $T\#$ that are prefixed by W. An additional structure that complements the suffix array in many applications is the *longest common prefix array* $\mathsf{LCP}_T[2 \ldots n + 1]$, which stores at position i the length of the longest prefix shared by suffix $T[\mathsf{SA}_T[i] \ldots n]\#$ and by suffix $T[\mathsf{SA}_T[i - 1] \ldots n]\#$. Clearly $\mathsf{LCP}_T[k] \geq |W|$ for all $k \in [i_W + 1 \ldots j_W]$. Again, we drop the subscript from SA, R, and LCP whenever the underlying string is clear from the context.

Suffix tree, suffix array, and LCP array are strongly intertwined, and they have connections to other substring recognizers, like the *directed acyclic word graph* (DAWG) and its compact variant (CDAWG). SA can be thought of as the ordered set of leaves of ST, and ST can be thought of as a search tree built on top of SA (Fig. 1, left). The full ST, including suffix links, can be built from SA and LCP with a $O(n)$-time scan [1], and SA can be built from ST with a $O(n)$ traversal. LCP itself can be built from SA in $O(n)$ time [18]. A number of ingenious algorithms have been proposed to build ST and SA in linear time directly from the string itself, even in the case of polynomial alphabets: see [10, 17, 19, 20, 25, 32, 33] for a sampler of such algorithms, and see [28] for a detailed taxonomy. Some applications require to maintain the suffix tree after edits to the underlying string: see [12, 13, 22] for a sampler of such algorithms. Finally, see [21] for a comparative study of space-efficient allocations of suffix trees.

Key Results

Suffix trees are extremely versatile indexes that allow one to solve a variety of string matching and analysis problems [2, 9, 14]. We review few such problems, classifying the corresponding algorithmic solutions based on the way they walk on the suffix tree and on the information they store in each node. This classification exposes recurrent design patterns, it highlights which parts of the suffix tree are needed by each application, and it helps decide which algorithms can be implemented on top of more succinct but less powerful representations of the suffix tree. The emphasis of this section is on the power of different traversals of the suffix tree, not necessarily on the most efficient solution of each string analysis problem.

Top-Down

Exact searching inside a string S of length n is the most natural example of top-down traversal of ST_S. Given a query string W, we can just match its characters from the root of ST in $O(|W|)$ time to determine whether W occurs in S or not. Since edges are labeled by substrings of S, the search for W can end in the middle of an edge (u, v): we say that v is the *locus* of W in ST, and we denote it by $\texttt{locus}(W)$. This approach generalizes to a set of patterns $W_1, W_2, \ldots, W_k$ of total length m, by building the suffix tree of the concatenation $W = W_1\#_1 W_2\#_2 \cdots \#_{k-1} W_k$ and by traversing ST_S and ST_W synchronously, where $i \neq j$ implies $\#_i \neq \#_j$ and $\#_i \neq \#$.

The total number of (possibly overlapping) occurrences of the label $\ell(v)$ of a node v of ST equals the number of leaves in the subtree rooted at v, which can be computed by a bottom-up traversal of the tree. All strings that end in the middle of edge (u, v) start exactly at the same positions as $\ell(v)$ in S; therefore, ST with frequency annotation allows one to return the frequency in S of any string W in $O(|W|)$ time. An important consequence of this is the fact that the number of *distinct frequencies* assumed by nonempty substrings of S is at most $|S|$. It is also possible to annotate every node of ST with the smallest and largest leaf in its subtree, supporting $O(|W|)$-time queries on the first and last occurrence in S of any string W. More generally, traversing the tree rooted at $\texttt{locus}(W)$ in $O(|W| + k)$ time allows one to print all the k starting positions of W in S.

Finding all the occurrences of W in S can also be done in $O(|W| \log n)$ time, by binary searching SA_S for strings $W\#$ and $W\$$, where $\$ = \sigma + 1$: the result of these searches are, respectively, the starting and ending position of the interval of all suffixes prefixed by W. Knowing this interval allows one to derive the number of occurrences of W in S in constant time and to output the starting positions of such occurrences in time linear in the size of the output. Using simple properties of LCP_S, it is possible to reduce the time of binary search to $O(|W| + \log n)$, by reusing information during the search [24].

The top-down navigation of a suitably annotated suffix tree of S allows one also to compute the Lempel-Ziv factorization of S [23]. Recall that this factorization scans the string from left to right, and it determines at every position i the longest prefix of $S[i \ldots n]$ that equals a prefix of $S[j \ldots n]$, where $j < i$. Let W be such longest prefix: the factorization outputs the tuple $(j, |W|, S[i + |W|])$. Clearly we can find all this information by annotating every node v of ST with the index j of the smallest leaf in the subtree rooted at v. Then, we can just match suffix $S[i \ldots n]$ from the root of ST until a mismatch occurs or until we find a node with index greater than i. More advanced solutions embed the factorization in an online, one-pass construction of ST [29].

Bottom-Up

A *square* is a string WW where $W \in \Sigma^+$ is not in the form Z^k with $k > 1$ for any $Z \in \Sigma^+$. Clearly, if a square WW occurs at position i in S, then there is a node v in ST_S such that $|\ell(v)| \geq |W|$ and such that leaves i and $i + |W|$ belong to the subtree rooted at v. The converse is also true [4]. Thus, we can output all the repeats of S by using the following bottom-up traversal of ST. Assume without loss of generality that all nodes in ST have exactly two children. Every node u of ST builds its list of occurrences, sorted by position in S, using the lists of its children. Then, it scans its list once to find all pairs of positions at distance at most $|\ell(v)|$ in S that are consecutive in the list: every such pair is a square, and positions at distance at most $|\ell(v)|$ that are not consecutive induce squares that are implied by the consecutive positions.

Let v and w be the two children of v, and assume without loss of generality that the list of occurrences of v is smaller than the list occurrences of w. Then, the list of node u can be built by extracting all elements from the list of node v and by inserting them into the list of node w. As a consequence of such insertions, the occurrences in the list of v move to a list that is at least twice the size of the original list: it follows that an occurrence can be pushed into at most $O(\log n)$ lists; therefore, the total number of extractions and insertions is bounded by $O(n \log n)$. If the lists of occurrences are implemented with balanced trees, the total time to extract all squares from S is $O(n \log^2 n)$. More advanced approaches manage to shave a logarithm, reaching optimal $O(n \log n)$ time [4], and to reduce the complexity to $O(n + \tau)$, where τ is the size of the output [15, 31].

The algorithm for detecting squares can be adapted to compute all the *maximal palindromes* of S, by applying it to string $T = S\#\underline{S}\$$. Note that a variant of the same algorithm can be implemented using the suffix array. First, it is easy to see that a bottom-up, in-order traversal of the internal nodes of ST_S can be simulated by a linear scan of SA_S and of LCP_S, maintaining a stack [1]. It follows that, for every interval (i_v, j_v) in SA of a node v in ST, we can just check whether $\mathsf{SA}[k] + |\ell(v)| \in [i_v \ldots j_v]$ and $S[\mathsf{SA}[k] + |\ell(v)|] \neq S[\mathsf{SA}[k] + 2|\ell(v)|]$, for every $k \in [i_v \ldots j_v]$: in this case, the occurrence of square $\ell(v)$ at position $\mathsf{SA}[k]$ is called *branching*. It is easy to see that all squares can be derived from squares with branching occurrences [31]. Moreover, if the occurrence at position $\mathsf{SA}[k]$ is branching, then suffixes $\mathsf{SA}[k] + |\ell(v)|$ and $\mathsf{SA}[k] + 2|\ell(v)|$ belong to distinct children of node v in ST: we can thus discard the child w of v with the largest number of leaves and check for every $k \in [i \ldots j]$ that does not belong to the interval of w whether $\mathsf{SA}[k] - |\ell(v)| \in [i_v \ldots j_v]$ and $S[\mathsf{SA}[k]] \neq S[\mathsf{SA}[k] + |\ell(v)|]$. The child of v with largest interval can be determined in constant time during the simulated bottom-up traversal of ST, and since the largest

interval is always excluded, the algorithm runs in $O(n \log n)$ time.

Given a collection of k strings of total length n, let S be the concatenation of all such strings, each terminated by a distinct symbol that does not belong to Σ. A bottom-up navigation of ST_S (called also the *generalized suffix tree* of the collection) allows one to compute the length of a longest string that occurs in $x \leq k$ strings. To solve this problem, we can annotate each leaf v of ST with a bitvector `which` of length k, such that `which`$[i] = 1$ iff the suffix associated with v starts inside string i. Then, every node of ST can be annotated with the same bitvector via a bottom-up, $O(nk)$ traversal, in which we compute the bitvector of a node by taking the logical `or` of the bitvectors of its children. More advanced algorithms solve this problem in $O(n)$ time [8]. As a byproduct, this annotation allows one to answer queries on the number of strings in the collection that contain a given substring, a problem known as *document counting*. A germane problem is that of *document listing*, in which we are given a pattern and we are asked to return the set of all documents that contain one or more copies of the pattern [26].

Top-Down and Suffix Links

Given two strings S and T, of length n and m, respectively, the *matching statistics array* $\mathsf{MS}_{S,T}[1 \ldots n]$ is such that $\mathsf{MS}_{S,T}[i]$ stores the length of the longest string that starts at position i in S and that occurs in T [33]. We can compute $\mathsf{MS}_{S,T}$ by scanning S from left to right, while simultaneously issuing child and suffix-link queries on ST_T. This results in a peculiar walk on ST_T that consists of alternating sequences of suffix-tree edges and of suffix links (we can also compute $\mathsf{MS}_{S,T}$ symmetrically, by scanning S from right to left and by simultaneously issuing parent and Weiner-link queries on ST_T [27]).

Specifically, assume that we are at position i in S, and let $W = S[i \ldots i + \mathsf{MS}_{S,T}[i] - 1]$. Note that W can end in the middle of an edge (u, v) of ST_T: let $W = aXY$ where $a \in \Sigma$, $X \in \Sigma^*$, $aX = \ell(u)$, and $Y \in \Sigma^*$. Moreover, let $u' =$ `suffixLink`(u) and $v' =$ `suffixLink`(v). Note that suffix links can project edge (u, v) onto a *path* $u', v_1, v_2, \ldots, v_k, v'$, where $v_j \in V$ for $j \in [1 \ldots k]$. Since $\mathsf{MS}_{S,T}[i+1] \geq \mathsf{MS}_{S,T}[i]-1$, the first step to compute $\mathsf{MS}_{S,T}[i + 1]$ is to find the position of XY in ST_T: we call this phase of the algorithm the *repositioning phase*. To implement the repositioning phase, it suffices to take the suffix link from u, to follow the outgoing edge from u' whose label starts by the first character of Y, and then to iteratively jump to the next internal node of ST_T and to choose the next outgoing edge according to the corresponding character of Y. After repositioning, we start matching the new characters of S on ST_T, i.e., we read characters $S[i + \mathsf{MS}_{S,T}[i]], S[i + \mathsf{MS}_{S,T}[i] + 1], \ldots$ until such an extension becomes impossible in ST_T. We call this phase of the algorithm the *matching phase*. Note that no character of S that has been read during the repositioning phase of $\mathsf{MS}_{S,T}[i + 1]$ will be read again during the repositioning phase of $\mathsf{MS}_{S,T}[i + k]$ with $k > 1$: it follows that every position j of S is consumed at most twice, once in the matching phase of some $\mathsf{MS}_{S,T}[i]$ with $i \leq j$ and once in the repositioning phase of some $\mathsf{MS}_{S,T}[k]$ with $i < k < j$. Since every mismatch can be charged to the position of which it concludes the matching statistics, the total number of mismatches encountered by the algorithm is bounded by the length of S.

These algorithms can be adapted to compute the *shortest unique substring array* $\mathsf{SUS}_S[1 \ldots n]$, which stores at index i the length of the shortest substring of S that occurs only at position i [33]. The average of the matching statistics vector can be used to estimate the cross-entropy of the probability distributions of two stationary, ergodic, stochastic processes with finite memory that generated S and T [11]. Moreover, a number of compositional similarity measures between two strings S and T can be computed by scanning S and by simultaneously navigating ST_T as in matching statistics: this has the advantage of building and annotating the suffix tree of just the shortest string [30]. Matching statistics on a suitably annotated suffix tree of T allows one also to approximate the probability that S was generated by the same variable-length Markov process that produced

T, another measure of similarity not based on sequence alignment [3].

Top-Down in the Suffix-Link Tree

A number of statistical applications require to annotate the nodes of ST_S with *empirical probabilities* rather than with raw frequencies. The empirical probability $p_S(W)$ of a string W is essentially the number of its occurrences $f_S(W)$ divided by the maximum number of occurrences that W can have in a string of length $|S| = n$. This number cannot exceed $n-|W|+1$, but it also depends on the number of overlaps that W has with itself, i.e., on the number of proper *borders* of W: thus, we set $p_S(W) = f_S(W)/b(W)$, where $b(W)$ is the length of the shortest period of W. Note that p_S can change inside an edge of ST. However, if we are interested only in the empirical probability of nodes of ST, we can compute all such values in overall linear time, by mapping the longest-border computation in the KMP algorithm onto a depth-first navigation *of the suffix-link tree* [5].

The exact computation of the *variance* of the frequency of a string W in S can be itself mapped onto the computation of the longest proper border of W. Under suitable statistical assumptions, computing the expectation and variance of the frequency of all right-maximal substrings of S suffices to detect all substrings of S with anomalous frequency: it is thus possible to discover all statistically frequent and rare substrings of S in overall linear time [5].

Any Order

A single pass over all nodes of ST *in any order*, coupled with a number of checks on the children and on the Weiner links of each node, suffices to solve a number of string analysis problems in linear time.

A string W is a *maximal unique match* (MUM) between two strings S and T if it occurs exactly once in S and exactly once in T and if neither aW nor Wb occur in both S and T for any $\{a, b\} \subseteq \Sigma$ (for simplicity, we disregard cases in which W occurs at the beginning or at the end of a string) [14]. Clearly W must be a right-maximal substring of $U = S\#T\$$, where # and \$ are separators not belonging to Σ. Therefore, we just need to iterate over every node v of ST_U in any order, checking the following conditions: (1) v has exactly two leaves as children; (2) the suffixes that correspond to such leaves start before and after position $|S| + 1$ in U, respectively; and (3) v has two Weiner links. A similar approach extends to MUMs of more than two strings, as well as to *maximal* (not necessarily unique) *exact matches* between two strings and to the *maximal repeats* [7] and the *minimal absent words* of a single string [16].

Symmetrically, it is easy to detect the MUMs of two strings S and T by a linear scan of the suffix array of $U = S\#T\$$ and of the corresponding LCP array. Indeed, a MUM corresponds to an interval $(i, i + 1)$ of size two in SA_U such that $\mathsf{LCP}_U[i] < \mathsf{LCP}_U[i + 1]$, $\mathsf{LCP}_U[i + 2] < \mathsf{LCP}_U[i + 1]$, $U[\mathsf{SA}_U[i] - 1] \neq U[\mathsf{SA}_U[i + 1] - 1]$, and $\mathsf{SA}_U[i] < |S| + 1 < \mathsf{SA}_U[i + 1]$. Similar criteria allow one to detect maximal repeats, *supermaximal repeats* [14], and maximal exact matches [1].

String Depth Annotation

Assume that every node v of ST_S is annotated with $|\ell(v)|$. Recall that the *shortest unique substring array* $\mathsf{SUS}_S[1 \ldots n]$ is such that $\mathsf{SUS}_S[i]$ is the length of the shortest substring of S that occurs only at position i. Since $S[i \ldots i + \mathsf{SUS}[i] - 1] = Wa$ where $a \in \Sigma$, since $\texttt{locus}(Wa)$ is a leaf v, and since $\texttt{locus}(W) = \texttt{parent}(v)$, traversing the nodes of ST in any order suffices to compute $\mathsf{SUS}[i]$ for every i. String depth annotations, coupled with a traversal of the nodes of ST in any order, suffice also to compute measures of compositional complexity of S, like the total number of distinct substrings, possibly of a fixed length k.

Frequency Annotation

Recall that $f_S(W)$ is the number of occurrences of string W in S. Assume that we want to compute $p(a|W) = f_S(Wa)/f_S(W)$ for all substrings W of S and for all characters $a \in \Sigma$ such that Wa is a substring of S. Such values are called *conditional probabilities*. Clearly $p(a|W) = 1$ if W ends in the middle of an edge of ST_S: it is thus sufficient to compute conditional probabilities

for the nodes of ST, and this can be done by traversing the nodes of ST in any order and by accessing their children.

String Depth and Frequency Annotation
Assume that every node v of ST_S is also annotated with the number of leaves in the subtree rooted at v. Then, traversing the nodes of ST in any order allows one to compute the longest substring of S that repeats at least τ times, or the most frequent string of length at least τ, for any user-specified threshold τ. String depth and frequency annotations, coupled with a traversal of the nodes of ST in any order, allow one also to compute the number of distinct substrings that occur τ times in S, for every frequency τ in a user-specified range.

Given a substring W of S, let $\texttt{right}(W)$ be the set of characters that occur in S after W. More formally, $\texttt{right}(W) = \{a \in \Sigma : f_S(Wa) > 0\}$. The *kth order empirical entropy* of S is defined as follows:

$$\mathsf{H}(S,k) = \frac{1}{|S|} \sum_{W \in \Sigma^k} \sum_{a \in \texttt{right}(W)} f_S(Wa) \log \left(\frac{f_S(W)}{f_S(Wa)} \right)$$

To compute $\mathsf{H}(S,k)$, it suffices again to traverse the nodes of ST_S in any order, to check whether $|\ell(v)| = k$, and to cumulate the contribution of v to $\mathsf{H}(S,k)$ by reading the frequency of its children. Strings of length k that end in the middle of an edge of ST do not contribute to $\mathsf{H}(S,k)$.

In a similar fashion, given a string S on alphabet Σ, let $\mathbf{S}$ be a vector indexed by all strings in Σ^k for a fixed $k > 0$, such that $\mathbf{S}[W]$ contains the frequency of string W in S. We call $\mathbf{S}$ the k-mer *composition vector* of string S. Given two strings S and T, assume that we want to compute a function $\kappa(S,T)$ that depends only on $N = \sum_{W \in \Sigma^k} f(\mathbf{S}[W], \mathbf{T}[W])$, $D_S = \sum_{W \in \Sigma^k} g(\mathbf{S}[W])$, and $D_T = \sum_{W \in \Sigma^k} h(\mathbf{T}[W])$, where f, g, and h are user-specified functions. $\kappa(S,T)$ if often called *k-mer kernel* in text classification. It is possible to compute $\kappa(S,T)$ in overall linear time by traversing the nodes of the generalized suffix tree of S and T in any order. A similar traversal of ST allows one to compute $\kappa(S,T)$ on composition vectors that are indexed by all possible substrings, of any length. In practice the frequencies used in composition vectors are normalized by their expected values under IID or Markov probability distributions: a number of kernels based on such normalized counts can still be computed in overall linear time by traversing the nodes of ST in any order [6].

Positional Annotations
Given two strings S and T, the longest string W that occurs in both S and T is clearly a right-maximal substring of the concatenation $U = S\#T\$$, where # and \$ are separators not belonging to Σ. Consider thus ST_U, and assume that every node v is annotated with $|\ell(v)|$ and with a bit $\texttt{flag}(v)$ set to one iff the subtree rooted at v contains at least one leaf that starts before position $|S|+1$ in U and at least one leaf starting after position $|S|+1$ in U. Such annotation can be carried out in a bottom-up traversal of ST. We can compute W by iterating over the nodes $v \in \mathsf{ST}$ with $\texttt{flag}(v) = 1$ and by cumulating the maximum of the lengths of the encountered labels. The set of *all common substrings* between S and T is the set of all prefixes of the labels of nodes $v \in \mathsf{ST}$ such that $\texttt{flag}(v) = 1$ and $\texttt{flag}(w) = 0$ for every child w of v. This approach generalizes immediately to more than two strings, and it allows one to compute the length of the longest substring common to *at least* τ strings in a collection of k strings in $O(k|U|)$ time and space. More advanced approaches solve this problem in $O(|U|)$ time [8].

Applications

The primitives discussed above find application in a wide set of domains. A list of the most salient ones includes exact and approximate string

searching, string compression, statistical pattern discovery, alignment-free string comparison, string kernels in learning theory, sequence analysis, and assembly in bioinformatics.

Problem Definition

Given a directed graph (digraph) $G(V, E)$ with a set of vertices V and a set of edges E, the Sugiyama algorithm solves the problem of finding a 2D hierarchical drawing of G subject to the following readability requirements:

(a) Vertices are drawn on horizontal lines without overlapping; each line represents a level in the hierarchy; all edges point downwards.
(b) Short-span edges (i.e., edges between adjacent levels) are drawn with straight lines.
(c) Long-span edges (i.e., edges between nonadjacent levels) are drawn as close to straight lines as possible.
(d) The number of edge crossings is the minimum.
(e) Vertices connected to each other are placed as close to each other as possible.
(f) The layout of edges coming into (or going out of) a vertex is balanced, i.e., edges are evenly spaced around a common target (or source) vertex.

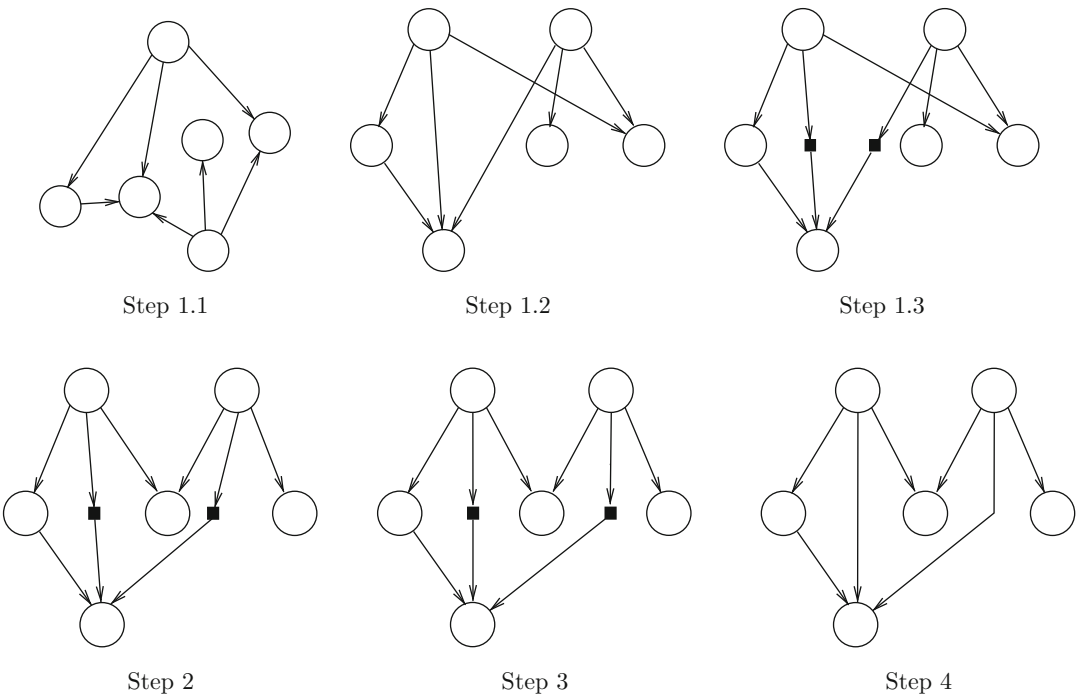
Requirements (a) and (b) are easy to meet and they are imposed as mandatory basic drawing rules. Requirements (c)–(f) are much harder to satisfy and typically they are met approximately [1, 4, 11].

Key Results

Sugiyama et al. propose a four-step procedure for finding a hierarchical drawing of a digraph subject to the readability requirements listed above. It is known as the Sugiyama algorithm, the Sugiyama method, or the Sugiyama framework [19]. The steps of the Sugiyama framework are illustrated in Fig. 1.

The Sugiyama Framework

Step 1: Preparatory step for transforming the input digraph G into a proper hierarchy.



Sugiyama Algorithm, Fig. 1 Illustration of the steps of the Sugiyama framework

Step 1.1: Transform the input digraph G into a directed acyclic graph (dag) by reversing the direction of some edges.

Step 1.2: Transform the dag into a multilevel digraph, called a *hierarchy*, by partitioning V into l levels (or layers) $V_1, V_2, \ldots, V_l$ such that for each edge $e = (v, w) \in E$ if $v \in V_i$ then $w \in V_{i+1}$. Levels are drawn on horizontal lines which determine the $y-$coordinates of the vertices.

Step 1.3 Transform the hierarchy into a *proper hierarchy* by introducing *dummy vertices* along long-span edges; one dummy vertex at each crossing of a long-span edge with a level.

Step 2: For each level V_i, specify a linear order σ_i of the vertices in V_i with the goal of minimizing the total number of edge crossing.

Step 3: Determine the $x-$coordinates of the vertices subject to requirements (c), (e), and (f) while preserving the linear order in the levels.

Step 4: Draw G in a 2D drawing area where dummy vertices are removed and the long-span edges are restored.

Steps 1.3 and 4 are trivial as computational problems. Steps 1.1 and 1.2 can be solved easily if the only readability requirements are those listed above. However, some sensible additional requirements can turn Steps 1.1 and 1.2 into difficult combinatorial optimization problems. For example, if we want to minimize the number of reversed edges at Step 1.1, then we need to solve the MINIMUM FEEDBACK ARC SET problem which is NP-hard [12]. Similarly, if we impose upper bounds on both the number of levels and the number of vertices per level, then the problem in Step 1.2, known as the *layering* problem, becomes NP-complete [4].

Following the work of Sugiyama et al., two types of solutions to the layering problem have been proposed in the research literature. The first type of layer assignment algorithm is list-scheduling algorithms (adapted from the area of static precedence-constrained multiprocessor

scheduling) which produce layer assignments with either the minimum number of levels or a specified maximum number of vertices per level [4]. These include the longest-path algorithm [13] and the Coffman-Graham algorithm [3] as well as the proposed by Nikolov et al. [15] MinWidth and StretchWidth heuristics which take into account the dummy vertices. The second type of algorithm employs network simplex and branch-and-cut techniques, respectively, for minimizing the number of dummy vertices with or without constraints on the number of levels and the number of vertices per level [9, 10].

Steps 2 and 3 are already hard to solve with the readability requirements listed above. It has also been suggested to precede Step 2 by an edge concentration or edge bundling step for achieving a more readable drawing [14, 16]. The other key results in the work of Sugiyama et al., besides defining the four-step framework, are efficient heuristics for Steps 2 and 3, respectively.

Reduction of the Number of Edge Crossings

Consider a proper hierarchy $G(V, E, \mathcal{L})$ with a set of vertices $V = \{v_1, v_2, \ldots, v_n\}$, a set of edges $E = \{e_1, e_2, \ldots, e_m\}$, and a partitioning $\mathcal{L} = \{V_1, V_2, \ldots, V_l\}$ of the vertex set V into l levels (the result of Step 1.3). Let $\sigma_i : V_i \to \{1, 2, \ldots |V_i|\}$ be a linear order of the vertices in level V_i and let S_i be the set of all possible orders σ_i. The problem at Step 2 of the Sugiyama algorithm is to find a set of linear orders $\sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_l\} \in S_1 \times S_2 \times \ldots \times S_l$ such that the total number of edge crossings is the minimum. Let $K(G, \sigma)$ be the total number of edge crossings for a hierarchy G and a set of linear orders σ, and let $K(V_i, V_{i+1}, \sigma_i, \sigma_{i+1})$ be the number of edge crossings between layers V_i and V_{i+1} with linear orders σ_i and σ_{i+1}, respectively.

The algorithm, proposed by Sugiyama et al. for Step 2, is a heuristic which consists in initially choosing a random order σ_1 for the vertices in level V_1 and then repeatedly executing the following five-step procedure, called Down-Up, until either σ does not change or an initially given maximum number of iterations is reached.

The Down-Up Procedure

Step A: $i \leftarrow 1$.

Step B: With a fixed linear order σ_i, find a linear order σ_{i+1} which minimizes $K(V_i, V_{i+1}, \sigma_i, \sigma_{i+1})$.

Step C: If $i < n - 1$, then $i \leftarrow i + 1$ and go to Step B. Otherwise, go to Step D.

Step D: With a fixed linear order σ_{i+1}, find a linear order σ_i which minimizes $K(V_i, V_{i+1}, \sigma_i, \sigma_{i+1})$.

Step E: If $i > 1$, then $i \leftarrow i - 1$ and go to Step D. Otherwise, stop.

Both Step B and Step D involve minimizing the number of edge crossings between two adjacent layers with the linear order in one of them being fixed. This problem is known as the ONE-SIDED CROSSING MINIMIZATION (OSCM) problem, which has been shown to be NP-hard [5]. Based on previous work by Warfield [20], Sugiyama et al. show how OSCM can be reduced to the MINIMUM FEEDBACK SET problem and propose a heuristic method, called the *barycentric method*, for solving it. Let $A = (a_{ij})$ be the adjacency matrix of G. In essence, with a fixed linear order σ_i, the barycentric method orders the vertices in level V_{i+1} in the increasing order of their barycenters B_j, defined with Eq. (1).

$$B_j = \sum_{k=1}^{|V_i|} a_{kj}\sigma_i(v_k) \Big/ \sum_{k=1}^{|V_i|} a_{kj}, \qquad j \in \{1, 2, \ldots, |V_{i+1}|\} \tag{1}$$

Sugiyama et al. evaluate the Down-Up procedure experimentally with 800 randomly generated hierarchies as well as with five hierarchies from practical applications. Their conclusion is

that the proposed heuristic is effective. It was observed that in most cases the Down-Up procedure requires a single iteration. Reportedly, the heuristic was successfully extended for the case when vertices in each level are partitioned into subsets where the vertices in each subset must be arranged adjacently.

Step 2 is probably the best studied part of the Sugiyama framework. Numerous improvements to the original technique as well as alternative algorithms for crossing minimization have been proposed since the introduction of the Sugiyama framework [1, 4, 5, 7, 9, 11]. Notable among them is the 3-approximation *median method* proposed by Eades and Wormald [5] for solving the OSCM problem. Having the order of the vertices in level V_i fixed, the median method consists of placing each vertex in level V_{i+1} at a position which corresponds to the median of the positions of its neighbors in level V_i. Since the median method is an approximation algorithm, it guarantees to find a solution without edge crossings if such exists.

Determination of x-Coordinates of Vertices

For Step 3 of their framework, Sugiyama et al. propose a version of the Down-Up procedure with the barycenter of a vertex based on the x-coordinates of the connected to it vertices in an adjacent level. Consider the *down* part of the Down-Up procedure (the *up* part is symmetrical). If the x-coordinates of the vertices in level V_i are known, the barycenters B_j^* of the vertices in level V_{i+1} are defined with Eq. (2).

$$B_j^* = \sum_{k=1}^{|V_i|} a_{kj} x(v_k) / \sum_{k=1}^{|V_i|} a_{kj}, \quad j \in \{1, 2, \ldots, |V_{i+1}|\} \qquad (2)$$

The x-coordinates of the vertices in level V_{i+1} are determined according to their priority. The highest priority has the dummy vertices (introduced in Step 1.3), and the priority of each other vertex in level V_{i+1} is the number of vertices in level V_i connected to it. The x-coordinate of each vertex $v_j \in V_{i+1}$ is the integer number which is the closest to B_j^* available horizontal position (without changing the linear order from Step 2 and without displacing already placed vertices with higher priority). In finding this position, it is allowed to displace vertices with a priority lower than the priority of v_j, where this displacement should be as little as possible.

Sugiyama et al. evaluate the effectiveness of this method for improving the readability requirements (c), (e), and (f) experimentally. Reportedly, they have extended their heuristic for the case when the dimensions of the vertices are not insignificant. Both the Step 2 and the Step 3 heuristics were successfully applied to a hierarchy with more than 500 vertices.

Alternative algorithms for Step 3 have been proposed by Gansner et al. [9], Eades et al. [6], and Sander [17]. Probably, the best solution for Step 3 to date is the $O(|V|)$ algorithm of Brandes and Köpf [2]. It assigns x-coordinates to vertices by computing four *extreme* vertex alignments which are then combined into a final layout with at most two bends per edge.

Applications

Hierarchical graph drawings are useful for providing insight into hierarchical structures in complex systems. In recent years, the Sugiyama algorithm has found an important application for visual analysis of large social and biological networks [8, 18].

Problem Definition

In the 1970s, sequence alignment was introduced to demonstrate the similarity of the sequences of genes and proteins [12]. A DNA sequence is a finite sequence over four nucleotides – adenine, guanine, cytosine, and thymine, whereas a protein sequence is over 20 amino acids. Homologous proteins have similar biological functions. Since they evolve from a common ancestral sequence, the sequences of homologous proteins and their encoding genes are often highly similar. Therefore, the DNA or amino acid sequence of a protein is often aligned with the sequences of well-studied proteins to infer the biological functions of the protein.

Formally, an alignment of two sequences, S and T, on an alphabet $\mathcal{B}$ is a two-row matrix with the following properties:

1. The letters in S are listed in order, interspersed with space symbols "–," in a row, where "–" represents the fact that a letter is missing at a position.
2. The letters in T are listed in the other row in the same manner.
3. Each column does not contain two "–."

An alignment of S and T poses a model of the evolution from their least common ancestral sequence to themselves. An alignment is scored using a scoring matrix that has a score for every pair of letters in $\mathcal{B} \cup \{-\}$. The score of an alignment is defined to be the sum of the scores of the pairs of letters appearing in the columns of the alignment.

Proteins often have multiple functions. Two proteins having a common function often have one or several highly similar regions in their DNA and amino acid sequences. Such "conserved" regions are found by solving the local alignment problem:

Input: Two sequences $S = s_1 s_2 \dots s_m$ and $T = t_1 t_2 \cdots t_n$ on an alphabet.
Find: Two subsequences $S' = s_i s_{i+1} \cdots s_j$ $(i \leq j)$ and $T' = t_k t_{k+1} \cdots t_l$ $(k \leq l)$ such that the alignment score of S' and T' is as large as possible.

The alignments between their subsequences are called *local alignments* of S and T.

A dynamic programming approach takes quadratic time to solve the local alignment problem [13]. Unfortunately, it is not fast enough for homology search against a database with millions of DNA or protein sequences. Therefore, a filtration technique was adopted to design fast algorithms for homology search in the 1990s [1], by which good local alignments between two sequences are found by first identifying short consecutive matches of a specified length between the sequences, called *seed hits*, and then extending them to obtain good local alignments.

The filtration technique has a dilemma over sensitivity and speed. Employing a long seed will miss some good local alignments between two sequences, decreasing sensitivity; on the other hand, using a short seed will waste time on extending many seed hits into local alignments that are not biologically meaningful, resulting in low speed.

In PatternHunter [10], Ma, Tromp, and Li introduced the idea of optimized spaced seeds to achieve good balance between the sensitivity and speed of the filtration approach. PatternHunter by default looks for nucleotide match in 11 positions in every region of 18 bases long, specified by the string $111 * 1 * *1 * 1 * *11 * 111$, to trigger the process of local alignment. Such hit patterns, called *spaced seeds*, led to surprisingly higher sensitivity as well as speed than the consecutive seed 11111111111 that has the same number of match positions [10]. Moreover, sensitivity can further be improved by employing multiple spaced seeds that are longer than 18 bases [8,14]. This motivates the study of how to find the optimal spaced seeds of given length and weight [2–5,7].

Key Results

A spaced seed Q can be represented by a string of 1's and $*$'s, where 1's give the match positions in a seed hit. The number of 1's in Q is called its *weight*, denoted by w_Q; the length of the corresponding string is called its *length*, denoted by L_Q. The relative positions in Q are denoted by $\mathcal{RP}(Q)$. For example, for $Q = 111 * 1 * *1 * 1 * *11 * 111$, $\mathcal{RP}(Q) = \{0, 1, 2, 4, 7, 9, 12, 13, 15, 16, 17\}$.

An alignment containing no –'s is called a *ungapped alignment*. A local ungapped alignment can be modeled as a 0-1 sequence by translating match columns (containing two identical letters) into 1's and mismatch columns into 0's. Hence, a hit of Q identifies an alignment if the relative positions of Q match 1's in a region in the corresponding 0-1 string of the alignment.

Assume match occurs independently with probability p at a position in a local ungapped alignment. The *sensitivity* of Q in detecting a local alignment of n columns of two sequences with identity p is then defined to be the probability that Q hits a Bernoulli random sequence, called a *uniform region*, in which 1

and 0 appear with probability p and $(1-p)$, respectively. A spaced seed is *optimal* for aligning sequences with identity p of length n if it has the largest hit probability over a uniform region of length n in which 1 appears with probability p at a position.

A straightforward method for identifying optimal spaced seeds is to exhaustively examine all the spaced seeds of given length and weight by keeping the largest sensitivity (or hit probability) over a uniform region. Unfortunately, the sensitivity of a spaced seed is unlikely computable in polynomial time.

Theorem 1 *Computing the sensitivity of a spaced seed over a uniform region is NP-hard.*

The hit probability of a spaced seed over a uniform region can be computed using a dynamic programming approach [7] or using recurrence relations [4,5]. Not surprisingly, these approaches become impractical for identifying long spaced seeds, because their complexities are an exponential function in the difference of the length and weight of spaced seeds under consideration. Here a simple polynomial-time approximation scheme is presented.

WISESAMPLE ALGORITHM

Input: A spaced seed Q, a positive integer n, $0 < p < 1$, and $\epsilon > 0$.
Find: An estimate of hit probability Q in a uniform region of length n in which bit 1 appears at a position with probability p.

Initialize an array A: $A[i] \leftarrow 0$ for $j = 1, 2, \ldots, n - L_Q$;
$N \leftarrow \lceil 6\epsilon^{-2} n^2 \log n \rceil$;
Repeats N times
  $R[i] \leftarrow 1$ for $i \in \mathcal{RP}(Q)$;
  $R[i] \leftarrow 1$ with probability p for $i \in \{1, 2, \ldots, n\} - \mathcal{RP}(Q)$;
  For $i = 1, 2, \ldots, L - L_Q$
    If Q does not hit the subregion $R[1, i + L_Q - 1]$
      $A[i] \leftarrow A[i] + 1$;
Output $p^{w_Q} \left(1 + N^{-1} \sum_{j=1}^{n-L_Q} n_j\right)$.

Theorem 2 *Let Q be a spaced seed and its hit probability be x on a uniform region with identity p of length n.* WISESAMPLE *outputs an estimate y of x on input Q, n, p, and $\epsilon >$ such that $|y - x| \leq \epsilon x$ with high probability.*

Let Q be a spaced seed and R a uniform region with identity p of length n. Following convention in renewal theory, Q hits R at position k if and only if $R[k - L_Q + i_j + 1] = 1$ for all $1 \leq j \leq w_Q$. Let A_k be the event that Q hits R at position k and $\bar{A}_k$ be the complement event of A_k. Then the probability f_k that Q **first** hits R at the k-th position is:

$$f_k = \Pr[\bar{A}_0 \bar{A}_1 \cdots \bar{A}_{k-2} A_{k-1}].$$

The hit probability $Q_n(p)$ of Q on R is equal to:

$$Q_n(p) = \Pr[A_0 \cup A_1 \cup \cdots \cup A_{n-1}].$$

When seed hits are extended into local alignments, two seed hits will give one local alignment if they overlap. Therefore, the sensitivity of a spaced seed is closely related to the number of its nonoverlapping hits in a uniform region. A nonoverlapping hit of a spaced seed is a recurrent event with the following convention: If a hit at position k is selected as a nonoverlapping hit, then the next nonoverlapping hit is the first hit at or after position $k + L_Q$.

The average distance, μ_Q, between two successive nonoverlapping hits of Q is defined to be

$$\mu_Q = \sum_{j \geq L_Q} j f_j.$$

A spaced seed is *nonuniform* if $g.c.d.(\mathcal{RP}(Q)) = 1$.

Theorem 3 *For any nonuniform spaced seed* Q,

$$\mu_Q \le \sum_{j=1}^{w_Q} p^{-j} + (L_Q - w_q) - (1-p)\left(p^{2-w_Q} - 1\right)/p.$$

Buhler et al. [3] proved that for any spaced seed Q, there are two constants α_Q and λ_Q that are independent of n such that $\lim_{n\to\infty}(1 - Q_n(p))/\left(\alpha_Q \lambda_Q\right) = 1$, where λ_Q is the largest eigenvalue of the transition matrix of a Markov chain model constructed from Q.

Theorem 4 *For the consecutive seed* B *of weight* w,

$$\frac{1}{\sum_{j=1}^{w} p^{-j} - w + 1} \le \lambda_B \le 1 - \frac{1}{\sum_{j=1}^{w}(p^{-j} + p^{j-1}) - w}.$$

For a spaced seed Q,

$$1 - \frac{1}{\mu_Q - L_Q + 1} \le \lambda_Q \le 1 - \frac{1}{\mu_Q}.$$

If $L_Q < (1-p)\left[p^{2-w_Q} - 1\right]/p + 1$, by Theorems 3 and 4, $\lambda_Q \le \lambda_B$. This implies that Q has a larger hit probability than the consecutive seed of the same weight in a long uniform region with identity p.

The detailed proofs of these results can be found in [11, 15].

Applications

Spaced seed approach finds applications in homology search and comparison of genome sequences. PatternHunter was used to compare the mouse and human genomes in the mouse genome project [6]. MegaBLAST and BLASTZ have adopted spaced seeds for homology search. Recently, the approach has also been used in mapping short reads into reference genome sequences.

Interestingly, spaced seed design is found to be closely related to optimal Golomb ruler design [9].

Open Problems

It is proved to be NP-hard to identify the optimal spaced seeds over a nonuniform region [8].

Open problem 1 Is it NP-hard to find the optimal spaced seed of a given length and weight over a uniform region?

It has been shown that a uniform spaced seed has a lower hit probability than the consecutive seed of the same weight over any uniform region [4, 7]. But the following problem is open:

Open problem 2 For any nonuniform spaced seed Q and $0 < p < 1$, is there $n(p, Q)$ such that Q has a larger hit probability than the consecutive seed of the same weight over a uniform region with identity p of length $n \ge n(p, Q)$?

1992; Boser, Guyon, Vapnik

Problem Definition

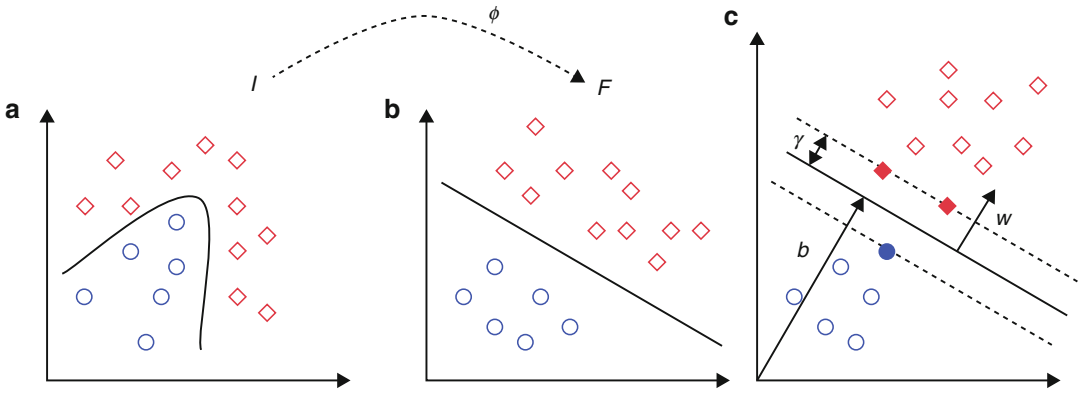
In 1992 Vapnik and coworkers [1] proposed a supervised algorithm for classification that has since evolved into what are now known as support vector machines (SVMs) [2]: a class of algorithms for classification, regression, and other applications that represent the current state of the art in the field. Among the key innovations of this method were the explicit use of convex optimization, statistical learning theory, and kernel functions.

Classification

Given a *training set* $S = \{(\mathbf{x}_1, y_1), \ldots, (\mathbf{x}_\ell, y_\ell)\}$ of data points $\mathbf{x}_i$ from $X \subseteq \mathbb{R}^n$ with corresponding labels y_i from $Y = \{-1, +1\}$, generated from an unknown distribution, the task of classification is to learn a function $g: X \to Y$ that correctly classifies new examples $(\mathbf{x}, y)$ (i.e., such that $g(\mathbf{x}) = y$) generated from the same underlying distribution as the training data.

A good classifier should guarantee the best possible generalization performance (e.g., the smallest error on unseen examples). Statistical learning theory [3], from which SVMs originated, provides a link between the expected generalization error for a given training set and a property of the classifier known as its capacity. The SV algorithm effectively regulates the capacity by considering the function corresponding to the hyperplane that separates, according to the labels, the given training data and it is maximally distant from them (*maximal margin hyperplane*). When no linear separation is possible, a nonlinear mapping into a higher dimensional *feature space* is realized. The hyperplane found in the feature space corresponds to a nonlinear decision boundary in the input space.

Let $\phi : I \subseteq \mathbb{R}^n \to F \subseteq \mathbb{R}^N$ be a mapping from the input space I to the feature space F (Fig. 1a). In the learning phase, the algorithm finds a hyperplane defined by the equation $\langle \mathbf{w}, \phi(\mathbf{x}_i) \rangle = b$ such that the *margin*



Support Vector Machines, Fig. 1 (**a**) The feature map simplifies the classification task. (**b**) A maximal margin hyperplane with its support vectors highlighted

$$\gamma = \min_{1 \le i \le \ell} \; y_i(\langle \mathbf{w}, \phi(\mathbf{x}_i)\rangle - b)$$
$$= \min_{1 \le i \le \ell} \; y_i g(\mathbf{x}_i) \qquad (1)$$

is maximized, where $\langle , \rangle$ denotes the inner product, $\mathbf{w}$ is a ℓ-dimensional vector of weights, and b is a threshold.

The quantity $(\langle \mathbf{w}, \phi(\mathbf{x}_i)\rangle - b)/||\mathbf{w}||$ is the signed distance of the sample $\mathbf{x}_i$ from the hyperplane. When multiplied by the label y_i, it gives a positive value for correct classification and a negative value for an uncorrect one. Given a new data point $\mathbf{x}$, a label is assigned evaluating the decision function:

$$g(\mathbf{x}) = \text{sign}(\langle \mathbf{w}, \phi(\mathbf{x})\rangle - b) \qquad (2)$$

Maximizing the Margin

For linearly separable classes, there exists a hyperplane $(\mathbf{w}, b)$ such that

$$y_i(\langle \mathbf{w}, \phi(\mathbf{x}_i)\rangle - b) \ge \gamma, \quad i = 1, \ldots, \ell. \qquad (3)$$

Imposing $||\mathbf{w}||^2 = 1$, the choice of the hyperplane such that the margin is maximized is equivalent to the following optimization problem:

$$\max_{\mathbf{w},b,\gamma} \gamma$$
$$\text{subject to } y_i(\langle \mathbf{w}, \phi(\mathbf{x}_i)\rangle - b) \ge \gamma, \; i = 1, \ldots, \ell, \qquad (4)$$
$$\text{and } ||\mathbf{w}||^2 = 1.$$

An efficient solution can be found in the dual space by introducing the Lagrange multipliers α_i, $i = 1, \ldots, \ell$. The problem (4) can be recast in the following dual form:

$$\max_{\alpha} \sum_{i=1}^{\ell} \alpha_i - \sum_{i=1}^{\ell} \sum_{j=1}^{\ell} \alpha_i \alpha_j y_i y_j \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j)\rangle \qquad (5)$$
$$\text{subject to } \sum_{i=1}^{\ell} \alpha_i y_i = 0, \quad \alpha_i \ge 0.$$

This formulation shows how the problem reduces to a *convex* (quadratic) optimization task. A key property of solutions α^* of this kind of problems is that they must satisfy the Karush-Kuhn-Tucker (KKT) conditions that ensure that only a subset of training examples needs to be associated to a nonzero α_i. This property is called *sparseness* of the SVM solution and is crucial in practical applications.

In the solution α^*, often only a subset of training examples is associated to nonzero α_i. These are called *support vectors* and correspond to the points that lie closest to the separating hyperplane (Fig. 1b). For the maximal margin hyperplane, the weight vector $\mathbf{w}^*$ is given by a linear function of the training points:

$$\mathbf{w}^* \sum_{i=1}^{\ell} \alpha_i^* y_i \phi(\mathbf{x}_i). \qquad (6)$$

S

Then the decision function (2) can equivalently be expressed as

$$g(\mathbf{x}) = \text{sign}(\sum_{i=1}^{\ell} \alpha_i^* y_i \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}) \rangle - b). \quad (7)$$

For a support vector $\mathbf{x}_i$, it is $\langle \mathbf{w}^*, \phi(\mathbf{x}_i) \rangle - b = y_i$ from which the optimum bias b^* can be computed. However, it is better to average the values obtained by considering all the support vectors [2]. Both the quadratic programming (QP) problem (5) and the decision function (7) depend only on the dot product between data points. The matrix of dot products with elements $K_{ij} = K(\mathbf{x}_i, \mathbf{x}_j) = \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle$ is called the *kernel matrix*. In the case of linear separation, we simply have $K(\mathbf{x}_i, \mathbf{x}_j) = \langle \mathbf{x}_i, \mathbf{x}_j \rangle$, but in general, one can use functions that provide nonlinear decision boundaries. Widely used kernels are the polynomial $K(\mathbf{x}_i, \mathbf{x}_j) = (\langle \mathbf{x}_i, \mathbf{x}_j \rangle + 1)^d$ or the Gaussian $K(\mathbf{x}_i, \mathbf{x}_j) = e^{-\frac{||\mathbf{x}_i - \mathbf{x}_j||^2}{\sigma^2}}$ where d and σ are user-defined parameters.

Key Results

In the framework of learning from examples, SVMs have shown several advantages compared to traditional neural network models (which represented the state of the art in many classification tasks up to 1992). The statistical motivation for seeking the maximal margin solution is to minimize an upper bound on the test error that is independent of the number of dimensions and inversely proportional to the separation margin (and the sample size). This directly suggests embedding of the data in a high-dimensional space where a large separation margin can be achieved; this can be done efficiently with kernels using techniques from convex optimization. The sparseness of the solution, implied by the KKT conditions, adds to the efficiency of the result.

The initial formulation of SVMs by Vapnik and coworkers [1] has been extended by many other researchers. Here we summarize some key contributions.

Soft Margin

In the presence of noise the SV algorithm can be subject to overfitting. In this case one needs to tolerate some training errors in order to obtain a better generalization power. This has led to the development of the *soft margin* classifiers [4]. Introducing the slack variables $\xi_i \geq 0$, optimal class separation can be obtained by

$$\begin{aligned} &\min_{\mathbf{w},b\gamma,\xi} -\gamma + C \sum_{i=1}^{\ell} \xi_i \\ &\text{subject to } y_i(\langle \mathbf{w}, \phi(\mathbf{x}_i) \rangle - b) \geq \gamma - \xi_i, \xi_i \geq 0 \\ &i = 1, \ldots, \ell \text{ and } ||\mathbf{w}||^2 = 1. \end{aligned} \quad (8)$$

The constant C is user defined and controls the trade-off between the maximization of the margin and the number of classification errors. The dual formulation is the same as (5) with the only difference in the bound constraints ($0 \leq \alpha_i \leq C, \quad i = 1, \ldots, \ell$). The choice of soft margin parameter is one of the two main design choices (together with the kernel function) in applications. It is an elegant result [5] that the entire set of solutions for all possible values of C can be found with essentially the same computational cost as finding a single solution: this set is often called the *regularization path*.

Regression

A SV algorithm for regression, called support vector regression (SVR), was proposed in 1996 [6]. A linear algorithm is used in the kernel-induced feature space to construct a function such that the training points are inside a tube of given radius ε. As for classification the regression function only depends on a subset of the training data.

Speeding Up the Quadratic Program

Since the emergence of SVMs, many researchers have developed techniques to effectively solve the problem (5): a quite time-consuming task,

especially for large training sets. Most methods decompose large-scale problems into a series of smaller ones. The most widely used method is that of Platt [7] and it is known as sequential minimal optimization.

Kernel Methods

In SVMs, both the learning problem and the decision function can be formulated only in terms of dot products between data points. Other popular methods (i.e., principal component analysis, canonical correlation analysis, fisher discriminant) have the same property. This fact has led to a huge number of algorithms that effectively use kernels to deal with nonlinear functions keeping the same complexity as the linear case. They are referred to as *kernel methods* [8, 9].

Choosing the Kernel

The main design choice when using SVMs is the selection of an appropriate kernel function, a problem of model selection that roughly relates to the choice of a topology for a neural network. It is a nontrivial result [10] that also this key task can be translated into a convex optimization problem (a semi-definite program) under general conditions. A kernel can be optimally selected from a kernel space resulting from all linear combinations of a basic set of kernels.

Kernels for General Data

Kernels are not just useful tools to allow us to deploy methods of linear statistics in a nonlinear setting. They also allow us to apply them to nonvectorial data: kernels have been designed to operate on sequences, graphs, text, images, and many other kinds of data [8].

Applications

Since their emergence, SVMs have been widely used in a huge variety of applications. To give some examples, good results have been obtained in text categorization, handwritten character recognition, and biosequence analysis.

Text Categorization

In automatic text categorization, text documents are classified into a fixed number of predefined categories based on their content. In the works performed by Joachims [11] and Dumais et al. [12], documents are represented by vectors with the so-called bag-of-words approach used in the information retrieval field. The distance between two documents is given by the inner product between the corresponding vectors. Experiments on the collection of Reuters news stories showed good results for SVMs compared to other classification methods.

Handwritten Character Recognition

This is the first real-world task on which SVMs were tested. In particular two publicly available data sets (USPS and NIST) have been considered since they are usually used for benchmarking classifiers. A lot of experiments, mainly summarized in [13], were performed which showed that SVMs can perform as well as other complex systems without incorporating any detailed prior knowledge about the task.

Bioinformatics

SVMs have been widely used also in bioinformatics. For example, Jaakkola and Haussler [14] applied SVMs to the problem of protein homology detection, i.e., the task of relating new protein sequences to proteins whose properties are already known. Brown et al. [15] describe a successful use of SVMs for the automatic categorization of gene expression data from DNA microarrays.

URL to Code

Many free software implementations of SVMs are available at the website

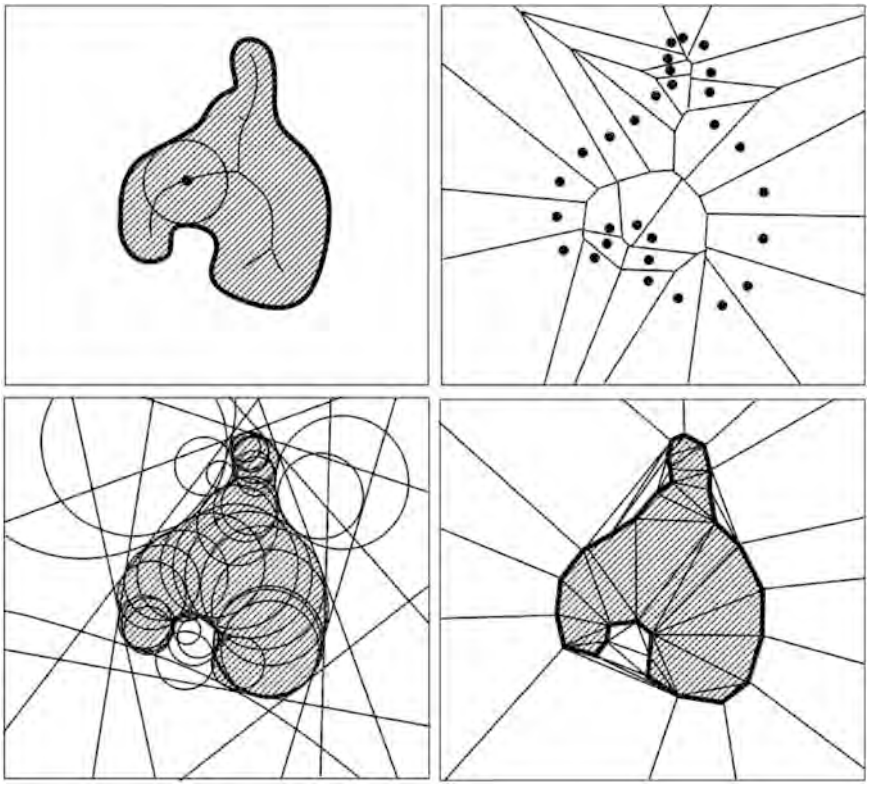
Problem Definition

Surface reconstruction, here, is the problem of producing a piecewise-linear representation of a two-dimensional surface S in $\mathbb{R}^3$, given as input a set P of point samples from the surface. Very



Surface Reconstruction, Fig. 1 The medial axis of an object; the Voronoi diagram of a set of samples from the object boundary; the set of polar balls, with those inside the object shaded; the corresponding cells of the weighted Voronoi diagram, again with those inside the object shaded

sparse sets of point samples clearly do not convey much about S, so in order to prove correctness, we need to assume that the sample P is somehow sufficiently dense. The minimum required density could vary across the surface, with more detailed areas requiring denser sampling. This idea is captured in the following definition [2]. Let S be a two-dimensional surface in $\mathbb{R}^3$. The *medial axis* of S is the closure of the set of points that have more than one nearest point on S; a two-dimensional example is shown in Fig. 1, top left.

Definition 1 The *local feature size* $f(x)$ at a point x is the minimum distance from x to the medial axis of S.

The distance from the medial axis to the surface is zero at a sharp feature such as a corner or a crease, so we usually assume that S is smooth. The algorithms described here make the following ϵ-*sampling assumption*: the minimum distance, at any surface point x, to the nearest sample point is at most $\epsilon f(x)$, for some small constant ϵ. This leads to algorithms that are provably correct in the following sense.

INPUT*: A point set P that is an ϵ-sample from a smooth surface S without boundary.*

OUTPUT*: A piecewise-linear manifold without boundary, homeomorphic to S, that everywhere lies within distance $O(\epsilon f(x))$ of S.* The monograph [7] is an excellent reference for this line of research.

Key Results

One key idea is that in the neighborhood of any point $p \in P$ sampled from S, the surface is well approximated by a plane. Specifically, for any surface point x closer to p than to any other

sample, the distance of x from the tangent plane at p is $O(\epsilon f(x))$, as is the difference between the surface normal at x and the surface normal at p [2] (with the corrected proof [3]). Another key idea is that some subset of the Voronoi vertices of P approximates the medial axis of S, as in Fig. 1, top right.

Crust Algorithm

The crust algorithm [2] approximates the medial axis with a subset of the three-dimensional Voronoi vertices, called the poles. Each sample point in $p \in P$ selects the vertex of its Voronoi cell farthest from p as its first pole and the vertex farthest in the opposite direction as its second. We then eliminate any Delaunay triangle all of whose circumspheres contain a pole; this is easy to implement by computing the Delaunay triangulation of the set P augmented with the set of poles and eliminating any output triangle adjacent to a pole. A subset of the remaining surface triangles can then be selected as the piecewise-linear output surface.

Cocone Algorithm

The cocone algorithm [4] provides a simpler way of selecting a set of surface Delaunay triangles, requiring only one Voronoi diagram computation. It relies on the fact that the direction vector from a sample $p \in P$ to its first pole is within $O(\epsilon)$ of the surface normal at p, under the ϵ-sampling assumption. We define the cocone at p as the complement of a double cone, such that the angle between the cone surface and this approximate normal vector is at least $\pi - \pi/8$. We consider the intersection of the cocone at p with the Voronoi cell of p; the Delaunay triangles dual to any edge in this intersection are marked as potential surface triangles. Triangles marked by all three of their vertices are included in the set of surface triangles.

Powercrust Algorithm

While it is easy in theory to select a subset of the surface triangles to form a piecewise-linear output surface, it can be difficult in practice when the sampling density fails to meet the assumption, as is inevitable at sharp features. The power crust algorithm [5] eliminates this issue by producing a piecewise-linear output surface. The Voronoi ball centered at a pole is the ball with its nearest input samples on the boundary; see Fig. 1, lower left. We begin by labeling the Voronoi balls of all of the poles either as inside or outside the object bounded by S, using an iterative algorithm. We then compute the weighted Voronoi diagram, also known as the power diagram, of these polar Voronoi balls. Any Voronoi face separating the cell of an inner pole from the cell of an outer pole is output as part of the surface (Fig. 1, lower right). The faces of the piecewise-linear output surface are convex polygons but not in general triangles.

Noisy Samples

When the input sample points have noise, not every pole will be near the medial axis. Nonetheless, if the level of noise is everywhere small relative to the local feature size f, some subset of Voronoi vertices will still approximate the medial axis. In [8], this idea is developed into a provably correct algorithm. In addition to the ϵ-sampling assumption, we need to assume that the noise level is $O(\epsilon^2 f(x))$ and that the distance from any sample p to the kth nearest sample p' is $O(\epsilon f(x))$. This allows us to recognize a Voronoi vertex of p as a pole only when it is significantly farther from p than the k-nearest neighbors of p. These poles are then labeled as either inner or outer. This algorithm produces a triangulation of the boundary of the union of the inner polar balls as the output surface.

Complexity

The complexity of all of these algorithms depends on the complexity of the Voronoi diagram. While in general the Voronoi diagram of n points in $\mathbb{R}^3$ might have complexity $O(n^2)$, Attali, Boissonnat, and Lietier [6] proved that the complexity of the Voronoi diagram for points distributed uniformly on a nondegenerate smooth surface in $\mathbb{R}^3$ is $O(n \lg n)$. Another idea, employed by Funke and Ramos [9] and advanced by Cheng et al. [12], is to replace the Voronoi diagram with a less computationally expensive structure to get an $O(n \lg n)$ algorithm.

Applications

Interest in this problem was motivated by the advent of laser-range and LiDAR scanners [10], which produce depth maps sampled by point clouds. It is often reasonable to assume noise-free surface samples, since there are preprocessing methods, such as moving least squares (MLS) [1], that attract noisy point clouds onto nearby surfaces; there has also been theoretical work on MLS. MLS, or simply local plane-fitting, can be used to produce a normal vector at each sample point. Another common assumption is that the normal vectors can be consistently oriented. Poisson surface reconstruction [11] is an optimization technique that constructs manifold surfaces from possibly noisy points with normals. Because of its very efficient implementations, it is currently the most popular method in practice.

Open Problems

Subsequent work in surface reconstruction, both in computer graphics and in computational geometry, has focused on the identification and reconstruction of sharp features and then using them to construct surfaces that are non-manifold. Proving that the complexity of the Voronoi diagram of points distributed on a generic smooth surface with noise or with boundary is $o(n^2)$ remains open.

URLs to Code and Data Sets

There is code available for the cocone algorithm (http://web.cse.ohio-state.edu/~tamaldey/cocone.html), with several subsequent variants. There is also code for the power crust algorithm (http://www.cs.ucdavis.edu/~amenta/powercrust.html). There is a set of benchmark data sets for surface reconstruction (http://www.cs.utah.edu/~bergerm/recon_bench).

Formal hardware verification

Years and Authors of Summarized Original Work

1990; Burch, Clarke, McMillan, Dill

Problem Definition

Design verification is the process of taking a design and checking that it works correctly. More specifically, every design verification paradigm has three components [6]: (1) a language for specifying the design in an unambiguous way, (2) a language for specifying properties that are to be checked of the design, and (3) a checking procedure, which determines whether the properties hold off the design.

The verification problem is very general: it arises in low-level designs, e.g., checking that a combinational circuit correctly implements arithmetic, as well as high-level designs, e.g., checking that a library written in high-level language correctly implements an abstract data type.

Hardware Verification

The verification of hardware designs is particularly challenging. Verification is difficult in part because the large number of concurrent operations make it very difficult to conceive of and construct all possible corner cases, e.g., one unit initiating a transaction at the same cycle as another receiving an exception. In addition, software models used for simulation run orders of several magnitude slower than the final chip operates at. Faulty hardware is usually impossible to correct after fabrication, which means that the cost of a defect is very high, since it takes several months to go through the process of designing and fabricating new hardware. Wile et al. [15] provide a comprehensive account of hardware verification.

State Explosion

Since the number of state-holding elements in digital hardware is bounded, the number of possible states that the design can be in is infinite, so complete automated verification is, in principle, possible. However, the number of states that a hardware design can reach from the initial state can be exponential in the size of the design; this phenomenon is referred to as "state explosion." In particular, algorithms for verifying hardware that explicitly record visited states, e.g., in a hash table, have very high time complexity, making them infeasible for all but the smallest designs. The problem of complete hardware verification is known to be PSPACE-hard, which means that any approach must be based on heuristics.

Hardware Model

A hardware design is formally described using *circuits* [4, 8]. A *combinational circuit* consists of *Boolean combinational elements* connected by *wires*. The Boolean combinational elements are *gates* and *primary inputs*. Gates come in three types: *NOT, AND*, and *OR*. The NOT gate functions as follows: it takes a single Boolean-valued *input* and produces a single Boolean-valued *output* which takes value 0 if the input is 1 and 1 if the input is 0. The AND gate takes two Boolean-valued inputs and produce a single output; the output is 1 if both inputs are 1 and 0 otherwise. The OR gate is similar to AND, except that its output is 1 if one or both inputs are 1. A circuit can be represented as a directed graph where the nodes represent the gates and

wires represent edges in the direction of signal flow.

A circuit can be represented by a directed graph where the nodes represent the gates and primary inputs, and edges represent wires in the direction of signal flow. Circuits are required to be acyclic, that is, there is no cycle of gates. The absence of cycles implies that a Boolean assignment to the primary inputs can be propagated through the gates in topological order.

A *sequential circuit* extends the notion of circuit described above by adding *stateful elements*. Specifically, a sequential circuit includes *registers*. Each register has a single input, which is referred to as its *next-state input*.

A *valuation* on a set V is a function whose domain is V. A *state* in a sequential circuit is a Boolean-valued valuation on the set of registers. An *input* to a sequential circuit is a Boolean-valued valuation on the set of primary inputs. Given a state s and an input i, the logic gates in the circuit uniquely define a Boolean-valued valuation t to the set of register inputs – this is referred to as the next state of the circuit at state s under input i and say s *transitions* to t on input i. It is convenient to denote such a transition by $s \xrightarrow{i} t$.

A sequential circuit can naturally be identified with a *finite state machine* (FSM), which is a graph defined over the set of all states; an edge (s, t) exists in the FSM graph if there exists an input i, state s transitions to t on input i.

Invariant Checking

An *invariant* is a set of states; informally, the term is used to refer to a set of states that are "good" in some sense. One common way to specify an invariant is to write a Boolean formula on the register variables – the states which satisfy the formula are precisely the states in the invariant.

Given states r and s, define r to be *reachable* from s if there is a sequence of inputs $i_0, i_1, \ldots, i_{n-1}$ such that $s = s_0 \xrightarrow{i_0} s_1 \xrightarrow{i_1} \cdots s_n = t$. A fundamental problem in hardware verification is the following: given an invariant A, and a state s, does there exists a state r reachable from s which is not in A?

Key Results

Symbolic model checking (SMC) is a heuristic approach to hardware verification. It is based on the idea that rather than representing and manipulating states one at a time, it is more efficient to use symbolic expressions to represent and manipulate sets of states.

A key idea in SMC is that given a set $A \subset \{0,1\}^n$, a Boolean function A can be constructed such that f_A: $\{0,1\}^n \to \{0,1\}$ given by $f(\alpha_1, \ldots, \alpha_n) = 1$ iff $(\alpha_1, \ldots, \alpha_n) \in A$. Note that given a characteristic function f_A, A can be obtained and vice versa.

There are many ways in which a Boolean function can be represented: formulas in DNF, general Boolean formulas, combinational circuits, etc. In addition to an efficient representation for state sets, the ability to perform fast computations with sets of states is also important, for example, in order to determine if an invariant holds, it is required to compute the set of states reachable from a given state. BDDs [2] are particularly well suited to representing Boolean functions, as they combine succinct representation with efficient manipulation; they are the data structure underlying SMC.

Image Computation

A key computation that arises in verification is determining the *image* of a set of states A in a design D – the image of A is the set of all states t for which there exists a state in A and an input i such that state s transitions to t under input i. The image of A is denoted by $\mathrm{Img}(A)$.

The *transition relation* of a design is the set of (s, i, t) triples such that s transitions to t under input i. Let the design have n registers and m primary inputs; then the transition relation is subset of $\{0,1\}^n \times \{0,1\}^m \times \{0,1\}^n$.

Conceptually, the transition relation completely captures the dynamics of the design – given an initial state, and input sequence, the evolution of the design is completely determined by the transition relation.

Since the transition relation is a subset of $\{0,1\}^{n+m+n}$, it has a characteristic function $f_T : \{0,1\}^{n+m+n} \rightarrow \{0,1\}$. View f_T as being defined over the variables $x_0, \ldots, x_{n-1}$, $i_0, \ldots, i_{m-1}$, $y_0, \ldots, y_{n-1}$. Let the set of states A be represented by the function f_A defined over variables $x_0, \ldots, x_{n-1}$. Then the following identity holds

$$\mathrm{Img}(A) = (\exists x_0 \cdot \exists x_{n-1} \exists i_0 \cdots \exists i_{m-1})(f_A \cdot f_T).$$

The identity holds because $(\beta_0, \ldots, \beta_{n-1})$ satisfies the right-hand side expression exactly when there are values $\alpha_0, \ldots, \alpha_{n-1}$, and $\iota_0, \ldots, \iota_{m-1}$ such that $(\alpha_0, \ldots, \alpha_{n-1}) \in A$ and the state $(\alpha_0, \ldots, \alpha_{n-1})$ transitions to $(\beta_0, \ldots, \beta_{n-1})$ on input $(\iota_0, \ldots, \iota_{m-1})$.

Invariant Checking

The set of all states reachable from a given set A is the limit as n tends to infinity of the sequence of states $R_0, R_1, \ldots$ defined below:

$$R_0 = A$$
$$R_{i+1} = R_i \cup \mathrm{Img}(R_i).$$

Since for all i, $R_i \subseteq R_{i+1}$ and the number of distinct state sets is finite, the limit is reached in some finite number of steps, i.e., for some n, it must be that $R_{n+1} = R_n$. It is straightforward to show that the limit is exactly equal to the set of states reachable from A – the basic idea is to inductively construct input sequences that lead from states in A to R_i and to show that state t is reachable from a state in A under an input sequence of length l, then t must be in R_l.

Given BDDs F and G representing functions f and g, respectively, there is an algorithm based on dynamic programming for performing conjunction, i.e., for computing the BDD for $f \cdot g$. The algorithm has polynomial complexity, specifically $O(|F| \cdot |G|)$, where $|B|$ denotes the number of nodes in the BDD B. There are similar algorithms for performing disjunction ($f + g$) and computing cofactors (f_x and $f_{x'}$). Together these yield an algorithm for the operation of existential quantification, since $(\exists x) f = f_x + f'_x$.

It is straightforward to build BDDs for f_A and $f_T : A$ is typically given using a propositional formula, and the BDD for f_A can be built up using functions for conjunction, disjunction, and negation. The BDD for f_T is built using from the BDDs for the next-state nodes, over the register and primary input variables. Since the only gate types are AND, OR, and NOT, the BDD can be built using the standard BDD operators for conjunction, disjunction, and negation. Let the next-state functions be $f_0, \ldots, f_{n-1}$; then f_T is $(y_0 = f_0) \cdot (y_1 = f_1) \cdot \cdots \cdot (y_{n-1} = f_{n-1})$, and so the BDD for f_T can be constructed using the usual BDD operators.

Since the image computation operation can be expressed in terms of f_A and F_T, and conjunction and existential quantification operations, it can be performed using BDDs. The computation of R_i involves an image operation, and a disjunction, and since BDDs are canonical, the test for fixed point is trivial.

Applications

The primary application of the technique described above is for checking properties of hardware designs. These properties can be invariants described using propositional formulae over the register variables, in which case the approach above is directly applicable. More generally, properties can be expressed in a *temporal logic* [5], specifically through formulae which express acceptable sequences of outputs and transitions.

CTL is one common temporal logic. A CTL formula is given by the following grammar: if x is a variable corresponding to a register, then $\mathbf{x}$ is a CTL formula; otherwise, if φ and ψ are CTL

formulas, then so as $(\neg\phi)$, $(\phi \vee \psi)$, $(\phi \wedge \psi)$, $(\phi \rightarrow \psi)$, and $EX\phi$, $E\phi U\psi$, and $EG\phi$.

A CTL formula is interpreted as being true at a state; a formula **x** is true at a state if that register is 1 in that state. Propositional connectives are handled in the standard way, e.g., a state satisfies a formula $(\phi \wedge \psi)$ if it satisfies both φ and ψ. A state s satisfies $EG\phi$ if there exists a state t such that s transitions to, and t satisfies φ. A state s satisfies $E\phi U\psi$ if there exists a sequence of inputs $i_0, \ldots, i_n$ leading through state $s_0 = s$, $s_1, s_2, \ldots, s_{n+1}$ such that s_{n+1} satisfies ψ, and all states $s_i, i \leq n+1$ satisfy φ. A state s satisfies $EG\phi$ if there exists an infinite sequence of inputs $i_0, i_1, \ldots$ leading through state $s_0 = s, s_1, s_2, \ldots$ such that all states s_i satisfy φ.

CTL formulas can be checked by a straightforward extension of the technique described above for invariant checking. One approach is to compute the set of states in the design satisfying subformulas of φ, starting from the subformulas at the bottom of the parse tree for φ. A minor difference between invariant checking and this approach is that the latter relies on *pre-image* computation; the pre-image of A is the set of all states t for which there exists an input i such that t transitions under i to a state in A.

Symbolic analysis can also be used to check the equivalence of two designs by forming a new design which operates the two initial designs in parallel and has a single output that is set to 1 if the two initial designs differ [14]. In practice this approach is too inefficient to be useful, and techniques which rely more on identifying common substructures across designs are more successful.

The complement of the set of reachable states can be used to identify parts of the design which are redundant and to propagate don't care conditions from the input of the design to internal nodes [12].

Many of the ideas in SMC can be applied to software verification – the basic idea is to "finitize" the problem, e.g., by considering integers to lie in a restricted range or setting an a priori bound on the size of arrays [7].

Experimental Results

Many enhancements have been made to the basic approach described above. For example, the BDD for the entire transition relation can grow large, so *partitioned transition relations* [11] are used instead; these are based on the observation that $\exists x.(f \cdot g) = f \cdot \exists x.g$, in the special case that f is independent of x. Another optimization is the use of *don't cares*; for example, when computing the image of A, the BDD for f_T can be simplified with respect to transitions originating at A' [13]. Techniques based on SAT have enjoyed great success recently. These approaches case the verification problem in terms of satisfiability of a CNF formula. They tend to be used for bounded checks, i.e., determining that a given invariant holds on all input sequences of length k [1]. Approaches based on *transformation-based verification* complement symbolic model checking by simplifying the design prior to verification. These simplifications typically remove complexity that was added for performance rather than functionality, e.g., pipeline registers.

The original paper by Clarke et al. [3] reported results on a toy example, which could be described in a few dozen lines of a high-level language. Currently, the most sophisticated model checking tool for which published results are ready is SixthSense, developed at IBM [10].

A large number of papers have been published on applying SMC to academic and industrial designs. Many report success on designs with an astronomical number of states – these results become less impressive when taking into consideration the fact that a design with n registers has 2^n states.

It is very difficult to define the complexity of a design. One measure is the number of registers in the design. Realistically, a hundred registers is at the limit of design complexity that can be handled using symbolic model checking. There are cases of designs with many more registers that have been successfully verified with symbolic model checking, but these registers are invariably part of a very regular structure, such as a memory array.

Data Sets

The SMV system described in [9] has been updated, and its latest incarnation nuSMV (http://nusmv.irst.itc.it/) includes a number of examples.

The VIS (http://embedded.eecs.berkeley.edu/pubs/downloads/vis) system from UC Berkeley and UC Boulder also includes a large collection of verification problems, ranging from simple hardware circuits to complex multiprocessor cache systems.

The SIS (http://embedded.eecs.berkeley.edu/pubs/downloads/sis/) system from UC Berkeley is used for logic synthesis. It comes with a number of sequential circuits that have been used for benchmarking symbolic reachability analysis.

Years and Authors of Summarized Original Work

2006; Hong, McKay and Eades

Problem Definition

Symmetry is one of the most important aesthetic criteria in graph drawing that clearly reveals the structure and properties of a graph. Many graphs in Graph Theory textbooks are often symmetric.

A symmetry of a drawing D of a graph G induces an *automorphism* ϕ of the graph G, a permutation of the vertex set that preserves

adjacency. If an automorphism ϕ can be displayed as a symmetry in a drawing of the graph G, then it is called a *geometric automorphism* [6]. A geometric automorphism ϕ of a *planar* graph G is a *planar automorphism*, if there is a *planar* drawing of G which displays ϕ. Note that not every automorphism is geometric, and not every geometric automorphism is planar.

In general, algorithms for constructing symmetric drawings of graphs have two steps:

1. *Symmetry finding step*: Find the geometric automorphisms of a graph
2. *Symmetry drawing step*: Draw the graph displaying these automorphisms as symmetries.

