Problem Definition

Given a directed, planar graph $G = (V, E)$ with arc capacities $c : E \to \Re^+$, a subset S of source vertices, and a subset T of sink vertices, the goal is to find a maximum flow from the source vertices to the sink vertices:

$$\max \sum_{su : s \in S, su \in E} f_{su}$$

$$\text{s.t.} \sum_{uv : uv \in E} f_{uv} - \sum_{vw : vw \in E} f_{vw} = 0 \qquad \forall v \in V \setminus (S \cup T) \tag{1}$$

$$0 \le f_e \le c_e \qquad \forall e \in E \tag{2}$$

Key Results

In general (i.e., nonplanar) graphs, multiple sources and sinks can be reduced to the single-source, single-sink case by introducing an artificial source and sink and connecting them to all the sources and sinks, respectively, but this reduction does not preserve planarity. Using Orlin's algorithm for sparse graphs [21] leads to a running time of $O(n^2/\log n)$. For integer capacities less than U, one could instead use the algorithm of Goldberg and Rao [9], which leads to a running time of $O(n^{1.5} \log n \log U)$.

Maximum flow in planar graphs with multiple sources and sinks was first studied by Miller and Naor [19]. They gave a divide-and-conquer algorithm for the case where all the sinks and the sources are on the boundary of a single face. Plugging in the linear-time shortest-path algorithm of Henzinger et al. [12] yields a running time of $O(n \log n)$. Borradaile and Harutyunyan

have given an iterative algorithm with the same running time [2]. Miller and Naor also gave an algorithm for the case where the sources and the sinks reside on the boundaries of k different faces. Using the $O(n \log n)$ time single-source, single-sink maximum flow algorithm of Borradaile and Klein [3] yields a running time of $O(k^2 n \log^2 n)$. Miller and Naor show that, when it is known how much of the commodity is produced/consumed at each source and each sink, finding a consistent routing of flow that respects arc capacities can be reduced to negative-length shortest paths [19], which can be solved in planar graphs in $O(n \log^2 n / \log \log n)$ time [20].

Near-Linear Time Algorithm

Borradaile et al. gave the first $O(n \text{poly} \log n)$ time algorithm for the multiple-source, multiple-sink maximum flow problem in directed planar graphs. The approach uses pseudoflows [10, 14] (flows which may violate the balance constraints (1) in a limited way) and a divide-and-conquer scheme influenced by that of Johnson and Venkatesan [15] and that of Miller and Naor [19], using the separators introduced by Miller: a (triangulated) planar graph G can be separated by a simple cycle C of $O(\sqrt{n})$ vertices [18].

In each of the two subgraphs, a more general problem is solved in which, after the two recursive calls have been executed, within each of the two subgraphs, there is no residual path from any source to any sink nor from any source to C or from C to any sink. Then, since C is a separator, there is no residual path from any source to any sink in G, but, however, the balance constraints (1) may not be satisfied for vertices in C. The flow is then balanced among the vertices in C by augmenting the flow so that there is no residual path in G from a vertex with positive inflow to a vertex with positive outflow. The resulting flow can then be turned into a maximum flow in linear time.

The core of the algorithm is this final balancing procedure which involves a series of $|C| - 1$ max-flow computations in G. Since $|C|$ is $O(\sqrt{n})$, the challenge is carrying out all these max-flow computations in near-linear time. The procedure uses a succinct representation to keep track of the changes to the pseudoflow without explicitly storing the changes. The representation relies on the relationship between circulations in G and shortest paths in the dual, and the computations make use of an adaptation of Fakcharoenphol and Rao's efficient implementation of Dijkstra's algorithm [7]. The resulting running time to balance the flow is $O(n \log^2 n)$ time for an overall running time of $O(n \log^3 n)$ time for the original multiple-source, multiple-sink maximum flow problem.

Applications

Multiple-source, multiple-sink min-cut arises in several computer vision problems including image segmentation (or binary labeling) [11]. For the case of more than two labels, there is a powerful and effective heuristic [5] using a very large-neighborhood [1] local search; the inner loop consists of solving the two-label case.

Maximum matching in a bipartite planar graph reduces to multiple-source, multiple-sink maximum flow. Multiple-source, multiple-sink maximum flow can also be used for finding *orthogonal drawings of planar graphs with a minimum number of bends* [6] and *uniformly monotone subdivisions of polygons* [23].

Problem Definition

Given a directed, planar graph $G = (V, E)$ with arc capacities $c : E \to \Re^+$, a source vertex s, and a sink vertex t, the goal is to find a flow assignment f_e for each arc $e \in E$ such that

$$\max \sum_{su : su \in E} f_{su}$$

$$\text{s.t.} \sum_{uv : uv \in E} f_{uv} - \sum_{vw : vw \in E} f_{vw} = 0 \qquad \forall v \in V \setminus \{s, t\} \tag{1}$$

$$0 \le f_e \le c_e \qquad \forall e \in E \tag{2}$$

Key Results

In the paper proposing the maximum flow problem in general graphs, Ford and Fulkerson [5] gave a generic method for computing a maximum flow: the augmenting-path algorithm. The algorithm is iterative: find a path P from the source to the sink such that capacity constraint (2) is loose for each arc on P (*residual*); increase the flow on each arc in P by a constant chosen so that at least one of the capacity constraints become tight; update the capacities of each arc, making note that the reverse of these arcs now have *residual capacity*; and repeat until there is no path from the source to the sink along which the flow can be augmented. By augmenting the flow along a path, the balance constraints (1) are always satisfied.

st-Planar Graphs

Ford and Fulkerson further showed that, in the case of planar graphs when the source and the sink are on a common face (st-planar graphs), by selecting the augmenting paths to be as far to the left as possible in each iteration (viewing s on the bottom and t on the top), each arc is saturated at most once, resulting in at most $|E|$ iterations [5]. In 1979, Itai and Shiloach showed that each iteration of this algorithm could be implemented in $O(\log n)$ time using a priority queue and gave a simple example showing that any implementation of this algorithm is capable of sorting n numbers [11]. In 1991, Hassin demonstrated that such a maximum st-flow could be derived from shortest-path distances in the planar dual G^* of G where capacities in G are interpreted as lengths in G^* [7]. Faster algorithms for computing shortest paths in planar graphs culminated in a linear-time algorithm for this case of maximum st-flow in planar graphs with s and t on a common face [9].

Undirected Planar Graphs

For undirected planar graphs, Reif gave an algorithm for computing the maximum st-flow where s and t need not be on a common face, by way of several shortest-path computations in the dual [19]. The algorithm finds a shortest path P in G^* from a vertex adjacent to the face corresponding to s to a vertex adjacent to the face corresponding to t. Reif proves that C only crosses P once; by finding the minimum separating cycle C_v through each vertex v of P, we will surely find C: C is the minimum of the cycles C_v. These cycles can be found in time $\log n$ times the time for one shortest-path computation via divide and conquer over the length of P. Hassin and Johnson show that the corresponding maximum flow can be computed within this framework by computing shortest-path distances between the nested cycles C_v [8]. The shortest-path algorithms of Henzinger et al. [9] or Klein [15] can be used to reimplement these algorithms in $O(n \log n)$ time. Italiano et al. [12] further improved this running time to $O(n \log \log n)$ by using an r-division to break the graph into sufficiently small pieces through which shortest paths can be efficiently computed.

If the capacities are all units, the maximum st-flow can be computed in linear time [1].

Directed Planar Graphs

Maximum st-flow in directed graphs is more general since the problem of maximum st-flow in an undirected graph can be converted to a directed problem by introducing two oppositely oriented arcs of equal capacity for each edge. Johnson and Venkatesan gave a divide-and-conquer algorithm that finds a flow of input value v in $O(n^{1.5} \log n)$ time [13]. The algorithm divides the graph using balanced separators, finding a flow in each side of value v. However, the flow on the $O(\sqrt{n})$-boundary edges of each subproblem might not be feasible. Each boundary edge is made feasible via an st-planar flow computation. Miller and Naor showed that finding a directed st-flow of value v could be reduced to computing shortest-path distances in a graph with positive and negatives lengths [17]. Here, v units of flow are routed (perhaps violating the capacity constraints) along any s-to-t path P. For those arcs whose capacity are violated, we must route the excess flow through the rest of the graph. This is a feasible circulation problem and can be solved using shortest-path distances in the dual graph, where lengths may be negative (representing the negative or violated capacities). Using an $O(n \text{ poly} \log n)$-time algorithm for computing shortest paths in a planar

graph with negative edge lengths [4, 16, 18] gives an $O(n \operatorname{poly} \log n \log C)$-time algorithm where C is the sum of the capacities.

If the capacities are all unit, the maximum st-flow can be computed in linear time [21].

Leftmost-Path Algorithm

Borradaile and Klein gave an augmenting-path, $O(n \log n)$-time algorithm for the maximum st-flow problem in directed planar graphs. The algorithm is a generalization of the algorithm for the st-planar case, augmenting flow repeatedly along the leftmost path from s to t. However, with s and t not on a common face, what leftmost is not clear. With the graph embedded such that t is on the external face and the clockwise cycles saturated, a leftmost path is well-defined and can be found with a left-first, depth-first search into t. Clockwise cycles can be initially saturated with a circulation defined by potentials on the faces given by shortest-path distances in the dual graph [14], and clockwise cycles remain saturated under leftmost augmentations. Borradaile and Klein, and Erickson improved the analysis [3] showed that under these conditions an arc and its reverse can be saturated at most once, resulting in at most $2n$ augmentations. Augmentations can be performed in $O(\log n)$ time using a dynamic tree data structure, resulting in an $O(n \log n)$ running time.

Applications

Maximum st-flow in directed planar graphs has applications to computer vision problems. Schmidt et al. [20] use it as a black box for image segmentation and Greig et al. [6] provide an example for smoothing noisy images.

Open Problems

Currently, maximum st-flow in undirected planar graphs can be computed more quickly than in directed. Can this gap be closed?

Experimental Results

Schmidt et al. [20] have implemented this algorithm and compared its performance on an image segmentation problem.

URLs to Code and Data Sets

Hoch and Wang have provided an open-source implementation of the algorithm [10]. Eisenstat has an implementation of the linear-time algorithm for unit-capacity graphs [2].

Problem Definition

Given a graph $G = (V, E)$, the *crossing number* $cr(G)$ of G is the smallest number of edge crossings possible for any drawing of G into the plane. Since its introduction in the mid-1940s, the crossing number problem has proved to be notoriously difficult. Even some of the oldest and seemingly simplest questions remain unanswered, despite the large amount of research.

Already the problem definition is more ambiguous than it may seem. We will usually only consider drawings where vertices are mapped to distinct points in the plane and edges to continuous non-self-intersecting curves between their end vertices. Any non-vertex point may only be contained in at most two edge curves, in which these curves have to meet transversally (i.e., *cross*). There are several different and specialized related crossing number variants; see [16] for a comprehensive annotated list.

A *planarization* of a nonplanar graph G is a planar graph obtained from G by drawing G into the plane and replacing the crossings by dummy vertices of degree 4. Observe that in other literature, the term *planarization* is also sometimes used to denote a (large) planar spanning subgraph of G.

Key Results

The (decision version of the) crossing number problem is NP-complete, even when all vertices have degree at most three [13] or when the removal of a single edge would give a planar graph [3]. There is, however, a fixed parameter tractable (FPT) algorithm to test in linear time

for a *constant* k (not part of the input), whether G allows a crossing number of at most k [15]. The dependency on k, however, is doubly exponential, and the algorithm is far from being applicable in practice. Most questions regarding the problem's approximability remain open; see below for details.

Planarization Algorithms

The practically strongest heuristic is the *planarization approach*, cf. Fig. 1: First, we seek a maximal planar subgraph (observe that finding a maximum planar subgraph is already NP-hard). In other words, we temporarily remove edges from G until it becomes planar. Then, we reinsert those edges with as few crossings as possible one after another. After each step, crossings are replaced by dummy vertices, such that we can consider a sequence of *edge insertion problems*: Given a planar graph H and an edge $e \notin E(H)$, let $H_e := H + e$. Since $cr(H_e)$ is still NP-hard to obtain, we ask for a crossing-minimum solution under the side-constraint that H is drawn planarly. An *embedding* is an equivalence class over planar drawings, based on the cyclic order of the edges around their incident vertices. For a fixed embedding of H, the insertion problem is trivially solvable via a breadth-first search in H's dual graph. However, the number of embeddings of H is exponential in general.

The seminal paper [12] shows that it is possible to find the best embedding *in linear time* using SPR-trees, or formally:

Theorem 1 *Let G be a planar graph and $v, w \in V(G)$ two vertices. We can find a planar embedding of G in $\mathcal{O}(|V(G)|)$ time, into which an edge $e = (v, w)$ can be inserted with the least possible number of edge crossings over all possible embeddings.*

To discuss this result, we first need to describe SPR-trees, which are used to decompose graphs into their triconnectivity structures. While their graph-theoretic foundation is based on Tutte [17], the data structure was first suggested by Di Battista and Tamassia [11] under the name *SPQR-tree*. Nowadays, we often drop the "Q" from the abbreviation, as the corresponding node type is not necessary, and use the following contemporary definition (see, e.g., [7]), illustrated in Fig. 2.

Definition 1 (SPR-tree) The *SPR-tree* $\mathcal{T}$ of a biconnected graph G is the unique smallest tree satisfying the following properties:

1. Each node ν in $\mathcal{T}$ holds a graph $S_\nu = (V_\nu, E_\nu)$, $V_\nu \subseteq V(G)$, called *skeleton*. Each edge of E_ν is either a *real* edge from $E(G)$ or a *virtual* edge $f = (u, v)$ where $\{u, v\}$ forms a 2-cut (a *split pair*) in G.
2. $\mathcal{T}$ has only three different node types with the following skeleton structures:
   - **S:** S_ν is a simple cycle – it represents a *serial* component.
   - **P:** S_ν consists of two vertices connected by multiple edges – a *parallel* component.
   - **R:** S_ν is a simple triconnected graph.
3. For every edge (ν, μ) in $\mathcal{T}$, S_ν (S_μ) contains a specific virtual edge e_μ (e_ν) which "represents" S_μ (S_ν, respectively). Both edges e_μ and e_ν connect the same vertices.
4. The original graph G can be obtained by recursively applying the following operation: For the edge (ν, μ) in $\mathcal{T}$, let e_μ, e_ν be the virtual edges as in (3) connecting the same vertices u, v. A merged graph $(S_\nu \cup S_\mu) - e_\mu - e_\nu$ is obtained by gluing the skeletons together at u, v and removing e_μ, e_ν.

There are several essential properties of any SPR-tree: First, it has linear size and can be constructed in linear time. Second, a simple triconnected graph – the skeleton of an R-node – allows only a unique embedding and its mirror; the embedding of an S-node skeleton is unique, and the possible embeddings of a P-node are precisely all cyclic permutations of its edges. Moreover, each embedding of G can be precisely described via the subembeddings of the skeletons.

In order to obtain Theorem 1, it is shown that we only need to consider the unique shortest path P in G's SPR-tree from any node whose skeleton contains v to any node whose skeleton contains w. We will specify an embedding for each skeleton S_μ of the nodes $\mu \in P$; the embedding of all other skeletons is irrelevant. Moreover, the

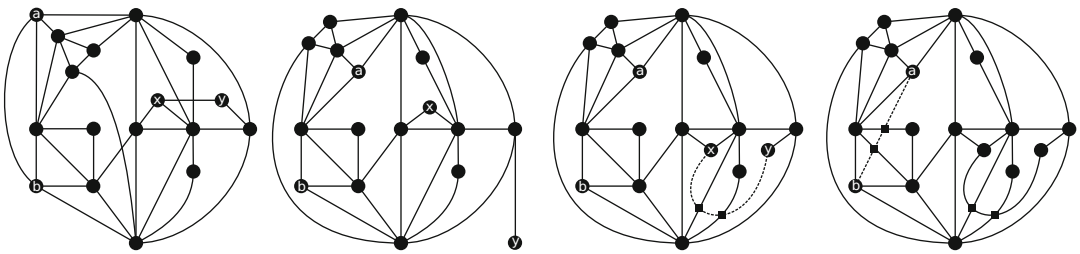
optimum embedding of each of the former skeletons can be chosen independent of the others: For each S_μ, we can specify a source s and a target t and ask for an embedding such that edge (s,t) can be inserted with the least possible number of edge crossings into planar S_μ: In the first (last) skeleton along P, the source (target) simply is v (w, respectively). In the other cases, the source (target) is the virtual edge corresponding to the predecessor (successor) along P. For simplicity, it may be helpful to consider a subdivision of such a virtual edge, such that each source and target can be represented by a vertex. If μ is an S-node, its skeleton has a unique embedding, (s,t) will require no crossings, and there is nothing to specify. If μ is a P-node, both the source and the target are virtual edges due to minimality of P; we pick any embedding where the two virtual edges appear consecutively, so that (s,t) again requires no crossings. Finally, if μ is an R-node, its skeleton allows only a unique embedding and its mirror and hence has a unique dual graph. We compute a shortest path between s and t via a simple breadth-first-search in the dual of S_μ as for the fixed embedding case.

Finally, traverse P and let μ, μ' be any two consecutive nodes. We want to establish that if the insertion path in S_μ enters its target virtual edge "from the left" (corresponding to some arbitrary predefined orientation of the virtual edges), it leaves the source virtual edge in $S_{\mu'}$ "to the right" or vice versa. If this is not already the case, it suffices to flip the embedding of $S_{\mu'}$ (we can ignore the case when μ' is an S-node). This establishes a suitable embedding of G.

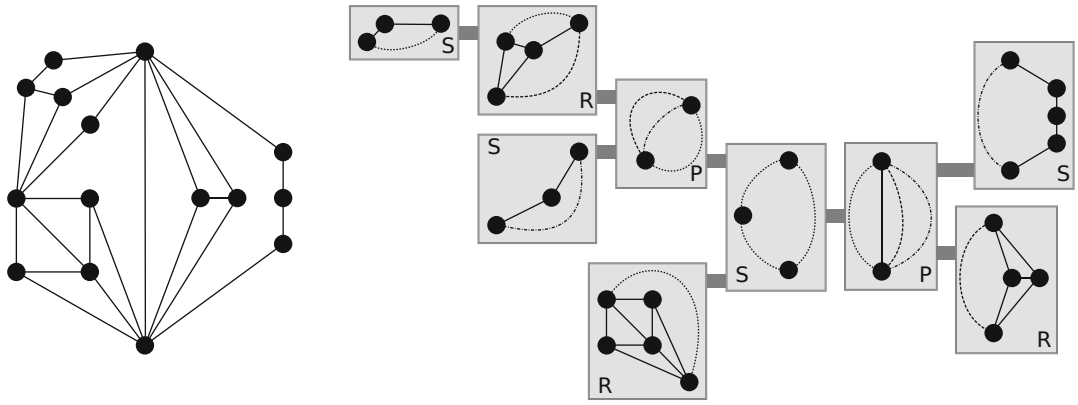
This algorithmic breakthrough has allowed the planarization heuristic to perform extraordinarily well in practice, both in terms of running time and of solution quality. The algorithm and its proofs also give rise to several strong pre- and postprocessing routines. Furthermore, it is pivotal to several later results such as insertion of stars [6] or insertion-based approximation algorithms [2, 7, 8]. The strongest of the latter considers the problem of inserting several edges F simultaneously into a planar graph G [7]: it can be shown that this multi-edge-insertion problem approximates $cr(G + F)$ [8], but is unfortunately itself already NP-hard. However, this insertion problem can in turn also be approximated. This approximation chain gives the currently only practically relevant approximation algorithm. In fact, it arguably gives the best running time vs. solution-quality trade-off among all known algorithms in practice [5].

Exact Approaches

In certain cases, a heuristic or approximate solution is not good enough, e.g., when the result is to be used as a base case in some formal graph-theoretic proof. There are exact approaches based on integer linear programs. The currently strongest one – constituting the second central paper of this entry – is able to solve typical "real-world graph drawing" instances (i.e., relatively



Planarisation and Crossing Minimisation, Fig. 1 The planarization heuristic: the first figure shows a graph drawn with the optimal number of three crossings. The planarization heuristic starts with a maximal (in the figure, in fact, maximum) planar subgraph (second figure) where the edges (x, y) and (a, b) are removed. Then, iteratively, we find optimal embeddings to reinsert these edges into the planarly drawn graph, simulating crossings by dummy vertices (shown as *squares*). Although the insertion problems are solved optimally, the result requires four crossings



Planarisation and Crossing Minimisation, Fig. 2 A graph (to the *left*) and its decomposition into triconnectivity structures, arranged within an SPR-tree. *Thick dashed* or *dotted edges* are virtual

sparse graphs with up to 80–100 vertices) to optimality in a couple of minutes [9]. The idea is to introduce binary indicator variables $x_{e,f}$ for each edge pair $e, f \in E$, which are 1 if and only if the two edges cross in the optimum solution. Minimizing the sum of these variables gives the desired objective function.