Note that the first step is more difficult than the second step. For example, finding automorphism of a graph is isomorphism-hard; however finding geometric automorphism of a graph is NP-hard in general [18]. For planar graphs, computing isomorphism (therefore, automorphism) of a graph can be solved in linear time [7, 17]. However, finding the *best plane embedding* of planar graphs that displays the maximum number of symmetries in a drawing of a planar graph is challenging, because a planar graph can have exponential number of possible plane embeddings.

Furthermore, the product of two geometric automorphisms is not necessarily geometric, because they may be displayed by different drawings. A subgroup A of the automorphism group of a graph is a *geometric automorphism group*, if there is a single drawing of the graph that displays every element of A. Therefore, to construct a maximally symmetric drawing of a graph, one needs to compute a *maximum size* geometric automorphism group for the graph. Therefore, the main research problem for Symmetric Graph Drawing can be defined as below.

Symmetric Graph Drawing Problem
Input: A graph G.
Output: A maximum size geometric automorphism group A of G, A symmetric drawing D of G that displays all elements of A.

Key Results

There are two types of symmetry in two-dimensional drawings: *rotational symmetry* (i.e., a rotation about a point) and *axial* (or *reflectional*) *symmetry* (i.e., a reflection about an axis). The *order* of an automorphism α is the smallest positive integer k such that α^k equals the identity I. A group-theoretic characterization of geometric automorphism group was given by Eades and Lin [6] as follows:

- A group of order 2 generated by an *axial automorphism*;
- A *cyclic group* of order k generated by a *rotational automorphism*;
- A *dihedral group* of order $2k$ generated by a rotational automorphism of order k and an axial automorphism. In this case there are k axial symmetries.

In two dimensions, the problem of determining whether a given graph can be drawn symmetrically is NP-complete in general [18]. Exact algorithms are devised based on Branch and Cut approach by Buchheim and Junger [3] and a group-theoretic approach by Abelson et al. [1]. Linear-time algorithms are available for trees and outerplanar graphs by Manning and Atallah [19, 20] and for series-parallel digraphs by Hong et al. [14]. Linear-time algorithms are presented for maximally symmetric drawings of triconnected planar graphs by Hong et al. [15] and for biconnected, oneconnected, and disconnected planar graphs by Hong and Eades [10, 12, 13]. Hong and Nagamochi presented a linear-time algorithm for constructing a *symmetric convex* drawings of internally trconnected planar graphs [16]. For a survey on symmetric drawings of graphs in two dimensions, see [5].

In three dimensions, the problem of determining whether a graph can be drawn symmetrically in three dimensions is *NP-hard* in general [8]. A group-theoretic characterization of symmetric drawing in n-dimensions and exact algorithms based on a group-theoretic approach are given

by Abelson et al. [1]. Linear-time algorithms are available for trees by Hong and Eades [9], series-parallel digraphs by Hong et al. [11], and biconnected and oneconnected planar graphs [8].

In this article, we review a linear-time algorithm for constructing maximally symmetric straight-line drawings of *triconnected planar graphs* by Hong, McKay, and Eades [15]. The following theorem summarizes their main results.

Theorem 1 *There is a linear-time algorithm that constructs straight-line drawings of maximally symmetric planar drawings of triconnected planar graphs.*

Computing a Planar Automorphism Group of Maximum Size

We first review the first step of the algorithm, i.e., symmetry finding step for triconnected planar graphs [15]. A geometric automorphism group A of a graph G is a *planar automorphism group*, if there is a *planar* drawing of the graph that displays every element of A.

Suppose that A is a group acting on a set X. The *stabilizer* of $x \in X$, denoted by $stab_A(x)$, is $\{g \in A \mid g(x) = x\}$, and the *orbit* of x, denoted by $orbit_A(x)$, is $\{g(x) \mid g \in A\}$. We say that $g \in A$ *fixes* $x \in X$ if $g(x) = x$; if g fixes x for every $g \in A$, then A fixes x. If $X' \subseteq X$ and $\phi(x') \in X'$ for all $x' \in X'$, then g *fixes* X'. Automorphisms $g_1, g_2, \ldots, g_k$ are called *generators* of $\langle g_1, g_2, \ldots, g_k \rangle$; the group consists of all permutations formed from products of elements of $\{g_1, g_2, \ldots, g_k\}$.

Hong et al. [15] characterize planar automorphisms as below.

Lemma 1 *Let G be a triconnected planar graph. An automorphism of G is a planar automorphism if and only if it fixes a face of G.*

To find the best plane embedding to compute a planar automorphism group with a maximum size, the algorithm uses the Stabilizer-Orbit theorem in group theory [2].

Theorem 2 (Stabilizer-Orbit theorem) *Suppose that A is a group acting on a set X and let $x \in X$. Then $|A| = |orbit_A(x)| \times |stab_A(x)|$.*

The overall algorithm computing a maximum size planar automorphism group of a triconnected planar graph can be described as follows;

Algorithm `Compute_Max_PAG`

1. Find a plane embedding which has a maximum size planar automorphism group.
2. Perform "star triangulation" for the given embedding.
3. Compute the *generators* of the planar automorphism group of the new embedding.

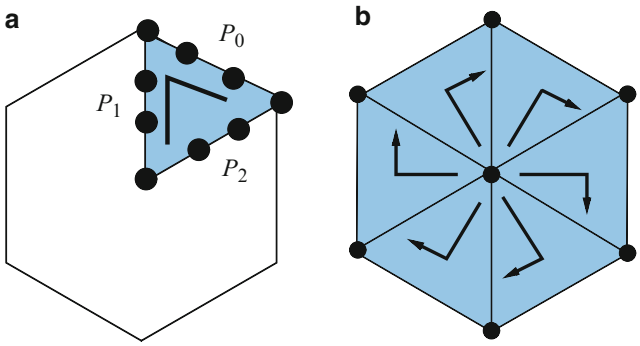
The first step of `Compute_Max_PAG` uses two applications of an algorithm of Fontet [7], which computes the orbits on vertices of the (full) automorphism group of a triconnected planar graph in linear time.

Theorem 3 *Fontet's algorithm [7] can be used to find a plane embedding of a triconnected graph G such that the corresponding planar automorphism group is maximized in linear time.*

Proof Based on Lemma 1, we take a dual graph of G^* of G and compute the orbits of G^* using Fontet's algorithm [7]. Choose an orbit O of minimum size; the stabilizer O has the maximum size, by Theorem 2. Taking a face $f \in O$ as the outer face of the plane embedding of G, we have an embedding that displays the maximum number of symmetries.

Once the outer face and thus the plane embedding is chosen, the second step of `Compute_Max_PAG` performs *star triangulation*, i.e., triangulate each internal face f by inserting a new vertex v in the face and joining v to each vertex of f. Clearly, this step takes linear time and simplifies the drawing algorithm.

The final step of `Compute_Max_PAG` is to compute the planar automorphism group for star-triangulated plane graph. Since an explicit representation of the planar automorphism group may take more than linear space, for a more compact representation, an algorithm for computing *minimal generators* was devised. For details on a linear-time algorithm for computing generators of a planar automorphism group, see [15].



Symmetric Graph Drawing, Fig. 1 Example of (**a**) a wedge and (**b**) merging step

Overview of the Drawing Algorithm

We now review a linear-time drawing algorithm for constructing a symmetric drawing of a triconnected planar graph that achieves that maximum with straight-line edges. The main characteristic of symmetric drawings is the repetition of congruent drawings of isomorphic subgraphs. To exploit this property, the drawing algorithm uses a divide and conquer approach: (i) divide the graph into isomorphic subgraphs; (ii) compute a drawing for a subgraph; and (iii) merge multiple copies of drawings of subgraphs to construct a symmetric drawing of the whole graph. Overall, each step of the drawing algorithm runs in linear time.

The input of the drawing algorithm is a triconnected planar graph with fixed plane embedding and a specified outer face, which maximize the number of symmetries. The symmetric drawing algorithm takes a different approach for each type of planar automorphism group: i.e., *cyclic* case, *one axial* case, and *dihedral* case.

The Cyclic Case

Here we describe how to display k rotational symmetries. Note that after star triangulation, there is a *central* vertex c, which is fixed by the planar automorphism group for $k \geq 3$. If $k = 2$, there exits either a central vertex or a central edge. If there is a central edge, then we preprocess the graph by inserting a dummy central vertex c into the central edge with two dummy edges.

The rotational symmetric drawing algorithm consists of three steps:

Algorithm **Cyclic**

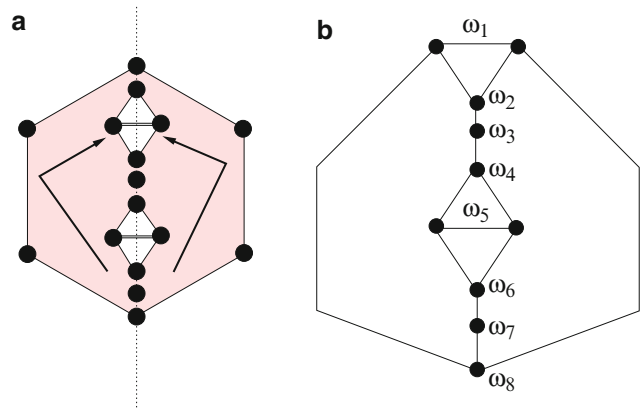
1. `Find_Wedge_Cyclic`.
2. `Draw_Wedge_Cyclic`.
3. `Merge_Wedges_Cyclic`.

The first step is to find a subgraph *wedge* W, which takes linear time:

Algorithm `Find_Wedge_Cyclic`

1. Find the *central* vertex c.
2. Find a shortest path P_1, from c to a vertex v_1 on the outer face, using breadth first search.
3. Find the path P_2 which is a mapping of P_1 under a minimal generator of the rotation.
4. Find the wedge W (see Fig. 1a), an induced subgraph of G enclosed by the cycle formed from P_1, P_2 and a path P_0 along the outer face from v_1 to v_2.

The second step, `Draw_Wedge_Cyclic`, constructs a drawing D of the wedge W using Algorithm `CYN`, the linear-time convex drawing algorithm by Chiba et al. [4], such that P_1, P_2, and P_0 are drawn as straight lines. The input to Algorithm `CYN` is an internally triconnected plane graph G with given outer face S and a straight-line drawing S^* of S as a *weakly convex polygon*, i.e., not every vertex of the outer face needs to be at an apex (i.e., the interior angle is less than π) of the polygon. Algorithm `CYN` chooses a vertex v and deletes it from G together with incident edges and divides the resulting graph $G' = G - v$ into the biconnected components $B_1, B_2, \ldots, B_p$, $p \geq 1$. It defines a convex polygon S_i^* of the outer facial cycle S_i of



Symmetric Graph Drawing, Fig. 2 Example of (**a**) a fixed string of diamonds and (**b**) ω_ℓ

each B_i and recursively applies the algorithm to draw B_i with S_i^* as outer boundary. For details, see [4].

The last step, `Merge_Wedges_Cyclic`, constructs a drawing of the whole graph G by replicating the drawing D of W, k times. Note that this merge step relies on the fact that P_1 and P_2 are drawn as straight lines. See Fig. 1b.

It is clear that Algorithm `Cyclic` constructs a straight-line drawing of a triconnected plane graph which shows k rotational symmetry in linear time.

One Axial Symmetry

Consider a drawing of a star-triangulated plane graph with one axial symmetry. There are fixed vertices, edges, and/or fixed faces on the axis; we need to characterize the subgraph formed by these.

A *diamond* is either a triangle or the 4-vertex graph. A *string of diamonds* is a graph formed from a path $P = (v_1, v_2, \ldots, v_k)$, $k \geq 2$, by a number (zero or greater) of "splitting" operations, as follows. If $1 \leq i \leq k-1$, then the edge (v_i, v_{i+1}) may be replaced by a diamond. Alternatively, each of the end edges (v_1, v_2) and (v_{k-1}, v_k) may be replaced by a triangle. Note that a string of diamonds is basically a path consisting of edges and diamonds; each end of the path may be a triangle; see Fig. 2a.

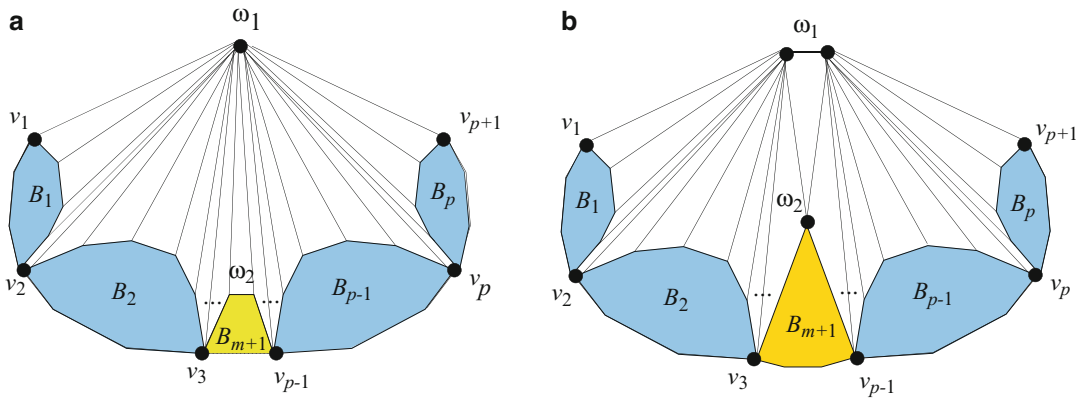
To display a single axial symmetry, we need two steps. First we identify the *fixed string of diamonds*; then use Algorithm `Symmetric_CYN`, a modified version of Algorithm `CYN`. More formally, the algorithm `One_Axial` is described below.

Algorithm `One_Axial`

1. Find a fixed string of diamonds. Suppose that $\omega_1, \omega_2, \ldots, \omega_k$ are the fixed edges and vertices in the fixed string of diamonds, in order from the outer face (ω_1 is on the outer face). For each ℓ, ω_ℓ may be a vertex or an edge (see Fig. 2b).
2. Choose a symmetric convex polygon S^* for the outer face S of G.
3. `Symmetric_CYN`$(1, S^*, G, y_1)$.

The main ingredient in Algorithm `One_Axial` is Algorithm `Symmetric_CYN`. To modify Algorithm `CYN` to display a single axial symmetry, the following three conditions should be satisfied:

- Choose the first vertex or edge on the fixed string of diamonds ω_1 (see Fig. 3).
- Let $D(B_i)$ be the drawing of B_i and α be the axial symmetry. Then, $D(B_i)$ should be a reflection of $D(B_j)$, where $B_j = \alpha(B_i)$, $i = 1, 2, \ldots, m$ and $m = \lfloor p/2 \rfloor$: To satisfy this condition, define S_j^* to be the reflection of S_i^*, $i = 1, 2, \ldots, m$. Then we apply Algorithm `CYN` for $B_i, i = 1, 2, \ldots, m$ and construct $D(B_j)$ using a reflection of $D(B_i)$.
- If p is odd, then $D(B_{m+1})$ should display axial symmetry: To satisfy this condition, we recursively apply Algorithm `Symmetric_CYN` to B_{m+1}.



Symmetric Graph Drawing, Fig. 3 Example of a symmetric version of CYN

Note that the position of ω_2 in Fig. 3 can be chosen arbitrarily along the axis of symmetry of S^* within S^*. This means that we can specify the positions of the fixed vertices and middle edges along the axis of symmetry a priori, that is, as input to the algorithm. The Algorithm `Symmetric_CYN` can be described as below:

Algorithm `Symmetric_CYN`

input: ℓ: index of vertex or middle edge on the fixed string of diamonds.
input: S^*: a weakly convex polygon of the outer face of S of G.
input: G: a triangulated planar graph.
input: y_ℓ: a position on the axis of symmetry for the fixed vertex or the fixed edge ω_ℓ.

1. Delete ω_ℓ from G together with edges incident to ω_ℓ. Divide the resulting graph $G' = G - \omega_\ell$ into the blocks $B_1, B_2, \ldots, B_p$, $p \geq 1$, ordered anticlockwise around the outer face. Let $m = \lfloor p/2 \rfloor$.
2. Determine a convex polygon S_i^* of the outer facial cycle S_i of each B_i such that B_i with S_i^* satisfy the conditions for convex drawing algorithm `CYN` and S_{p-i+1}^* is a reflection of S_i^*.
3. For each $i = 1$ to m,
   (a) Construct a drawing $D(B_i)$ of B_i using Algorithm `CYN`.
   (b) Construct $D(B_{p-i+1})$ as a reflection of $D(B_i)$.
4. If p is odd, then construct a drawing $D(B_{m+1})$ using `Symmetric_CYN`$(\ell + 1, S_{m+1}^*, B_{m+1}, y_{\ell+1})$.
5. Merge the $D(B_i)$ to form a drawing of G, placing ω_ℓ at y_ℓ.

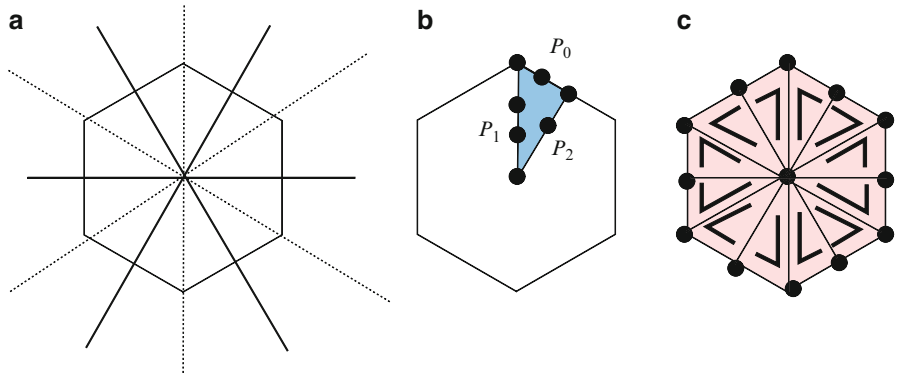
Since Algorithm `CYN` [4] runs in linear time, clearly Algorithm `Symmetric_CYN` and Algorithm `One_Axial` takes linear time.

The Dihedral Case

We now review an algorithm for displaying a dihedral group $< \rho, \alpha >$, where ρ is a rotation of order k and α is an axial automorphism. As with the cyclic case, we assume that there is a central vertex.

The drawing algorithm adopts the same strategy as for the cyclic case: (i) divide the graph into "wedges"; (ii) draw each wedge; and (iii) merge the drawings of wedges to construct a symmetric drawing of the whole graph. However, the dihedral case is more difficult than the cyclic case, because an axial symmetry in the dihedral group can have fixed faces as well as fixed edges; i.e., the boundary of a wedge may be a fixed string of diamonds as in the one axial case. To achieve dihedral symmetry, the axis of symmetry must be the perpendicular bisector of the middle edge of each diamond. This makes the merging operation more difficult.

Consider a drawing of a triconnected planar graph with a dihedral symmetry group of size $2k$.



Symmetric Graph Drawing, Fig. 4 Wedge for the dihedral case

There are k axial symmetries, with axes at angles of $\pi i/k$, $0 \leq i \leq k-1$, to the x axis, as in Fig. 4a. Roughly speaking, a wedge is the area between two adjacent axes, as in Fig. 4b. Note that in these wedges, the boundaries P_1 and P_2 may be strings of diamonds. These may terminate in a triangle.

As with the cyclic case, Algorithm `Dihedral` has three steps: (i) `Find_Wedge_Dihedral`, (ii) `Draw_Wedge_Dihedral`, and (iii) `Merge_Wedges_Dihedral`.

The first step is to define the "wedge" subgraph by finding two fixed strings of diamonds. Note that one can find the central vertex c and the two fixed strings of diamonds P_1 and P_2 in linear time using the generators of the group.

Algorithm `Find_Wedge_Dihedral`

1. Find the central vertex c.
2. Find a string of diamonds P_1 that is fixed by α, from c to a vertex v or an edge e on the outer face.
3. Traverse the outer face, clockwise from v (or e) to the vertex v' or edge e' that is fixed by $\rho^{-1}\alpha\rho$. Let P_0 denote the path so traversed.
4. Find the string of diamonds P_2 for $\rho^{-1}\alpha\rho$, from c to v' (or e').
5. Define the wedge W to be the subgraph enclosed by P_0, P_1, and P_2, including the vertices and edges of P_0, P_1, and P_2.

The second step, `Draw_Wedge_Dihedral`, constructs a drawing of the wedge, which is the most complicated step of the drawing algorithm. This step must ensure that the middle edge of each diamond on the boundary is orthogonal to the axis of reflection.

Roughly speaking, the algorithm `Draw_Wedge_Dihedral` runs as follows: (i) Find all *special diamonds* of P_1 and P_2 that share fixed vertices or fixed edges, and draw them first using algorithm `Draw_Special_Diamonds`; (ii) choose the positions of all the fixed vertices of P_1 and P_2 that have not been drawn so far; (iii) subdivide the wedge in various ways to form "subwedges"; (iv) draw each of these subwedges using Algorithms `CYN` and `Symmetric_CYN` accordingly. For details, see [15].

The final step, Algorithm `Merge_Wedges_Dihedral` simply constructs a drawing for the whole graph by merging the drawing D of the wedge W. Clearly each step of Algorithm `Dihedral` takes linear time.

Synchronizers, Spanners

Michael Elkin
Department of Computer Science, Ben-Gurion University, Beer-Sheva, Israel

Keywords

Low-stretch spanning subgraphs; Network synchronization

Years and Authors of Summarized Original Work

1985; Awerbuch

Problem Definition

Consider a communication network, modeled by an n-vertex undirected unweighted graph $G = (V, E)$, for some positive integer n. Each vertex of G hosts a processor of unlimited computational power; the vertices have unique identity numbers, and they communicate via the edges of G by sending messages of size $O(\log n)$ each.

In the *synchronous* setting, the communication occurs in discrete *rounds*, and a message sent in the beginning of a round R arrives at its destination before the round R ends. In the *asynchronous* setting, each vertex maintains its own clock, and clocks of distinct vertices may disagree. It is assumed that each message sent (in the asynchronous setting) arrives at its destination within a certain time τ after it was sent, but the value of τ is not known to the processors.

It is generally much easier to devise algorithms that apply to the synchronous setting (henceforth, synchronous algorithms) rather than to the asynchronous one (henceforth, asynchronous algorithms). In [1] Awerbuch initiated the study of simulation techniques that translate synchronous algorithms to asynchronous ones. These simulation techniques are called *synchronizers*.

To devise the first synchronizers, Awerbuch [1] constructed a certain graph partition which is of its own interest. In particular, Peleg and Schäffer noticed [8] that this graph partition induces a subgraph with certain interesting properties. They called this subgraph a *graph spanner*. Formally, for a positive integer parameter k, a k-spanner of a graph $G = (V, E)$ is a subgraph $G' = (V, H)$, $H \subseteq E$, such that for every edge $e = (v, u) \in E$, the distance between the vertices v and u in H, $\text{dist}'_G(v, u)$, is at most k.

Key Results

Awerbuch devised three basic synchronizers, called α, β, and γ. The synchronizer α is the simplest one; using it results in only a constant overhead in time, but in a very significant overhead in communication. Specifically, the latter overhead is linear in the number of edges of the underlying network. Unlike the synchronizer α, the synchronizer β requires a somewhat costly initialization stage. In addition, using it results in a significant time overhead (linear in the number of vertices n), but it is more communication efficient than α. Specifically, its communication overhead is linear in n.

Finally, the synchronizer γ represents a trade-off between the synchronizers α and β. Specifically, this synchronizer is parametrized by a positive integer parameter k. When k is small, then the synchronizer behaves similarly to the synchronizer α, and when k is large, it behaves similarly to the synchronizer β. A particularly important choice of k is $k = \log n$. At this point on the trade-off curve, the synchronizer γ has a logarithmic in n time overhead and a linear in n communication overhead. The synchronizer γ has, however, a quite costly initialization stage.

The main result of [1] concerning spanners is that for every $k = 1, 2, \ldots$, and every n-vertex unweighted undirected graph $G = (V, E)$, there exists an $O(k)$-spanner with $O(n^{1+1/k})$ edges. (This result was explicated by Peleg and Schäffer [8].)

Applications

Synchronizers are extensively used for constructing asynchronous algorithms. The first applications of synchronizers are constructing the *breadth-first-search tree* and computing the *maximum flow*. These applications were presented and analyzed by Awerbuch in [1]. Later synchronizers were used for maximum matching [10], for computing shortest paths [7], and for other problems.

Graph spanners were found useful for a variety of applications in distributed computing. In particular, some constructions of synchronizers employ graph spanners [1, 9]. In addition, spanners were used for routing [4] and for computing almost shortest paths in graphs [5].

Open Problems

Synchronizers with improved properties were devised by Awerbuch and Peleg [3] and Awerbuch et al. [2]. Both these synchronizers have polylogarithmic time and communication overheads. However, the synchronizers of Awerbuch and Peleg [3] require a large initialization time. (The latter is at least linear in n.) On the other hand, the synchronizers of [2] are randomized. A major open problem is to obtain *deterministic* synchronizers with polylogarithmic time and communication overheads and sublinear in n initialization time. In addition, the degrees of the logarithm in the polylogarithmic time and communication overheads in synchronizers of [2, 3] are quite large. Another important open problem is to construct synchronizers with improved parameters.

In the area of spanners, spanners that distort large distances to a significantly smaller extent than they distort small distances were constructed by Elkin and Peleg in [6]. These spanners fall short from achieving a *purely additive distortion*. Constructing spanners with a purely additive distortion is a major open problem.

Table Compression

Raffaele Giancarlo[1] and Adam L. Buchsbaum[2]
[1]Department of Mathematics and Applications, University of Palermo, Palermo, Italy
[2]Madison, NJ, USA

Keywords

Compression and transmission of tables; Compression of multidimensional data; Compressive estimates of entropy; Storage

Years and Authors of Summarized Original Work

2003; Buchsbaum, Fowler, Giancarlo

Problem Definition

Table compression was introduced by Buchsbaum et al. [3] as a unique application of compression, based on several distinguishing characteristics. Tables are collections of fixed-length records and can grow to be terabytes in size. They are often generated by information systems and kept in data warehouses to facilitate ongoing operations. These data warehouses will typically manage many terabytes of data online, with significant capital and operational costs. In addition, the tables must be transmitted to different parts of an organization, incurring additional costs for transmission. Typical examples are tables of transaction activity, like phone calls and credit card usage, which are stored once but then shipped repeatedly to different parts of an organization: for fraud detection, billing, operations support, etc. The goals of table compression are to be fast, online, and effective: eventual compression ratios of 100:1 or better are desirable. Reductions in required storage and network bandwidth are obvious benefits.

Tables are different than general databases [3]. Tables are written once and read many times, while databases are subject to dynamic updates. Fields in table records are fixed in length, and records tend to be homogeneous; database records often contain intermixed fixed- and variable-length fields. Finally, the goals of compression differ. Database compression stresses index preservation, the ability to retrieve an arbitrary record, under compression [7]. Tables are typically not indexed at the level of individual records; rather, they are scanned in toto by downstream applications.

Consider each record in a table to be a row in a matrix. A naive method of table compression is to compress the string derived from scanning the table in row-major order. Buchsbaum et al. [3] observe experimentally that partitioning the table into contiguous intervals of columns and compressing each interval separately in this fashion can achieve significant compression improvement. The partition is generated by a one-time, off-line training procedure, and the resulting compression strategy is applied online

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

to the table. In their application, tables are generated continuously, so off-line training time can be ignored. They also observe heuristically that certain rearrangements of the columns prior to partitioning further improve compression by grouping dependent columns more closely. For example, in a table of addresses and phone numbers, the area code can often be predicted by the zip code when both are defined geographically. In information-theoretic terms, these dependencies are *contexts*, which can be used to predict parts of a table. Analogously to strings, where knowledge of context facilitates succinct codings of symbols, the existence of contexts in tables implies, in principle, the existence of a more succinct representation of the table.

Three main avenues of research have followed, one based on the notion of combinatorial dependency [3, 4], another on the notion of column dependency [17, 18], and the third on the notion of motifs and templates [1]. The first formalizes dependencies analogously to the joint entropy of random variables, while the second does so analogously to conditional entropy [8]. The third finds inspiration in classic paradigms of data compression such as textual substitution [19, 20]. These approaches to table compression have deep connections to universal similarity metrics [12], based on Kolmogorov complexity and compression, and their later uses in classification [6]. The first two approaches are instances of a new emerging paradigm for data compression, referred to as *boosting* [9], where data are reorganized to improve the performance of a given compressor. A software platform to facilitate the investigation of such invertible data transformations is described by Vo [16]

Notations

Let T be a table of $n = |T|$ columns and m rows. Let $T[i]$ denote the ith column of T. Given two tables T_1 and T_2, let T_1T_2 be the table formed by their juxtaposition. That is, $T = T_1T_2$ is defined so that $T[i] = T_1[i]$ for $1 \leq i \leq |T_1|$ and $T[i] = T_2[i - |T_1|]$ for $|T_1| < i \leq |T_1| + |T_2|$. We use the shorthand $T[i, j]$ to represent the projection $T[i]\cdots T[j]$ for any $j \geq i$. Also, givena sequence P of column indices, we denote by $T[P]$ the table obtained from T by projecting the columns with indices in P.

Combinatorial Dependency and Joint Entropy of Random Variables

Fix a compressor $\mathcal{C}$: e.g., gzip, based on LZ77 [19]; compress, based on LZ78 [20]; or bzip, based on Burrows-Wheeler [5]. Let $H_{\mathcal{C}}(T)$ be the size of the result of compressing table T as a string in row-major order using $\mathcal{C}$. Let $H_{\mathcal{C}}(T_1, T_2) = H_{\mathcal{C}}(T_1, T_2).H_{\mathcal{C}}(\cdot)$ is thus a cost function defined on the ordered power set of columns. Two tables T_1 and T_2, which might be projections of columns from a common table T, are *combinatorially dependent* if $H_{\mathcal{C}}(T_1, T_2) < H_{\mathcal{C}}(T_1) + H_{\mathcal{C}}(T_2)$ – if compressing them together is better than compressing them separately – and *combinatorially independent* otherwise. Buchsbaum et al. [3] show that combinatorial dependency is a compressive estimate of statistical dependency when formalized by the joint entropy of two random variables, i.e., the statistical relatedness of two objects is measured by the gain realized by compressing them together rather than separately. Indeed, combinatorial dependency becomes statistical dependency when $H_{\mathcal{C}}$ is replaced by the joint entropy function [8]. Analogous notions starting from Kolmogorov complexity are derived by Li et al. [12] and used for classification and clustering [6]. Figure 1 exemplifies why rearranging and partitioning columns may improve compression.

9	0	8	2	7	3
9	0	8	3	7	5
9	0	8	5	7	6
9	0	8	2	7	5

Table Compression, Fig. 1 The first three columns of the table, taken in row-major order, form a repetitive string that can be very easily compressed. Therefore, it may be advantageous to compress these columns separately. If the fifth column is swapped with the fourth, we get an even longer repetitive string that, again, can be compressed separately from the other two columns

Problem 1 Find a partition $\mathcal{P}$ of T into sets of contiguous columns that minimizes $\sum_{Y \in \mathcal{P}} H_C(Y)$ over all such partitions.

Problem 2 Find a partition $\mathcal{P}$ of T that minimizes $\sum_{Y \in \mathcal{P}} H_C(Y)$ over all partitions.

The difference between Problems 1 and 2 is that the latter does not require the parts of $\mathcal{P}$ to be sets of contiguous columns.

Column Dependency and Conditional Entropy of Random Variables

Definition 1 For any table T, a *dependency relation* is a pair (P, c) in which P is a sequence of distinct column indices (possibly empty) and $c \notin P$ is another column index. If the length of P is less than or equal to k, then (P, c) is called a k-relation. P is the *predictor sequence* and c is the *predictee*.

Definition 2 Given a dependency relation (P, c), the *dependency transform* $dt_P(c)$ of c is formed by permuting column $T[c]$ based on the permutation induced by a stable sort of the rows of P.

Definition 3 A collection D of dependency relations for table T is said to be a k-transform if and only if (a) each column of T appears exactly once as a predictee in some dependency relation (P, c), (b) the dependency hypergraph $G(D)$ is acyclic, and (c) each dependency relation (P, c) is a k-relation.

Let $\omega(P, c)$ be the cost of the dependency relation (P, c), and let $\delta(m)$ be an upper bound on the cost of computing $\omega(P, c)$. Intuitively, $\omega(P, c)$ gives an estimate of how well a rearrangement of column c will compress, using the rows of P as contexts for its symbols. We will provide an example after the formal definitions.

Problem 3 Find a k-transform D of minimum cost $\omega(D) = \sum_{(P,c) \in D} \omega(P, c)$.

Definition 1 extends to columns the notion of context that is well known for strings. Definition 3 defines a microtransformation that reorganizes the column symbols by grouping together those that have similar contexts. The context of a column symbol is given by the corresponding row in $T[P]$. The fundamental ideas here are the same as in the Burrows and Wheeler transform [5]. Finally, Problem 3 asks for an optimal strategy to reorganize the data prior to compression. The cost function ω provides an estimate of how well c can be compressed using the knowledge of $T[P]$.

Vo and Vo [18] connect these ideas to the conditional entropy of random variables. Let S be a sequence, $\mathcal{A}(S)$ its distinct elements, and f_a the frequency of each element a. The *zeroth-order empirical entropy* of S [15] is

$$H_0(S) = -\frac{1}{|S|} \sum_{\alpha \in \mathcal{A}(S)} f_a \lg \frac{f_a}{|S|},$$

and the *modified zeroth-order empirical entropy* [15] is

$$H_0^*(S) = \begin{cases} 0 & \text{if} |S| = 0, \\ (1 + \lg |S|)/|S| & \text{if} |S| \neq 0 \text{ and } H_0(S) = 0, \\ H_0(S) & \text{otherwise.} \end{cases}$$

For a dependency relation (P, c) with nonempty P, the *modified conditional empirical entropy* of c given P is then defined as

$$H_P^*(c) = \frac{1}{m} \sum_{\rho \in \mathcal{A}(T[P])} |\rho_c| H_0^*(\rho_c),$$

where ρ_c is the string formed by catenating the symbols in c corresponding to positions of ρ in $T[P]$ [15]. A possible choice of $\omega(P, c)$ is given by $H_P^*(c)$. Vo and Vo also develop another notion of entropy, called *run length entropy*, to approximate more effectively the compressibility of low-entropy columns and define another cost function ω accordingly.

Key Results

Combinatorial Dependency

Problem 1 admits a polynomial-time algorithm, based on dynamic programming. Using the definition of combinatorial dependency, one can show:

Theorem 1 ([3]) *Let $E[i]$ be the cost of an optimal, contiguous partition of $T[1, i]$. $E[n]$ is thus the cost of a solution to Problem 1. Define $E[0] = 0$; then, for $1 \leq i \leq n$,*

$$E[i] = \min_{0 \leq j < i} E[j] + H_{\mathcal{C}}(T_{j+1}, \ldots, T_i). \quad (1)$$

The actual partition with cost $E[n]$ can be maintained by standard backtracking.

The only known algorithmic solution to Problem 2 is the trivial one based on enumerating all possible feasible solutions to choose an optimal one. Some efficient heuristics based on asymmetric TSP, however, have been devised and tested experimentally [4]. Define a weighted, complete, directed graph, $G(T)$, with a vertex T_i for each column $T[i] \in T$; the *weight* of edge $\{T_i, T_j\}$ is $w(T_i, T_j) = \min(H_{\mathcal{C}}(T_i, T_j), H_{\mathcal{C}}(T_i) + H_{\mathcal{C}}(T_j))$. One then generates a set of tours of various weights by iteratively applying standard optimizations (e.g., 3-opt, 4-opt). Each tour induces an ordering of the columns, which are then optimally partitioned using the dynamic program (1).

Buchsbaum et al. [4] also provide a general framework for studying the computational complexity of several variations of table compression problems based on notions analogous to combinatorial dependence, and they give some initial MAX-SNP-hardness results. Particularly relevant is the set of abstract problems in which one is required to find an optimal arrangement of a set of strings to be compressed, which establishes a nontrivial connection between table compression and the classical shortest common superstring problem [2]. Giancarlo et al. [11] connect table compression to the Burrows and Wheeler transform [5] by deriving the latter as a solution to an analog of Problem 2.

Column Dependency

Theorem 2 ([17, 18]) *For $k \geq 2$, Problem 3 is NP-hard.*

Theorem 3 ([17, 18]) *An optimum 1-transform for a table T can be found in $O(n^2\delta(m))$ time.*

Theorem 4 ([17, 18]) *A 2-transform can be computed in $O(n^2\delta(m))$ time.*

Theorem 5 ([18]) *For any dependency relation (P, c) and some constant ϵ, $|\mathcal{C}(dt_P(c))| \leq 5m H_p^*(c) + \epsilon$.*

Motifs

Apostolico et al. [1] propose improved versions of Table Compression based on Motifs, i.e., regular expressions characterizing a set of templates based on which the rows of a table are compressed by textual substitution. They also discuss applications of the technique in Computational Biology.

Applications

Storage and transmission of alphanumeric tables. Moreover, the Citing Articles of the papers in [1, 3, 4, 17, 18] in Google Scholar provide a full range of applications and related work.

Open Problems

All the techniques discussed use the general paradigms of context-dependent data rearrangement for compression boosting. It remains open to apply these paradigms to other domains, e.g., XML data [13, 14], where high-level structures

can be exploited, and to domains where pertinent structures are not known a priori.

Experimental Results

Buchsbaum et al. [3] showed that optimal partitioning alone (no column rearrangement) yielded about 55 % better compression compared to gzip on telephone usage data, with small training sets. Buchsbaum et al. [4] experimentally supported the hypothesis that good TSP heuristics can effectively reorder the columns, yielding additional improvements of 5–20 % relative to partitioning alone. They extended the data sets used to include other tables from the telecom domain as well as biological data. Vo and Vo [17,18] showed further 10–35 % improvement over these combinatorial dependency methods on the same data sets.

Data Sets

Some of the data sets used for experimentation are public [4].

URL to Code

The pzip package, based on combinatorial dependency, is available at http://www.research.att.com/~gsf/pzip/pzip.html. The Vcodex package, related to invertible transforms, is available at http://www.research.att.com/~gsf/download/ref/vcodex/vcodex.html. Although for the time being Vcodex does not include procedures to compress tabular data, it is a useful toolkit for their development.

Problem Definition

Consider a *random allocation* of m balls to n bins where each ball is placed in a bin chosen uniformly and independently. The properties of the resulting distribution of balls among bins have been the subject of intensive study in the probability and statistics literature [3, 4]. In computer science, this process arises naturally in randomized algorithms and probabilistic analysis. Of particular interest is the *occupancy problem* where the random variable under consideration is the number of empty bins.

In this entry a series of bounds are presented (reminiscent of the Chernoff bound for binomial distributions) on the tail of the distribution of the number of empty bins; the tail bounds are successively tighter, but each new bound has a more complex closed form. Such strong bounds do not seem to have appeared in the earlier literature.

Key Results

The following notation in presenting sharp bounds on the tails of distributions. The notation $F \sim G$ will denote that $F = (1 + o(1))G$; further, $F \asymp G$ will denote that $\ln F \sim \ln G$. The proof that $f \asymp g$, is used for the purposes of later claiming that $2^f \asymp 2^g$. These asymptotic equalities will be treated like actual equalities and it will be clear that the results claimed are unaffected by this "approximation".

Consider now the probabilistic experiment of throwing m balls, independently and uniformly, into n bins.

Definition 1 Let Z be the number of empty bins when m balls are placed randomly into n bins, and define $r = m/n$. Define the function $H(m, n, z)$ as the probability that $Z = z$. The expectation of Z is given by

$$\mu = \mathbf{E}[Z] = n\left(1 - \frac{1}{n}\right)^m \sim n\,\mathrm{e}^{-r}.$$

The following three theorems provide the bounds on the tail of the distribution of the random variable Z. The proof of the first bound is based on a martingale argument.

Theorem 1 (Occupancy Bound 1) *For any* $\theta > 0$,

$$\boldsymbol{P}\left[|Z - \mu| \geq \theta\mu\right] \leq 2\exp\left(-\frac{\theta^2\mu^2(n - \frac{1}{2})}{n^2 - \mu^2}\right).$$

Remark that for large r this bound is asymptotically equal to

$$2\exp\left(-\frac{\theta^2\,\mathrm{e}^{-2r}n}{1 - \mathrm{e}^{-2r}}\right).$$

The reader may wish to compare this with the following heuristic estimate of the tail probability assuming that the distribution of Z is well approximated by the approximating normal distribution also far out in the tails [3, 4].

$$\boldsymbol{P}\left[|Z-\mu| \geq \theta\mu\right] \leq 2\exp\left(-\frac{\theta^2 \mathrm{e}^{-r} n}{2\left(1-(1+r)\mathrm{e}^{-r}\right)}\right).$$

The next two bounds are in terms of point probabilities rather than tail probabilities (as was the case in the Binomial Bound), but the unimodality of the distribution implies that the two differ by at most a small (linear) factor. These more general bounds on the point probability are essential for the application to the satisfiability problem. The next result is obtained via a generalization of the Binomial Bound to the case of dependent Bernoulli trials.

Theorem 2 (Occupancy Bound 2) *For* $\theta > -1$,

$$H(m,n,(1+\theta)\mu) \leq \exp\left(-\left((1+\theta)\ln[1+\theta]-\theta\right)\mu\right).$$

In particular, for $-1 \leq \theta < 0$,

$$H(m,n,(1+\theta)\mu) \leq \exp\left(-\frac{\theta^2\mu}{2}\right).$$

The last result is proved using ideas from large deviations theory (Weiss A (1993) Personal Communication).

Theorem 3 (Occupancy Bound 3) *For* $|z-\mu| = \Omega(n)$,

$$H(m,n,z) \asymp \exp\left(\left[-n\left(\int_0^{1-\frac{z}{n}} \ln\left[\frac{k-x}{1-x}\right] \mathrm{d}x - r\ln k\right)\right]\right)$$

where k *is defined implicitly by the equation* $z = n(1-k(1-\mathrm{e}^{-r/k}))$.

Applications

Random allocations of balls to bins is a basic model that arises naturally in many areas in computer science involving choice between a number of resources, such as communication links in a network of processors, actuator devices in a wireless sensor network, processing units in a multi-processor parallel machine etc. For such situations, randomization can be used to "spread" the load evenly among the resources, an approach particularly useful in a parallel or distributed environment where resource utilization decisions have to be made locally at a large number of sites without reference to the global impact of these decisions. In the process of analyzing the performance of such algorithms, of particular interest is the occupancy problem where the random variable under consideration is the number of empty bins (i.e., machines with no jobs, routes with no load, etc.). The properties of the resulting distribution of balls among bins and the corresponding tails bounds may help in order to analyze the performance of such algorithms.

1987; Keutzer

Problem Definition

Technology mapping is the problem of implementing a sequential circuit using the gates of a particular technology library. It is an integral component of any automated VLSI circuit design flow. In the prototypical chip design flow, combinational logic gates and sequential memory elements are composed to form sequential circuits. These circuits are subject to various logic optimizations to minimize area, delay, power, and other performance metrics. The resulting optimized circuits still consist of primitive logic functions such as AND and OR gates. The next step is to efficiently realize these circuits in a specific VLSI technology using a library of gates available from the semiconductor vendor. Such a library would typically consist of gates of varying sizes and speeds for primitive logic functions (AND and OR) and more complex functions (exclusive-OR, multiplexer). However, a naïve translation of generic logic elements to gates in the library will fall short of realistic performance goals. The challenge is to construct a mapping that maximally utilizes the gates in the library to implement the logic function of the circuit and achieve some performance goal, for example, minimum area with the critical path delay less than a target value. This is accomplished by *technology mapping*. For the sake of simplicity, in the following discussion, it is presumed that the sequential memory elements are stripped from the digital circuit and mapped directly into memory elements of the particular technology. Then, only Boolean circuits composed of combinational logic gates remain to be mapped. Further, each remaining Boolean circuit is necessarily a directed acyclic graph (DAG).

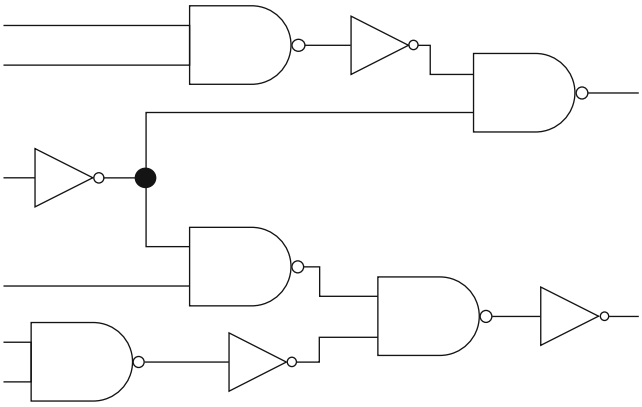
The technology mapping problem can be restated in a more general graph-theoretic setting: *find a minimum cost covering of the subject graph (Boolean circuit) by choosing from the collection of pattern graphs (gates) available in a library.* The inputs to the problem are:

(a) *Subject graph:* This is a directed acyclic graph representation of a Boolean circuit expressed using a set of primitive functions (e.g., 2-input NAND gates and inverters). An example subject graph is shown in Fig. 1.
(b) *Library of pattern graphs:* This is a collection of gates available in the technology library. The pattern graphs are also DAGs expressed using the same primitive functions used to construct the subject graph. Additionally, each gate is annotated with a number of values for different cost functions, such as area, delay, and power. An example library and associated cost model is shown in Fig. 2.

A *valid cover* is a network of pattern graphs implementing the function of the subject graph such that (a) every vertex (i.e., gate) of the subject graph is contained in some pattern graph and (b) each input required by a pattern graph is actually an output of some other pattern graph (i.e., the inputs of a gate must exist as outputs of other gates). Technology mapping can then be viewed as an optimization problem to find a valid cover of minimum cost of the subject graph.

Key Results

To be viable in a realistic design flow, an algorithm for minimum cost graph-covering for technology mapping should ideally possess



Technology Mapping, Fig. 1 Subject graph (DAG) of a Boolean circuit expressed using NAND2 and INVERTER gates

Technology Mapping, Fig. 2 Library of pattern graphs (composed of NAND2 and INVERTER gates) and associated costs

the following characteristics: (a) the algorithm should be easily adaptable to diverse libraries and cost models; if the library is expanded or replaced, the algorithm must be able to utilize the new gates effectively; (b) it should allow detailed cost models to accurately represent the performance of the gates in the library; and (c) it should be fast and robust on large subject graph instances and large libraries. One technique for solving the minimum cost graph-covering problem is to formulate it as a binate-covering problem, which is a specialized integer linear program [10]. However, binate-covering for a DAG is NP-Hard for any set of primitive functions and is typically unwieldy on large circuits. The DAGON algorithm suggested solving the technology mapping problem through DAG-covering and advanced an alternate approach for DAG-covering based on a *tree-covering* approximation that produced near-optimal solutions for practical circuits and was very fast even for large circuits and large libraries [7].

DAGON was inspired by prevalent techniques for pattern matching employed in the domain of code generation for programming language compilers [1]. The fundamental concept was to partition the subject graph (DAG) into a forest of trees and solve the minimum cost covering problem independently for each tree. The approach was motivated by the existence of efficient dynamic programming algorithms for optimum tree-covering [2]. The three salient components of the DAGON algorithm are (a) subject graph partitioning, (b) pattern matching, and (c) covering.

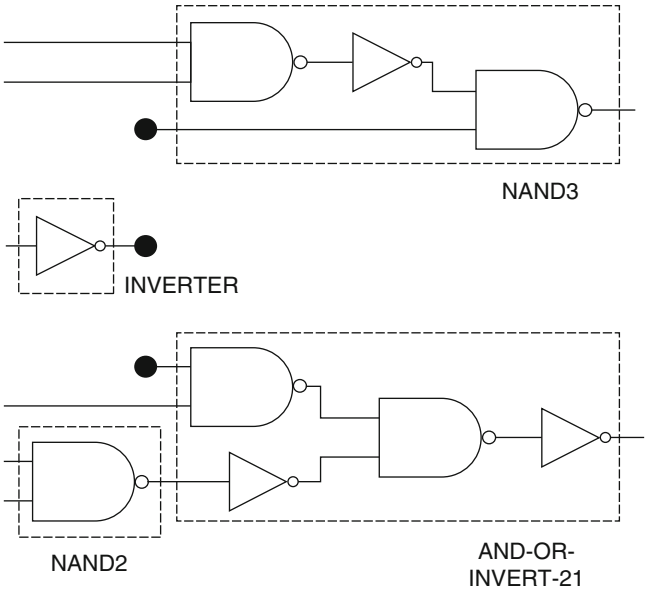
(a) *Subject graph partitioning*: To apply the tree-covering approximation the subject graph is first partitioned into a forest of trees. One approach is to break the graph at each vertex which has an out-degree greater than 1 (multiple fan-out point). The root of each tree is the primary output of the corresponding sub-circuit and the leaves are the primary inputs. Other heuristic partitions of the subject graph that consider duplication of vertices can also be applied to improve the quality of the final cover. Alternate subject graph partitions can also be derived starting from different decompositions of the original Boolean circuit in terms of the primitive functions.

(b) *Pattern matching*: The optimum covering of a tree is determined by generating the complete set of matches for each vertex in the tree (i.e., the set of pattern graphs which are candidates for covering a particular vertex) and then selecting the optimum match from among the candidates. An efficient approach for structural pattern matching is to reduce the tree matching problem to a *string matching* problem [2]. Fast string matching algorithms, such as the Aho-Corasick and the Knuth-Morris-Pratt algorithms, can then be used to find all strings (pattern graphs) which match a given vertex in the subject graph in time proportional to the length of the longest string in the set of pattern graphs. Alternatively, Boolean matching techniques can be used to find matches based on logic functions [5]. Boolean matching is slower than structural string matching, but it can compute matches independent of the actual local decompositions and under different input permutations.

(c) *Covering*: The final step is to generate a valid cover of the subject tree using the pattern graph matches computed at each vertex. Consider the problem of finding a valid cover of minimum area for the subject tree. Every pattern graph in the library has an associated area and the area of a valid cover is the sum of the area of the pattern graphs in the cover. The key property that makes minimum area tree-covering efficient is this: *the minimum area cover of a tree rooted at some vertex v can be computed using only the minimum area covers of vertices below v*. It follows that for every pattern graph that matches the tree rooted at vertex v, the area of the minimum cover containing that match equals the sum of the area of the corresponding match at v and the sum of the areas of the optimal covers of the vertices which are inputs to that match. This property enables a dynamic programming algorithm to compute the minimum area cover of the tree rooted at each vertex of the subject tree. The base case is the minimum area cover of a leaf (primary input) of the subject tree. The area of a match at a leaf is set to 0. A recursive formulation of this dynamic programming concept is summarized in the Algorithm *minimum_area_tree_cover* shown below. As an example, the minimum area cover displayed in Fig. 3 is a result of applying this algorithm to the tree partitions of the subject graph from Fig. 1 using the library from Fig. 2.

Given a vertex v in the subject tree, let $M(v)$ denote the set of candidate matches from the library of pattern graphs for the sub-tree rooted at v.

In this algorithm, each vertex in the tree is visited exactly once. Hence, the complexity of the algorithm is proportional to the number of vertices in the subject tree times the maximum number of pattern matches at any vertex. The maximum number of matches is a function of the pattern graph library and is independent of the subject tree size. As a result, the complexity of computing the minimum cost valid cover of a tree is linear in the size of the subject tree, and the memory requirements are also linear in the size of the subject tree. The algorithm computes the optimum cover when the subject graph is a tree. In the general case of the subject graph being a DAG, empirical results have shown that the tree-covering approximation yields industrial-quality results achieving aggressive area and timing requirements on large real circuit design problems [6, 12].



Technology Mapping, Fig. 3 Result of a minimum area tree-covering of the subject graph in Fig. 1 using the library of pattern graphs in Fig. 2

Applications

Technology mapping is the key link between technology-independent logic synthesis and technology-dependent physical design of VLSI circuits. This motivates the need for efficient and robust algorithms to implement large Boolean circuits in a technology library. Early algorithms for technology mapping were founded on rule-based local transformations [4]. DAGON was the first in advancing an algorithmic foundation in terms of graph transformations that was practicable in the inner loop of iterative procedures in the VLSI design flow [7]. From a theoretical standpoint, the graph-covering formulation provided a formal description of the problem and specified optimality criteria for evaluating solutions. The algorithm was naturally adaptable to diverse libraries and cost models, and was relatively easy to implement and extend. The concept of partitioning the subject graph into trees and covering the trees optimally was effective for varied optimization objectives such as area, delay, and power. The DAGON approach has been incorporated in academic (SIS from the University of California at Berkeley [11]) and industrial (Synopsys™ Design Compiler) tool offerings for logic synthesis and optimization.

The graph-covering formulation has also served as a starting point for advancements in algorithms for technology mapping over the last decade. Decisions related to logic decomposition were integrated in the graph-covering algorithm, which in turn enabled technology independent logic optimizations in the technology mapping phase [9, 14]. Similarly, heuristics were proposed to impose placement constraints and make technology mapping more aware of the physical design and layout of the final circuit [8]. To combat the problem of high power dissipation in modern sub-micron technologies, the graph algorithms were enhanced to minimize power under area and delay constraints [13]. Specializations of these graph algorithms for technology mapping have found successful application in design flows for Field Programmable Gate Array (FPGA) technologies [3, 15]. We recommend the following works for a comprehensive treatment of algorithms for technology mapping and a

```
Algorithm minimum_area_tree_cover (Vertex v) {
// the algorithm minimum_area_tree_cover finds an
optimal cover of the tree rooted at Vertex v
// the algorithm computes best_match(v) and
area_of_best_match(v), which denote the best
pattern graph match at v and the associated area of
the optimal cover of the tree rooted at v, respectively
// check if v is a leaf of the tree
if (v is a leaf) {
area_of_best_match(v) = 0;
best_match(v) = leaf;
return;
}
// compute optimal cover for each input of v
foreach (input of Vertex v) {
minimum_area_tree_cover(input);
}
// each tree rooted at each input of v is now
annotated with its optimal cover
//find the optimal cover of the tree rooted at Vertex v
area_of_best_match(v) = INFINITY;
best_match(v) = NULL;
foreach (Match m in the set of matches M(v)) {
// compute the area of match m at Vertex v
// area_of_match(v,m) denotes the area of the cover
when Match m is selected for v
area_of_match(v,m) = area(m);
foreach input pin vi of match m {
area_of_match (v,m) = area_of_match(v,m) +
area_of_best_match(vi)
}
// update best pattern graph match and associated
area of the optimal cover at Vertex v
if (area_of_match(v,m) < area_of_best_match(v)) {
area_of_best_match(v) = area_of_match(v,m);
best_match(v) = m;
}
}
}
```

survey of new developments and challenges in the design of modern VLSI circuits: [5, 6, 12].

Open Problems

The enduring problem with DAGON-related technology mappers is handling non-tree pattern graphs that arise from modeling circuit elements such as multiplexors, Exclusive-Ors, or memory-elements (e.g., flip-flops) with associated logic (e.g., scan logic). On the other hand, approaches that do not use the tree-covering formulation face challenges in easily representing diverse technology libraries and in matching the subject graph in a computationally efficient manner.

Problem Definition

Suppose there are two spatially separated parties Alice and Bob and Alice wants to send a quantum state consisting of n quantum bits (qubits) ρ to Bob. Since classical communication is much more reliable, and possibly cheaper, than quantum communication, it is desirable that this task be achieved by communicating just classical bits. Such a procedure is referred to as *teleportation*.

Unfortunately, it is easy to argue that this is in fact not possible if arbitrary quantum states need to be communicated faithfully. However, Bennett, Brassard, Crepeau, Jozsa, Peres, and Wootters [8] presented a nice solution to it by modifying the assumptions about the resources that are available to Alice and Bob.

Key Results

Let $\{|0\rangle, |1\rangle\}$ be the standard basis for the state space of one quantum bit (which is equal to $\mathbb{C}^2$). For simplicity of notation $|0\rangle \otimes |0\rangle$ are represented as $|0\rangle|0\rangle$ or simply $|00\rangle$. An EPR pair is a special two-qubit quantum state defined as $|\psi\rangle \stackrel{\Delta}{=} \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$.

Alice and Bob are said to share an EPR pair if each holds one qubit of the pair. In this article a standard notation is followed in which classical bits are called "cbits" and shared EPR pairs are called "ebits." Bennett et al. showed the following:

Theorem 1 *Teleportation of an arbitrary n-qubit state can be achieved with $2n$ cbits and n ebits.*

These shared EPR pairs are referred to as *prior entanglement* to the protocol since they are shared at the beginning of the protocol (before Alice gets her input state) and are independent of Alice's input state. This solution is a good compromise since it is conceivable that Alice and Bob share several EPR pairs at the beginning, when they are possibly together, in which case they do not require a quantum channel. Later they can use these EPR pairs to transfer several quantum states when they are spatially separated.

Let us now see how Bennett et al. [8] achieve teleportation. Let us first note that in order to show Theorem 1, it is enough to show that a single qubit, which is possibly a part of a larger state ρ, can be teleported, while preserving its entanglement with the rest of the qubits of ρ, using 2 cbits and 1 ebit. Let us also note that the larger state ρ can now be assumed to be a pure state without loss of generality.

Theorem 2 *Let $|\phi\rangle_{AB} = a_0|\phi_0\rangle_{AB}|0\rangle_A + a_1|\phi_1\rangle_{AB}|1\rangle_A$, where a_0, a_1 are complex numbers with $|a_0|^2 + |a_1|^2 = 1$. Subscripts A, B (representing Alice and Bob, respectively) on qubits signify their owner.*

It is possible for Alice to send two classical bits to Bob such that at the end of the protocol the final state is $a_0|\phi_0\rangle_{AB}|0\rangle_B + a_1|\phi_1\rangle_{AB}|1\rangle_B$.

Proof For simplicity of notation, let us assume below that $|\phi_0\rangle_{AB}$ and $|\phi_1\rangle_{AB}$ do not exist. The proof is easily modified when they do exist by tagging them along. Let an EPR pair $|\psi\rangle_{AB} = \frac{1}{\sqrt{2}}(|0\rangle_A|0\rangle_B + |1\rangle_A|1\rangle_B)$ be shared between Alice and Bob. Let us refer to the qubit under concern that needs to be teleported as the input qubit.

The combined starting state of all the qubits is

$$\begin{aligned}|\theta_0\rangle_{AB} &= |\phi\rangle_{AB}|\psi\rangle_{AB} \\ &= (a_0|0\rangle_A + a_1|1\rangle_A)\left(\frac{1}{\sqrt{2}}(|0\rangle_A|0\rangle_B + |1\rangle_A|1\rangle_B)\right)\end{aligned}$$

Let CNOT (*controlled-not*) gate be a two-qubit unitary operation described by the operator $|00\rangle\langle 00| + |01\rangle\langle 01| + |11\rangle\langle 10| + |10\rangle\langle 11|$. Alice now performs a CNOT gate on the input qubit and her part of the shared EPR pair. The resulting state is then

$$\begin{aligned}|\theta_1\rangle_{AB} =& \frac{a_0}{\sqrt{2}}|0\rangle_A(|0\rangle_A|0\rangle_B + |1\rangle_A|1\rangle_B) \\ &+ \frac{a_1}{\sqrt{2}}|1\rangle_A(|1\rangle_A|0\rangle_B + |0\rangle_A|1\rangle_B)\end{aligned}$$

Let the Hadamard transform be a single-qubit unitary operation with operator $\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)\langle 0| + \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)\langle 1|$. Alice next performs a Hadamard transform on her input qubit. The resulting state then is

$$\begin{aligned}|\theta_2\rangle_{AB} =& \frac{a_0}{2}(|0\rangle_A + |1\rangle_A)(|0\rangle_A|0\rangle_B + |1\rangle_A|1\rangle_B) \\ &+ \frac{a_1}{2}(|0\rangle_A - |1\rangle_A)(|1\rangle_A|0\rangle_B + |0\rangle_A|1\rangle_B) \\ =& \frac{1}{2}(|00\rangle_A(a_0|0\rangle_B + a_1|1\rangle_B) \\ &+ |01\rangle_A(a_0|1\rangle_B + a_1|0\rangle_B)) \\ &+ \frac{1}{2}(|10\rangle_A(a_0|0\rangle_B - a_1|1\rangle_B) \\ &+ |11\rangle_A(a_0|1\rangle_B - a_1|0\rangle_B))\end{aligned}$$

Alice next measures the two qubits in her possession in the standard basis for $\mathbb{C}^4$ and sends the result of the measurement to Bob.

Let the four Pauli gates be the single-qubit unitary operations: identity, $P_{00} = |0\rangle\langle 0| + |1\rangle\langle 1|$; bit flip, $P_{01} = |1\rangle\langle 0| + |0\rangle\langle 1|$; phase flip, $P_{10} = |0\rangle\langle 0| - |1\rangle\langle 1|$; and bit flip together with phase flip, $P_{11} = |1\rangle\langle 0| - |0\rangle\langle 1|$. On receiving the two bits c_0c_1 from Alice, Bob performs the Pauli gate $P_{c_0c_1}$ on his qubit. It is now easily verified that the resulting state of the qubit with Bob would be $a_0|0\rangle_B + a_1|1\rangle_B$. The input qubit is successfully teleported from Alice to Bob! Please refer to Fig. 1 for the overall protocol. ■

Super-Dense Coding

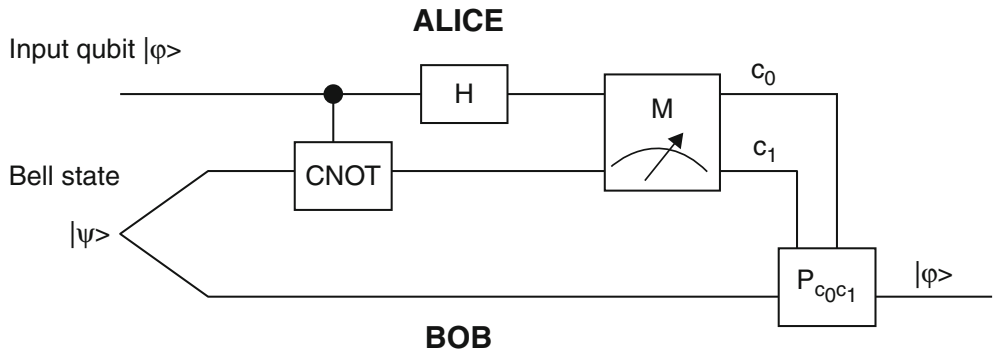
Super-dense coding [22] protocol is a dual to the teleportation protocol. In this protocol, Alice transmits 2 cbits of information to Bob using 1 qubit of communication and 1 shared ebit. It is discussed more elaborately in another article in the encyclopedia.

Lower Bounds on Resources

The above implementation of teleportation requires 2 cbits and 1 ebit for teleporting 1 qubit. It was argued in [8] that these resource requirements are also independently optimal. That is, 2 cbits need to be communicated to teleport a qubit independent of how many ebits are used. Also 1 ebit is required to teleport one qubit independent of how much (possibly two-way) communication is used.

Remote State Preparation

Closely related to the problem of teleportation is the problem of *remote state preparation* (RSP) introduced by Lo [21]. In teleportation Alice is just given the state to be teleported in some input register and has no other information about it. In contrast, in RSP, Alice knows a *complete*



Teleportation of Quantum States, Fig. 1 Teleportation protocol. H represents Hadamard transform and M represents measurement in the standard basis for $\mathbb{C}^4$

description of the input state that needs to be teleported. Also in RSP, Alice is not required to maintain any correlation of the input state with the other parts of a possibly larger state as is achieved in teleportation. The extra knowledge that Alice possesses about the input state can be used to devise protocols for probabilistically exact RSP with one cbit and one ebit per qubit asymptotically [9]. In a probabilistically exact RSP, Alice and Bob can abort the protocol with a small probability; however, when they do not abort, the state produced with Bob at the end of the protocol is exactly the state that Alice intends to send.

Teleportation as a Private Quantum Channel

The teleportation protocol also satisfies an interesting privacy property as follows. If there was a third party, say Eve, having access to the communication channel between Alice and Bob, then Eve learns nothing about the input state of Alice that she is teleporting to Bob. This is because the distribution of the classical messages of Alice is always uniform, independent of her input state. Such a channel is referred to as a *private quantum channel* [2, 11, 18].

Quantum State Redistribution

The teleportation protocol is a part of a wide range of information theoretical tasks. A more general task, referred to as *quantum state redistribution*, is as follows. Three parties, Alice, Bob, and Referee, share a joint quantum state $|\Psi\rangle_{ACBR}$, where A, C registers are with Alice, B is with Bob, and R is with Referee. The task is to transfer register C to Bob. In the *asymptotic setting* (in this limit of infinite copies of the input state), it was shown by [14, 26] that the number of cbits to be transmitted is I(R : C|B) (quantum mutual information between R and C conditioned on B). A sub-task of quantum state redistribution in which register A is not present is referred to as *quantum state merging*, which was used by [17] to give an operational interpretation to negative *quantum conditional entropy*. Another sub-task in which register B is not present is referred to as *quantum state splitting*. These protocols have also been well studied in the *single-shot* setting where a single copy of the quantum state is available [1, 4, 5, 13].

Applications

Apart from the main application of transporting quantum states over large distances using only classical channel, the teleportation protocol finds other important uses as well. A generalization of this protocol to implement unitary operations [12] is used in *fault-tolerant computation* in order to construct an infinite class of fault-tolerant gates in a uniform fashion. In another application, a form of teleportation called as the error correcting teleportation, introduced by

Knill [19], is used in devising quantum circuits that are resistant to very high levels of noise.

Ideas from quantum teleportation form the basis of measurement-based models of quantum computation. Starting from an arbitrary state $|\psi\rangle = a|0\rangle + b|1\rangle$, and an ancilla $|+\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$, apply the controlled-Z gate on the two qubits to obtain $a|0,+\rangle + b|1,-\rangle$ (here $|-\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$). Measuring the first qubit in $\{|+\rangle, |-\rangle\}$ basis gives the state $X^m|\psi\rangle$, where $m \in \{0, 1\}$ is the measurement outcome. In particular, if a phase gate Z_θ acted after controlled-Z unitary, then outcome would be $X^m Z_\theta|\psi\rangle$. Thus, the information about the state $|\psi\rangle$ is still preserved after the measurement. By preparing large arrays of standard entangled states, and performing single-qubit unitary measurement, one can hence simulate any quantum circuit, up to unitaries that depend on measurement outcomes. More details can be found in [23].

This protocol can in particular be used to perform a blind quantum computation. Given a state $|\psi\rangle$, Alice can apply a random Pauli operator on it and obtain the state $|\psi'\rangle$. Then the state is sent to Bob, who uses the idea in previous paragraph to realize a desired phase gate Z_θ on the state. The input state to Bob is completely random, yet a unitary upto measurement outcome is realized by Bob, who then sends the state back to Alice. Since Alice knows which Pauli operation she applied, she can recover back the state $Z_\theta|\psi\rangle$. More details can be found in [6, 16].

Experimental Results

Teleportation protocol has been experimentally realized in various different forms, to name a few, by Boschi et al. [3] using optical techniques, by Bouwmeester et al. [10] using photon polarization, by Nielsen et al. [24] using *Nuclear magnetic resonance* (NMR), and by Ursin et al. [25] using photons for long distance.

Krauter et al. [20] have achieved the teleportation of a complicated quantum state: a continuous variable state stored in the collective spin of an atomic ensemble. Unlike qubits that can be measured only in the 0 or 1 state, the outcome of a continuous variable measurement is a real number, like the position and momentum. The quantum states prepared and teleported in the experiment are actually similar to the coherent states of a harmonic oscillator – describing a particle in a harmonic potential well moving under the influence of a classical force.

Majorana bound states are localized zero-energy excitations of a superconductor. An isolated Majorana bound state is an equal superposition of electron and hole excitations and therefore not a fermionic state. Instead, two spatially separated Majorana bound states together make one zero-energy fermion level which can be either occupied or empty. This defines a two-level system which can store quantum information nonlocally, as needed to realize topological quantum computation. In [15] a nonlocal electron transfer process due to Majorana bound states in a mesoscopic superconductor is predicted. An electron which is injected into one Majorana bound state can go out from another one far apart maintaining phase coherence. The transmission phase shift is independent of the distance "traveled." In this sense this phenomenon can be called "electron transportation."

In summary this work reveals a striking nonlocal electron transport phenomenon through Majorana bound states in a finite-sized superconductor with charging energy. Most interestingly, the transmission phase shift detects the state of a qubit made of two spatially separated Majorana bound states.

In Baur et al. [7] have benchmarked a teleportation algorithm by tomographic reconstruction of the three-qubit entangled state generated by the circuit up to the single-qubit measurements. Using an entanglement witness, they showed that this state has genuine tripartite entanglement. This technique presents an important step toward making use of teleportation in quantum processors realized in superconducting circuits.

Problem Definition

Self-assembly is a process by which a small number of fundamental components automatically coalesce to form a target structure. In 1998, Winfree [10] introduced the abstract Tile Assembly Model (aTAM) as a deliberately oversimplified, discrete mathematical model of the DNA tile self-assembly pioneered by Seeman [6]. The aTAM "effectivizes" classical Wang tiling [9] in the sense that the former augments the latter with a mechanism for sequential "growth" of a tile assembly. Very briefly, in the aTAM, the fundamental components are un-rotatable, translatable square "tile types" whose sides are labeled with (alpha-numeric) glue "colors" and (integer) "strengths." Two tiles that are placed next to each other *bind* if the glues on their abutting sides match in both color and strength, and the common strength is at least a certain (integer) "temperature." Self-assembly starts from a "seed" tile type, typically assumed to be placed at the origin of the coordinate system, and proceeds nondeterministically and asynchronously as tiles bind to the seed-containing assembly one at a time.

The *multiple temperature* model [2, 3, 8] is a natural generalization of the aTAM, where the temperature of a tile system is dynamically adjusted by the experimenter as self-assembly proceeds. In the multiple temperature model, a tile assembly system (TAS) is defined as an ordered triple $\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$, where T is a tile set, σ is a "seed assembly," and the third component $\langle \tau_i \rangle_{i=0}^{k-1}$ is a sequence of nonnegative integer temperatures.

Intuitively, self-assembly in the multiple temperature TAS $\mathcal{T}$ is carried out in k phases. In the first temperature phase, tiles are added to the existing assembly as they normally would be in the aTAM until a τ_0-stable terminal assembly is reached. In phase two, tiles can accrete to the existing assembly if they can do so with at least strength τ_1. Also, and at any time during the second temperature phase, if there is ever a cut of the assembly having a strength less than τ_1, then all of the tiles on the side of the cut not containing the seed can be removed from the assembly. When a τ_1-stable terminal assembly is reached in phase two, phase three begins and proceeds in a similar fashion. This process continues through the final temperature phase in which tiles are added or removed with respect to the temperature τ_{k-1} until reaching a τ_{k-1}-stable terminal assembly. See Fig. 1 for an example of this process.

Problem 1 (Reducing tile complexity for the self-assembly of shapes through temperature programming) Given a *shape* $X \subseteq \mathbb{Z}^2$, find a TAS $\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$ such that X uniquely self-assembles in $\mathcal{T}$ and $|T|$ and k are minimal.

In some cases, it is sufficient to uniquely self-assemble a scaled-up version of X, i.e., $X^c = \left\{(x, y) \in \mathbb{Z}^2 \mid \left(\left\lfloor \frac{x}{c} \right\rfloor, \left\lfloor \frac{y}{c} \right\rfloor\right) \in X\right\}$. Intuitively, X^c is the shape obtained by replacing each point in X with a $c \times c$ block of points. We refer to the natural number c as the *scaling factor* or *resolution loss*.

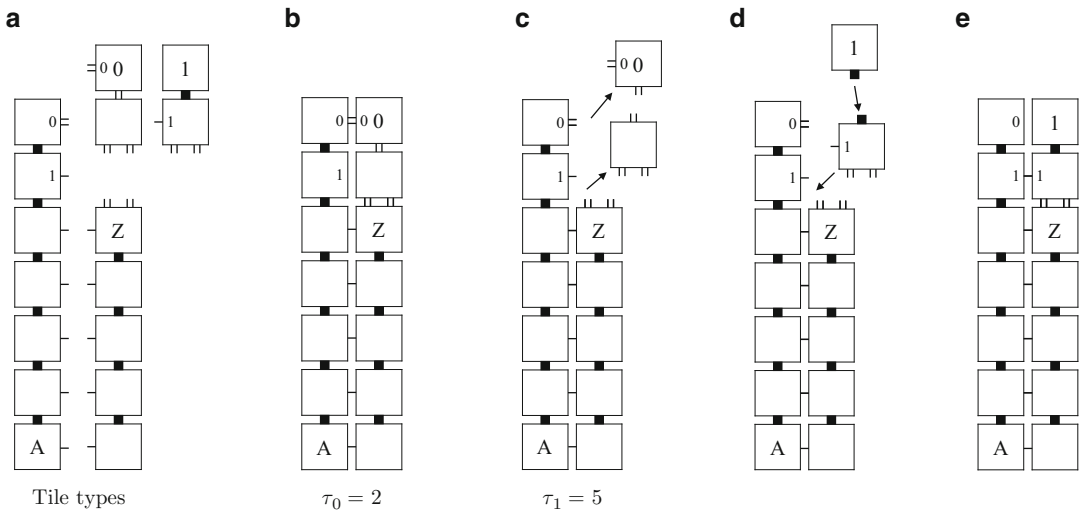
Key Results

Thin Rectangles

Aggarwal, Cheng, Goldwasser, Kao, Moisset de Espanés, and Schweller [2] proved that, in the aTAM, $\Omega\left(\frac{N^{1/k}}{k}\right)$ unique tile types are required to uniquely self-assemble a rectangle of size $k \times N$, where $k < \frac{\log N}{\log\log N - \log\log\log N}$ (this restriction makes the rectangle "thin"). In the same paper, the authors reduced this bound to $O\left(\frac{\log N}{\log\log N}\right)$ in the 2-temperature model. Intuitively, their construction builds a $j \times N$ rectangle for an optimal value of $j \gg k$. Then, when the temperature is raised, the top $j - k$ rows detach, leaving a (stable) $k \times N$ rectangle.

Squares

In the aTAM, the minimum number of unique tile types required to uniquely self-assemble an $N \times N$ square is $O\left(\frac{\log N}{\log\log N}\right)$ [1]. In 2006, Kao and Schweller [3] reduced this bound to $O(1)$ using $O(\log N)$ temperature changes. Their construction relies on a simple yet ingenious gadget called the "bit-flip gadget." Basically, a bit-flip



Temperature Programming in Self-Assembly, Fig. 1 Thick notches are strength 5, and thin notches are strength 1. Not all glue labels are shown

gadget is a constant set of tile types that can be programmed, via a carefully chosen sequence of temperature values, to build a rectangle of constant size that encodes either 0 or 1. Figure 1 gives an example of a simple bit-flip gadget. In their main construction, Kao and Schweller first self-assemble a sequence of $O(\log N)$ bit-flip gadgets, using $O(\log N)$ temperature changes. The result is a rectangle of length $O(\log N)$ that encodes N in binary. Finally, the temperature is lowered to 2, and a standard square-building tile set (i.e., [5], but without the "seed row" tile types) is used to fill in the rest of the square. In the same paper, Kao and Schweller also prove that there is no smooth tradeoff, i.e., for a TAS $\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$ that uniquely self-assembles an $N \times N$ square, it cannot be the case that $|T| = o\left(\frac{\log N}{\log \log N}\right)$ and $k = o(\log N)$.

Scaled Finite Shapes

In [3], Kao and Schweller posed the following question: Is it possible to have a tile set of size $O(1)$ that can, via some sequence of temperature values, uniquely self-assemble into an arbitrary finite shape (as specified by the sequence of temperature values)? In 2012, Summers [8] investigated this question and discovered the following:

1. **The answer to the previous question is "NO."** It turns out that a tile set of size $O(1)$ cannot uniquely self-assemble an arbitrary finite shape via (any number of) temperature values. Technically speaking, Summers proved that, for every tile set T, there exists a finite shape $X \subset \mathbb{Z}^2$, such that, for each temperature sequence $\langle \tau_i \rangle_{i=0}^{k-1}$, $\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$ does not uniquely self-assemble X. In the proof, X is always a line of length $|T| + 1$.

2. **Short temperature sequence, big scale factor.** On the positive side, there exists a universal tile set that can be programmed via temperature values to build a scaled version of an arbitrary finite shape. For instance, Summers exhibited a construction in which the bit-flip gadget of Kao and Schweller [3] is combined with the non-seed portion of the optimal shape-building construction by Soloveichik and Winfree [7] to get the following result: there exists a tile set T with $|T| = O(1)$, such that, for every finite shape X, there exists $c \in \mathbb{N}$ and a temperature sequence $\langle \tau_i \rangle_{i=0}^{k-1}$ with $m = O(K(X))$, where $K(X)$ is the Kolmogorov complexity of X (see [4]), such that,

$\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$ uniquely self-assembles X^c.