It remains to ensure that the variables are set correctly. To this end, we introduce *Kuratowski constraints*. The famous Kuratowski theorem states that planar graphs are characterized by the absence of subdivisions of certain small subgraphs (namely, K_5 and $K_{3,3}$). In other words, for each such subgraph K, we can require that at least one edge pair $e, f \in E(K)$ crosses. Unfortunately, there may be an exponential number of such subgraphs in G, and we also have to take care of Kuratowski subgraphs that only arise because certain other edge pairs cross (establishing a dummy vertex). Even when solving all these challenges, a further crucial problem remains: Consider a (presumably optimum) 0/1-assignment to the x-variables, satisfying all Kuratowski constraints. It is still NP-complete to decide whether this solution is at all feasible! Consider an edge e that is crossed by edges f and g. Our x-variables establish these crossings, but we do not know the order of f and g along e. Deciding whether any feasible order exists is what makes the problem still hard. There are two methods to solve the problem: We can subdivide each edge e sufficiently often and allow at most one crossing per edge segment. Alternatively we can introduce additional variables $y_{e,f,g}$ to explicitly describe a linear ordering of all edges crossing edge e, for all edges e. Of course, we have to modify the Kuratowski constraints accordingly.

While the second modeling approach is practically more efficient, we like to showcase the central ideas only with a simplified version of the first model here. Let U be any upper bound on the crossing number of G, e.g., found via the planarization heuristic described above. Clearly, any optimum solution will have at most U crossings on any edge. Therefore, let H be the graph obtained from G by subdividing each edge into U *edge segments*. Now, we solve the problem on H instead of G, where we can require that each segment is crossed at most once:

$$\min \sum_{e,f \in E(H), e \neq f} x_{\{e,f\}}, \text{ subject to} \quad (1)$$

$$\sum_{f \in E(H) \setminus \{e\}} x_{\{e,f\}} \leq 1 \qquad \forall e \in E(H) \quad (2)$$

$$x_{\{e,f\}} \in \{0,1\} \qquad \forall e, f \in E(H), e \neq f \quad (3)$$

This model minimizes the sum of the variables indicating a crossing between a pair of edge segments and allows at most one crossing per segment. It remains to discuss the Kuratowski

constraints to establish that only graph-theoretically feasible solutions are allowed. Let $\mathcal{X}_s$ denote the set of all binary solution vectors satisfying (2), and consider any solution vector $\bar{x} \in \mathcal{X}_s$. Furthermore, let $R(\bar{x})$ be the set of edge pairs $\{e, f\}$ for which $\bar{x}_{\{e,f\}} = 1$. Starting with H, we can *realize* $\bar{x}$ by, for each $\{e, f\} \in R(\bar{x})$, subdividing e and f and identifying the two new vertices. This vertex may be called a *dummy vertex*, representing the crossing. We obtain a final graph $H[\bar{x}]$ and let $\mathcal{K}(\bar{x})$ denote the set of all Kuratowski subdivisions in $H[\bar{x}]$. Intuitively, for any subdivision $K \in \mathcal{K}(\bar{x})$, we need to require at least one crossing on K, if the crossings $R(\bar{x})$ exist. Formally, this establishes the final constraint class:

$$\sum_{e,f \in K, e \neq f} x_{\{e,f\}} \geq 1 - \sum_{\{e,f\} \in R(\bar{x})} (1 - x_{\{e,f\}})$$
$$\forall \bar{x} \in \mathcal{X}_s, K \in \mathcal{K}(\bar{x}) \qquad (4)$$

Independent on whether we use the just described subdivision-based model or the stronger one based on linear orderings, the obtained ILP models are much too large to solve directly. We require both special separation and column-generation routines, in order to produce the actually necessary constraints and variables on the fly. The approaches' practical applicability is furthermore only possible due to the strong heuristics described above (which often give optimum upper bounds early on), heavy preprocessing [4], and efficient planarity testing routines.

Open Problems

The area of crossing numbers is filled with interesting open questions. Let us pinpoint two of them:

The original question, as stated in 1944 by Pál Turán, was for the crossing number of complete bipartite graphs. We still do not know the answer for this graph class, nor do we for complete graphs. While we have upper bounds, which are conjectured to be optimal, we are stuck with partial proofs and positive results for small graphs.

We know that crossing number is APX-hard [1], i.e., there cannot be a polynomial approximation scheme. However, even for graphs with bounded maximum degree, the best approximation ratios are only slightly sublinear in $|V|$ [10] or dependent on parameters like the graph's genus [14] or the number of edges required to remove in order to become planar [7]. Does there exist a constant factor approximation to the crossing number problem? At least for graphs with bounded degree?

Planar embedding; Planarity testing

Years and Authors of Summarized Original Work

1976; Booth, Lueker

Problem Definition

The problem is to determine whether or not the input graph G is planar. The definition pertinent to planarity-testing algorithms is: G is planar if there is an *embedding* of G into the plane (vertices of G are mapped to distinct points and edges of G are mapped to curves between their respective endpoints) such that edges do not cross. Algorithms that test the planarity of a graph can be modified to obtain such an embedding of the graph.

Key Results

Theorem 1 *There is an algorithm that given a graph G with n vertices, determines whether or not G is planar in O(n) time.*

The first linear-time algorithm was obtained by Hopcroft and Tarjan [5] by analyzing an iterative version of a recursive algorithm suggested by Auslander and Parter [1] and corrected by Goldstein [4]. The algorithm is based on the observation that a connected graph is planar if and only if all its biconnected components are planar. The recursive algorithm works with each biconnected component in turn: find a separating cycle C and partition the edges of G not in C; define a component of the partition as consisting of edges connected by a path in G that does not use an edge of C; and, recursively consider each cyclic component of the partition. If each component of the partition is planar and the components can be combined with C to give a planar graph, then G is planar.

Another method for determining planarity was suggested by Lempel, Even, and Cederbaum [6]. The algorithm starts with embedding a single vertex and the edges adjacent to this vertex. It then considers a vertex adjacent to one of these edges. For correctness, the vertices must be considered in a particular order. This algorithm was first implemented in $O(n)$ time by Booth and Lueker [2] using an efficient implementation of the PQ-trees data structure. Simpler implementations of this algorithm have been given by Boyer and Myrvold [3] and Shih and Hsu [8].

Tutte gave an algebraic method for giving a *straight-line embedding* of a graph that, if the input graph is 3-connected and planar, is guaranteed to generate a planar embedding. The key idea is to fix the vertices of one face of the graph to be the corners of a convex polygon and then embed every other vertex as the geometric average of its neighbors.

Applications

Planarity testing has applications to computer-aided circuit design and VLSI layout by determining whether a given network can be realized in the plane.

Problem Definition

Point location is a well-studied problem in computational geometry with many applications in geometric information systems and computer-aided design. In general terms, the problem is to find which element of a given object contains a given query point. More precisely, we are given a subdivision $\mathcal{S}$ of a metric space, usually the Euclidean plane. The goal is then to preprocess $\mathcal{S}$ so that for a query point p we can determine which region of the subdivision contains p. There are many variants of the problem, with different constraints on the subdivision. The most common

variant and the focus of this overview is planar point location, where $\mathcal{S}$ is a polygonal subdivision of the Euclidean plane. In fact, for several data structures, we assume that the input is a triangulation. (Note that a polygonal subdivision can be triangulated in linear time [1].) As for most query data structures, the efficiency of a point location structure is measured by its space requirement, the time needed to preprocess the input, and the query time. The efficiency of the algorithms and data structures described here will be expressed as a function of n, the number of vertices in the subdivision.

Key Results

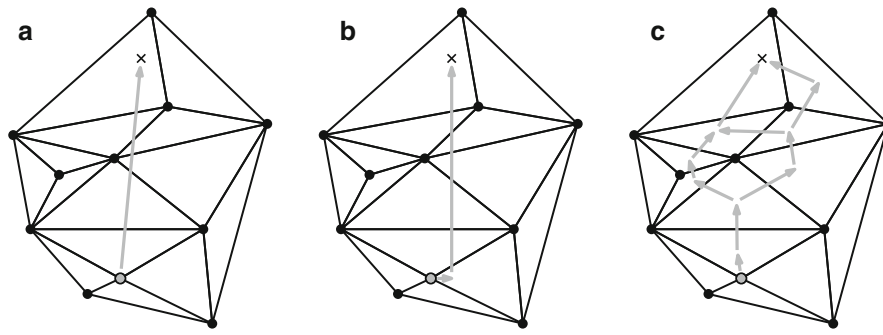
Most solutions for the point location problem build upon one (or a combination) of three basic ideas: walking in a triangulation, a trapezoidal decomposition, or a hierarchical triangulation. The three methods provide a basic trade-off between space usage and query time and are described in more detail below.

Walking in a Triangulation

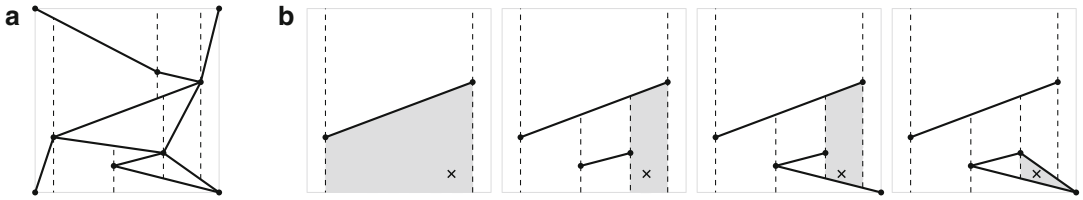
This approach is the simplest of the three and requires no additional storage or preprocessing if the input is provided in a suitable format in which it takes constant time to access the neighbors of a triangle. For each query, we start in some triangle or vertex of the triangulation and walk to the query point by traversing the triangulation, walking from the current triangle to a neighbor in each step. The triangle to visit next is determined by a walking strategy. Devillers et al. [3] describe three walking strategies that are described below and illustrated in Fig. 1.

- *Straight-line walk.* Starting at a vertex of the triangulation we walk along a straight line toward the query point.
- *Orthogonal walk.* Instead of walking along a straight line, we first walk parallel to the x-axis and then parallel to the y-axis.
- *Visibility walk.* For each triangle visited, we pick an edge of the triangle (at random or in some specific order) and test if its supporting line separates the query point from the triangle. If this is the case, then we continue our walk by crossing that edge into a new triangle.

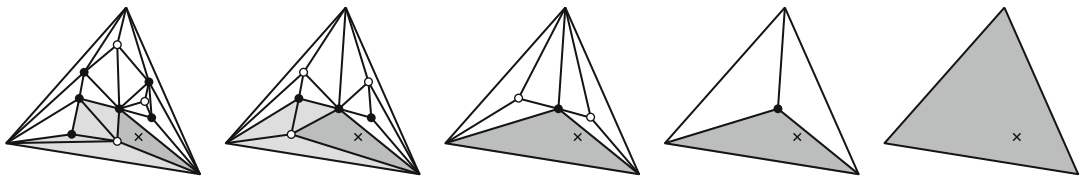
The worst-case behavior of each of the walking strategies is very bad as there are triangulations where each walk visits $\Omega(n)$ triangles in expectation given a random starting point and query point. In fact, the visibility walk is not guaranteed to reach the query point if edges are picked in a fixed order and the randomized version may require exponential time [3]. However, this seems to require many long and thin triangles, which do not occur in most practical applications, where the subdivision is often closer to a Delaunay triangulation. Experiments on Delaunay triangulations of random point sets suggest that the methods are comparable in total query time, though they provide a trade-off between the number of triangles visited and the time spent per triangle.



Point Location, Fig. 1 The paths traversed by (**a**) a straight-line walk, (**b**) an orthogonal walk, and (**c**) a visibility walk. Note that any path following the *arrows* is possible in the visibility walk



Point Location, Fig. 2 (**a**) Part of a trapezoidal decomposition with (**b**) a sequence of trapezoids visited by a query



Point Location, Fig. 3 The triangulations of the hierarchy from left to right. Triangles containing the query point are marked with *dark gray* and other triangles inspected with *light gray*

That is, the straight-line walk visits the fewest triangles, but needs most time to determine which triangle to visit next, whereas the visibility walk visits the most triangles, but spends the least time per triangle.

Trapezoidal Decomposition

The first data structure for point location to achieve $O(\log n)$ query time for point was provided by Dobkin and Lipton [6]. The structure is created by cutting the subdivision into slices using vertical lines through each of its vertices. Point location can then be done using two binary searches, first on the slices and then within a slice. This creates $O(n^2)$ trapezoids, but Sarnak and Tarjan [11] show we don't have to explicitly store all of them and instead only need $O(n)$ space and $O(n \log n)$ time to store them implicitly in a search structure.

A subdivision into trapezoids can also be created in a more careful way so that only $O(n)$ trapezoids are created. For a polygonal subdivision, its *trapezoidal decomposition* is defined as the result of shooting vertical rays upward and downward from each vertex of the subdivision until they hit an edge of the subdivision – if they do not hit such an edge, they extend to infinity (see also Fig. 2). A trapezoidal decomposition can be constructed by incrementally adding the edges of the subdivision [10]. Each insertion of an edge can interrupt some rays and introduces two new ones, namely, the rays from the endpoints of the edge. Seidel [12] showed that the history of this process can be recorded in a directed acyclic graph, which can be used for point location. Using randomized incremental construction, that is, adding the edges in random order, the longest path in the graph has an expected length of $O(\log n)$. Building the structure itself takes $O(n \log n)$ expected time and $O(n)$ expected space. For a guaranteed query time of $O(\log n)$, we can find the longest path and reconstruct if needed resulting in $O(n \log n)$ expected preprocessing time and $O(\log n)$ guaranteed query time [13].

Hierarchical Triangulation

Point location can also be done using a so-called hierarchical triangulation. We start with a triangulation of the subdivision and in each level of the hierarchy, we remove a subset of the points and compute a triangulation of the remainder. Each triangle of this new triangulation then stores a list of triangles from the previous triangulation that intersect it as illustrated in Fig. 3. This process is repeated until only one triangle remains. (Here, we assume that the outer face of the input triangulation is a triangle and these vertices are never removed.) To query for a point p, we traverse this hierarchy of triangles starting

at the top level consisting of only one triangle. At each level, we know the triangle T that contains p and find the triangle T' from the previous level that contains p by a linear search on the triangles that intersect T (see Fig. 3 from right to left).

The query time depends on the number of levels and the number of intersections each triangle has with the previous level. Kirkpatrick [9] showed that it is possible to find a constant size set of points, such that its removal creates triangles that each intersect a constant number of triangles from the previous level. He also shows that such a set of points can be found in $O(n)$ time. By picking and removing points from each level in this way, we create at most $O(\log n)$ levels and each triangle will intersect at most $O(1)$ triangles from the previous level. As a result, a point location query takes $O(\log n)$ time in total, while the structure requires $O(n)$ space.

Hybrid and Refined Approaches

The walking strategy requires no additional memory and is fast on small instances, but has very poor performance on larger instances, both in theory and in practice. To make the walking approach more feasible for larger inputs, several structures have been proposed that combine walking strategies with other methods to obtain fast query times with low overhead costs in terms of space and preprocessing time.

Delaunay Hierarchy. Hierarchical triangulations can be combined with walking algorithms to reduce the number of levels in the hierarchy. Finding the correct triangle in the next level of the hierarchy is done using a walking algorithm as opposed to a linear search. Devillers [2,3] showed that this results in a very fast query time without requiring a lot of preprocessing time or space.

Jump and Walk. In most walking strategies, the starting point is chosen at random. In the jump-and-walk approach, we use a set S of several starting points and start our walk from the one that is nearest to the query point. The set S can either be chosen at random for each new query [5] or picked more carefully and stored in a data structure for nearest-neighbor searches [4]. Depending on the size of S and the complexity of the search structure, query times between $O(\sqrt[3]{n})$ and $O(\log n)$ can be achieved.

Experimental Results

Several solutions have been implemented in CGAL, the Computational Geometry Algorithm Library. Haran and Halperin [7] compared several of the implementations from CGAL. Their results show that the various methods provide a trade-off between how much memory and preprocessing time is used and the resulting query time. Overall, they conclude that a jump-and-walk algorithm performs well, if the set of potential starting points is carefully chosen and stored in an efficient search structure. Recently, the CGAL variant of the trapezoidal decomposition approach has received a major overhaul [8]. Unlike some of the other variants, this implementation guarantees a $O(\log n)$ query time, while experiments show that the implementation is still competitive with other approaches.

Point Pattern Matching

Veli Mäkinen and Esko Ukkonen
Department of Computer Science, Helsinki Institute for Information Technology (HIIT), University of Helsinki, Helsinki, Finland

Keywords

Geometric alignment; Geometric matching; Largest common point set; Point set matching

Years and Authors of Summarized Original Work

2003; Ukkonen, Lemström, Mäkinen

Problem Definition

Let $\mathbb{R}$ denote the set of reals and $\mathbb{R}^d$ the d-dimensional real space. A finite subset of $\mathbb{R}^d$ is called a *point set*. The set of all point sets (subsets of $\mathbb{R}^d$) is denoted $\mathcal{P}(\mathbb{R}^d)$.

Point pattern matching problems ask for finding similarities between point sets under some transformations. In the basic set–up a *target* point set $T \subset \mathbb{R}^d$ and a *pattern* point set (*point pattern*) $P \subset \mathbb{R}^d$ are given, and the problem is to locate a subset I of T (if it exists) such that P *matches* I. Matching here means that P becomes exactly or approximately equal to I when a *transformation* from a given set $\mathcal{F}$ of transformations is applied on P.

Set $\mathcal{F}$ can be, for example, the set of all *translations* (a constant vector added to each point in P), or all compositions of translations and *rotations* (after a translation, each point is rotated with respect to a common origin; this preserves the distances and is also called a *rigid movement*), or all compositions of translations, rotations, and *scales* (after translating and rotating, distances to the common origin are multiplied by a constant).

The problem variant with exact matching, called the *Exact Point Pattern Matching (EPPM)* problem, requires that $f(P) = I$ for some $f \in \mathcal{F}$. In other words, the EPPM problem is to decide whether or not there is an allowed transformation f such that $f(P) \subset T$. For example, if $\mathcal{F}$ is the set of translations, the problem is simply to decide whether $P + t \subset T$ for some $t \in \mathbb{R}^d$.

Approximate matching is a better model of many situations that arise in practice. Then the quality of the matching between $f(P)$ and I is controlled using a *threshold parameter* $\varepsilon \geq 0$ and a *distance function* δ: $(\mathcal{P}(\mathbb{R}^d), \mathcal{P}(\mathbb{R}^d)) \rightarrow \mathbb{R}$ for measuring distances between point sets. Given $\varepsilon \geq 0$, the *Approximate Point Pattern Matching (APPM)* problem is to determine whether there is a subset $I \subset T$ and a transformation $f \in \mathcal{F}$ such that $\delta(f(P), I) \leq \varepsilon$.

The choice of the distance function δ is another source of diversity in the problem statement. A variant requires that there is a *one-to-one* mapping between $f(P)$ and I, and each point p of $f(P)$ is *ε-close* to its one-to-one counterpart p^* in I, that is, $|p - p^*| \leq \varepsilon$. A commonly studied relaxed version uses matching under a *many-to-one* mapping: it is only required that each point of $f(P)$ has *some* point of I that is *ε-close*; this distance is also known

as the *directed Hausdorff distance*. Still more variants come from the choice of the *norm* $|\cdot|$ to measure the distance between points.

Another form of approximation is obtained by allowing a minimum amount of unmatched points in P: The *Largest Common Point Set (LCP)* problem asks for the largest $I \subset T$ such that $I \subset f(P)$ for some $f \in \mathcal{F}$. In the *Largest Approximately Common Point Set (LACP)* problem each point $p^* \in I$ must occur *ε-close* to a point $p \in f(P)$.

Finally, a problem closely related to point pattern matching is to evaluate for point sets A and B their smallest distance $\min_{f\in\mathcal{F}} \delta(f(A), B)$ under transformations $\mathcal{F}$ or to test if this distance is $\leq \varepsilon$. This problem is called the *distance evaluation problem*.

Key Results

A folk theorem is a voting algorithm to solve EPPM under translations in $O(|P||T| \log(|T||P|))$ time: Collect all translations mapping each point of P to each point of T, sort the set, and report the translation getting most votes. If some translation gets $|P|$ votes, then a subset I such $f(P) = I$ is found. With some care in organizing the sorting, one can achieve $O(|P||T| \log |P|)$ time [13].

The voting algorithm also solves the LCP problem under translations. A faster algorithm specific to EPPM is as follows: Let $p_1, p_2, \cdots p_m$ and $t_1, t_2, \cdots t_n$ be the lists of pattern and target points, respectively, *lexicographicly ordered* according to their d-dimensional coordinate values. Consider the translation $f_{i_1} = t_{i_1} - p_1$, for any $1 \leq i_1 \leq n$. One can scan the target points in the lexicographic order to find a point t_{i_2} such that $p_2 + f_{i_1} = t_{i_2}$. If such is found, one can continue scanning from t_{i_2+1} on to find t_{i_3} such that $p_3 + f_{i_1} = t_{i_3}$. This process is continued until a translated point of P does not occur in T or until a translated occurrence of the entire P is found. Careful implementation of this idea leads to the following result showing that the time bound of the naive string matching algorithm is possible also for the exact point pattern matching under translations.

Theorem 1 (Ukkonen et al. 2003 [13]) *The EPPM problem under translations for point pattern P and target T can be solved in $O(mn)$ time and $O(n)$ space where $m = |P| \leq |T| = n$.*

Quadratic running times are probably the best one can achieve for PPM algorithms:

Theorem 2 (Clifford et al. 2006 [10]) *The LCP problem under translations is 3SUM-hard.*

This means that an $o(|P||T|)$ time algorithm for LCP would yield an $o(n^2)$ algorithm for the `3SUM` problem, where $|T| = n$ and $|P| = \Theta(n)$. The `3SUM` problem asks, given n numbers, whether there are three numbers a, b, and c among them such that $a + b + c = 0$; finding a sub-quadratic algorithm for `3SUM` would be a surprise [5]. For a more in-depth combinatorial characterization of the geometric properties of the EPPM problem, see [7].