3. **Long temperature sequence, small scale factor.** Note that, in the previously mentioned construction, the scaling factor can be quite large. Technically, the scaling factor c depends on the running time of π, whence $c = \text{poly}(\text{time}(\pi))$. In a truly nanoscale setting, it is necessary to have a construction in which the scaling factor is always small or, better yet, bounded by a constant independent of the shape being assembled. Summers gave such a construction: there exists a tile set T with $|T| = O(1)$, such that, for every finite shape X, there exists a temperature sequence $\langle \tau_i \rangle_{i=0}^{k-1}$ with $m = O(|X|)$, such that, $\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$ uniquely self-assembles X[22]. This construction utilizes a modified bit-flip gadget, in the form of a bit-flip "square," which is essentially a bit-flip gadget that can be programmed (via temperature values) to follow the directions specified by a Hamiltonian path through a shape (not every shape has a Hamiltonian path, but every shape scaled up by a factor of 2 does).

Open Problems

Does there exist a tile set T, with $|T| = O(1)$ and $c \in \mathbb{N}$, such that, for every finite shape X, there exists a temperature sequence $\langle \tau_i \rangle_{i=0}^{k-1}$, with $m = O(K(X))$, such that, X^c uniquely self-assembles in $\mathcal{T} = \left(T, \sigma, \langle \tau_i \rangle_{i=0}^{k-1}\right)$?

Problem Definition

A graph is bipartite (or 2-colorable) if its vertices can be partitioned into two sets such that there are no edges between pairs of vertices that reside in the same set.

Given a (simple) graph, the task is to determine whether it is bipartite or is "far" from being bipartite. Thus, the standard decision problem is relaxed by allowing any answer when the graph is not bipartite but is "close" to some bipartite graph. We focus on dense graphs (i.e., for which the number of edges is quadratic in the number of vertices) and wish to solve the aforementioned "approximate decision" problem in constant time, given access to a data structure that answers adjacency queries in unit time.

To complete the formulation of the problem, we need to define the distance between graphs and describe how the graph is accessed. The distance between the graphs $G_1 = (V, E_1)$ and $G_2 = (V, E_2)$ is determined by the symmetric difference between their edge sets (i.e., $E_1 \Delta E_2$), and we say that they are ϵ-close (resp., ϵ-far) if $|E_1 \Delta E_2| \leq \epsilon \cdot |V|^2$ (resp., $|E_1 \Delta E_2| > \epsilon \cdot |V|^2$). Note that this definition is appropriate for dense graphs (i.e., when the number of edges is $\Omega(|V|^2)$), whereas any two sparse graphs are deemed to be close by it. (An alternative model that is more suitable for sparse graphs is presented in this encyclopedia's entry *Testing Bipartiteness of Graphs in Sublinear Time*.) We say that $G = (V, E)$ is ϵ-far from a graph property $\mathcal{P}$ (i.e., a set of graphs that is closed under isomorphism) if for every $G' \in \mathcal{P}$ it holds that G is ϵ-far from G'.

We consider algorithms that make oracle queries to the input graph, denoted $G = (V, E)$. Specifically, the algorithm can perform adjacency queries of the form $(u, v) \in V^2$, which are answered by 1 if $\{u, v\} \in E$ any by 0 otherwise. We can now define property testing in this model.

Definition 1 (testing graph properties in the dense-graph model) A tester for a graph property $\mathcal{P}$ is a randomized algorithm that is given as input a size parameter N and a proximity parameter ϵ as well as access to an adjacency oracle for an N-vertex graph $G = ([N], E)$. The tester should output a binary verdict that satisfies the following two conditions.

1. If $G \in \mathcal{P}$, then the tester accepts with probability at least $2/3$.
2. If G is ϵ-far from $\mathcal{P}$, then the tester accepts with probability at most $1/3$.

A tester has one-sided error if it accepts every graph in $\mathcal{P}$ with probability 1. A tester is nonadaptive if it determines all its queries based solely on its internal coin tosses *(and the parameters N and ϵ)*; otherwise it is adaptive.

Here we are interested in the case that $\mathcal{P}$ is the set of all bipartite graphs, and we seek a tester of time complexity that only depends on the proximity parameter, denoted ϵ, and is independent of the size of the graph.

Key Results

Goldreich, Goldwasser, and Ron [9] showed that there exists a tester for bipartiteness that, given a proximity parameter ϵ and access to an N-vertex graph, runs in time $\text{poly}(1/\epsilon)$. Furthermore, the tester is nonadaptive and has one-sided error; that is, it always accepts bipartite graphs.

The fact that there exist properties that can be tested in time that only depends on the proximity parameter should not come as a surprise. It is well known that the average value of a (bounded) function defined over a huge domain can be approximated up to a factor of $1 \pm \epsilon$ by taking $O(1/\epsilon^2)$ samples. This approximation problem

can be cast as a property testing problem (even as one that refers to graphs in the current model, by considering the edge density of a graph). But the foregoing approximation problem is highly unstructured (i.e., it merely refers to the average of values regardless of anything else), whereas bipartite graphs are highly structured (and the edge density in them is almost arbitrary).

Turning back to bipartiteness, this property is a special case of k-colorability, where $k = 2$. (A graph is k-colorable if its vertices can be partitioned into k sets such that there are no edges between pairs of vertices that reside in the same set.) The tester for bipartiteness, and more generally for k-colorability (for any $k \geq 2$), is very simple. It merely selects a sample of $\text{poly}(1/\epsilon)$ random vertices and accepts if and only if the subgraph induced by the selected vertices is k-colorable. In fact, as shown by Alon and Krivelevich [1] (improving on the bounds obtained in [9]), in the case of $k = 2$ (bipartiteness), a sample of $\tilde{O}(1/\epsilon)$ vertices suffices, and in general a sample of size $\tilde{O}(k/\epsilon^2)$ is sufficient. (The notation $\tilde{O}(q)$ "hides" polylogarithmic factors in q.)

Clearly, the algorithm always accepts k-colorable graphs, and its running time is $\text{poly}(1/\epsilon)$ if $k = 2$ and exponential in $\text{poly}(1/\epsilon)$ (the sample size) otherwise. The analysis boils down to proving that if the graph G is ϵ-far from being k-colorable, then it is rejected with probability at least $2/3$. Below we shall sketch the argument for the case of $k = 2$ and when one uses a sample of $\tilde{O}(1/\epsilon^2)$ random vertices.

We view the random sample (of vertices) as a union of two disjoint sets, denoted U and S, where $t \stackrel{\text{def}}{=} |U| = \tilde{O}(1/\epsilon)$ and $m \stackrel{\text{def}}{=} |S| = O(t/\epsilon)$. We consider all possible (2-way) partitions of U and associate a partial partition of V with each such partition of U. Specifically, given a partition of U, denoted (U_1, U_2), we place all neighbors of U_1 (resp., of U_2) opposite to U_1 (resp., U_2). Indeed, such a placing is forced if we seek a partition of V that is consistent with the given partition (U_1, U_2) of U. One may show that, with high probability, most high-degree vertices in V have at least one neighbor in U, and so the partition of these vertices is forced by the partition of U. Since there are relatively few edges incident to vertices that do not neighbor U, there must be many edges that violate the partition induced by (U_1, U_2) (i.e., their endpoints are forced to be on the same side of the induced partition). It follows that when we take the additional sample S and perform all queries on pairs in $U \times S$ and $S \times S$, with high probability, we detect a violating edge with respect to each of the $2^{|U|}$ induced partitions, thus ruling out all potential partitions of U. This implies that with high probability, the subgraph induced by $U \cup S$ is not bipartite. Let us stress the key observation: *It suffices to rule out relatively few* (partial) *partitions of* V (i.e., these $2^{|U|}$ partitions induced by partitions of U) rather than all ($2^{|V|}$) possible partitions of V.

Applications

The procedure employed in the above analysis yields a randomized $\text{poly}(1/\epsilon) \cdot N$-time algorithm for 2-partitioning a bipartite graph such that (with high probability) at most ϵN^2 edges lie within the same side. This is done by running the tester, determining a partition of U (defined as in the proof) that is consistent with the bipartite partition of $U \cup S$, and partitioning V as done in the proof (with vertices that do not neighbor U, or neighbor both U_1 and U_2, placed arbitrarily). Thus, the placement of each vertex is determined by inspecting at most $\tilde{O}(1/\epsilon)$ entries of the adjacency matrix. Furthermore, the aforementioned partition of U constitutes a succinct representation of the 2-partition of the entire graph. All this is a typical consequence of the fact that the analysis of the tester follows the "enforce-and-test" paradigm (see the survey of Ron [12, Sec. 4]).

Open Problems

As stated above, a more refined analysis yields a nonadaptive tester that inspects the subgraph induced by $\tilde{O}(1/\epsilon)$ random vertices. One can easily show that this result is almost optimal with respect to testers that inspect an induced subgraph. Furthermore, as Bogdanov and Trevisan show [3], a query complexity of $O(1/\epsilon^2)$ is optimal for any nonadaptive

tester for bipartiteness, whereas any adaptive tester requires $\Omega(\epsilon^{-3/2})$ queries. This raises the question of *what is the query complexity of adaptive testers for bipartiteness*.

While Goldreich and Trevisan [8] have shown that the gap between adaptive and nonadaptive testers (in the dense-graph model) is at most quadratic, the above question falls within the uncertainly left open by the quadratic upper bound. Furthermore, Gonen and Ron [10] showed that N-vertex graphs of maximum degree $O(\epsilon N)$ can be tested for bipartiteness in time $\tilde{O}(\epsilon^{-3/2})$, whereas the aforementioned lower bound of [3] holds also for such graphs.

The general question of the gap between adaptive and nonadaptive testers was studied by Goldreich and Ron [7]. They showed that there exist graph properties that have an adaptive tester that runs in time $\tilde{O}(1/\epsilon)$, for which any nonadaptive tester requires $\Omega(\epsilon^{-3/2})$ queries. They conjectured that there exist graph properties that have an adaptive tester that runs in time $\tilde{O}(1/\epsilon)$, for which any nonadaptive tester requires $\Omega(\epsilon^{-2})$ queries.

Comments for the Recommended Reading

The current entry falls within the scope of property testing (see the surveys [5, 6, 11, 12]). A general definition of this setting was first put forward by Rubinfeld and Sudan [13]. This definition was further generalized and systematically investigated by Goldreich, Goldwasser, and Ron [9], who focused on testing graph properties in the dense-graph model. Alternative models for testing graph properties are discussed in this encyclopedia's entry cited above.

As already noted, the tester for k-colorability described above was suggested and analyzed in [9]. A tighter analysis that yields the best bounds known was subsequently provided in [1]. Testers for any "graph partition property" (including testing that a graph contains a clique of certain density or has a bisection of certain density) were also presented in [9].

The fact that all these (nonadaptive) testers operate by inspecting a random induced subgraph was shown to be no coincidence in [8]. We also mention that the class of graph properties that can be tested (in the dense-graph model) within complexity that is independent of the size of the graph was characterized by Alon et al. [2]. Their characterization is related to Szemerédi's Regular Partitions [14]. A different characterization, based on graph limits, was proved independently by Borgs et al. [4].

Problem Definition

A graph is bipartite (or 2-colorable) if its vertices can be partitioned into two sets such that there are no edges between pairs of vertices that reside in the same set.

Given a (simple) graph, the task is to determine whether it is bipartite or is "far" from being bipartite. Thus, the standard decision problem is relaxed by allowing any answer when the graph is not bipartite but is "close" to some bipartite graph. We wish to solve this "approximate decision" problem in sublinear time, given access to a data structure that answers adjacency and incidence queries in unit time.

To complete the formulation of the problem, we need to define the distance between graphs and describe how the graph is accessed. The distance between two graphs $G_1 = (V, E_1)$ and $G_2 = (V, E_2)$ is determined by the symmetric difference between their edge sets (i.e., $E_1 \Delta E_2$), where they are ϵ-close (resp., ϵ-far) if $|E_1 \Delta E_2| \leq \epsilon \cdot (|E_1| + |E_2|)$ (resp., $|E_1 \Delta E_2| > \epsilon \cdot (|E_1| + |E_2|)$). A *graph property* is a set of graphs that is closed under isomorphism, and we say that $G = (V, E)$ is ϵ-far from a graph property $\mathcal{P}$ if for every $G' \in \mathcal{P}$ it holds that G is ϵ-far from G'.

We consider algorithms that make oracle queries to the input graph, denoted $G = (V, E)$. Specifically, an algorithm can perform adjacency queries of the form $(u, v) \in V^2$, which are answered by 1 if $\{u, v\} \in E$ and by 0 otherwise, and incidence queries of the form $(u, i) \in V \times [|V| - 1]$, which are answered by v if v is the ith neighbor of u and by $\perp$ if u has less than i neighbors. (Note that adjacency queries may be quite useless when the graph is very sparse.) We now define property testing in this model.

Definition 1 (testing graph properties with adjacency and incidence queries) A tester for a graph property $\mathcal{P}$ is a randomized algorithm that is given as input a size parameter N and a proximity parameter ϵ as well as access to adjacency and incidence oracles for an N-vertex graph $G = ([N], E)$. The tester should output a binary verdict that satisfies the following two conditions.

1. If $G \in \mathcal{P}$, then the tester accepts with probability at least $2/3$.
2. If G is ϵ-far from $\mathcal{P}$, then the tester accepts with probability at most $1/3$.

A tester has one-sided error if it accepts every graph in $\mathcal{P}$ with probability 1.

Here we are interested in the case that $\mathcal{P}$ is the set of all bipartite graphs, and we seek a tester of time complexity that is sublinear in the size of the graph. The dependence of the running time on the proximity parameter, denoted ϵ, is of secondary concern.

Key Results

Building on the work of Goldreich and Ron [6] on testing bipartiteness of bounded-degree graphs, Kaufman, Krivelevich, and Ron [9] presented a tester for bipartiteness that, given a proximity parameter ϵ and access to an N-vertex graph, runs in time $\sqrt{N} \cdot \text{poly}(\log(N), 1/\epsilon)$. This algorithm uses only incidence queries. In case the number of edges, denoted M, is larger than $N^{3/2}$, the running time can be reduced to $(N^2/M) \cdot \text{poly}(\log N, 1/\epsilon)$ by also using adjacency queries. Furthermore, in both cases, the testers have one-sided error; that is, they always accept bipartite graphs.

From now on, we focus on the special case that $M = O(N)$ and further assume that the graph has constant maximum degree, denoted d.

As a warm-up, we note that the case of $d = 2$ is easy. In this case, we are guaranteed that the graph consists of a collection of paths and cycles, and we only need to check that it does not have short cycles of odd length. Note that such an N-vertex graph is ϵ-far from being bipartite if and only if it contains more than ϵN cycles of odd length, where most of these cycles must have length at most $2/\epsilon$. Hence, in this case, testing bipartiteness can be performed by selecting $O(1/\epsilon)$ random vertices and exploring their neighborhoods up to distance $1/\epsilon$.

In contrast, in the case that $d \geq 3$, any tester for bipartiteness must perform $\Omega(\sqrt{N})$ queries. As shown by Goldreich and Ron [7], this can be proved by considering the following two families of N-vertex graphs (for any even N):

1. The first family, denoted $\mathcal{G}_1^N$, consists of all degree-3 graphs that are composed of the union of a Hamiltonian cycle and a perfect matching. That is, there are N edges connecting the vertices in a cycle, and the other $N/2$ edges form a perfect matching.
2. The second family, denoted $\mathcal{G}_2^N$, is the same as the first, *except* that the perfect matchings allowed are restricted as follows. The distance on the cycle between every two vertices that are connected by a perfect matching edge must be odd.

Clearly, all graphs in $\mathcal{G}_2^N$ are bipartite. It can be shown that almost all graphs in $\mathcal{G}_1^N$ are far from being bipartite. On the other hand, one can prove that an algorithm that performs $o(\sqrt{N})$ queries cannot distinguish between a graph chosen randomly from $\mathcal{G}_2^N$ (which is always bipartite) and a graph chosen randomly from $\mathcal{G}_1^N$ (which with high probability is far from bipartite). Loosely speaking, this follows from the fact that in both cases the algorithm is unlikely to encounter a cycle (among the vertices that it has inspected).

The algorithm itself is based on taking many (i.e., $\text{poly}(1/\epsilon) \cdot \tilde{O}(N^{1/2})$) *random walks* from few (i.e., $O(1/\epsilon)$) randomly selected start vertices, where each walk has length $\text{poly}(\epsilon^{-1} \log N)$. Specifically, given as input N, d, ϵ as well as access to an incidence oracle for an N-vertex graph, $G = (V, E)$, of degree bound d, the algorithm repeats the following steps $T \stackrel{\text{def}}{=} \Theta(\frac{1}{\epsilon})$ times:

1. Uniformly select a vertex s in V.
2. Try to find an odd-length cycle through s:
   (a) Perform $K \stackrel{\text{def}}{=} \text{poly}((\log N)/\epsilon) \cdot \sqrt{N}$ random walks starting from s, each of length $L \stackrel{\text{def}}{=} \text{poly}((\log N)/\epsilon)$.
   (b) Let R_0 (respectively, R_1) denote set of vertices reached from s in an even (respectively, odd) number of steps in any of these walks.
   (c) If $R_0 \cap R_1$ is not empty, then reject.

If the algorithm did not reject in any of the foregoing T iterations, then it accepts.

Clearly, the algorithm always accepts bipartite graphs. Hence, the analysis boils down to proving that if the graph G is ϵ-far from being bipartite, then it is rejected with probability at least $2/3$.

The analysis is quite involved. We confine ourselves to the special case where the graph has a "rapid mixing" feature. It is convenient to modify the random walks so that at each step each neighbor is selected with probability $1/2d$, and otherwise (with probability at least $1/2$) the walk remains at the present vertex. Furthermore, we will consider a single execution of Step (2) starting from an arbitrary vertex, s, which is fixed

in the rest of the discussion. The rapid mixing feature we assume is that, for every vertex v, a (modified) random walk of length L starting at s reaches v with probability approximately $1/N$ (say, up to a factor of 2). Note that if the graph is an expander, then this is certainly the case (since $L = \omega(\log N)$).

The key quantities in the analysis are the following probabilities, referring to the parity *of the length of a path obtained from the random walk by omitting the self-loops* (transitions that remain at current vertex). Let $p^0(v)$ (respectively, $p^1(v)$) denote the probability that a (modified) *random walk of length L, starting at s, reaches v while making an even* (respectively, *odd*) *number of real* (i.e., non-self-loop) *steps*. By the rapid mixing assumption (for every $v \in V$), it holds that

$$\frac{1}{2N} \;<\; p^0(v) + p^1(v) \;<\; \frac{2}{N}\,. \qquad (1)$$

We consider two cases regarding the sum $\sum_{v \in V} p^0(v)p^1(v)$: If the sum is (relatively) "small," we show that V can be 2-partitioned so that there are relatively few edges between vertices that are placed in the same part, which implies that G is close to being bipartite. Otherwise (i.e., when the sum is not "small"), we show that with significant probability, when Step (2) is started at vertex s, it is completed by rejecting G.

In general, the input graph may not be "rapidly mixing," and so the actual analysis, which appears in [6], is far more complex. Another layer of complexity is added when we move from the case of constant degree bound (i.e., d) to the case where the vertex degrees may vary significantly; see [9].

Applications

The foregoing algorithm can be used to find odd-length cycles (of polylogarithmic length) in graphs that are far from lacking such cycles. In general, any one-sided error tester for a property $\mathcal{P}$ finds subgraphs that are inconsistent with the property when invoked on a graph that is far from having property $\mathcal{P}$. Thus, the fact that the bipartite tester finds odd cycles (when invoked on graphs that are far from lacking such cycles) follows directly from its definition, but the fact that these cycles are short is a feature of the specific tester presented above.

Comments for the Recommended Reading

The current entry falls within the scope of property testing (see [4,5,11,12]). A general definition of this setting was first put forward by Rubinfeld and Sudan [13]. This definition was further generalized and systematically investigated by Goldreich, Goldwasser, and Ron [8], who focused on testing graph properties in the dense-graph model (see this Encyclopedia's entry cited above). The model considered in this entry was suggested by Kaufman, Krivelevich, and Ron [9]. It generalizes a model proposed by Parnas and Ron [10], which in turn generalizes the bounded-degree model of Goldreich and Ron [7]. The latter paper focuses on testers of complexity that only depends on the proximity parameter (i.e., independent of the size of the graph). Among these testers is a two-sided error tester of cycle-freeness; a one-sided error tester for this problem is presented in [3], but its complexity depends on the size of the graph (where this dependence is unavoidable).

As already noted, the bipartiteness tester for the bounded-degree model is due to Goldreich and Ron [6], and it was extended to the general model by Kaufman, Krivelevich, and Ron [9]. In contrast to these results, Bogdanov, Obata, and Trevisan [2] proved that 3-colorability cannot be tested with sublinear query complexity, even in the bounded-degree model. The problem of testing colorability of general graphs was further studied by Ben-Eliezer et al. [1].

Problem Definition

Suppose we would like to check whether a given array of real numbers is sorted (say, in nondecreasing order). Performing this task exactly requires reading the entire array. Here we consider the approximate version of the problem: testing whether an array is sorted or "far" from sorted. We consider two natural definitions of the distance of a given array from a sorted array. Intuitively, we would like to measure how much the input array must change to become sorted. We could measure the change by:

1. The number of entries changed
2. The sum of the absolute values of changes in all entries

It is not hard to see that looking at the number of entries that must be deleted in an array to make it sorted is equivalent to the measure in item 1.

To define the two distance measures formally, let $a = (a_1, \ldots, a_n)$ be the input array and $\mathcal{S}$ be the set of all sorted arrays of length n. We denote by $[n]$ the set $\{1, 2, \ldots, n\}$. The *Hamming distance* from a to $\mathcal{S}$, denoted $\mathrm{dist}(a, \mathcal{S})$, is $\min_{b \in \mathcal{S}} |\{i \in [n] : a_i \neq b_i\}|$. The L_1 *distance* from a to $\mathcal{S}$, denoted $\mathrm{dist}_1(a, \mathcal{S})$, is $\min_{b \in \mathcal{S}} \sum_{i \in [n]} |a_i - b_i|$. Given a parameter $\epsilon \in (0, 1)$, an array is ϵ-far from sorted with respect to the Hamming distance or, respectively, L_1 distance, if the corresponding distance from a to $\mathcal{S}$ is at least ϵn.

A *tester* for sortedness is a randomized algorithm that is given parameters $\epsilon \in (0, 1)$ and n and direct access to an input array a. It is required to accept with probability at least 2/3 if the array is sorted and reject with probability at least 2/3 if the array is ϵ-far from sorted. We consider two types of testers, Hamming and L_1, corresponding to the two distance measures we defined. The

query complexity of a tester is the number of array entries it reads. The goal is to design testers for sortedness with the smallest possible query complexity and running time.

There are two special cases of testers we will discuss. A tester is *nonadaptive* if it makes all queries in advance, before receiving any query answers. A tester has *1-sided error* if it always accepts all sorted arrays.

Bibliographical Notes

The Hamming testers for sortedness were first studied by Ergün et al. [7]. The L_1-testers (and, more generally, L_p-testers, which use the L_p distance for some $p \geq 1$) were introduced by Berman, Raskhodnikova, and Yaroslavtsev [2]. The two distance measures we discussed, dist and dist_1, are identical for arrays with 0/1 entries, which we call Boolean arrays. The L_1-tester in [2] builds on the sortedness tester for Boolean arrays by Dodis et al. [6].

Observe that an array $(a_1, a_2, \ldots, a_n)$ of real numbers can be represented by a function $f : [n] \to \mathbb{R}$ defined by $f(i) = a_i$ for all $i \in [n]$. The formulated problem is equivalent to testing if a function f over an ordered finite domain is monotone. In fact, the L_1-tester we will discuss can be easily adapted to work for functions over infinite domains (specifically, bounded intervals), because its complexity is independent of the domain size. The problem of Hamming testing monotonicity of functions over domain $[n]^d$ was first investigated by Goldreich et al. [11]; general partially ordered domains were studied by Fischer et al. [10]. These problems are discussed in the encyclopedia entry "Monotonicity Testing."

Key Results

Ergün et al. [7] designed two Hamming testers for sortedness that run in time $O\left(\frac{\log n}{\epsilon}\right)$. Later, Bhattacharyya et al. [3] and Chakrabarty and Seshadhri [5] gave different testers with the same complexity, with additional features that made them useful as subroutines in testing monotonicity of high-dimensional functions. Fischer [9] proved that the running time of these testers is optimal. Berman, Raskhodnikova, and Yaroslavtsev [2] gave an L_1-tester for sortedness with running time $O(1/\epsilon)$, which is also optimal.

Here we present two Hamming testers from [3, 7] and the L_1-tester from [2].

Hamming Testers for Sortedness

A Tester Based on Binary Search [7]

We present and analyze the first tester for sortedness (Algorithm 1) with the assumption that all entries in the array a are distinct. This assumption can be removed by treating element a_i as $\langle a_i, i \rangle$ for all $i \in [n]$.

Algorithm 1: Hamming Tester for Sortedness Based on Binary Search

input : parameters n and ϵ; direct access to array a.

1 **repeat** $\lceil \frac{\ln 3}{\epsilon} \rceil$ times:
2 pick $i \in [n]$ uniformly at random;
3 perform a binary search for the value a_i in the array a;
4 **if** a_i is not located by the binary search,
   `// it leads to another position`
5 **reject**;
6 **accept**

Analysis of the First Tester

The tester always accepts all sorted arrays. Now consider an array that is ϵ-far from sorted (in Hamming distance). We say that a position $i \in [n]$ is *searchable* if a_i can be found by a binary search in Step 3 and *not searchable* otherwise. If positions i and j such that $i < j$ are both searchable, then $a_i < a_j$, because both a_i and a_j are in the correct position with respect to their common ancestor in the binary search tree. Thus, all numbers in searchable positions are sorted. Since the array is ϵ-far from sorted, at least ϵn positions must be unsearchable. If the tester picks an unsearchable position in Step 2, it rejects. The probability that it happens in one trial is at least ϵ. Therefore, the probability that it fails to happen in $\lceil \frac{\ln 3}{\epsilon} \rceil$ trials is at most

$$(1-\epsilon)^{\lceil \frac{\ln 3}{\epsilon} \rceil} \leq \exp\left(-\epsilon \cdot \frac{\ln 3}{\epsilon}\right) = 1/3. \quad (1)$$

Thus, the tester rejects an array that is ϵ-far from sorted with probability at least 2/3.

A Tester Based on Graph Spanners [3]

The next tester we discuss is based on graph spanners. We can represent the requirement that the array is sorted as a directed graph G, where nodes are positions in $[n]$, and there is an edge (i, j) for all $i < j$. That is, an edge (i, j) represents that $a_i \leq a_j$. A *2-spanner* of G is a subgraph H of G with vertex set $[n]$ such that for every edge (i, j) in G, there is a path of length at most 2 from i to j in H. It is not hard to construct a 2-spanner of G with at most $n \log n$ edges[3, 12]. (e.g., it can be done using divide-and-conquer as follows: connect all nodes to the one in the middle, orienting the edges towards the nodes with larger indices; remove the middle node; and recurse on the two resulting sublists.)

The tester simply repeats the following step $\lceil \frac{(2 \ln 3) \log n}{\epsilon} \rceil$ times: pick a uniformly random edge (i, j) of the 2-spanner H, and reject if this edge is *violated*, namely, if $a_i > a_j$. If the tester does not find a violated edge, it accepts.

Analysis of the Second Tester

If the input array is sorted, it does not have any violated edges, and the tester always accepts. Now consider an array that is ϵ-far from sorted (in Hamming distance). We call a position $i \in [n]$ *bad* if node i is an endpoint of a violated edge in the 2-spanner H; otherwise, i is *good*. Note that any two good positions i, j such that $i < j$ are connected by a path of length at most 2 of non-violated edges in H. If this path is (i, j), it implies that $a_i \leq a_j$. If this path is (i, k, j) for some node k, it implies that $a_i \leq a_k \leq a_j$. Consequently, for any two good positions i, j such that $i < j$, the numbers a_i and a_j are in the correct order. That is, all numbers in good positions are sorted. As in the analysis of Algorithm 1, we can conclude that there are at least ϵn bad positions. But each bad position is adjacent to a violated edge. Each violated edge can contribute at most two new bad positions. Thus, there are at least $\epsilon n/2$ violated edges. By a simple calculation similar to (1), the second algorithm rejects an array that is ϵ-far from sorted with probability at least 2/3.

L_1-Tester for Sortedness

The L_1-tester for sortedness [2] requires only a uniform sample from the input (as opposed to the ability to query an arbitrary position). It picks $\lceil \frac{2 \ln 6}{\epsilon} \rceil$ positions uniformly and independently at random and accepts iff the numbers in these positions are sorted.

The main ingredient in the analysis of the tester is a reduction to the case of Boolean arrays. It states that if the tester is nonadaptive and has 1-sided error, it suffices to show that it works for Boolean arrays. We omit the proof of the reduction.

Clearly, the L_1-tester is nonadaptive and always accepts sorted arrays. Now consider a Boolean array a which is ϵ-far from sorted. It remains to show that it is rejected with probability at least 2/3. Let X_0 be the set of the $\epsilon n/2$ largest indices i for which $a_i = 0$. Similarly, let X_1 be the set of the $\epsilon n/2$ smallest indices i for which $a_i = 1$. It is easy to show that $i < j$ for all $i \in X_1$ and $j \in X_0$, because a is ϵ-far from sorted. The L_1-tester samples no index from X_0 with probability at most 1/6. The same holds for X_1. Thus, by a union bound, with probability at least 2/3, it samples an index from X_0 and an index from X_1 and detects a violation.

Running time

We explained why the algorithm that samples $\lceil \frac{2 \ln 6}{\epsilon} \rceil$ positions uniformly and independently at random is an L_1-tester for sortedness. Now we analyze its running time for the case of general arrays. The L_1-tester makes $O(1/\epsilon)$ queries. To determine whether the elements in these positions are sorted, the tester can use bucket sort to sort the sampled positions and then simply check if the sequence of queried elements is nondecreasing. Since the positions are sampled uniformly at random, the bucket sort can be implemented to run in expected time $O(1/\epsilon)$, where the expectation is taken over the choice of the samples. By standard methods, the algorithm can be modified to run in $O(1/\epsilon)$ time in the worst case. Observe that the running time does not depend on the length of the input. This is impossible for Hamming testers for sortedness, which, as we mentioned, must query $\Omega(\log n)$ positions [9].

Applications

Testers for sortedness are used as subroutines in other property testers, e.g., for monotonicity of high-dimensional functions [2, 5, 6] and for the property that given points represent ordered vertices of a convex polygon [7]. They are also used to construct fast approximate probabilistically checkable proofs for different optimization problems [8]. Ben-Moshe et al. [1] employed sortedness testers (with additional features) to speed up query evaluation in databases.

Open Problem

Consider the case when all numbers in the input array lie in some specified small set such as $[r]$ for some integer r. As we discussed, for Boolean arrays, testing sortedness can be done in $O(1/\epsilon)$ time [2, 6]. It is not hard to see that for larger ranges, it can be done in $O(r/\epsilon)$ time. When $r \ll n$, can one test sortedness it time polylogarithmic in r? Is $O\left(\frac{\log r}{\epsilon}\right)$ running time achievable?

Fischer's lower bound for testing sortedness [9] applies only to $n \ll r$. The best known lower bound that takes into account both parameters is $\Omega(\min(\log r, \log n))$, due to [4], but it applies only to nonadaptive testers.

Problem Definition

Fix positive integers n and k with $n \geq k$. The function $f : \{0,1\}^n \to \{0,1\}$ is a *k-junta* if it depends on at most k of the input coordinates. Formally, f is a k-junta if there exists a set $J \subseteq \{1,2,\ldots,n\}$ of size $|J| \leq k$ such that for all inputs $x, y \in \{0,1\}^n$ that satisfy $x_i = y_i$ for each $i \in J$, we have $f(x) = f(y)$. Juntas play an important role in different areas of computer science. In machine learning, juntas provide an elegant framework for studying the problem of learning with datasets that contain many irrelevant attributes [9, 10]. In the analysis of Boolean functions, they essentially capture the set of functions of low complexity under natural measures such as total influence [19] and noise sensitivity [12].

How efficiently can we distinguish k-juntas from functions that are far from being k-juntas? We can formalize this question in the setting of property testing. Define the distance between two functions $f, g : \{0,1\}^n \to \{0,1\}$ to be the fraction of inputs on which f and g take different values: $\mathrm{dist}(f,g) := \frac{1}{2^n}|\{x \in \{0,1\}^n : f(x) \neq g(x)\}$. When $\mathrm{dist}(f,g) \geq \epsilon$ for every k-junta g, we say that f is *ϵ-far* from being a k-junta; otherwise we say that f is *ϵ-close* to being a k-juntas. An *ϵ-test* for k-juntas is a randomized algorithm that queries the value of $f : \{0,1\}^n \to \{0,1\}$ on some of its inputs and then with probability at least $\frac{2}{3}$

1. accepts if f is a k-junta, and
2. rejects if f is ϵ-far from being a k-junta.

(The algorithm is free to output anything when f is not a k-junta but is ϵ-close to being a k-junta.)

Problem 1 What is the minimum number of queries to $f : \{0,1\}^n \to \{0,1\}$ required to ϵ-test if f is a k-junta?

Key Results

Testing 1-Juntas

One important class of functions related to junta testing is *dictator* functions – the functions $f : \{0,1\}^n \to \{0,1\}$ of the form $f(x) = x_i$ for some $i \in [n]$. Bellare, Goldreich, and Sudan [3], in a work that was stated in terms of testing the *long code* and part of their analysis of probabilistically checkable proofs (PCPs), showed that dictator functions can be ϵ-tested with $O(1/\epsilon)$ queries. (See the ▸ Locally Testable Codes entry for more details.) This result was later extended by Parnas, Ron, and Samorodnitsky [21]. The class of 1-juntas includes dictator functions, their negations (known as *anti-dictator* functions), and the constant functions; using the algorithms in [3, 21], we can test 1-juntas with $O(1/\epsilon)$ queries.

Testing k-Juntas

The first result on testing k-juntas for values $k > 1$ followed from related work on the problem of *learning* juntas. Blum, Hellerstein, and Littlestone [11] introduced an algorithm that queries a k-junta $f : \{0,1\}^n \to \{0,1\}$ on $O(k \log n + k/\epsilon + 2^k)$ inputs and with probability at least $\frac{5}{6}$ returns a k-junta $h : \{0,1\}^n \to \{0,1\}$ such that $\mathrm{dist}(f,h) \leq \epsilon$. Shortly afterward, Goldreich, Goldwasser, and Ron [20] gave a general reduction showing that a proper learning algorithm with query complexity q for a class C of functions can be used to ϵ-test the class C with $q + O(1/\epsilon)$ queries. This result, combined with the Blum–Hellerstein–Littlestone algorithm, shows that k-juntas can be tested with $O(k \log n + 2^k + 1/\epsilon)$ queries.

Fischer, Kindler, Ron, Safra, and Samorodnitsky [18] showed that, remarkably, it is possible to test k-juntas with a number of queries that is *independent* of n. Specifically, they introduced ϵ-tests for k-juntas with query complexity $O(k^2/\epsilon^2)$. This result was sharpened in [4, 5], leading to the following theorem.

Theorem 1 ([5]) *It is possible to ϵ-test if $f : \{0,1\}^n \to \{0,1\}$ is a k-junta with $O(k \log k + k/\epsilon)$ queries.*

Chockler and Gutfreund [16] showed that $\Omega(k)$ queries are required to test k-juntas, so the bound in Theorem 1 is nearly optimal. (See also [4, 7, 13] for related lower bounds.)

Theorem 1 can be generalized to apply to the setting where $X_1, \ldots, X_n$, and Y are arbitrary

finite sets, and we wish to test whether a function $f : X_1 \times \cdots \times X_n \to Y$ is a k-junta. Interestingly, the query complexity of the k-junta test remains unchanged in this general setting as well. See [5] for the details.

Junta-Testing Algorithm

The proof of Theorem 1 contains two main ingredients.

The first ingredient is a simple modification of the Blum–Hellerstein–Littlestone learning algorithm. The original learning algorithm proceeds in two stages: first, the algorithm learns the k relevant coordinates of the junta; then, it queries f for all 2^k different values of the k relevant coordinates. When we test k-juntas, the second stage is unnecessary and can be replaced with a simpler test that checks whether the (at most) k relevant coordinates that have been identified completely determine the value of f or not. With this modification, we obtain an ϵ-test for k-juntas with query complexity $O(k \log n + k/\epsilon)$. Note that this result already yields the desired bound in Theorem 1 when $n = \text{poly}(k)$.

The second ingredient in the proof of Theorem 1 is a dimension reduction argument. Consider a random partition of the n coordinates into $m = \text{poly}(k)$ parts $S_1, \ldots, S_m$. A function $f : \{0,1\}^n \to \{0,1\}$ is isomorphic to a function $f' : X_1 \times \cdots \times X_m \to \{0,1\}$ where $X_i = \{0,1\}^{|S_i|}$. The function f' is defined over a domain with much smaller dimension, and it satisfies two useful properties. First, when f is a k-junta, then so is f'. Second, when f is ϵ-far from k-juntas and $m = \Omega(k^2)$, then with high probability f' is $\frac{\epsilon}{2}$-far from k-juntas as well. The second fact is far from obvious. It was established in [5] using Fourier analysis and in [8] using a combinatorial argument. These two properties let us complete the algorithm for testing k-juntas by applying the modified Blum–Hellerstein–Littlestone algorithm on the function f'. More details on the algorithm itself can be found in the original papers [5, 18] and the survey [6].

Applications

Feature Selection

Feature selection is the general machine learning task of identifying the features (also known as *attributes* or *variables*) in a dataset that suffice to describe the model being studied. This task is formalized within the junta framework as follows: given a function $f : \{0,1\}^n \to \{0,1\}$, the algorithm seeks to identify a set $J \subseteq [n]$ of size $|J| = k$ where (i) k is as small as possible, and (ii) there is a k-junta $h : \{0,1\}^n \to \{0,1\}$ on the set J that is close to f.

The junta testing algorithm can be used to approximate the minimal value of k for which these two conditions can be satisfied. For example, by executing the junta testing algorithm with $k = 1, 2, 4, 8, \ldots$ until it accepts, we obtain the following estimation result.

Corollary 1 *There is an algorithm that, given query access to $f : \{0,1\}^n \to \{0,1\}$, outputs an estimate $\hat{k}$ such that f is ϵ-close to a k-junta and such that f is not an ℓ-junta for any $\ell < k/2$. Furthermore, this algorithm makes $O(k \log k + k/\epsilon)$ queries to f.*

Testing by Implicit Learning

Let $\mathcal{C}$ be any class (i.e., family) of Boolean functions where every function in $\mathcal{C}$ is close to a being a k-junta. Many natural classes of Boolean functions that have been studied in learning theory and computational complexity fall into this framework. For example, functions with bounded, decision tree complexity, DNF complexity, circuit complexity, and sparse polynomial representation all satisfy this condition. (See the) Diakonikolas et al. [17] gave a general result showing that for each of these classes $\mathcal{C}$, we can ϵ-test the property of being in the class $\mathcal{C}$ efficiently. This result has since been sharpened by Chakraborty et al. [14], yielding the following bounds.

Theorem 2 ([14]) *Fix $s > 0$ and $\epsilon > 0$. We can ϵ-test whether $f : \{0,1\}^n \to \{0,1\}$ can be represented by*

1. *a DNF with s terms,*
2. *a size-s Boolean formula,*
3. *an s-sparse polynomial over* $\mathbb{F}_2^n$*, or*
4. *a decision tree of size s*

with $O(s/\epsilon^2 \cdot \text{polylog}(s/\epsilon))$ *queries.*

The proof of Theorem 2 is remarkable in that the ϵ-test algorithm in [14,17] learns the function $f : \{0,1\}^n \to \{0,1\}$ when f is a k-junta, but without identifying which of the k coordinates of f are part of the junta. This technique is called *testing by implicit learning*, and it is obtained by using and building on the junta testing algorithm.

Testing Function Isomorphism

Two functions $f, g : \{0,1\}^n \to \{0,1\}$ are *isomorphic* to each other when they are identical up to relabeling of the input variables. In the *function isomorphism testing* problem, we are given query access to (an unknown function) f and must determine whether it is isomorphic to (the known function) g or whether it is ϵ-far from being so. How many queries to f do we need to perform this task? The answer, it turns out, depends on the choice of the function g. The functions g for which we can test isomorphism to g with a constant number of queries are called *efficiently isomorphism testable*.

Every symmetric function is efficiently isomorphism testable. Using the junta testing algorithm, Fischer et al. [18] showed that for any constant $k \geq 0$, every k-junta is also efficiently isomorphism testable. An important open problem in property testing is to characterize the set of functions that are efficiently isomorphism testable. The state of the art on this question is a recent result – also building on the junta testing algorithm – showing that every partially symmetric function is also efficiently isomorphism testable. A function $f : \{0,1\}^n \to \{0,1\}$ is *k-partially symmetric* if there is a function $g : \{0,1\}^k \times \{0,1,2,\ldots,n\} \to \{0,1\}$ and a mapping $\rho : [k] \to [n]$ such that $f(x) = g(x_{\rho(1)}, \ldots, x_{\rho(k)}, \|x\|)$ where $\|x\| = \sum_i x_i$ the Hamming weight of x.

Theorem 3 ([8, 15]) *For every constant $k \geq 0$, every k-partially symmetric function is efficiently isomorphism testable.*

Open Problems

There are two particularly appealing open problems related to the junta testing problem that are motivated by its application to the feature selection problem.

Distance Approximation

Theorem 1 shows that we can distinguish k-juntas from functions that are ϵ-far from k-juntas with few queries. Can we also approximate the distance of a function to its closest k-junta with a small number of queries?

Problem 2 What is the minimum number of queries to $f : \{0,1\}^n \to \{0,1\}$ required to approximate the distance of f to its closest k-junta within an additive error of $\pm\epsilon$, where $\epsilon \in [0, \frac{1}{2}]$ is a parameter given to the algorithm?

In some cases, property testing algorithms can also be used directly for the corresponding distance approximation problem. This is the case, for example, for the BLR linearity test in the ▸ Linearity Testing/Testing Hadamard Codes chapter. But it is currently not known whether the junta testing algorithms in [18] or [5] can be extended to yield distance approximators or not.

Testing with Random Samples

The query model we have discussed throughout this chapter – where the algorithm is free to query the target function on any input of its choosing – is known as the *membership query model* in machine learning. In some applications, however, we must consider weaker query models where we restrict the queries that the algorithm can make in some ways. Can we also test k-juntas efficiently in restricted query models?

Problem 3 In which restricted query models can we test whether $f : \{0,1\}^n \to \{0,1\}$ is a k-junta

with a number of queries that is asymptotically smaller than the number of queries required to learn k-juntas in the same settings?

Two examples of restricted query models include the passive sampling model (where each query is drawn independently at random from some fixed distribution) and the active query model (where the algorithm can choose its queries from a larger set of inputs drawn from some distribution). Some initial results on this problem can be found in [1, 2].

String indexing

Years and Authors of Summarized Original Work

1993; Manber, Myers

Problem Definition

Text or string data naturally arises in many contexts including document processing, information retrieval, natural and computer language processing, and describing molecular sequences. In broad terms, the goal of text indexing is to design methodologies to store text data so as to significantly improve the speed and performance of answering queries. While text indexing has been studied for a long time, it shot into prominence during the last decade due to the ubiquity of web-based textual data and search engines to explore it, design of digital libraries for archiving human knowledge, and application of string techniques to further understanding of modern biology. Text indexing differs from the typical indexing of keys drawn from an underlying total order – text data can have varying lengths, and queries are often more complex and involve substrings, partial matches, or approximate matches.

Queries on text data are as varied as the diverse array of applications they support. Consequently, numerous methods for text indexing have been developed and this continues to be an active area of research. Text indexing methods can be classified into two categories: (i) methods that are generalizations or adaptations of indexing methods developed for an ordered set of one-dimensional keys, and (ii) methods that are specifically designed for indexing text data. The most classic query in text processing is to find all occurrences of a pattern P in a given text T (or equivalently, in a given collection of strings). Important and practically useful variants of this problem include finding all occurrences of P subject to at most k mismatches, or at most k insertions/deletions/mismatches. The focus in this entry is on these two basic problems and remarks on generalizations of one-dimensional data structures to handle text data.

Key Results

Consider the problem of finding a given pattern P in text T, both strings over alphabet Σ. The case of a collection of strings can be trivially handled by concatenating the strings using a unique end of string symbol, not in Σ, to create text T. It is worth mentioning the special case where T is structured – i.e., T consists of a sequence of words and the pattern P is a word. Consider a total order of characters in Σ. A string (or word) of length k can be viewed as a k-dimensional key and the order on Σ can be naturally extended to lexicographic order between multidimensional keys of variable length. Any one-dimensional search data structure that supports $O(\log n)$ search time can be used to index a collection of strings using lexicographic order such that a string of length k can be searched in $O(k \log n)$ time. This can be considerably improved as below [8]:

Theorem 1 *Consider a data structure on one-dimensional keys that relies on constant-time comparisons among keys (e.g., binary search trees, red-black trees etc.) and the insertion of a key identifies either its predecessor or successor. Let $O(\mathcal{F}(n))$ be the search time of the data structure storing n keys (e.g., $O(\log n)$ for red-black trees). The data structure can be converted to index n strings using O(n) additional space such that the query for a string s can be performed in $O(\mathcal{F}(n))$ time if s is one of the strings indexed, and in $O(\mathcal{F}(n) + |s|)$ otherwise.*

A more practical technique that provides $O(\mathcal{F}(n) + |s|)$ search time for a string s under more restrictions on the underlying one-dimensional data structure is given in [9]. The technique is nevertheless applicable to several classic one-dimensional data structures, in particular binary search trees and its balanced variants. For a collection of strings that share long common prefixes such as IP addresses and XML path strings, a faster search method is described in [5].

When answering a sequence of queries, significant savings can be obtained by promoting

frequently searched strings so that they are among the first to be encountered in a search path through the indexing data structure. Ciriani et al. [4] use self-adjusting skip lists to derive an expected bound for a sequence of queries that matches the information-theoretic lower bound.

Theorem 2 *A collection of n strings of total length N can be indexed in optimal O(N) space so that a sequence of m string queries, say* $s_1,\cdots,s_m$, *can be performed in* $O(\sum_{j=1}^{m}|s_j| + \sum_{i=1}^{n} n_i \log(m/n_i))$ *expected time, where* n_i *is the number of times the ith string is queried.*

Notice that the first additive term is a lower bound for reading the input, and the second additive term is a standard information-theoretic lower bound denoting the entropy of the query sequence. Ciriani et al. also extended the approach to the external memory model, and to the case of dynamic sets of strings. More recently, Ko and Aluru developed a self-adjusting tree layout for dynamic sets of strings in secondary storage that provides optimal number of disk accesses for a sequence of string or substring queries, thus providing a deterministic algorithm that matches the information-theoretic lower bound [4].

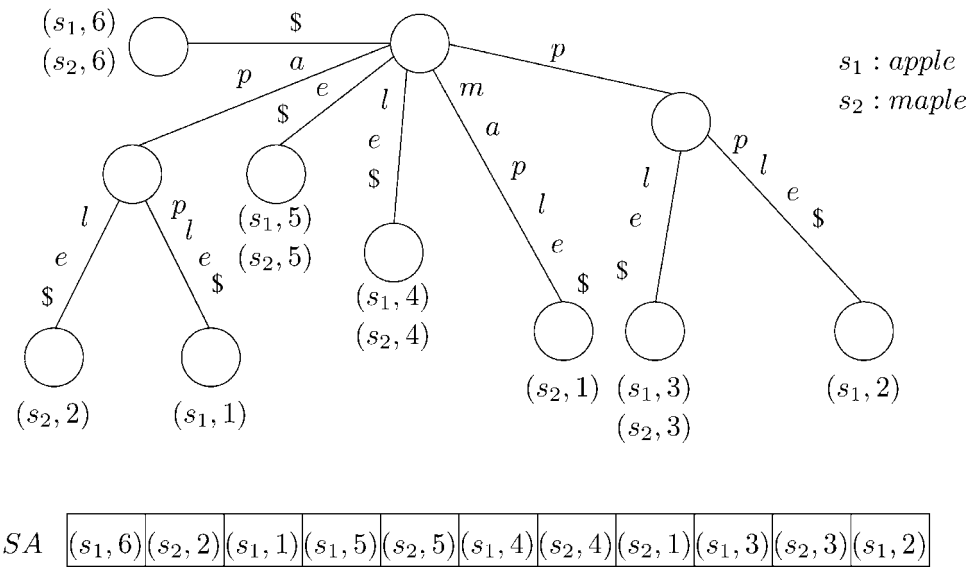
The next part of this entry deals with some of the widely used data structures specifically designed for string data, suffix trees, and suffix arrays. These are particularly suitable for querying unstructured text data, such as the genomic sequence of an organism. The following notation is used: Let $s[i]$ denote the ith character of string s, $s[i \ldots j]$ denote the substring $s[i]s[i+1]\ldots s[j]$, and $S_i = s[i]s[i+1]\ldots s[|s|]$ denote the suffix of s starting at ith position. The suffix S_i can be uniquely described by the integer i. In case of multiple strings, the suffix of a string can be described by a tuple consisting of the string number and the starting position of the suffix within the string. Consider a collection of strings over Σ, having total length n, each extended by adding a unique termination symbol $\$ \notin \Sigma$. The suffix tree of the strings is a compacted trie of all suffixes of these extended strings. The suffix array of the strings is the lexicographic sorted order of all suffixes of these extended strings. For convenience, we list '$', the last suffix of each string, just once. The suffix tree and suffix array of strings 'apple' and 'maple' are shown in Fig. 1. Both these data structures take $O(n)$ space and can be constructed in $O(n)$ time [11, 13], both directly and from each other.

Without loss of generality, consider the problem of searching for a pattern P as a substring of a single string T. Assume the suffix tree ST of T is available. If P occurs in T starting from position i, then P is a prefix of suffix $T_i = T[i]T[i+1]\ldots T[|T|]$ in T. It follows that P matches the path from root to leaf labeled i in ST. This property results in the following simple algorithm: Start from the root of ST and follow the path matching characters in P, until P is completely matched or a mismatch occurs. If P is not fully matched, it does not occur in T. Otherwise, each leaf in the subtree below the matching position gives an occurrence of P. The positions can be enumerated by traversing the subtree in $O(occ)$ time, where occ denotes the number of occurrences of P. If only one occurrence is desired, ST can be preprocessed in $O(|T|)$ time such that each internal node contains the suffix at one of the leaves in its subtree.

Theorem 3 *Given a suffix tree for text T and a pattern P, whether P occurs in T can be answered in* $O(|P|)$ *time. All occurrences of P in T can be found in* $O(|P| + occ)$ *time, where occ denotes the number of occurrences.*

Now consider solving the same problem using the suffix array SA of T. All suffixes prefixed by P appear in consecutive positions in SA. These can be found using binary search in SA. Naively performed, this would take $O(|P| * \log|T|)$ time. It can be improved to $O(|P| + \log|T|)$ time as follows [15]:

Let $SA[L \ldots R]$ denote the range in the suffix array where the binary search is focused. To begin with, $L = 1$ and $R = |T|$. Let $\prec$ denote "lexicographically smaller", $\preceq$ denote "lexicographically smaller or equal", and



Text Indexing, Fig. 1 Suffix tree and suffix array of strings *apple* and *maple*

$lcp(\alpha, \beta)$ denote the length of the longest common prefix between strings α and β. At the beginning of an iteration, $T_{SA[L]} \preceq P \preceq T_{SA[R]}$. Let $M = \lceil (L + R)/2 \rceil$. Let $l = lcp(P, T_{SA[L]})$ and $r = lcp(P, T_{SA[R]})$. Because SA is lexicographically ordered, $lcp(P, T_{SA[M]}) \geq \min(l, r)$. If $l = r$, then compare P and $T_{SA[M]}$ starting from the (l+1)th character. If $l \neq r$, consider the case when $l > r$.

Case I: $l < lcp(T_{SA[L]}, T_{SA[M]})$. In this case, $T_{SA[M]} \prec P$ and $lcp(P, T_{SA[M]}) = lcp(P, T_{SA[L]})$. Continue search in $SA[M \ldots R]$. No character comparisons required.

Case II: $l > lcp(T_{SA[L]}, T_{SA[M]})$. In this case, $P \prec T_{SA[M]}$ and $lcp(P, T_{SA[M]}) = lcp(T_{SA[L]}, T_{SA[M]})$. Continue search in $SA[L \ldots M]$. No character comparisons required.

Case III: $l = lcp(T_{SA[L]}, T_{SA[M]})$. In this case, $lcp(P, T_{SA[M]}) \geq l$. Compare P and $T_{SA[M]}$ beyond lth character to determine their relative order and *lcp*.

Similarly, the case when $r > l$ can be handled such that comparisons between P and $T_{SA[M]}$, if at all needed, start from $(r + 1)$th character. To start the execution of the algorithm, $lcp(P, T_{SA[1]})$ and $lcp(P, T_{SA[|T|]})$ are computed directly using at most $2|P|$ character comparisons. It remains to be described how the $lcp(T_{SA[L]}, T_{SA[M]})$ and $lcp(T_{SA[R]}, T_{SA[M]})$ values required in each iteration are computed. Let $Lcp[1 \ldots |T| - 1]$ be an array such that $Lcp[i] = lcp(SA[i], SA[i + 1])$. The *Lcp* array can be computed from *SA* in $O(|T|)$ time [12]. For any $1 \leq i < j \leq n$, $lcp(T_{SA[i]}, T_{SA[j]}) = \min_{k=i}^{j-1} Lcp[k]$. In order to find the *lcp* values required by the algorithm in constant time, note that the binary search can be viewed as traversing a path in the binary tree corresponding to all possible search intervals used by any execution of the binary search algorithm [15]. The root of the tree denotes the interval $[1 \ldots n]$. If $[i \ldots j]$ $(j - i \geq 2)$ is the interval at an internal node of the tree, its left child is given by $[i \ldots \lceil (i + j)/2 \rceil]$ and its right child is given by $[\lceil (i + j)/2 \rceil \ldots j]$. The *lcp* value for each interval in the tree is precomputed and recorded in $O(n)$ time and space.

Theorem 4 *Given the suffix array SA of text T and a pattern P, the existence of P in T can be checked in* $O(|P| + \log |T|)$ *time. All occurrences of P in T can be found in O(occ) additional time, where occ denotes their number.*

Proof The algorithm makes at most $2|P|$ comparisons in determining $lcp(P, T_{SA[1]})$ and $lcp(P, T_{SA[n]})$. A comparison made in an iteration to determine $lcp(P, T_{SA[M]})$ is categorized *successful* if it contributes the *lcp*, and categorized *failed* otherwise. There is at most one failed comparison per iteration. As for successful comparisons, note that the comparisons start with $(\max(l, r) + 1)^{\text{th}}$ character of P, and each successful comparison increases the value of $\max(l, r)$ for the next iteration. Thus, each character of P is involved only once in a successful comparison. The total number of character comparisons is at most $3|P| + \log|T| = O(|P| + \log|T|)$. □

Abouelhoda et al. [1] reduce this time further to $O(|P|)$ by mimicking the suffix tree algorithm on a suffix array with some auxiliary information. The strategy is useful in other applications based on top-down traversal of suffix trees. At this stage, the distinction between suffix trees and suffix arrays is blurred as the auxiliary information stored makes the combined data structure equivalent to a suffix tree. Using clever implementation techniques, the space is reduced to approximately $6n$ bytes. A major advantage of the suffix tree and suffix array based methods is that the text T is often large and relatively static, while it is queried with several short patterns. With suffix trees and enhanced suffix arrays [1], once the text is preprocessed in $O(|T|)$ time, each pattern can be queried in $O(|P|)$ time for constant size alphabet. For large alphabets, the query can be answered in $O(|P| * \log|\Sigma|)$ time using $O(n|\Sigma|)$ space (by storing an ordered array of $|\Sigma|$ pointers to potential children of a node), or in $O(|P| * |\Sigma|)$ time using $O(n)$ space (by storing pointers to first child and next sibling). (Recently, Cole et al. (2006) showed how to further reduce the search time to $O(|P| + \log|\Sigma|)$ while still keeping the optimal $O(|T|)$ space). For indexing in various text-dynamic situations, see [3, 7] and references therein. The problem of compressing suffix trees and arrays is covered in more detail in other entries.

While exact pattern matching has many useful applications, the need for approximate pattern matching arises in several contexts ranging from information retrieval to finding evolutionary related biomolecular sequences. The classic approximate pattern matching problem is to find substrings in the text T that have an edit distance of k or less to the pattern P, i.e., the substring can be converted to P with at most k insert/delete/substitute operations. This problem is covered in more detail in other entries. Also see [16], the references therein, and Chapter 36 of [2].

Applications

Text indexing has many practical applications – finding words or phrases in documents under preparation, searching text for information retrieval from digital libraries, searching distributed text resources such as the web, processing XML path strings, searching for longest matching prefixes among IP addresses for internet routing, to name just a few. The reader interested in further exploring text indexing is referred to the book by Crochemore and Rytter [6], and to other entries in this Encyclopedia. The last decade of explosive growth in computational biology is aided by the application of string processing techniques to DNA and protein sequence data. String indexing and aggregate queries to uncover mutual relationships between strings are at the heart of important scientific challenges such as sequencing genomes and inferring evolutionary relationships. For an in depth study of such techniques, the reader is referred to Parts I and II of [10] and Parts II and VIII of [2].

Open Problems

Text indexing is a fertile research area, making it impossible to cover many of the research results or actively pursued open problems in a short amount of space. Providing better algorithms and data structures to answer a flow of string-search queries when caches or other query models are taken into account, is an interesting research issue [4].

Three-Dimensional Graph Drawing

David R. Wood
School of Mathematical Sciences, Monash University, Melbourne, VIC, Australia

Keywords

Track layout; Three-dimensional straight-line grid drawing; Treewidth

Years and Authors of Summarized Original Work

2005; Dujmović, Morin, Wood

Problem Definition

A *three-dimensional straight-line grid drawing* of a graph, henceforth called a *3D drawing*, represents the vertices by distinct grid-points in $\mathbb{Z}^3$ and represents each edge by the line segment between its end vertices, such that no two edges cross. In contrast to the case in the plane, it is folklore that every graph has a 3D drawing. For example, the "moment curve" algorithm places the ith vertex at (i, i^2, i^3). It is easily seen that no four vertices are coplanar, and thus no two edges cross. Since every graph has a 3D drawing, we are interested in optimizing certain measures of their aesthetic quality. If a 3D drawing is contained in

an axis-aligned box with side lengths $X-1$, $Y-1$, and $Z-1$, then we speak of an $X \times Y \times Z$ drawing with *volume* $X \cdot Y \cdot Z$. This entry considers the problem of producing a 3D drawing of a given graph with small volume.

Key Results

Observe that the drawings produced by the moment curve algorithm have $\mathcal{O}(n^6)$ volume, where n is the number of vertices. Cohen et al. [2] improved this bound, by proving that if p is a prime with $n < p \leq 2n$, and the ith vertex is at $(i, i^2 \bmod p, i^3 \bmod p)$, then there is still no crossing. The resulting $\mathcal{O}(n^3)$ volume bound is optimal for the complete graph K_n since each grid plane may contain at most four vertices. It is therefore of interest to identify fixed graph parameters that allow for 3D drawings with small volume, as summarized in the following table.

Graph family	Min. volume	Reference
Arbitrary	$\Theta(n^3)$	[2]
Bounded chromatic number	$\Theta(n^2)$	[19]
Bounded maximum degree	$\mathcal{O}(n^{3/2})$	[7]
Bounded degeneracy	$\mathcal{O}(n^{3/2})$	[9]
H-minor-free (H fixed)	$n \log^{\mathcal{O}(1)} n$	[12]
Bounded genus	$\mathcal{O}(n \log n)$	[12]
Apex-minor-free	$\mathcal{O}(n \log n)$	[12]
Planar	$\mathcal{O}(n \log n)$	[6]
Bounded treewidth	$\Theta(n)$	[11]

The first such parameter to be studied was the chromatic number. Pach et al. [19] proved that graphs of bounded chromatic number have 3D drawings with $\mathcal{O}(n^2)$ volume. If p is a suitably chosen prime, the main step of their algorithm represents the vertices in the ith color class by grid-points in the set $\{(i, t, it) : t \equiv i^2 \pmod p\}$. It follows that the volume bound is $\mathcal{O}(k^2 n^2)$ for k-colorable graphs.

Pach et al. [19] also proved an $\Omega(n^2)$ lower bound for the volume of 3D drawings of the complete bipartite graph $K_{n,n}$. This lower bound was generalized for all graphs by Bose et al. [1], who proved that every 3D drawing of an n-vertex m-edge graph has volume at least $\frac{1}{8}(n + m)$. In particular, the maximum number of edges in an $X \times Y \times Z$ drawing is exactly $(2X-1)(2Y-1)(2Z-1) - XYZ$.

Graphs with bounded maximum degree have bounded chromatic number and, thus, by the result of Pach et al. [19], have 3D drawings with $\mathcal{O}(n^2)$ volume. Pach et al. [19] conjectured that such graphs have 3D drawings with $o(n^2)$ volume, which was verified by Dujmović and Wood [7], who proved a $\mathcal{O}(n^{3/2})$ bound. The best lower bound is $\Omega(n)$. Determining the optimal volume for 3D drawings of bounded degree graphs is a challenging open problem; see [13]. The $\mathcal{O}(n^{3/2})$ upper bound for bounded degree graphs was generalized for graphs with bounded degeneracy [9].

The first nontrivial $\mathcal{O}(n)$ volume bound was established by Felsner et al. [15] for outerplanar graphs. Their elegant algorithm "wraps" a 2D drawing around a triangular prism to obtain a 3D drawing. This result naturally led to the following open problem due to Felsner et al. [15], which motivated much subsequent research: does every planar graph have a 3D drawing with $\mathcal{O}(n)$ volume?

For some time, the $\mathcal{O}(n^2)$ bound for 2D drawings was the best known bound in 3D. Then Dujmović and Wood [7] proved that every planar graph has a 3D drawing with $\mathcal{O}(n^{3/2})$ volume. A breakthrough came with the $\mathcal{O}(n \log^8 n)$ bound of Di Battista et al. [4], which was improved to $\mathcal{O}(n \log n)$ by Dujmović [6] (with a much simpler proof). The most recent work in this direction, by Dujmović et al. [12], extended this $\mathcal{O}(n \log n)$ bound to all graphs of bounded Euler genus and more generally proved that every graph excluding a fixed minor has a 3D drawing with $n \log^{\mathcal{O}(1)} n$ volume.

The $\mathcal{O}(n)$ volume bound for outerplanar graphs mentioned above was generalized by Dujmović et al. [11] as follows:

Theorem 1 ([11]) *Graphs with bounded treewidth have 3D drawings with $\mathcal{O}(n)$ volume.*

This result is the focus of the remainder of this entry. Treewidth is a measure of the similarity of a graph to a tree. It can be defined as follows. A graph is *chordal* if every induced cycle is a triangle. The *treewidth* of a graph G is the minimum

integer k such that G is a spanning subgraph of a chordal graph with no $(k+2)$-clique. Many graphs arising in applications of graph drawing have small treewidth. Trees have treewidth 1, while outerplanar and series-parallel graphs have treewidth 2. Another example arises in software engineering applications. Thorup [20] proved that the control-flow graphs of go-to free programs in many programming languages have treewidth bounded by a small constant, in particular, 3 for Pascal and 6 for C.

Reference [11] is also important because it discovered the connection between 3D drawings, track layouts, and queue layouts; also see [10, 16].

Track Layouts

Track layouts are a combinatorial tool that effectively eliminates the geometry from 3D drawings and exposes the underlying combinatorial structure. They were introduced in [11] although they are implicit in some previous work [15, 16].

Let $V_1, \ldots, V_t$ be the color classes in a (proper) vertex t-coloring of a graph G. Suppose that each color class V_i is equipped with a total order, denoted by $\preceq$. Call V_i a *track* and $V_1, \ldots, V_t$ a *t-track assignment*. An *X-crossing* in $V_1, \ldots, V_t$ consists of two edges vw and xy such that $v \prec x$ in some track V_i and $y \prec w$ in some other track V_j. A t-track assignment with no X-crossing is called a *t-track layout*.

One can produce a track layout from an $A \times B \times C$ drawing of a graph G as follows. Let $V_{x,y}$ be the set of vertices of G with an X-coordinate of x and a Y-coordinate of y. Order each set $V_{x,y}$ by the corresponding Z-coordinates. We obtain an AB-track layout of G, except that consecutive vertices in each track might be adjacent. Doubling each track and putting alternate vertices in $V_{x,y}$ on distinct tracks gives a $2AB$-track layout of G. Most interestingly, a converse result is also true.

Theorem 2 ([11]) *If an n-vertex graph has a t-track layout, then G has a $\mathcal{O}(t) \times \mathcal{O}(t) \times \mathcal{O}(n)$ drawing with $\mathcal{O}(t^2 n)$ volume.*

The proof of Theorem 2 is inspired by the generalizations of the moment curve algorithm by Cohen et al. [2] and Pach et al. [19]. Loosely speaking, Cohen et al. [2] allow three "free" dimensions, whereas Pach et al. [19] use a coloring to "fix" one dimension with two dimensions free. Theorem 2 uses a track layout to fix two dimensions with one dimension free; see Fig. 1. In particular, say $(V_1, \ldots, V_t)$ is the given t-track layout. Let p be the smallest prime such that $p > k$. Then $p \leq 2k$ by Bertrand's postulate. For $1 \leq i \leq k$, represent the vertices in V_i by the grid-points $\{(i, i^2 \bmod p, t) : 1 \leq t \leq p \cdot |V_i|,\ t \equiv i^3 \pmod p\}$, such that the Z-coordinates respect the given total order of V_i.

Note that Dujmović and Wood [7] combined the method of Pach et al. [19] with the proof of Theorem 2 to conclude a $\mathcal{O}(tn)$ volume bound of 3D drawings of t-track graphs with bounded chromatic number.

As an example of how to construct a track layout, we now show that every tree T has a 3-track layout (which is implicitly proved in [15]). Let r be a vertex of T. Let V_i be the vertices at distance i from r. Note that $(V_0, V_1, \ldots)$ is a coloring of T. Clearly, each color class V_i can be ordered so that there is no X-crossing; see Fig. 2a. Hence $(V_0, V_1, \ldots)$ is a track layout. Note that, working from the root down, the child nodes of each node can be ordered arbitrarily. This will be important later. Now, imagine wrapping this track layout around a prism; see Fig. 2b. That is, for $0 \leq i \leq 2$, group tracks $V_i \prec V_{3+i} \prec V_{6+i} \prec \ldots$ to obtain a 3-track layout of T.

An Algorithm for Graphs of Bounded Treewidth

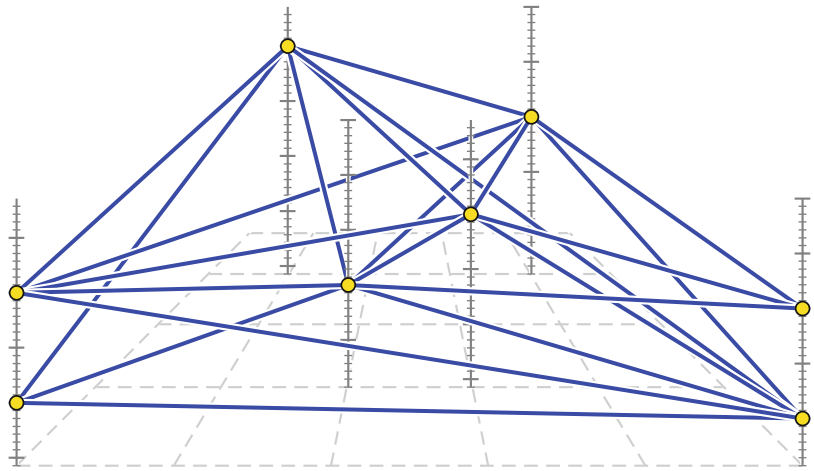
Theorem 1 is an immediate consequence of Theorem 2 and the following claim, which we prove by induction on $k \geq 0$: for each integer $k \geq 0$, there is an integer t_k such that every k-tree has a t_k-track layout. A 0-tree has no edges and thus has a 1-track layout. A 1-tree is a tree which has a 3-track layout. Thus the result holds with $t_0 = 1$ and $t_1 = 3$. Let G be a k-tree. Various authors have proved that G can be decomposed as follows [11, 18]. There is a tree T rooted at some node r and a partition $\{B_x : x \in V(T)\}$ of $V(G)$ indexed by the nodes of T with the following properties:

- For each edge vw of G, there is a node x of T such that $v, w \in B_x$, or there is an edge xy of T such that $v \in B_x$ and $w \in B_y$.
- For each node x of T, the induced subgraph $G[B_x]$ is a $(k-1)$-tree.
- For each non-root node y of T, if x is the parent node of y, and C_y is the set of vertices in B_x adjacent to some vertex in B_y, then C_y is a clique in G called the *parent clique* of y.

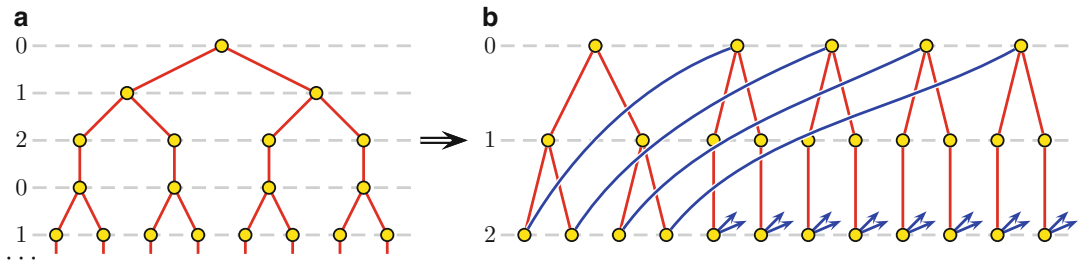
By induction, for each node x of T, there is a t_{k-1}-track layout of $G[B_x]$. Each clique C in $G[B_x]$ has size at most k. Define the *signature* of C to be the set of (at most k) tracks that contain C. Since there is no X-crossing, the set of cliques of $G[B_x]$ with the same signature can be linearly ordered $C_1 \prec \cdots \prec C_p$, such that if v and w are vertices in the same track, and in distinct cliques C_i and C_j with $i < j$, then $v \prec w$ in that track. Call this a *clique ordering*.

Let T_0, T_1, T_2 be a 3-track layout of T described above. Replace each track T_i by t_{k-1} subtracks, and replace each node $x \in T_i$ by the t_{k-1}-track layout of $G[B_x]$. This defines a $3 \cdot t_{k-1}$ track assignment for G. Clearly an edge in some $G[B_x]$ is in no X-crossing with any other edge. There is no X-crossing between two edges between a parent bag B_x and some same child bag B_y, since the end points in B_x of such edges form a clique (the parent clique of y) and therefore are in distinct tracks. The only possible X-crossing is between edges ab and cd, where a and c are in some parent bag B_x and b and d are in distinct child bags B_y and B_z, respectively.

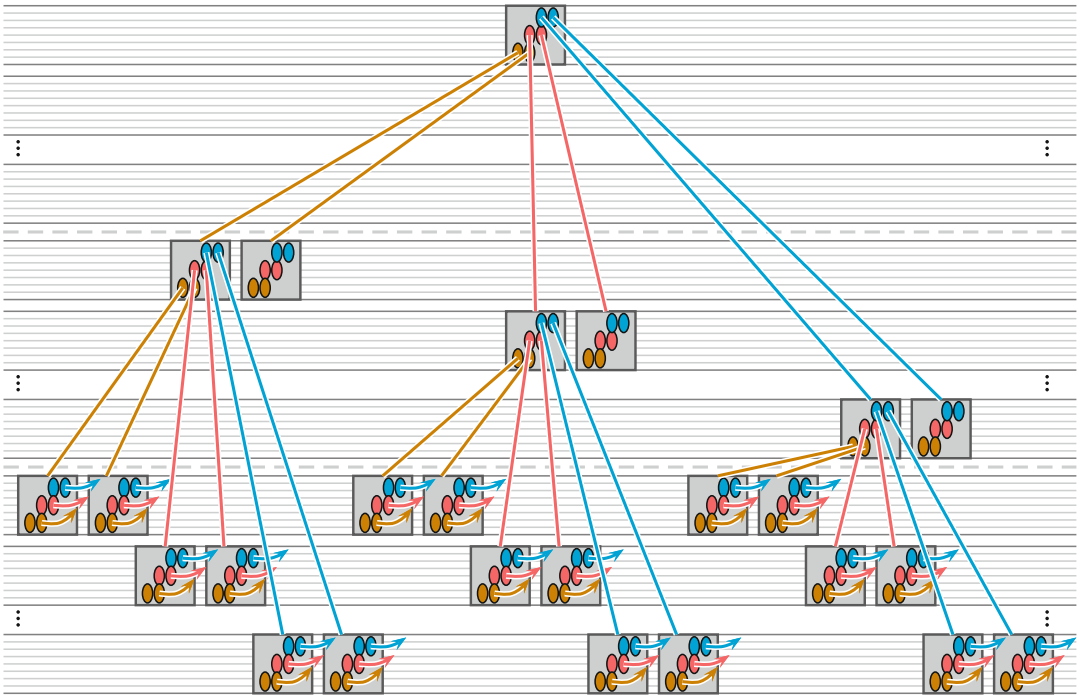
To solve this problem, when determining the 3-track layout of T, the child nodes of each node x are ordered in their track so that $y \prec z$ whenever the parent cliques C_y and C_z have the same signature and $C_y \prec C_z$ in the clique ordering. Then group the child nodes of x according to



Three-Dimensional Graph Drawing, Fig. 1 A 3D drawing produced from a track layout



Three-Dimensional Graph Drawing, Fig. 2 A 3-track layout of a tree



Three-Dimensional Graph Drawing, Fig. 3 Final track layout with $3(t_{k-1})^k$ groups of t_{k-1} tracks

the signatures of their parent cliques, and for each signature σ, use a distinct set of t_{k-1} tracks for the child bags whose parent cliques have signature σ. Now the ordering of the child bags with the same signature agrees with the clique ordering of their parent cliques and therefore agrees with the ordering of any neighbors in the parent bag. It follows that there is no X-crossing, as illustrated in Fig. 3. The number of tracks is at most $3t_{k-1}$ times the number of signatures, which is at most $\sum_{i=1}^{k} \binom{t_{k-1}}{i} \leq (t_{k-1})^k$. This completes the proof with $t_k := 3(t_{k-1})^{k+1}$.

This proof makes no effort to reduce the bound on t_k. The recurrence roughly solves to $3^{(k+2)!}$. The original proof by Dujmović et al. [11] reduces this bound to a doubly exponential function in k. Further improvements were made by Di Giacomo et al. [5], but the bound is still doubly exponential. The best lower bound, due to Dujmović et al. [11], is $\Omega(k^2)$. For $k = 2$, the best upper bound is 15, due to Di Giacomo et al. [5].

Other Models for 3D Graph Drawing

- Polyline grid drawings, where bends in the edges are allowed (at grid-points) [3,8]
- Orthogonal 3D drawings, where the edges are routed along the grid-lines [14,21]
- Upward 3D drawings of directed acyclic graphs [5,9]
- Symmetrical 3D drawings with vertices in $\mathbb{R}^3$ [17]

Problem Definition

Consider n Boolean variables $V = \{x_1, \ldots, x_n\}$ and the corresponding set of $2n$ literals $L = \{x_1\overline{x}_1 \ldots, x_n, \overline{x}_n\}$. A k-clause is a disjunction of k literals of distinct underlying variables. A random formula $\phi_{n,m}$ in k conjunctive normal form (k-CNF) is the conjunction of m clauses, each selected in a uniformly random and independent way among the $2^k \binom{n}{k}$ possible k-clauses on n variables in V. The density r_k of a k-CNF formula $\phi_{n,m}$ is the clauses-to-variables ratio m/n.

It was conjectured that for each $k \geq 2$ there exists a critical density ${r_k}^*$ such that asymptotically almost all (a.a.a.) k-CNF formulas with density $r < {r_k}^*$ ($r > {r_k}^*$) are satisfiable (unsatisfiable, respectively). So far, the conjecture has been proved only for $k = 2$ [3, 11]. For $k \geq 3$, the conjecture still remains open but is supported by experimental evidence [14] as well as by theoretical, but non-rigorous, work based on statistical physics [15]. The value of the putative threshold ${r_3}^*$ is estimated to be around 4.27. Approximate values of the putative threshold for larger values of k have also been computed.

As far as rigorous results are concerned, Friedgut [10] proved that for each $k \geq 3$, there exists a sequence $r_k^*(n)$ such that for any $\epsilon > 0$, a.a.a. k-CNF formulas ϕ_n, $\lfloor (r_k^*(n) - \epsilon)n \rfloor$ (ϕ_n, $\lfloor (r_k^*(n) + \epsilon)n \rfloor$) are satisfiable (unsatisfiable, respectively). The convergence of the sequence $r_k^*(n), n = 0, 1, \ldots$ for $k \geq 3$ remains open.

Let now

$$r_k^{*-} = \underline{\lim}_{n\to\infty} r_k^*(n)$$
$$= \sup\{r_k : \Pr[\phi_{n,\lfloor r_k n \rfloor} \text{ is satisfiable} \to 1]\}$$

and

$$r_k^{*+} = \overline{\lim}_{n\to\infty} r_k^*(n)$$
$$= \inf\{r_k : \Pr[\phi_{n,\lceil r_k n \rceil} \text{ is satisfiable} \to 0]\}.$$

Obviously, $r_k{}^{*-} \leq r_k{}^{*+}$. Bounding from below (from above) $r_k{}^{*-}$ ($r_k{}^{*+}$, respectively) with an as large as possible (as small as possible, respectively) bound has been the subject of intense research work in the past decade.

Upper bounds to $r_k{}^{*+}$ are computed by counting arguments. To be specific, the standard technique is to compute the expected number of satisfying truth assignments of a random formula with density r_k and find an as small as possible value of r_k for which this expected value approaches zero. Then, by Markov's inequality, it follows that for such a value of r_k, a random formula $\phi_{n,\lceil rkn \rceil}$ is unsatisfiable asymptotically almost always. This argument has been refined in two directions: First, consider not all satisfying truth assignments but a subclass of them with the property that a satisfiable formula always has a satisfying truth assignment in the subclass considered. The restriction to a judiciously chosen such subclass forces the expected value of the number of satisfying truth assignments to get closer to the probability of satisfiability and thus leads to a better (smaller) upper bound r_k. However, it is important that the subclass should be such that the expected value of the number of satisfying truth assignments can be computable by the available probabilistic techniques.

Second, make use in the computation of the expected number of satisfying truth assignments of *typical* characteristics of the random formula, i.e., characteristics shared by a.a.a. formulas. Again this often leads to an expected number of satisfying truth assignments that is closer to the probability of satisfiability (nontypical formulas may contribute to the increase of the expected number). Increasingly better upper bounds to $r_3{}^{*+}$ have been computed using counting arguments as above (see the surveys [6, 13]). Dubois, Boufkhad, and Mandler [7] proved $r_3{}^{*+} < 4.506$. The latter remains the best upper bound to date.

On the other hand, for fixed and small values of k (especially for $k = 3$), lower bounds to $r_k{}^{*-}$ are usually computed by algorithmic methods. To be specific, one designs an algorithm that for an as large as possible r_k it returns a satisfying truth assignment for a.a.a. formulas $\phi_{n,\lfloor rkn \rfloor}$. Such an r_k is obviously a lower bound to $r_k{}^{*-}$. The simpler the algorithm, the easier to perform the probabilistic analysis of returning a satisfying truth assignment for a given r_k, but the smaller the r_k's for which a satisfying truth assignment is returned asymptotically almost always. In this context, backtrack-free DPLL algorithms [4, 5] of increasing sophistication were rigorously analyzed (see the surveys [1, 9]). At each step of such an algorithm, a literal is set to TRUE and then a *reduced* formula is obtained by (i) deleting clauses where this literal appears and by (ii) deleting the negation of this literal from the clauses it appears. At steps at which 1-clauses exist (known as forced steps), the selection of the literal to be set to TRUE is made so as a 1-clause becomes satisfied. At the remaining steps (known as free steps), the selection of the literal to be set to TRUE is made according to a heuristic that characterizes the particular DPLL algorithm. A free step is followed by a round of consecutive forced steps. To facilitate the probabilistic analysis of DPLL algorithms, it is assumed that they never backtrack: if the algorithm ever hits a contradiction, i.e., a 0-clause is generated, it stops and reports failure; otherwise, it returns a satisfying truth assignment. The previously best lower bound for the satisfiability threshold obtained by such an analysis was $3.26 < r_3{}^{*-}$ [2].

The previously analyzed such algorithms (with the exception of the *Pure Literal* algorithm [8]) at a free step take into account only the clause size where the selected literal appears. Due to this limited information exploited on selecting the literal to be set, the reduced formula in each step remains random conditional only on the current numbers of 3- and 2-clauses and the number of yet unassigned variables. This retention of "strong" randomness permits a successful probabilistic analysis of the algorithm in a not very complicated way. However, for $k = 3$, it succeeds to show satisfiability only for densities up to a number slightly larger than 3.26. In particular, in [2] it is shown that this is the optimal value that can be attained by such algorithms.

Key Results

In [12], a DPLL algorithm is described (and then probabilistically analyzed) such that each free step selects the literal to be set to TRUE, taking into account its *degree* (i.e., its number of occurrences) in the current formula.

Algorithm *Greedy*

The first variant of the algorithm is very simple: At each free step, a literal with the maximum number of occurrences is selected and set to TRUE (Section 4.A in [12]). Notice that in this greedy variant, a literal is selected irrespectively of the number of occurrences of its negation. This algorithm successfully returns a satisfying truth assignment for a.a.a. formulas with density up to a number slightly larger than 3.42, establishing that ${r_3}^{*-} > 3.42$. Its simplicity, contrasted with the improvement over the previously obtained lower bounds, suggests the importance of analyzing heuristics that take into account degree information of the current formula.

Algorithm *CL*

In the second variant, at each free step t, the degree of the negation $\overline{\tau}$ of the literal τ that is set to TRUE is also taken into account (Section 5.A in [12]). Specifically, the literal to be set to TRUE is selected so as upon the completion of the round of forced steps that follow the free step t, the marginal expected increase of the flow from 2-clauses to 1-clauses per unit of expected decrease of the flow from 3-clauses to 2-clauses is minimized. The marginal expectation corresponding to each literal can be computed from the numbers of its positive and negative occurrences. More specifically, if $m_i, i = 2, 3$ equals the expected flow of i-clauses to $(i-1)$-clauses at each step of a round, and τ is the literal set to TRUE at the beginning of the round, then τ is chosen so as to minimize the ratio $|\frac{\Delta m_2}{\Delta m_3}|$ of the differences Δm_2 and Δm_3 between the beginning and the end of the round. This has an effect to the bounding of the rate of generation of 1-clauses by the smallest possible number throughout the algorithm. For the probabilistic analysis to go through, we need to know for each i, j the number of literals with degree i whose negation has degree j. This heuristic succeeds in returning a satisfying truth assignment for a.a.a. formulas with density up to a number slightly larger than 3.52, establishing that ${r_3}^{*-} > 3.52$.

Applications

Some applications of SAT solvers include sequential circuit verification, artificial intelligence, automated deduction and planning, VLSI, CAD, model-checking, and other types of formal verification. Recently, automatic SAT-based model-checking techniques were used to effectively find attacks on security protocols.

Open Problems

The main open problem in the area is to formally show the existence of the threshold ${r_k}^*$ for all (or at least some) $k \geq 3$. To rigorously compute upper and lower bounds better than the ones mentioned here still attracts some interest. Related results and problems arise in the framework of variants of the satisfiability problem and also the problem of colorability.

Topology Approach in Distributed Computing

Maurice Herlihy
Department of Computer Science, Brown University, Providence, RI, USA

Keywords

Wait-free renaming

Years and Authors of Summarized Original Work

1999; Herlihy Shavit

Problem Definition

The application of techniques from Combinatorial and Algebraic Topology has been successful at solving a number of problems in distributed computing. In 1993, three independent teams [3, 15, 17], using different ways of generalizing the classical graph-theoretical model of distributed computing, were able to solve *set agreement* a long-standing open problem that had eluded the standard approaches. Later on, in 2004, journal articles by Herlihy and Shavit [15] and by Saks and Zaharoglou [17] were to win the prestigious Gödel prize. This paper describes the approach taken by the Herlihy/Shavit paper, which was the first draw the connection between Algebraic and Combinatorial Topology and Distributed Computing.

Pioneering work in this area, such as by Biran, Moran, and Zaks [2] used graph-theoretic notions to model uncertainty, and were able to express

certain lower bounds in terms of graph connectivity. This approach, however, had limitations. In particular, it proved difficult to capture the effects of multiple failures or to analyze decision problems other then consensus.

Combinatorial topology generalizes the notion of a graph to the notion of a *simplicial complex*, a structure that has been well-studied in mainstream mathematics for over a century. One property of central interest to topologists is whether a simplicial complex has no "holes" below a certain dimension k, a property known as *k-connectivity*. Lower bounds previously expressed in terms of connectivity of graphs can be generalized by recasting them in terms of k-connectivity of simplicial complexes. By exploiting this insight, it was possible to solve some open problems (k-set agreement, renaming), to pose and solve some new problems ([13]), and to unify a number of disparate results and models [14].

Key Results

A *vertex* $\vec{v}$ is a point in a high-dimensional Euclidean space. Vertexes $\vec{v}_0, \ldots, \vec{v}_n$ are *affinely independent* if $\vec{v}_1 - \vec{v}_0, \ldots, \vec{v}_n - \vec{v}_0$ are linearly independent. An *n-dimensional simplex* (or *n-simplex*) $S^n = (\vec{s}_0, \ldots, \vec{s}_n)$ is the convex hull of a set of $n+1$ affinely-independent vertexes. For example, a 0-simplex is a vertex, a 1-simplex a line segment, a 2-simplex a solid triangle, and a 3-simplex a solid tetrahedron. Where convenient, superscripts indicate dimensions of simplexes. The $\vec{s}_0, \ldots, \vec{s}_n$ are said to *span* S^n. By convention, a simplex of dimension $d < 0$ is an empty simplex.

A *simplicial complex* (or complex) is a set of simplexes closed under containment and intersection. The *dimension* of a complex is the highest dimension of any of its simplexes. $\mathcal{L}$ is a *subcomplex* of $\mathcal{K}$ if every simplex of $\mathcal{L}$ is a simplex of $\mathcal{K}$. A map $\mu: \mathcal{K} \to \mathcal{L}$ carrying vertexes to vertexes is *simplicial* if it also induces a map of simplexes to simplexes.

Definition 1 A complex $\mathcal{K}$ is *k-connected* if every continuous map of the k-sphere to $\mathcal{K}$ can be extended to a continuous map of the $(k+1)$-disk. By convention, a complex is (-1) *-connected* if and only if it is nonempty, and every complex is *k-connected* for $k < -1$.

A complex is 0-connected if it is connected in the graph-theoretic sense, and a complex is k-connected if it has no holes in dimensions k or less. The definition of k-connectivity may appear difficult to use, but fortunately reasoning about connectivity can be done in a combinatorial way, using the following elementary consequence of the Mayer–Vietoris sequence.

Theorem 2 *If $\mathcal{K}$ and $\mathcal{L}$ are complexes such that $\mathcal{K}$ and $\mathcal{L}$ are k-connected, and $\mathcal{K} \cap \mathcal{L}$ is $(k-1)$-connected, then $\mathcal{K} \cup \mathcal{L}$ is k-connected.*

This theorem, plus the observation that any non-empty simplex is k-connected for all k, allows reasoning about a complex's connectivity inductively in terms of the connectivity of its components.

A set of $n+1$ sequential *processes* communicate either by sending messages to one another or by applying operations to shared objects. At any point, a process may *crash*: it stops and takes no more steps. There is a bound f on the number of processes that can fail. Models differ in their assumptions about timing. At one end of the spectrum is the *synchronous model* in which computation proceeds in a sequence of rounds. In each round, a process sends messages to the other processes, receives the messages sent to it by the other processes in that round, and changes state. (Or it applies operations to shared objects.) All processes take steps at exactly the same rate, and all messages are delivered with exactly the same message delivery time. At the other end is the *asynchronous model* in which there is no bound on the amount of time that can elapse between process steps, and there is no bound on the time it can take for a message to be delivered. Between these extremes is the *semi-synchronous model* in which process step times and message delivery times can vary, but are bounded between constant upper and lower bounds. Proving a lower bound in any of these models requires a deep

understanding of the global states that can arise in the course of a protocol's execution, and of how these global states are related.

Each process starts with an *input value* taken from a set V, and then executes a deterministic *protocol* in which it repeatedly receives one or more messages, changes its local state, and sends one or more messages. After a finite number of steps, each process chooses a *decision value* and halts.

In the k-set agreement task [5], processes are required to (1) choose a decision value after a finite number of steps, (2) choose as their decision values some process's input value, and (3) collectively choose no more than k distinct decision values. When $k = 1$, this problem is usually called *consensus* [16].

Here is the connection between topological models and computation. An initial local state of process P is modeled as a vertex $\vec{v} = \langle P, v \rangle$ labeled with P's process id and initial value v. An initial global state is modeled as an n-simplex $S^n = (\langle P_0, v_0 \rangle, \ldots, \langle P_n, v_n \rangle)$, where the P_i are distinct. The term $ids(S^n)$ denotes the set of process ids associated with S^n, and $vals(S^n)$ the set of values. The set of all possible initial global states forms a complex, called the *input complex*.

Any protocol has an associated *protocol complex* $\mathcal{P}$, defined as follows. Each vertex is labeled with a process id and a possible local state for that process. A set of vertexes $\langle P_0, v_0 \rangle, \ldots, \langle P_d, v_d \rangle$ spans a simplex of $\mathcal{P}$ if and only if there is some protocol execution in which $P_0, \ldots, P_d$ finish the protocol with respective local states $v_0, \ldots, v_d$. Each simplex thus corresponds to an equivalence class of executions that "look the same" to the processes at its vertexes. The term $\mathcal{P}(S^m)$ to denote the subcomplex of $\mathcal{P}$ corresponding to executions in which only the processes in $ids(S^m)$ participate (the rest fail before sending any messages). If $m < n - f$, then there are no such executions, and $\mathcal{P}(S^m)$ is empty. The structure of the protocol complex $\mathcal{P}$ depends both on the protocol and on the timing and failure characteristics of the model. $\mathcal{P}$ often refers to both the protocol and its complex, relying on context to disambiguate.

A protocol *solves* k-set agreement if there is a simplicial map δ, called *decision map*, carrying vertexes of $\mathcal{P}$ to values in V such that if $\vec{p} \in \mathcal{P}(S^n)$ then $\delta(\vec{p}) \in vals(S^n)$, and δ maps the vertexes of any given simplex in $\mathcal{P}(S^n)$ to at most k distinct values.

Applications

The renaming problem is a key tool for understanding the power of various asynchronous models of computation.

Open Problems

Characterizing the full power of the topological approach to proving lower bounds remains an open problem.

▸ Renaming

Recommended Reading

Perhaps the first paper to investigate the solvability of distributed tasks was the landmark 1985 paper of Fischer, Lynch, and Paterson [6] which showed that *consensus*, then considered an abstraction of the database commitment problem, had no 1-resilient message-passing solution. Other tasks that attracted attention include *renaming* [1, 12, 15] and *set agreement* [3, 5, 12, 10, 15, 17].

In 1988, Biran, Moran, and Zaks [2] gave a graph-theoretic characterization of decision problems that can be solved in the presence of a single failure in a message-passing system. This result was not substantially improved until 1993, when three independent research teams succeeded in applying combinatorial techniques to protocols that tolerate delays by more than one processor: Borowsky and Gafni [3], Saks and Zaharoglou [17], and Herlihy and Shavit [15].

Later, Herlihy and Rajsbaum used homology theory to derive further impossibility results for set agreement and to unify a variety of known impossibility results in terms of the theory of chain maps and chain complexes [12]. Using the same simplicial model.

Biran, Moran, and Zaks [2] gave the first decidability result for decision tasks, showing that tasks are decidable in the 1-resilient message-passing model. Gafni and Koutsoupias [7] were the first to make the important observation that the contractibility problem can be used to prove that tasks are undecidable, and suggest a strategy to reduce a specific wait-free problem for three processes to a contractibility problem. Herlihy and Rajsbaum [11] provide a more extensive collection of decidability results.

Borowsky and Gafni [3], define an iterated immediate snapshot model that has a recursive structure. Chaudhuri, Herlihy, Lynch, and Tuttle [4] give an inductive construction for the synchronous model, and while the resulting "Bermuda Triangle" is visually appealing and an elegant combination of proof techniques from the literature, there is a fair amount of machinery needed in the formal description of the construction. In this sense, the formal presentation of later constructions is substantially more succinct.

More recent work in this area includes separation results [8] and complexity lower bounds [9].

Trading off update time for query time in dynamic graph problems

Years and Authors of Summarized Original Work

2005; Demetrescu, Italiano

Problem Definition

A dynamic graph algorithm maintains a given property $\mathcal{P}$ on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property $\mathcal{P}$ quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. A typical definition is given below:

Definition 1 (Dynamic graph algorithm) Given a graph and a graph property $\mathcal{P}$, a *dynamic graph algorithm* is a data structure that supports any intermixed sequence of the following operations:

`insert`(u, v): insert edge (u, v) into the graph.
`delete`(u, v): delete edge (u, v) from the graph.
`query(...)`: answer a query about property $\mathcal{P}$ of the graph.

A graph algorithm is *fully dynamic* if it can handle both edge insertions and edge deletions and *partially dynamic* if it can handle either edge insertions or edge deletions, but not both: it is *incremental* if it supports insertions only, and *decremental* if it supports deletions only. Some papers study variants of the problem where more than one edge can be deleted of inserted at the same time, or edge weights can be changed. In some cases, an update may be the insertion or deletion of a node along with all edges incident to them. Some other papers only deal with specific classes of graphs, e.g., planar graphs, directed acyclic graphs (DAGs), etc.

There is a vast literature on dynamic graph algorithms. Graph problems for which efficient dynamic solutions are known include graph connectivity, minimum cut, minimum spanning tree, transitive closure, and shortest paths (see, e.g., [3] and the references therein). Many of them update explicitly the property $\mathcal{P}$ after each update in order to answer queries in optimal time. This may be a good choice in scenarios where there are few updates and many queries. In applications where the numbers of updates and queries are comparable, a better approach would be to try to reduce the update time, possibly at the price of increasing the query time. This is typically achieved by relaxing the assumption that the property $\mathcal{P}$ should be maintained explicitly.

This entry focuses on algorithms for dynamic graph problems that maintain the graph property implicitly, and thus require non-constant query time while supporting faster updates. In particular, it considers two problems: *dynamic transitive closure* (also known as *dynamic reachability*) and *dynamic all-pairs shortest paths*, defined below.

Definition 2 (Fully dynamic transitive closure) The *fully dynamic transitive closure problem* consists of maintaining a directed graph under an intermixed sequence of the following operations:

`insert`(u, v): insert edge (u, v) into the graph.
`delete`(u, v): delete edge (u, v) from the graph.
`query`(x, y): return *true* if there is a directed path from vertex x to vertex y, and *false* otherwise.

Definition 3 (Fully dynamic all-pairs shortest paths) The *fully dynamic transitive closure problem* consists of maintaining a weighted directed graph under an intermixed sequence of the following operations:

`insert`(u, v): insert edge (u, v) into the graph with weight w.
`delete`(u, v): delete edge (u, v) from the graph.
`query`(x, y): return the distance from x to y in the graph, or $+\infty$ if there is no directed path from x to y.

Recall that the distance from a vertex x to a vertex y is the weight of a minimum-weight path from x

to y, where the weight of a path is defined as the sum of edge weights in the path.

Key Results

This section presents a survey of query/update tradeoffs for dynamic transitive closure and dynamic all-pairs shortest paths.

Dynamic Transitive Closure

The first query/update tradeoff for this problem was devised by Henzinger and King [6], who proved the following result:

Theorem 1 (Henzinger and King 1995 [6]) *Given a general directed graph, there is a randomized algorithm with one-sided error for the fully dynamic transitive closure that supports a worst-case query time of $O(n/\log n)$ and an amortized update time of $O(m\sqrt{n}\log^2 n)$.*

The first subquadratic algorithm for this problem is due to Demetrescu and Italiano for the case of directed acyclic graphs [4, 5]:

Theorem 2 (Demetrescu and Italiano 2000 [4, 5]) *Given a directed acyclic graph with n vertices, there is a randomized algorithm with one-sided error for the fully dynamic transitive closure problem that supports each query in $O(n^\epsilon)$ time and each insertion/deletion in $O(n^{\omega(1,\epsilon,1)-\epsilon} + n^{1+\epsilon})$, for any $\epsilon \in [0,1]$, where $\omega(1,\epsilon,1)$ is the exponent of the multiplication of an $n \times n^\epsilon$ matrix by an $n^\epsilon \times n$ matrix.*

Notice that the dependence of the bounds upon parameter ε leads to a full range of query/update tradeoffs. Balancing the two terms in the update bound of Theorem 2 yields that ε must satisfy the equation $\omega(1,\epsilon,1) = 1 + 2\epsilon$. The current best bounds on $\omega(1,\epsilon,1)$ [2, 7] imply that $\epsilon < 0.575$. Thus, the smallest update time is $O(n^{1.575})$, which gives a query time of $O(n^{0.575})$ (Table 1):

Corollary 1 (Demetrescu and Italiano 2000 [4, 5]) Given a directed acyclic graph with n vertices, there is a randomized algorithm with one-sided error for the fully dynamic transitive closure problem that supports each query in $O(n^{0.575})$ time and each insertion/deletion in $O(n^{1.575})$ time.

This result has been generalized to the case of general directed graphs by Sankowski [13]:

Theorem 3 (Sankowsk 2004 [13]) *Given a general directed graph with n vertices, there is a randomized algorithm with one-sided error for the fully dynamic transitive closure problem that supports each query in $O(n)$ time and each insertion/deletion in $O(n^{\omega(1,\epsilon,1)-\epsilon} + n^{1+\epsilon})$, for any $\epsilon \in [0,1]$, where $\omega(1,\epsilon,1)$ is the exponent of the multiplication of an $n \times n^\epsilon$ matrix by an $n^\epsilon \times n$ matrix.*

Corollary 2 (Sankowski 2004 [13]) *Given a general directed graph with n vertices, there is a randomized algorithm with one-sided error for the fully dynamic transitive closure problem that supports each query in $O(n^{0.575})$ time and each insertion/deletion in $O(n^{1.575})$ time.*

Sankowski has also shown how to achieve an even faster update time of $O(n^{1.495})$ at the expense of a much higher $O(n^{1.495})$ query time:

Theorem 4 (Sankowski 2004 [13]) *Given a general directed graph with n vertices, there is a randomized algorithm with one-sided error for the fully dynamic transitive closure problem that supports each query and each insertion/deletion in $O(n^{1.495})$ time.*

Roditty and Zwick presented algorithms designed to achieve better bounds in the case of sparse graphs:

Theorem 5 (Roditty and Zwick 2002 [10]) *Given a general directed graph with n vertices and m edges, there is a deterministic algorithm for the fully dynamic transitive closure problem that supports each insertion/deletion in $O(m\sqrt{n})$ amortized time and each query in $O(\sqrt{n})$ worst-case time.*

Theorem 6 (Roditty and Zwick 2004 [11]) *Given a general directed graph with n vertices and m edges, there is a deterministic algorithm for the fully dynamic transitive closure problem that supports each insertion/deletion in $O(m + n\log n)$ amortized time and each query in $O(n)$ worst-case time.*

Trade-Offs for Dynamic Graph Problems, Table 1 Fully dynamic transitive closure algorithms with implicit solution representation

Type of graphs	Type of algorithm	Update time	Query time	Reference
General	Monte Carlo	$O(m\sqrt{n}\log^2 n)$*amort*	$O(n/\log n)$	HK [6]
DAG	Monte Carlo	$O(n^{1.575})$	$O(n^{0.575})$	DI [4]
General	Monte Carlo	$O(n^{1.575})$	$O(n^{0.575})$	Sank. [13]
General	Monte Carlo	$O(n^{1.495})$	$O(n^{1.495})$	Sank. [13]
General	Deterministic	$O(m\sqrt{n})$*amort*	$O(\sqrt{n})$	RZ [10]
General	Deterministic	$O(m + n\log n)$*amort*	$O(n)$	RZ [11]

Observe that the results of Theorem 5 and Theorem 6 are subquadratic for $m = o(n^{1.5})$ and $m = o(n^2)$, respectively. Moreover, they are not based on fast matrix multiplication, which is theoretically efficient but impractical.

Dynamic Shortest Paths

The first effective tradeoff algorithm for dynamic shortest paths is due to Roditty and Zwick in the special case of sparse graphs with unit edge weights [12]:

Theorem 7 (Roditty and Zwick 2004 [12]) *Given a general directed graph with n vertices, m edges, and unit edge weights, there is a randomized algorithm with one-sided error for the fully dynamic all-pairs shortest paths problem that supports each distance query in* $O(t + \frac{n\log n}{k})$ *worst-case time and each insertion/deletion in* $O(\frac{mn^2\log n}{t^2} + km + \frac{mn\log n}{k})$ *amortized time.*

By choosing $k = (n\log n)^{1/2}$ and $(n\log n)^{1/2} \leq t \leq n^{3/4}(\log n)^{1/4}$ in Theorem 7, it is possible to obtain an amortized update time of $O(\frac{mn^2\log n}{t^2})$ and a worst-case query time of $O(t)$. The fastest update time of $O(m\sqrt{n\log n})$ is obtained by choosing $t = n^{3/4}(\log n)^{1/4}$.

Later, Sankowski devised the first subquadratic algorithm for dense graphs based on fast matrix multiplication [14]:

Theorem 8 (Sankowski 2005 [14]) *Given a general directed graph with n vertices and unit edge weights, there is a randomized algorithm with one-sided error for the fully dynamic all-pairs shortest paths problem that supports each distance query in* $O(n^{1.288})$ *time and each insertion/deletion in* $O(n^{1.932})$ *time.*

Applications

The transitive closure problem studied in this entry is particularly relevant to the field of databases for supporting transitivity queries on dynamic graphs of relations [16]. The problem also arises in many other areas such as compilers, interactive verification systems, garbage collection, and industrial robotics.

Application scenarios of dynamic shortest paths include network optimization [1], document formatting [8], routing in communication systems, robotics, incremental compilation, traffic information systems [15], and dataflow analysis. A comprehensive review of real-world applications of dynamic shortest path problems appears in [9].

Open Problems

It is a fundamental open problem whether the fully dynamic all pairs shortest paths problem of Definition 3 can be solved in subquadratic time per operation in the case of graphs with real-valued edge weights.

Problem Definition

A *transactional memory* (TM) is a concurrency control mechanism for executing accesses to memory shared by multiple processes. A *transaction*, in this context, is a section of code that executes a series of reads and writes to the shared memory as one *atomic* indivisible unit. As a result, intermediate states of a transaction are hidden from other concurrent transactions, and it is only possible to see either all of the modifications of a transaction or none of them.

The goal of transactional memory is to provide an alternative to lock-based concurrency control. A programmer can replace the use of lock-based critical sections with transactions and rely on the TM system to execute these sections concurrently while preserving their atomicity. During the execution, the TM system tracks the reads and writes to the shared memory by the different transactions and, in this way, is able to detect conflicts: situations in which transactions are executing operations to the same memory location. Most TM systems are optimistic, executing with the expectation that there will be few conflicts or none. When a conflict is detected, the TM system may have to abort and restart the transaction. The modifications to memory performed by a transaction must thus be reversible.

The concept of transactional memory and a pure hardware implementation of it (HTM) were proposed by Herlihy and Moss [9] in 1993. Two years later, Shavit and Touitou proposed a pure software implementation (STM) [16], and since then HTM and STM systems have been in the focus of intensive research efforts to make them simple and practical for general use. Today's TM systems are not pure hardware or software, but rather a hybrid of HTM and STM.

```
int red_black_tree_contains(node *root, int value) {
    node *cur_node = root;

  __transaction_atomic
  {
     while (cur_node != NULL)
     {
        If (cur_node.value == value) {
           return true;
        }
        If (cur_node.value < value) {
          cur_node = cur_node.left;
        } else {
          cur_node = cur_node.right;
        }
     }
     return false;
  }
}
```

Transactional Memory, Fig. 1 An example of using the GCC TM mechanism to define the red-black tree contains(. . .) operation as a transaction

Key Results

TM C/C++ Specification and Compiler Support

Transactional memory became an industry standard with the addition of transactional language constructs into the C++ specification [1]. The latest GNU C/C++ compiler implements these TM constructs and provides runtime support for state-of-the-art TM algorithms. Figure 1 shows an example of a GCC TM transaction that is defined by using the new *__transaction_atomic* keyword.

HTM in Mainstream Processors

The latest commodity Intel and IBM processors provide support for hardware transactions by leveraging the processor's hardware cache-coherence protocol to track transactional reads and writes and detect conflicts. They unfortunately provide no progress guarantee for hardware transactions: a transaction may fail due to a hardware-related reason (like an L1 cache capacity overflow or an interrupt), and this can happen repeatedly so the transaction may never succeed. To overcome this limitation and provide a progress guarantee, researchers have developed hybrid TM systems [5, 10, 11] that execute failed hardware transactions in an all-software fallback path.

STM Implementations

Software transactions have become much faster and more practical since their introduction by Shavit and Touitou. The state-of-the-art TL2/LSA style STM designs [6, 7] provide software transactions with a guarantee of opacity [8]: the transaction always executes on a consistent memory state. Opacity enables simple STM runtime implementations, since it effectively eliminates the need to detect and handle any runtime errors that could be generated by inconsistent executions.

The TL2/LSA style STMs use a global clock and per object metadata to coordinate transactions, which introduce high constant overheads for reads and writes compared to the pure execution of those reads and writes in hardware. As a result, the TL2/LSA STMs usually perform

well at high concurrency levels, but exhibit poor results for low concurrency. Unlike hardware transactions, they provide a progress guarantee. An alternative design to TL2/LSA is the NORec STM [4] that has no per object metadata and only uses a single global clock to coordinate transactions. The overheads of NORec are very low and operate well at low concurrency levels.

Hardware Lock Elision

Hardware lock elision (HLE) [14] is a mechanism provided by the HTM systems of Intel and IBM and used to optimize lock-based critical sections. The idea of HLE is simple: try to execute the lock-based critical sections concurrently, by using hardware transactions, and if there is a conflict, then fall back to the serial lock-based execution. In this way, the HLE can automatically introduce concurrency into non-conflicting lock-based critical sections, without the need to modify the existing application's code.

Hybrid TM

In order to provide both the performance of hardware and the guarantee of progress of the software implementations, recent TM systems are a hybrid of HTM and STM. A typical hybrid TM first tries to execute transactions in hardware, and if the transaction fails to commit, then it falls back to execute it in software. The key feature of a good hybrid TM is that it provides concurrency between transactions, some of which are executing in hardware and some in software. Recent research shows that it is challenging to provide hardware-software coordination to make hybrid TMs work efficiently [2, 3, 12, 13, 15].

TM Applications

It is still not clear how exactly TM will be used. The intention is that TM will replace the use of locks in application code. Replacing locks in existing code is proving to be a complex task. The main issues arise from the fact that transactions must be able to abort. This means that any side effect or update of a transaction must be reversible, and this constrains the programmer to use only functions that can be undone. The main problem now is that the standard libraries and the C++ STL do not provide full support for TM. Providing such support would be a major step forward toward simple applicability.

The hope going forward is that new programming languages will include transactional memory mechanisms in the language itself and thus allow future code to be written a priori in a transactional fashion without the use of locks.

Problem Definition

In the *traveling salesman problem* (TSP) n cities 1, 2, …, n together with all the pairwise distances $d(i, j)$ between cities i and j are given. The goal is to find the shortest tour that visits every city exactly once and in the end returns to its starting city. The TSP is one of the most famous problems in combinatorial optimization, and it is well-known to be NP-hard. For more information on the TSP, the reader is referred to the book by Lawler, Lenstra, Rinnooy Kan, and Shmoys [14].

A special case of the TSP is the so-called *Euclidean TSP*, where the cities are points in the Euclidean plane, and the distances are simply the Euclidean distances. A special case of the Euclidean TSP is the *convex Euclidean TSP*, where the cities are further restricted so that they lie in convex position. The Euclidean TSP is still NP-hard [4, 17], but the convex Euclidean TSP is quite easy to solve: Running along the boundary of the convex hull yields a shortest tour. Motivated by these two facts, the following natural question is posed: What is the influence of the number of inner points on the complexity of the problem? Here, an *inner point* of a finite point set P is a point from P which lies in the interior of the convex hull of P. Intuition says that "Fewer inner points make the problem easier to solve."

The result below answers this question and supports the intuition above by providing simple exact algorithms.

Key Results

Theorem 1 *The special case of the Euclidean TSP with few inner points can be solved in the*

following time and space complexity. Here, n denotes the total number of cities and k denotes the number of cities in the interior of the convex hull. 1. In time $O(k!kn)$ *and space* $O(k)$*. 2. In time* $O(2^k k^2 n)$ *and space* $O(2^k kn)$ *[1].*

Here, assume that the convex hull of a given point set is already determined, which can be done in time $O(n \log n)$ and space $O(n)$. Further, note that the above space bounds do not count the space needed to store the input but they just count the space in working memory (as usual in theoretical computer science).

Theorem 1 implies that, from the viewpoint of parameterized complexity [2, 3, 16], these algorithms are fixed-parameter algorithms, when the number k of inner points is taken as a parameter, and hence the problem is fixed-parameter tractable (FPT). (A *fixed-parameter algorithm* has running time $O(f(k)\text{poly}(n))$, where n is the input size, k is a parameter and $f : \mathbb{N} \to \mathbb{N}$ is an arbitrary computable function. For example, an algorithm with running time $O(5^k n)$ is a fixed-parameter algorithm whereas one with $O(n^k)$ is not.) Observe that the second algorithm gives a polynomial-time exact solution to the problem when $k = O(\log n)$.

The method can be extended to some generalized versions of the TSP. For example, Deĭneko et al. [1] stated that the prize-collecting TSP and the partial TSP can be solved in a similar manner.

Applications

The theorem is motivated more from a theoretical side rather than an application side. No real-world application has been assumed.

As for the theoretical application, the viewpoint (introduced in the problem definition section) has been applied to other geometric problems. Some of them are listed below.

The Minimum Weight Triangulation Problem: Given n points in the Euclidean plane, the problem asks to find a triangulation of the points which has minimum total length. The problem is now known to be NP-hard [15]. Hoffmann and Okamoto [10] proved that the problem is fixed-parameter tractable with respect to the number k of inner points. The time complexity they gave is $O(6^k n^5 \log n)$. This is subsequently improved by Grantson, Borgelt, and Levcopoulos [6] to $O(4^k kn^4)$ and by Spillner [18] to $O(2^k kn^3)$. Yet other fixed-parameter algorithms have also been proposed by Grantson, Borgelt, and Levcopoulos [7, 8]. The currently best time complexity was given by Knauer and Spillner [13] and it is $O(2^{c\sqrt{k}\log k} k^{3/2} n^3)$ where $c = (2+\sqrt{2})/(\sqrt{3}-\sqrt{2}) < 11$.

The Minimum Convex Partition Problem: Given n points in the Euclidean plane, the problem asks to find a partition of the convex hull of the points into the minimum number of convex regions having some of the points as vertices.

Grantson and Levcopoulos [9] gave an algorithm running in $O(k^{6k-5} 2^{16k} n)$ time. Later, Spillner [19] improved the time complexity to $O(2^k k^3 n^3)$.

The Minimum Weight Convex Partition Problem: Given n points in the Euclidean plane, the problem asks to find a convex partition of the points with minimum total length.

Grantson [5] gave an algorithm running in $O(k^{6k-5} 2^{16k} n)$ time. Later, Spillner [19] improved the time complexity to $O(2^k k^3 n^3)$.

The Crossing Free Spanning Tree Problem: Given an n-vertex geometric graph (i.e., a graph drawn on the Euclidean plane where every edge is a straight line segment connecting two distinct points), the problem asks to determine whether it has a spanning tree without any crossing of the edges. Jansen and Woeginger [11] proved this problem is NP-hard.

Knauer and Spillner [12] gave algorithms running in $O(175^k k^2 n^3)$ time and $O(2^{33\sqrt{k}\log k} k^2 n^3)$ time.

The method proposed by Knauer and Spillner [12] can be adopted to the TSP as well. According to their result, the currently best time complexity for the TSP is $2^{O(\sqrt{k}\log k)}\text{poly}(n)$.

Open Problems

Currently, no lower bound result for the time complexity seems to be known. For example, is it possible to prove under a reasonable complexity-theoretic assumption the impossibility for the existence of an algorithm running in $2^{O(\sqrt{k})}\text{poly}(n)$ for the TSP?

Problem Definition

A tree is a connected graph with no cycle. A rooted tree is a tree with one designated vertex, called the root. For each vertex v except the root in a rooted tree, the parent of v is the neighbor vertex of v on the path between v and the root. If vertex p is the parent of vertex c, then c is a child of p. An ordered tree is a rooted tree in which the children of each vertex are ordered. The five ordered trees having four vertices are shown in Fig. 1. An unordered tree is a rooted tree in which the ordering of the children of each vertex does not matter. The four ordered trees having four vertices are shown in Fig. 2

Given an integer n the problem of *tree enumeration* asks for generating all ordered (or unordered) trees with n vertices. Several tree generation algorithms are explained in [3] and [2].

Key Results

Tree counting began with Cayley in 1889 to enumerate the saturated hydrocarbons, "C_nH_{2n+2}," which can be modeled as trees.

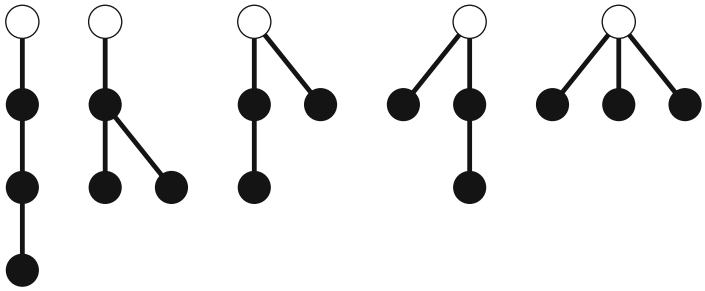
The number of ordered trees with n vertices is C_{n-1} [6], where C_n is the nth Canatal number, defined as follows:

$$C_n = \frac{{}_{2n}C_n}{n+1}$$

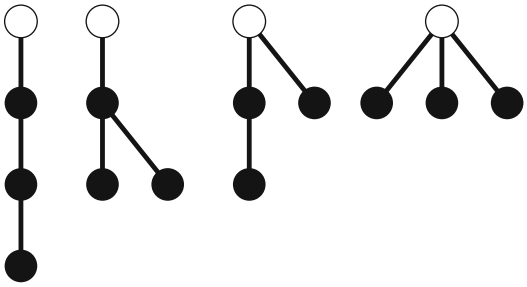
The number of binary trees with n leaves is C_n. No formula for the number of unordered trees with n vertices is known, but the number for $n \leq 40$ is listed at [6, p. 624]. There is a natural one-to-one correspondence between ordered trees with n vertices and binary tree with n leaves [3]. (For each vertex v of an ordered tree if we regard its first child and its next younger sibling as the left child and the right child of v one can have a binary tree in which the root has only one child.) So one can use enumeration algorithm for ordered trees to enumerate binary trees.

Enumeration of All Ordered Trees

Using *reverse search* method [1], one can enumerate all ordered trees with n vertices in $O(1)$ time for each [4]. We sketch the method in [4].



Tree Enumeration, Fig. 1 The ordered trees with four vertices



Tree Enumeration, Fig. 2 The unordered trees with four vertices

Let S_n be the set of all ordered trees with $n > 1$ vertices. Let T be a tree in S_n and $RP = (r_0, r_1, \ldots, r_k)$ be the "rightmost path" of T, which is the path from the root to the rightmost leaf (a leaf is a vertex having no child) such that r_i is the rightmost child of r_{i-1} for each $i = 1, 2, \ldots, k$. Removing the last vertex r_k and the edge attaching to it results in a tree with one less vertices. We repeat such removal of the last vertex of the rightmost path, until the resulting tree consists of exactly one vertex. An example of such repetitive removal is shown in Fig. 3. We call the sequence of ordered trees *the removal sequence* of T. The sequence has n trees and always ends with the tree with exactly one vertex. If we merge the removal sequences of all T in S_n, then we have the (unordered) tree T_n, called *the family tree* of S_n. An example is shown in Fig. 4. Note that T_n has all trees in S_n at its leaves.

The *reverse search* method [1] efficiently traverses the family tree (without storing the family tree in the memory) and output each tree in S_n at each leaf. Thus, we can efficiently enumerate all trees in S_n. The algorithm enumerates all ordered trees with n vertices in $O(1)$ time for each [4].

With some additional ideas, given two integers n and k, one can also enumerate all ordered trees with n vertices including k leaves in $O(1)$ time for each [7].

Enumeration of All Unordered Trees

Using a generalized version of the algorithm above, one can also enumerate all unordered trees with n vertices in $O(1)$ time for each [5]. The algorithm generates the next tree in $O(1)$ time using the "prepostorder traversal" technique [3, p. 31]. Since the ordering of the children of each vertex is not fixed we define a "canonical" ordered tree for each unordered tree and define the family tree of the canonical ordered trees. The structure of the family tree is not so simple and this result in a more complicated algorithm.

Treewidth of Graphs

Hans L. Bodlaender
Department of Computer Science, Utrecht University, Utrecht, The Netherlands

Keywords

Dimension; k-decomposable graphs; Partial k-tree

Years and Authors of Summarized Original Work

1987; Arnborg, Corneil, Proskurowski

Problem Definition

The treewidth of graphs is defined in terms of tree decompositions. A *tree decomposition* of a graph $G = (V, E)$ is a pair $(\{X_i | i \in I\}, T = (I, F))$ with $\{X_i | i \in I\}$ a collection of subsets of V, called *bags*, and T, a tree, such that

- $O(k\sqrt{\log k})$.
- For all $\{v, w\} \in E$, there is an $i \in I$ with $v, w \in X_i$.
- For all $v \in V$, the set $\{i \in I | v \in X_i\}$ induces a connected subtree of T.

The *width* of a tree decomposition is $\max_{i \in I} |X_i| - 1$, and the treewidth of a graph G is the minimum width of a tree decomposition of G (Fig. 1).

An alternative definition is in terms of chordal graphs. A graph $G = (V, E)$ is *chordal*, if and only if each cycle of length at least 4 has a chord, i.e., an edge between two vertices that are not successive on the cycle. A graph G has treewidth at most k, if and only if G is a subgraph of a chordal graph H that has maximum clique size at most k.

A third alternative definition is in terms of orderings of the vertices. Let π be a permutation (called *elimination scheme* in this context) of the vertices of $G = (V, E)$. Repeat the following step for $i = 1, \ldots, |V|$: take vertex $\pi(i)$, turn the set of its neighbors into a clique, and then remove v. The *width* of π is the maximum over all vertices of its degree when it was eliminated. The treewidth of G equals the minimum width over all elimination schemes.

In the treewidth problem, the given input is an undirected graph $G = (V, E)$, assumed to be given in its adjacency list representation, and a positive integer $k < |V|$. The problem is to decide if G has treewidth at most k and, if so, to give a tree decomposition of G of width at most k.

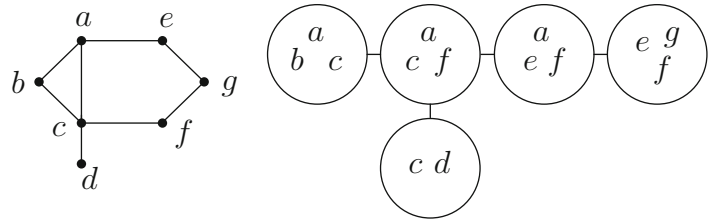
Key Results

Theorem 1 (Arnborg et al. [2]) *The problem, given a graph G and an integer k, is to decide if the treewidth of G of at most k is nondeterministic polynomial-time (NP) complete.*

For many applications of treewidth and tree decompositions, the case where k is assumed to be a fixed constant is very relevant. Arnborg et al. [2] gave in 1987 an algorithm that solves this problem in $O(n^{k+2})$ time. A number of faster algorithms for the problem with k fixed have been found; see, e.g., [6] for an overview.

Theorem 2 (Bodlaender [5]) *For each fixed k, there is an algorithm that, given a graph $G = (V, E)$ and an integer k, decides if the treewidth of G is at most k and, if so, that finds a tree decomposition of width at most k in $O(n)$ time.*

This result of Theorem 2 is of theoretical importance only: in a practical setting, the algorithm appears to be much too slow owing to the large constant factor, hidden in the Onotation. For treewidth 1, the problem is equivalent to recognizing trees. Efficient algorithms based on a small set of reduction rules exist for treewidth 2 and 3 [1].



Treewidth of Graphs, Fig. 1 A graph and a tree decomposition of width 2

Two often-used heuristics for treewidth are the *minimum fill-in* and *minimum degree* heuristic. In the *minimum degree* heuristic, a vertex v of minimum degree is chosen. The graph G', obtained by making the neighborhood of v a clique and then removing v and its incident edges, is built. Recursively, a chordal supergraph H' of G' is made with the heuristic. Then, a chordal supergraph H of G is obtained, by adding v and its incident edges from G to H'. The *minimum fill-in* heuristic works similarly, but now a vertex is selected such that the number of edges that is added to make the neighborhood of v a clique is as small as possible.

Theorem 3 (Fomin and Villanger [11]) *There is an algorithm that, given a graph $G = (V, E)$, determines the treewidth of G and finds a tree decomposition of G of minimum width that uses $O(1.7549^n)$ time.*

Bouchitté and Todinca [10] showed that the treewidth can be computed in polynomial time for graphs that have a polynomial number of minimal separators. This implies polynomial-time algorithms for several classes of graphs, e.g., permutation graphs, weakly triangulated graphs.

Applications

One of the main applications of treewidth and tree decomposition is that many problems that are intractable (e.g., NP-hard) on arbitrary graphs become polynomial time or linear time solvable when restricted to graphs of bounded treewidth. The problems where this technique can be applied include many of the classic graph and network problems, like Hamiltonian circuit, Steiner tree, vertex cover, independent set, and graph coloring, but it can also be applied to many other problems. The technique can sometimes be used for directed graphs [12]. It is also used in the algorithm by Lauritzen and Spiegelhalter [14] to solve the inference problem on probabilistic ("Bayesian," or "belief") networks. Such algorithms typically have the following form. First, a tree decomposition of bounded width is found, and then a dynamic programming algorithm is run that uses this tree decomposition. Often, the running time of this dynamic programming algorithm is exponential in the width of the tree decomposition that is used, and thus one wants to have a tree decomposition whose width is as small as possible.

There are also general characterizations of classes of problems that are solvable in linear time on graphs of bounded treewidth. Most notable is the class of problems that can be formulated in *monadic second-order logic* and extensions of these.

Treewidth has been used in the context of several applications or theoretical studies, including graph minor theory, data bases, constraint satisfaction, frequency assignment, compiler optimization, and electrical networks.

Open Problems

There are polynomial-time approximation algorithms for treewidth that guarantee a width of $\bigcup_{i \in I} X_i = V$ for graphs of treewidth k. Austrin et al. [3] show that there is no constant factor approximation for treewidth under the small set expansion conjecture. A long-standing open problem is whether there is a polynomial-time algorithm to compute the treewidth of planar graphs.

Also open is to find an algorithm for the case where the bound on the treewidth k is fixed and whose running time as a function on n is

polynomial and as a function on k improves significantly on the algorithm of Theorem 2.

The base of the exponent of the running time of the algorithm of Theorem 3 can possibly be improved.

Experimental Results

Many algorithms (upper-bound heuristics, lower-bound heuristics, exact algorithms, and preprocessing methods) for treewidth have been proposed and experimentally evaluated. An overview of many of such results is given in [10]. A variant of the algorithm by Arnborg et al. [2] was implemented by Shoikhet and Geiger [18]. Röhrig [17] has experimentally evaluated the linear-time algorithm of Bodlaender [5] and established that it is not practical, even for small values of k. The *minimum degree* and *minimum fill-in* heuristics are frequently used [13].

Data Sets

A collection of test graphs and results for many of the algorithms on these graphs can be found in the TreewidthLIB collection [7].

Problem Definition

This problem investigates the effect of the lack of input information on computational hardness. The central question under investigation is the following:

> How much extra difficulty is introduced due to the lack of input knowledge?

We explore this question by studying search problems. Suppose that on an input instance x, there is a set $S(x)$ of *solutions*. A search problem is to find a solution $s \in S(x)$ for the input x. More specifically, we consider the fairly broad class of Constraint Satisfaction Problems (CSPs): Suppose that there is an input space $\{0,1\}^n$ and a space $\Omega = \{0,1\}^m$ of candidate solutions. The problem is defined by a number of constraints $C_1, C_2, \ldots, C_m(,\ldots)$, where each $C_i : \{0,1\}^{n+m} \to \{0,1\}$ is a 0-1 function on the input and solution variables. The valid solutions for input x are defined as those s that satisfy all constraints C_i, i.e., those in $\{s : C_i(x,s) = 1, \forall i\}$. Note that the number of constraints can range from constant to polynomial, exponential, or even infinite. CSPs form a subject with intensive research in theoretical computer science, artificial intelligence, and operations research, and they provide a common basis for exploration of a large number of problems with both theoretical and practical importance.

The standard setting for CSP is to find a solution s on a given input x. Now consider the situation in which the input x is unknown. For a search problem A, denote by A_u A_u the same search problem with unknown inputs. For example, in the StableMatching problem, the input contains the preference lists of all men and women; in $\mathsf{StableMatching}_\mathsf{u}$, these preference lists are unknown to us. The constraints are that all man-woman pairs (m,w) are not blocking pairs, and the task is to find a solution that satisfies all constraints, namely, a stable matching.

The method of searching for a solution of an unknown CSP follows a trial and error approach. Trial and error is a basic methodology in problem solving and knowledge acquisition, and it has also been used extensively in product design and experiments. In our setting for CSPs, an algorithm can propose a candidate solution s. If s is not a valid solution, then we are told so by a *verification oracle* V, and furthermore, V also gives the *index* of one constraint that is not satisfied. If s is a valid solution, i.e., it satisfies all constraints, V returns an affirmative answer, and the problem is solved. Two remarks:

- If more than one constraint is violated, then (the index of) any one of them can be returned by V.
- Note that V does not reveal the constraint itself, but only its index.

Given the verification oracle V, an algorithm is an interactive process with V. The algorithm chooses candidate solutions (i.e., trials), and the oracle returns violations (i.e., errors). The process is adaptive, i.e., a newly proposed solution can be based on the historical information returned by the oracle.

Because the focus is on how much *extra* difficulty is introduced by the lack of input information for a search problem A, we single out this by comparing the unknown-input and known-

input complexities. To this end, the algorithms are equipped with another oracle, the *computation oracle*, which can solve the known-input version of the same problem A. Thus overall, trial-and-error algorithms can access two oracles, the verification oracle and the computation oracle.

The model is motivated from several applications in practice; please see [4] for more discussions.

Time Complexity

As is standard in complexity theory, a query to either oracle has a unit time cost. The *time complexity* of a problem with unknown inputs is the minimum time needed for an algorithm to solve it for all inputs and all verification oracles consistent with the input. The standard notation in computational complexity theory for complexity classes such as **P** and **NP** and also for oracles are employed. For example, $\mathsf{A}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{A}}$ means that problem A_u can be solved by a polynomial-time algorithm with verification oracle V and the computation oracle that can solve the known-input version of A. If this occurs, then one consider the extra complexity (resulting from the unknown input) not to be very high. The central question can therefore be translated to the following. Given a search problem A, is $\mathsf{A}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{A}}$? If the given known-input problem A is in **P**, then the computation oracle can be omitted, and the problem becomes "Is $\mathsf{A}_\mathsf{u} \in \mathbf{P}^{\mathsf{V}}$?"

Trial Complexity

The *trial complexity* of an unknown-input problem A_u is defined as the minimum number of queries to the verification oracle that any algorithm needs to make, regardless of its computational power. As is standard in query complexity theory, one can consider deterministic or (Las Vegas) randomized algorithms. Denote by $\mathsf{D}(A_\mathsf{u})$ and $\mathsf{R}(A_\mathsf{u})$ the deterministic and randomized trial complexities of A_u, respectively.

Key Results

The trial and time complexities of a number of problems are investigated in the trial and error model.

Theorem 1 ([4]) *For the following problems* A*, we have* $\mathsf{A}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{A}}$.

- Nash*: Find a Nash equilibrium of a normal-form game.*
- Core*: Find a core of a cooperative game.*
- StableMatching*: Find a stable matching of a two-sided market with preference lists.*
- SAT*: Find a satisfying assignment of a CNF formula.*

Nash is a fundamental problem in game theory, and its complexity has been characterized as **PPAD**-complete [6, 7]. Core is a fundamental problem in cooperative game theory [10]. Both problems are naturally defined as CSPs. Nash can be formulated as a CSP of finding a pair of mixed strategies, where the constraints are that for each player, for each strategy, adopting that strategy is not better than the current (mixed) strategy. StableMatching is a problem with interesting combinatorial structures and many applications, such as the pairing of graduating medical students with hospital residencies [11, 12]. Formally, given are two sets of elements M and W, each element having a preference list of elements in the other set. The task is to find a matching of the two sets *s.t.* No two unmatched elements (m_i, w_j) both prefer each other to the currently assigned one. In the unknown input version, the preference list of each individual is not known. The algorithm can propose a matching; if it is not stable in the above sense, then a pair (m_i, w_j) not satisfying the above property, sometimes called "blocking pair," is returned. SAT is a natural CSP, with the constraints being the OR of some literals.

Considering the practical significance of StableMatching and SAT, the next theorem takes a closer look at their trial complexities.

Theorem 2 ([4])

- $\Omega(n^2) \le \mathsf{R}(\mathsf{StableMatching}_\mathsf{u}) \le \mathsf{D}(\mathsf{StableMatching}_\mathsf{u}) \le O(n^2 \log n)$*, where* n *is the number of agents.*
- *Given a formula with* n *variables and* m *clauses,* $\mathsf{R}(\mathsf{SAT}_\mathsf{u}) \le \mathsf{D}(\mathsf{SAT}_\mathsf{u}) = O(mn)$.

Further, $\mathsf{R}(\mathsf{SAT}_\mathsf{u}) = \Omega(mn)$ *if* $m = \Omega(n^2)$, *and* $\mathsf{R}(\mathsf{SAT}_\mathsf{u}) = \Omega(m^{3/2})$ *if* $m = o(n^2)$.

It is somewhat surprising that knowing only the indices of violated constraints is already sufficient to admit quite a number of efficient algorithms. It is therefore natural to wonder whether the lack of input information adds any extra difficulty at all in any problem. The answer turns out to be affirmative: there are problems whose unknown-input versions are considerably more difficult than their known versions. Two representatives are GraphIso and GroupIso, the problems of deciding whether two given graphs or groups are isomorphic.

Theorem 3 ([4])

- *If* $\mathsf{GraphIso}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{GraphIso}}$, *then the polynomial hierarchy (***PH***) collapses to the second level.*
- *If* $\mathsf{GroupIso}(\cdot, \mathbb{Z}_p)_\mathsf{u} \in \mathbf{P}^{\mathsf{V}}$, *then we have* $\mathbf{P} = \mathbf{NP}$. *(Here,* $\mathsf{GroupIso}(\cdot, \mathbb{Z}_p)$ *is the group isomorphism problem with the second group known as* $\mathbb{Z}_p$ *for a prime* p.*) If* $\mathsf{GroupIso}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{GroupIso}}$, *then we have* $\mathbf{NP} \subseteq \mathbf{P}^{O(\log n)}$.

However, if SAT *is given as the computation oracle, then deterministic polynomial-time algorithms exist for* GraphIso *and* GroupIso, *i.e.,* $\mathsf{GraphIso}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{SAT}}$ *and* $\mathsf{GroupIso}_\mathsf{u} \in \mathbf{P}^{\mathsf{V},\mathsf{SAT}}$, *with* $O(n^2)$ *and* $O(n^6)$ *trials, respectively.*

Note that $\mathsf{GroupIso}(\cdot, \mathbb{Z}_p)$ (with a known input) admits a simple polynomial-time algorithm by comparing the multiplication tables. Actually, GroupIso is in **P** if the two groups are Abelian. However, if the multiplication table of the input group is unknown, then surprisingly, the problem becomes **NP**-hard. Putting the computational hardness and the low trial complexity together, one can see that if more computational time (enough to solve an **NP** problem) is given, then less trials are needed. This interesting trade-off between the two complexity measures is not commonly seen in other query models.

Finally, beyond all of the foregoing problems that can be solved in $\mathbf{P}^{\mathsf{V},\mathsf{SAT}}$, one can show via an information theoretical argument that the following two problems have exponential lower bounds for the randomized trial complexity.

- LinearProgramming: Find a feasible solution of a linear program with n variables and m constraints.
- SubsetSum: Decide whether a given set of n integers can be partitioned into two parts with equal summation of elements.

Theorem 4 ([4,5])

- $\mathsf{R}(\mathsf{LinearProgramming}_\mathsf{u}) = \Omega(m^{\lfloor n/2 \rfloor})$.
- $\mathsf{R}(\mathsf{SubsetSum}_\mathsf{u}) = \Omega(2^n)$.

The approaches for Nash and LP are actually similar, yet the running time differs significantly. The key property that guarantees the efficiency of the algorithm for Nash is the existence of Nash equilibrium for any finite game. The algorithm for Nash could thus serve as an interesting example to illustrate how the solution-existing property helps computational efficiency.

Moreover, the following time complexity upper bound for $\mathsf{LinearProgramming}_\mathsf{u}$ is established, which is exponential in the number of variables but not in the number of constraints.

Theorem 5 ([5]) *The* $\mathsf{LinearProgramming}_\mathsf{u}$ *problem with* m *constraints,* n *variables, and input size* L *can be deterministically solved in time* $(mnL)^{poly(n)}$. *In particular, the algorithm is of polynomial time for constant dimensional linear programming (i.e., constant number of variables* n*).*

In summary, these results illustrate the variety of time and trial complexities that arise from the lack of input information for different problems and imply distinct levels of the cruciality of input information for different problems.

Related Work

The trial and error model bears a resemblance to certain other problems and models, e.g., learning,

algorithm design in unknown environments, ellipsoid method, and query complexity. However, there are fundamental distinctions between these models and ours. (More discussions are referred to [4].)

Learning

Trial and error model has apparent connections to various learning theories (e.g., concept learning with membership or equivalence query [1], decision tree learning, reinforcement learning [3], and (semi-)supervised learning [2]), but fundamental differences also exist. A common high-level philosophy of various learning models is to "sample and predict," which is very different from our "trial and search" (for a solution) in current setting. With its solution-oriented objective and advantages in computational efficiency, the trial and error model is hopefully to serve as a useful supplement to existing learning theories, particularly in contexts in which the unknown object itself is impossible or unaffordable to learn and the only available access to the unknown is through a solution-verification process.

Ellipsoid Method

The ellipsoid method is an elegant approach for proving the polynomial time solvability of a class of combinatorial optimization problems (see, e.g., [8]); it applies even when the explicit expressions of the constraints are unknown. The algorithm works as long as there exists an oracle that, on a proposed candidate solution, returns a violation in the form of a separating hyperplane.

In general, trial and error model has a similarity to the ellipsoid method, in which a point is proposed as a trial and a separating hyperplane is returned as an error. Our $\mathsf{LinearProgramming}_{\mathsf{u}}$ problem studies how to solve linear programs where the returned error is merely the *index* of a violated hyperplane (with the actual hyperplane still hidden). Moreover, the trial and error model includes a much broader class of search problems – not only convex optimization problems, but also many with pure combinatorial structures (e.g., the SAT, GroupIso, and GraphIso problems discussed here). From this perspective, the ellipsoid method is only one possible approach for the trial and error search problems in current model.

Problem Definition

The main problem consists in designing space-efficient data structures allowing to represent the connectivity of triangle meshes while supporting fast navigation and local updates.

Mesh Structures: Definition

Triangle meshes are among the most common representations of shapes. A *triangle mesh* is a collection of triangle faces that define a polyhedral approximation of a surface. A mesh is *manifold* if every edge is bounding either one or two triangles and if the faces incident to a same vertex define a closed or open fan. Here we focus on manifold meshes. Assuming that the genus and the number of boundary edges are negligible when compared to the number n of vertices, the number m of faces is roughly equal to $2n$.

Data Structures: Classification

Mesh data structures can be compared with respect to several criteria. A basic requirement (the *traversability*) for mesh representations is to provide fast navigational operators allowing to perform a mesh traversal (such as walking around a vertex). Most representations are also *indexable*, allowing to access in constant time to the description of a given vertex or triangle, given its index. In order to support efficient processing of large meshes, one needs to reduce memory trashing during navigation. An effective way of doing so is to design *compact data structures* requiring small storage. Many applications ask for the *modifiability*: the manipulation of meshes requires to perform updates such as vertex insertions/deletions, edge collapses, and edge flips. The choice of the data structure should also depend on the *simplicity* of its implementation and on its *practical efficiency* on common input data.

Standard Mesh Representations

Some common mesh representations are implemented in the explicit pointer-based form. References are used to describe incidence relations between mesh elements, and navigation is performed throughout address indirection. For example, a face-based representation [2] provides operators $\texttt{vertex}(\triangle, i)$ (giving the ith vertex of a triangle $\triangle$) and $\texttt{neighbor}(\triangle, i)$ (giving the i-neighbor of $\triangle$), as well as operator $\texttt{face}(v)$ (returning a triangle incident to vertex v). As illustrated in Fig. 1a, the combination of these operators allows to implement operators $\texttt{faceIndex}(\triangle_1, \triangle_2)$ (giving the index of $\triangle_1$ among the neighbors of $\triangle_2$) and $\texttt{vertexIndex}(v, \triangle)$ (giving the index of a vertex in $\triangle$). An alternative solution is given by the *Corner Table* proposed by Rossignac and colleagues, which uses integer indices to integer tables and provides a triangulation interface involving the corner operators defined in Fig. 2.

The two abstract data types above fully support local navigation in the mesh: the face-based as well as corner operators support efficient mesh exploration (see Figs. 1 and 2). A simple implementation stores explicitly all incidence

Triangulation Data Structures, Fig. 1 (**a**) Triangle-based data structure: each triangle stores references to the 3, neighbors and to the 3 incident vertices yielding $13rpv$. (**b**) Catalog-based representation: using a catalog of size 3 one can guarantee that any quad is adjacent to at most two other quads, leading to a cost of $8.5\,rpv$

relations involving faces or corners, using 6 references per triangle plus one reference per vertex (describing the map from vertices to faces): according to Euler formula, this leads to a storage cost of 13 *references per vertex* (rpv). The results of `triangle`(c) and `next`(c) are not stored explicitly but calculated assuming that the three corners of each triangle are assigned consecutive indices.

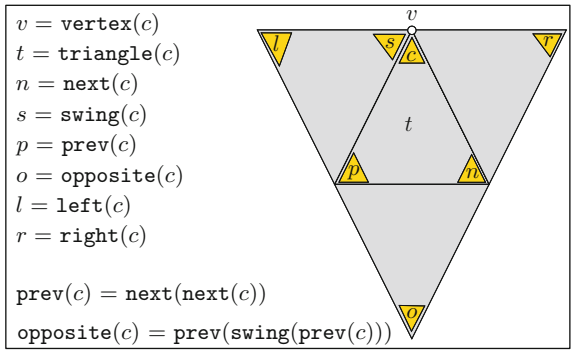
Key Results

A Theoretically Optimal Representation

From the information theory point of view, encoding a planar triangulation requires 3.24 *bits per vertex* (bpv), which is much less than the $13 \log n\, bpv$ used by standard representations. *Succinct representations* provide theoretically optimal encodings for triangulations, which match the optimal asymptotic bound of $3.24\,bpv$ (or equivalently $1.62m$ bits), while efficiently supporting navigational operations [4, 5], as stated below.

Theorem 1 *Given a planar triangulation $\mathcal{T}$ of m triangles, there exists a succinct representation that uses $1.62m + O\left(\frac{m \log\log m}{\log m}\right)$ bits, supporting navigation in worst case $O(1)$ time.*

This result is achieved with a multilevel hierarchical structure. The initial triangulation of size m is decomposed into *small triangulations*, each having $\Theta(\log^2 m)$ triangles: such a decomposition leads to a map $\mathcal{F}$ describing adjacency relations between small triangulations. Small triangulations are then decomposed into *tiny triangulations* of size $\Theta(\log m)$, whose adjacency relations are described by a map $\mathcal{G}$. Map $\mathcal{F}$ has $O\left(\frac{m}{\log^2 m}\right)$ nodes and



```
int c = seed;
visited[vertex(next(c))] = true;
visited[vertex(previous(c))] = true;
do {
   if(!visited[vertex(c)]){
     visited[vertex(c)] = true;
     explored[triangle(c)] = true;
   }
  else if(!explored[triangle(c)]) c = opposite(c);
  c = right(c);
}while(c! = opposite(s));
```

Triangulation Data Structures, Fig. 2 The *Corner Table*: corner operators allow to implement local navigation, as illustrated by the code of the *Ring-Expander* procedure [10]

arcs and can be stored in sublinear space using $O\left(\frac{m}{\log^2 m}\right)$ references of size $O(\log m)$ (actually $O\left(\log \frac{m}{\log^2 m}\right) < O(\log m)$). Map $\mathcal{G}$ has $O\left(\frac{m}{\log m}\right)$ nodes and arcs: adjacencies between two tiny triangulation within the same small triangulation need references of size $O\left(\log \frac{\log^2 m}{\log m}\right) = O(\log \log m)$ while adjacencies crossing the small triangulation boundaries are accessed by referring to $\mathcal{F}$. In that way the storage of both $\mathcal{F}$ and $\mathcal{G}$ is sublinear. The structure of tiny triangulations is optimally encoded throughout lookup into a table storing all possible triangulations of size $O(\log m)$. Such a framework can be extended in order to support updates: vertex deletions and edge flips are performed in $O(\log^2 m)$ amortized time (vertex insertions require $O(1)$ amortized time). The optimality stated by Theorem 1 is obtained combining the two-level representation with a careful decomposition of the mesh into tiny regions, involving a bijection between triangulations and a special class of vertex spanning trees [13].

A different approach, based on small separators, leads to compact representations [1] using $O(n)$ bits for more general classes of meshes (storage performances are difficult to evaluate precisely).

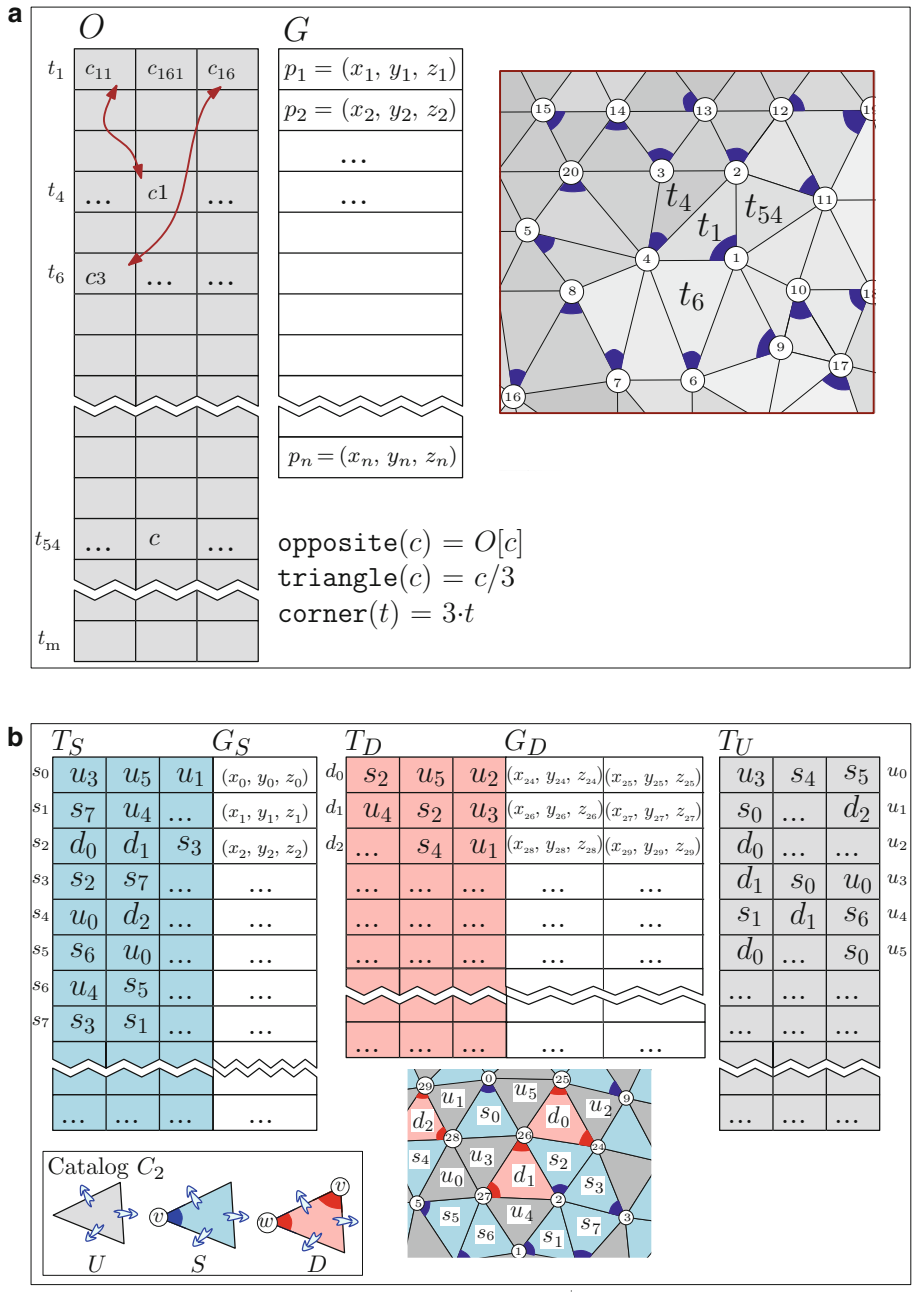
A More Practical Solution

Succinct representations run under the *word-RAM model* and are mainly of theoretical interest, since the amount of memory required in practice is quite important even for very large meshes. Some attempts to exploit the algorithmic framework of succinct representations in practice had lead to a space-efficient dynamic data structure [6]. The main idea is to gather together neighboring faces into small groups of triangles (called *patches*). While references are still of size $\Theta(\log n)$, grouping triangles allows to save some references (corresponding to edges internal to a given patch). For example, using a catalog consisting only of triangles and quadrangles, we encode a triangulation with at most $10.6\,rpv$ (a 19 % improvement over simple representations mentioned earlier). More sophisticated choices of patches lead to dynamic structures with smaller storage (e.g., Fig. 1b), as stated below:

Theorem 2 *Given a triangulation (possibly having handles and boundaries), there exists a data structure using* $7.67\,rpv$*, which allows* $O(1)$ *time navigation and supports updates in* $O(1)$ *amortized time.*

Reducing Redundancy Throughout Face Reordering

The main idea used in the SOT data structure [8] is to implicitly represent the map from triangles to corners (`triangle` operator), and the map from corners to vertices (`vertex` operator), through face reordering. First, match each vertex to an incident triangle (in such a way a triangle is matched with at most one vertex). Then permute triangles in such a way that the triangle associated



Triangulation Data Structures, Fig. 3 Illustrations of the SOT (**a**) and ESQ (**b**) data structures

with the ith vertex v_i has number i (thus, the first n triangles appearing in this ordering are the ones associated with a vertex). The corners of a triangle are listed consecutively, and the first one corresponds to the vertex matched for the triangle. The incidence relations are stored in an array O (of length $3m$) having 3 entries per triangle: $O[i]$ stores the index of the corner opposite to c_i (which is matched to vertex v_i, for $i \leq m$). Corner operators are supported in $O(1)$ time performing arithmetic operations (see Fig. 3a). Accessing a vertex v_i requires to walk

around its incident faces until c_i is reached (v_i being matched to c_i).

Theorem 3 ([8]) *Given a triangulation (possibly having handles and boundaries), there exists a data structure using* $6\,rpv$ *which supports* $O(1)$ *time navigation (retrieving a vertex of degree* d *requires* $O(d)$ *time).*

More Compact (Static) Representations

Combining this reordering approach with a pairing of adjacent triangles into quads, the SQUAD data structure [9] reaches better storage requiring slightly more than $4\,rpv$ according to experimental results on common meshes (the worst case upper bound is still $6\,rpv$). If one is allowed to perform a reordering of the input vertices, it is possible to guarantee a storage of $4\,rpv$ in the worst case (with same time performances as before): the edge-based representation described in [3] matches this bound exploiting Schnyder woods decompositions [14]. Various heuristics allows to further reduce storage requirements in practice [10–12].

A Dynamic Representation

Combining the reordering approach described above with the decomposition into triangle patches, the ESQ data structure [7] exhibits the same navigation performances as in SOT, while supporting local updates. As in [6] the mesh is decomposed into a collection of patches, each consisting of one or more triangles, and vertices are matched to patches. The assumption that each vertex is matched to a different triangle is relaxed. The catalog thus consists of a collection of k patch types (having possible one or more marked corners, describing how vertices are matched). Adjacency relations between faces are stored in k tables $T_1, \ldots, T_k$, one for each patch type (see Fig. 3b). Extending the approach introduced in SOT, a reordering of the input vertices allows to represent the maps from vertices to triangles and from triangles to vertices. A table T_S of type $S = (c, b)$ (with b boundary edges and c matched vertices) contains b references for each entry; the entries in the associated table G_S (containing geometric coordinates) are ordered accordingly. The decomposition into patches is maintained under local modifications with a constant number of memory updates in tables T_i.

Theorem 4 ([7]) *Given a triangulation (possibly having handles and boundaries), there exists a dynamic data structure using* $4.8\,rpv$*, which allows* $O(1)$ *time navigation and* $O(d)$ *time access to a vertex of degree* d*. Updates (vertex insertions/deletions and edge flips) are supported in* $O(1)$ *amortized time.*

Experimental Results

In [9] are reported timing comparisons of operators for SOT, SQUAD, and Corner Table data structures: experimental evaluations concern adjacency and navigational operations. On the tested mesh (the 55 millions triangles David), SQUAD requires 20 s and uses 2.2 GB of RAM for the construction (on a MacbookPro, equipped with 2.66 GHz Intel Core i7, 8 GB). When the whole mesh fits in main memory, compact data structures (SQUAD and SOT) perform slower than Corner Table. When the allowed memory is reduced, SQUAD performances are comparable and sometimes even better than Corner Table performances for high-level tasks (e.g., valence computations).

Problem Definition

This problem is concerned with designing truthful (dominant strategy) mechanisms for domains where each agent's private information is expressed by a single positive real number. The goal of the mechanisms is to allocate loads placed on the agents, and an agent's private information is the cost incurred per unit load. Archer and Tardos [4] give an exact characterization for the algorithms that can be used to design truthful mechanisms for such load balancing problems using appropriate payments. The characterization shows that the allocated load must be monotonic in the cost (decreasing when the cost on an agent increases, fixing the costs of the others). Thus, truthful mechanisms are characterized by a condition on the allocation rule, and payments that ensure voluntary participation can be calculated using the given characterization.

The characterization is used to design polynomial time truthful mechanisms for several problems in combinatorial optimization to which the celebrated VCG mechanism does not apply. For scheduling related parallel machines to minimize makespan ($Q\|C_{\max}$), Archer and Tardos [4] present a 3-approximation mechanism based on randomized rounding of the optimal fractional solution. This mechanism is truthful only in expectation (a weaker notion of truthfulness in which truthful bidding maximizes the agent's *expected* utility). Archer [3] improves it to a randomized 2-approximation truthful mechanism. Andelman, Azar, and Sorani [2] provide a deterministic truthful mechanism that is 5-approximation. Kovács improves it to 3-approximation in [12] and to 2.8-approximation in [13] (Kovács also gives other results for two special cases). Andelman, Azar, and Sorani [2] also present a deterministic Fully Polynomial Time Approximation Scheme (FPTAS) for scheduling on a fixed number of machines, as well as a suitable payment

scheme that yields a deterministic truthful mechanism. Dhangwatnotai et al. [8] present a randomized Polynomial Time Approximation Scheme (PTAS) that is truthful-in-expectation. Christodoulou and Kovács [7] present a truthful deterministic Polynomial Time Approximation Scheme (PTAS); this matches the best possible result for the computational problem (without incentives) by Hochbaum and Shmoys [10] (it is known that this problem is strongly NP-hard [9]). This result shows that there is no "cost of truthfulness" for this problem, as the best approximation with incentive constraints is as good as the best approximation without these constraints.

Archer and Tardos [4] also present results for goals other than minimizing the makespan. They present a truthful mechanism for $Q \| \sum C_j$ (scheduling related machines to minimize the sum of completion times) and show that for $Q \| \sum w_j C_j$ (minimizing the weighted sum of completion times) $\frac{2}{\sqrt{3}}$ is the best approximation ratio achievable by a truthful mechanism.