For the distance evaluation problems there are plethora of results. An excellent survey of the key results until 1999 is by Alt and Guibas [2]. As an example, consider in the 2-dimensional case how one can decide in $O(n \log n)$ time whether there is a transformation f composed of translation, rotation and scale, such that $f(A) = B$, where $A, B \subset \mathbb{R}^2$ and $n = |A| = |B|$: The idea is to convert A and B into an invariant form such that one can easily check their congruence under the transformations. First, scale is taken into account by scaling A to have the same *diameter* as B (in $O(n \log n)$ time). If A and B are congruent, then they must have the same *centroids* (which can be computed $O(n)$ time). Consider rotating a line from the centroid and listing the angles and distances to other points in the order they are met during the rotation. Having done this (in $O(n \log n)$ time) on both A and B, the lists of angles and distances should be *cyclic shifts* of each other; the list L_A of A occurs as a substring in $L_B L_B$, where L_B is the list of B. This latter step can be done in $O(n)$ time using any linear time exact string matching algorithm. One obtains the following result.

Theorem 3 (Atkinson 1987 [4]) *It is possible to decide in $O(n \log n)$ time whether there is*

a transformation f composed of translation, rotation and scale, such that $f(A) = B$, where $A, B \subset \mathbb{R}^2$ and $|A| = |B| = n$.

Approximate variant of the above problem is much harder. Denote by $f(A) =^{\varepsilon} B$ the *directed approximate congruence* of point sets A and B, meaning that there is a one-to-one mapping from $f(A)$ to B such that for each point in $f(A)$ its image in B is ε-close. The following result demonstrates the added difficulty.

Theorem 4 (Alt et al. 1988 [3]) *It is possible to decide in $O(n^6)$ time whether there is a translation f such that $f(A) =^{\varepsilon} B$, where $A, B \subset \mathbb{R}^2$ and $|A| = |B| = n$. The same algorithm solves the corresponding LACP problem for point pattern P and target T under the one-to-one matching condition in $O((mn)^3)$ time, where $m = |P| \leq |T| = n$.*

To get an idea of the techniques to achieve the $O((mn)^3)$ time algorithm for LACP, consider first the one-dimensional version, i.e., let $P, T \subset \mathbb{R}$. Observe, that if there is a translation f' such that $f'(P) =^{\varepsilon} T$, then there is a translation f such that $f(P) =^{\varepsilon} T$ *and* a point $p \in P$ that is mapped *exactly* at ε-distance of a point $t \in T$. This lets one concentrate on these $2mn$ *representative translations*. Consider these translations sorted from left to right. Denote the left-most translation by f. Create a bipartite graph, whose nodes are the points in P and in T on the different parties. There is an edge between $p \in P$ and $t \in T$ if and only if $f(p)$ is ε-close to t. Finding a maximum matching in this graph tells the size of the largest approximately common point set after applying the translation f. One can repeat this on each representative translation to find the overall largest common point set. When the representative translations are considered from left to right, the bipartite graph instances are such that one can compute the maximum matchings greedily at each translation in time $O(|P|)$ [6]. Hence, the algorithm solves the one-dimensional LACP problem under translations and one-to-one matching condition in time $O(m^2 n)$, where $m = |P| \leq |T| = n$.

In the two-dimensional case, the set of representative translations is more implicitly defined: In short, the mapping of each point $p \in P$ ε-close to each point $t \in T$, gives mn circles. The boundary of each such circle is partitioned into intervals such that the end points of these intervals can be chosen as representative translations. There are $O((mn)^2)$ such representative translations. As in the one-dimensional case, each representative translation defines a bipartite graph. Once the representative translations along a circle are processed e.g., counterclockwise, the bipartite graph changes only by one edge at a time. This allows an $O(mn)$ time update for the maximum matching at each representative translation yielding an overall $O((mn)^3)$ time algorithm [3].

More efficient algorithms for variants of this problem have been developed by Efrat, Itai, and Katz [11], as by-products of more efficient bipartite matching algorithms for points on a plane. Their main result is the following:

Theorem 5 (Efrat et al. 2001 [11]) *It is possible to decide in $O(n^5 \log n)$ time whether there is a translation f such that $f(A) =^{\varepsilon} B$, where $A, B \subset \mathbb{R}^2$ and $|A| = |B| = n$.*

The problem becomes somewhat easier when the one-to-one matching condition is relaxed; one-to-one condition seems to necessitate the use of bipartite matching in one form or another. Without the condition, one can match the points independently of each other. This gives many tools to preprocess and manipulate the point sets during the algorithm using dynamic geometric data structures. Such techniques are exploited e.g., in the following result.

Theorem 6 (Chew and Kedem 1992 [8]) *The LACP problem under translations and using directed Hausdorff distance and the L_1 norm, can be solved in $O(mn \log n)$ time, where $P, T \subset \mathbb{R}^2$ and $m = |P| \leq |T| = n$. The distance evaluation problem for directed Hausdorff distance can be solved in $O(n^2 \log^2 n)$ time.*

Most algorithms revisited here have relatively high running times. To obtain faster algorithms, it seems that randomization and approximation

techniques are necessary. See [9] for a comprehensive summary of the main achievements in that line of development.

Finally, note that the linear transformations considered here are not always enough to model a real-world problem–even when approximate congruence is allowed. Sometimes the proper transformation between two point sets (or between their subsets) is non-linear, without an easily parametrizable representation. Unfortunately, the formulations trying to capture such non-uniformness have been proven NP-hard [1] or even NP-hard to approximate within any constant factor [12].

Applications

Point pattern matching is a fundamental problem that naturally arises in many application domains such as computer vision, pattern recognition, image retrieval, music information retrieval, bioinformatics, dendrochronology, and many others.

Problem Definition

Definition 1 A *simple polygon* is a polygon whose interior is simply connected, i.e., it consists of a single connected component and does not contain holes.

Definition 2 A triangulation of a simple polygon P with N vertices is a partition of the polygon, considered as a full-dimensional subset of the plane, into $N-2$ nonoverlapping triangles such that the set of vertices of these triangles is the set of vertices of P, such that no edge of a triangle lies outside of P, and such that no triangle edges intersect except in their common endpoints.

Key Results

In addition to the regularization-based approach by Garey et al. [7], three other $\mathcal{O}(N \log N)$-time algorithms are milestones on the way toward an optimal linear-time algorithm. In the first of these algorithms [2], Chazelle uses a linear-time "polygon-cutting" approach to partition a simple polygon by a suitably chosen diagonal; the resulting divide-and-conquer scheme yields an $\mathcal{O}(N \log N)$-time algorithm for simple polygons. Hertel and Mehlhorn [8] present an $\mathcal{O}(N \log N)$-time plane-sweep algorithm and refine its analysis to yield an $\mathcal{O}(N + R \log R)$-time upper bound, where R is the number of concave polygon angles. Chazelle and Incerpi [4] present a divide-and-conquer algorithm with $\mathcal{O}(N + S \log S)$ running time; here, S denotes the maximum number of times the boundary of the polygon changes from "spiraling" to "antispiraling."

Polygon Triangulation in $o(N \log N)$ Time

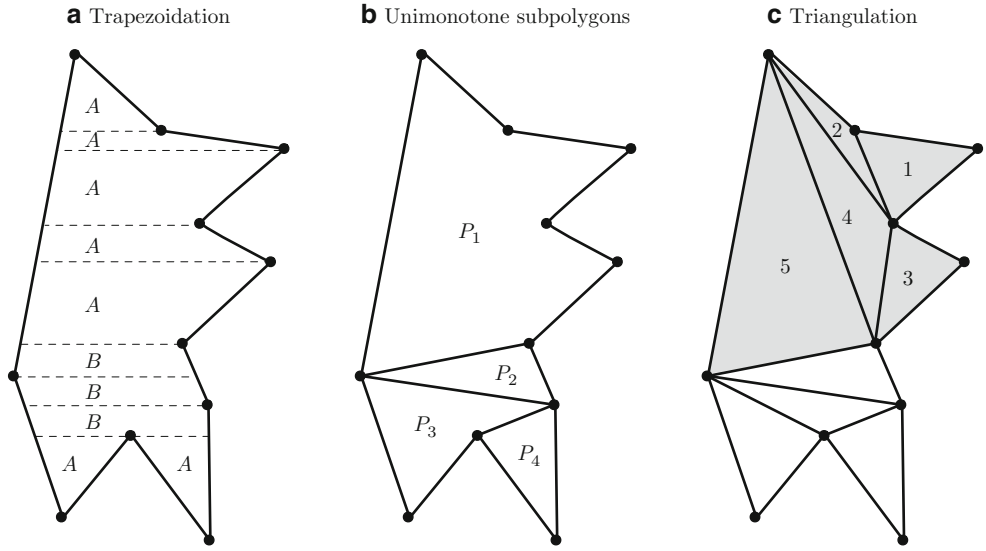
Algorithms with $o(N \log N)$ running time were developed by Tarjan and van Wyk [14] (using Jordan sorting and finger trees) and Kirkpatrick, Klawe, and Tarjan [10] (using efficient point-location structures). Both algorithms can be shown to run in $\mathcal{O}(N \log \log N)$ time; the algorithm by Kirkpatrick et al. can be made to run in $\mathcal{O}(N \log^* N)$ time if the polygon's vertices have bounded integer coordinates. Clarkson, Tarjan, and van Wyk [7] restate the algorithm by Tarjan and van Wyk in a randomized setting using random sampling and develop a Las Vegas algorithm with $\mathcal{O}(N \log^* N)$ expected running time. The same expected running time can be obtained by a considerably simpler randomized incremental construction presented by Seidel [7]; as an added benefit, this algorithm constructs an efficient data structure for vertical ray shooting among a set of line segments.

Polygon Triangulation via Trapezoidation

The key to an efficient polygon triangulation algorithm was that polygon triangulation is linear-time equivalent to polygon trapezoidation. Here, the task is to compute for each vertex v of a simple polygon P the point (if any) of the boundary of P that is visible from v when shooting horizontal rays (*chords*) from v toward $\pm\infty$ through the interior of P. The resulting structure is called the *visibility map* of P.

Theorem 1 ([6]) *Given the trapezoidal decomposition of a simple polygon P, a triangulation of P can be computed in linear time and vice versa.*

The proof builds upon the fact that a trapezoidation for a set of points in general position, i.e., a set in which no two points share the same y-coordinate, consists of trapezoids, which may degenerate into triangles that have exactly two polygon vertices on their boundary. A trapezoid T is said to be a *class-A*-trapezoid if these vertices lie on the same side of T (this includes the case of triangles); otherwise, it is said to be a *class-B*-trapezoid. Fournier and Montuno observed that a polygon can be partitioned into so-called unimonotone polygons by adding diagonals between the vertices of class-B-trapezoids



Polygon Triangulation, Fig. 1 Phases of Fournier and Montuno's algorithm [6]. By connecting the vertices of class-B-trapezoids in (**a**), the polygon is subdivided in unimonotone polygons as shown in (**b**). The numbers in (**c**) indicate the order in which the ear-cutting algorithms construct the triangles in the triangulation of the unimonotone subpolygon P_1 (shown in *gray*)

and that these unimonotone polygons can be triangulated independently in linear time – see Fig. 1.