This family of problems belongs to the field of Algorithmic Mechanism Design, initiated in the seminal paper of Nisan and Ronen [15]. Nisan and Ronen consider makespan minimization for scheduling on *unrelated* machines and prove upper and lower bounds (note that for unrelated machines agents have more than one parameter). Mu'alem and Schapira [14] present improved lower bounds. Other papers consider the problem of scheduling on related machines to minimize the makespan. Auletta et al. [5] and Ambrosio and Auletta [1] present truthful mechanisms for several NP-hard restrictions of this problem. Nisan and Ronen [15] also introduce a model in which the mechanism is allowed to observe the machines' actual processing time and compute the payments afterward (in such a model the machines essentially cannot claim to be faster than they are); Auletta et al. [6] present additional results for this model. In particular, they show that it is possible to overcome the lower bound of $\frac{2}{\sqrt{3}}$ for $Q \| \sum w_j C_j$ (minimizing the weighted sum of completion times) and provide a polynomial time $(1+\epsilon)$-approximation truthful mechanism (with verification) when the number of machines (m) is constant.

The Mechanism Design Framework

Let I be the set of agents. Each agent $i \in I$ has some private *value* (type) consisting of a single parameter $t_i \in \mathbb{R}$ that describes the agent, and which only i knows. Everything else is public knowledge. Each agent will report a *bid* b_i to the mechanism. Let t denote the vector of true values, and b the vector of bids.

There is some set of *outcomes* O, and given the bids b the mechanism's output algorithm computes an outcome $o(b) \in O$. For any types t, the mechanism aims to choose an outcome $o \in O$ that minimizes some function $g(o,t)$. Yet, given the bids b the mechanism can only choose the outcome as a function of the bids ($o = o(b)$) and has no knowledge of the true types t. To overcome the problem that the mechanism knows only the bids b, the mechanism is designed to be truthful (using payments), that is, in such a mechanism it is a dominant strategy for the agents to reveal their true types ($b = t$). For such mechanisms minimizing $g(o,t)$ is done by assuming that the bids are the true types (and this is justified by the fact that truth telling is a dominant strategy).

In the framework discussed here we assume that outcome $o(b)$ will assign some amount of *load* or work $w_i(o(b))$ to each agent i, and given $o(b)$ and t_i, agent i incurs some monetary *cost*, $cost_i(t_i, o(b)) = t_i w_i(o(b))$. Thus, agent i's private data t_i measures her cost per unit work. Each agent i attempts to maximize her *utility* (profit), $u_i(t_i, b) = P_i(b) - cost_i(t_i, o(b))$, where $P_i(b)$ is the *payment* to agent i.

Let b_{-i} denote the vector of bids, not including agent i, and let $b = (b_{-i}, b_i)$. Truth telling is a *dominant strategy* for agent i if bidding t_i always maximizes her utility, regardless of what the other agents bid. That is, $u_i(t_i, (b_{-i}, t_i)) \geq u_i(t_i, (b_{-i}, b_i))$ for all b_{-i} and b_i.

A mechanism M consists of the pair $M = (o(\cdot), P(\cdot))$, where $o(\cdot)$ is the *output function* and $P(\cdot)$ is the *payment scheme*, i.e., the vector of payment functions $P_i(\cdot)$. An output function *admits a truthful payment scheme* if there exist payments $P(\cdot)$ such that for the mechanism $M = (o(\cdot), P(\cdot))$, truth telling is a dominant

strategy for each agent. A mechanism that admits a truthful payment scheme is *truthful*.

Mechanism M satisfies the *voluntary participation* condition if agents who bid truthfully never incur a net loss, i.e., $u_i(t_i, (b_{-i}, t_i)) \geq 0$ for all agents i, true values t_i, and other agents' bids b_{-i}.

Definition 1 With the other agents' bids b_{-i} fixed, the *work curve* for agent i is $w_i(b_{-i}, b_i)$ considered as a single-variable function of b_i. The output function o is *decreasing* if each of the associated work curves is decreasing (i.e., $w_i(b_{-i}, b_i)$ is a decreasing function of b_i, for all i and b_{-i}).

Scheduling on Related Machines

There are n jobs and m machines. The jobs represent amounts of work $p_1 \geq p_2 \geq \ldots \geq p_n$, and let p denote the set of jobs. Machine i runs at some speed s_i, so it must spend p_j/s_i units of time processing each job j assigned to it. The input to an algorithm is b, the (reported) speed of the machines, and the output is $o(b)$, an assignment of jobs to machines. The load on machine i for outcome $o(b)$ is $w_i(b) = \sum p_j$, where the sum runs over jobs j assigned to i. Each machine incurs a cost proportional to the time it spends processing its jobs. The cost of machine i is $cost_i(t_i, o(b)) = t_i w_i(o(b))$, where $t_i = 1/s_i$ and $w_i(b)$ is the total load assigned to i when the speeds are b. Let C_j denote the completion time of job j. One can consider the following goals for scheduling related parallel machines:

- Minimizing the makespan $(Q\|C_{\max})$, the mechanism's goal is to minimize the completion time of the last job on the last machine, i.e., $g(o,t) = C_{\max} = \max_i t_i \cdot w_i(b)$.
- Minimize the sum of completion times $(Q\|\sum C_j)$, i.e., $g(o,t) = Q\|\sum C_j = \sum_j C_j$
- Minimize the weighted sum of completion times $(Q\|\sum w_j C_j)$, i.e., $g(o,t) = Q\|\sum w_j C_j = \sum_j w_j C_j$ where w_j is the weight of job j.

An algorithm is a *c-approximation algorithm* with respect to g, if for every instance (p,t), it outputs an outcome of cost at most $c \cdot g(o(t),t)$. A *c-approximation mechanism* is a mechanism whose output algorithm is an c-approximation. Note that if the mechanism is truthful the approximation is with respect to the true speeds. A *PTAS* (Polynomial Time Approximation Scheme) is a family of algorithms such that for every $\epsilon > 0$ there exists a $(1+\epsilon)$-approximation algorithm. If the running time is also polynomial in $1/\epsilon$, the family of algorithms is a *FPTAS* (Fully Polynomial Time Approximation Scheme).

Key Results

The following two theorems hold for the mechanism design framework as defined in section "Problem Definition."

Theorem 1 ([4]) *The output function $o(b)$ admits a truthful payment scheme if and only if it is decreasing. In this case, the mechanism is truthful if and only if the payments $P_i(b_{-i}, b_i)$ are of the form*

$$h_i(b_{-i}) + b_i w_i(b_{-i}, b_i) - \int_0^{b_i} w_i(b_{-i}, u)du$$

where the h_i are arbitrary functions.

Theorem 2 ([4]) *A decreasing output function admits a truthful payment scheme satisfying voluntary participation if and only if $\int_0^\infty w_i(b_{-i}, u)du < \infty$ for all i, b_{-i}. In this case, the payments can be defined by*

$$P_i(b_{-i}, b_i) = b_i w_i(b_{-i}, b_i) + \int_{b_i}^\infty w_i(b_{-i}, u)du$$

Theorem 3 ([4]) *There is a truthful mechanism (not polynomial time) that outputs an optimal solution for $Q\|C_{\max}$ and satisfies voluntary participation.*

Theorem 4 ([2, 7]) *For the problem of minimizing the makespan $(Q\|C_{\max})$:*

- *There exists a deterministic Polynomial Time Approximation Scheme (PTAS) for scheduling*

on related machines that admits a truthful payment scheme [7]. The mechanism created satisfies voluntary participation.

- *There exists a deterministic Fully Polynomial Time Approximation Scheme (FPTAS) for scheduling on a* fixed *number of machines that admits a truthful payment scheme [2]. The mechanism created satisfies voluntary participation.*

Theorem 5 ([4]) *There is a truthful polynomial time mechanism that outputs an optimal solution for* $Q \| \sum C_j$ *and satisfies voluntary participation.*

Theorem 6 ([4]) *No truthful mechanism for* $Q \| \sum w_j C_j$ *can achieve an approximation ratio better than* $\frac{2}{\sqrt{3}}$*, even on instances with just two jobs and two machines.*

Applications

Archer and Tardos [4] apply the characterization of truthful mechanisms to problems other than scheduling. They present results for the uncapacitated facility location problem as well as the maximum flow problem.

Kis and Kapolnai [11] consider the problem of scheduling of groups of identical jobs on related machines with sequence independent setup times ($Q|u_j, p_{jk} = p_j \| C_{\max}$). They provide a truthful, polynomial time, randomized mechanism for the batch scheduling problem with a deterministic approximation guarantee of 4 to the minimal makespan, based on the characterization of truthful mechanisms presented above.

Open Problems

The problem of designing truthful mechanisms for related machines to minimize the makespan was completely resolved, as a deterministic PTAS [7] is the best one can hope for. For this problem there is no gap between the best approximation with and without incentives. The main open problem left is of finding some natural single-parameter setting in which there is a gap between the approximation that is achievable by algorithms and truthful mechanisms.

Problem Definition

Several mechanisms [1, 3, 5, 9], which essentially all belong to the VCG mechanism family, have been proposed in the literature to prevent the selfish behavior of unicast routing in a wireless network. In these mechanisms, the least cost path, which maximizes the social efficiency, is used for routing. Wang, Li, and Wang [8] studied the *truthful* multicast routing protocol for a selfish wireless network, in which selfish wireless terminals will follow their own interests. The multicast routing protocol is composed of two components: (1) the tree structure that connects the sources and receivers, and (2) the payment to the relay nodes in this tree. Multicast poses a unique challenge in designing strategyproof mechanisms due to the reason that (1) a VCG mechanism uses an output that maximizes the *social efficiency*; (2) it is NP-hard to find the tree structure with the minimum cost, which in turn maximizes the social efficiency. A range of multicast structures, such as the least cost path tree (LCPT), the pruning minimum spanning tree (PMST), virtual minimum spanning tree (VMST), and Steiner tree, were proposed to replace the optimal multicast tree. In [8], Wang et al. showed how payment schemes can be designed for existing multicast tree structures so that rational selfish wireless terminals will follow the protocols for their own interests.

Consider a communication network $G = (V, E, c)$, where $V = \{v_1, \cdots, v_n\}$ is the set of communication terminals, $E = \{e_1, e_2, \cdots, e_m\}$ is the set of links, and c is the cost vector of all agents. Here agents are terminals in a node weighted network and are links in a link weighted network. Given a set of sources and receivers $Q = \{q_0, q_1, q_2, \cdots, q_{r-1}\} \subset V$, the multicast problem is to find a tree $T \subset G$ spanning all terminals Q. For simplicity, assume that $s = q_0$ is the sender of a multicast session if it exists. All terminals or links are required to declare a cost of relaying the message. Let d be the declared costs of all nodes, i.e., agent i declared a cost d_i. On the basis of the declared cost profile d, a multicast tree needs to be constructed and the payment $p_k(d)$ for each agent k needs to be

decided. The utility of an agent is its payment received, minus its cost if it is selected in the multicast tree. Instead of reinventing the wheels, Wang et al. still used the previously proposed structures for multicast as the output of their mechanism. Given a multicast tree, they studied the design of strategyproof payment schemes based on this tree.

Notations

Given a network H, $\omega(H)$ denotes the total cost of all agents in this network. If the cost of any agent i (link e_i or node v_i) is changed to c'_i, the new network is denoted as $G' = (V, E, c|^i c'_i)$, or simply $c|^i c'_i$. If one agent i is removed from the network, it is denoted as $c|^i \infty$. For the simplicity of notation, the cost vector c is used to denote the network $G = (V, E, c)$ if no confusion is caused. For a given source s and a given destination q_i, $\mathsf{LCP}(s, q_i, c)$ represents the shortest path between s and q_i when the cost of the network is represented by vector c. $|\mathsf{LCP}(s, q_i, d)|$ denotes the total cost of the least cost path $\mathsf{LCP}(s, q_i, d)$. The notation of several multicast trees is summarized as follows.

1. Link Weighted Multicast Tree
   - **LCPT**: The union of all least cost paths from the source to receivers is called the *least cost path tree*, denoted by *LCPT*(*d*).
   - **PMST**: First construct the minimum spanning tree *MST*(*G*) on the graph *G*. Take the tree *MST*(*G*) rooted at sender *s*, prune all subtrees that do not contain a receiver. The final structure is called the Pruning Minimum Spanning Tree (PMST).
   - **LST**: The Link Weighted Steiner Tree (LST) can be constructed by the algorithm proposed by Takahashi and Matsuyama [6].
2. Node Weighted Multicast Tree
   - **VMST**: First construct a virtual graph using all receivers plus the sources as the vertices and the cost of LCP as the link weight. Then compute the minimum spanning tree on the virtual graph, which is called virtual minimum spanning tree (VMST). Finally, choose all terminals on the VMST as the relay terminals.
   - **NST**: The node weighted Steiner tree (NST) can be constructed by the algorithm proposed by [4].

Algorithm 1 Non-VCG mechanism for LCPT

1: For each receiver $q_i \neq s$, computes the least cost path from the source s to q_i, and compute a payment $p_k^i(d)$ to every link e_k on the $\mathsf{LCP}(s, q_i, d)$ using the scheme for unicast

$$p_k^i(d) = d_k + |\mathsf{LCP}(s, q_i, d|^k \infty)| - |\mathsf{LCP}(s, q_i, d)|.$$

2: The final payment to link $e_k \in LCPT$ is then

$$p_k(d) = \max_{q_i \in Q} p_k^i(d). \quad (1)$$

The payment to each link not on LCPT is simply 0.

Key Results

If the LCPT tree is used as the multicast tree, Wang et al. proved the following theorem.

Theorem 1 *The VCG mechanism combined with LCPT is not truthful.*

Because of the failure of the VCG mechanism, they designed their non-VGC mechanism for the LCPT-based multicast routing as follows.

Theorem 2 *Payment (defined in Eq. (1)) based on LCPT is truthful and it is minimum among all truthful payments based on LCPT.*

More generally, Wang et al. [8] proved the following theorem.

Theorem 3 *The VCG mechanism combined with either one of the LCPT, PMST, LST, VMST, NST is not truthful.*

Because of this negative result, they designed their non-VCG mechanisms for all multicast structures they studied: LCPT, PMST, LST, VMST, NST. For example, Algorithm 2 is the algorithm for PMST. For other algorithms, please refer to [8].

Algorithm 2 Non-VCG mechanism for PMST

1: Apply VCG mechanism on the MST. The payment for edge $e_k \in PMST(d)$ is

$$p_k(d) = \omega(MST(d|^k \infty)) - \omega(MST(d)) + d_k. \quad (2)$$

2: For every edge $e_k \notin PMST(d)$, its payment is 0.

Regarding all their non-VGC mechanisms, they proved the following theorem.

Theorem 4 *The non-VCG mechanisms designed for the multicast structures LCPT, PMST, LST, VMST, NST are not only truthful, but also achieve the minimum payment among all truthful mechanisms.*

Applications

In wireless ad hoc networks, it is commonly assumed that, each terminal contributes its local resources to forward the data for other terminals to serve the common good, and benefits from resources contributed by other terminals to route its packets in return. On the basis of such a fundamental design philosophy, wireless ad hoc networks provide appealing features such as enhanced system robustness, high service availability and scalability. However, the critical observation that individual users who own these wireless devices are generally selfish and noncooperative may severely undermine the expected performances of the wireless networks. Therefore, providing incentives to wireless terminals is a must to encourage contribution and thus maintains the robustness and availability of wireless networking systems. On the other hand, to support a communication among a group of users, multicast is more efficient than unicast or broadcast, as it can transmit packets to destinations using fewer network resources, thus increasing the social efficiency. Thus, most results of the work of Wang et al. can apply to multicast routing in wireless networks in which nodes are selfish. It not only guarantees that multicast routing behaves normally but also achieves good social efficiency for both the receivers and relay terminals.

Open Problems

There are several unsolved challenges left as future work in [8]. Some of these challenges are listed below.

- How to design algorithms that can compute these payments in asymptotically optimum time complexities is presently unknown.
- Wang et al. [8] only studied the tree-based structures for multicast. Practically, mesh-based structures may be more needed for wireless networks to improve the fault tolerance of the multicast. It is unknown whether a strategyproof multicast mechanism can be designed for some mesh-based structures used for multicast.
- All of the tree construction and payment calculations in [8] are performed in a centralized way, it would be interesting to design some distributed algorithms for them.
- In the work by Wang et al. [8] it was assumed that the receivers will always relay the data packets for other receivers for free, the source node of the multicast will pay the relay nodes to compensate their cost, and the source node will not charge the receivers for getting the data. As a possible future work, the budget balance of the source node needs to be considered if the receivers have to pay the source node for getting the data.
- Fairness of payment sharing needs to be considered in a case where the receivers share the total payments to all relay nodes on the multicast structure. Notice that this is different from the cost-sharing studied in [2], in which they assumed a fixed multicast tree, and the link cost is publicly known; in that work they showed how to share the total link cost among receivers.
- Another important task is to study how to implement the protocols proposed in [8] in a distributed manner. Notice that, in [3, 9],

distributed methods have been developed for a truthful unicast using some cryptography primitives.

TSP-Based Curve Reconstruction

Edgar Ramos
School of Mathematics, National University of Colombia, Medellín, Colombia

Years and Authors of Summarized Original Work

2001; Althaus, Mehlhorn

Problem Definition

An instance of the curve reconstruction problem is a finite set of *sample* points V in the plane, which are assumed to be taken from an unknown planar curve γ. The task is to construct a geometric graph G on V such that two points in V are connected by an edge in G if and only if the points are adjacent on γ. The curve γ may consist of one or more connected components, and each of them may be closed or open (with endpoints), and may be smooth everywhere (tangent defined at every point) or not.

Many heuristic approaches have been proposed to solve this problem. This work continues a line of reconstruction algorithms with *guaranteed* performance, i.e., algorithms which probably solve the reconstruction problem under certain assumptions of γ and V. Previous proposed solutions with guaranteed performances were mostly *local*: a subgraph of the complete geometric graph defined by the points is considered (in most cases the Delaunay edges), and then *filtered* using a local criteria into a subgraph that will constitute the reconstruction. Thus, most of these algorithms fail to enforce that the solution have the global property of being a path/tour or collection of paths/tours and so usually require a dense sampling to work properly and have difficulty handling nonsmooth curves. See [6, 7, 8] for surveys of these algorithms.

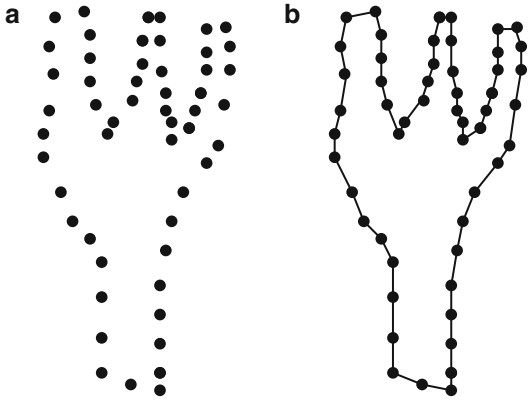
This work concentrates on a solution approach based on the *traveling salesman problem (TSP)*. Recall that a *traveling salesman path (tour)* for a set V of points is a path (cycle) passing through all points in V. An optimal traveling salesman path (tour) is a traveling salesman path (tour) of shortest length. The first question is under which conditions for γ and V a traveling salesman path (tour) is a correct reconstruction. Since the construction of an optimal traveling salesman path (tour) is an NP-hard problem, a second question is whether for the specific instances under consideration, an efficient algorithm is possible.

A previous work of Giesen [9] gave a first weak answer to the first question: For every benign semiregular closed curve γ, there exists an $\epsilon > 0$ with the following property: If V is a finite sample set from γ so that for every $x \in \gamma$ there is a $p \in V$ with $\|pv\| \leq \epsilon$, then the optimal traveling salesman tour is a polygonal reconstruction of γ. For a curve $\gamma : [0, 1] \to R^2$, its left and right tangents at $\gamma(t_0)$, are defined as the limits of the ratio $|\gamma(t_2) - \gamma(t_1)| / |t_2 - t_1|$ as (t_1, t_2) converges to (t_0, t_0) from the right $(t_0 < t_1 < t : 2)$ and from the right $(t_1 < t_2 < t : 0)$ respectively. A curve is semiregular if both tangents exist at every points and regular if the tangents exist and coincide at every point. The *turning* angle of γ at p is the angle between the left and right tangents at a points p. A semiregular curve is *benign* if the turning angle is less than π.

To investigate the TSP-based solution of the reconstruction problem, this work considers its integer linear programming *(ILP)* formulation and the corresponding linear programming *(LP)* relaxation. The motivation is that a successful method for solving the TSP is to use a branch-and-cut algorithm based on the LP-relaxation. See Chapter 7 in [5]. For a path with endpoints a and b, the formulation is based on variables $x_{u,v} \in \{0, 1\}$ for each pair u, v in V (indicating whether the edge uv is in the path $(x_{uv} = 1)$ or not $(x_{uv} = 0)$ and consists of the following objective function and constraints ($x_{uu} = 0$ for all $u \in V$):

$$
\begin{aligned}
\text{minimize} \quad & \sum_{u,v \in V} \|uv\| \cdot x_{uv} \\
\text{subject to} \quad & \sum_{v \in V} x_{uv} = 2 \text{ for all } u \in V \setminus \{a, b\} \\
& \sum_{v \in V} x_{uv} = 1 \text{ for } u \in \{a, b\} \\
& \sum_{u,v \in V'} x_{uv} \leq |V'| - 1 \text{ for } V' \subseteq V, \\
& V' \neq \emptyset \\
& x_{uv} \in \{0, 1\} \text{ for all } u, v \in V.
\end{aligned}
$$

Here $\|uv\|$ denotes the Euclidean distance between u and v and so the objective function is the total length of the selected edges. This is called the *subtour-ILP for the TSP with specified endpoints*. The equality constraints are called the *degree constraints*, the inequality ones are called *subtour elimination constraints* and the last ones are called the *integrality constraints*. If the degree and integrality constraints hold, the corresponding graph could include disconnected cycles (subtours), hence the need for the subtour elimination constraints. The relaxed LP is obtained by replacing the integrality constraints by the constraints $0 \leq x_{uv} \leq 1$ and is called the *subtour-LP for the TSP with specified endpoints*. There is a polynomial time algorithm that given a candidate solution returns a violated constraint if it exists: the degree constraints are trivial to check and the subtour elimination constraints are checked using a min cut algorithm (if a, b are joined by an edge and all edge capacities are made equal to one, then a violated subtour constraint corresponds to a cut smaller than two). This means that the subtour-LP for the TSP with specified endpoints can potentially be solved in polynomial time in the bit size of the input description, using the ellipsoid method [10].



TSP-Based Curve Reconstruction, Fig. 1 Sample data and its reconstruction

Key Results

The main results of this paper are that, given a sample set V with $a, b \in V$ from a benign semiregular open curve γ with endpoints a, b and satisfying certain *sampling condition* [it], then

- The optimal traveling salesman path on V with endpoints a, b is a polygonal reconstruction of γ from V,
- The subtour-LP for traveling salesman paths has an optimal integral solution which is unique.

This means that, under the sampling conditions, the subtour-LP solution provides a TSP solution and also suggests a reconstruction algorithm: solve the subtour-LP and, if the solution is integral, output it. If the input satisfies the sampling condition, then the solution will be integral and the result is indeed a polygonal reconstruction. Two algorithms are proposed to solve the subtour-LP. First, using the simplex method and the cutting plane framework: it starts with an LP consisting of only the degree constraints and in each iteration solves the current LP and checks whether that solution satisfies all the subtour elimination constraints (using a min cut algorithm) and, if not, adds a violated constraint to the current LP. This algorithm has a potentially exponential running time. Second, using a similar approach but with the ellipsoid method. This can be implemented so that the running time is polynomial in the bit size of the input points. This requires justification for using approximate point coordinates and distances.

The main tool in deriving these results is the connection between the subtour-LP and the so-called *Held–Karp bound*. The line of argument is as follows:

- Let $c(u, v) = \|uv\|$ and $\mu : V \to R$ be a *potential function*. The corresponding *modified distance function* c_μ is defined by $c_\mu(u, v) = c(u, v) - \mu(u) - \mu(v)$.
- For any traveling salesman path T with endpoints a, b,

$$c_\mu(T) = c(T) - 2\sum_{v \in V} \mu(v) + \mu(a) + \mu(b),$$

and so an optimal traveling salesman path with endpoints a, b for c_μ is also optimal for c.
- Let C_μ be the cost of a minimum spanning tree MST_μ under c_μ, then since a traveling salesman path is a spanning tree, the optimal traveling salesman T_0 satisfies $C_\mu \leq c_\mu(T_0) = c(T_0) - 2\sum_{v \in V} \mu(v) + \mu(a) + \mu(b)$, and so

$$\max_\mu \left(C_\mu + 2\sum_{v \in V} \mu(v) - \mu(a) - \mu(b) \right) \leq c(T_0)\,.$$

The term on the left is the so called Held–Karp bound.
- Now, if for a particular μ, MST_μ is a path with endpoints a, b, then MST_μ is in fact an optimal traveling salesman path with endpoints a, b, and the Held–Karp bound matches $c(T_0)$.
- The Held–Karp bound is equal to the optimal objective value of the subtour-LP. This follows by relaxation of the degree constraints in a Lagrangian fashion (see [5]) and gives an effective way to compute the Held-Karp bound: solve the subtour-LP.
- Finally, a potential function μ is constructed for γ so that, for an appropriately dense sample set V, MST_μ is unique and is a polygonal

reconstruction with endpoints a, b. This then implies that solving the subtour-LP will produce a correct polygonal reconstruction.

Note that the potential function μ enters the picture only as an analysis tool. It is not needed by the algorithm. The authors extend this work to the case of open curves without specified endpoints and of closed curves using variations of the ILP formulation and a more restricted sampling condition. They also extend it to the case of a collection of closed curves. The latter requires preprocessing that partitions points into groups that are expected to form individual curves. Then each subgroup is processed with the subtour-LP approach and then the quality of the result assessed and then that partition may be updated.

Finite Precision

The above results are obtained assuming exact representation of point samples and the distances between them, so claiming a polynomial time algorithm is not immediate as the running time of the ellipsoid method is polynomial in the bit size of the input. The authors extend the results to the case in which points and the distances between them are known only approximately and from this they can conclude the polynomial running time.

Relation to Local Feature Size

The defined potential function μ is related to the so called *local feature size* function f used in the theory of smooth curve reconstruction, where $f(p)$ is defined as the distance from p to the medial axis of the curve γ. In this paper, $\mu(p)$ is defined as $d(p)/3$ where $d(p)$ is the size of the largest neighborhood of p so that γ in that neighborhood does not *deviate significantly* from a flat segment of curve. This paper shows $f(p) < 3d(p)$. In fact, $\mu(p)$ amounts to a generalization of the local feature size to nonsmooth curves (for a corner point p, $\mu(p)$ is proportional to the size of the largest neighborhood of p such that γ inside does not deviate significantly from a corner point with two nearly flat legs incident to it, and for points near the corner, μ is defined as an appropriate interpolation of the two definitions), and is in fact similar to definitions proposed elsewhere.

Applications

The curve reconstruction problem appears in applied areas such as cartography. For example, to determine level sets, features, object contours, etc. from samples. Admittedly, these applications usually may require the ability to handle very sparse sampling and noise. The 3D version of the problem is very important in areas such as industrial manufacturing, medical imaging, and computer animation. The 2D problem is often seen as a simpler (toy) problem to test algorithmic approaches.

Open Problems

A TSP-based solution when the curve γ is a collection of curves, not all closed, is not given in this paper. A solution similar to that for closed curves (partitioning and then application of subtour-LP for each) seems feasible for general collections, but some technicalities need to be solved. More interesting is the study of corresponding reconstruction approaches for surfaces in 3D.

Experimental Results

The companion paper [2] presents results of experiments comparing the TSP-based approach to several (local) Delaunay filtering algorithms. The TSP implementation uses the simplex method and the cutting plane framework (with a potentially exponential running time algorithm). The experiments show that the TSP-based approach has a better performance, allowing for much sparser samples than the others. This is to be expected given the global nature of the TSP-based solution. On the other hand, the speed of the TSP-based solution is reported to be competitive when compared to the speed of the others, despite its potentially bad worst-case behavior.

Data Sets

None reported. Experiments in [2] were performed with a simple reproducible curve based on a sinusoidal with varying number of periods and samples.

URL to Code

The code of the TSP-based solution as well as the other solutions considered in the companion paper [2] are available from: http://www.mpi-inf.mpg.de/~althaus/LEP:Curve-Reconstruction/curve.html

Problem Definition

Definition 1 Let T be a two-dimensional $n \times n$ array over some alphabet Σ.

1. The *unit pixels array* for T (T^{1X}) consists of n^2 unit squares, called pixels in the real plane $\Re^2$. The corners of the pixel $T[i, j]$ are $(i - 1, j-1)$, $(i, j-1)$, $(i-1, j)$, and (i, j). Hence the pixels of T form a regular $n \times n$ array that covers the area between $(0, 0)$, $(n, 0)$, $(0, n)$, and (n, n). Point $(0, 0)$ is the *origin* of the unit pixel array. The *center* of each pixel is the geometric center point of its square location. Each pixel $T[i, j]$ is identified with the value from Σ that the original array T had in that position. Say that the pixel has a color or

a character from Σ. See Fig. 1 for an example of the grid and pixel centers of a 7×7 array.

2. Let $r \in \Re, r \geq 1$. The *r-ary pixels array* for T (T^{rX}) consists of n^2 *r-squares*, each of dimension $r \times r$ whose *origin* is $(0,0)$ and covers the area between $(0,0)$, $(nr,0)$, $(0,nr)$, and (nr,nr). The corners of the pixel $T[i,j]$ are $((i-1)r,(j-1)r)$, $(ir,(j-1)r)$, $((i-1)r,jr)$, and (ir,jr). The *center* of each pixel is the geometric center point of its square location.

Notation: Let $r \in \Re$. $[r]$ denotes the *rounding* of r, i.e.,

$$[r] = \begin{cases} \lfloor r \rfloor & \text{if } r - \lfloor r \rfloor < .5; \\ \lceil r \rceil & \text{otherwise.} \end{cases}$$

Definition 2 Let T be an $n \times n$ text array, P be an $m \times m$ pattern array over alphabet Σ, and let $r \in \Re, 1 \leq r \leq \frac{n}{m}$. Say that there is an *occurrence of P scaled to r* at text location (i,j) if the following conditions hold:

Let T^{1X} be the unit pixels array of T and P^{rX} be the r-ary pixel arrays of P. Translate P^{rX} onto T^{1X} in a manner that the origin of P^{rX} coincides with location $(i-1, j-1)$ of T^{1X}. Every center of a pixel in T^{1X} which is within the area covered by $(i-1, j-1), (i-1, j-1+mr), (i-1+mr, j-1)$ and $(i-1+mr, j-1+mr)$ has the same color as the r-square of P^{rX} in which it falls.

The colors of the centers of the pixels in T^{1X} which are within the area covered by $(i-1, j-1), (i-1, j-1+mr), (i-1+mr, j-1)$ and $(i-1+mr, j-1+mr)$ define a $[mr] \times [mr]$ array over Σ. This array is denoted by $P^{s(r)}$ and called *P scaled to r*.

The above definition is the one provided in the *geometric model*, pioneered by Landau and Vishkin [15], and Fredriksson and Ukkonen [14]. Prior to the advent of the geometric model, the only discrete definition of scaling was to natural scales, as defined by Amir, Landau and Vishkin [10]:

Definition 3 Let $P[m \times m]$ be a two-dimensional matrix over alphabet Σ (not necessarily bounded). Then P scaled by s (P^s) is the $sm \times sm$ matrix where every symbol $P[i,j]$ of P is replaced by a $s \times s$ matrix whose elements all equal the symbol in $P[i,j]$. More precisely,

$$P^s[i,j] = P[\lceil \frac{i}{s} \rceil, \lceil \frac{j}{s} \rceil] .$$

Say that pattern $P[m \times m]$ *occurs* (or an occurrence of P starts) at location (k,l) of the text T if for any $i \in \{1,\ldots,m\}$ and $j \in \{1,\ldots,m\}$, $T[k+i-1, l+j-1] = P[i,j]$.

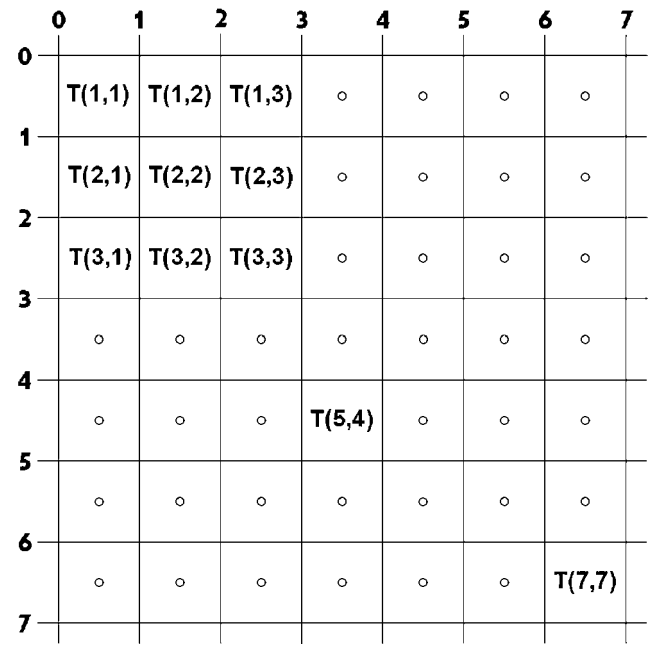
The *two dimensional pattern matching problem with natural scales* is defined as follows.

INPUT: Pattern matrix $P[i,j]$ $i = 1,\ldots m; j = 1,\ldots,m$ and Text matrix $T[i,j]$ $i = 1,\ldots,n; j = 1,\ldots,n$ where $n > m$.

OUTPUT: all locations in T where an occurrence of P scaled by s (an s-occurrence) starts, for any $s = 1,\ldots,\lfloor \frac{n}{m} \rfloor$.

The natural scales definition cannot answer normal everyday occurrences such as an image scaled to, say, 1.3. This led to the geometric model. The geometric model is a discrete adaptation, without smoothing, of scaling as used in computer graphics. The definition is pleasing in a "real-world" sense. Figure 2 shows "lenna" scaled to non-discrete scales by the geometric model definition. The results look natural.

It is possible, of course, to consider a *one dimensional* version of scaling, or scaling in *strings*. Both above definitions apply for one dimensional scaling where the text and pattern are taken to be matrices having a single row. The interest in one dimensional scaling lies because of two reasons: (1) There is a faster algorithm for one dimensional scaling in the geometric model than the restriction of the two dimensional scaling algorithm to one dimension. (2) Historically, before the geometric model was defined, there was an attempt [3] to define real scaling on strings as follows.



Two-Dimensional Scaled Pattern Matching, Fig. 1 The grid and pixel centers of a unit pixel array for a 7×7 array

Two-Dimensional Scaled Pattern Matching, Fig. 2 An original image, scaled by 1.3 and scaled by 2, using the geometric model definition of scaling

Definition 4 Denote the string $aa \cdots a$, where a is repeated r times, by a^r. The *one dimensional floor real scaled matching problem* is the following.

INPUT: A pattern $P = a_1^{r_1} a_2^{r_2} \ldots a_j^{r_j}$, of length m, and a text T of length n.

OUTPUT: All locations in the text where the substring $a_1^{c_1} a_2^{\lfloor r_2 k \rfloor} \ldots a_{j-1}^{\lfloor r_{j-1} k \rfloor} a_j^{c_j}$ appears, where $c_1 \geq \lfloor r_1 k \rfloor$ and $c_j \geq \lfloor r_j k \rfloor$.

This definition indeed handles real scaling but has a significant weakness in that a string of length m scaled to r may be significantly shorter than mr. For this reason the definition could not be generalized to two dimensions. The geometric model does not suffer from these deficiencies.

Key Results

The first results in scaled natural matching dealt with fixed finite-sized alphabets.

Theorem 1 (Amir, Landau, and Vishkin [10]) *There exists an $O(|T|\log|\Sigma|)$ worst-case time solution to the two dimensional pattern matching problem with natural scales, for fixed finite alphabet Σ.*

The main idea behind the algorithm is analyzing the text with the aid of *power columns*. Those are the text columns appearing $m-1$ columns apart, where P is an $m \times m$ pattern. This dependence on the pattern size make the power columns useless where a dictionary of different sized patterns is involved. A significantly simpler algorithm with an additional advantage of being alphabet-independent was presented in [6].

Theorem 2 (Amir and Calinescu [6]) *There exists an $O(|T|)$ worst-case time solution to the two dimensional pattern matching problem with natural scales.*

The alphabet independent time complexity of this algorithm was achieved by developing a scaling-invariant "signature" of the pattern. This idea was further developed to scaled dictionary matching.

Theorem 3 (Amir and Calinescu [6]) *Given a static dictionary of square pattern matrices. It is possible in $O(|D|\log k)$ preprocessing, where $|D|$ is the total dictionary size and k is the number of patterns in the dictionary, and $O(|T|\log k)$ text scanning time, for input text T, to find all occurrences of dictionary patterns in the text in all natural scales.*

This is identical to the time at [8], the best non-scaled matching algorithm for a static dictionary of square patterns. It is somewhat surprising that scaling does not add to the complexity of single matching nor dictionary matching.

The first algorithm to solve the scaled matching problem for real scales, was a one dimensional real scaling algorithm using Definition 4.

Theorem 4 (Amir, Butman, and Lewenstein [3]) *There exists an $O(|T|)$ worst-case time solution to the one dimensional floor real scaled matching problem.*

The first algorithm to solve the two dimensional scaled matching problem for real scales in the geometric model is the following.

Theorem 5 (Amir, Butman, Lewenstein, and Porat [4]) *Given an $n \times n$ text and $m \times m$ pattern. It is possible to find all pattern occurrences in all real scales in time $O(nm^3 + n^2 m\log m)$ and space $O(nm^3 + n^2)$.*

The above result was improved.

Theorem 6 (Amir and Chencinski [7]) *Given an $n \times n$ text and $m \times m$ pattern. It is possible to find all pattern occurrences in all real scales in time $O(n^2 m)$ and space $O(n^2)$.*

This algorithm achieves its time by exploiting geometric characteristics of nested scales occurrences and a sophisticated use of dueling [1, 16].

The assumption in both above algorithms is that the scaled occurrence of the pattern starts at the top left corner of some pixel.

It turns out that one can achieve faster times in the *one dimensional* real scaled matching problem, even in the geometric model.

Theorem 7 (Amir, Butman, Lewenstein, Porat, and Tsur [5]) *Given a text string T of length n and a pattern string P of length m, there exists an $O(n\log m + m\sqrt{nm\log m})$ worst-case time solution to the one dimensional pattern matching problem with real scales in the geometric model.*

Applications

The problem of finding approximate occurrences of a template in an image is a central one in digital libraries and web searching. The current

algorithms to solve this problem use methods of computer vision and computational geometry. They model the image in another space and seek a solution there. A deterministic worst-case algorithm in pixel-level images does not yet exist. Yet, such an algorithm could be useful, especially in raw data that has not been modeled, e.g., movies. The work described here advances another step toward this goal from the scaling point of view.

Open Problems

Finding all scaled occurrences without fixing the scaled pattern start at the top left corner of the text pixel would be important from a practical point of view. The final goal is an integration of scaling with rotation [2, 11–13] and local errors (edit distance) [9].

Two-Interval Pattern Problems

Stéphane Vialette
IGM-LabInfo, University of Paris-East, Descartes, France

Keywords

2-intervals; RNA structures

Years and Authors of Summarized Original Work

2004; Vialette
2007; Cheng, Yang, Yuan

Problem Definition

The problem is concerned with finding large constrained patterns in sets of 2-intervals. Given

a single-stranded RNA molecule, a sequence of contiguous bases of the molecule can be represented as an interval on a single line, and a possible pairing between two disjoint sequences can be represented as a 2-interval, which is merely the union of two disjoint intervals. Derived from arc-annotated sequences, 2-interval representation considers thus only the bonds between the bases and the pattern of the bonds, such as hairpin structures, knots and pseudoknots. A maximum cardinality disjoint subset of a candidate set of 2-intervals restricted to certain prespecified geometrical constraints can provide a useful valid approximation for RNA secondary structure determination.

The geometric properties of 2-intervals provide a possible guide for understanding the computational complexity of finding structured patterns in RNA sequences. Using a model to represent nonsequential information allows us to vary restrictions on the complexity of the pattern structure. Indeed, two disjoint 2-intervals, i.e., two 2-intervals that do not intersect in any point, can be in precedence order ($<$), be allowed to nest ($\sqsubset$) or be allowed to cross ($\between$). Furthermore, the set of 2-intervals and the pattern can have different restrictions, e.g., all intervals have the same length or all the intervals are disjoint. These different combinations of restrictions alter the computational complexity of the problems, and need to be examined separately. This examination produces efficient algorithms for more restrictive structured patterns, and hardness results for those that are less restrictive.

Notations

Let $I = [a, b]$ be an interval on the line. Write $\mathsf{start}(I) = a$ and $\mathsf{end}(I) = b$. A *2-interval* is the union of two disjoint intervals defined over a single line and is denoted by $D = (I, J)$; I is completely to the left of J. Write $\mathsf{left(D)} = \mathsf{I}$ and $\mathsf{right(D)} = \mathsf{J}$. Two 2-intervals $D_1 = (I_1, J_1)$ and $D_2 = (I_2, J_2)$ are said to be *disjoint* (or *nonintersecting*) if both 2-intervals share no common point, i.e., $(I_1 \cup J_1) \cap (I_2 \cup J_2) = \emptyset$. For such disjoint pairs of 2-intervals, three natural binary relations, denoted $<$, $\sqsubset$ and $\between$, are of special interest:

- $D_1 < D_2$ (D_1 *precedes* D_2), if $I_1 < J_1 < I_2 < J_2$,
- $D_1 \sqsubset D_2$ (D_1 is *nested in* D_2), if $I_2 < I_1 < J_1 < J_2$, and
- $D_1 \between D_2$ (D_1 *crosses* D_2), if $I_1 < I_2 < J_1 < J_2$.

A pair of 2-intervals D_1 and D_2 is said to be *R-comparable* for some $R \in \{<, \sqsubset, \between\}$, if either $D_1 R D_2$ or $D_2 R D_1$. Note that any two disjoint 2-intervals are R-comparable for some $R \in \{<, \sqsubset, \between\}$. A set of disjoint 2-intervals $\mathcal{D}$ is said to be *$\mathcal{R}$-comparable* for some $\mathcal{R} \subseteq \{<, \sqsubset, \between\}$, $\mathcal{R} \neq \emptyset$, if any pair of distinct 2-intervals in $\mathcal{D}$ is R-comparable for some $R \in \mathcal{R}$. The nonempty subset $\mathcal{R}$ is called a *model* for $\mathcal{D}$.

The 2-interval-pattern problem asks one to find in a set of 2-intervals a largest subset of pairwise compatible 2-intervals. In the present context, compatibility denotes the fact that any two 2-intervals in the solution are (1) nonintersecting and (2) satisfy some prespecified geometrical constraints. The 2-interval-pattern problem is formally defined as follows:

Problem 1 (2-interval-pattern)
INPUT: A set of 2-intervals $\mathcal{D}$ and a model $\mathcal{R} \subseteq \{<, \sqsubset, \between\}$.
SOLUTION: A $\mathcal{R}$-comparable subset $\mathcal{D}' \subseteq \mathcal{D}$.
MEASURE: The size of the solution, i.e., $|\mathcal{D}'|$.

According to the above definition, any solution for the 2-interval-pattern problem for some model $\mathcal{R} \subseteq \{<, \sqsubset, \between\}$ corresponds to an RNA structure constrained by $\mathcal{R}$. For example, a solution for the 2-interval-pattern problem for the $\mathcal{R} = \{<, \sqsubset\}$ model corresponds to a pseudoknot-free structure (a *pseudoknot* in an RNA sequence $S = s_1, s_2, \ldots, s_n$ is composed of two interleaving nucleotide pairings (s_i, s_j) and $(s_{i'}, s_{j'})$ such that $i < i' < j < j'$).

Some additional definitions are needed for further algorithmic analysis. Let $\mathcal{D}$ be a set of 2-intervals. The *width* (respectively *height*, *depth*) is the size of a maximum cardinality $\{<\}$-comparable (respectively $\{\sqsubset\}$-comparable, $\{\between\}$-comparable) subset $\mathcal{D}' \subseteq \mathcal{D}$. The *interleaving distance* of a 2-interval $D_i \in \mathcal{D}$ is defined to

be the distance between the two intervals of D_i, i.e., $\mathsf{start}(\mathsf{right}(\mathsf{D_i})) - \mathsf{end}(\mathsf{left}(\mathsf{D_i}))$. The *total interleaving distance* of the set of 2-intervals $\mathcal{D}$, written $\mathcal{L}(\mathcal{D})$, is the sum of all interleaving distances, i.e., $\mathcal{L}(\mathcal{D}) = \sum_{D_i \in \mathcal{D}} \mathsf{start}(\mathsf{right}(\mathsf{D_i})) - \mathsf{end}(\mathsf{left}(\mathsf{D_i}))$. The *interesting coordinates* of $\mathcal{D}$ are defined to be the set $X(\mathcal{D}) = \bigcup_{D_i \in \mathcal{D}} \{\mathsf{end}(\mathsf{left}(\mathsf{D_i})), \mathsf{start}(\mathsf{right}(\mathsf{D_i}))\}$. The *density* of $\mathcal{D}$, written $d(\mathcal{D})$, is the maximum number of 2-intervals in $\mathcal{D}$ over a single point. Formally, $d(\mathcal{D}) = \max_{x \in X(\mathcal{D})} \{D \in \mathcal{D} : \mathsf{end}(\mathsf{left}(\mathsf{D})) \leq \mathsf{x} < \mathsf{start}(\mathsf{right}(\mathsf{D}))\}$.

Constraints

The structure of the set of all (simple) intervals involved in a set of 2-intervals $\mathcal{D}$ turns out to be of particular importance for algorithmic analysis of the 2-interval-pattern problem. The *interval ground set* of $\mathcal{D}$, denoted $\mathcal{I}(\mathcal{D})$, is the set of all intervals involved in $\mathcal{D}$, i.e., $\mathcal{I}(\mathcal{D}) = \{\mathsf{left}(\mathsf{D_i}) : \mathsf{D_i} \in \mathcal{D}\} \cup \{\mathsf{right} < (\mathsf{D} : \mathsf{i}) : \mathsf{D_i} \in \mathcal{D}\}$. In [7, 20], four types of interval ground sets were introduced.

1. *Unlimited*: no restriction on the structure.
2. *Balanced*: each 2-interval $D_i \in \mathcal{D}$ is composed of two intervals having the same length, i.e., $|\mathsf{left}(\mathsf{D_i})| = |\mathsf{right}(\mathsf{D_i})|$.
3. *Unit*: the interval ground set $\mathcal{I}(\mathcal{D})$ is solely composed of unit length intervals.
4. *Disjoint*: no two distinct intervals in the interval ground set $\mathcal{I}(\mathcal{D})$ intersect.

Observe that a unit 2-interval set is balanced, while the converse is not necessarily true. Furthermore, for most applications, one may assume that a disjoint 2-interval set is unit. Observe that in this latter case, a set of 2-intervals reduces to a graph $G = (V, E)$ equipped with a numbering of its vertices from 1 to $|V|$, and hence the 2-interval-pattern problem for disjoint interval ground sets reduces to finding a constrained maximum matching in a linear graph. Considering additional restrictions such as:

- Bounding the width, the height or the depth of either the input set of 2-intervals or the solution subset
- Bounding the interleaving distances

is also of interest for practical applications.

Key Results

The different combinations of the models and interval ground sets alter the computational complexity of the 2-interval-pattern problem. The main results are summarized in Tables 1 (time complexity and hardness) and 2 (approximation for hard instances).

Theorem 1 *The 2-interval-pattern problem is approximable (APX) hard for models $\mathcal{R} = \{<, \sqsubset, \between\}$ and $\mathcal{R} = \{\sqsubset, \between\}$, and is nondeterministic polynomial-time (NP) complete – in its natural decision version – for model $\mathcal{R} = \{<, \between\}$, even when restricted to unit interval ground sets.*

Notice here that the 2-interval-pattern problem for model $\mathcal{R} = \{<, \between\}$ is not APX-hard. Two hard cases of the 2-interval-pattern turn out to be polynomial-time-solvable when restricted to disjoint-interval ground sets.

Theorem 2 *The 2-interval-pattern problem for a disjoint-interval ground set is solvable in*

- *$O(n\sqrt{n})$ time for model $\mathcal{R} = \{<, \sqsubset, \between\}$ (trivial reduction to the standard maximum matching problem)*

Two-Interval Pattern Problems, Table 1 Complexity of the 2-interval-pattern problem for all combinations of models and interval ground sets. For the polynomial-time cases, $n = |\mathcal{D}|$, $\mathcal{L} = \mathcal{L}(\mathcal{D})$ and $d = d(\mathcal{D})$

	Interval ground set $\mathcal{I}(\mathcal{D})$	
Model $\mathcal{R}$	Unlimited, balanced, unit	Disjoint
$\{<, \sqsubset, \between\}$	APX-hard [1]	$O(n\sqrt{n})$ [15]
$\{<, \between\}$	NP-complete [3]	**unknown**
$\{\sqsubset, \between\}$	APX-hard [19]	$O(n \log n + \mathcal{L})$ [8]
$\{<, \sqsubset\}$	$O(n \log n + nd)$ [8]	
$\{<\}$	$O(n \log n)$ [19]	
$\{\sqsubset\}$	$O(n \log n)$ [3]	
$\{\between\}$	$O(n \log n + \mathcal{L})$ [8]	

- $O(n \log n + \mathcal{L})$ *time for model* $\mathcal{R} = \{\sqsubset, \between\}$

The complexity of the 2-interval-pattern problem for model $\mathcal{R} = \{<, \between\}$ and a disjoint-interval ground set is still unknown. Three cases of the 2-interval-pattern problem are polynomial-time-solvable, regardless of the structure of the interval ground sets.

Theorem 3 *The 2-interval-pattern problem is solvable in*

- $O(n \log n + nd)$ *time for model* $\mathcal{R} = \{<, \sqsubset\}$
- $O(n \log n)$ *time for models* $\mathcal{R} = \{<\}$ *and* $\mathcal{R} = \{\sqsubset\}$
- $O(n \log n + \mathcal{L})$ *time for model* $\mathcal{R} = \{\between\}$

One may now turn to approximating hard instances of the 2-interval-pattern problem. Surprisingly enough, no significant differences (in terms of approximation guarantees) have yet been found for the 2-interval-pattern problem between the model $\mathcal{R} = \{<, \sqsubset, \between\}$ and the model $\mathcal{R} = \{\sqsubset, \between\}$ (the approximation algorithms are, however, different).

Theorem 4 *The 2-interval-pattern problem for model* $\mathcal{R} = \{<, \sqsubset, \between\}$ *or model* $\mathcal{R} = \{\sqsubset, \between\}$ *is approximable within ratio*

- *4 for unlimited-interval ground sets, and*
- $2 + \epsilon$ *for unit-interval ground sets.*

The 2-interval-pattern problem for model $\mathcal{R} = \{<, \between\}$ *is approximable within ratio* $1 + 1/\epsilon$, $\epsilon \geq 2$ *for all models.*

A practical 3-approximation algorithm for model $\mathcal{R} = \{<, \sqsubset, \between\}$ (resp. $\mathcal{R} = \{\sqsubset, \between\}$) and unit interval ground set that runs in $\mathcal{O}(n \lg n)$ (resp. $\mathcal{O}(n^2 \lg n)$) time has been proposed in [1] (resp. [7]). For model $\mathcal{R} = \{<, \between\}$, a more practical 2-approximation algorithm that runs in $\mathcal{O}(n^3 \lg n)$ time has been proposed in [10]. Notice that Theorem 4 holds true for the weighted version of the 2-interval-pattern problem [7] except for models $\mathcal{R} = \{<, \sqsubset, \between\}$ and $\mathcal{R} = \{\sqsubset, \between\}$ and unit interval ground set where the best approximation ratio is $2.5 + \epsilon$ [5].

Applications

Sets of 2-intervals can be used for modeling stems in RNA structures [20, 21], determining DNA sequence similarities [13] or scheduling jobs that are given as groups of nonintersecting segments in the real line [1, 9]. In all these applications, one is concerned with finding a maximum cardinality subset of nonintersecting 2-intervals. Some other classical combinatorial problems are also of interest [5]. Also, considering sets of t-intervals (each element is the union of at most t disjoint intervals) and their corresponding intersection graph has proved to be useful.

It is computationally challenging to predict RNA structures including pseudoknots [14]. Practical approaches to cope with intractability are either to restrict the class of pseudoknots under consideration [18] or to use heuristics [6, 17, 19]. The general problem of establishing a general representation of structured patterns, i.e., *macroscopic describers* of RNA structures, was considered in [20]. Sets of 2-intervals provide such a natural geometric description.

Constructing a relevant 2-interval set from a RNA sequence is relatively easy: stable stems are selected, usually according to a simplified thermodynamic model without accounting for loop energy [2, 16, 19–21]. Predicting a reliable RNA structure next reduces to finding a maximum subset of nonconflicting 2-intervals, i.e., a subset of disjoint 2-intervals. Considering in addition a model $\mathcal{R} \subseteq \{<, \sqsubset, \between\}$ allows us to vary restrictions on the complexity of the pattern structure. In [21], the treewidth of the intersection graph of the set of 2-intervals is considered for speeding up the computation.

For sets of 2-intervals involved in practical applications, restrictions on the interval ground set are needed. Unit interval ground sets were considered in [7]. Of particular importance in the context of molecular biology (RNA structures

Two-Interval Pattern Problems, Table 2 Performance ratios for hard instances of the 2-interval-pattern problem. LP stands for *Linear Programming* and N/A stands for *Not Applicable*

	Interval ground set $\mathcal{I}(\mathcal{D})$			
Model $\mathcal{R}$	Unlimited	Balanced	Unit	Disjoint
$\{<, \sqsubset, \between\}$	4 LP [1]	4 $\mathcal{O}(n \lg n)$ [7]	$2 + \epsilon\mathcal{O}(n^2 + n^{\mathcal{O}(\log 1/\epsilon)})$ [13]	N/A
$\{\sqsubset, \between\}$	4 LP [7]	4 $\mathcal{O}(n^2 \lg n)$ [7]	$2 + \epsilon\mathcal{O}(n^2 + n^{\mathcal{O}(\log 1/\epsilon)})$ [13]	N/A
$\{<, \between\}$	$1 + 1/\epsilon\mathcal{O}(n^{2\epsilon+3})$, $\epsilon \geq 2$ [14]			

and DNA sequence similarities) are balanced interval ground sets, where each 2-interval is composed of two equally length intervals.

Open Problems

A number of problems related to the 2-interval-pattern problem remain open. First, improving the approximation ratios for the various flavors of the 2-interval-pattern problem is of particular importance. For example, the existence of a fast approximation algorithm with good performance guarantee for the 2-interval-pattern problem for model $\mathcal{R} = \{<, \sqsubset, \between\}$ remains an apparently challenging open problem. A related open research area is concerned with balanced-interval ground sets. In particular, no evidence has shown yet that the 2-interval-pattern problem becomes easier to approximate for balanced-interval ground sets. This question is of special importance in the context of RNA structures where most 2-intervals are balanced.

A number of important question are still open for model $\mathcal{R} = \{<, \between\}$. First, it is still unknown whether the 2-interval-pattern problem for disjoint-interval ground sets and model $\mathcal{R} = \{<, \between\}$ is polynomial-time-solvable. Observe that this problem trivially reduces to the following graph problem: Given a graph $G = (V, E)$ with $V = \{1, 2, \ldots, n\}$, find a maximum cardinality matching $\mathcal{M} \subseteq E$ such that for any two distinct edges $\{i, j\}$ and $\{k, l\}$ of $\mathcal{M}$, $i < j$, $k < l$ and $i < k$, either $j < k$ or $j < l$. Another open question concerns the approximation of the 2-interval-pattern problem for balanced interval ground set. Is this special case better approximable than the general case?

A last direction of research is concerned with the parameterized complexity of the 2-interval-pattern problem. For example, it is not known whether the 2-interval-pattern problem for models $\mathcal{R} = \{<, \sqsubset, \between\}$, $\mathcal{R} = \{\sqsubset, \between\}$ or $\mathcal{R} = \{<, \between\}$ is fixed-parameter-tractable when parameterized by the size of the solution. Also, investigating the parameterized complexity for parameters such as the maximum number of pairwise crossing intervals in the input set or the treewidth of the corresponding intersection 2-interval graph, which are expected to be relatively small for most practical applications, is of particular interest.

Problem Definition

The UNDIRECTED FEEDBACK VERTEX SET (UFVS) problem is defined as follows:

Input: An undirected graph $G = (V, E)$ and an integer $k \geq 0$.

Task: Find a *feedback vertex set* $F \subseteq V$ with $|F| \leq k$ such that each cycle in G contains at least one vertex from F. (The removal of all vertices in F from G results in a forest.)

Karp [11] showed that UFVS is NP-complete. Lund and Yannakakis [12] proved that there exists some constant $\epsilon > 0$ such that it is NP-hard to approximate the optimization version of UFVS to within a factor of $1 + \epsilon$. The best-known polynomial-time approximation algorithm for UFVS has a factor of 2 [1, 4]. There is a simple and elegant randomized algorithm due to Becker et al. [3] which solves UFVS in $O(c{\cdot}4^k{\cdot}k\,n)$ time on an n-vertex and m-edge graph by finding a feedback vertex set of size k with probability at least $1 - (1 - 4^{-k})^{c4^k}$ for an arbitrary constant c. An exact algorithm for UFVS with a running time of $O(1.7548^n)$ was recently found by Fomin et al. [9]. In the context of parameterized complexity [8, 13], Bodlaender [5] and Downey and Fellows [7] were the first to show that the problem is *fixed-parameter tractable*, i.e., that the combinatorial explosion when solving it can be confined to the parameter k. The currently best fixed-parameter algorithm for UFVS runs in $O(c^k{\cdot}mn)$ for a constant c [6, 10] (see [6] for the so far best running time analysis leading to a constant $c = 10.567$). This algorithm is the subject of this entry.

Key Results

The $O(c^k{\cdot}mn)$-time algorithm for the UNDIRECTED FEEDBACK VERTEX SET is based on the so-called "iterative compression" technique, which was introduced by Reed et al. [14]. The central observation of this technique is quite simple but fruitful: To derive a fixed-parameter algorithm for a minimization problem, it suffices to give a fixed-parameter "compression routine"

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

that, given a size-$(k+1)$ solution, either proves that there is no size-k solution or constructs one. Starting with a trivial instance and iteratively applying this compression routine a linear number of rounds to larger instances, one obtains a fixed-parameter algorithm of the problem. The main challenge of applying this technique to UFVS lies in showing that there is a fixed-parameter compression routine.

The compression routine from [6, 10] works as follows:

1. Consider all possible partitions (X, Y) of the size-$(k+1)$ feedback vertex set F with $|X| \leq k$ under the assumption that set X is entirely contained in the new size-k feedback vertex set F' and $Y \cap F' = \emptyset$
2. For each partition (X, Y), if the vertices in Y induce cycles, then answer "no" for this partition; otherwise, remove the vertices in X. Moreover, apply the following data reduction rules to the remaining graph:
   - Remove degree-1 vertices.
   - If there is a degree-2 vertex v with two neighbors v_1 and v_2, where $v_1 \notin Y$ or $v_2 \notin Y$, then remove v and connect v_1 and v_2. If this creates two parallel edges between v_1 and v_2, then remove the vertex of v_1 and v_2 that is not in Y and add it to any feedback vertex set for the reduced instance.

   Finally, exhaustively examine every vertex set S with size at most $k - |X|$ of the reduced graph as to whether S can be added to X to form a feedback vertex set of the input graph. If there is one such vertex set, then output it together with X as the new size-k feedback vertex set.

The correctness of the compression routine follows from its brute-force nature and the easy to prove correctness of the two data reduction rules. The more involved part is to show that the compression routine runs in $O(c^k \cdot m)$ time: There are 2^k+1 partitions of F into the above sets (X, Y) and one can show that, for each partition, the reduced graph after performing the data reduction rules has at most $d \cdot k$ vertices for a constant d; otherwise, there is no size-k feedback vertex set for this partition. This then gives the $O(c^k \cdot m)$-running time. For more details on the proof of the $d \cdot k$-size bound see [6, 10].

Given as input a graph G with vertex set $\{v_1, \ldots, v_n\}$, the fixed-parameter algorithm from [6, 10] solves UFVS by iteratively considering the subgraphs $G_i := G[\{v_1, \ldots, v_i\}]$. For $i = 1$, the optimal feedback vertex set is empty. For $i > 1$, assume that an optimal feedback vertex set X_i for G_i is known. Obviously, $X_i \cup \{v_{i+1}\}$ is a solution set for G_{i+1}. Using the compression routine, the algorithm can in $O(c^k \cdot m)$ time either determine that $X_i \cup \{v_{i+1}\}$ is an optimal feedback vertex set for G_{i+1}, or, if not, compute an optimal feedback vertex set for G_{i+1}. For $i = n$, we thus have computed an optimal feedback vertex set for G in $O(c^k \cdot mn)$ time.

Theorem 1 Undirected Feedback Vertex Set *can be solved in $O(c^k \cdot mn)$ time for a constant c.*

Applications

The Undirected Feedback Vertex Set is of fundamental importance in combinatorial optimization. One typical application, for example, appears in the context of combinatorial circuit design [1]. For applications in the areas of constraint satisfaction problems and Bayesian inference, see Bar-Yehuda et al. [2].

Open Problems

It is open to explore the practical performance of the described algorithm. Another research direction is to improve the running time bound given in Theorem 1. Finally, it remains a long-standing open problem whether the Feedback Vertex Set on *directed* graphs

is fixed-parameter tractable. The answer to this question would represent a significant breakthrough in the field.

Problem Definition

The notion of searching a graph, in particular visiting each vertex in a systematic preordained fashion, is as old as graph theory itself. Indeed, Euler's paper in 1736 [13] presented conditions on the vertex degrees of a graph that would certify the presence or absence of a path (or circuit) of edges visiting each edge exactly once. Later it was shown by Fleury that an easy algorithm to find such a path (or circuit) can be achieved using depth-first search (DFS) [14]. In the late nineteenth century, C. P. Trémaux [22] and G. Tarry [28] presented DFS-based algorithms for maze traversal; similarly, breadth-first search (BFS) algorithms were used to find the shortest possible successful maze traversals.

In the 1960s and 1970s, these searches were used in many of the early graph algorithms for problems such as distance and diameter determination, network flows, planar graph recognition, and connected and 2-connected components; see [4, 27]. A "generic" (GENS) search, as defined by Tarjan [27], is one in which an unvisited vertex adjacent to a visited vertex must be chosen before an arbitrary unvisited vertex. Note that this criterion includes the standard graph searches, but does not include some useful vertex orderings such as nonincreasing vertex degree. We caution the reader that by BFS we follow Golumbic [16] and refer to the distance layering where unvisited neighbors of the currently visited vertex are placed at the end of a queue data structure. Note that in [4] BFS is defined as distance layering, but their implementation of distance layering uses a queue. Throughout this note, we assume that our graphs are connected.

In a seminal 1976 paper, Rose, Tarjan, and Lueker [24] introduced a variation of BFS, called lexicographic breadth-first search (LBFS), and showed that an arbitrary LBFS search could be used to achieve a linear time algorithm to recognize chordal graphs (there is no induced cycle of size strictly greater than 3). After the appearance of this paper, there were a few new applications of LBFS, mostly on applications on graph families related to chordal graphs. In the 1990s there was a marked increase in the application of LBFS in which a previous vertex ordering (usually a previous LBFS ordering) was used to break ties when there was more than one vertex eligible to be visited next. Such tiebreaking is referred to as a "+-sweep," as defined below.

Definition 1 Given a search $\mathcal{S}$ and vertex ordering σ of graph G, a **plus $\mathcal{S}$ sweep with respect to** σ (denoted $\mathcal{S}^+(G,\sigma)$) is the vertex ordering where the next vertex to be visited is the rightmost (as ordered by σ) T vertex (where T denotes the set of tied vertices).

Such "multi-sweep" LBFS algorithms were used for the recognition of interval graphs (for definitions of, and basic results on, various graph classes mentioned in this paper, see [3]), unit interval graphs, and cographs as well as finding dominating pairs (a pair of vertices (x, y) such that every $x - y$ path P dominates G in the sense that every vertex of G is either on P or has a neighbor on P) for asteroidal triple-free graphs. See [5] for an overview of these applications of LBFS. More recently, applications of LBFS have been found for graphs in general for such problems as modular decomposition [29] and split decomposition [15].

The proofs of correctness of multi-sweep LBFS algorithms typically are based on the following "4-vertex ordering characterization of LBFS":

Theorem 1 ([2, 16]) *A vertex total ordering σ could be produced by an LBFS if and only if for every triple of vertices $\{a, b, c\}$ where $a <_\sigma b <_\sigma c, ac \in E$, and $ab \notin E$ there exists vertex d such that $d <_\sigma a, db \in E$, and $dc \notin E$.*

Having seen the importance of Theorem 1 to the development of multi-sweep LBFS algorithms, a natural question and the question that is the basis of the Graph Searching Paper [6] is:

> Do other standard graph searches have a similar "4-vertex ordering characterization"?

Key Results

The first reaction to the question posed above is to try to understand exactly what is the structure of the search imposed by the $\{a, b, c\}$ vertices. The relevant question is:

> In the presence of the ac edge, how could b have been visited before c?

Since we are dealing with "generic" searches, some vertex d which is adjacent to b must have been visited before b since otherwise a would have to be chosen before b. If the search we are considering does not impose any further conditions on which unvisited vertices are eligible to be chosen, then the existence of d with $db \in E$ and $d <_\sigma b$ is a "4-vertex ordering characterization of GENS search." The full statement of the main theorem proved in [6] is:

Theorem 2 ([6]) *For $\mathcal{S}$ a graph search in {GENS, BFS, DFS, MNS, LBFS, LDFS} a total ordering σ of the set of vertices of the given graph could have been produced by $\mathcal{S}$ if and only if for every triple $a <_\sigma b <_\sigma c$ in σ where $ac \in E, ab \notin E$ there exists vertex d satisfying the requirements stated in the following table:*

Search $\mathcal{S}$	Requirements on d	
	Location	Adjacencies
GENS	$d < b$	$db \in E$
BFS	$d < a$	$db \in E$
DFS	$a < d < b$	$db \in E$
MNS	$d < b$	$db \in E, dc \notin E$
LBFS	$d < a$	$db \in E, dc \notin E$
LDFS	$a < d < b$	$db \in E, dc \notin E$

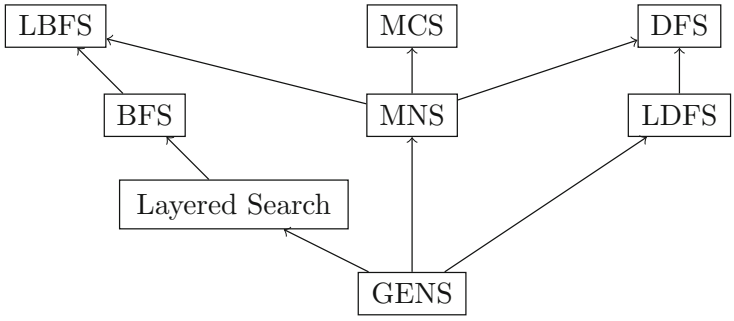
Note that the hierarchy among these different searches (and layered search) is shown in Fig. 1.

In the case of BFS, the characterization states that b must have a neighbor d where $d <_\sigma a$. In effect, this location for d reflects the role played by the queue in the BFS algorithm. Similarly, for DFS the location of d is between a and b reflecting the role played by the stack in the DFS algorithm. Note that the locations of d imposed by BFS and DFS capture the full range allowed by GENS search thereby exhibiting a type of duality between BFS and DFS.

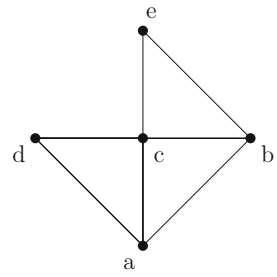
Now look at the difference between the characterizations of both BFS and LBFS. Both have the same location requirement for vertex d; however, BFS requires d to be a neighbor of b, whereas LBFS strengthens this condition so that d has to be a **private neighbor** of b with respect to c. This means that b's neighborhood in the set of visited vertices is **maximal with respect to set inclusion**. This raises the question of what happens to both DFS and GENS search if we add the "lexicographic" property – i.e., as with LBFS, that d has to be a private neighbor of b with respect to c, and thus that b's neighborhood in the set of visited vertices is maximal with respect to set inclusion. In the case of the "lexical" version of GENS search, this search was already known as the maximal neighbor search (MNS) [25], in particular, a search that chooses any vertex that has a maximal (by set inclusion) neighborhood in the set of visited vertices. Interestingly, this vertex ordering was presented in [24] where they showed that any search that obeys this property would produce a perfect elimination ordering (PEO) if the given graph is chordal. Thus, they concluded that both maximum cardinality search and LBFS suffice. Turning to LDFS, we see that d has the same location requirement as DFS, and adding the "lexical" property shows that LDFS is also a restricted version of MNS, and thus, it too is guaranteed to produce a PEO on chordal graphs. Note that in [6] all of these conditions are shown to be characterizations of the specific searches.

To illustrate the differences and relationships among these various searches, consider the graph in Fig. 2:

Regarding complexity issues, all searches mentioned in Theorem 2, except LDFS, have a linear time implementation (see [17] for LBFS); the current best LDFS implementation for arbitrary graphs uses van Emde Boas



Unified View of Graph Searching and LDFS-Based Certifying Algorithms, Fig. 1 Summary of the hereditary relationships proved in Theorem 2. An arc from search S to search S' indicates that S' is a restriction of S



$a\,b\,d\,c\,e \in BFS \setminus \{LBFS, DFS\}$

$a\,b\,c\,d\,e \in \{LBFS, DFS\} \setminus LDFS$

$a\,b\,e\,c\,d \in DFS \setminus \{LDFS, BFS\}$

$a\,b\,c\,e\,d \in LDFS \setminus BFS$

$c\,a\,b\,e\,d \in \{MNS \cap BFS\} \setminus LBFS$

$b\,a\,c\,e\,d \in \{MNS \cap DFS\} \setminus LDFS$

Unified View of Graph Searching and LDFS-Based Certifying Algorithms, Fig. 2 Sample graph and illustrative searches

trees [26] and runs in time $O(\max(n^2, n + m\log\log n))$. The key question arising from [6] is:

Are there any applications of LDFS?

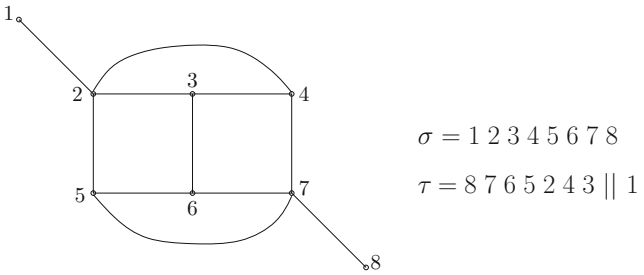
Problem Definition (cont.)

The first few attempts to find such an application quickly failed. The first was to see if LDFS could enjoy the same success as LBFS in building recognition algorithms for various restricted families of graphs (apart from chordal graphs); in all cases easily found counterexamples thwarted the various attempts. The second approach was to determine if LDFS$^+$ could be helpful in finding Hamilton paths (HP) or more generally minimum path covers (MPC) where the goal is to find a minimum cardinality set of subpaths of given graph G such that each vertex belongs to exactly one such path. Unfortunately, LDFS$^+$ fails when applied to an interval ordering (G is an interval graph if and only if there is an **interval ordering**, σ, of the vertices such that for all triples $a <_\sigma b <_\sigma c$ where $ac \in E$, then ab must also belong to E). To see this, consider a vertex universal to two disjoint paths on three vertices. From examples, it seems, however, that DFS$^+$ will find an HP, if one exists.

In fact, [1] and [11] independently showed that using the rightmost neighbor (RMN) sweep on an interval ordering yields an MPC of the given interval graph. Note that RMN when presented with an ordering σ greedily builds paths by starting at the rightmost unvisited vertex of σ and proceeding to its rightmost unvisited neighbor if such a vertex exists; if not, a new path is started at the rightmost unvisited vertex. (Note that this backtracking is different than the DFS$^+$ restarting.) Building off this algorithm, Dalton [10] presented a simple algorithm that certifies the correctness of the computed set of paths by either finding a set of vertices S (called a "scattering set") where the number of connected components of $G \setminus S$ equals $|S|$ plus the number of paths in the path cover or concludes that the given vertex ordering is not an interval ordering.

The next step was to try to lift this simple MPC algorithm to the superclass of cocomparability graphs. Note that a graph is a cocomparability graph if and only if its complement $\overline{G}$ has a transitive orientation of its edges. This orientation condition in $\overline{G}$ immediately translates into a vertex ordering characterization of cocomparability graphs. In particular, G is a cocomparability graph if and only if there is a **cocomp ordering**, σ, of the vertices such that for all triples $a <_\sigma b <_\sigma c$ where $ac \in E$, at least one of ab and bc must also belong to E.

Although there were polynomial time algorithms that solved the MPC problem on cocomparability graphs, all of these algorithms solved the "bump number" problem on the poset associated with the given graph and used the fact that any linear extension that minimizes the bump number contains the set of paths in a minimum path cover. The goal of this research was to find an MPC cocomparability graph algorithm that is directly graph theoretical and hopefully extends the interval graph MPC algorithm mentioned above. Examples immediately showed that applying RMN to an arbitrary cocomp ordering does not work, so many attempts were made to



Unified View of Graph Searching and LDFS-Based Certifying Algorithms, Fig. 3 LBFS counterexample

use multi-sweep LBFS to yield such a cocomp ordering. (Note that if σ is a cocomp ordering and $\tau = \text{LBFS}^+(\sigma)$, then τ is also a cocomp ordering.) This approach continued until the graph shown in Fig. 3 was discovered. On this graph every LBFS cocomp σ ordering fails, in the sense that RMN applied to σ does not produce a Hamiltonian path! A sample LBFS and the resulting RMN (which consists of two paths) are included in Fig. 3.

> Having seen the failure of LBFS, is there any chance that LDFS could work?

Key Results (cont.)

If there is such a role for LDFS, the counterexample for interval graphs mentioned previously shows that LDFS could not be expected to produce a minimum path cover itself; possibly LDFS could be used as a preprocessing step. If so, the simplest possible algorithm would be:

1. Let π be an arbitrary cocomp ordering.
2. Let σ be $\text{LDFS}^+(\pi)$.
3. Let τ be $\text{RMN}(\sigma)$.
4. If τ is not a Hamiltonian path, then from τ, use Dalton's algorithm to construct a separator S that certifies τ; otherwise, conclude π is not a cocomp ordering.

First of all, as with LBFS, LDFS when applied as a $+$-sweep on a given cocomp ordering returns a cocomp ordering. In this algorithm the hope is that an LDFS cocomp ordering would capture the "interval structure of cocomparability graphs," at least from the perspective of the MPC problem.

Somewhat surprisingly, this algorithm worked on all attempted examples. In an attempt to understand the structure exposed by an LDFS cocomp ordering, there are two points. First of all, why we do not see the LDFS structure in interval graphs? From the vertex ordering characterization of interval graphs, we see that there can never be an ordered triple of vertices $a < b < c$ with edge ac and nonedge ab, and thus, every interval ordering is simultaneously an example of every search mentioned in Theorem 2. Secondly, since an interval graph is chordal, every LBFS and LDFS must be a perfect elimination ordering implying that every vertex is simplicial in the graph formed on it and all vertices before it in the ordering. By considering a C_4, this property will not hold for LDFS cocomp orderings. There is however a crucial observation of the structure guaranteed by a nonsimplicial vertex in an LDFS cocomp ordering.

Lemma 1 ([7]) *Let σ be an LDFS cocomp ordering of cocomparability graph G. If z is a nonsimplicial vertex in σ as witnessed by $x <_\sigma y <_\sigma z$ where $xz, yz \in E, xy \notin E$, then there exists vertex w, $x <_\sigma w <_\sigma y$ where $xw, wy \in E, wz \notin E$.*

Proof By the LDFS vertex ordering characterization applied to the triple $\{x, y, z\}$, vertex w exists and satisfies all conditions of the lemma, except possibly $xw \in E$; if this is not the case, then the triple $\{x, w, z\}$ violates σ being a cocomp ordering.

This lemma plays a critical role in the proof of correctness of the MPC algorithm stated above.