Polygon Triangulation in Linear Time

The only deterministic linear-time algorithm for triangulating a simple polygon known so far is due to Chazelle [3]. Chazelle's algorithm uses a divide-and-conquer approach to compute the visibility map of a simple polygon. Since the divide-and-conquer approach subdivides the polygon's boundary into polygonal chains, there is no proper notion of the interior of the polygon through which the chords are supposed to pass. Instead, the polygon is embedded into the spherical plane on which the chords can "warp around infinity," and the visibility map is computed by always shooting rays in both directions.

Stated in terms of visibility maps, the algorithm's task now can be reduced to merging two visibility maps. To avoid linear-time merging steps which in turn would lead to $\Theta(N \log N)$ runtime, the algorithm proceeds as follows: in a first, bottom-up phase, the algorithm repeatedly merges the visibility maps of two subchains of the same length that share a common vertex. To ensure a sublinear running time, however, the algorithm does not compute the full visibility map, i.e., the map obtained by shooting rays from each vertex. Instead, for a subchain consisting of $2^{\lambda} + 1$ vertices, the algorithm maintains a $2^{\lceil \beta\lambda \rceil}$-*granular* visibility map.

Definition 3 A visibility map for a polygonal chain P is γ-granular for some $\gamma > 0$ if no part of the boundary of any region consists of more than γ consecutive edges of P and if no two adjacent regions can be merged without violating this property.

The consequence of this definition is that for polygons in general position, i.e., polygons for which no two vertices share the same y-coordinate, a γ-granular visibility map consists of $\mathcal{O}\left(\frac{N}{\gamma} + 1\right)$ regions, each of which is bounded by a constant number of chords and polygonal chains with a total complexity of $\mathcal{O}(\gamma)$. This enables a compact representation of each submap

along with a uniform upper bound on the coarseness of the approximation of the visibility map.

For each subchain π considered throughout the bottom-up phase, the algorithm computes two "oracle" data structures, which are reused in the final phase of the algorithm. The first oracle, the so-called ray shooter, returns in $\mathcal{O}(f(\gamma))$ time for any point in the plane the first point of the γ-granular visibility map of π that is seen when shooting a horizontal ray in either direction. This oracle, whose construction is based upon Lipton and Tarjan's planar separator theorem [11], is used when merging the visibility map of π with the visibility map of a subchain π' that shares a common vertex p with π. Starting with p, the algorithm walks along π and π' and uses the respective ray shooter to update the visibility information for as many vertices as needed to guarantee the desired granularity. Due to Chazelle's polygon-cutting theorem [2], each region in either submap is closed under visibility. This implies that the "ray-shooter" oracle can be defined for each region separately, and only one oracle for a region in π needs to be queried for any vertex in π' (and vice versa) as long as the algorithm keeps track of the region the vertex currently under consideration lies in.

The second oracle, the so-called arc cutter, subdivides π in $\mathcal{O}(g(\gamma))$ time into $g(\gamma)$ subarcs each of which is given along with an $h(\gamma)$-granular visibility map. Using these two oracles, merging a γ_1-granular visibility map for a subchain consisting of N_1 vertices with a γ_2-granular visibility map for a subchain consisting of N_2 vertices, $\gamma_2 \geq \gamma_1$, can be done in

$$\mathcal{O}\left(\left(\frac{N_1}{\gamma_1} + \frac{N_2}{\gamma_2} + 1\right) f(\gamma_2) g(\gamma_2)(h(\gamma_2) + \log(N_1 + N_2))\right)$$

time. Chazelle proves that one can maintain these oracles such that $f(x) \in x^{0.74}$, $g(x) \in \mathcal{O}(\log x)$, and $h(x) \in \mathcal{O}(x^{0.20})$, with $\gamma_2 \in \mathcal{O}(N_2^{0.20})$; this eventually implies a sublinear merging step and hence a linear-time complexity of the bottom-up phase.

The final, top-down phase incrementally refines all regions of the visibility maps produced in the bottom-up phase. Using the "arc-cutter" oracle, each polygonal chain on the boundary of a region is subdivided into an appropriate number of subchains. As a result of the bottom-up phase and by carefully aligning the subchains considered in that phase with the results of the arc cutter, visibility maps, ray shooters, and arc cutters are available for each of these chains. The algorithm then uses the ray shooters to construct new chords and the arc cutters to further refine the visibility maps until the recursion bottoms out, and visibility maps of constant size can be refined by a brute-force algorithm. An inductive proof yields a linear runtime for the refinement of each region in the visibility map that was constructed in the bottom-up phase; hence, the overall running time is linear.

While Chazelle's algorithm uses only reasonably complicated data structures and subroutines, the analysis of both phases strongly suggests large constant factors hidden in the Big-Oh notation. In addition, the algorithm requires rather delicate implementation issues to be solved, in particular regarding the representation of the visibility maps, and thus it is not surprising that Chazelle mentioned developing a simpler, randomized algorithm with expected linear runtime as a major open problem.

Randomized Polygon Triangulation in Expected Linear Time

Over a decade after the publication of Chazelle's deterministic, linear-time algorithm, Amato, Goodrich, and Ramos [1] affirmatively answered Chazelle's question. Their algorithm follows Chazelle's two-phase approach and uses a bottom-up phase to preprocess helper data structures for so-called portal queries in the subchains' visibility maps. The top-down phase also subdivides the polygonal chain into smaller chains and refines the visibility maps. In contrast to Chazelle's algorithm, however, this refinement

step is done on a random sample of the subchains only. As the sampling probability tends to one as the size of the subchain approaches $\mathcal{O}(1)$, both correctness and an expected linear runtime can be shown.

Applications

Being able to efficiently triangulate simple polygons has a variety of applications in computational geometry, computer graphics, and geographic information systems. For some of the problems considered, using a linear-time polygon triangulation algorithm is the key to obtaining an optimal algorithm. One such example among a variety of results is the optimal point-location scheme presented by Kirkpatrick [9] whose preprocessing time is linear assuming the availability of a linear-time triangulation algorithm. Several other applications are covered in O'Rourke's textbook on art gallery problems [12].

Open Problems

The main open problem is to devise an optimal deterministic algorithm that is reasonably efficient in practice.

Experimental Results

Due to its inherent complexity, Chazelle's algorithm has eluded a rigorous experimental evaluation so far. Preliminary results reported by Vahrenhold [15], however, seem to indicate that running even the first nontrivial stage of the bottom-up process takes significantly more time than running, e.g., Seidel's randomized algorithm [13] in full. Similarly, Amato et al. [1] conjecture that their randomized algorithm, despite its expected optimal runtime, is "not likely to be of practical value," either. Hence, for practical purposes, the simplicity of the deterministic algorithm by Hertel and Mehlhorn [8] and the randomized algorithm by Seidel [13] strongly advocates their use.

Adword auction

Years and Authors of Summarized Original Work

2005; Varian

Problem Definition

This problem is concerned with the Nash equilibria of a game based on the ad auction used by Google and Yahoo. This research work [5] is motivated by the huge revenue that the adword auction derives every year. It defines two types of Nash equilibrium in the position auction game, applies economic analysis to the equilibria, and provides some empirical evidence that the Nash equilibria of the position auction describes the basic properties of the prices observed in Google's adword auction reasonably accurately. The problem being studied is closely related to the assignment game studied by [4, 1, 3]. And [2] has independently examined the problem and developed related results.

The Model and Its Notations

Consider the problem of assigning agents $a = 1, 2, \ldots, A$ to slots $s = 1, 2, \ldots, S$ where agent a's valuation for slot s is given by $u_{as} = v_a x_s$. The slots are numbered such that $x_1 > x_2 > \cdots > x_S$. It is assumed that $x_S = 0$ for all $s > S$ and the number of agents is greater than the number of slots. A higher position receives more clicks, so x_s can be interpreted as the click-through rate for slot s. The value $v_a > 0$ can be interpreted as the expected profit per click so $u_{as} = v_a x_s$ indicates the expected profit to advertiser a from appearing in slot s.

The slots are sold via an auction. Each agent bids an amount b_a, with the slot with the best click through rate being assigned to the agent with the highest bid, the second-best slot to the agent with the second highest bid, and so on. Renumbering the agents if necessary, let v_s be the value per click of the agent assigned to slot s. The price agent s faces is the bid of the agent immediately below him, so $p_t = b_{t+1}$. Hence the net profit that agent a can expect to make if he acquires slot s is $(v_a - p_s)\, x_s = (v_a - b_{s+1})\, x_s$.

Definitions

Definition 1 A Nash equilibrium set of prices ***(NE)*** satisfies

$$(v_s - p_s)\, x_s \geq (v_s - p_t)\, x_t, \text{for } t > s$$
$$(v_s - p_s)\, x_s \geq (v_s - p_{t-1})\, x_t, \text{for } t < s$$

where $p_t = b_{t+1}$.

Definition 2 A symmetric Nash equilibrium set of prices ***(SNE)*** satisfies

$$(v_s - p_s)\, x_s \geq (v_s - p_t)\, x_t \text{ for all } t \text{ and } s.$$

Equivalently,

$$v_s\, (x_s - x_t) \geq p_s x_s - p_t x_t \text{ for all } t \text{ and } s.$$

Key Results

Facts of NE and SNE

Fact 1 (Non-negative surplus) In an SNE, $v_s \geq p_s$.

Fact 2 (Monotone values) In an SNE, $v_{s-1} \geq v_s$, for all s.

Fact 3 (Monotone prices) In an SNE, $p_{s-1} x_{s-1} > p_s x_s$ and $p_{s-1} \geq p_s$ for all s. If $v_s > p_s$ then $p_{s-1} > p_s$.

Fact 4 ($NE \supset SNE$) If a set of prices is an SNE then it is an NE.

Fact 5 (One-step solution) If a set of bids satisfies the symmetric Nash equilibria inequalities for $s + 1$ and $s - 1$, then it satisfies these inequalities for all s.

Fact 6 The maximum revenue NE yields the same revenue as the upper recursive solution to the SNE.

A Sufficient and Necessary Condition of the Existence of a Pure Strategy Nash Equilibrium in the Position Auction Game

Theorem 1 *In the position auction described before, a pure strategy Nash equilibrium exists if and only if all the intervals*

$$\left[\frac{p_s x_s - p_{s+1}x_{s+1}}{x_s - x_{s+1}}, \frac{p_{s-1}x_{s-1} - p_s x_s}{x_{s-1} - x_s}\right], \quad \text{for } s = 2, 3, \ldots, S$$

are non-empty.

Applications

The model studied in this paper is a simple and elegant abstraction of the real adword auctions used by search engines such as Google and Yahoo. Different search engines have slightly different rules. For example, Yahoo ranks the advertisers according to their bids, while Google ranks the advertisers not only according to their bids but also according to the likelihood of their links being clicked.

However, similar analysis can be applied to real world situations, as the author has demonstrated above for the Google adword auction case.

Problem Definition

The power grid of an integrated system is responsible for providing reliable supply and ground voltages to every circuit element in the system. Degradations in the supply voltage levels can result in parametric failures due to increased delays, whereby circuits no longer meet their specifications, as well as catastrophic failures due to incorrect gate switching. Further, power grids are susceptible to reliability faults due to catastrophic failure modes such as electromigration. Therefore, accurate power grid analysis is a vital step in integrated circuit design.

Power grids may be analyzed under DC waveforms that reflect the steady-state currents drawn by the circuit or under transient analysis that captures the response of the grid to specific time-varying current waveforms; inductive effects, particularly in the integrated circuit

package; and decoupling capacitors that are deliberately placed in the circuit to temper the effect of large transients. For both DC and transient analysis, the problem can be abstracted as solving a set of linear algebraic equations of the following form:

$$G\mathbf{V} = \mathbf{E}, \tag{1}$$

where $G \in \Re^{N \times N}$ models the conductances in the system, $\mathbf{V} \in \Re^{N}$ is the vector of unknown node voltages, and $\mathbf{E} \in \Re^{N}$ is the right-hand side (RHS) vector, modeling the current loads. In case of DC analysis, a single such system must be solved, while in case of transient analysis, one such system is solved at each time step. For computational efficiency, a constant time step is often used during transient analysis of power grids in order to ensure that the G matrix, whose entries depend on the time step, remains unchanged through the simulation.

Given a power grid topology with $|E|$ resistors, these equations can be formulated using modified nodal analysis [2] in $O(|E|)$ time. Matrix G is sparse and diagonally dominant ($\sum_{i \neq j} |g_{ij}| \leq g_{ii}, \forall i$), and all off-diagonals of G are less than or equal to zero.

The task of power grid analysis is to determine all voltage levels in the system and verify that the maximum deviation from their ideal values is within a user-specified bound and to ensure that the current density in each wire is within a user-specified limit in order to assure resilience to electromigration failure.

Key Results

Mainstream methods for solving such systems include direct methods such as LU/Cholesky factorization and iterative methods. Due to the favorable structural properties of the power grid, notably sparsity and diagonal dominance, it is possible to solve these systems efficiently. However, the scale of the problem, where power grids may have hundreds of millions or billions of resistors, poses large memory and computation challenges even to the most efficient solvers. As a result, there has been considerable work on developing specialized solvers for power grids. Notable contributions in this direction are described below.

Hierarchy-Based Solvers

In real designs, the power grid is inherently hierarchical since it is created as a part of a hierarchical design process, where individual blocks with locally constructed power are first designed individually and then assembled at the chip level. This structure is exploited in [9] to build a hierarchical solution to the grid.

Based on inherent hierarchy, the power grid has k local partitions, corresponding to blocks, and a global partition that connects the power grids within these blocks. The *global grid* is then defined to include the set of nodes that lie in the global partition and the port nodes, while the grid in a local partition constitutes a *local grid*. The local grid is connected to the global grid through a set of nodes called *ports*, and due to the hierarchical structure, the number of port nodes is a small fraction of all nodes. The technique consists of the following steps:

Macromodeling Each of the k local grids may be modeled as a multi-port linear element represented by a macromodel of the type $\mathbf{I} = A \cdot \mathbf{V} + \mathbf{S}$, where $\mathbf{I}$ and $\mathbf{V}$ are the vectors of port voltages and A and $\mathbf{S}$ are, respectively, a constant matrix and a constant vector. Here, the A matrix is sparsified with bounded and minimal loss of accuracy using an integer knapsack scheme.

Solution of the global grid Once the macromodels for all the local grids are generated, the entire network is abstracted simply as the global grid, with the macromodel elements connected to it at the port nodes. This system is solved to determine the voltages at all ports.

Solution of the local grids Given the port voltages, the local grids are then each separately solved to provide the solution to the entire system.

Multigrid-Based Solvers

Multigrid-based approaches are an effective way of solving large systems of equations and have been customized to solve power grids [3]. The solution proceeds by creating a coarsened form of the network with a reduced number of nodes, which can be solved efficiently, and then by propagating the result of this solution to the full network. The technique consists of four steps:

Grid reduction, in which the large power grid is coarsened by selecting a subset of nodes that are to be maintained, while the other nodes are removed. The number of variables is therefore significantly reduced from from n to m.

Interpolation, in which an $n \times m$ interpolation operator matrix P is defined to map the original grid to the coarsened grid. This interpolation operator relates the voltages on the removed nodes to those on the coarsened grid, thereby allowing the solution of the coarsened grid to accurately reflect that of the original grid.

Solution of the coarsened grid, in which a solution is found for the voltages in the coarsened grid by solving the above linear equations.

Mapping the solution from the coarsened grid to the original grid by applying the interpolation operator concludes the process.

Random Walk-Based Solvers

The diagonal dominance of the power grid enables a special property that creates an exact mapping between the solution of the power grid equations and the use of random walks on a network. This idea has been used in [8] and further sped up in [6]. Unlike other approaches that require all (or most) nodes in a system to be solved together, random walk approaches allow for a single node to be solved alone. This is particularly useful during incremental analysis and optimization [1].

The family of random walk methods has been extended to solve entire systems, in a marriage with iterative linear solvers based on conjugate gradient methods. The intuition is that since random walks provide approximate solutions rapidly, they can be used to build effective preconditioners for iterative solvers [7].

Applications

Power grid analysis is a vital ingredient in the design of every integrated circuit, and there are several commercial offerings of design automation tools that analyze power grids. Aside from the problem of solving the linear system, the issue of determining the worst-case excitation is also a difficult problem. In spite of numerous efforts, automated tools for this purpose have been excessively pessimistic and therefore ineffective. It is generally accepted that user-specified patterns are the most effective way to provide input excitations, particularly in a design world where the power grid must be analyzed at multiple corners and multiple modes (corresponding to different supply voltages that could be applied to the circuit).

Experimental Results

Intelligent solutions for solving linear systems of equations have found extensive use in the analysis of power grids. Solvers that are used include direct solvers as well as iterative solvers based on methods such as preconditioned conjugate gradient-based solvers. Preconditioners based on methods such as support trees have been found to be useful, and random walk preconditioners have also been shown to outperform conventional methods. Due to the computational nature of this task, there has been active work on developing parallel and multithreaded power grid solvers. For example, the 2011 and 2012 editions of the Tau workshop have hosted contests on solving power grid problems [4, 5].

Keywords

IP lookup; Predecessor problem; Successor problem

Years and Authors of Summarized Original Work

2006; Pătraşcu, Thorup

Problem Definition

Consider an ordered universe U, and a set $T \subset U$ with $|T| = n$. The goal is to preprocess T, such that the following query can be answered efficiently: given $x \in U$, report the predecessor of x, i.e., $\max\{y \in T \mid y < x\}$. One can also consider the dynamic problem, where elements are inserted and deleted into T. Let t_q be the query time, and t_u the update time.

This is a fundamental search problem, with an impressive number of applications. Later, this entry discusses IP lookup (forwarding packets on the Internet), orthogonal range queries and persistent data structures as examples.

The problem was considered in many computational models. In fact, most models below were initially defined to study the predecessor problem.

Comparison model: The problem can be solved through binary search in $\Theta(\lg n)$ comparisons. There is a lot of work on adaptive bounds, which may be sublogarithmic. Such bounds may depend on the finger distance, the working set, entropy etc.

Binary search trees: Predecessor search is one of the fundamental motivations for binary search trees. In this restrictive model, one can hope for an instance optimal (competitive) algorithm. Attempts to achieve this are described in a separate entry. ($O(\log \log n)$-*competitive Binary Search Trees* (2004; Demaine, Harmon, Iacono, Pătraşcu))

Word RAM: Memory is organized as words of b bits, and can be accessed through indirection. Constant-time operations include the standard operations in a language such as C (addition, multiplication, shifts and bitwise operations).

It is standard to assume the universe is $U = \{1, \ldots, 2^\ell\}$, i.e., one deals with ℓ-bit integers.

The floating point representation was designed so that order is preserved when values are interpreted as integers, so any algorithm will also work for ℓ-bit floating point numbers.

The standard *transdichotomous* assumption is that $b = \ell$, so that an input integer is represented in a word. This implies $b \geq \lg n$.

Cell-probe model: This is a nonuniform model stronger than the word RAM, in which the operations are arbitrary functions on the memory words (cells) which have already been probed. Thus, t_q only counts the number of cell probes. This is an ideal model for lower bounds, since it does not depend on the operations implemented by a particular computer.

Communication games: Let Alice have the query x, and Bob have the set T. They are trying to find the predecessor of x through τ rounds of communication, where in each round Alice sends m_A bits, and Bob replies with m_B bits.

This can simulate the cell-probe model when $m_B = b$ and m_A is the logarithm of the memory size. Then $\tau \leq t_q$ and one can use communication complexity to obtain cell-probe lower bounds.

External memory: The unit of access is a page, containing B words of ℓ bits each. B-trees solve the problem with query and update time $O(\log_B n)$, and one can also achieve this oblivious to the value of B (See *Cache-oblivious B-tree* (2005; Bender, Demaine, Farach-Colton).). The cell-probe model with $b = B \cdot \ell$ is stronger than this model.

AC^0 RAM: This is a variant of the word RAM in which allowable operations are functions that have constant depth, unbounded fan-in circuits. This excludes multiplication from the standard set of operations.

RAMBO: this is a variant of the RAM with a nonstandard memory, where words of memory can overlap in their bits. In the static case this is essentially equivalent to a normal RAM. However, in the dynamic case updates can be faster due to the word overlap [5].

The worst-case logarithmic bound for comparison search is not particularly informative when efficiency really matters. In practice, B-trees and variants are standard when dealing with huge data sets. Solutions based on RAM tricks are essential when the data set is not too large, but a fast query time is crucial, such as in software solutions to IP lookup [7].

Key Results

Building on a long line of research, Pătraşcu and Thorup [15, 16] finally obtained matching upper and lower bounds for the static problem in the word RAM, cell-probe, external memory and communication game models.