Open Problems

We first list a number of recent results that have grown out of the work presented in [6, 7]:

- Köhler and Mouatadid [20] have recently shown that LDFS on a cocomparability graph can be done in linear time, thereby avoiding the log log$n$ off linear factor in the MPC paper [7].
- Mertzios and Corneil [23] have "lifted" the $O(n^4)$ longest path algorithm on interval graphs [18] to achieve the same result and time bound for cocomparability graphs. As with the MPC algorithm, a LDFS cocomp ordering was required.
- A similar technique of using an LDFS cocomparability ordering as a preprocessing step for a simple linear time interval graph algorithm has resulted in a linear time algorithm for the maximum independent set (and minimum vertex cover) problems on cocomparability graphs [8]. Note that the algorithm also produces a minimum cardinality clique cover in order to certify the maximum independent set produced by the algorithm. This algorithm also uses the linear time LDFS cocomp ordering algorithm presented in [20]. Very recently Köhler and Mouatadid [19] have presented a linear time algorithm that computes a maximum weighted independent set of a cocomparability graph; this algorithm works on any cocomp ordering and, in particular, does not require an LDFS cocomp ordering.
- In [8] the authors also characterized the search orderings that are "cocomp ordering preserving" in the sense that when used as a $+$-sweep, the output is a cocomp ordering when the input is a cocomp ordering. They showed that dfgreedy is such a preserving search and can be used to simplify the current best recognition algorithm for permutation graphs.
- In his PhD thesis, Dusart [12] studied the maximal clique lattice of a cocomparability graph and showed that a graph G is a cocomparability graph if and only if the set of maximal cliques of G satisfies specific lattice properties. Furthermore, he defined a new cocomp ordering preserving search called local MNS to compute a maximal interval subgraph of G. The new characterization together with MNS yields linear time algorithms to compute the simplicial vertices, the clique separators, and associated components of a cocomparability graph.
- Recently a new model of graph searching called "tiebreaking label search" (TBLS) [9] has been announced. This model builds off the vertex ordering characterization model appearing in [6] as well as the General Label Search formalism of Krueger, Simonet, and Berry [21]. The TBLS model incorporates the $+$-sweep use of graph searches, restricts labels to be sets of integers, and presents some new vertex ordering characterizations.

We now turn to some new directions for further research. From a graph algorithm perspective, the most interesting question is whether the results on cocomparability graphs can be easily extended to asteroidal triple-free graphs, an inclusive family that has received considerable attention. Further results, both structural and algorithmic are expected for cocomparability graphs and their associated posets. We expect that graph searching will continue to play a major role in these developments.

Problem Definition

The Model

A *mobile robotic sensor* (or simply *sensor*) is modeled as a computational unit with sensorial capabilities: it can perceive the spatial environment within a fixed distance $V > 0$, called *visibility range*, it has its own local working memory, and it is capable of performing local computations [6, 7].

Each sensor is a point with its own local coordinate system, which might not be consistent with the ones of the other sensors. The sensor can move in any direction, but it may be stopped before reaching its destination, e.g., because of limits to its motion energy; however, it is assumed that the distance traveled in a move by a sensor is not infinitesimally small (unless it brings the sensor to its destination).

The sensors have no means of direct communication to other sensors. Thus, any communication occurs in a totally implicit manner, by observing the other sensors' positions. Moreover, they are *autonomous* (i.e., without a central control) *identical* (i.e., they execute the same protocol), and *anonymous* (i.e., without identifiers that can be used during the computation).

The sensors can be *active* or *inactive*. When *active*, a sensor performs a *Look-Compute-Move* cycle of operations: it first observes the portion of the space within its visibility range obtaining a snapshot of the positions of the sensors in its range at that time (*Look*); using the snapshot as an input, the sensor then executes the algorithm to determine a destination point (*Compute*); finally, it moves toward the computed destination, if different from the current location (*Move*). After that, it becomes *inactive* and stays idle until the next activation. Sensors are *oblivious*: when a sensor becomes active, it does not remember any information from previous cycles.

Depending on the degree of synchronization among the cycles of different sensors, three submodels are traditionally identified: *synchronous*, *semi-synchronous*, and *asynchronous*. In the *synchronous* (FSYNC) and in the *semi-synchronous* (SSYNC) models, there is a global clock tick reaching all sensors simultaneously, and a sensor's cycle is an instantaneous event that starts at a clock tick and ends by the next. In FSYNC, at each clock tick all sensors become active, while in SSYNC some sensors might not be active in each cycle. In the *asynchronous* model (ASYNC), there is no global clock and the sensors do not have a common notion of time. Furthermore, the duration of each activity (or inactivity) is finite but unpredictable. As a result, sensors can be seen while moving, and computations can be made based on obsolete observations.

The Problem

The (distributed) *uniform covering* problem refers to sensors, randomly dispersed in a *bounded* region of space, that must scatter themselves throughout the region so to "cover" it satisfying some optimization criteria. Consider the case of a circular rim $\mathcal{R}$ (i.e., a ring), and let $S = \{s_0, \ldots, s_{n-1}\}$ be the sensors initially arbitrarily placed in different points on $\mathcal{R}$, with s_i preceding s_{i+1} clockwise (the index operations are modulo n). We emphasize that these names are used for presentation purposes only, and are not known to the sensors. If the sensors agree on the notion of clockwise, we say that they have a *common orientation*. Let $d = L_{\mathcal{R}}/n$ where $L_{\mathcal{R}}$ is the length of the ring. In the following, unless otherwise stated, the sensors are assumed to have visibility range $V \geq 2d$. Let $d_i(t)$ be the distance between sensors s_i and s_{i+1} at time t; when no ambiguity arises, we shall omit the time and simply indicate the distance as d_i. The sensors are said to have reached an *exact uniform covering* (*exact covering* for simplicity) at time t if $d_i(t) = d$ for all $0 \leq i \leq n-1$. Given $\epsilon > 0$, the sensors are said to have reached an *ϵ-approximate covering* at time t if $d - \epsilon \leq d_i(t) \leq d + \epsilon$ for all $0 \leq i \leq n-1$.

Key Results

The Ring

Exact Uniform Covering

There is a strong impossibility result that stresses the importance of having common orientation. If the sensors have only a local notion of left and right, but do not share a *common orientation* of the ring, the exact covering problem is unsolvable. This result holds even if the sensors had unbounded memory and visibility, and under a SSYNC scheduler.

Theorem 1 ([5]) *Let the sensors be on a ring $\mathcal{R}$. In absence of common orientation, there is no*

deterministic exact covering algorithm even if the sensors have unbounded persistent memory, their visibility range is unlimited, and the scheduling is SSYNC.

To see why this is the case, consider the following setting. Let n be even; partition the sensors in two sets, $S_1 = \{s_1, \ldots, s_{n/2}\}$ and $S_2 = S \backslash S_1$, and place the sensors of S_1 and S_2 on the vertexes of two regular $(n/2)$-gons on $\mathcal{R}$, rotated of an angle $\alpha < 360°/n$. Furthermore, all sensors have their local coordinate axes rotated so that they all have the same view of the world. In other words, the sensors in S_1 share the same orientation, while those in S_2 share the opposite orientation of $\mathcal{C}$. If activating only the sensors in S_1, an exact covering (resp. *no* exact covering) on $\mathcal{R}$ is reached at time step t_{i+1}, then the same is true also activating only the ones in S_2. Clearly, in such a case, activating both sets no exact covering would be reached at time step t_{i+1}, and the system would be an analogous configuration as the one of time step t_i, with different angles. Using this property, it is easy to design an adversary that will force any algorithm to never succeed in solving the problem; its behavior would be as follows: (i) If activating only the sensors in S_1 (resp. S_2) no exact covering on $\mathcal{R}$ is reached, then activate all sensors in S_1 (resp. S_2), while all sensors in S_2 (resp. S_1) are inactive; (ii) otherwise, activate all sensors. Go to (i).

On the other hand, assuming common orientation and knowledge of the final inter-distance d among sensors, a simple algorithm that solves the exact covering in ASYNC is for each sensor to move toward the point at distance d from its clockwise successor (if visible). We remind that $V \geq 2d$.

Protocol RINGCOVERINGEXACT (for sensor s_i)
Assumptions: Orientation, knowledge of d.

1. If s_{i+1} is not visible, move distance d clockwise.
2. else, if $d_i > d$ move toward point x at distance d from s_{i+1}.

Theorem 2 ([5]) *The exact covering of the ring problem is solvable in* ASYNC*, with common orientation and knowledge of the final inter-distance.*

Approximate Covering

Assuming common orientation but no knowledge of the final inter-distance among sensors, an ϵ-approximate covering is still possible for any $\epsilon > 0$, but no exact covering algorithm is known. Also this algorithm is very simple: the sensors asynchronously and independently *Look* in both directions, then they position themselves in the middle between the closest observed sensors (if any). Correctness is shown by proving that the minimum distance between any two neighboring sensors eventually grows, while the maximum distance eventually shrinks in such a way that there is a time when all sensors are within $d \pm \epsilon$ distance.

Theorem 3 ([5]) *The approximate covering of the ring problem is solvable in* ASYNC *with common orientation.*

Algorithm RINGCOVERINGAPPROX (for sensor s_i)
Assumptions: Orientation

- If no sensor is visible clockwise (resp. counterclockwise), let $d_i = V$ (resp. $d_{i-1} = V$).
- If $d_i \leq d_{i-1}$ do not move.
- If $d_i > d_{i-1}$ move distance $\frac{d_i + d_{i-1}}{2} - d_{i-1}$ clockwise.

Note that the covering problem has been also studied in discrete rings [4].

The Line

The case of a line segment is quite different from the one of the ring, and perhaps surprisingly, it is not easier. Let $S = \{s_0, \ldots, s_{n-1}\}$ be the sensors initially arbitrarily placed in different points on a line $\mathcal{L}$ with s_0 and s_{n-1} being two special immobile sensors delimiting the segment to be covered and with s_i preceding s_{i+1} $(0 < i < n-2)$. Let $d = L_{\mathcal{L}}/(n-1)$, where $L_{\mathcal{L}}$ denotes

the length of the segment. *Exact covering* and ϵ-*approximate covering* are defined analogously to the case of the ring.

Exact Uniform Covering

With common orientation and known final inter-distance, an algorithm has been recently shown for oriented sensors in ASYNC [3]. The algorithm works even if the visibility range is just enough to sense the final inter-distance ($V = d$). Let $\delta \leq \frac{d}{2}$ be a fixed positive (arbitrarily small) constant the sensors agree upon.

Protocol CORRIDORCOVERINGEXACT (for sensor s_i)
Assumptions: Orientation, knowledge of d, $V = d$

- If s_{i-1} is not visible, move distance $\frac{d}{2}$ to the left.
- else, let $a := d - d_{i-1}$
  If $d_i \geq d$ and $a > 0$, move distance $min(\frac{d}{2} - \delta, a)$ to the right.

Theorem 4 ([3]) *The exact covering of the line problem is solvable in* ASYNC *with common orientation and knowledge of the final inter-distance.*

With fixed visibility, a distributed algorithm has been proposed for FSYNC in a discrete setting, to solve the slightly different problem of barrier coverage [2].

Approximate Covering

Approximate covering has been studied in a slightly different visibility model where each sensor is able to perceive up to the next sensor on the line [1]. In other words, in each direction, a sensor sees the closest sensor (if it exists), regardless of its distance, but its visibility is blocked by it (*neighbor visibility*). For presentation purposes, a global linear coordinate system (not known to the sensors) is used here with $s_0(t) = 0$ and $s_{n-1}(t) = 1$. For the sensors to be spread uniformly, sensor s_i should then occupy position $\frac{i}{n-1}$. The following is a simple approximate covering algorithm.

Protocol CORRIDORSPREAD (for sensor s_i)
Assumptions: SSYNC, neighbour visibility

- If no sensor is visible in either direction, do nothing.
- Otherwise, move toward point $x = \frac{1}{2}(s_{i+1} + s_{i-1})$.

The idea of the convergence proof in FSYNC is sketched below. Let $\mu_i[t]$ be the *shift* of the s_i's location at time t from its final position. According to the protocol, the position of sensor s_i changes from $s_i(t)$ to $s_i(t+1) = \frac{1}{2}(s_{i-1}(t) + s_{i+1}(t))$ for $1 \leq i \leq n-2$, while sensors s_0 and s_{n-1} never move. Therefore, the shifts changes with time as $\mu_i[t+1] = \frac{1}{2}(\mu_{i+1}[t] + \mu_{i-1}[t])$. Considering the *progress* measure, $\psi[t] = \Sigma_{i=1}^{i=n} \mu^2[t]$, it can be shown that $\psi[t]$ is a decreasing function of t unless the sensors are already equally spread; more precisely, it is shown that every $O(n^2)$ cycle, $\psi[t]$ is at least halved thus reaching approximate covering. More complex but analogous reasoning is followed for SSYNC.

Theorem 5 ([1]) *The approximate covering of the line problem is solvable in* SSYNC *with* neighbor visibility.

With a simple modification of the algorithm, the result above can be extended to any fixed visibility $V > d$, provided that d is known, as described below [3].

Protocol CORRIDORSPREAD2 (for sensor s_i)
Assumptions: SSYNC, d known, $V > d$

- If only one sensor $s_j \in \{s_{i+1}, s_{i-1}\}$ is visible to s_i and $d' = dist(s_i, s_j) < d$: move distance $\frac{d-d'}{2} + \frac{V-d}{2}$ away from s_j
- If both s_{i+1}, s_{i-1} are visible and $d_1 = dist(s_{i-1}, s_i) < d_2 = dist(s_{i+1}, s_i)$ (resp. $d_1 = dist(s_{i+1}, s_i) < d_2 = dist(s_{i-1}, s_i)$): move $\frac{d_2-d_1}{2}$ toward s_{i+1} (resp. toward s_{i-1})

Applications

Uniform covering problems are important in many applications; covering of a circular rim occurs, for example, when the sensors have to surround a dangerous area and can only move along its outer perimeter. On the other hand, coverings of the line (often called *barrier coverings*) guarantee that any intruder attempting to cross the perimeter of a protected region (e.g., crossing an international border) is detected by one or more of the sensors. These problems are studied under a variety of assumption; the majority of the studies uses sensors provided with memory, explicit communication devices, global localization capabilities (e.g., GPS), and centralized approaches. The advantage of memoryless sensors are self-stabilization and tolerance to loss of sensors, the use of local coordinate systems has clear advantages over the full strength of a GPS; finally, decentralized solutions offer better fault tolerance.

Open Problems

It is known that the exact covering of the ring is impossible without orientation in SSYNC, but the impossibility does not extend to FSYNC where, however, no algorithm is known. Moreover, the only existing exact covering algorithm in ASYNC assumes orientation, which is needed, and knowledge of the inter-distance d, which is possibly not needed, so a tighter result might be possible. Finally, approximate covering is achieved in the ring in SSYNC assuming orientation, which is not shown to be necessary, furthermore, no solution exists for ASYNC.

In the case of the line, the only impossibility result for exact covering [3] holds for fully disoriented sensors (not even able to locally distinguish between their two directions) and with small visibility range $V = d$. As for approximate covering, the only known result in this model is for SSYNC, and it is not known whether an algorithm exists for the ASYNC model.

Problem Definition

A Boolean formula F is said to be in conjunctive normal form (CNF) if it is a conjunction of

disjunction of literals. If furthermore every disjunction (called clause) is over at most k literals, F is said to be in k-CNF. k-SAT, the decision problem whether a k-CNF formula admits a satisfying assignment, is one of the most prominent NP-complete problems. A special case of k-SAT is (promise) unique k-SAT, where the k-CNF is additionally promised to have either a unique or no satisfying assignment.

Suppose F has n variables. The trivial algorithm tries all 2^n satisfying assignments. For k-SAT and especially 3-SAT, there have been many successive improvements [3–9, 11]. The best of them are *randomized* in the sense that they always correctly report unsatisfiability but might fail to report satisfiability with probability $\frac{1}{3}$, say.

Problem 1 (k-SAT)

INPUT: A k-CNF formula F.
OUTPUT: "No" if F is not satisfiable. "Yes" with probability at least $\frac{2}{3}$ if F is satisfiable.

Problem 2 (Unique k-SAT)

INPUT: A k-CNF formula F with at most one satisfying assignment.
OUTPUT: "No" if F is not satisfiable. "Yes" with probability at least $\frac{2}{3}$ if F is satisfiable.

It is conjectured that unique k-SAT and k-SAT have the same exponential complexity; however, this could only be shown for $k \to \infty$ [1]. Especially for PPSZ [9], the fastest known (randomized) algorithm for unique k-SAT, the analysis results in a gap between k-SAT and unique k-SAT for $k = 3, 4$. Furthermore, the PPSZ algorithm has been derandomized for unique k-SAT [10] but not for general k-SAT.

Notation For a CNF formula F over a variable set V, denote by $\mathrm{sat}(F)$ the set of satisfying assignments of F on V. For x a variable and b a Boolean value, define $F^{[x \mapsto b]}$ the restriction of F by $x \mapsto b$, i.e., the formula obtained by replacing x by b in F.

Key Results

The bounds of the PPSZ algorithm for unique k-SAT hold for general k-SAT also if $k = 3, 4$ [2]. This makes PPSZ the fastest known k-SAT algorithm for all k. In the analysis of [2], the PPSZ algorithm is slightly modified.

Theorem 1 *There is a randomized algorithm for 3-SAT running in time* $O(2^{0.387n})$.

Theorem 2 *There is a randomized algorithm for 4-SAT running in time* $O(2^{0.555n})$.

Algorithm 1 PPSZ(k-CNF formula F)

$V \leftarrow$ variables of F
Choose β uniformly at random from all assignments on V
Choose π uniformly at random from all permutations of V
Let α be a partial assignment over V, initially the empty assignment
for all $x \in V$ in the order prescribed by π **do**
  while there is an $\log n$-implied assignment $y \mapsto a$ of F **do**
    $F \leftarrow F^{[y \mapsto a]}$
    $\alpha(y) \leftarrow a$
  end while
  if $\alpha(x)$ not fixed yet **then**
    $F \leftarrow F^{[x \mapsto \beta(x)]}$
    $\alpha(x) \leftarrow \beta(x)$
  end if
end for
return If α satisfies F, return 'satisfiable', otherwise return 'failure'.

If F is not satisfiable, then PPSZ will never find a satisfying assignment and thus is always correct. Hence, let F be a satisfiable k-CNF formula over n variables V. The PPSZ algorithm tries to find a satisfying assignment of F by iteratively setting variables as follows: Go through the variables one by one, in random order. If a variable x is not set at its step, then its value will be guessed uniformly at random. Between steps, we might infer the value of some variables in subexponential time: Setting x to a is called $\log n$-implied (by F) if there is a set of $\log n$ clauses G in F such that all satisfying assignments of G set x to a. $\log n$-implication can be checked in subexponential time by brute

force; the algorithm fixes all $\log n$-implications accordingly between steps.

If a variable is determined by $\log n$-implication, it is called *forced*; otherwise, it is called *guessed*. The key result of [9] for unique k-SAT is the following: If F is in k-CNF and has a unique satisfying assignment α, then given that $\beta = \alpha$ (i.e., all guesses are according to α), a variable is forced with a certain probability R_k. By Jensen's inequality one can then show that α is found with probability $2^{-(1-R_k)n}$. We have $R_3 = 2 - 2\ln 2 \approx 0.613$ and $R_4 \approx 0.445$. Repeating PPSZ inversely proportional to its success, probability will match the above theorems for unique 3-SAT and unique 4-SAT.

If there are multiple satisfying assignments, there is no bound on the probability that a variable is forced. For example, the empty CNF formula that always evaluates to true will never have a forced variable, as being forced depends on certain assignments not being satisfying. However, the following can be done: Given a satisfiable CNF formula F, call a variable x *frozen* if it has the same value in all satisfying assignments of F, and call x *non-frozen* otherwise. If x is frozen, the same bound on the probability that it is forced holds by the arguments of [9]. If x is non-frozen, then it can be set both ways and the resulting formula remains satisfiable. The remaining problem is that the probability for frozen variables depends on a fixed satisfying assignment and a uniform permutation; however, depending on the permutation, certain assignments will be more or less likely. This leads to a correlation issue that has to be solved by balancing the correlation and the benefit of non-frozen variables by careful bookkeeping.

Let V_f be the frozen variables of F and V_n be the non-frozen variables of F. The *likelihood* of an assignment α in F, $\mathrm{lkhd}(F, \alpha)$, is recursively defined as follows: If α does not satisfy F, then $\mathrm{lkhd}(F, \alpha) = 0$. If α is the unique satisfying assignment of F, then $\mathrm{lkhd}(\alpha) = 1$. Otherwise, let $\mathrm{lkhd}(\alpha) = \frac{1}{|V_f|+2|V_n|}\left(\sum_{x \in V} \mathrm{lkhd}(\alpha, F^{[x \mapsto \alpha(x)]})\right)$. The likelihood simulates how likely an assignment would be returned by PPSZ in an ideal setting.

With this, the cost F is defined as follows: For a non-frozen variable x, $\mathrm{cost}(F, x) = 1 - R_k$. For a frozen variable x, first defined for a satisfying assignment α, $\mathrm{cost}(F, x, \alpha)$ is the probability that x is guessed if executing PPSZ conditioned on $\beta = \alpha$. Then $\mathrm{cost}(F, x) = \sum_{\alpha \in \mathrm{sat}(F)} \mathrm{lkhd}(F, \alpha)\mathrm{cost}(F, x, \alpha)$. Observe that $\mathrm{cost}(F, x) \leq 1 - R_k$, as frozen variables are guessed with probability at most $1 - R_k$. In total we define $\mathrm{cost}(F) = \sum_{x \in V} \mathrm{cost}(F, x) \leq (1 - R_k)n$. The following theorem relates the cost to the probability that PPSZ finds an assignment:

Theorem 3

$$\Pr(\textit{PPSZ finds some satisfying assignment of } F) \geq 2^{-c(F)}.$$

This theorem immediately implies Theorems 1 and 2. The theorem is by induction on the number of variables of F. After a single PPSZ step, the cost decreases in expectation; the more the more frozen variables there are. On the other hand, the more non-frozen variables there are, the higher the probability is to retain a satisfiable formula. Balancing these factors and applying Jensen's inequality gives the theorem. It is noteworthy that the proof relies on the inequality $0.613 \approx R_3 \leq \frac{1}{2\ln 2} \approx 0.721$, meaning that if PPSZ would be improved beyond this bound, the unique case might indeed be better.

Open Problems

- Is the exponential complexity of k-SAT and unique k-SAT the same? Here this has been shown for the specific case of the PPSZ algorithm.
- Does PPSZ perform even better on formulas with exponentially many satisfying assignments?
- Can PPSZ be derandomized for general k-SAT?

Problem Definition

Given a set of jobs $J = \{1, 2, \ldots, n\}$ with processing times $p_j \in \mathbb{R}_+$ and weights $w_j \in \mathbb{R}_+$, the task is to find a schedule for all jobs on a single machine that minimizes $\sum w_j C_j$, where C_j is the completion time of job j.

Under the standard scheduling assumption of an ideal machine that runs at constant speed, an optimal schedule is obtained by sequencing the jobs in nonincreasing order of the ratio w_j/p_j; this is known as Smith's Rule [12]. Unfortunately, as we shall see shortly, this sequence may per-

form arbitrarily bad when the machine is not ideal.

This note is concerned with the setting in which the machine may change its processing speed over time or it may fully break down and is unavailable until it is fixed. Given a sequence, the jobs are processed in this order no matter how the machine behaves. In case of a machine breakdown, the job that is currently running is preempted and resumes processing when the machine becomes available again at a later time. The aim is to compute a *universal sequence* that, for any given machine behavior, is a good approximation of an optimal schedule for that particular machine behavior.

Definition 1 A sequence π is a *universal c-approximation* if for any machine behavior the total weighted completion times of π is at most a factor c larger than the objective value of an optimal solution for this machine behavior.

To illustrate this definition consider the following toy instance with two jobs: $p_1 = w_1 = 2$ and $p_2 = w_2 = N \gg 2$. There are only two possible sequences: $(1, 2)$ and $(2, 1)$. Both sequences are optimal on an ideal machine and are consistent with Smith's Rule. Now suppose our machine breaks down at $t = N + 1$ and stays offline for $T = N^2$ units of time. The cost of $(1, 2)$ on this faulty machine is $4 + N(N + 2 + T) = \Theta(N^3)$, while the cost of $(2, 1)$ is $N^2 + 2(N + 2 + T) = \Theta(N^2)$. This example shows that Smith's Rule can produce a sequence that is not a universal $O(1)$-approximation. In fact, it is not clear that such a universal sequence should always exist.

Key Results

Epstein et al. [3] initiated the study of universal sequencing. They showed that universal $O(1)$-approximate sequences do indeed exist and established tight lower bounds on the universal approximation ratio that can be achieved. Their study was subsequently furthered by Megow and Mestre [10] who showed that the best universal schedule can be approximated in polynomial time up to any desired level of accuracy.

Bounding the Performance of a Universal Sequence

The key observation needed to bound the performance of a universal sequence is that approximating the min-sum objective value on a machine with unknown processing behavior is equivalent to approximating the total weight of uncompleted jobs at any point in time on an ideal machine. To that end, let $W^\pi(t)$ denote, for any $t \geq 0$, the total weight of outstanding jobs at time t in the schedule obtained for job sequence π on an ideal machine. Define $W^*(t) := \min_\pi W^\pi(t)$ for all $t \geq 0$.

Lemma 1 *Let π be a sequence of jobs. Then, the objective value of the corresponding schedule is at most c times the value of an optimum schedule for any machine behavior, if and only if*

$$W^\pi(t) \leq c \cdot W^*(t) \qquad \text{for all } t \geq 0.$$

A Universal Sequencing Algorithm

The universal sequencing algorithm computes the job sequence iteratively backwards. In each iteration it solves the subproblem of finding a set of jobs that has maximum total processing time and total weight within a given bound. This bound is doubled in each iteration.

This approach is related to, but not equivalent to, an algorithm of Hall et al. [6] for online scheduling on ideal machines – the doubling there happens in the time horizon. Indeed, *doubling* strategies have been applied successfully in the design of approximation and online algorithms for various problems; see, e.g., the survey by Chrobak and Kenyon-Mathieu [1].

Doubling Algorithm:

1. For $i \in \{0, 1, \ldots, \lceil \log w(J) \rceil\}$, find a subset J_i^* of jobs of maximum total processing time $p(J_i^*)$, such that the total weight satisfies $w(J_i^*) \leq 2^i$.
2. Construct a permutation π as follows. Start with an empty sequence of jobs. For $i = \lceil \log w(J) \rceil$ down to 0, append the jobs in $J_i^* \setminus \bigcup_{k=0}^{i-1} J_k^*$ in any order at the end of the sequence.

Finding the subsets of jobs J_i^* is a KNAPSACK problem and, thus, NP-hard [8]. Using straightforward dynamic programming, the algorithm runs in pseudo-polynomial time and achieves a performance guarantee of 4 as shown below. However, FPTASes for the knapsack problem can be adopted such that the *Doubling Algorithm* runs in polynomial time loosing an arbitrarily small constant in the performance guarantee.

Theorem 1 *For every scheduling instance, the* Doubling Algorithm *produces a universal* 4*-approximation for all machine behaviors.*

Proof By Lemma 1 it is sufficient to show that $W^\pi(t) \leq 4W^*(t)$ for all $t \geq 0$. Let $t \geq 0$ and let i be minimal such that $p(J_i^*) \geq p(J) - t$. By construction of π, only jobs j in $\bigcup_{k=0}^{i} J_k^*$ can have a completion time $C_j^\pi > t$. Thus,

$$W^\pi(t) \leq \sum_{k=0}^{i} w(J_k^*) \leq \sum_{k=0}^{i} 2^k = 2^{i+1} - 1. \tag{1}$$

In case $i = 0$, the claim is trivially true since $w_j \geq 1$ for any $j \in J$, and thus, $W^*(t) = W^\pi(t)$. Suppose $i \geq 1$; then by our choice of i, it holds that $p(J_{i-1}^*) < p(J) - t$. Therefore, in any sequence π', the total weight of jobs completing after time t is larger than 2^{i-1}, because otherwise we get a contradiction to the maximality of $p(J_{i-1}^*)$. That is, $W^*(t) > 2^{i-1}$. Together with (1) this concludes the proof. □

This result is best possible for universal sequencing on a single machine.

Theorem 2 *For any $c < 4$, there exists an instance for which there is no universal c-approximation.*

This can be shown through a connection to the *online bidding problem* and the corresponding lower bounds shown by Chrobak et al. [2].

Randomized Universal Schedules

It is possible to obtain a better approximation ratio if we select the sequence at random and slightly relax the universality requirement.

Definition 2 A probability distribution over sequences is a *randomized universal c-approximation* if for any machine behavior the *expected* total weighted completion times of a sequence chosen according to the distribution is at most a factor c larger than the objective value of an optimal solution for this machine behavior.

By randomizing the "doubling parameter" in the Doubling Algorithm, the algorithm can achieve an approximation ratio of $e \approx 2.718$, which is best possible for randomized strategies.

Theorem 3 *For every scheduling instance, a randomized variant of the* Doubling Algorithm *produces a randomized universal e-approximation for all machine behaviors. Furthermore, for any $c < e$, there exists an instance for which there is no randomized universal c-approximation.*

Generalizations

Global Cost Functions

The universality of the sequence constructed by the *Doubling Algorithm* can be driven even further. Consider the generalized min-sum objective $\min \sum w_j f(C_j)$ for any nondecreasing, nonnegative, differentiable cost function f.

Theorem 4 *The Doubling Algorithm computes a universal* 4*-approximation (randomized e-approximation) for all machine behaviors and all considered cost functions f simultaneously.*

Precedence Constraints

A natural generalization of the universal sequencing problem requires that jobs must be sequenced in compliance with given *precedence constraints*. To a certain extent the *Doubling Algorithm* can be adopted to this more general problem setting. Essentially, the knapsack-related subroutine must respect the precedence constraints, *and* it must ensure that prepending the subsets found in different iterations, starting in the end, does not violate the precedence order.

This corresponds to solving a so-called *partially ordered knapsack* (POK) problem on the reverse of the given partial order.

Theorem 5 *The Doubling Algorithm computes a universal* 4*-approximation (randomized e-approximation) for the universal scheduling problem respecting given precedence constraints if the POK problem for the given partial order can be solved in polynomial time.*

In general, POK is strongly NP-hard [7] and hard to approximate [5]. However, FPTASes exist for special partial orders, including directed out-trees, two-dimensional orders, and the complement of chordal bipartite orders [7, 9].

Release Dates

If jobs have *release dates*, we cannot hope for a universal sequence with bounded approximation ratio unless the scheduler is allowed to preempt jobs. We can think of a universal sequence as a priority order of the jobs guiding a preemptive list scheduling procedure: At any point in time, we work on the job of highest priority that has not been finished yet and that has already been released. Unfortunately, even with this flexibility, the problem is significantly harder.

Theorem 6 *There exists an instance with n jobs with release dates and unit weights, where the performance guarantee of any universal schedule is* $\Omega(\log n / \log \log n)$.

The proof relies on the classical theorem of Erdős and Szekeres [4] on the existence of long increasing/decreasing subsequences of a given sequence of distinct real numbers.

Despite this negative result, there is a non-trivial algorithm that produces a universal 5-approximate sequencing for the class of instances with release dates in which the processing time of each job is proportional to its weight.

Instance-Sensitive Performance Guarantee

Theorem 1 says that the *Doubling Algorithm* produces for every instance a universal 4-approximation. Theorem 2 proves that this is best possible since there are particular instances that do not admit a sequence with a smaller approximation ratio. Many instances, however, admit better-than-4-approximate universal sequences, yet the Doubling Algorithm is only guaranteed to find a 4-approximation. This motivates the problem of finding the best possible universal sequence on an *instance-by-instance* basis.

Theorem 7 *For any fixed* $\epsilon > 0$ *and* $c > 1$*, there is a polynomial time algorithm that given an instance either finds a* $(c + \epsilon)$*-approximate universal sequence or determines that there is no universal* c*-approximation for this particular instance.*

Applications

The unreliable machine scheduling problem addresses the demand for high-quality scheduling solutions in the dynamic real-world environments of manufacturing processes or in operating systems. The machine could be, for example, a computer server that slows down due to unpredictable third-party usage or an aging production unit prone to unexpected breakdowns. Another setting where the model is applicable is where a higher authority may give priority to another batch of jobs, thus delaying the execution of our jobs. In general, universally good performance regardless of the actual machine behavior is desirable in highly automated systems in which changing the schedule at an arbitrary point in time is too costly or technically infeasible.

Open Problems

The worst-case performance of universal sequences is quite well understood. While the analysis in the model without release dates is tight, it remains open in the setting with release dates if it is possible to obtain a universal $o(n)$-approximation for general instances. The best known lower bound is $\Omega(\log n / \log \log n)$.

While the worst-case analysis assumes arbitrary machine behaviors, it would be interesting to develop and analyze more realistic speed functions. For example, it is reasonable to assume that when a machine breaks down, then it will be repaired or replaced within a certain (possibly fixed) amount of time; or in a stochastic model, the availability periods between breakdowns may be assumed to be exponentially distributed. What improvements in the approximation guarantee do such restrictions allow?

A different approach in aiming for more practice-relevant guarantees is to relax the strict universality requirement. In many situations, changing the scheduling sequence is possible to a certain extent at some extra cost. A very interesting problem is to quantify the amount of adaptivity an algorithm needs to achieve a certain performance guarantee. Ideally, there is a parameter describing the adaptivity that allows to scale between the nonadaptive 4-approximation (Theorem 1) and a fully adaptive $(1 + \epsilon)$-approximation, given by a PTAS that constructs an individual scheduling solution for a specific machine behavior [11].

Keywords

Directed graphs; Flow networks; Graph planarity; Hierarchical drawings

Years and Authors of Summarized Original Work

1994; Bertolazzi, Di Battista, Liotta, Mannino

Problem Definition

Upward graph drawing is concerned with computing two-dimensional layouts of directed graphs where all edges flow in the upward direction. Namely, given a directed graph $G(V, E)$ (also called a *digraph* for short), an *upward drawing* of G is a drawing such that: (i) each vertex $v \in V$ is mapped to a distinct point p_v of the plane and (ii) each edge $(u, v) \in E$ is drawn as a simple curve from p_u and p_v, monotonically increasing in the upward direction.

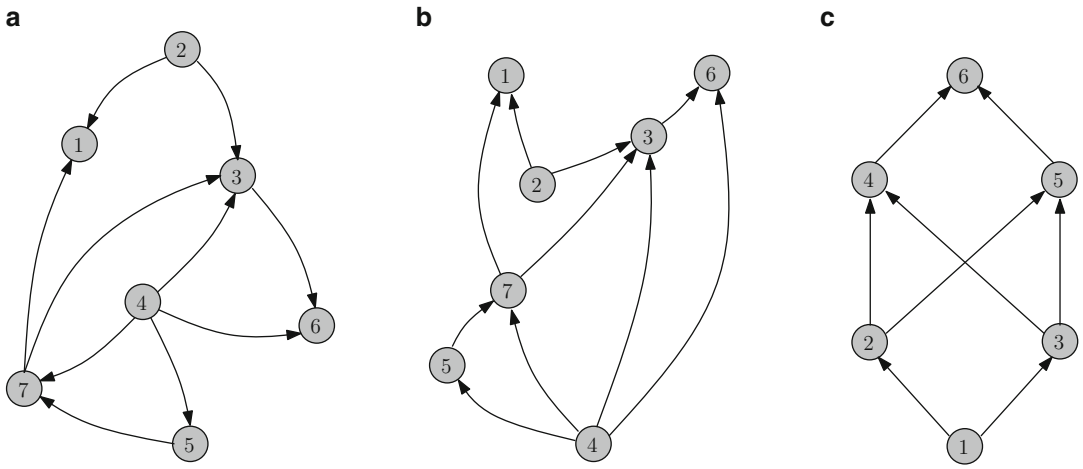
Clearly, G admits an upward drawing only if it does not contain directed cycles; if we allow edge crossings, acyclicity is also a sufficient condition for the existence of an upward drawing. Instead, if G is planar and we require that also the upward drawing of G is crossing-free, acyclicity is only a necessary condition, and the upward drawability of G becomes a much more intriguing problem. An upward drawing with no edge crossing is called an *upward planar drawing*; deciding whether a planar digraph G admits such a drawing is recognized as the *upward planarity testing* problem. This problem can be studied in two different settings:

- **Variable embedding setting.** The existence of an upward planar drawing of G is checked over all possible planar embeddings of G.
- **Fixed embedding setting.** The existence of an upward planar drawing of G is checked for a given planar embedding of G, i.e., the drawing must preserve the given embedding.

Both these settings have been widely studied in the literature. In the next section we briefly survey few seminal results on the upward planarity testing problem, and then we concentrate on the first and most popular polynomial-time algorithm for the fixed embedding setting. Figure 1 shows a planar digraph G with a given planar embedding, an embedding-preserving upward planar drawing of G, and a planar digraph G that does not admit upward planar drawings.

Key Results

Let $G(V, E)$ be a planar digraph. We will assume that G is connected (indeed, a digraph admits an upward planar drawing if and only if each of its connected components admits an upward



Upward Graph Drawing, Fig. 1 (**a**) A planar digraph G with a given planar embedding. (**b**) An upward planar drawing of G that preserves the embedding of G. (**c**) A planar digraph G that has no upward planar drawing

planar drawing). A *source* (resp. a *sink*) of G is a vertex with only outgoing (resp. incoming) edges. An *internal* vertex of G is a vertex with both outgoing and incoming edges. We denote by S, T, and I the set of sources, sinks, and internal vertices of G, respectively. Digraph G is a *planar st-digraph* if it has only one source s and one sink t and a planar embedding where s and t belong to the same face. Di Battista and Tamassia proved different equivalent characterizations of upward planar drawable digraphs, as stated in the following result [7]:

Theorem 1 ([7]) *Let G be a planar digraph. The following properties are equivalent:*

(a) G admits an upward planar drawing;
(b) G admits an upward planar drawing with straight-line edges;
(c) G is the spanning subgraph of a planar st-digraph.

Using Theorem 1, Garg and Tamassia focused on straight-line drawings and showed that the upward planarity testing problem in the variable embedding setting is NP hard [9]. As a consequence of this hardness result, polynomial-time algorithms in the variable embedding setting have been devised for restricted classes of planar digraphs, like single-source digraphs [6] and series-parallel digraphs [8], while exponential-time algorithms have been proposed for more general planar digraphs (see, e.g., [1, 8]).

Conversely, Bertolazzi et al. showed that the upward planarity testing problem can be solved in polynomial time in the fixed embedding setting [2]. In the following we describe this breakthrough result, which inspired several subsequent papers on the subject.

Polynomial-Time Upward Planarity Testing

Let $G(V, E)$ be an embedded planar digraph, and still denote by S, T, and I the number of sources, sinks, and internal vertices of G, respectively. The result in [2] is based on an elegant combinatorial characterization of the planar embedded digraphs that are upward planar drawable. We first recall few basic definitions.

Digraph G is *bimodal* if for every vertex $v \in I$, the outgoing edges of v are consecutive in the cyclic clockwise order around v (which implies that also the incoming edges of v are consecutive in the cyclic clockwise order around v). It is immediate to see that if a digraph G admits an embedding-preserving upward planar drawing, G is necessarily bimodal.

Let f be a face of G, and let $a = (e_1, v, e_2)$ be a triplet such that $v \in V$ is a vertex of the boundary of f and e_1, e_2 are two edges incident to v that are consecutive on the boundary of f (e_1 and e_2 may coincide if G is not biconnected). Triplet a is called an *angle at v in face f*, or simply an *angle of f*, or an *angle at v*. If both e_1 and e_2 are outgoing edges of v, we call a a *source-switch* angle of f; if both e_1 and e_2 are incoming edges of v, we call a a *sink-switch* angle of f. Denote by $S(f)$ and $T(f)$ the number of source-switch angles and the number of sink-switch angles of f, respectively. It can be easily observed that $S(f) = T(f)$. The *capacity* of f is defined as $cap(f) = \frac{S(f)+T(f)}{2} - 1$ if f is an internal face of G and as $cap(f) = \frac{S(f)+T(f)}{2} + 1$ if f is the external face of G. The number of sources and sinks in the digraph is nicely related to the face capacities, as stated by the following theorem.

Theorem 2 ([2]) *If G is a bimodal embedded planar digraph and F is the set of faces of G, then $\sum_{f \in F} cap(f) = |S| + |T|$.*

Now, given any upward planar drawing Γ, denote by $L(v)$ the number of geometric angles larger than π at vertex v in Γ and by $L(f)$ the number of geometric angles larger than π in face f in Γ. The following result establishes which kinds of angles in Γ can occur around the vertices and inside the faces of the digraph:

Theorem 3 ([2]) *Let G be an embedded planar digraph and let Γ be an embedding-preserving upward planar drawing of G. We have that:*

(i) $L(v) = 0$ for each $v \in I$ and $L(v) = 1$ for each $v \in S \cup T$;
(ii) $L(f) = cap(f)$, for each $f \in F$.

Motivated by Theorem 3, for any given embedded planar digraph G, one can look for an assignment of the angles of G to the faces of G, with these properties:

(a) For each source or sink v, exactly one angle at v is assigned to a face incident to v.
(b) For each face f, the number of angles assigned to f equals $cap(f)$.

Such an assignment is called an *upward-consistent assignment* of G. The following result translates the upward planarity testing problem into the problem of deciding whether G admits an upward-consistent assignment.

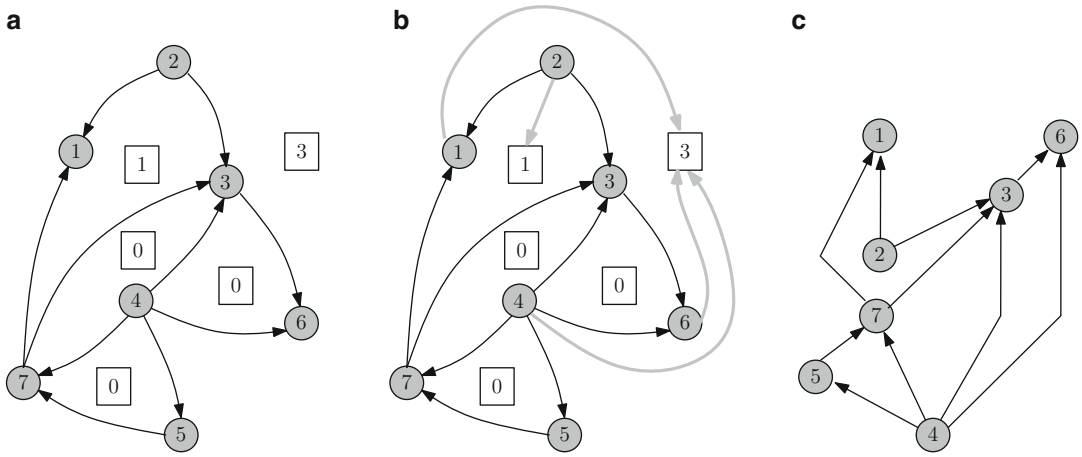
Theorem 4 ([2]) *Let G be an acyclic bimodal embedded planar digraph. G admits an embedding-preserving upward planar drawing if and only if G admits an upward-consistent assignment.*

In [2] it is proved that an upward-consistent assignment can be used to construct in linear time an upward planar drawing where each angle assigned to a face corresponds to a geometric angle larger than π. This is done by exploiting Theorem 1; namely, G is first augmented to an st-planar digraph G', then an upward drawing of G' is computed, and finally the dummy edges are removed from the drawing of G', thus obtaining an upward planar drawing of G.

Deciding whether G admits an upward-consistent assignment, and in case finding one, can be done using a network flow model. Namely, construct a bipartite flow network $N(G)$ having a node $n(v)$ for each source or sink v of G, called a *vertex-node*, and a node $n(f)$ for each face f of G, called a *face node*. Each vertex-node $n(v)$ supplies flow 1, while each face-node $n(f)$ demands a flow equal to $cap(f)$. Also, $N(G)$ has a directed arc $(n(v), (f))$ if v is a source or a sink that belongs to the boundary of f in G. A unit of flow on an arc $(n(v), (f))$ indicates that an angle at v in f must be assigned to f. Each feasible flow in $N(G)$ defines an upward-consistent assignment of G. Using standard flow algorithms, testing whether $N(G)$ has a feasible flow, and in case computing one, can be done in $O(n + r^2)$, where n is the number of vertices of G and $r = |S| + |T|$. Figure 2 illustrates the algorithmic approach described above for the upward planarity testing problem.

The next theorem summarizes the main result of [2].

Theorem 5 ([2]) *Let G be an acyclic bimodal embedded planar digraph with n vertices, and let r be the total number of sources and sinks of G.*



Upward Graph Drawing, Fig. 2 (**a**) An embedded planar digraph G; each face is represented by a *small box* reporting its capacity. (**b**) An upward consistent assignment of G; a *light gray arrow* indicates the assignment of an angle to a face. (**c**) An embedding-preserving upward planar drawing constructed from the upward-consistent assignment; the angles of G assigned to a face correspond to geometric angles larger than π in the drawing

There exists an $O(n + r^2)$-time algorithm that tests whether G admits an embedding-preserving upward planar drawing of G and that computes such a drawing if the test is positive.

Applications

Upward drawings can be effectively used to represent PERT networks, ISA hierarchies in knowledge-representation diagrams, and subroutine call charts. A generalized model, called *quasi-upward drawing*, strongly enlarges the range of application domains of upward graph drawing, making it possible to also represent cyclic digraphs [1] by allowing an edge to break its upward monotonicity in a finite number of points. Petri nets are examples of diagrams that can be represented as quasi-upward drawings; Petri nets are widely used to describe distributed systems.

Efficient C++ graph drawing libraries, like GDToolkit [5] and OGDF [3], implement advanced upward graph drawing algorithms.

Experimental Results

Extensive experimental studies on upward planarity testing are described in [1, 4]. Other references on experimental work about upward graph drawing algorithms can be found in [3, 5].

Problem Definition

This problem deals with the design of efficiently computable incentive compatible, or truthful, mechanisms for combinatorial optimization

problems with selfish one-parameter agents and a single seller. The focus is on approximation algorithms for NP-hard mechanism design problems. These algorithms need to satisfy certain monotonicity properties to ensure truthfulness.

A *one parameter agent* is an agent who as her private data has some *resource* as well as a *valuation*, i.e., the maximum amount of money she is willing to pay for this resource. Sometimes, however, the resource is assumed to be known to the mechanism. The scenario where a single seller offers these resources to the agents is primarily considered. Typically, the seller aims at maximizing the social welfare or her revenue. The work by Briest, Krysta and Vöcking [6] will mostly be considered, but also other existing models and results will be surveyed.

Utilitarian Mechanism Design

A famous example of mechanism design problems is given by combinatorial auctions (CAs), in which a single seller, auctioneer, wants to sell a collection of goods to potential buyers. A wider class of problems is encompassed by a *utilitarian mechanism design (maximization) problem* Π defined by a finite set of *objects* $\mathcal{A}$, a set of feasible outputs $O_\Pi \subseteq \mathcal{A}^n$ and a set of n agents. Each agent declares a set of objects $S_i \subseteq \mathcal{A}$ and a valuation function $v_i : \mathcal{P}(\mathcal{A}) \times \mathcal{A}^n \to \mathbb{R}$ by which she values all possible outputs. Given a vector $S = (S_1, \ldots, S_n)$ of declarations one is interested in output $o^* \in O_\Pi$ maximizing the *social welfare*, i.e., $o^* \in \operatorname{argmax}_{o \in O_\Pi} \sum_{i=1}^n v_i(S_i, o)$. In CAs, an object a corresponds to a subset of goods. Each agent declares all the subsets she is interested in and the prices she would be willing to pay. An output specifies the sets to be allocated to the agents.

Here, a limited type of agents called *single-minded* is considered, introduced by Lehmann et al. [10]. Let $R_\preceq \subseteq \mathcal{A}^2$ be a reflexive and transitive relation on $\mathcal{A}$, such that there exists a special object $\varnothing \in \mathcal{A}$ with $\varnothing \preceq a$ for any $a \in \mathcal{A}$ to model the situation in which some agent does not contribute to the solution at all. For $a, b \in \mathcal{A}(a, b) \in R_\preceq$ will be denoted by $a \preceq b$. The single-minded agent i declares a *single* object a_i and is fully defined by her *type* (a_i, v_i), with $a_i \in \mathcal{A}$ and $v_i > 0$. The valuation function introduced earlier reduces to

$$v_i(a_i, o) = \begin{cases} v_i, & \text{if } a_i \preceq o_i \\ 0, & \text{else.} \end{cases}$$

Agent i is called *known* if object a_i is known to the mechanism [11]. Here, mostly unknown agents will be considered. Intuitively, each a_i corresponds to an object agent i offers to contribute to the solution, v_i describes her valuation of any output o that indeed selects a_i. In CAs, relation $R_\preceq$ is set inclusion: an agent interested in set S will is also satisfied by S' with $S \subseteq S'$. For ease of notation let $(a, v) = ((a_1, v_1), \ldots, (a_n, v_n))$, $(a_{-i}, v_{-i}) = ((a_1, v_1), \ldots, (a_{i-1}, v_{i-1}), (a_{i+1}, v_{i+1}), \ldots, (a_n, v_n))$ and $((a_i, v_i), (a_{-i}, v_{-i})) = (a, v)$.

Mechanism

A *mechanism* $M = (A, p)$ consists of an algorithm A computing a solution $A(a, v) \in O_\Pi$ and an n-tuple $p(a, v) = (p_1(a, v), \ldots, p_n(a, v)) \in \mathbb{R}_+^n$ of payments collected from the agents. If $a_i \preceq A(a, v)_i$, agent i is *selected*, and let $S(A(a, v)) = \{i \,|\, a_i \preceq A(a, v)_i\}$ be the set of selected agents. Agent i's type is her private knowledge. Thus, the types declared by agents may not match their true types. To reflect this, let (a_i^*, v_i^*) refer to agent i's true type and (a_i, v_i) be the declared type. Given an output $o \in O_\Pi$, the *utility* of agent i is $u_i(a, v) = v_i(a_i^*, o) - p_i(a, v)$. Each agent's goal is to maximize her utility. To achieve this, she will try to manipulate the mechanism by declaring a false type if this could result in higher utility. A mechanism is called *truthful*, or *incentive compatible*, if no agent i can gain by lying about her type, i.e., given declarations (a_{-i}, v_{-i}), $u_i((a_i^*, v_i^*), (a_{-i}, v_{-i})) \geq u_i((a_i, v_i), (a_{-i}, v_{-i}))$ for any $(a_i, v_i) \neq (a_i^*, v_i^*)$.

Monotonicity

A sufficient condition for truthfulness of approximate mechanisms for single-minded CAs was

first given by Lehmann et al. [10]. Their results can be adopted for the considered scenario. An algorithm A is *monotone* with respect to $R_{\preceq}$ if

$$i \in S(A((a_i, v_i), (a_{-i}, v_{-i}))) \Rightarrow i \in S(A((a_i', v_i'), (a_{-i}, v_{-i})))$$

for any $a_i' \preceq a_i$ and $v_i' \geq v_i$. Intuitively, one requires that a winning declaration (a_i, v_i) remains winning if an object a_i', smaller according to $R_{\preceq}$, and a higher valuation v_i' are declared. If declarations (a_{-i}, v_{-i}) are fixed and object a_i declared by i, algorithm A defines a *critical value* θ_i^A, i.e., the minimum valuation v_i that makes (a_i, v_i) winning, i.e., $i \in S(A((a_i, v_i), (a_{-i}, v_{-i})))$ for any $v_i > \theta_i^A$ and $i \notin S(A((a_i, v_i), (a_{-i}, v_{-i})))$ for any $v_i < \theta_i^A$. The *critical value payment scheme* p^A associated with A is defined by $p_i^A(a, v) = \theta_i^A$, if $i \in S(A(a, v))$, and $p_i^A(a, v) = 0$, otherwise. The critical value for any fixed agent i can be computed, e.g., by performing binary search on interval $[0, v_i]$ and repeatedly running algorithm A to check if i is selected. Also, mechanism $M_A = (A, p^A)$ is *normalized*, i.e., agents that are not selected pay 0. Algorithm A is *exact*, if for declarations (a, v), $A(a, v)_i = a_i$ or $A(a, v)_i = \varnothing$ for all i. In analogy to [10] one obtains the following.

Theorem 1 *Let A be a monotone and exact algorithm for some utilitarian problem Π and single-minded agents. Then mechanism $M_A = (A, p^A)$ is truthful.*

Additional Definitions

In the *unsplittable flow problem* (UFP), an undirected graph $G = (V, E)$, $|E| = m$, $|V| = n$, with edge capacities b_e, $e \in E$, and a set K of $k \geq 1$ commodities described by terminal pairs $(s_i, t_i) \in V \times V$ and a demand d_i and a value c_i are given. One assumes that $\max_i d_i \leq \min_e b_e$, $d_i \in [0, 1]$ for each $i \in K = \{1, \ldots, k\}$, and $b_e \geq 1$ for all $e \in E$. Let $B = \min_e\{b_e\}$. A feasible solution is a subset $K' \subseteq K$ and a single flow s_i-t_i-path for each $i \in K'$, such that the demands of K' can simultaneously and unsplittably be routed along the paths and the capacities are not exceeded. The goal in *UFP*, called *B-bounded UFP*, is to maximize the total value of the commodities in K'. A generalization is allocating bandwidth for multicast communication, where commodity is a set of terminals that should be connected by a multicast tree.

Key Results

Monotone Approximation Schemes

Let Π be a given utilitarian (maximization) problem. Given declarations (a, v), let $Opt(a, v)$ denote an optimal solution to Π on this instance and $w(Opt(a, v))$ the corresponding social welfare. Assuming that A_Π is a pseudopolynomial exact algorithm for Π an algorithm A_Π^k and monotone FPTAS for Π is defined in Fig. 1.

Theorem 2 *Let Π be a utilitarian mechanism design problem among single-minded agents, A_Π monotone pseudopolynomial algorithm for Π with running time $poly(n, V)$, where*

Algorithm A_Π^k:
1 $\alpha_k := \frac{n}{\varepsilon \cdot 2^k}$;
2 **for** $i = 1, \ldots, n$ **do**
3 $v_i' := \min\{v_i, 2^{k+1}\}$;
4 $v_i'' := \lfloor \alpha_k \cdot v_i' \rfloor$;
5 return $A_\Pi(a, v'')$;

Algorithm A_Π^{FPTAS}
1 $V := \max_i v_i$, $Best := (\emptyset, \ldots, \emptyset)$, $best := 0$;
2 **for** $j = 0, \ldots, \lceil \log(1 - \varepsilon)^{-1} n \rceil + 1$ **do**
3 $k := \lfloor \log(V) \rfloor - j$;
4 **if** $w_k(A_\Pi^k(a, v)) > best$ **then**
5 $Best := A_\Pi^k(a, v)$; $best := w_k(A_\Pi^k(a, v))$;
6 return $Best$;

Utilitarian Mechanism Design for Single-Minded Agents, Fig. 1 A monotone FPTAS for utilitarian problem Π and single-minded agents

$V = \max_i v_i$, and assume that $V \le w(Opt(a, v))$ for declaration (a, v). Then A_{Π}^{FPTAS} is a monotone FPTAS for Π.

Theorem 2 can also be applied to minimization problems. Section "Applications" describes how these approximation schemes can be used for forward multi-unit auctions and job scheduling with deadlines.

Truthful Primal-Dual Mechanisms

For an instance $G = (V, E)$ of UFP defined above, let S_i be the set of all s_i-t_i-paths in G, and $S = \bigcup_{i=1}^{k} S_i$. Given $S \in S_i$, let $q_S(e) = d_i$ if $e \in S$, and $q_S(e) = 0$ otherwise. UFP is the following integer linear program (ILP)

$$\max \quad \sum_{i=1}^{k} c_i \cdot \left(\sum_{S \in S_i} x_S \right) \tag{1}$$

$$\text{s.t.} \quad \sum_{S : S \in S, e \in S} q_S(e) x_S \le b_e \quad \forall e \in E \tag{2}$$

$$\sum_{S \in S_i} x_S \le 1 \quad \forall i \in \{1, \ldots, k\} \tag{3}$$

$$x_S \in \{0, 1\} \quad \forall S \in S\,. \tag{4}$$

The linear programming (LP) relaxation is the same linear program with constraints (4) replaced with $x_S \ge 0$ for all $S \in S$. The corresponding dual linear program is

$$\min \quad \sum_{e \in E} b_e y_e + \sum_{i=1}^{k} z_i \tag{5}$$

$$\text{s.t.} \quad z_i + \sum_{e \in S} q_S(e) y_e \ge c_i \quad \forall i \in \{1, \ldots, k\}\ \forall S \in S_i \tag{6}$$

$$z_i, y_e \ge 0 \quad \forall i \in \{1, \ldots, k\}\ \forall e \in E. \tag{7}$$

Based on these LPs, Fig. 2 specifies a primal-dual mechanism for routing, called Greedy-1. Greedy-1 ensures feasibility by using y_e's: if an added set exceeded the capacity b_e of some $e \in E$, then this would imply the stopping condition already in the previous iteration. Using the weak duality of LPs the following result can be shown.

Theorem 3 *Greedy-1 outputs a feasible solution, and it is a $(\frac{e\gamma B}{B-1}(m)^{1/(B-1)})$-approximation algorithm if there is a polynomial time algorithm that finds a γ-approximate set S_i in line 4.*

In case of UFP $\gamma = 1$, as the shortest s_i-t_i-path computation finds set S_i in line 4 of Greedy-1. For multicast routing, this problem corresponds to the NP-hard Steiner tree problem, for which one can take $\gamma = 1.55$. Greedy-1 can easily be shown to be monotone in demands and valuations as required in Theorem 1. Thus it implies a truthful mechanism for allocating network resources. The commodities correspond to bidders, the terminal nodes of bidders are known, but the bidders might lie about their demands and valuations. In the multicast routing the set of terminals for each bidder is known but the demands and valuations are unknown.

Utilitarian Mechanism Design for Single-Minded Agents, Fig. 2 Truthful mechanism for network (multicast) routing. $e \approx 2.718$ is Euler number

Algorithm Greedy-1:

1 $\mathcal{T} := \emptyset$; $K := \{1, \ldots, k\}$;
2 **forall** $e \in E$ **do** $y_e := 1/b_e$;
3 **repeat**
4 **forall** $i \in K$ **do** $S_i := \operatorname{argmin} \left\{ \sum_{e \in S} y_e \;\middle|\; S \in S_i \right\}$;
5 $j := \operatorname{argmax} \left\{ \dfrac{c_i}{d_i \sum_{e \in S_i} y_e} \;\middle|\; i \in K \right\}$;
6 $\mathcal{T} := \mathcal{T} \cup \{S_j\}$; $K := K \setminus \{j\}$;
7 **forall** $e \in S_j$ **do** $y_e := y_e \cdot \left(e^{B-1} m\right)^{q_{S_j}(e)/(b_e - 1)}$;
8 **until** $\sum_{e \in E} b_e y_e \ge e^{B-1} m$ **or** $K = \emptyset$;
9 return $\mathcal{T}$.

Utilitarian Mechanism Design for Single-Minded Agents, Fig. 3 Truthful mechanism for multi-unit CAs among unknown single-minded bidders. For CAs without multisets: $q_S(e) \in \{0, 1\}$ for each $e \in U$, $S \in \mathcal{S}$

Algorithm Greedy-2:

$\mathcal{T} := \emptyset$;
forall $e \in U$ **do** $y_e := 1/b_e$;
repeat
  $S := \text{argmax}\left\{ \frac{c_S}{\sum_{e \in U} q_S(e) y_e} \;\middle|\; S \in \mathcal{S} \setminus \mathcal{T} \right\}$;
  $\mathcal{T} := \mathcal{T} \cup \{S\}$;
  forall $e \in S$ **do** $y_e := y_e \cdot (e^B m)^{q_S(e)/b_e}$;
until $\sum_{e \in U} b_e y_e \geq e^B m$;
return $\mathcal{T}$.

Corollary 1 *Given any $\epsilon > 0$, $B \geq 1 + \epsilon$, Greedy-1 is a truthful $O(m^{1/(B-1)})$-approximation mechanism for UFP (unicast routing) as well as for the multicast routing problem, where the demands and valuations of the bidders are unknown.*

When B is large, $\Omega(\log m)$, then the approximation factor in Corollary 1 becomes constant. Azar et al. [4] presented further results in case of large B. Awerbuch et al. [3] gave randomized online truthful mechanisms for uni- and multicast routing, obtaining an expected $O(\log(\mu m))$-approximation if $B = \Omega(\log m)$, where μ is the ratio of the largest to smallest valuation. Their approximation holds in fact with respect to the revenue of the auctioneer, but they assume that the demands are known to the mechanism. Bartal et al. [5] give a truthful $O(B \cdot (m/\theta)^{1/(B-2)})$-approximation mechanism for UFP with unknown valuations and demands, where $\theta = \min_i \{d_i\}$.

Greedy-1 can be modified to give truthful mechanisms for multi-unit CAs among unknown single-mined bidders. (In the case of *unknown* single-minded bidders, the bidders have as private data not only their valuations (as in the case of *known* single-minded bidders) but also the sets they demand.) Archer et al. [2] used randomized rounding to obtain a truthful mechanism for multi-unit CAs, but only in a probabilistic sense and only for known bidders. Multi-unit CA among single-minded bidders is a special case of ILP (1)–(4), where $|S_i| = 1$ for each $i \in K$, and $q_S(e) \in \{0, 1\}$ for each $e \in U$, $S \in \mathcal{S}$ (E is U in CAs). A bid of bidder $i \in K$ is $(a_i, v_i) = (S, c_S)$, $S \in S_i$, and $c_S = c_i$ is the valuation. The relation $R_{\preceq}$ is $\subseteq$. Algorithm Greedy-2 in Fig. 3 is exact and monotone for CAs with unknown single-minded bidders, as needed in Theorem 1.

Theorem 4 *Algorithm Greedy-2 is a truthful $O(m^{\frac{1}{B}})$-approximation mechanism for multi-unit CAs among unknown single-minded bidders.*

Bartal et al. [5] presented a truthful mechanism for this problem among unknown single-minded bidders which is $O(B \cdot m^{1/(B-2)})$-approximate. (It works in fact for more general bidders.)

Applications

Applications of the techniques described above are presented and a short survey of other results.

Applications of Monotone Approximation Schemes

In a *forward multi-unit auction* a single auctioneer wants to sell m identical items to n possible buyers (bidders). Each single-minded bidder specifies the number of items she is interested in and a price she is willing to pay. Elements in the introduced notation correspond to the requested and allocated numbers of items. Relation $R_{\preceq}$ describes that bidder i requesting q_i items will be satisfied also by any larger number of items. Mu'alem and Nisan [11] give a 2-approximate monotone algorithm for this problem. Theorem 2 gives a monotone FPTAS for multi-unit auctions among unknown single-minded bidders. This FP-

TAS is truthful with respect to agents where both the number of items and price are private.

In *job scheduling with deadlines (JSD)*, each agent i has a job with running time t_i, deadline d_i and a price v_i she is willing to pay if her job is processed by deadline d_i. Element a_i is defined as $a_i = (t_i, d_i)$. Output for agent i is a time slot for processing i's job. For two elements $a_i = (t_i, d_i)$ and $a'_i = (t'_i, d'_i)$ one has $a_i \preceq a'_i$ if $t_i \leq t'_i$ and $d_i \geq d'_i$. Theorem 2 leads to a monotone FPTAS, which, however, is not exact (see Theorem 1) with respect to deadlines, and so it is a truthful mechanism only if the deadlines are known. The techniques of Theorem 2 apply also to minimization mechanism design problems with a single buyer, such as reverse multi-unit auctions, scheduling to minimize tardiness, constrained shortest path and minimum spanning tree problems [6].

Applications of the primal dual algorithms

The applications of the primal dual algorithms are combinatorial auctions and auctions for unicast and multicast routing. As these applications are tied very much to the algorithms, they have already been presented in section "Key Results".

Survey of Other Results

First truthful mechanisms for single-minded CAs were designed by Lehmann et al. [10], where they introduced the concept of single-minded agents, identified the role of monotonicity, and used greedy algorithms to design truthful mechanisms. Better approximation ratios of these greedy mechanisms were proved by Krysta [9] with the help of LP duality. A tool-box of techniques for designing truthful mechanisms for CAs was given by Mu'alem and Nisan [11].

The previous section presented a monotone FPTAS for job scheduling with deadlines where jobs are selfish agents and the seller offers the agents the facilities to process their jobs. Such scenarios when jobs are selfish agents to be scheduled on (possibly selfish) machines have been investigated further by Andelman and Mansour [1], see also references therein.

So far social welfare was mostly assumed as the objective, but for a seller probably more important is to maximize her revenue. This objective turns out to be much harder to enforce in mechanism design. Such truthful (in probabilistic sense) mechanisms were obtained for auctioning unlimited supply goods among one-parameter agents [7, 8]. Another approach to maximizing seller's revenue is known as optimal auction design [12]. A seller wants to auction a single good among agents and each agent has a private value for winning the good. One assumes that the seller knows a joint distribution of those values and wants to maximize her expected revenue [13, 14].

Cross-References

Mechanisms that approximately maximize revenue for unlimited-supply goods as of Goldberg, Hartline and Wright [8] are presented in entry ▸ Competitive Auction.

Problem Definition

In the *vector bin packing problem*, we are given an integral dimension $d \geq 1$ and a list $L = (x_1, x_2, \ldots, x_n)$ of items, where each item is a d-dimensional tuple $x_i = (x_{i,1}, x_{i,2}, \ldots, x_{i,d})$ with rational entries $x_{i,j} \in [0, 1]$. The goal is to assign the items to a minimum number of multidimensional *bins*, where if X is the set of items assigned to a bin, we must have, for each j, $1 \leq j \leq d$,

$$\sum_{x_i \in X} x_{i,j} \leq 1.$$

Note that when $d = 1$, the vector bin packing problem reduces to the classic (one-dimensional) *bin packing* problem.

One potential application of the vector bin packing problem is that of assigning jobs to servers in a shared hosting platform, where each job may require a specific number of cycles per second and specific amounts of memory, bandwidth, and other resources [12]. Here the servers

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

would correspond to the bins, the dimension d is the number of resources, the items are the jobs, and $x_{i,j}$ is the fraction of the total amount of a server's jth resource that job x_i requires.

In the early literature, this problem was often called the *multidimensional bin packing* problem. That term, however, is now more typically reserved for the related problem where the items are d-dimensional rectangular parallelepipeds (rectangles, when $d = 2$), the bins are d-dimensional unit cubes, and the items assigned must not only be assigned to bins but also to specific positions in the bins, in such a way that no point in any bin is in the interior of more than one item. With vector bin packing, in contrast, the dimensions are all independent and there is no geometric interpretation of the items.

Key Results

As a generalization of bin packing, vector bin packing is clearly NP-hard in the strong sense, and so most of the research on this problem has been directed toward the study of approximation algorithms for it. This will be the primary topic in this entry. Most of the theoretical results concerning these algorithms can be expressed in terms of *asymptotic worst-case ratios*. For a given algorithm A and a list of items L, let $A(L)$ denote the number of bins used by A for L. Let *OPT(L)* denote the optimal number of bins for list L. We define the asymptotic worst-case ratio $R_A^\infty(d)$ for algorithm A on d-dimensional instances as follows.

$$R_A^N(d) = \max\left\{\frac{A(L)}{OPT(L)} : L \text{ is a list of } d\text{-dimensional items with } OPT(L) = N\right\}$$

$$R_A^\infty(d) = \limsup_{N\to\infty} R_A^N(d)$$

Generalizations of Classical Bin Packing Algorithms

Generalizing First Fit and First Fit Decreasing

Several classic one-dimensional bin packing algorithms have been generalized to vector bin packing. Imagine we have a potentially infinite sequence of empty bins $B_1, B_2, \ldots$, and let $X_{h,j}$ denote the total amount of resource j used by the items currently assigned to B_h. In the generalized "First Fit" algorithm, the first item goes in bin B_1, and thereafter each item goes into the lowest-index bin into which it can be legally placed, subject to the resource constraints. In generalized "Best Fit," each item is assigned to a bin with the maximum value of $\sum_{j=1}^{d} X_{h,j}$ among those to which it can legally be added, ties broken in favor of the smallest index h.

As in the one-dimensional case, a plausible way to improve the above two online algorithms is to first reorder the list in decreasing order, and then apply the packing algorithm. Now, however, there are a variety of ways to define "decreasing order," each leading to different algorithms. For example, in FFDmax items are ordered by nonincreasing value of $\max_{j=1}^{d} x_{i,j}$ and then FF is applied. Similarly, in FFDsum, the items are ordered by nonincreasing value of $\sum_{j=1}^{d} x_{i,j}$ and, in FFDprod, they are ordered by nonincreasing value of $\prod_{j=1}^{d} x_{i,j}$. In FFDlex, they are ordered so that x_i precedes $x_{i'}$ only if either $x_{i,j} = x_{i',j}$, $1 \le j \le d$, or there is a $j^* \le d$ such that $x_{i,j} = x_{i',j}$, $1 \le j < j^*$ and $x_{i,j^*} < x_{i',j^*}$. The algorithms BFDmax, BFDsum, BFCprod, and BFDlex are defined analogously, with Best Fit being used to pack the reordered list instead of First Fit.

Call an algorithm "reasonable" if it produces packings in which no two bins can be combined, that is, are such that all the items contained in the two would collectively fit together in a single bin [9]. All of the above algorithms are easily seen to be reasonable, and, indeed, any vector bin packing algorithm has a "reasonable" counterpart that uses no more bins and spends at most $O(n^2 d)$ additional time (in a final pass that

combines legally combinable pairs of bins as long as such pairs exist). A general upper bound on asymptotic worst-case behavior is the following.

Theorem 1 ([9]) *If A is a reasonable vector bin packing algorithm, then for all $d \geq 1$,*

$$R_A^\infty(d) \leq d + 1.$$

Unfortunately, none of the above algorithms are much better.

Theorem 2 ([9, 11]) *For each of the 10 algorithms defined above and all $d \geq 1$,*

$$R_A^\infty(d) \geq d.$$

Tighter bounds have been proved for two of the algorithms.

Theorem 3 ([6]) *For all $d \geq 1$, $R_{\mathrm{FF}}^\infty(d) = d + \frac{7}{10}$.*

Theorem 4 ([6]) *For all $d \geq 1$, $d + \frac{d-1}{d(d+1)} \leq R_{\mathrm{FFDmax}}^\infty(d) \leq d + \frac{1}{3}$.*

Note that the classic one-dimensional bin packing results of [8] yield $R_{\mathrm{FF}}^\infty(1) = 17/10$ (the precise specialization of Theorem 3) and $R_{\mathrm{FFD}}^\infty(1) = 11/9$ (a tighter result than the specialization of Theorem 4). Matching upper and lower bounds are not known for $R_{\mathrm{FFDmax}}^\infty(d)$ for any $d > 1$. In special cases, however, the lower bounds can be improved. It was observed in [6] that the lower bounds for $d \in \{2, 3\}$ could be increased to $d + 11/60$ using ideas from [8]. And Csirik et al. [4] showed that for odd $d \geq 5$, the lower bound of Theorem 2 could be increased by $1/(d(d+1)(d+2))$.

Generalizing the de la Vega and Lueker Asymptotic Approximation Scheme

In [5], de la Vega and Lueker devised an "asymptotic polynomial-time approximation scheme" (APTAS) for one-dimensional bin packing, that is, a collection of polynomial-time algorithms A_ϵ with $R_{A_\epsilon}^\infty(1) \leq 1 + \epsilon$ for all $\epsilon > 0$. In that same paper, they also showed how to generalize the algorithms to provide a collection of vector bin packing algorithms B_ϵ such that for each ϵ and each integer $d \geq 1$, $R_{B_\epsilon}^\infty(d) \leq d + \epsilon$.

The algorithm B_ϵ is quite simple. Divide L into d sublists, $L_1, L_2, \ldots, L_d$, where L_j consists of all those items x for which j is the index of the dimension with the largest entry in the corresponding tuple, ties broken arbitrarily. Then apply $A_{\epsilon/d}$ to each list L_j separately, viewed as an instance of one-dimensional bin packing with the size of item x_i being $x_{i,j}$, and output the union of the d packings. Unfortunately, although the running times for the B_ϵ's are linear in dn, they contain additive constants that are potentially exponential in $(d/\epsilon)^2$, and so they may not be practical for small ϵ.

In contrast, FF, FFDmax, and all their variants mentioned in the previous section have straightforward $O(dn^2)$ implementations, and, although the data structures that allow them to be sped up to $O(n \log n)$ when $d = 1$ do not extend to higher dimensions, speedups should be possible by using d-dimensional dynamic range searching procedures to identify the set of bins that can contain the next item to be packed [11].

Hardness of Approximation Results

In [14], Yao observed that, under a standard decision tree model of computation, any vector bin packing algorithm A that has $R_A^\infty(d) < d$ for all d cannot have $o(n \log n)$ running time. This is not much of a constraint, however, since almost all the algorithms that have been proposed for Vector Bin Packing are slower than this. For those algorithms, a weaker bound applies. Assuming P $\neq$ NP, no polynomial-time vector bin packing algorithm A can have $R_A^\infty(d) < \sqrt{d} - \epsilon$ for all d and any $\epsilon > 0$. This follows from a straightforward reduction of graph coloring to vector bin packing and a result of Zuckerman [15] for the former [3]. Under the same assumption, there can be no APTAS for any fixed $d \geq 2$ [13].

Algorithms with $R_A^\infty(d) < d$

Chekuri and Khanna [3] devised the first polynomial-time algorithms to guarantee $R_A^\infty(d) < d$ for all sufficiently large d.

Theorem 5 ([3]) *For any* $\epsilon > 0$ *there is a polynomial-time algorithm* C_ϵ *such that*

$$R^{\infty}_{C_\epsilon}(d) < \epsilon \cdot d + \ln(\epsilon^{-1}) + 2.$$

The algorithm works in three phases. The first considers the following linear program (LP). Let $z_{i,k}$ be a decision variable with value 1 if item x_1 is packed in bin j. The LP's constraints are

$$\sum_{k=1}^{m} z_{i,k} = 1, \quad 1 \le i \le n \tag{1}$$

$$\sum_{i=1}^{n} x_{i,j} \cdot z_{i,k} \le 1, \quad 1 \le k \le m, 1 \le j \le d \tag{2}$$

$$z_{i,k} \ge 0, \quad 1 \le i \le n, 1 \le k \le m \tag{3}$$

This is the LP relaxation of an integer program (with $z_{i,k} \in \{0, 1\}$) which has a feasible solution if and only if our list can be packed into m bins. The first set of constraints insures that each item is packed into exactly one bin. The second set insures that all resource constraints are satisfied by the packing.

Let M be the least value of m such that this LP is feasible. Then we clearly must have $OPT(L) \ge M$. Moreover we can in polynomial time determine M and a basic feasible solution for the corresponding LP, by using binary search and a polynomial time LP-solver. In this basic feasible solution, there will be at most $n + dM$ positive variables (the number of nontrivial constraints). Since each of the n items x_i by (1) must be assigned to at least one bin, at least one of the variables $z_{i,k}$ must be positive for each i, meaning that at most dM of the items can be assigned to more than one bin. That leaves $n - dM$ items assigned to exactly one bin, and consequently our LP solution yields a feasible packing of these items into $M \le OPT(L)$ bins, which is the output of our first phase. The remaining dM or fewer items will be packed into additional bins in two additional phases as follows.

Let $k = \lceil 1/\epsilon \rceil$. While there are at least k unpacked items that will fit in a single bin, find such a set and pack them all in a new bin (Phase 2). Otherwise, find a maximum size set of unpacked items that will fit in a bin, assign them to a new bin, and repeat until all items are packed (Phase 3). Note that in both of these phases the next set of items to be packed can be found in time $O(n^k kd)$, which is polynomial for fixed ϵ. Thus the overall time for the algorithm is itself polynomial for fixed ϵ. Phase 2 creates at most $dM/k < \epsilon d \cdot OPT(L)$ bins. Phase 3 can be interpreted as implementing the Greedy algorithm for Set Covering, as applied to the instance in which the elements to be covered are the items left to be packed after Phase 2, the sets are the collections of those items which will fit in a bin, and no set has size exceeding $k - 1$. Thus, by standard results about Greedy Set Covering (see [7] for example), the number of bins added in this phase is less than $(\ln(k-1)+1) \cdot OPT(L) < (\ln(1/\epsilon) + 1) \cdot OPT(L)$. Adding up the above three terms yields the claimed theorem.

Note that if we set $\epsilon = 1/d$ in the above, we get a series of algorithms $C_{1/d}$ with $R^{\infty}_{C_{1/d}}(d) \le \ln(d) + 3$, where the running time of each is polynomial in n, although exponential in d. A slight improvement to this has recently been obtained by Bansal et al. [1]. They devise algorithms $D_{d,\epsilon}$ that run in polynomial time for fixed d and ϵ (although exponential in both) that have $R^{\infty}_{D_{d,\epsilon}} \le \ln(d + \epsilon) + 1 + \epsilon$, which, for $d \ge 2$, already beats $\ln(d) + 3$ when $\epsilon = 1$.

Experimental Results

There have been several experimental studies of approximation algorithms for vector bin packing [2, 10–12]. These studies were for the most part limited to $d \le 10$ and $n \le 500$, which may well make sense in the context of the proposed applications, and used distinct sets of randomly generated test instances. In two cases ([10] and [12]), the algorithms were compared using objective functions other than the number of bins packed. Nevertheless, certain common conclusions emerge. The FFD algorithms in particular yielded substantially better packings than worst-case analysis suggests. Both [11] and [12] suggest, however, that a different class of algorithms, ones that attempt to keep the bins as "balanced"

as possible, may perform even better. An example of such an algorithm is the "norm-based greedy" algorithm of [11], which packs the bins one-by-one, at each step adding to the current bin B_h that item x_i that fits and yields the smallest weighted L^2 norm for the resulting "gap vector" $(X_{h,1} - x_{i,1}, X_{h,2} - x_{i,2}, \ldots, X_{h,d} - x_{i,d})$. For more details, see [11]. As for the algorithms described above with $R_A^\infty(d) < d$ for large d, the only ones with hopes of feasible running times are the algorithms $C_{1/d}$ from [3] when n^d is of manageable size. Limited experiments from [12] indicate that the packings these algorithms produce are not competitive.

2004; Chekuri, Khanna

Problem Definition

Vector scheduling is a multidimensional extension of traditional machine scheduling problems. Whereas in traditional machine scheduling a job only uses a single resource, normally time, in vector scheduling a job uses several resources. In traditional scheduling, the load of a machine is the total resource consumption by the jobs that it serves. In vector scheduling, we define the load of a machine as the maximum resource usage over all resources of the jobs that are served by this machine. In the setting that we consider here, the

makespan, which is normally defined to be the time by which all jobs are completed, is equal to the maximum machine load.

To define the vector scheduling problem that we consider more formally, we let $\|\mathbf{x}\|_\infty$ denote the standard ℓ_∞-norm of the vector $\mathbf{x}$. In the vector scheduling problem, the input consists of a set J of n jobs, where each job j is associated with a d-dimensional vector $\mathbf{p_j} \in [0,1]^d$, and m identical machines. The goal is to find an assignment of the jobs to the m machines such that $\max_{1\le i\le m} \| \sum_{j\in M_i} \mathbf{p_j}\|_\infty$ is minimized, where M_i denotes the set of jobs that are assigned to machine i.

The traditional machine scheduling problem corresponds to the case $d = 1$, and this is known to be strongly NP-hard [8]. For $d = 1$, Graham's well-known list scheduling algorithm has a performance guarantee of 2 [9] and Hochbaum and Shmoys developed at PTAS [10]. For general vector scheduling, Graham's list scheduling algorithm can be extended to the d-dimensional case, having a performance guarantee of $d + 1$. In this entry we focus on the work of Chekuri and Khann [5], who developed a PTAS for fixed d and gave a polylogarithmic approximation factor for the case of general d.

Key Results

Constant Dimension *d*

Chekuri and Khann [5] designed an approximation scheme that runs in polynomial time whenever the dimension d of the job vectors is constant.

Theorem 1 *For any $\epsilon > 0$, there exists an $(1+\epsilon)$-approximation algorithm that has a running time of $O((nd/\epsilon)^{O(s)})$, where s is in $O\left((\frac{\log(d/\epsilon)}{\epsilon})^d\right)$.*

The proof of this theorem is a nontrivial generalization of the ideas that Hochbaum and Shmoys used for the 1-dimensional case [10]. In this primal-dual approach, the main idea is to view the scheduling problem as a bin-packing problem in which the jobs need to be packed into a number of bins of a certain capacity B. If all jobs fit into m bins, then the makespan is bounded by B. Hochbaum and Shmoys gave an algorithm that determines whether the jobs fit into m bins of capacity $(1+\epsilon)B$ or the jobs need to be packed into at least $m+1$ bins of capacity B. Chekuri and Khanna extended this idea by using d-dimensional bins, where the jobs assigned to one bin should have a total resource usage of at most B in any of the d dimensions. By standard scaling techniques, we assume w.l.o.g. that $B = 1$.

Like in the 1-dimensional case, Chekuri and Khanna divide the jobs in small and large jobs, where the size of a job is based on the ℓ_∞ norm. They first do a preprocessing step in which each coordinate of the vectors is set to 0 whenever it is too small compared to the maximum value of the coordinates in the same vector. To find an $(1+\epsilon)$-approximation, the algorithm performs two stages. In the first stage all large jobs will be assigned to the machines, and in the second stage all small jobs will be assigned to the machines. Whereas in the 1-dimensional case the assignment of the small jobs can be done greedily on top of the large jobs, for $d \ge 2$ the interaction between the two stages needs to be taken into account.

To accommodate this interaction, Chekuri and Khanna define a *capacity configuration* as a d-tuple $(c_1,\ldots,c_d)$ such that c_k is an integer between 0 and $\lceil 1/\epsilon\rceil$. A set of jobs S can be feasible, scheduled on one machine according to a capacity configuration $(c_1,\ldots,c_d)$ when for any dimension k, it holds that $\left(\sum_{j\in S}\mathbf{p_j}\right)_k \le a_k\cdot\epsilon$, i.e., in each dimension k the resource usage is not more than $c_k\cdot\epsilon$. The number of distinct capacity configurations is given by $t = (1+\lceil 1/\epsilon\rceil)^d$.

A capacity configuration describes approximately how a machine is filled. As there are m machines available to process the jobs, a *machine configuration* can be described by a t-tuple $(m_1,\ldots,m_t)$, satisfying $m_i \ge 0$ and $\sum_i m_i = m$, where m_i denotes the number of machines of the ith capacity configuration. The number

of distinct machine configurations is certainly bounded from above by m^t.

After the preprocessing of the vectors and the splitting of the jobs in small and large, it needs to be determined whether all large jobs can be scheduled according to a machine configuration M. As a first step, all nonzero elements of the large vectors are rounded (down) to the begin points of geometrically increasing intervals. Moreover, as the vectors are in some sense large, not too many vectors can be scheduled on one machine. Therefore, using a dynamic programming approach, one can approximately determine whether the set of large vectors can be scheduled according to machine configuration M.

When the set of large jobs are scheduled such that a certain machine i is scheduled according to a capacity configuration $(c_1, \ldots, c_d)$, then the small jobs on this machine need to be scheduled according to the *empty capacity configuration*, i.e., the capacity configuration $(1 + \lceil 1/\epsilon \rceil) \cdot (1, 1, \ldots, 1) - (c_1, \ldots, c_d)$. Given a machine configuration M, we let $\bar{M}$ denote the corresponding machine configuration as the one obtained by taking the empty capacity configurations for each of the machines in M.

To see whether the small jobs can be scheduled according to a machine configuration $\bar{M}$, Chekuri and Khanna present an integer programming (ILP) formulation that assigns the vectors to the machines. Moreover, they show that solving the LP relaxation of this ILP formulation and distributing the fractionally assigned vectors equally over the machines result in a solution in which each dimension of each machine is only overloaded by a factor of $(1 + \epsilon)$.

Once they have found a machine configuration M according to which the large jobs can be scheduled and corresponding machine configuration $\bar{M}$ according to which the small jobs can be scheduled, Chekuri and Khanna have shown that all jobs can be scheduled such that the load of any machine does not exceed $1 + \epsilon$. If for all machine configurations M and corresponding machine configuration $\bar{M}$ the large jobs cannot be scheduled according to M or the small jobs cannot be scheduled according to $\bar{M}$, then the vectors cannot be scheduled such that the load of each machine is at most 1.

General Dimension *d*

For the general case in which the dimension d of the vectors is not restricted to be a constant, Chekuri and Khanna present several approximation algorithms. Also for the general case, they assume that all vectors can be scheduled such that the makespan is bounded by 1. For two algorithms, they use as a subroutine an approximation algorithm for finding a set of vectors S that maximizes the volume of these vectors, i.e., the sum of all coordinates of all these vectors $\sum_{j \in S} \sum_{k=1}^{d} (\mathbf{p_j})_k$, restricted to $\| \sum_{j \in S} \mathbf{p_j} \|_\infty \leq 1$. This resulted in the following results.

Theorem 2 *There exists a polynomial-time $O(\log^2 d)$-approximation algorithm for the vector scheduling problem.*

Theorem 3 *There exists a $O(\log d)$-approximation algorithm for the vector scheduling problem that runs in time polynomial in n^d.*

These approximation results are good when d is small compared to the number of machines m. On the other hand, Chekuri and Khanna also give a randomized algorithm, which just assigns each job uniformly at random to one of the machines, obtaining a performance guarantee that is better when d is large compared to m.

Theorem 4 *There exists a randomized algorithm that has a performance guarantee of $O(\log d m / \log \log d m)$ with high probability.*

Finally, there is also a hardness result for the vector scheduling problem.

Theorem 5 *For any constant $\rho > 1$, there is no polynomial-time approximation algorithm with a performance guarantee of ρ, unless NP = ZPP.*

Extensions

Epstein and Tassa [6, 7] extended the vector scheduling problem to deal with more general objective functions. Instead of defining the load of a machine as the maximum resource usage over all resources of the jobs that are

served by this machine, they defined the load as the sum of the vectors $\mathbf{p_j}$ assigned to the machine. That is, the load itself is now also a d-dimensional vector. Letting $\mathbf{l_i} = \sum_{j \in M_i} \mathbf{p_j}$ denote the load of machine i, then in [6] they gave PTASes for several objective functions of the form $F(S) = f(g(\mathbf{l_1}), \ldots, g(\mathbf{l_m}))$. Note that the vector scheduling problem as discussed in this entry is equal to the case that $f = g = \max$. In [7], they extended their results to the more general case where the function g may vary per machine, i.e., $F(S) = f(g_1(\mathbf{l_1}), \ldots, g_m(\mathbf{l_m}))$.

Bonifaci and Wiese [4] extended the vector scheduling problem to the ℓ_p norm and the case of unrelated machines. That is, a job j has a d-dimensional resource usage $\mathbf{p_{ij}}$ on machine i. They considered the case in which the number of types of machines is constant: on the same type of machine, a certain job has the same resource usage. Moreover, they restricted themselves to the case of having only a constant number of resources, that is, the vectors $\mathbf{p_{ij}}$ are d dimensional for a constant d. For this setting, they developed a PTAS.

The PTAS of Chekuri and Khanna has a running time that is doubly exponential in d. Bansal, Vredeveld, and Van der Zwaan [2] showed that this double exponential dependence on d is necessary. For $\epsilon < 1$, they showed that unless the exponential time hypothesis fails, there is no $(1 + \epsilon)$-approximation algorithm with running time $\exp(o(\lfloor 1/\epsilon \rfloor^{d/3}))$. Moreover, they showed that unless NP has subexponential algorithms, no $(1+\epsilon)$-approximation algorithm exists with running time $\exp(\lfloor 1/\epsilon \rfloor^{o(d)})$. These lower bounds even hold for the case that ϵm more machines are allowed, for sufficiently small $\epsilon > 0$. Moreover, they also gave a $(1+\epsilon)$-approximation algorithm with running time $\exp((1/\epsilon)^{O(d \log \log d)} + nd)$, which is the first efficient approximation scheme (EPTAS) for the problem with constant d.

Open Problems

The gap between the lower bounds and upper bounds on the running time of $(1 + \epsilon)$-approximation algorithms has almost been closed. The question remains whether this is also the case when instead of the ℓ_∞-norm, the ℓ_p-norm is minimized. Furthermore, it would be interesting to know whether one can obtain better running times when the vectors are highly structured. These highly structured vectors may occur, for example, in applications of real-time scheduling; see, e.g., [1, 3].

Problem Definition

Let G be an undirected graph. A subset C of vertices in G is a *vertex cover* for G if every edge in G has at least one end in C. The (parametrized) VERTEX COVER problem is for each given instance (G, k), where G is a graph and $k \geq 0$ is an integer (the parameter), to determine whether the graph G has a vertex cover of at most k vertices.

The VERTEX COVER problem is one of the six "basic" NP-complete problems according to Garey and Johnson [4]. Therefore, the problem cannot be solved in polynomial time unless P = NP. However, the NP-completeness of the problem does not obviate the need for solving it because of its fundamental importance and wide applications. One approach was initiated based on the observation that in many applications, the parameter k is small. Therefore, by taking the advantages of this fact, one may be able to solve this NP-complete problem effectively and practically for instances with a small parameter. More specifically, algorithms of running time of the form $f(k)p(n)$ have been studied for VERTEX COVER, where $p(n)$ is a low-degree polynomial of the number $n = |G|$ of vertices in G and $f(k)$ is a function independent of n.

There has been an impressive sequence of improved algorithms for the VERTEX COVER problem. A number of new techniques have been developed during this research, including kernelization, folding, and refined branch-and-search. In particular, the *kernelization* method is the study of polynomial time algorithms that can significantly reduce the instance size for VERTEX COVER. The following are some concepts related to the kernelization method:

Definition 1 Two instances (G, k) and (G', k') of VERTEX COVER are *equivalent* if the graph G has a vertex cover of size $\leq k$ if and only if the graph G' has a vertex cover of size $\leq k'$.

Definition 2 A *kernelization algorithm* for the VERTEX COVER problem takes an instance (G, k) of VERTEX COVER as input and produces an equivalent instance (G', k') for the problem, such that $|G'| \leq |G|$ and $k' \leq k$.

The kernelization method has been used extensively in conjunction with other techniques in the development of algorithms for the VERTEX COVER problem. Two major issues in the study of kernelization method are (1) effective reductions of instance size; and (2) the efficiency of kernelization algorithms.

Key Results

A number of kernelization techniques are discussed and studied in the current paper.

Preprocessing Based on Vertex Degrees

Let (G, k) be an instance of VERTEX COVER. Let v be a vertex of degree larger than k in G. If a vertex cover C does not include v, then C must contain all neighbors of v, which implies that C contains more than k vertices. Therefore, in order to find a vertex cover of no more than k vertices, one must include v in the vertex cover, and recursively look for a vertex cover of $k - 1$ vertices in the remaining graph.

The following fact was observed on vertices of degree less than 3.

Theorem 1 *There is a linear time kernelization algorithm that on each instance (G, k) of vertex cover, where the graph G contains a vertex of degree less than 3, produces an equivalent instance* (G', k') *such that* $|G'| < |G|$ *and/or* $k < k'$.

Therefore, vertices of high degree (i.e., degree $> k$) and low degree (i.e., degree < 3) can always be handled efficiently before any more time-consuming process.

Nemhauser-Trotter Theorem

Let G be a graph with vertices $v_1, v_2, \ldots, v_n$. Consider the following integer programming problem:

$$\begin{aligned} \text{(IP)Minimize} \quad & x_1 + x_2 + \cdots + x_n \\ \text{Subject to} \quad & x_i + x_j \geq 1 \\ & \text{for each edge } [v_i, v_j] \text{ in G} \\ & x_i \in \{0, 1\}, \quad 1 \leq i \leq n \end{aligned}$$

It is easy to see that there is a one-to-one correspondence between the set of feasible solutions to (IP) and the set of vertex covers of the graph G. A natural LP-relaxation (LP) of the problem (IP) is to replace the restrictions $x_i \in \{0, 1\}$ with $x_i \geq 0$ for all i. Note that the resulting linear programming problem (LP) now can be solved in polynomial time.

Let $\sigma = \{x_1^0, \ldots, x_n^0\}$ be an optimal solution to the linear programming problem (LP). The vertices in the graph G can be partitioned into three disjoint parts according to σ:

$$\begin{aligned} I_0 &= \{v_i \mid x_i^0 < 0.5\}, \\ C_0 &= \{v_i \mid x_i^0 > 0.5\}, \text{ and} \\ V_0 &= \{v_i \mid x_i^0 = 0.5\} \end{aligned}$$

The following nice property of the above vertex partition of the graph G was first observed by Nemhauser and Trotter [5].

Theorem 2 ***(Nemhauser-Trotter)*** *Let* $G[V_0]$ *be the subgraph of G induced by the vertex set* V_0. *Then (1) every vertex cover of* $G[V_0]$ *contains at least* $|V_0|/2$ *vertices; and (2) every minimum vertex cover of* $G[V_0]$ *plus the vertex set* C_0 *makes a minimum vertex cover of the graph G.*

Let k be any integer, and let $G' = G[V_0]$ and $k' = k - |C_0|$. As first noted in [3], by Theorem 2, the instances (G, k) and (G', k') are equivalent, and $|G'| \leq 2k'$ is a necessary condition for the graph G' to have a vertex cover of size k'. This observation gives the following kernelization result.

Theorem 3 *There is a polynomial-time algorithm that for a given instance (G, k) for the vertex cover problem, constructs an equivalent instance* (G', k') *such that* $k' \leq k$ *and* $|G'| \leq 2k'$.

A Faster Nemhauser-Trotter Construction

Theorem 3 suggests a polynomial-time kernelization algorithm for VERTEX COVER. The algorithm is involved in solving the linear programming problem (LP) and partitioning the graph vertices into the sets I_0, C_0, and V_0. Solving the linear programming problem (LP) can be done in polynomial time but is kind of costly in particular when the input graph G is dense. Alternatively, Nemhauser and Trotter [5] suggested the following algorithm without using linear programming. Let G be the input graph with vertex set $\{v_1, \ldots, v_n\}$.

1. construct a bipartite graph B with vertex set $\{v_1^L, \ldots, v_n^L, v_1^R, \ldots, v_n^R\}$ such that $[v_i^L, v_j^R]$ is an edge in B if and only if $[v_i, v_j]$ is an edge in G;
2. find a minimum vertex cover C_B for B;
3. $I_0' = \{v_i \mid \text{if neither } v_i^L \text{ nor } v_i^R \text{ is in } C_B\}$;
   $C_0' = \{v_i \mid \text{if both } v_i^L \text{ and } v_i^R \text{ are in } C_B\}$;
   $V_0' = \{v_i \mid \text{if exactly one of } v_i^L \text{ and } v_i^R \text{ is in } C_B\}$

It can be proved [5] (see also [2]) that Theorem 2 still holds true when the sets C_0 and V_0 in the theorem are replaced by the sets C_0' and V_0', respectively, constructed in the above algorithm.

The advantage of this approach is that the sets C_0' and V_0' can be constructed in time $O(m\sqrt{n})$ because the minimum vertex cover C_B for the bipartite graph B can be constructed via a maximum matching of B, which can be constructed in time $O(m\sqrt{n})$ using Dinic's maximum flow algorithm, which is in general faster than solving the linear programming problem (LP).

Crown Reduction

For a set S of vertices in a graph G, denote by $N(S)$ the set of vertices that are not in S but adjacent to some vertices in S. A *crown* in a graph G is a pair (I, H) of subsets of vertices in G satisfying the following conditions: (1) $I \neq \emptyset$ is an independent set, and $H = N(I)$; and (2) there is a matching M on the edges connecting I and H such that all vertices in H are matched in M.

It is quite easy to see that for a given crown (I, H), there is a minimum vertex cover that includes all vertices in H and excludes all vertices in I. Let G' be the graph obtained by removing all vertices in I and H from G. Then, the instances (G, k) and (G', k') are equivalent, where $k' = k - |H|$. Therefore, identification of crowns in a graph provides an effective way for kernelization.

Let G be the input graph. The following algorithm is proposed.

1. construct a maximal matching M_1 in G; let O be the set of vertices unmatched in M_1;
2. construct a maximum matching M_2 of the edges between O and $N(O)$; $i = 0$; let I_0 be the set of vertices in O that are unmatched in M_2;
3. repeat until $I_i = I_{i-1}$ $\{H_i = N(I_i)$; $I_{i+1} = I_i \cup N_{M_2}(H_i)$;$i = i + 1$; $\}$; (where $N_{M_2}(H_i)$ is the set of vertices in O that match the vertices in H_i in the matching M_2)
4. $I = I_i$; $H = N(I_i)$; output (I, H).

Theorem 4 *(1) if the set I_0 is not empty, then the above algorithm constructs a crown (I, H); (2) if both $|M_1|$ and $|M_2|$ are bounded by k, and $I_0 = \emptyset$, then the graph G has at most 3k vertices.*

According to Theorem 4, the above algorithm on an instance (G, k) of VERTEX COVER either (1) finds a matching of size larger than k – which implies that there is no vertex cover of k vertices in the graph G; or (2) constructs a crown (I, H) – which will reduce the size of the instance; or (3) in case neither of (1) and (2) holds true, concludes that the graph G contains at most $3k$ vertices. Therefore, repeatedly applying the algorithm either derives a direct solution to the given instance, or constructs an equivalent instance (G', k') with $k' \leq k$ and $|G'| \leq 3k'$.

Applications

The research of the current paper was directly motivated by authors' research in bioinformatics. It is shown that for many computational biological problems, such as the construction of phylogenetic trees, phenotype identification, and analysis of microarray data, preprocessing based on the kernelization techniques has been very effective.

Experimental Results

Experimental results are given for handling graphs obtained from the study of phylogenetic trees based on protein domains, and from the analysis of microarray data. The results show that in most cases the best way to kernelize is to start handling vertices of high and low degrees (i.e., vertices of degree larger than k or smaller than 3) before attempting any of the other kernelization techniques. Sometimes, kernelization based on Nemhauser-Trotter Theorem can solve the problem without any further branching. It is also observed that sometimes particularly on dense graphs, kernelization techniques based on Nemhauser-Trotter Theorem are kind of time-consuming but do not reduce the instance size by much. On the other hand, the techniques based on high-degree vertices and crown reduction seem to work better.

Data Sets

The experiments were performed on graphs obtained based on data from NCBI and SWISS-PROT, well known open-source repositories of biological data.

Problem Definition

The VERTEX COVER problem is one of the six "basic" NP-complete problems according to Garey and Johnson [7]. Therefore, the problem cannot be solved in polynomial time unless P = NP. However, the NP-completeness of the problem does not obviate the need for solving it because of its fundamental importance and wide applications.

One approach is to develop *parameterized algorithms* for the problem, with the computational complexity of the algorithms being measured in terms of both input size and a parameter value. This approach was initiated based on the observation that in many applications, the instances of the problem are associated with a small parameter. Therefore, by taking the advantages of the small parameters, one may be able to solve this NP-complete problem effectively and practically.

The problem is formally defined as follows. Let G be an (undirected) graph. A subset C of vertices in G is a *vertex cover* for G if every edge in G has at least one end in C. An instance of the (parameterized) VERTEX COVER problem consists of a pair (G, k), where G is a graph and k is an integer (the parameter), which is to determine whether the graph G has a vertex cover of k vertices. The goal is to develop parameterized algorithms of running time $O(f(k)p(n))$ for the VERTEX COVER problem, where $p(n)$ is a lower-degree polynomial of the input size n, and $f(k)$ is the non-polynomial part that is a function of the parameter k but independent of the input size n. It would be expected that the non-polynomial function $f(k)$ is as small as possible. Such an algorithm would become "practically effective" when the parameter value k is small. It should be pointed out that unless an unlikely consequence occurs in complexity theory, the function $f(k)$ is at least an exponential function of the parameter k [8].

Key Results

A number of techniques have been proposed in the development of parameterized algorithms for the VERTEX COVER problem.

Kernelization

Suppose (G, k) is an instance for the VERTEX COVER problem, where G is a graph and k is the parameter. The *kernelization* operation applies a polynomial time preprocessing on the instance (G, k) to construct another instance (G', k'), where G' is a smaller graph (the *kernel*) and $k' \leq k$, such that G' has a vertex cover of k' vertices if and only if G has a vertex cover of k vertices. Based on a classical result by Nemhauser and Trotter [9], the following kernelization result was derived.

Theorem 1 *There is an algorithm of running time $O(kn + k^3)$ that for a given instance (G, k) for the* VERTEX COVER *problem, constructs another instance (G′, k′) for the problem, where the graph G′ contains at most 2k′ vertices andk′ ≤ k, such that the graph G has a vertex cover of k vertices if and only if the graph G′ has a vertex cover of k′ vertices.*

Therefore, kernelization provides an efficient preprocessing for the VERTEX COVER problem, which allows one to concentrate on graphs of small size (i.e., graphs whose size is only related to k).

Folding

Suppose v is a degree-2 vertex in a graph G with two neighbors u and w such that u and w are not adjacent to each other. Construct a new graph G' as follows: remove the vertices v, u, and w and introduce a new vertex v_0 that is adjacent to all remaining neighbors of the vertices u and w in G. The graph G' is said being obtained from the graph G by *folding the vertex* v. The following result was derived.

Theorem 2 *Let G′ be a graph obtained by folding a degree-2 vertex v in a graph G, where the two neighbors of v are not adjacent to each other. Then the graph G has a vertex cover of k vertices if and only if the graph G′ has a vertex cover of $k - 1$ vertices.*

An folding operation allows one to decrease the value of the parameter k without branching. Therefore, folding operations are regarded as very efficient in the development of exponential time algorithms for the VERTEX COVER problem. Recently, the folding operation has be generalized to apply to a set of more than one vertex in a graph [6].

Branch and Search

A main technique is the *branch and search* method that has been extensively used in the development of algorithms for the VERTEX COVER problem (and for many other NP-hard problems). The method can be described as follows. Let (G, k) be an instance of the VERTEX COVER problem. Suppose that somehow a collection $\{C_1, \ldots, C_b\}$ of vertex subsets in the graph G is identified, where for each i, the subset C_i has c_i vertices, such that if the graph G contains a vertex cover of k vertices, then at least for one C_i of the vertex subsets in the collection, there is a vertex cover of k vertices for G that contains all vertices in C_i. Then a collection of (smaller) instances (G_i, k_i) can be constructed, where $1 \leq i \leq b, k_i = k - c_i$, and G_i is obtained from G by removing all vertices in C_i. Note that the original graph G has a vertex cover of k vertices if and only if for one (G_i, k_i) of the smaller instances the graph G_i has a vertex cover of k_i vertices. Therefore, now the process can be branched into b sub-processes, each on a smaller instance (G_i, k_i) recursively searches for a vertex cover of k_i vertices in the graph G_i.

Let $T(k)$ be the number of leaves in the search tree for the above branch and search process on the instance (G, k), then the above branch operation gives the following recurrence relation:

$$T(k) = T(k - c_1) + T(k - c_2) + \cdots + T(k - c_b)$$

To solve this recurrence relation, let $T(k) = x^k$ so that the above recurrence relation becomes

$$x^k = x^{k-c_1} + x^{k-c_2} + \cdots + x^{k-c_b}$$

It can be proved [3] that the above polynomial equation has a unique root x_0 larger than 1. From this, one gets $T(k) = x_0^k$, which, up to a polynomial factor, gives an upper bound on the running time of the branch and search process on the instance (G, k).

The simplest case is that a vertex v of degree $d > 0$ in the graph G is picked. Let $w_1, \ldots, w_d$ be the neighbors of v. Then either v is contained in a vertex cover C of k vertices, or, if v is not contained in C, then all neighbors $w_1, \ldots, w_d$ of v must be contained in C. Therefore, one obtains a collection of two subsets $C_1 = \{v\}$ and $C_2 = \{w_1, \ldots, w_d\}$, on which the branch and search process can be applied.

The efficiency of a branch and search operation depends on how effectively one can identify the collection of the vertex subsets. Intuitively, the larger the sizes of the vertex subsets, the more efficient is the operation. Much effort has been made in the development of VERTEX COVER algorithms to achieve larger vertex subsets. Improvements on the size of the vertex subsets have been involved with very complicated and tedious analysis and enumerations of combinatorial structures of graphs. The current paper [3] achieved a collection of two subsets C_1 and C_2 of sizes $c_1 = 1$ and $c_2 = 6$, respectively, and other collections of vertex subsets that are at least as good as this (the techniques of kernelization and vertex folding played important roles in achieving these collections). This gives the following algorithm for the VERTEX COVER problem.

Theorem 3 *The* VERTEX COVER *problem can be solved in time* $O(kn + 1.2852^k)$.

Very recently, a further improvement over Theorem 3 has been achieved that gives an algorithm of running time $O(kn + 1.2738^k)$ for the VERTEX COVER problem [4].

Applications

The study of parameterized algorithms for the VERTEX COVER problem was motivated by ETH Zürich's DARWIN project in computational biology and computational biochemistry (see, e.g., [10, 11]). A number of computational problems in the project, such as multiple sequence alignments [10] and biological conflict resolving [11], can be formulated into the VERTEX COVER problem in which the parameter value is in general not larger than 100. Therefore, an algorithm of running time $O(kn + 1.2852^k)$ for the problem becomes very effective and practical in solving these problems.

The parameterized algorithm given in Theorem 3 has also induced a faster algorithm for another important NP-hard problem, the MAXIMUM INDEPENDENT SET problem on sparse graphs [3].

Open Problems

The main open problem in this line of research is how far one can go along this direction. More specifically, how small the constant $c > 1$ can be for the VERTEX COVER problem to have an algorithm of running time $O(c^k n^{O(1)})$? With further more careful analysis on graph combinatorial structures, it seems possible to slightly improve the current best upper bound [4] for the problem. Some new techniques developed more recently [6] also seem very promising to improve the upper bound. On the other hand, it is known that the constant c cannot be arbitrarily close to 1 unless certain unlikely consequence occurs in complexity theory [8].

Experimental Results

A number of research groups have implemented some of the ideas of the algorithm in Theorem 3 or its variations, including the Parallel Bioinformatics project in Carleton University [2], the High Performance Computing project in University of Tennessee [1], and the DARWIN project in ETH Zürich [10, 11]. As reported in [5], these implementations showed that this algorithm and the related techniques are "quite practical" for the VERTEX COVER problem with parameter value k up to around 400.

Problem Definition

The whole process of designing, analyzing, implementing, tuning, debugging and experimentally evaluating algorithms can be referred to as *Algorithm Engineering*. Algorithm Engineering views algorithmics also as an engineering discipline rather than a purely mathematical discipline. Implementing algorithms and engineering algorithmic codes is a key step for the transfer of algorithmic technology, which often requires a high-level of expertise, to different and broader communities, and for its effective deployment in industry and real applications.

Experiments can help measure practical indicators, such as implementation constant factors, real-life bottlenecks, locality of references, cache effects and communication complexity, that may be extremely difficult to predict theoretically. Unfortunately, as in any empirical science, it may be sometimes difficult to draw general conclusions about algorithms from experiments. To this aim, some researchers have proposed accurate and comprehensive guidelines on different

aspects of the empirical evaluation of algorithms maturated from their own experience in the field (see, for example [1, 15, 16, 20]). The interested reader may find in [18] an annotated bibliography of experimental algorithmics sources addressing methodology, tools and techniques.

The process of implementing, debugging, testing, engineering and experimentally analyzing algorithmic codes is a complex and delicate task, fraught with many difficulties and pitfalls. In this context, traditional low-level textual debuggers or industrial-strength development environments can be of little help for algorithm engineers, who are mainly interested in high-level algorithmic ideas rather than in the language and platform-dependent details of actual implementations. Algorithm visualization environments provide tools for abstracting irrelevant program details and for conveying into still or animated images the high-level algorithmic behavior of a piece of software.

Among the tools useful in algorithm engineering, visualization systems exploit interactive graphics to enhance the development, presentation, and understanding of computer programs [27]. Thanks to the capability of conveying a large amount of information in a compact form that is easily perceivable by a human observer, visualization systems can help developers gain insight about algorithms, test implementation weaknesses, and tune suitable heuristics for improving the practical performances of algorithmic codes. Some examples of this kind of usage are described in [12].

Key Results

Systems for algorithm visualization have matured significantly since the rise of modern computer graphic interfaces and dozens of algorithm visualization systems have been developed in the last two decades [2, 3, 4, 5, 6, 8, 9, 10, 13, 17, 25, 26, 29]. For a comprehensive survey the interested reader can be referred to [11, 27] and to the references therein. The remainder of this entry discusses the features of algorithm visualization systems that appear to be most appealing for their deployment in algorithm engineering.

Critical Issues

From the viewpoint of the algorithm developer, it is desirable to rely on systems that offer visualizations at a *high level of abstraction*. Namely, one would be more interested in visualizing the behavior of a complex data structure, such as a graph, than in obtaining a particular value of a given pointer.

Fast prototyping of visualizations is another fundamental issue: algorithm designers should be allowed to create visualization from the source code at hand with little effort and without heavy modifications. At this aim, *reusability* of visualization code could be of substantial help in speeding up the time required to produce a running animation.

One of the most important aspects of algorithm engineering is the development of *libraries*. It is thus quite natural to try to interface visualization tools to algorithmic software libraries: libraries should offer default visualizations of algorithms and data structures that can be refined and customized by developers for specific purposes.

Software visualization tools should be able to animate *not just "toy programs"*, but significantly complex algorithmic codes, and to test their behavior on large data sets. Unfortunately, even those systems well suited for large information spaces often lack advanced navigation techniques and methods to alleviate the screen bottleneck. Finding a solution to this kind of limitations is nowadays a challenge.

Advanced debuggers take little advantage of sophisticated graphical displays, even in commercial software development environments. Nevertheless, software visualization tools may be very beneficial in addressing problems such as finding memory leaks, understanding anomalous program behavior, and studying performance. In particular, environments that provide interpreted execution may more easily integrate advanced facilities in support to *debugging and performance monitoring*, and

many recent systems attempt at exploring this research direction.

Techniques

One crucial aspect in visualizing the dynamic behavior of a running program is the way it is conveyed into graphic abstractions. There are two main approaches to bind visualizations to code: the event-driven and the state-mapping approach.

Event-Driven Visualization

A natural approach to algorithm animation consists of annotating the algorithmic code with calls to visualization routines. The first step consists of identifying the relevant actions performed by the algorithm that are interesting for visualization purposes. Such relevant actions are usually referred to as *interesting events*. As an example, in a sorting algorithm the swap of two items can be considered an interesting event. The second step consists of associating each interesting event with a modification of a graphical scene. Animation scenes can be specified by setting up suitable visualization procedures that drive the graphic system according to the actual parameters generated by the particular event. Alternatively, these visualization procedures may simply log the events in a file for a *post-mortem* visualization. The calls to the visualization routines are usually obtained by annotating the original algorithmic code at the points where the interesting events take place. This can be done either by hand or by means of specialized editors. Examples of toolkits based on the event-driven approach are Polka [28] and *GeoWin*, a `C++` data type that can be easily interfaced with algorithmic software libraries of great importance in algorithm engineering such as CGAL [14] and LEDA [19].

State Mapping Visualization

Algorithm visualization systems based on state mapping rely on the assumption that observing how the variables change provides clues to the actions performed by the algorithm. The focus is on capturing and monitoring the data modifications rather than on processing the interesting events issued by the annotated algorithmic code. For this reason they are also referred to as "data driven" visualization systems. Conventional debuggers can be viewed as data driven systems, since they provide direct feedback of variable modifications. The main advantage of this approach over the event-driven technique is that a much greater ignorance of the code is allowed: indeed, only the interpretation of the variables has to be known to animate a program. On the other hand, focusing only on data modification may sometimes limit customization possibilities making it difficult to realize animations that would be natural to express with interesting events. Examples of tools based on the state mapping approach are Pavane [23, 25], which marked the first paradigm shift in algorithm visualization since the introduction of interesting events, and Leonardo [10] an integrated environment for developing, visualizing, and executing C programs.

A comprehensive discussion of other techniques used in algorithm visualization appears in [7, 21, 22, 24, 27].

Applications

There are several applications of visualization in algorithm engineering, such as testing and debugging of algorithm implementations, visual inspection of complex data structures, identification of performance bottlenecks, and code optimization. Some examples of uses of visualization in algorithm engineering are described in [12].

Open Problems

There are many challenges that the area of algorithm visualization is currently facing. First of all, the real power of an algorithm visualization system should be in the hands of the final user, possibly inexperienced, rather than of a professional programmer or of the developer of the tool. For instance, instructors may greatly benefit from fast and easy methods for tailoring animations to their specific educational needs, while they might be discouraged from using systems that are difficult to install or heavily dependent on particular software/hardware platforms. In addition to

being easy to use, a software visualization tool should be able to animate significantly complex algorithmic codes without requiring a lot of effort. This seems particularly important for future development of visual debuggers. Finally, visualizing the execution of algorithms on large data sets seems worthy of further investigation. Currently, even systems designed for large information spaces often lack advanced navigation techniques and methods to alleviate the screen bottleneck, such as changes of resolution and scale, selectivity, and elision of information.

Voltage Scheduling

Ming Min Li
Computer Science and Technology, Tsinghua University, Beijing, China

Keywords

Dynamic speed scaling

Years and Authors of Summarized Original Work

2005; Li, Yao

Problem Definition

This problem is concerned with scheduling jobs with as little energy as possible by adjusting the processor speed wisely. This problem is motivated by *dynamic voltage scaling (DVS)* (or *speed scaling*) technique, which enables a processor to operate at a range of voltages and frequencies. Since energy consumption is at least a quadratic function of the supply voltage (hence CPU frequency/speed), it saves energy to execute jobs as slowly as possible while still satisfying all timing constraints. The associated scheduling problem is referred to as min-energy DVS scheduling. Previous work showed that the min-energy DVS schedule can be computed in cubic time. The work of Li and Yao [7] considers the discrete model where the processor can only choose its speed from a finite speed set. This work designs an $O(dn \log n)$ two-phase algorithm to compute the min-energy DVS schedule for the discrete model (d represents the number of speeds) and also proves a lower bound of $\Omega(n \log n)$ for the computation complexity.

Notations and Definitions

In the variable voltage scheduling model, there are two important sets:

1. Set J (job set) consists of n jobs: $j_1, j_2, \ldots j_n$. Each job j_k has three parameters as its information: a_k representing the arrival time of j_k, b_k representing the deadline of j_k, and R_k representing the total CPU cycles required by j_k. The parameters satisfy $0 \le a_k < b_k \le 1$.
2. Set SD (speed set) consists of the possible speeds that can be used by the processor. According to the property of SD, the scheduling model is divided into the following two categories:

   Continuous model: The set SD is the set of positive real numbers.
   Discrete model: The set SD consists of d positive values: $s_1 > s_2 > \cdots > s_d$.

A schedule S consists of the following two functions: $s(t)$ which specifies the processor speed at time t and job(t) which specifies the job executed at time t. Both functions are piecewise constant with finitely many discontinuities.

A feasible schedule must give each job its required number of cycles between arrival time and deadline, therefore satisfying the property $\int_{a_k}^{b_k} s(t)\delta(k, \text{job}(t))\text{d}t = R_k$, where $\delta(i, j) = 1$ if $i = j$ and $\delta(i, j) = 0$ if otherwise.

The EDF principle defines an ordering on the jobs according to their deadlines. At any time t, among jobs j_k that are available for execution, that is, j_k satisfying $t \in [a_k, b_k)$ and j_k not yet finished by t, it is the job with minimum b_k that will be executed during $[t, t + \epsilon]$.

The power P, or energy consumed per unit of time, is a convex function of the processor speed. The energy consumption of a schedule $S = (s(t), \text{job}(t))$ is defined as $E(S) = \int_0^1 P(s(t))\text{d}t$.

A schedule is called an optimal schedule if its energy consumption is the minimum possible among all the feasible schedules. Note that for the continuous model, the optimal schedule uses the same speed for the same job.

The work of Li and Yao considers the problem of computing an optimal schedule for the discrete model under the following assumptions.

Assumptions

1. **Single processor:** At any time t, only one job can be executed.
2. **Preemptive:** Any job can be interrupted during its execution.
3. **Non-precedence:** There is no precedence relationship between any pair of jobs.
4. **Offline:** The processor knows the information of all the jobs at time 0.

This problem is called min-energy discrete dynamic voltage scaling (MEDDVS).

Problem 1 (MEDDVS$_{J,SD}$)

INPUT: Integer n, set $J = \{j_1, j_2, \ldots, j_n\}$ and $SD = \{s_1, s_2, \ldots, s_d\} \cdot j_k = \{a_k, b_k, R_k\}$.
OUTPUT: Feasible schedule $S = (s(t), \text{job}(t))$ that minimizes $E(S)$.

Kwon and Kim [6] proved that the optimal schedule for the discrete model can be obtained by first calculating the optimal schedule for the continuous model and then individually adjusting the speed of each job appropriately to adjacent levels in set SD. The time complexity is $O(n^3)$.

Key Results

The work of Li and Yao finds a direct approach for solving the MEDDVS problem without first computing the optimal schedule for the continuous model.

Definition 1 An s-schedule for J is a schedule which conforms to the EDF principle and uses constant speed s in executing any job of J.

Lemma 1 *The s-schedule for J can be computed in $O(n \log n)$ time.*

Definition 2 Given a job set J and any speed s, let $J^{\geq s}$ and $J^{<s}$ denote the subset of J consisting of jobs whose executing speeds are $\geq s$ and $< s$, respectively, in the optimal schedule for J in the continuous model. The partition $J^{\geq s}, J^{<s}$ is referred to as the s-partition of J.

By extracting information from the s-schedule, a partition algorithm is designed to prove the following lemma:

Lemma 2 *The s-partition of J can be computed in $O(n \log n)$ time.*

By applying s-partition to J using all the d speeds in SD consecutively, one can obtain d subsets $J_1, J_2, \ldots, J_d$ of J where jobs in the same subset J_i use the same two speeds s_i and s_{i+1} in the optimal schedule for the Discrete Model ($s_{d+1} = 0$).

Lemma 3 *Optimal schedule for job set J_i using speeds s_i and s_{i+1} can be computed in $O(n \log n)$ time.*

Combining the above three lemmas together, the main theorem follows:

Theorem 1 *The min-energy discrete DVS schedule can be computed in $O(dn \log n)$ time.*

A lower bound to compute the optimal schedule for the *discrete model* under the algebraic decision tree model is also shown by Li and Yao.

Theorem 2 *Any deterministic algorithm for computing min-energy discrete DVS schedule with* $d \geq 2$ *voltage levels requires* $\Omega(n \log n)$ *time for n jobs.*

Applications

Currently, dynamic voltage scaling technique is being used by the world's largest chip companies, e.g., Intel's SpeedStep technology and AMD's PowerNow technology. Although the scheduling algorithms being used are mostly online algorithms, offline algorithms can still find their places in real applications. Furthermore, the techniques developed in the work of Li and Yao for the computation of optimal schedules may have potential applications in other areas.

People also study energy-efficient scheduling problems for other kinds of job sets. Yun and Kim [10] proved that it is NP-hard to compute the optimal schedule for jobs with priorities and gave an FPTAS for that problem. Aydin et al. [1] considered energy-efficient scheduling for real-time periodic jobs and gave an $O(n^2 \log n)$ scheduling algorithm. Chen et al. [4] studied the weakly discrete model for non-preemptive jobs where speed is not allowed to change during the execution of one job. They proved the NP-hardness to compute the optimal schedule.

Another important application for this work is to help investigating scheduling model with more hardware restrictions (Burd and Brodersen [3] explained various design issues that may happen in dynamic voltage scaling). Besides the single-processor model, people are also interested in the multiprocessor model [11].

Open Problems

A number of problems related to the work of Li and Yao remain open. In the discrete model, Li and Yao's algorithm for computing the optimal schedule requires time $O(dn \log n)$. There is a gap between this and the currently known lower bound $\Omega(n \log n)$. Closing this gap when considering d as a variable is an open problem.

Another open research area is the computation of the optimal schedule for the continuous model. Li, Yao, and Yao [8] obtained an $O(n^2 \log n)$ algorithm for computing the optimal schedule. The bottleneck for the log n factor is in the computation of s-schedules. Reducing the time complexity for computing s-schedules is an open problem. It is also possible to look for other methods to deal with the continuous model.

Computational geometry; Delaunay triangulation; Distance problem; Edge flip; Minimum spanning tree; Sweepline; Voronoi diagram

Years and Authors of Summarized Original Work

1975; Shamos, Hoey
1987; Fortune

Problem Definition

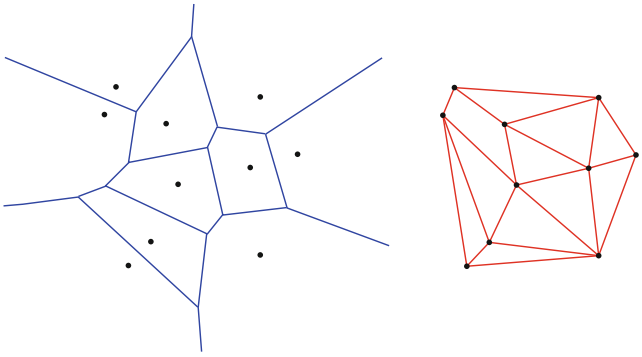
Suppose there is some set of objects p called *sites* that exert influence over their surrounding space, M. For each site p, we consider the set of all points z in M for which the influence of p is strongest.

Such decompositions have already been considered by R. Descartes [5] for the fixed stars in solar space. In mathematics and computer science, they are called *Voronoi diagrams*, honoring work by G.F. Voronoi on quadratic forms. Other sciences know them as *domains of action, Johnson-Mehl model, Thiessen polygons, Wigner-Seitz zones*, or *medial axis transform*.

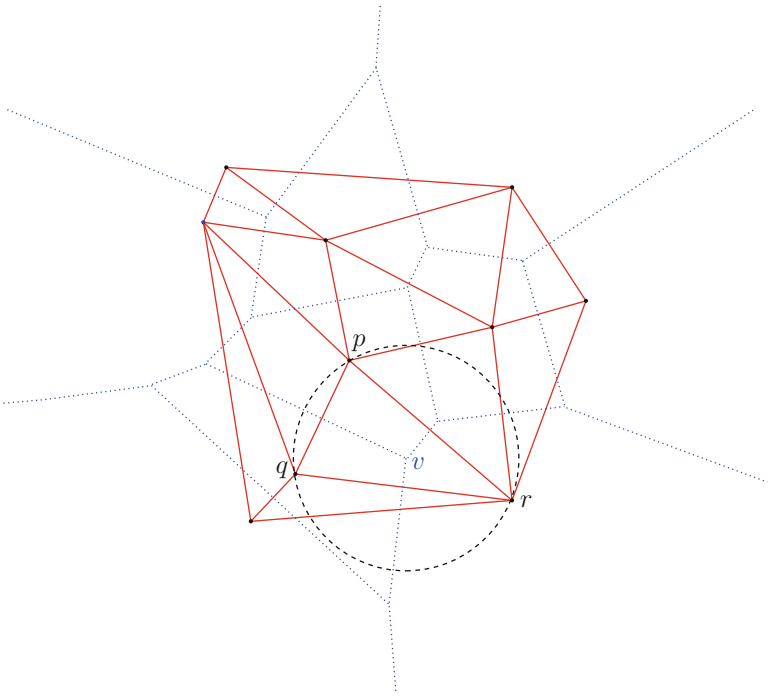
In the case most frequently studied, the space M is the real plane, the sites are n points, and influence corresponds to proximity in the Euclidean metric, so that the points most strongly influenced by site p are those for which p is the nearest neighbor among all sites. They form a convex region called the *Voronoi region* of p. The common boundary of two adjacent regions of p and q is a segment of their *bisector* $B(p,q)$, the locus of all points of equal distance to p and q. An example of 10 point sites is depicted in Fig. 1.

Let us assume that the set S of point sites is in general position, so that no three points are situated on a line, and no four on a circle. Then the Voronoi diagram $V(S)$ of S is a connected planar graph. Its vertices are those points in the plane which have three nearest neighbors in S, while the interior edge points have two. As a consequence of the Euler formula, $V(S)$ has only $O(n)$ many edges and vertices.

If we connect with line segments, those sites in S whose Voronoi regions share an edge in $V(S)$, a triangulation $D(S)$ of S results, called the *Delaunay triangulation* or *Dirichlet tessellation*; see Fig. 1. Each triangle with vertices p,q,r in S is dual to a vertex v of $V(S)$ situated on the boundary of the Voronoi regions of p,q, and r. Because p,q,r are the nearest neighbors of v in S, the circle through p,q,r centered at v contains no other point of S. Thus, $D(S)$ consists of triangles with vertices in S whose circumcircles are empty of points in S; see Fig. 2. Conversely,



Voronoi Diagrams and Delaunay Triangulations, Fig. 1
Voronoi diagram and Delaunay triangulation of 10 point sites in the Euclidean plane



Voronoi Diagrams and Delaunay Triangulations, Fig. 2
The empty circle property

each triangle with empty circumcircle occurs in $D(S)$.

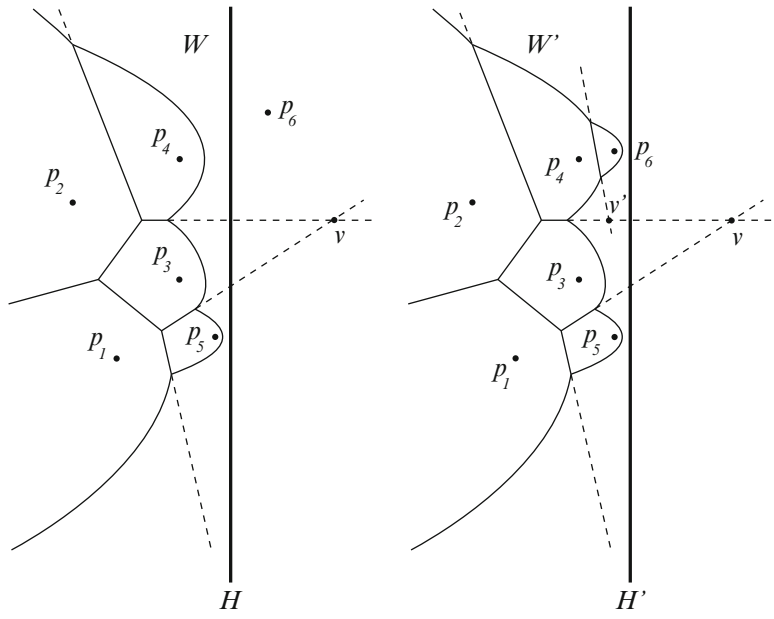
Given a set S of n point sites, the problem is to efficiently construct one of $V(S)$ or $D(S)$; the dual structure can then easily be obtained in linear time.

Generalizations

Voronoi diagrams can be generalized in several ways. Instead of point sites, other geometric objects can be considered. One can replace the Euclidean distance with distance measures more suitable to model a given situation. Instead of forming regions of all points that have the same nearest site, one can consider higher-order Voronoi diagrams where all points share a region for which the nearest k sites are the same, for some k between 2 and $n-1$. Many more variants can be found in [9] and [1]. Abstract Voronoi diagrams provide a unifying framework for some of the variants mentioned; see the corresponding chapter in this encyclopedia.

Key Results

Quite a few algorithms for constructing the Voronoi diagram or the Delaunay triangulation



Voronoi Diagrams and Delaunay Triangulations, Fig. 3 The sweepline advancing to the right

of n points in the Euclidean plane have been developed.

Divide and Conquer

The first algorithm was presented in the seminal paper [11], which gave birth to the field of computational geometry. It applies the *divide and conquer* paradigm. Site set S is split by a line into subsets L and R of equal cardinality. After recursively computing $V(L)$ and $V(R)$, one needs to compute the bisector $B(L, R)$, the locus of all points in the plane that have a nearest neighbor in L and in R. This bisector is an unbounded monotone polygonal chain. In time $O(n)$ one can find a starting segment of $B(L, R)$ at infinity, and trace the chain through $V(L)$ and $V(R)$ simultaneously. Thus, the algorithm runs in time $O(n \log n)$ and linear space, which is optimal.

Sweep

How to design a left-to-right *sweepline* algorithm for constructing $V(S)$ is not obvious. When the advancing sweepline H enters the Voronoi region of p before site p has been detected, it is not clear how to correctly maintain the Voronoi diagram along H. This difficulty has been overcome in [7] by applying a transformation that ensures that each site is the leftmost point of its Voronoi region. In [10] and [4], a more direct version of this approach was suggested. At each time during the sweep, one maintains the Voronoi diagram of all point sites to the left of sweepline H, and of H itself, which is considered a site of its own; see Fig. 3. Because the bisector of a point and a line is a parabola, the Voronoi region of H is bounded by a connected chain of parabolic segments, called the *wavefront* W. As H moves to the right, W follows at half the speed. Each point z to the left of W is closer to some point site p left of H than to H and, all the more, to all point sites to the right of H that are yet to be discovered. Thus, the Voronoi regions of the point sites to the left of W keep growing, as sweepline H proceeds, along the extensions of Voronoi edges beyond W; these *spikes* are depicted by dashed lines in Fig. 3.

There are two kinds of events one needs to handle during the sweep. When sweepline H hits a new point site (like point p_6 in Fig. 3), a new wave separating this point site from H must be added to W. When wavefront W hits the intersection of two neighboring spikes, the wave between them must be removed from W;

this will first happen in Fig. 3 when W' arrives at v'. Intersections between neighboring spikes can be determined as in the standard line segment intersection algorithm [2]. There are only $O(n)$ many events, one for each point site and one for each Voronoi vertex v of $V(S)$. Since wavefront W is always of linear size, the sweepline algorithm runs in $O(n \log n)$ time using linear space.

Reduction to Convex Hull

A rather different approach [3] obtains the Delaunay triangulation in dimension 2 from the convex hull in dimension 3, which can itself be constructed in time $O(n \log n)$. As suggested in [6], one vertically lifts the point sites to the paraboloid $Z = X^2 + Y^2$ in 3-space. The lower convex hull of the lifted points, projected onto the XY-plane, equals the Delaunay triangulation, $D(S)$.

Incremental Construction

Another, very intuitive algorithm first suggested in [8] constructs the Delaunay triangulation incrementally. In order to insert a new point site p_i into an existing Delaunay triangulation $D(S_{i-1})$, one first finds the triangle containing p_i and connects p_i to its vertices by line segments. Should p_i be contained in the circumcircles of adjacent triangles, the Delaunay property must be restored by *edge flips* that replace the common edge of two adjacent triangles T, T' by the other diagonal of the convex quadrilateral formed by T and T'. If the insertion sequence of the p_i is randomly chosen, a running time in $O(n \log n)$ can be expected. Details on all algorithms can be found in [1].

Applications

Although of linear size, Voronoi diagram and Delaunay triangulation contain a lot of information on the point set S. Once $V(S)$ or $D(S)$ are available, quite a few distance problems can be solved very efficiently. We mention only the most basic applications here and refer to [1] and [9] for further reading.

By definition, the Voronoi diagram reduces the *post office* or *nearest neighbor* problem to a point location problem: given an arbitrary query point z, the site in S nearest to z can be found by determining the Voronoi region containing z. In order to find the *largest empty circle* whose center z lies inside a convex polygon C over m vertices, one needs to inspect only three types of candidates for z, the vertices of $V(S)$, the intersections of the edges of $V(S)$ with the boundary of C, and the vertices of C. All these can be done in time $O(n + m)$.

If the site set S is split into subsets L and R, then the closest pair $p \in L$ and $q \in R$ forms an edge of the Delaunay triangulation $D(S)$ (which crosses the Voronoi edge separating the regions of p and q). This fact has nice consequences. First, the nearest neighbor of a site $p \in S$ must be one of its neighboring vertices in $D(S)$. Hence, *all nearest neighbors* and the *closest pair* in S can be found in linear time once $D(S)$ is available, because $D(S)$ has only $O(n)$ many edges. Second, $D(S)$ contains the *minimum spanning tree* of S, which can be extracted from $D(S)$ in linear time.

Remarkable and useful is the *equiangularity property* of $D(S)$. Of all (exponentially many) triangulations of S, the Delaunay triangulation maximizes the ascending sequence of angles occurring in the triangles, with respect to lexicographic order. In particular, the minimum angle is as large as possible. In fact, if a triangulation is not Delaunay, it must contain two adjacent triangles, such that the circumcircle of one contains the third vertex of the other. By flipping their common edge, a new triangulation with larger angles is obtained.

Wait-Free Synchronization

Mark Moir
Sun Microsystems Laboratories, Burlington, MA, USA

Years and Authors of Summarized Original Work

1991; Herlihy

Problem Definition

The traditional use of locking to maintain consistency of shared data in concurrent programs has a number of disadvantages related to software engineering, robustness, performance, and scalability. As a result, a great deal of research effort has gone into *nonblocking* synchronization mechanisms over the last few decades.

Herlihy's seminal paper *Wait-Free Synchronization* [12] studied the problem of implementing concurrent data structures in a *wait-free manner*, i.e., so that every operation on the data structure completes in a finite number of steps by the invoking thread, regardless of how fast or slow other threads run and even if some or all of them halt permanently. Implementations based on locks are not wait-free because, while one thread holds a lock, others can take an unbounded number of steps waiting to acquire the lock. Thus, by requiring implementations to be wait-free, some of the disadvantages of locks may potentially be eliminated.

The first part of Herlihy's paper examined the power of different synchronization primitives for wait-free computation. He defined the *consensus number* of a given primitive as the maximum number of threads for which we can solve wait-free consensus using that primitive (together with read-write registers). The consensus problem requires participating threads to *agree* on a value (e.g., true or false) amongst values proposed by the threads. The ability to solve this problem is a key indicator of the power of synchronization primitives because it is central to many natural problems in concurrent computing. For example, in a software transactional memory system, threads must agree that a particular transaction either committed or aborted.

Herlihy established a *hierarchy* of synchronization primitives according to their consensus number. He showed (i) that the consensus number of read-write registers is 1 (so wait-free consensus cannot be solved for even two threads), (ii) that the consensus number of stacks and FIFO queues is 2, and (iii) that there are so-called *universal* primitives, which have consensus number ∞. Common examples include `compare-and-swap` (`CAS`) and the `load-linked/store-conditional` (`LL/SC`) pair.

There are a number of papers which examine Herlihy's hierarchy in more detail. These show that seemingly minor variations in the model or

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

in the semantics of primitives can have a surprising effect on results. Most of this work is primarily of theoretical interest. The key practical point to take away from Herlihy's hierarchy is that we need universal primitives to support effective wait-free synchronization in general. Recognizing this fact, all modern shared-memory multiprocessors provide some form of universal primitive.

Herlihy additionally showed that a solution to consensus can be used to implement any shared object in a wait-free manner, and thus that any universal primitive suffices for this purpose. He demonstrated this idea using a so-called *universal construction*, which takes sequential code for an object and creates a wait-free implementation of the object using consensus to resolve races between concurrent operations. Despite the important practical ramifications of this result, the universal construction itself was quite impractical. The basic idea was to build a list of operations, using consensus to determine the order of operations, and to allow threads to iterate over the list applying the operations in order to determine the current state of the object. The construction required $O(N^3)$ space to ensure enough operations are retained to allow the current state to be determined. It was also very slow, requiring many threads to recompute the same information, and thus preventing parallelism between operations in addition.

Later, Herlihy [13] presented a more concrete universal construction based on the `LL`/`SC` instruction pair. This construction required $N + 1$ copies of the object for N threads and still did not admit any parallelism; thus it was also not practical. Despite this, work following on from Herlihy's has brought us to the point today that we can support practical programming models that provide nonblocking implementations of arbitrary shared objects. The remainder of this chapter discusses the state of nonblocking synchronization today, and mentions some history along the way.

Weaker Nonblocking Progress Conditions

Various researchers, including us, have had some success attempting to overcome the disadvantages of Herlihy's wait-free constructions. However, the results remain impractical due to excessive overhead and overly complicated algorithms. In fact, there are still no nontrivial wait-free shared objects in widespread practical use, either implemented directly or using universal constructions.

The biggest advances towards practicality have come from considering weaker progress conditions. While theoreticians worked on wait-free implementations, more pragmatic researchers sought lock-free implementations of shared objects. A *lock-free* implementation guarantees that, after a finite number of steps of any operation, *some* operation completes. In contrast to wait-free algorithms, it is in principle possible for one operation of a lock-free data structure to be continually starved by others. However, this rarely occurs in practice, especially because contention control techniques such as exponential backoff [1] are often used to reduce contention when it occurs, which makes repeated interference even more unlikely. Thus, the lack of a strong progress guarantee like wait-freedom has often been found to be acceptable in practice.

The observation that weaker nonblocking progress conditions allow simpler and more practical algorithms led Herlihy et al. [15] to define an even weaker condition: An *obstruction-free* algorithm does not guarantee that an operation completes unless it eventually encounters no more interference from other operations. In our experience, obstruction-free algorithms are easier to design, simpler, and faster in the common uncontended case than lock-free algorithms. The price paid for these benefits is that obstruction-free algorithms can "livelock", with two or more operations repeatedly interfering with each other forever. This is not merely a theoretical concern: it has been observed to occur in practice [16]. Fortunately, it is usually straightforward to eliminate livelock in practice through contention control mechanisms that control and manipulate when operations are executed to avoid repeated interference.

The obstruction-free approach to synchronization is thus to design simple and efficient

algorithms for the weak obstruction-free progress condition, and to integrate orthogonal contention control mechanisms to facilitate progress when necessary. By largely separating the difficult issues of correctness and progress, we significantly ease the task of designing effective nonblocking implementations: the algorithms are not complicated by tightly coupled mechanisms for achieving lock-freedom, and it is easy to modify and experiment with contention control mechanisms because they are separate from the algorithm and do not affect its correctness. We have found this approach to be very powerful.

Transactional Memory

The severe difficulty of designing and verifying correct nonblocking data structures has led researchers to investigate the use of tools to produce them, rather than designing them directly. In particular, *transactional memory* [5, 17, 23] has emerged as a promising direction. Transactional memory allows programmers to express sections of code that should be executed atomically, and the transactional memory system (implemented in hardware, software, or a combination of the two) is responsible for managing interactions between concurrent transactions to ensure this atomicity. Here we concentrate on software transactional memory (STM).

The progress guarantee made by a concurrent data structure implemented using STM depends on the STM implementation. It is possible to characterize the progress conditions of transactional memory implementations in terms of a system of threads in which each operation on a shared data structure is executed by repeatedly attempting to apply it using a transaction until an attempt successfully commits. In this context, say the transactional memory implementation is obstruction-free if it guarantees that, if a thread repeatedly executes transactions and eventually encounters no more interference from other threads, then it eventually successfully commits a transaction.

Key Results

This section briefly discusses some of the most relevant results concerning nonblocking synchronization, and obstruction-free synchronization in particular.

While progress towards practicality was made with lock-free implementations of shared objects as well as lock-free STM systems, this progress was slow because simultaneously ensuring correctness and lock-freedom proved difficult. Before the introduction of obstruction-freedom, the lock-free STMs still had some severe disadvantages such as the need to declare and initialize all memory to be accessed by transactions in advance, the need for transactions to know in advance which memory locations they will access, unacceptable constraints on the layout of such memory, etc.

In addition to the work on tools such as STM for building nonblocking data structures, there has been a considerable amount of work on direct implementations. While this work has not yielded any practical wait-free algorithms, a handful of practical lock-free implementations for simple data structures such as queues and stacks have been achieved [21, 24]. There are also a few slightly more ambitious implementations in the literature that are arguably practical, but the algorithms are complicated and subtle, many are incorrect, and almost none has a formal proof. Proofs for such algorithms are challenging, and minor changes to the algorithm require the proofs to be redone.

The next section, discusses some of the results that have been achieved by applying the obstruction-free approach. The remainder of this section, briefly discusses a few results related to the approach itself.

An important practical aspect of using an obstruction-free algorithm is how contention is managed when it arises. In introducing obstruction-freedom, Herlihy et al. [15] explained that contention control is necessary to facilitate progress in the face of contention because obstruction-free algorithms do not directly make any progress guarantee in this case. However,

they did not directly address *how* contention control mechanisms could be used in practice.

Subsequently, Herlihy et al. [16] presented a dynamic STM system (see next section) that provides an interface for a modular contention manager, allowing for experimentation with alternative contention managers. Scherer and Scott [22] experimented with a number of alternatives, and found that the best contention manager depends on the workload. Guerraoui et al. [9] described an implementation that supports changing contention managers on the fly in response to changing workload conditions.

All of the contention managers discussed in the above-mentioned papers are ad hoc contention managers based on intuition; no analysis is given of what guarantees (if any) are made by the contention managers. Guerraoui et al. [10] made a first step towards a formal analysis of contention managers by showing that their `Greedy` contention manager guarantees that every transaction eventually completes. However, using the `Greedy` contention manager results in a blocking algorithm, so their proof necessarily assumes that threads do not fail while executing transactions.

Fich et al. [7] showed that any obstruction-free algorithm can be automatically transformed into one that is *practically* wait-free in any real system. "Practically" is said because the wait-free progress guarantee depends on partial synchrony that exists in any real system, but the transformed algorithm is not technically wait-free, because this term is defined in the context of a fully asynchronous system. Nonetheless, an algorithm achieved by applying the transformation of Fich et al. to an obstruction-free algorithm does guarantee progress to non-failed transactions, even if other transactions fail.

Work on incorporating contention management techniques into obstruction-free algorithms has mostly been done in the context of STM, so the contention manager can be called directly from the STM implementation. Thus, the programmer using the STM need not be concerned with how contention management is integrated, but this does not address how contention management is integrated into direct implementations of obstruction-free data structures.

One option is for the programmer to manually insert calls to a contention manager, but this approach is tedious and error prone. Guerraoui et al. [11] suggested a version of this approach in which the contention manager is abstracted out as a failure detector. They also explored what progress guarantees can be made by what failure detectors.

Attiya et al. [4] and Aguilera et al. [2] suggested changing the semantics of the data structure's operations so that they can return a special value in case of contention, thus allowing contention management to be done outside the data structure implementation. These approaches still leave a burden on the programmer to ensure that these special values are always returned by an operation that cannot complete due to contention, and that the correct special value is returned according to the prescribed semantics.

Another option is to use system support to ensure that contention management calls are made frequently enough to ensure progress. This support could be in the form of compiled-in calls, runtime support, signals sent upon expiration of a timer, etc. But all of these approaches have disadvantages such as not being applicable in general purpose environments, not being portable, etc.

Given that it remains challenging to design and verify direct obstruction-free implementations of shared data structures, and that there are disadvantages to the various proposals for integrating contention control mechanisms into them, using tools such as STMs with built-in contention management interfaces is the most convenient way to build nonblocking data structures.

Applications

The obstruction-free approach to nonblocking synchronization was introduced by Herlihy et al. [15], who used it to design a double-ended queue (deque) based on the widely available `CAS` instruction. All previous nonblocking deques

either require exotic synchronization instructions such as `double-compare-and-swap` (`DCAS`), or have the disadvantage that operations at opposite ends of the queue always interfere with each other.

Herlihy et al. [16] introduced Dynamic STM (DSTM), the first STM that is dynamic in the following two senses: new objects can be allocated on the fly and subsequently accessed by transactions, and transactions do not need to know in advance what objects will be accessed. These two advantages made DSTM much more useful than previous STMs for programming dynamic data structures. As a result, nonblocking implementations of sophisticated shared data structures such as balanced search trees, skip lists, dynamic hash tables, etc. were suddenly possible.

The obstruction-free approach played a key role in the development of both of the results mentioned above: Herlihy et al. [16] could concentrate on the functionality and correctness of DSTM without worrying about how to achieve stronger progress guarantees such as lock-freedom.

The introduction of DSTM and of the obstruction-free approach have led to numerous improvements and variations by a number of research groups, and most of these have similarly followed the obstruction-free approach. However, Harris and Fraser [8] presented a dynamic STM called OSTM with similar advantages to DSTM, but it is lock-free. Experiments conducted at the University of Rochester [20] showed that DSTM outperformed OSTM by an order of magnitude on some workloads, but that OSTM outperformed DSTM by a factor of 2 on others. These differences are probably due to various design decisions that are (mostly) orthogonal to the progress condition, so it is not clear what we can conclude about how the choice of progress condition affects performance in this case.

Perhaps a more direct comparison can be made between another pair of algorithms, again an obstruction-free one by Herlihy et al. [14] and a similar but lock-free one by Harris and Fraser [8]. These algorithms, invented independently of each other, implement `MCAS` (`CAS` generalized to access M independently chosen memory locations). The two algorithms are very similar, and a close comparison revealed that the only real differences between them were due to Harris and Fraser's desire to have a lock-free implementation. As a result of this, their algorithm is somewhat more complicated, and also requires a minimum of $3M + 1$ `CAS` operations, whereas the algorithm of Herlihy et al. [14] requires only $2M + 1$. The authors are unaware of any direct performance comparison of these algorithms, but they believe the obstruction-free one would outperform the lock-free one, particularly in the absence of conflicting `MCAS` operations.

Open Questions

Because transactional memory research has grown out of research into nonblocking data structures, it was long considered mandatory for STM implementations to support the development of nonblocking data structures. Recently, however, a number of researchers have observed that at least the software engineering benefits of transactional memory can be delivered even by a blocking STM. There are ongoing debates whether STM needs to be nonblocking and whether there is a fundamental cost to being nonblocking.

While we agree that blocking STMs are considerably easier to design, and that in many cases a blocking STM is acceptable, this is not always true. Consider, for example, an interrupt handler that shares data with the interrupted thread. The interrupted thread will not run again until the interrupt handler completes, so it is critical that the interrupted thread does not block the interrupt handler. Thus, if using STM is desired to simplify the code for accessing this shared data, the STM *must* be nonblocking. The authors are therefore motivated to continue research aimed at improving nonblocking STMs and to understand what fundamental gap, if any, exists between blocking and nonblocking STMs.

Progress in improving the common-case performance of nonblocking STMs continues [19], and the authors see no reason to believe that nonblocking STMs should not be very competitive

with blocking STMs in the common case, i.e., until the system decides that one transaction should not wait for another that is delayed (an option that is not available with blocking STMs).

It is conjectured that indeed a separation between blocking and nonblocking STMs can be proved according to some measure, but that this will not imply significant performance differences in the common case. Indeed results of Attiya et al. [3] show a separation between obstruction-free and blocking algorithms according to a measure that counts the number of distinct base objects accessed by the implementation plus the number of "memory stalls", which measure how often the implementation can encounter contention for a variable from another thread. While this result is interesting, it is not clear that it is useful for deciding whether to implement blocking or obstruction-free objects, because the measure does not account for the time spent waiting by blocking implementations, and thus is biased in their favor. For now, remain optimistic that STMs can be made to be nonblocking without paying a severe performance price in the common case.

Another interesting question, which is open as far as the authors know, is whether there is a fundamental cost to implementing stronger nonblocking progress conditions versus obstruction-freedom. Again, they conjecture that there is. It is known that there is a fundamental difference between obstruction-freedom and lock-freedom in systems that support only reads and writes: It is possible to solve obstruction-free consensus but not lock-free consensus in this model [15]. While this is a fascinating observation, it is mostly irrelevant from a practical standpoint as all modern shared memory multiprocessors support stronger synchronization primitives such as `CAS`, with which it is easy to solve consensus, even wait-free. The interesting question therefore is whether there is a fundamental cost to being lock-free as opposed to obstruction-free in real systems.

To have a real impact on design directions, such results need to address common case performance, or some other measure (perhaps space) that is relevant to everyday use. Many lower bound results establish a separation in worst-case time complexity, which does not necessarily have a direct impact on design decisions, because the worst case may be very rare. So far, efforts to establish a separation according to potentially useful measures have only led to stronger results than we had conjectured were possible. In the authors first attempt [18], they tried to establish a separation in the number of CAS instructions needed in the absence of contention to solve consensus, but found that this was not a very useful measure, as were able to come up with a wait-free implementation that avoids CAS in the absence of contention. The second attempt [6] was to establish a separation according to the *obstruction-free step complexity* measure, which counts the maximum number of steps to complete an operation once the operation encounters no more contention. They knew we could implement obstruction-free DCAS with constant obstruction-free step complexity, and attempt to prove this impossible for lock-free DCAS, but achieved such an algorithm. These experiences suggest that, in addition to their direct advantages, obstruction-free algorithms may provide a useful stepping stone to algorithms with stronger progress properties.

Finally, while a number of contention managers have proved effective for various workloads, it is an open question whether a single contention manager can adapt to be competitive with the best on all workloads, and how close it can come to making optimal contention management decisions. Experience to date suggests that this will be very challenging to achieve. Therefore, as in any system, the first priority should be avoiding contention in the first place. Fortunately, transactional memory has the potential to make this much easier than in lock-based programming models, because it offers the benefits of fine-grained synchronization without the programming complexity that accompanies fine-grained locking schemes.

Problem Definition

A *radio network* is modeled as a directed, strongly connected graph G with n *nodes*. The nodes of a network G correspond to transmitting/receiving wireless devices, and directed edges represent their immediately reached neighbors: if a node w is within the transmission range of a node v, then G contains an edge (v, w). We call w an *out-neighbor* of v and v an *in-neighbor* of w.

Each node v has a unique *label* ℓ_v from the set $[N] = \{1, \ldots, N\}$, where $N = O(n)$. Initially, each node knows only its label and the values of n and N.

The time is divided into discrete time steps. It is assumed that nodes have unlimited computing power and can perform arbitrary computations within one time step. However, only one transmission or message receipt is allowed in one time step. Each node has its own local clock, whose initial value at the time of its activation is 0. All local clocks run at the same speed.

A message M transmitted in time step t by a node v is sent instantly to all its out-neighbors. However, an out-neighbor w of v *successfully receives* M in time step t only if no collision occurred in this time step, that is, if no other in-neighbor of w transmits in step t. Collision cannot be distinguished from the background noise: if w does not receive any message in time step t, it knows that either none of its in-neighbors transmitted in step t, or that at least two did, but it does not know which of these two events occurred. It is assumed that nodes only transmit wake-up signals (to their neighbors); no other messages are used.

A *wake-up schedule* is a vector $\omega = (\omega_x)_{x \in V}$, where ω_x denotes the time step in which x wakes-up spontaneously. For any set $X \subseteq V$, ω_X denotes the earliest wake-up time step in X, i.e., $\omega_X = \min_{x \in X} \omega_x$. Without loss of generality, one can assume that $\omega_V = \min_{x \in V} \omega_x = 0$. A *wake-up network* is the pair $\langle G, \omega \rangle$, where G is a radio network G and ω is a wake-up schedule.

A *deterministic wake-up protocol* $\mathcal{W}$ is a function that, for each label ℓ and for each $\tau = 1, 2, 3, \ldots$, given all past messages received by the node v with label $\ell_v = \ell$, specifies whether v will transmit the wake-up signal in time step τ since its activation. A *randomized wake-up protocol* is defined for each node as a probability distribution over the class of deterministic protocols for that node.

The running time of a wake-up protocol $\mathcal{W}$ is the smallest T such that, for any wake-up network $\langle G, \omega \rangle$, all nodes are activated by time T.

Synchronizers

All efficient deterministic wake-up algorithms are based on the combinatorial notion of a *radio synchronizer*, called also a *synchronizer* for short (see also a simpler notion of related structures called selectors [5], efficiently exploited in the context of broadcasting in radio networks).

Let $\mathcal{S} = \{\mathcal{S}^x\}_{x \in [N]}$, where each $\mathcal{S}^x = S_1^x S_2^x \ldots S_m^x$ is a 0-1 sequence of length m. The set $\mathcal{S}$ is a (N, k, m)-*synchronizer* if it satisfies the following property:

(∗) For any nonempty set $X \subseteq [N]$ of cardinality at most k, and for any wake-up schedule ω, there exists t, where $\omega_X < t \leq \omega_X + m$, such that,

$$\sum_{x \in X} S^x_{t-\omega_x} = 1.$$

It is assumed here that $S^x_i = 0$ for $i \leq 0$.

The set $\mathcal{S}$ as above can be interpreted as a transmission protocol, where $S^x_i = 1$ indicates that node x transmits in time step $\omega_x + i$. Thus the condition (∗) states that, in at most m time steps after the first node in X wakes-up, there will be a time step when exactly one node in X transmits.

More details about radio synchronizers and synchronization protocols can be found in the survey [8].

Key Results

A Deterministic Wake-Up Protocol

Lemma 1 ([3, 4]) *Let $C \geq 31$ be an integer constant. For each N and $k \leq N$, there exists an (N, k, m)-synchronizer with $m = Ck^2 \log N$.*

The key ingredient of the wake-up algorithm in [3, 4] ([3] is a conference version of [4]) is an application of (N, k, m)-synchronizer with $k = N^{1/3}$ and $m = CN^{2/3} \log N$, where $C = 31$. The analysis of this algorithm relies on the fact that it is sufficient to prove that the algorithm satisfies claimed time bounds for *path graphs*. A directed graph H is called a *path graph* if the nodes of H can be partitioned into sets L_i, $i = 0, \ldots, D$, each with a distinguished node $v_i \in L_i$ and the edges of H are of the form (v, v_{i+1}), where $0 \leq i < D$ and $v \in L_i$. Moreover, $L_D = \{v_D\}$.

Theorem 1 ([3, 4]) *There exists a deterministic protocol that completes the wake-up process in each n-node strongly connected directed graph in time $O(n^{5/3} \log n)$.*

A Randomized Wake-Up Protocol

In [7], the authors presented a randomized wake-up protocol Probability Increase for complete networks working in time $O(\log n \log(1/\epsilon))$ with probability $1 - \epsilon$ (see [6] for deterministic wake-up algorithms for complete graphs). Using this protocol along with appropriate formal analysis, one can obtain a randomized Monte Carlo wake-up protocol for general multi-hop radio networks.

Theorem 2 ([3, 4]) *One can build a randomized protocol which completes wake-up in time $O(D \log n \log(n/\epsilon))$ in each wake-up network with n nodes and diameter D with probability at least $1 - \epsilon$.*

The Monte Carlo protocol from Theorem 2 can be modified to obtain Las Vegas protocol with low expected running time.

Theorem 3 ([3, 4]) *One can build a randomized protocol which completes wake-up in expected time $O(D \log^2 n)$ in each wake-up network with n nodes and diameter D.*

All the above randomized protocols do not require labels.

Applications

Universal Synchronizers and Faster Wake-Up Protocols

The notion of a synchronizer has been generalized to a *universal synchronizer* [1].

Let $g : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ be a nondecreasing function. Let $\mathcal{S} = \{\mathcal{S}^x\}_{[N]}$, where each $\mathcal{S}^x = S^x_1 S^x_2 \ldots S^x_m$ is a 0-1 sequence of length $g(N, N)$. The set $\mathcal{S}$ is a (N, g)-*universal synchronizer* if it satisfies the following property:

(∗) For any nonempty set $X \subseteq [N]$ and for any wake-up schedule ω, there exists t, where $\omega_X < t \leq \omega_X + g(N, |X|)$, such that,

$$\sum_{x \in X} S^x_{t-\omega_x} = 1.$$

Chlebus and Kowalski proved in [1] that there exist (N, g)-universal synchronizers for $g(k) = O(k \min\{k, \sqrt{n}\} \log n)$. Using this result they

showed that there exists a wake-up protocol running in time $O(n^{3/2} \log n)$. In [2], Chlebus *et al.* provided an existential proof of the fact that much shorter universal synchronizers exist and obtained a corresponding faster wake-up protocol.

Lemma 2 ([2]) *For each N there exists a (N, g)-universal synchronizer for $g(N, k) = ck \log k \log N$, where c is a fixed constant.*

Theorem 4 ([2]) *There exists a deterministic protocol that completes the wake-up process in each n-node strongly connected directed graph in time $O(n \log^2 n)$.*

Leader Election and Clock Synchronization

In [3,4], applications of wake-up protocols for the problems of *leader election* and *clock synchronization* were considered.

In the *leader election* problem, the goal is to designate one node as *the leader*, and to announce its identity to all nodes in the network. In the *clock synchronization* problem, upon the completion of the protocol, all nodes must agree on a common global time. For clock synchronization, messages may include numerical values representing the global time.

It has been shown in [3, 4] that any wake-up protocol $\mathcal{W}$ (deterministic or randomized) can be transformed into a leader election protocol or a clock synchronization protocol with only a logarithmic overhead. The leader election protocol is obtained by an execution of appropriately composed $O(\log n)$ executions of a wake-up protocol, in which nodes gradually learn consecutive bits of the node with the largest label. In the clock synchronization protocol, the leader is elected first and then it broadcasts its clock state over the whole network.

Open Problems

The exact complexity of the wake-up problem is not known – there is a logarithmic gap between the complexities of the best known protocols and lower bounds. No efficient algorithms for a construction of (universal) synchronizers described in Lemmata 1 and 2 are known (i.e., polynomial time construction with a polylogarithmic overhead to the length), and thus the results from Theorems 1 and 4 are nonconstructive either. It is not known whether the logarithmic overhead in the complexity of leader election and clock synchronization with respect to wake-up is necessary.

Problem Definition

The wavelet tree is a data structure that represents a recursive partition of a sequence S of length n according to its symbols. Letting $\Sigma = \{1, \ldots \sigma\}$ be the alphabet of symbols of S, the wavelet tree for S has the root representing S itself and σ leaves representing the positions of the symbols: leaf $c \in \Sigma$ represents all the positions i such that $S[i] = c$ and $1 \leq i \leq n$. The internal nodes describe how the symbols are grouped. In the original wavelet tree, nodes are binary and thus there are two groups, called the `0`-group and the `1`-group, which form an alphabet partition. In the multi-ary wavelet tree, the nodes are obtained by forming more than two groups each time. We focus on binary wavelet trees in the following.

For example, consider the sequence $S =$ `SENSELESSNESS#` in Fig. 1. Here we divide the symbols in two groups $\{\mathtt{E}, \mathtt{L}\}$, and $\{\mathtt{N}, \mathtt{S}, \#\}$, giving rise to the two children of the root: the left child contains the subsequence of S obtained by copying the symbols in $\{\mathtt{E}, \mathtt{L}\}$; the right child contains the subsequence of S obtained by copying the rest of the symbols (which are in $\{\mathtt{N}, \mathtt{S}, \#\}$). The partition of $\{\mathtt{E}, \mathtt{L}\}$ into $\{\mathtt{E}\}$ and $\{\mathtt{L}\}$ produces two leaves. The partition of $\{\mathtt{N}, \mathtt{S}, \#\}$ into $\{\mathtt{N}\}$ and $\{\mathtt{S}, \#\}$ gives rise to a leaf and an internal node. The latter represents the partition of $\{\mathtt{S}, \#\}$ giving rise to two leaves.

In general each internal node of the wavelet tree represents a subsequence S' of the input sequence S, obtained by selecting certain symbols from S. More precisely, if Σ' is the alphabet for the symbols in S', then S' is formed by selecting *all* the symbols of S belonging to Σ'. Note that $\Sigma' = \{c\}$ if and only if the node storing S' is the leaf whose associated symbol is c. For an internal node, its two children are determined by the choice of the `0`-group Σ'_0 and of the `1`-group Σ'_1 partitioning $\Sigma' = \Sigma'_0 \cup \Sigma'_1$. To this end, a bitvector $B_{S'}$ is associated with S', where the `0`'s mark which positions of S' contain symbols from Σ'_0 and the `1`'s mark which positions contain symbols from `1`-group Σ'_1.

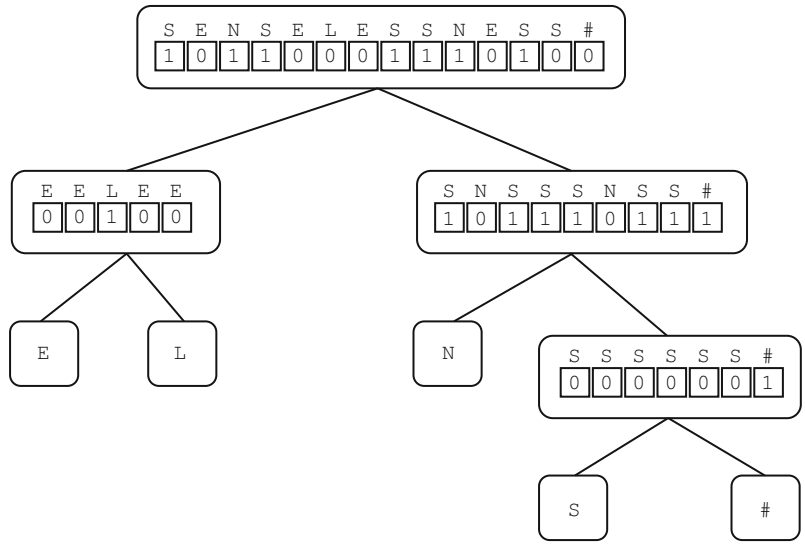
It is worth noting that any choice for the recursive alphabet partitioning in `0`- and `1`-groups can be translated into a simple dichotomy test at each node by suitably reordering the alphabet Σ: without loss of generality, we assume that given a node representing S' over alphabet Σ', there exists a symbol $c' \in \Sigma'$ such that c belongs to the `0`-group Σ'_0 if and only if $c \in \Sigma'$ and $c \leq c'$.

Finally, the sequences S and S' can be actually dropped from the nodes of the wavelet tree: just knowing the symbols from Σ associated with its leaves allows us to reconstruct the dropped sequences in its internal nodes as we discuss next.

Key Results

Despite its simplicity, the wavelet tree is a versatile data structure that offers solutions to a variety of situations using small additional space.

- *Compressed sequences*. Sequence S can be stored using a number of bits close to the 0-order entropy and still supporting random access and other operations such as rank and select of individual symbols.
- *Geometric points and 2D data*. The leaves represent the individual points in x-order, while



Wavelet Trees, Fig. 1 A wavelet tree for the sequence $S = \texttt{SENSELESSNESS\#}$ with $\Sigma = \{\texttt{E}, \texttt{L}, \texttt{N}, \texttt{S}, \#\}$. Only the symbols in the leaves and the bitvectors are actually stored

the root represents the same points but in y-order. Range and percentile queries can be performed in this way.

- *Permutations, shufflings, and reorderings*. The leaves represent the elements in a certain order and the root represents the same set in a permuted order. Mapping these two orders can be done efficiently.

As for the construction of the wavelet tree, it can be easily done in $O(n \log \sigma)$ time and space. More sophisticated algorithms have been developed to lower the construction time and/or the additional working space. In the following, we focus here on the usage of the original wavelet tree.

Compressed Sequences

The first natural question is how to `access` symbol $S[i]$ from the wavelet tree for S. We can only use the bitvectors $B_{S'}$ in the internal nodes and the mapping from the leaves to the symbols of Σ. We start out from the root, check bit $B_S[i]$, and count the number i' of bits equal to $B_S[i]$ in the first i positions of B_S. After that, we repeat the step on the left child (if $B_S[i] = \texttt{0}$) or the right child (if $B_S[i] = \texttt{1}$), setting the new value of $i = i'$ and using the bitvector $B_{S'}$ of that child. Eventually we end up in a leaf, and the symbol c corresponding to that leaf gives the answer that $S[i] = c$.

Regarding the time and space complexity, we need an operation to count how many `1`'s occur in the first i positions of a bitvector (as the number of `0`'s can be obtained by subtracting this count from i). This operation is called `rank` in the literature and takes constant time by preprocessing the bitvector and adding a little-oh number of bits to it. In this way, the cost of `access` operation is given by the height of the wavelet tree, which is $O(\log \sigma)$ in case of a balanced shape.

As for the space complexity, note that any binary tree shape with σ leaves is feasible. Using a Huffman tree shape, less frequent symbols correspond to deeper leaves. Note that each symbol occurrence in a leaf can be charged a bit from each bitvector in its ancestors. Equivalently, the sum of the lengths of the bitvectors in all the internal nodes of the wavelet tree is equal to the sum of the lengths of the Huffman encodings of the symbols of the input sequence S. In other words, the space required by the bitvectors is equal to the space achieved by the Huffman encoding. The additional `rank` data structures use little-oh of that space. Letting $H_0 \leq \log \sigma$ (logarithms in base 2) denote the 0-order entropy of S, the total space to store a wavelet tree is therefore $nH_0 + o(nH_0)$ bits, which can be lowered to $nH_0 + o(n)$ with additional machinery. For compressible sequences S, this is better than storing them in $n \log \sigma$ bits with the standard format. In general,

any prefix-free encoding of the symbols in Σ can be used in place of the Huffman coding, giving the same number of bits of the chosen encoding: it suffices to choose as a shape the resulting prefix tree of the chosen encoding of the symbols in Σ. (Note that storing the tree shape and symbol mappings requires $O(\sigma \log \sigma)$ further bits.)

Interestingly, the above space bound can be obtained using any shape if the bitvectors are stored in compressed format. For example, one compressed bitvector representation stores a bitvector of length m with k `1`'s using the theoretic information minimum of $\log \binom{m}{k} + o(m)$ bits and supports constant time `rank` and `select` operations. The latter operation returns the position of the jth `1` in the bitvector (same for the jth `0`). It can be shown that for *any shape* of the wavelet tree, summing the $\log \binom{m}{k} + o(m)$ contribution of all the bitvectors in its nodes still gives a total space of $nH_0 + o(n)$ bits to store the wavelet tree. In other words, the 0-order entropy bound can be achieved independently of the tree shape.

As a by-product of what we discussed above, the wavelet tree allows us to extend the `rank` and `select` operations from a bitvector to any sequence over an alphabet Σ. To see why, suppose we want to know how many occurrences of symbols c occur in the first i positions of S. We perform the same steps as described above for the `access` operation (where we initially set $i' = i$) except that now we already know that the path to follow is from the root to the leaf representing c. In the generic step, we can easily test if c belongs to the `0`- or `1`-group of the current node, and branch according to the target leaf, updating the value of i'. However, when we reach the leaf for c, we have to return the corresponding value of i' as the answer for `rank` of c, since it tells how many c's are up to position i. As for the `select` operation on c, suppose that we want to identify the jth occurrence of c in S. This time we proceed from the leaf corresponding to c backwards to the root. We initially set $i' = j$ and then reverse the branching process: at the generic step, we are in a node storing S' and on position i'. We reach the parent p of the current node, and select the i'th `0` (if arriving from the left child) or the i'th `1` (if arriving from the right child) in the bitvector stored in p. We set i' to be the resulting position and iterate. Eventually we reach the root and return the current value of i' as the answer for `select` of c.

Time cost is proportional to the height of the wavelet tree, which is $O(\log \sigma)$ in case of a balanced shape. Using multi-ary wavelet trees, the height can be reduced and so does the cost, achieving $O(1 + \log \sigma / \log w)$ time with a word size $w = \Omega(\log n)$.

Geometric Points and Two-Dimensional Data

Given a set of n points $\langle x_i, y_i \rangle$ in the plane, or equivalently 2D data, where $x_1 \leq x_2 \leq \cdots x_n$, we can use the wavelet tree as a space-efficient data structure for storing and querying them. We store these coordinates in two vectors X and Y, such as $X[i] = x_i$ and $Y[i] = y_i$ for $1 \leq i \leq n$. We then build the wavelet tree where $S \equiv Y$ and Σ is the set of distinct values in Y.

As a result, we obtain a compacted hierarchical space decomposition for the n points. To see why, we can conceptually think of the n points as belonging to a $n \times n$ grid stored in the root of the wavelet tree, where the actual coordinates are those stored in X and Y. The geometric interpretation of alphabet partitioning in `0`- and `1`-groups is that of choosing a value y' and splitting the points in two groups, those having coordinate $y_i \leq y'$ (the `0`-group) and those having $y_i > y'$ (the `1`-group). Let n_0 be the size of the `0`-group for the root and n_1 be the size of the `1`-group, where $n = n_0 + n_1$. In each group, only the rows and the columns that still contain points survive. As a result, two grids of size $n_0 \times n_0$ and $n_1 \times n_1$ are produced from one of size $n \times n$. Here, the left child corresponds to a subsequence Y'_0 of Y that represents the n_0 points (with $y_i \leq y'$) in the grid of size $n_0 \times n_0$, and the right child represents the sequence Y'_1 of n_1 points (with $y_i > y'$) in the grid of size $n_1 \times n_1$. The leaves of the wavelet tree are in y-order, and each of them stores the points sharing the same y-coordinate.

As for the storage, we observe that the values in X can be represented compactly as they are in

x-order. The values of Y do not need to be stored separately as they are represented in the wavelet tree. Total space is $O(n \log n)$ bits but can be less if the sequences of coordinates are compressible.

The supported operations exploit the aforementioned hierarchical space decomposition for the two-dimensional data as illustrated next. For example, consider the classical 2D range query, reporting (or counting) the points contained in the range $[a \ldots b] \times [c \ldots d]$. If the current cutting coordinate y' is outside the range $[c \ldots d]$, we move to one of the two children; otherwise, we branch on both children, using respectively the ranges $[a \ldots b] \times [c \ldots y']$ and $[a \ldots b] \times (y' \ldots d]$. Note that the restriction $[a \ldots b]$ on the x-coordinates can be used to test if the grid represented by the reached child has a nonempty intersection with the range: the mechanism is the same as that of `rank`. This means that each reported occurrence potentially requires a traversal down to a leaf; thus the cost is proportional to the number of reported points times the height of the wavelet tree. A refined version of this idea allows for $O(\log n / \log \log n)$ time for a counting query.

Another interesting use is quantile queries. For the range $[a \ldots b]$, consider the values in $V_{ab} = \{y_i \mid a \leq x_i \leq b\}$ obtained as the y-coordinates of the points in that range. For any given a, b, and k, the query asks to find the kth element in V_{ab}. Using the above wavelet tree, we can find the rank i_a of a and that i_b of b. Then, using `rank` operations on the bitvector B_S in the root, we can count how many `0`'s and `1`'s are in $B_s[i_a \ldots i_b]$. If there are at least k `0`'s, we know that the kth value in V_{ab} is smaller than or equal than the cutting coordinate y', and we iterate in the left child; otherwise, we subtract the number of `0`'s from k, and we iterate in the right child. When we reach a leaf, we return the associated value as the answer for the quantile query. Along the same lines, we can also report the topmost k values in V_{ab}. Once again, the cost is proportional to the wavelet tree height for each reported value.

Permutations, Shufflings, and Reorderings

The above discussion brings the combinatorial structure of wavelet tree to light as we can store two orders inside it: the former is the order in the sequence stored at the root, and the latter is obtained by a left-to-right traversal of the leaves. The bitvectors are internal routers that guide how elements are permuted and shuffled to produce the reordering. Mergesort can be modeled according to this view: the internal nodes merge the content of their children, and the bitvectors tell who goes where in the resulting merged reordering.

An immediate application of the above observations is setting S to be a permutation π of the integers in $\{1, 2, \ldots, n\}$. Traversing the wavelet tree upward (as in the `select`) computes $\pi(i)$, while traversing it downward computes the inverse permutation π^{-1}. The best cost is $O(\log n / \log \log n)$ time.

In general, we can store two orders using the wavelet tree, one being a permutation of the other. Inverted lists in information retrieval can store document IDs in increasing order of enumeration, but they also want to store these IDs in decreasing order of importance through some raking function. As it is clear now, these are two orders that can be simultaneously preserved inside the wavelet tree.

Applications

Looking back at previous work, some ideas behind the wavelet tree can be found in Kärkkäinen's PhD thesis and in Chazelle's functional approach to data structures for multidimensional searching. The wavelet tree in its explicit and fully functional form has been introduced by Grossi, Gupta, and Vitter to store the Burrows-Wheeler transform (BWT) for obtaining compressed text indexes (able to support fast pattern searching). Its natural application is supporting `rank` and `select` queries for the symbols of the resulting compressed BWT. Since then, many papers have explored the properties of the wavelet trees in several applications. Apart from compressed full-text indexes, researchers have employed wavelet trees in inverted lists, graphs, binary relations, numeric sequences, colored range queries, XPath queries, semi-structure data, and frequent item sets, to name a few. The wavelet

trie extends the wavelet tree to store a sequence of strings, rather than a sequence of symbols, thus allowing the supported operations to operate also on the prefixes of the strings. The wavelet matrix is a variant of a balanced wavelet tree, in which all the bitvectors on the same level are concatenated, and is particularly efficient for large alphabet size σ.

Minimum weighted connected dominating set

Years and Authors of Summarized Original Work

2005; Wang, Wang, Li

Problem Definition

This problem is concerned with a weighted version of the classical minimum connected dominating set problem. This problem has numerous motivations including wireless networks and distributed systems. Previous work [1, 2, 4, 5, 6, 14] in wireless networks focuses on designing efficient distributed

algorithms to construct the connected dominating set which can be used as the virtual backbone for the network. Most of the proposed methods try to minimize the number of nodes in the backbone (i.e., the number of clusterheads). However, in many applications, minimizing the size of the backbone is not sufficient. For example, in wireless networks different wireless nodes may have different costs for serving as a clusterhead, due to device differences, power capacities, and information loads to be processed. Thus, by assuming each node has a cost to being in the backbone, there is a need to study distributed algorithms for weighted backbone formation. Centralized algorithms to construct a weighted connected dominating set with minimum weight have been studied [3, 7, 9]. Recently, the work of Wang, Wang, and Li [12, 13] proposes an efficient distributed method to construct a weighted backbone with low cost. They proved that the total cost of the constructed backbone is within a small constant factor of the optimum when either the nodes' costs are smooth (i.e., the maximum ratio of costs of adjacent nodes is bounded) or the network maximum node degree is bounded. To the best knowledge of the entry authors, this work is the first to consider this weighted version of minimum connected dominating set problem and provide a distributed approximation algorithm.

Notations

A communication graph $G = (V, E)$ over a set V of wireless nodes has an edge uv between nodes u and v if and only if u and v can communicate directly with each other, i.e., inside the transmission region of each other. Let $d_G(u)$ be the degree of node u in a graph G and Δ be the maximum node degree of all wireless nodes (i.e., $\Delta = \max_{u \in V} d_G(u)$). Each wireless node u has a cost $c(u)$ of being in the backbone. Let $\delta = \max_{ij \in E} c(i)/c(j)$, where ij is the edge between nodes i and j, E is the set of communication links in the wireless network G, and the maximum operation is taken on all pairs of adjacent nodes i and j in G. In other words, δ is the maximum ratio of costs of two adjacent nodes and can be called the *cost smoothness* of the network. When δ is bounded by some small constant, the node costs are *smooth*. When the transmission region of every wireless node is modeled by a unit disk centered at itself, the communication graph is often called a *unit disk graph*, denoted by $UDG(V)$. Such networks are also called *homogeneous networks*.

A subset S of V is a *dominating set* if each node in V is either in S or is adjacent to some node in S. Nodes from S are called dominators, while nodes not in S are called dominatees. A subset B of V is a *connected dominating set* (CDS) if B is a dominating set and B induces a connected subgraph. Consequently, the nodes in B can communicate with each other without using nodes in $V - B$. A dominating set with minimum cardinality is called *minimum dominating set* (MDS). A CDS with minimum cardinality is the *minimum connected dominating set* (MCDS). In the weighted version, assume that each node u has a cost $c(u)$. Then a CDS B is called *weighted connected dominating set* (WCDS). A subset B of V is a *minimum weighted connected dominating set* (MWCDS) if B is a WCDS with minimum total cost. It is well-known that finding either the *minimum connected dominating set* or the *minimum weighted connected dominating set* is a NP-hard problem even when G is a unit disk graph. The work of Wang et al. studies efficient approximation algorithms to construct a low-cost backbone which can approximate the MWCDS problem well. For a given communication graph $G = (V, E, C)$ where V is the set of nodes, E is the edge set, and C is the set of weights for edges, the corresponding minimum weighted connected dominating set problem is as follows.

Problem 1 (Minimum Weighted Connected Dominating Set)
INPUT: The weighted communication graph $G = (V, E, C)$.
OUTPUT: A subset A of V is a *minimum weighted connected dominating set*, i.e., (1) A is a dominating set; (2) A induces a connected subgraph; (3) the total cost of A is minimum.

Another related problem is independent set problem. A subset of nodes in a graph G is an

independent set if for any pair of nodes, there is no edge between them. It is a *maximal independent set* if no more nodes can be added to it to generate a larger independent set. Clearly, any maximal independent set is a dominating set. It is a *maximum independent set* (MIS) if no other independent set has more nodes. The independence number, denoted as $\alpha(G)$, of a graph G is the size of the MIS of G. The *k-local independence number*, denoted by $\alpha^{[k]}(G)$, is defined as $\alpha^{[k]}(G) = \max_{u \in V} \alpha(G_k(u))$. Here, $G_k(u)$ is the induced graph of G on k-hop neighbors of u (denoted by $N_k(u)$), i.e., $G_k(u)$ is defined on $N_k(u)$, and contains all edges in G with both end-points in $N_k(u)$. It is well-known that for a unit disk graph, $\alpha^{[1]}(UDG) \leq 5$ [2] and $\alpha^{[2]}(UDG) \leq 18$ [11].

Key Results

Since finding the minimum weighted connected dominating set (MWCDS) is NP-hard, centralized approximation algorithms for MWCDS have been studied [3, 7, 9]. In [9], Klein and Ravi proposed an approximation algorithm for the node-weighted Steiner tree problem. Their algorithm can be generalized to compute a $O(\log \Delta)$ approximation for MWCDS. Guha and Khuller [7] also studied the approximation algorithms for node-weighted Steiner tree problem and MWCDS. They developed an algorithm for MWCDS with an approximation factor of $(1.35 + \epsilon) \log \Delta$ for any fixed $\epsilon > 0$. Recently, Ambuhl et al. [3] provided a constant approximation algorithm for MWCDS under UDG model. Their approximation ratio is bounded by 89. All these algorithms are centralized algorithms, while the applications in wireless ad hoc networks prefer distributed solutions for MWCDS.

In [12, 13], Wang et al. proposed a distributed algorithm that constructs a weighted connected dominating set for a wireless ad hoc network G. Their method has two phases: the first phase (clustering phase, Algorithm 1 in [12, 13]) is to find a set of wireless nodes as the dominators (clusterheads) and the second phase (Algorithm 2 in [12, 13]) is to find a set of nodes, called *connectors*, to connect these dominators to form the final backbone. Wang et al. proved that the total cost of the constructed backbone is no more than $\min(\alpha^{[2]}(G) \log (\Delta + 1), (\alpha^{[1]}(G) - 1)\delta + 1) + 2\alpha^{[1]}(G)$ times of the optimum solution.

Algorithm 1 first constructs a maximal independent set (MIS) using classical greedy method with the node cost as the selection criterion. For each node v in MIS, it then runs a local greedy set cover method on the *local neighborhood* $N_2(v)$ to find some nodes ($GRDY_v$) to cover all one-hop neighbors of v. If $GRDY_v$ has a total cost smaller than v, then it uses $GRDY_v$ to replace v, which further reduces the cost of MIS. The following theorem of the total cost of this selected set is proved in [12, 13].

Theorem 1 *For a network modeled by a graph G, Algorithm 1 (in* [12, 13]*) constructs a dominating set whose total cost is no more than* $\min(\alpha^{[2]}(G) \log(\Delta+1), (\alpha^{[1]}(G)-1)\delta+1)$ *times of the optimum.*

Algorithm 2 finds some *connectors* among all the dominatees to connect the dominators into a backbone (CDS). It forms a CDS by finding connectors to connect any pair of dominators u and v if they are connected in the original graph G with at most 3 hops. A distributed algorithm to build a MST then is performed on the CDS. The following theorem of the total cost of these connectors is proved in [12, 13].

Theorem 2 *The connectors selected by Algorithm 2 (in* [12, 13]*) have a total cost no more than* $2 \cdot \alpha^{[1]}(G)$ *times of the optimum for networks modeled by G.*

Combining Theorems 1 and 2, the following theorem is the main contributions of the work of Wang et al..

Theorem 3 *For any communication graph G, Algorithm 1 and Algorithm 2 construct a weighted connected dominating set whose total cost is no more than*

$$\min(\alpha^{[2]}(G)\log(\Delta+1), (\alpha^{[1]}(G)-1)\delta+1) + 2\alpha^{[1]}(G)$$

times of the optimum.

Notice that, for homogeneous wireless networks modeled by UDG, it implies that the constructed backbone has a cost no more than $\min(18\log(\Delta+1), 4\delta+1)+10$ times of the optimum. The advantage of the constructed backbone is that the total cost is small compared with the optimum when either the costs of wireless nodes are smooth, i.e., two neighboring nodes' costs differ by a small constant factor, or the maximum node degree is low.

In term of time complexity, the most time-consuming step in the proposed distributed algorithm is building the MST. In [10], Kuhn et al. gave a lower bound on the distributed time complexity of any distributed algorithm that wants to compute a minimum dominating set in a graph. Essentially, they proved that even for the unconnected and unweighted case, any distributed approximation algorithm with poly-logarithmic approximation guarantee for the problem has to have a time-complexity of at least $\Omega(\log \Delta / \log\log \Delta)$.

Applications

The proposed distributed algorithms for MWCDS can be used in ad hoc networks or distributed system to form a low-cost network backbone for communication application. The cost used as the input of the algorithms could be a *generic* cost, defined by various practical applications. It may represent the *fitness* or *priority* of each node to be a clusterhead. The lower cost means the higher priority. In practice, the cost could represent the power consumption rate of the node if a backbone with small power consumption is needed; the robustness of the node if fault-tolerant backbone is needed; or a function of its security level if a secure backbone is needed; or a combined weight function to integrate various metrics such as traffic load, signal overhead, battery level, and coverage. Therefore, by defining different costs, the proposed low-cost backbone formation algorithms can be used in various practical applications. Beside forming the backbone for routing, the weighted clustering algorithm (Algorithm 1) can also be used in other applications, such as selecting the mobile agents to perform intrusion detection in ad hoc networks [8] (to achieve more robust and power efficient agent selection), or select the rendezvous points to collect and store data in sensor networks [15] (to achieve the energy efficiency and storage balancing).

Open Problems

A number of problems related to the work of Wang, Wang, and Li [12, 13] remain open. The proposed method assumes that the nodes are almost-static in a reasonable period of time. However, in some network applications, the network could be highly dynamic (both the topology or the cost could change). Therefore, after the generation of the weighted backbone, the dynamic maintenance of the backbone is also an important issue. It is still unknown how to update the topology efficiently while preserving the approximation quality.

In [12, 13], the following assumptions on wireless network model is used: omni-directional antenna, single transmission received by all nodes within the vicinity of the transmitter. The MWCDS problem will become much more complicated if some of these assumptions are relaxed.

Experimental Results

In [12, 13], simulations on random networks are conducted to evaluate the performances of the proposed weighted backbone and several backbones built by previous methods. The simulation results confirm the theoretical results.

Weighted Popular Matchings

Julián Mestre
Department of Computer Science, University of Maryland, College Park, MD, USA
School of Information Technologies, The University of Sydney, Sydney, NSW, Australia

Years and Authors of Summarized Original Work

2006; Mestre

Problem Definition

Consider the problem of matching a set of individuals X to a set of items Y where each individual has a weight and a personal preference over the items. The objective is to construct a matching M that is stable in the sense that there is no matching M' such that the weighted majority vote will choose M' over M.

More formally, a bipartite graph (X, Y, E), a weight $w(x) \in R^+$ for each individual $x \in X$, and a rank function $r : E \to \{1, \ldots, |Y|\}$ encoding the individual preferences are given. For every applicant x and items $y_1, y_2 \in Y$ say applicant x prefers y_1 over y_2 if $r(x, y_1) < r(x, y_2)$, and x is indifferent between y_1 and y_2 if $r(x, y_1) = r(x, y_2)$. The preference

lists are said to be strictly ordered if applicants are never indifferent between two items, otherwise the preference lists are said to contain ties.

Let M and M' be two matchings. An applicant x prefers M over M' if x prefers the item he/she gets in M over the item he/she gets in M'. A matching M is *more popular than* M' if the applicants that prefer M over M' outweigh those that prefer M' over M. Finally, a matching M is *weighted popular* if there is no matching M' more popular than M.

In the *weighted popular matching problem* it is necessary to determine if a given instance admits a popular matching, and if so, to produce one. In the *maximum weighted popular matching problem* it is necessary to find a popular matching of maximum cardinality, provided one exists.

Abraham et al. [2] gave the first polynomial time algorithms for the special case of these problems where the weights are uniform. Later, Mestre [8] introduced the weighted variant and developed polynomial time algorithms for it.

Key Results

Theorem 1 *The weighted popular matching and maximum weighted popular matching problems on instances with strictly ordered preferences can be solved in* $O(|X| + |E|)$ *time.*

Theorem 2 *The weighted popular matching and maximum weighted popular matching problems on instances with arbitrary preferences can be solved in* $O(\min\{k\sqrt{|X|}, |X|\}|E|)$ *time.*

Both results rely on an alternative easy-to-compute characterization of weighted popular matchings called *well-formed* matchings. It can be shown that every popular matching is well-formed. While in unweighted instances every well-formed matching is popular [2], in weighted instances there may be well-formed matchings that are not popular. These non-popular well-formed matchings can be weeded out by pruning certain bad edges that cannot be part of any popular matching. In other words, the instance can be pruned so that a matching is popular if and only if it is well-formed and is contained in the pruned instance [8].

Applications

Many real-life problems can be modeled using one-sided preferences. For example, the assignment of graduates to training positions [5], families to government-subsidized housing [10], students to projects [9], and Internet rental markets [1] such as Netflix where subscribers are assigned DVDs.

Furthermore, the weighted framework allows one to model the naturally occurring situation in which some subset of users has priority over the rest. For example, an Internet rental site may offer a "premium" subscription plan and promise priority over "regular" subscribers.

Problem Definition

The problem of random sampling without replacement (RS) calls for the selection of m distinct random items out of a population of size n. If all items have the same probability to be selected, the problem is known as uniform RS. Uniform random sampling in one pass is discussed in [1, 6, 11]. Reservoir-type uniform sampling algorithms over data streams are discussed in [12]. A parallel uniform random sampling algorithm is given in [10]. In weighted random sampling (WRS) the items are weighted and the probability of each item to be selected is determined by its relative weight. WRS can be defined with the following algorithm D:

Algorithm D, a definition of WRS

Input: A population V of n weighted items
Output: A set S with a WRS of size m
1: For $k = 1$ to m do
2: Let $p_i(k) = w_i / \sum_{s_j \in V-S} w_j$ be the probability of item v_i to be selected in round k
3: Randomly select an item $v_i \in V - S$ and insert it into S
4: End-For

Problem 1 (WRS)
INPUT: A population V of n weighted items.
OUTPUT: A set S with a weighted random sample.

The most important algorithms for WRS are the Alias Method, Partial Sum Trees and the Acceptance/Rejection method (see [9] for a summary of WRS algorithms). *None of these algorithms is appropriate for one-pass WRS.* In this work, an algorithm for WRS is presented. The algorithm is simple, very flexible, and solves the WRS problem over data streams. Furthermore, the algorithm admits parallel or distributed implementation. To the best knowledge of the entry authors, this is the first algorithm for WRS over data streams and for WRS in parallel or distributed settings.

Definitions

One-pass WRS is the problem of generating a weighted random sample in one-pass over a population. If additionally the population size is initially unknown (e.g., a data streams), the random sample can be generated with *reservoir sampling* algorithms. These algorithms keep an auxiliary storage, the reservoir, with all items that are candidates for the final sample.

Notation and Assumptions

The item weights are initially unknown, strictly positive reals. The population size is n, the size of the random sample is m and the weight of item v_i is w_i. The function $random(L, H)$ generates a uniform random number in (L, H). X denotes a random variable. Infinite precision arithmetic is assumed. Unless otherwise specified, all sampling problems are without replacement. Depending on the context, WRS is used to denote a weighted random sample or the operation of weighted random sampling.

Key Results

All the results with their proofs can be found in [4].

The crux of the WRS approach of this work is given with the following **algorithm A:**

Algorithm A

Input: A population V of n weighted items
Output: A WRS of size m
1: For each $v_i \in V$, $u_i = random(0, 1)$ and $k_i = u_i^{(1/w_i)}$
2: Select the m items with the largest keys k_i as a WRS

Theorem 1 *Algorithm A generates a WRS.*

A reservoir-type adaptation of algorithm A is the following **algorithm A-Res**:

Algorithm A with a Reservoir (A-Res)

Input: A population V of n weighted items
Output: A reservoir R with a WRS of size m
1: The first m items of V are inserted into R
2: For each item $v_i \in R$: Calculate a key $k_i = u_i^{(1/w_i)}$, where $u_i = random(0, 1)$
3: Repeat Steps 4–7 for $i = m + 1, m + 2, \ldots, n$
4: The smallest key in R is the current threshold T
5: For item v_i: Calculate a key $k_i = u_i^{(1/w_i)}$, where $u_i = random(0, 1)$
6: If the key k_i is larger than T, then:
7: The item with the minimum key in R is replaced by item v_i

Algorithm A-Res performs the calculations required by algorithm A and hence by Theorem 1 A-Res generates a WRS. The number of reservoir operations for algorithm A-Res is given by the following Proposition:

Theorem 2 *If A-Res is applied on n weighted items, where the weights $w_i > 0$ are independent random variables with a common continuous distribution, then the expected number of reservoir insertions (without the initial m insertions) is:*

$$\sum_{i=m+1}^{n} P\,[\text{item } i \text{ is inserted into } S] = \sum_{i=m+1}^{n} \frac{m}{i} = O\left(m \cdot \log\left(\frac{n}{m}\right)\right).$$

Let S_w be the sum of the weights of the items that will be skipped by A-Res until a new item enters the reservoir. If T_w is the current threshold to enter the reservoir, then S_w is a continuous random variable that follows an exponential distribution. Instead of generating a key for every item, it is possible to generate random jumps that correspond to the sum S_w. Similar techniques have been applied for uniform random sampling (see for example [3]). The following algorithm A-ExpJ is an exponential jumps-type adaptation of algorithm A:

Theorem 3 *Algorithm A-ExpJ generates a WRS.*

The number of exponential jumps of A-ExpJ is given by Proposition 2. Hence algorithm A-ExpJ reduces the number of random variates that have to be generated from $O(n)$ (for A-Res) to $O(m \log(n/m))$. Since generating high-quality random variates can be a costly operation this is a significant improvement for the complexity of the sampling algorithm.

Applications

Random sampling is a fundamental problem in computer science with applications in many fields

Algorithm A with exponential jumps (A-ExpJ)

Input: A population V of n weighted items
Output: A reservoir R with a WRS of size m

1: The first m items of V are inserted into R
2: For each item $v_i \in R$: Calculate a key $k_i = u_i^{(1/w_i)}$, where $u_i = random(0, 1)$
3: The threshold T_w is the minimum key of R
4: Repeat Steps 5–10 until the population is exhausted
5: Let $r = random(0, 1)$ and $X_w = \log(r)/log(T_w)$
6: From the current item v_c skip items until item v_i, such that:
7: $w_c + w_{c+1} + \cdots + w_{i-1} < X_w \leq w_c + w_{c+1} + \cdots + w_{i-1} + w_i$
8: The item in R with the minimum key is replaced by item v_i
9: Let $t_w = T_w^{w_i}$, $r_2 = random(t_w, 1)$ and v_i's key: $k_i = r_2^{(1/w_i)}$
10: The new threshold T_w is the new minimum key of R

including databases (see [5, 9] and the references therein), data mining, and approximation algorithms and randomized algorithms [7]. Consequently, algorithm A for WRS is a general tool that can find applications in the design of randomized algorithms. For example, algorithm A can be used within approximation algorithms for the k-Median [7].

The reservoir based versions of algorithm A, A-Res and A-ExpJ, have very small requirements for auxiliary storage space (m keys organized as a heap) and during the sampling process their reservoir continuously contains a weighted random sample that is valid for the already processed data. This makes the algorithms applicable to the emerging area of algorithms for processing data streams [2, 8].

Algorithms A-Res and A-ExpJ can be used for weighted random sampling with replacement from data streams. In particular, it is possible to generate a weighted random sample with replacement of size k with A-Res or A-ExpJ, by running concurrently, in one pass, k instances of A-Res or A-ExpJ respectively. Each algorithm instance must be executed with a trivial reservoir of size 1. At the end, the union of all reservoirs is a WRS with replacement.

URL to Code

The algorithms presented in this work are easy to implement. An experimental implementation in Java can be found at: http://utopia.duth.gr/~pefraimi/projects/WRS/index.html

Well Separated Pair Decomposition

Rolf Klein
Institute for Computer Science, University of Bonn, Bonn, Germany

Keywords

Proximity algorithms for growth-restricted metrics; Unit-disk graphs

Years and Authors of Summarized Original Work

1995; Callahan, Kosaraju

Problem Definition

Well-separated pair decomposition, introduced by Callahan and Kosaraju [4], has found numerous applications in solving proximity problems for points in the Euclidean space. A pair of point sets (A, B) is *c well separated* if the distance between A and B is at least c times the diameters of both A and B. A well-separated pair decomposition of a point set consists of a set of well-separated pairs that "cover" all the pairs of distinct points, i.e., any two distinct points belong to the different sets of some pair. Callahan and Kosaraju [4] showed that for any point set in a Euclidean space and for any constant $c \geq 1$, there always exists a c-well-separated pair decomposition (c-WSPD) with linearly many pairs. This fact has been very useful for obtaining nearly linear-time algorithms for many problems, such as computing k-nearest neighbors, N-body potential fields, geometric spanners, approximate minimum spanning trees, etc. Well-separated pair decomposition has also been shown to be very useful for obtaining efficient dynamic, parallel, and external memory algorithms.

The definition of well-separated pair decomposition can be naturally extended to any metric space. However, a general metric space may not admit a well-separated pair decomposition with a subquadratic size. Indeed, even for the metric induced by the shortest path distance in a star tree with unit weight on each edge, any well-separated pair decomposition requires quadratically many pairs. This makes the well-separated pair decomposition useless for such a metric. However, it has been shown that for the unit-disk graph metric, there do exist well-separated pair decompositions with almost linear size, and therefore many proximity problems under the unit-disk graph metric can be solved efficiently.

Unit-Disk Graphs

Denote by $\mathrm{d}(\cdot,\cdot)$ the Euclidean metric. For a set of points S in the plane, the unit-disk graph $I(S) = (S, E)$ is defined to be the weighted graph where an edge $e = (p, q)$ is in the graph if $\mathrm{d}(p, q) \leq 1$, and the weight of e is $\mathrm{d}(p, q)$. Likewise, one can define the unit-ball graph for points in higher dimensions [5].

Unit-disk graphs have been used extensively to model the communication or influence between objects [9, 12] and have been studied in many different contexts [5, 10]. For an example, wireless ad hoc networks can be modeled by unit-disk graphs [8], as two wireless nodes can directly communicate with each other only if they are within a certain distance. In unsupervised learning, for a dense sampling of points from some unknown manifold, the length of the shortest path on the unit-ball graph is a good approximation of the geodesic distance on the underlying (unknown) manifold if the radius is chosen appropriately [6, 14]. By using well-separated pair decomposition, one can encode the all-pair distances approximately by a compact data structure that supports approximate distance queries in $O(1)$ time.

Metric Space

Suppose that (S, π) is a metric space where S is a set of elements and π the distance function defined on $S \times S$. For any subset $S_1 \subseteq S$, the *diameter* $D_\pi(S_1)$ (or $D(S_1)$ when π is clear from the context) of S is defined to be $\max_{s_1, s_2 \in S_1} \pi(s_1, s_2)$. The *distance* $\pi(S_1, S_2)$ between two sets $S_1, S_2 \subseteq S$ is defined to be $\min_{s_1, \in S_1, s_2 \in S_2} \pi(s_1, s_2)$.

Well-Separated Pair Decomposition

For a metric space (S, π), two nonempty subsets $S_1, S_2 \subseteq S$ are called *c well separated* if $\pi(S_1, S_2) \geq c \cdot \max(D_\pi(S_1), D_\pi(S_2))$.

Following the definition in [4], for any two sets A and B, a set of pairs $\mathcal{P} = \{P_1, P_2, \ldots, P_m\}$, where $P_i = (A_i, B_i)$, is called a *pair decomposition* of (A, B) (or of A if $A = B$) if:

- For all the i's, $A_i \subseteq A$, and $B_i \subseteq B$.
- $A_i \cap B_i = \varnothing$.
- For any two elements $a \in A$ and $b \in B$, there exists a unique i such that $a \in A_i$, and $b \in B_i$. Call (a, b) is *covered* by the pair (A_i, B_i).

If in addition, every pair in $\mathcal{P}$ is c well separated, $\mathcal{P}$ is called a *c-well-separated pair decomposition* (or c-WSPD for short). Clearly, any metric space admits a c-WSPD with quadratic size by using the trivial family that contains all the pairwise elements.

Key Results

In [7], it was shown that for the metric induced by the unit-disk graph on n points and for any constant $c \geq 1$, there does exist a c-WSPD with $O(n \log n)$ pairs, and such a decomposition can be computed in $O(n \log n)$ time. It was also shown that the bounds can be extended to higher dimensions. The following theorems state the key results for two and higher dimensions:

Theorem 1 *For any set S of n points in the plane and any $c \geq 1$, there exists a c-WSPD $\mathcal{P}$ of S under the unit-disk graph metric where $\mathcal{P}$ contains $O\left(c^4 n \log n\right)$ pairs and can be computed in $O\left(c^4 n \log n\right)$ time.*

Theorem 2 *For any set S of n points in $\mathbb{R}^k$, for $k \geq 3$, and for any constant $c \geq 1$, there exists a c-WSPD $\mathcal{P}$ of S under the unit-ball graph metric where $\mathcal{P}$ contains $O\left(n^{2-2/k}\right)$ pairs and can be constructed in $O\left(n^{4/3} \text{polylog}\, n\right)$ time for $k = 3$ and in $O\left(n^{2-2/k}\right)$ time for $k \geq 4$.*

The difficulty in obtaining a well-separated pair decomposition for the unit-disk graph metric is that two points that are close in space are not necessarily close under the graph metric. The above bounds are first shown for the point set with constant-bounded density, i.e., a point set where any unit disk covers only a constant number of points in the set. The upper bound on the number of pairs is obtained by using a packing argument similar to the one used in [1].

For a point set with unbounded density, one applies a clustering technique similar to the one used in [8] to the point set and obtains a set of "clusterheads" with a bounded density. Then the result for bounded density is applied to those clusterheads. Finally, the well-separated pair decomposition is obtained by combining the well-separated pair decomposition for the bounded density point sets and for the Euclidean metric. The number of pairs is dominated by the number of pairs constructed for a constant density set, which is in turn dominated by the bound given by the packing argument. It has been shown that the bounds on the number of pairs is tight for $k \geq 3$.

Applications

For a pair of well-separated sets, the distance between two points from different sets can be approximated by the "distance" between the two sets or the distance between any pair of points in different sets. In other words, a well-separated pair decomposition can be thought of as a compressed representation to approximate the $\Theta(n^2)$ pairwise distances. Many problems that require the pairwise distances to be checked can therefore be approximately solved by examining those distances between the well-separated pairs of sets. When the size of the well-separated pair decomposition is subquadratic, it often results in more efficient algorithms than examining all the pairwise distances. Indeed, this is the intuition behind many applications of the geometric well-separated pair decomposition. By using the same intuition, one can apply the well-separated pair decomposition in several proximity problems under the unit-disk graph metric.

Suppose that (S, d) is a metric space. Let $S_1 \subseteq S$. Consider the following natural proximity problems:

- **Furthest neighbor, diameter, center.** The furthest neighbor of $p \in S_1$ is the point in S_1 that maximizes the distance to p. Related problems include computing the *diameter*, the maximum pairwise shortest distance for points in S_1, and the *center*, the point that minimizes the maximum distance to all the other points.
- **Nearest neighbor, closest pair.** The nearest neighbor of $p \in S_1$ is the point in S_1 with the minimum distance to p. Related problems include computing the *closest pair*, the pair with the minimum shortest distance, and the *bichromatic closest pair*, the pair that minimizes the distance between points from two different sets.
- **Median.** The median of S is the point in S that minimizes the average (or total) distance to all the other points.
- **Stretch factor.** For a graph G defined on S, its stretch factor with respect to the unit-disk graph metric is defined to be the maximum ratio $\pi_G(p,q)/\pi(p,q)$, where π_G, π are the distances induced by G and by the unit-disk graph, respectively.

All the above problems can be solved or approximated efficiently for points in the Euclidean space. However, for the metric induced by a graph, even for planar graphs, very little is known besides solving the expensive all-pair shortest-path problem. For computing the diameter, there is a simple linear-time method that achieves a 2-approximation (Select an arbitrary node v and compute the shortest-path tree rooted at v. Suppose that the furthest node from v is distance D away. Then the diameter of the graph is no longer than $2D$, by triangle inequality.) and a 4/3-approximate algorithm with running time $O\left(m\sqrt{n\log n} + n^2 \log n\right)$, for a graph with n vertices and m edges, by Aingworth et al. [2].

By using the well-separated pair decomposition, Gao and Zhang [7] showed that one can obtain better approximation algorithms for the above proximity problems for the unit-disk graph metric. Specifically, one can obtain almost linear-time algorithms for computing the 2.42-approximation and $O\left(n\sqrt{n\log n}/\varepsilon^3\right)$ time algorithms for computing the $(1+\varepsilon)$-approximation for any $\varepsilon > 0$. In addition, the well-separated pair decomposition can be used to obtain an $O(n\log n/\varepsilon^4)$ space distance oracle so that any $(1+\varepsilon)$ distance query in the unit-disk graph can be answered in $O(1)$ time.

The bottleneck of the above algorithms turns out to be computing the approximation of the shortest-path distances between $O(n\log n)$ pairs. The algorithm in [7] only constructs well-separated pair decompositions without computing a good approximation of the distances. The approximation ratio and the running time are dominated by that of the approximation algorithms used to estimate the distance between each pair in the well-separated pair decomposition. Once the distance estimation has been made, the rest of the computation only takes almost linear time.

For a general graph, it is unknown whether $O(n\log n)$ pairs shortest-path distances can be computed significantly faster than all-pair shortest-path distances. For a planar graph, one can compute the $O(n\log n)$ pairs shortest-path distances in $O\left(n\sqrt{n\log n}\right)$ time by using separators with $O\left(\sqrt{n}\right)$ size [3]. This method extends to the unit-disk graph with constant-bounded density since such graphs enjoy a separator property similar to that of planar graphs [13]. As for approximation, Thorup [15] recently discovered an algorithm for planar graphs that can answer any $(1+\varepsilon)$-shortest-distance query in $O(1/\varepsilon)$ time after almost linear-time preprocessing. Unfortunately, Thorup's algorithm uses balanced shortest-path separators in planar graphs which do not obviously extend to the unit-disk graphs. On the other hand, it is known that there does exist a planar 2.42-spanner for a unit-disk graph [11]. By applying Thorup's algorithm to that planar spanner, one can compute

the 2.42-approximate shortest-path distance for $O(n \log n)$ pairs in almost linear time.

Open Problems

The most notable open problem is the gap between $\Omega(n)$ and $O(n \log n)$ on the number of pairs needed in the plane. Also, the time bound for $(1 + \varepsilon)$-approximation is still about $\tilde{O}\left(n\sqrt{n}\right)$ due to the lack of efficient methods for computing the $(1 + \varepsilon)$-approximate shortest-path distances between $O(n)$ pairs of points. Any improvement to the algorithm for that problem will immediately lead to improvement to all the $(1 + \varepsilon)$-approximate algorithms presented in this entry.

Problem Definition

Notations

Given a finite point set A in $\mathbb{R}^d$, its *bounding box* $R(A)$ is the d-dimensional hyperrectangle $[a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_d, b_d]$ that contains A and has minimum extension in each dimension.

Two point sets A, B are said to be *well separated* with respect to a separation parameter $s > 0$ if there exist a real number $r > 0$ and two d-dimensional spheres C_A and C_B of radius r each, such that the following properties are fulfilled:

1. $C_A \cap C_B = \emptyset$
2. C_A contains the bounding box $R(A)$ of A
3. C_B contains the bounding box $R(B)$ of B
4. $|C_A C_B| \geq s \cdot r$.

Here $|C_A C_B|$ denotes the smallest Euclidean distance between two points of C_A and C_B, respectively. An example is depicted in Fig. 1. Given the bounding boxes $R(A)$, $R(B)$, it takes time only $O(d)$ to test if A and B are well separated with respect to s.

Two points of the same set, A or B, have a Euclidean distance at most $2/s$ times the distance any pair $(a, b) \in A \times B$ can have. Also, any two such pairs $(a, b), (a', b')$ differ in their distances $|a - b|, |a' - b'|$ by a factor of at most $1 + 4/s$.

Given a set S of n points in $\mathbb{R}^d$, a *well-separated pair decomposition* of S with respect to separation parameter s is a sequence $(A_1, B_1), (A_2, B_2), \ldots, (A_m, B_m)$ where

1. $A_i, B_i \subset S$, for $i = 1 \ldots m$.
2. A_i and B_i are well separated with respect to s, for $i = 1 \ldots m$.
3. For all points $a, b \in S, a \neq b$, there exists a unique index i in $1 \ldots m$ such that $a \in A_i$ and $b \in B_i$, or $b \in A_i$ and $a \in B_i$ hold.

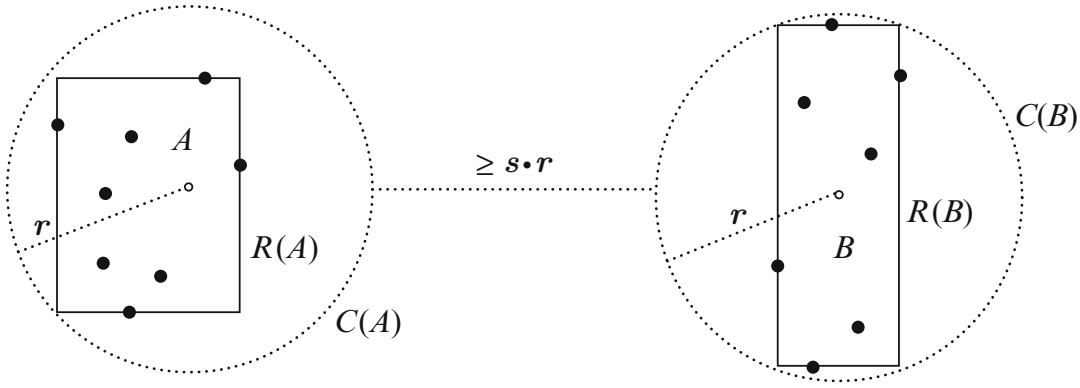
Obviously, each set $S = \{s_1, \ldots, s_n\}$ possesses a well-separated pair decomposition. One can simply use all singleton pairs $(\{s_i\},\{s_j\})$ where $i < j$. The question is if decompositions consisting of fewer than $O(n^2)$, many pairs exist and how to construct them efficiently.

Key Results

In fact, the following result has been shown by Callahan and Kosaraju [1, 2].

Theorem 1 *Given a set S of n points in $\mathbb{R}^d$ and a separation parameter s, there exists a well-separated pair decomposition of S with respect to s that consists of $O(s^d d^{d/2} n)$ many pairs (A_i, B_i). It can be constructed in time $O(dn \log n + s^d d^{d/2+1} n)$.*

Thus, if dimension d and separation parameter s are fixed – which is the case in many applications – then the number of pairs is in



Well Separated Pair Decomposition for Unit-Disk Graph, Fig. 1 The sets A, B are well-separated with respect to s

$O(n)$, and the decomposition can be computed in time $O(n \log n)$.

The main tool in constructing the well-separated pair decomposition is the split tree $T(S)$ of S. The root, r, of $T(S)$ contains the bounding box $R(S)$ of S. Its two child nodes are obtained by cutting through the middle of the longest dimension of $R(S)$, using an orthogonal hyperplane. It splits S into two subsets S_a, S_b, whose bounding boxes $R(S_a)$ and $R(S_b)$ are stored at the two children a and b of root r. This process continues until only one point of S remains in each subset. These singleton sets form the leaves of $T(S)$. Clearly, the split tree $T(S)$ contains $O(n)$ many nodes. It needs not be balanced, but it can be constructed in time $O(dn \log n)$.

A well-separated pair decomposition of S, with respect to a given separation parameter s, can now be obtained from $T(S)$ in the following way. For each internal node of $T(S)$ with children v and w, the following recursive procedure FindPairs(v, w) is called. If S_v and S_w are well separated, then the pair (S_v, S_w) is reported. Otherwise, one may assume that the longest dimension of $R(S_v)$ exceeds in length the longest dimension of $R(S_w)$ and that v_l, v_r are the child nodes of v in $T(S)$. Then, FindPairs(v_l, w) and FindPairs(v_r, w) are invoked.

The total number of procedure calls is bounded by the number of well-separated pairs reported, which can be shown to be in $O(s^d d^{d/2} n)$ by a packing argument. However, the total size of all sets A_i, B_i in the decomposition is in general quadratic in n.

Applications

From now on the dimension d is assumed to be a constant. The well-separated pair decomposition can be used in efficiently solving proximity problems for points in $\mathbb{R}^d$.

Theorem 2 *Let S be a set of n points in $\mathbb{R}^d$. Then a closest pair in S can be found in optimal time $O(n \log n)$.*

Indeed, let $q \in S$ be a nearest neighbor of $p \in S$. One can construct a well-separated pair decomposition with separation parameter $s > 2$ in time $O(n \log n)$, and let (A_i, B_i) be the pair where $p \in A_i$ and $q \in B_i$. If there were another point p' of S in A_i, one would obtain $|pp'| \leq 2/s \cdot |pq| < |pq|$, which is impossible. Hence, A_i is a singleton set. If (p, q) is a closest pair in S, then B_i must be singleton, too. Therefore, a closest pair can be found by inspecting all singleton pairs among the $O(n)$ many pairs of the well-separated pair decomposition.

With more effort, the following generalization can be shown.

Theorem 3 *Let S be a set of n points in $\mathbb{R}^d$, and let $k \leq n$. Then for each $p \in S$, its k nearest neighbors in S can be computed in total time $O(n \log n + nk)$. In particular, for each point in S can a nearest neighbor in S be computed in optimal time $O(n \log n)$.*

In dimension $d = 2$, one would typically use the Voronoi diagram for solving these problems. But as the complexity of the Voronoi diagram of n points can be as large as $n^{\lfloor d/2 \rfloor}$, the well-separated pair decomposition is much more convenient to use in higher dimensions.

A major application of the well-separated pair decomposition is the construction of good spanners for a given point set S. A spanner of S of dilation t is a geometric network N with vertex set S such that for any two vertices $p, q \in S$, the Euclidean length of a shortest path connecting p and q in N is at most t times the Euclidean distance $|pq|$.

Theorem 4 *Let S be a set of n points in $\mathbb{R}^d$, and let $t > 1$. Then a spanner of S of dilation t containing $O(s^d n)$ edges can be constructed in time $O(s^d n + n \log n)$, where $s = 4(t+1)(t-1)$.*

Indeed, if one edge (a_i, b_i) is chosen from each pair (A_i, B_i) of a well-separated pair decomposition of S with respect to s, these edges form a t-spanner of S, as can be shown by induction on the rank of each pair $(p, q) \in S^2$ in the list of all such pairs, sorted by distance.

Since spanners have many interesting applications of their own, several articles of this encyclopedia are devoted to this topic.

Open Problems

An important open question is which metric spaces admit well-separated pair decompositions. It is easy to see that the packing arguments used in the Euclidean case carry over to the case of convex distance functions in $\mathbb{R}^d$. More generally, Talwar [6] has shown how to compute well-separated pair decompositions for point sets of bounded aspect ratio in metric spaces of bounded doubling dimension.

On the other hand, for the metric induced by a disk graph in $\mathbb{R}^2$, a quadratic number of pairs may be necessary in the well-separated pair decomposition. (In a disk graph, each point $p \in S$ is center of a disk D_p of radius r_p. Two points p, q are connected by an edge if and only if $D_p \cap D_q \neq \emptyset$. The metric is defined by Euclidean shortest path length in the resulting graph. If this graph is a star with rays of identical length, a well-separated pair decomposition with respect to $s > 4$ must consist of singleton pairs.) Even for a unit disk graph, $\Omega(n^{2-2/d})$ many pairs may be necessary for points in $\mathbb{R}^d$, as Gao and Zhang [4] have shown.

1999; Chu, Wong

Problem Definition

The problem is about minimizing the delay of an interconnect wire in a very-large-scale integration (VLSI) circuit by changing the width (i.e., sizing) of the wire. The delay of interconnect wire has become a dominant factor in determining VLSI circuit performance for advanced VLSI technology. Wire sizing has been shown to be an effective technique to minimize the interconnect delay. The work of Chu and Wong [1] shows that the wire sizing problem can be transformed into a convex quadratic program. This quadratic programming approach is very efficient and can be naturally extended to simultaneously consider buffer insertion, which is another popular interconnect delay minimization technique. Previous approaches apply either a dynamic programming approach [2], which is computationally more ex-

pensive, or an iterative greedy approach [3, 4], which is hard to combine with buffer insertion.

The wire sizing problem is formulated as follows and is illustrated in Fig. 1. Consider a wire of length L. The wire is connecting a driver with driver resistance R_D to a load with load capacitance C_L. In addition, there is a set $H = \{h_1, \ldots, h_n\}$ of n wire widths allowed by the fabrication technology. Assume $h_1 > \cdots > h_n$. The wire sizing problem is to determine the wire width function $f(x) : [0, L] \to H$ so that the delay for a signal to travel from the driver through the wire to the load is minimized.

As in most previous works on wire sizing, the work of Chu and Wong uses the Elmore delay model to compute the delay. The Elmore delay model is a delay model for RC circuits (i.e., circuits consisting of resistors and capacitors). The Elmore delay for a signal path is equal to the sum of the delays associated with all resistors along the path, where the delay associated with each resistor is equal to its resistance times its total downstream capacitance. For a wire segment of length l and width h, its resistance is $r_0 l/h$ and its capacitance is $c(h)l$, where r_0 is the wire sheet resistance and $c(h)$ is the unit length wire capacitance. $c(h)$ is an increasing function in practice. The wire segment can be modeled as a π-type RC circuit as shown in Fig. 2.

Key Results

Lemma 1 *The optimal wire width function $f(x)$ is a monotonically decreasing function.*

Lemma 1 above can be used to greatly simplify the wire sizing problem. It implies that an optimally sized wire can be divided into n segments such that the width of i-th segment is h_i. The length of each segment is to be determined. The simplified problem is illustrated in Fig. 3.

Lemma 2 *For the wire in Fig. 3, the Elmore delay is*

$$D = \frac{1}{2}\boldsymbol{l}^T \boldsymbol{\Phi} \boldsymbol{l} + \boldsymbol{\rho}^T \boldsymbol{l} + R_D C_L$$

where

$$\boldsymbol{\Phi} = \begin{pmatrix} c(h_1)r_0/h_1 & c(h_2)r_0/h_1 & c(h_3)r_0/h_1 & \cdots & c(h_n)r_0/h_1 \\ c(h_2)r_0/h_1 & c(h_2)r_0/h_2 & c(h_3)r_0/h_2 & \cdots & c(h_n)r_0/h_2 \\ c(h_3)r_0/h_1 & c(h_3)r_0/h_2 & c(h_3)r_0/h_3 & \cdots & c(h_n)r_0/h_3 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ c(h_n)r_0/h_1 & c(h_n)r_0/h_2 & c(h_n)r_0/h_3 & \cdots & c(h_n)r_0/h_n \end{pmatrix},$$

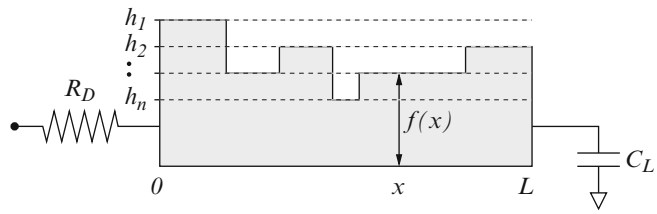
$$\boldsymbol{\rho} = \begin{pmatrix} R_D c(h_1) + C_L r_0/h_1 \\ R_D c(h_2) + C_L r_0/h_2 \\ R_D c(h_3) + C_L r_0/h_3 \\ \vdots \\ R_D c(h_n) + C_L r_0/h_n \end{pmatrix} \text{ and } \boldsymbol{l} = \begin{pmatrix} l_1 \\ l_2 \\ l_3 \\ \vdots \\ l_n \end{pmatrix}.$$

So the wire sizing problem can be written in the following quadratic program:

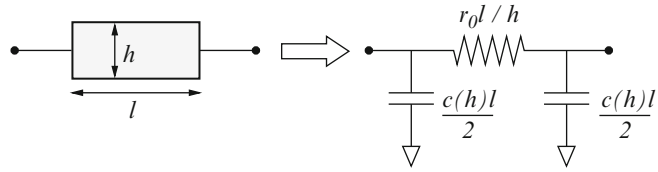
$$\begin{aligned} \mathcal{WS}: \text{minimize } & \tfrac{1}{2}\boldsymbol{l}^T \boldsymbol{\Phi} \boldsymbol{l} + \boldsymbol{\rho}^T \boldsymbol{l} \\ \text{subject to } & l_1 + \cdots + l_n = L \\ & l_i \geq 0 \text{ for } 1 \leq i \leq n \end{aligned}$$

Quadratic programming is NP-hard in general. In order to solve $\mathcal{WS}$ efficiently, some properties of the Hessian matrix $\boldsymbol{\Phi}$ are explored.

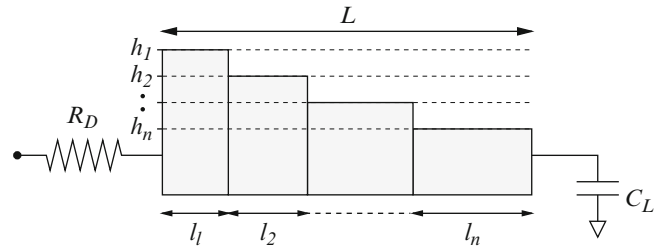
Definition 1 (Symmetric Decomposable Matrix) Let $\boldsymbol{Q} = (q_{ij})$ be an $n \times n$ symmetric matrix. If for some $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_n)^T$ and



Wire Sizing, Fig. 1 The wire sizing problem



Wire Sizing, Fig. 2 The model of a wire segment by a π-type RC circuit



Wire Sizing, Fig. 3 The simplified wire sizing problem

$\boldsymbol{v} = (v_1, \ldots, v_n)^T$ such that $0 < \alpha_1 < \cdots < \alpha_n$, $q_{ij} = q_{ji} = \alpha_i v_i v_j$ for $i \leq j$, then $\boldsymbol{Q}$ is called a symmetric decomposable matrix. Let $\boldsymbol{Q}$ be denoted as $SDM(\boldsymbol{\alpha}, \boldsymbol{v})$.

Lemma 3 *If $\boldsymbol{Q}$ is symmetric decomposable, then $\boldsymbol{Q}$ is positive definite.*

Lemma 4 *$\boldsymbol{\Phi}$ in $\mathcal{WS}$ is symmetric decomposable.*

Lemma 3 together with Lemma 4 implies that the Hessian matrix $\boldsymbol{\Phi}$ of $\mathcal{WS}$ is positive definite. Hence, the problem $\mathcal{WS}$ is a *convex* quadratic program and is solvable in polynomial time [5].

The work of Chu and Wong proposes to solve $\mathcal{WS}$ by active set method. The active set method transforms a problem with some inequality constraints into a sequence of problems with only equality constraints. The method stops when the solution of the transformed problem satisfies both the feasibility and optimality conditions of the original problem. For the problem $\mathcal{WS}$, the active set method keeps track of an active set $\mathcal{A}$ in each iteration. The method sets $l_j = 0$ for all $j \in \mathcal{A}$ and ignores the constraints $l_j \geq 0$ for all $j \notin \mathcal{A}$. Let $\{j_1, \ldots, j_r\} = \{1, \ldots, n\} - \mathcal{A}$. Then $\mathcal{WS}$ is transformed into the following equality-constrained wire sizing problem:

$$\mathcal{ECWS}: \text{minimize } \tfrac{1}{2}\boldsymbol{l}_{\mathcal{A}}^T \boldsymbol{\Phi}_{\mathcal{A}} \boldsymbol{l}_{\mathcal{A}} + \boldsymbol{\rho}_{\mathcal{A}}^T \boldsymbol{l}_{\mathcal{A}} \quad \text{subject to } \boldsymbol{\Gamma}_{\mathcal{A}} \boldsymbol{l}_{\mathcal{A}} = L$$

where $\boldsymbol{l}_{\mathcal{A}} = (l_{j_1}, \ldots, l_{j_r})^T$, $\boldsymbol{\Gamma}_{\mathcal{A}} = (1\ 1\ \cdots\ 1)$, $\boldsymbol{\rho}_{\mathcal{A}} = (R_D c(h_{j_1}) + C_L r_0 / h_{j_1}, \ldots, R_D c(h_{j_r}) + C_L r_0 / h_{j_r})^T$, and $\boldsymbol{\Phi}_{\mathcal{A}}$ is the symmetric decomposable matrix corresponding to $\mathcal{A}$ (i.e., $\boldsymbol{\Phi}_{\mathcal{A}} = SDM(\boldsymbol{\alpha}_{\mathcal{A}}, \boldsymbol{v}_{\mathcal{A}})$ with $\boldsymbol{\alpha}_{\mathcal{A}} = \left(\frac{r_0}{c(h_{j_1}) h_{j_1}}, \ldots, \frac{r_0}{c(h_{j_r}) h_{j_r}} \right)^T$ and $\boldsymbol{v}_{\mathcal{A}} = (c(h_{j_1}), \ldots, c(h_{j_r}))^T$).

Lemma 5 *The solution of $\mathcal{ECWS}$ is*

$$\lambda_{\mathcal{A}} = -(\boldsymbol{\Gamma}_{\mathcal{A}} \boldsymbol{\Phi}_{\mathcal{A}}^{-1} \boldsymbol{\Gamma}_{\mathcal{A}}^T)^{-1} (\boldsymbol{\Gamma}_{\mathcal{A}} \boldsymbol{\Phi}_{\mathcal{A}}^{-1} \boldsymbol{\rho}_{\mathcal{A}} + L)$$
$$\boldsymbol{l}_{\mathcal{A}} = -\boldsymbol{\Phi}_{\mathcal{A}}^{-1} \boldsymbol{\Gamma}_{\mathcal{A}}^T \lambda_{\mathcal{A}} - \boldsymbol{\Phi}_{\mathcal{A}}^{-1} \boldsymbol{\rho}_{\mathcal{A}}$$

Lemma 6 *If $\boldsymbol{Q}$ is symmetric decomposable, then $\boldsymbol{Q}^{-1}$ is tridiagonal. In particular, if $\boldsymbol{Q} = SDM(\boldsymbol{\alpha}, \boldsymbol{v})$, then $\boldsymbol{Q}^{-1} = (\theta_{ij})$*

$$\textit{where} \quad \theta_{ii} = \frac{1}{(\alpha_i - \alpha_{i-1})v_i^2} + \frac{1}{(\alpha_{i+1} - \alpha_i)v_i^2},$$
$$\theta_{i,i+1} = \theta_{i+1,i} = \frac{-1}{(\alpha_{i+1} - \alpha_i)v_i v_{i+1}} \textit{ for } 1 \le i \le n-1, \; \theta_{nn} = \frac{1}{(\alpha_n - \alpha_{n-1})v_n^2}, \textit{ and } \theta_{ij} = 0 \textit{ otherwise.}$$

By Lemmas 5 and 6, $\mathcal{ECWS}$ can be solved in $O(n)$ time. To solve $\mathcal{WS}$, in practice, the active set method takes less than n iterations and hence the total runtime is $O(n^2)$. Note that unlike previous works, the runtime of this convex quadratic programming approach is independent of the wire length L.

Applications

The wire sizing technique is commonly applied to minimize the wire delay and hence to improve the performance of VLSI circuits. As there are typically millions of wires in modern VLSI circuits, and each wire may be sized many times in order to explore different architecture, logic design, and layout during the design process, it is very important for wire sizing algorithms to be very efficient.

Another popular technique for delay minimization of slow signals is to insert buffers (also called repeaters) to strengthen and accelerate the signals. The work of Chu and Wong can be naturally extended to simultaneously handle buffer insertion. It is shown in [1] that the delay minimization problem for a wire by simultaneous buffer insertion and wire sizing can also be formulated as a convex quadratic program and be solved by active set method. The runtime is only m times more than that of wire sizing, where m is the number of buffers inserted. m is typically 5 or less in practice.

About one third of all nets in a typical VLSI circuit are multi-pin nets (i.e., nets with a tree structure to deliver a signal from a source to several sinks). It is important to minimize the delay of multi-pin nets. The work of Chu and Wong can also be applied to optimize multi-pin nets. The extension is described in Mo and Chu [6]. The idea is to integrate the quadratic programming approach into a dynamic programming framework. Each branch of the net is solved as a convex quadratic program, while the overall tree structure is handled by dynamic programming.

Open Problems

After two decades of active research, the wire sizing problem by itself is now considered a well-solved problem. Some important solutions are [1–4, 6–15]. The major remaining challenge is to simultaneously apply wire sizing with other interconnect optimization techniques to improve circuit performance. Wire sizing, buffer insertion, and gate sizing are three most commonly used interconnect optimization techniques. It has been demonstrated that better performance can be achieved by applying these three techniques simultaneously rather sequentially. One very practical problem is to perform simultaneous wire sizing, buffer insertion, and gate sizing to a combinational circuit such that the total resource usage (e.g., wire/buffer/gate area, power consumption) is minimized while the delay of all input-to-output paths are less than a given target.

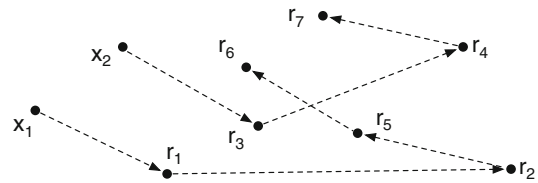
Problem Definition

In the *k-Server Problem*, the task is to schedule the movement of k-servers in a metric space $\mathbb{M}$ in response to a sequence $\varrho = r_1, r_2, \ldots, r_n$ of *requests*, where $r_i \in \mathbb{M}$ for all i. The servers initially occupy some configuration $X_0 \subseteq \mathbb{M}$. After each request r_i is issued, one of the k-servers must move to r_i. A *schedule* S specifies which server moves to each request. The task is to compute a schedule with minimum *cost*, where the cost of a schedule is defined as the total distance traveled by the servers. The example below shows a schedule for 2 servers on a sequence of requests (Fig. 1).

In the offline case, if the complete request sequence ϱ is known, the optimal schedule can be computed in polynomial time [9].

Most of the research on the k-Server Problem focussed on the *online* variant, where the requests are issued one at a time. After the ith request r_i is issued, an online algorithm must decide, irrevocably, which server to move to r_i before the next request r_{i+1} is issued. It is quite easy to see that in this Online scenario it is not possible to guarantee an optimal schedule for all request sequences. The accuracy of solutions produced by



Work-Function Algorithm for *k*-Servers, Fig. 1 A schedule for 2 servers on a request sequence $\varrho = r_1, r_2, \ldots, r_7$. The initial configuration is $X_0 = \{x_1, x_2\}$. Server 1 serves r_1, r_2, r_5, r_6, while server 2 serves r_3, r_4, r_7. The cost of this schedule is $d(x_1, r_1) + d(r_1, r_2) + d(r_2, r_5) + d(r_5, r_6) + d(x_2, r_3) + d(r_3, r_4) + d(r_4, r_7)$, where $d(x, y)$ denotes the distance between points x, y

such online algorithms is often evaluated within the framework of competitive analysis. Denote by $cost_{\mathcal{A}}(\varrho)$ the cost of the schedule produced by an online k-server algorithm $\mathcal{A}$ on a request sequence ϱ, and let $opt(\varrho)$ be the cost of an optimal schedule on ϱ. $\mathcal{A}$ is called *R-competitive* if $cost_{\mathcal{A}}(\varrho) \leq R \cdot opt(\varrho) + B$, where B is a constant that may depend on $\mathbb{M}$ and X_0. The smallest such R is called the *competitive ratio* of $\mathcal{A}$. Of course, the smaller the ratio R the better.

The k-Server Problem was introduced by Manasse, McGeoch, and Sleator [14, 15], who proved that no (deterministic) online algorithm can achieve a competitive ratio smaller than k, in any metric space with at least $k+1$ points. They also gave a 2-competitive algorithm for $k = 2$ and stated what is now known as the *k-Server Conjecture*, which postulates that there exists a k-competitive online algorithm for all k. Koutsoupias and Papadimitriou [11, 12] (see also [3, 8, 10]) proved that the *Work-Function Algorithm*, presented in the next section, has competitive ratio at most $2k-1$, which to date remains the best upper bound on the competitive ratio.

Key Results

The idea of the Work-Function Algorithm is to balance two greedy strategies when a new request is issued. The first one is to simply serve the request with the closest server. The second strategy attempts to follow the optimum schedule. Roughly, from among the k possible new configurations, this strategy chooses the one where the optimum schedule would be at this time, if no more requests remained to be issued.

To formalize this idea, for each request sequence ϱ and a k-server configuration X, let $\omega_\varrho(X)$ be the minimum cost of serving ϱ under the constraint that at the end the server configuration is X. (Assume, for simplicity, that the initial configuration X_0 is fixed.) The function $\omega_\varrho(\cdot)$ is called the *work function* after the request sequence ϱ.

Algorithm WFA. Denote by σ the sequence of past requests, and suppose that the current server configuration is $S = \{s_1, s_2, \ldots, s_k\}$, where s_j is the location of the j-th server. Let r be the new request. Choose $s_j \in S$ that minimizes the quantity $\omega_{\sigma r}(S - \{s_j\} \cup \{r\}) + d(s_j, r)$, and move server j to r.

Theorem 1 ([11, 12]) *Algorithm* WFA *is* $(2k-1)$*-competitive.*

As observed in [6], Algorithm WFA can be interpreted as a primal-dual algorithm.

Applications

The k-Server Problem can be viewed as an abstraction of online problems that arise in emergency crew scheduling, caching (or paging) in two-level memory systems, scheduling of disk heads, and other. Nevertheless, in its pure abstract form, it is mostly of theoretical interest.

Algorithm WFA can be applied to some generalizations of the k-Server Problem. In particular, it is $(2n-1)$-competitive for n-state metrical task systems, matching the lower bound [3, 4, 8]. See [1, 3, 5] for other applications and extensions.

Open Problems

Theorem 1 comes tantalizingly close to settling the k-Server Conjecture described earlier in this section. In fact, it has been even conjectured that Algorithm WFA itself is k-competitive for k-servers, but the proof of this conjecture, so far, remains elusive.

For $k \geq 3$, k-competitive online k-server algorithms are known only for some restricted metric spaces, including trees, metric spaces with up to $k+2$ points, and the Manhattan plane for $k = 3$ (see [2, 7, 9, 13]). As the analysis of Algorithm WFA in the general case appears difficult, it would be of interest to prove its k-competitiveness for some natural special cases, for example in the plane (with any reasonable metric) for $k \geq 4$ servers.

Very little is known about the competitive ratio of the k-Server Problem in the randomized case. In fact, it is not even known whether a ratio better than 2 can be achieved for $k = 2$.