Let S be the number of words of space available. (In external memory, this is equivalent to S/B pages.) Define $a = \lg S \cdot \ell / n$. Also define $\lg x = \lceil \log_2(x+2) \rceil$, so that $\lg x \geq 1$ even if $x \in [0, 1]$. Then the optimal search time is, up to constant factors:

$$\min \begin{cases} \log_b n = \Theta(\min\{\log_B n, \log_\ell n\}) \\ \lg \frac{\ell - \lg n}{a} \\ \frac{\lg \frac{\ell}{a}}{\lg\left(\frac{a}{\lg n} \cdot \lg \frac{\ell}{a}\right)} \\ \frac{\lg \frac{\ell}{a}}{\lg\left(\frac{\lg \frac{\ell}{a}}{\lg \frac{\lg n}{a}}\right)} \end{cases} \tag{1}$$

The bound is achieved by a deterministic query algorithm. For any space S, the data structure can be constructed in time $O(S)$ by a randomized algorithm, starting with the set T given in sorted order. Updates are supported in expected time $t_q + O(S/n)$. Thus, besides locating the element through one predecessor query, updates change a minimal fraction of the data structure.

Lower bounds hold in the powerful cell-probe model, and hold even for randomized algorithms. When $S \geq n^{1+\varepsilon}$, the optimal trade-off for communication games coincides to (1). Note that the case $S = n^{1+o(1)}$ essentially disappears in the reduction to communication complexity, because Alice's messages only depends on $\lg S$.

Thus, there is no asymptotic difference between $S = O(n)$ and, say, $S = O(n^2)$.

Upper Bounds

The following algorithmic techniques give the optimal result:

- *B-trees* give $O(\log_B n)$ query time with linear space.
- *Fusion trees*, by Fredman and Willard [10], achieve a query time of $O(\log_b n)$. The basis of this is a *fusion node*, a structure which can search among b^ε values in constant time. This is done by recognizing that only a few bits of each value are essential, and packing the relevant information about all values in a single word.
- *Van Emde Boas search* [18] can solve the problem in $O(\lg \ell)$ time by binary searching for the length of the longest common prefix between the query and a value in T. Beginning the search with a table lookup based on the first $\lg n$ bits, and ending when there is enough space to store all answers, the query time is reduced to $O(\lg((\ell - \lg n)/a))$.
- A technique by *Beame and Fich* [4] can perform a multiway search for the longest common prefix, by maintaining a careful balance between ℓ and n. This is relevant when the space is at least $n^{1+\varepsilon}$, and gives the third branch of (1). Pătraşcu and Thorup [15] show how related ideas can be implemented with smaller space, yielding the last branch of (1).

Observe that external memory only features in the optimal trade-off through the $O(\log_B n)$ term coming from B-trees. Thus, it is optimal to either use the standard, comparison-based B-trees, or use the best word RAM strategy which completely ignores external memory.

Lower Bounds

All lower bounds before [15] where shown in the communication game model. Ajtai [1] was the first to prove a superconstant lower bound. His results, with a correction by Miltersen [12], show that for polynomial space, there exists n as a function of ℓ making the query time $\Omega(\sqrt{\lg \ell})$, and likewise there exists ℓ a function of n making the query complexity $\Omega(\sqrt[3]{\lg n})$.

Miltersen et al. [13] revisited Ajtai's proof, extending it to randomized algorithms. More importantly, they captured the essence of the proof in an independent *round elimination lemma*, which is an important tool for proving lower bounds in asymmetric communication.

Beame and Fich [4] improved Ajtai's lower bounds to $\Omega(\lg \ell / \lg \lg \ell)$ and $\Omega(\sqrt{\lg n / \lg \lg n})$ respectively. Sen and Venkatesh [17] later gave an improved round elimination lemma, which can reprove these lower bounds, but also for randomized algorithms.

Finally, using the message compression lemma of [6] (an alternative to round elimination), Pătraşcu and Thorup [15] showed an optimal trade-off for communication games. This is also an optimal lower bound in the other models when $S \geq n^{1+\varepsilon}$, but not for smaller space.

More importantly, [15] developed the first tools for proving lower bounds exceeding communication complexity, when $S = n^{1+o(1)}$. This showed the first separation ever between a data structure or polynomial size, and one of near linear size. This is fundamentally impossible through a direct communication lower bound, since the reduction to communication games only depends on $\lg S$.

The full result of Pătraşcu and Thorup [15] it the trade-off (1). Initially, this was shown only for deterministic query algorithms, but eventually it was extended to a randomized lower bound as well [16]. Among the surprising consequences of this result was that the classic van Emde Boas search is optimal for near-linear space (and thus for dynamic data structures), whereas with quadratic space it can be beaten by the technique of Beame and Fich.

A key technical idea of [15] is to analyze many queries simultaneously. Then, one considers a communication game involving all queries, and proves a direct-sum version of the round elimination lemma. Arguably, the proof is even simpler than for the regular round elimination lemma. This is achieved by considering

a stronger model for the inductive analysis, in which the algorithm is allowed to *reject* a large fraction of the queries before starting to make probes.

Bucketing

The rich recursive structure of the problem can not only be used for fast queries, but also to optimize the space and update time – of course, within the limits of (1). The idea is to place ranges of consecutive values in buckets, and include a single representative of each bucket in the predecessor structure. After performing a query on the predecessor structure (now with fewer elements), one need only search within the relevant bucket.

Because buckets of size $w^{O(1)}$ can be handled in constant time by fusion trees, it follows that factors of w in space are irrelevant. A more extreme application of the idea is given by *exponential trees* [3]. Here buckets have size $\Theta(n^{1-\gamma})$, where γ is a sufficiently small constant. Buckets are handled recursively in the same way, leading to $O(\lg \lg n)$ levels. If the initial query time is at least $t_q \geq \lg^{\varepsilon} n$, the query times at each level decrease geometrically, so overall time only grows by a constant factor. However, any polynomial space is reduced to linear, for an appropriate choice of γ. Also, the exponential tree can be updated in $O(t_q)$ time, even if the original data structure was static.

Applications

Perhaps the most important application of predecessor search is IP lookup. This is the problem solved by routers for each packet on the Internet, when deciding which subnetwork to forward the packet to. Thus, it is probably the most run algorithmic problem in the world. Formally, this is an *interval stabbing* query, which is equivalent to predecessor search in the static case [9]. As this is a problem where efficiency really matters, it is important to note that the fastest deployed software solutions [7] use integer search strategies (not comparison-based), as theoretical results would predict.

In addition, predecessor search is used pervasively in data structures, when reducing problems to *rank space*. Given a set T, one often wants to relabel it to the simpler $\{1, \ldots, n\}$ ("rank space"), while maintaining order relations. If one is presented with new values dynamically, the need for a predecessor query arises. Here are a couple of illustrative examples:

- In orthogonal range queries, one maintains a set of points in U^d, and queries for points in some rectangle $[a_1, b_1] \times \cdots \times [a_d, b_d]$. Though bounds typically grow exponentially with the dimension, the dependence on the universe can be factored out. At query time, one first runs $2d$ predecessor queries transforming the universe to $\{1, \ldots, n\}^d$.
- To make pointer data structures persistent [8], an outgoing link is replaced by a vector of pointers, each valid for some period of time. Deciding which link to follow (given the time being queried) is a predecessor problem.

Finally, it is interesting to note that the lower bounds for predecessor hold, by reductions, for all applications described above. To make these reductions possible, the lower bounds are in fact shown for the weaker *colored predecessor* problem. In this problem, the values in T are colored red or blue, and the query only needs to find the color of the predecessor.

Open Problems

It is known [2] how to implement fusion trees with AC^0 instructions, but not the other query strategies. What is the best query trade-off achievable on the AC^0 RAM? In particular, can van Emde Boas search be implemented with AC^0 instructions?

For the dynamic problem, can the update times be made deterministic? In particular, can van Emde Boas search be implemented with fast deterministic updates? This is a very appealing problem, with applications to deterministic dictionaries [14]. Also, can fusion nodes be updated

deterministically in constant time? Atomic heaps [11] achieve this when searching only among $(\lg n)^{\varepsilon}$ elements, not b^{ε}.

Finally, does an update to the predecessor structure require a query? In other words, can $t_u = o(t_q)$ be obtained, while still maintaining efficient query times?

Problem Definition

Given a set S of n keys from the set $[1 \dots 2^\ell]$, the goal of *predecessor search* is to return, given a key $y \in [1 \dots 2^\ell]$, the largest key $x \in S$ such that $x \leq y$. We have the following models:

Comparison model Balanced binary search trees [1, 6] can solve the problem in optimal $O(\log n)$ time in the comparison model, in which the key can only be manipulated through comparisons with each other.

External memory model In this model, it is assumed that the data is read and written into blocks of B elements (integers in our case) and the cost of a query or algorithm is the number of read or written blocks. In this model, B-trees [7] can solve the problem in $O(\log_B n)$ time and $O(n)$ space.

RAM model This is the main subject of study. The model assumes that all standard arithmetic and logic operations (including multiplication) on integers of length w take constant time, where w is the computer word size. It is assumed that $w \geq \ell \geq \log n$.

AC^0 RAM model This model is similar to the RAM model except that it only contains instructions that can be implemented with circuits of polynomial size, constant depth and unfounded fan-in. The only affected instruction is multiplication which cannot be implemented with such circuits. While this model has been often considered in the literature in the past, modern computers support multiplications very fast, and the bottleneck is usually the memory access.

Cell probe model This model is used to prove lower bounds. It also has an associated word size w, but the cost of a query or an update is just the number of accessed memory words (computations have zero cost).

Useful Concepts

The two main techniques used for predecessor search are *cardinality reduction* and *length reduction*. At every step of the query, one would wish to either reduce the cardinality of the searched set or reduce the length of the searched keys.

Balanced Binary Search Tree

Cardinality reduction is achieved through the use of *balanced binary search tree*. This allows doing a predecessor search in $O(\log n)$ time in the comparison model. The B-tree is a generalization of the balanced binary search trees, where every node can have B children instead of just two. A static balanced binary search tree allows one to divide the set of searched keys by 2 at every level. A static B-tree allows one to divide the set by B. In the dynamic case, the cardinality can be reduced by a factor less than 2 (less than B for a dynamic B-tree) at every level, but it is guaranteed that the cardinality goes to one after $\Theta(\log n)$ levels ($\Theta(\log_B n)$ for a B-tree).

Trie

A key concept is that of a *trie*. A predecessor search for a key in a trie takes $O(\ell)$ time. A trie built on a set S of n keys from $[1 \dots 2^\ell]$ is a binary tree with ℓ levels numbered top-down. All the leaves of the trie are at level ℓ. Every edge in the tree has a label that is either 0 or 1. Let $x[i]$ denote the bit number i of the integer x, where $i \in [1 \dots \ell]$ and the bits are numbered from the most to the least significant bit ($x[1]$ is the most significant bit). Denote by $x[i \dots j]$ the binary string that consists in the concatenation of the bits $x[i], \dots x[j]$. A node of the trie at depth $d \in [0, \ell]$ will be labeled by a binary string of length d, formed by concatenating the edge labels from the root to the node. There will be a node of depth d labeled by binary string p if and only if there exists at least an element $x \in S$ such that $x[1 \dots d] = p$. A node at depth $d < \ell$ labeled by string p will have as children the nodes at depth $d + 1$ labeled by $p0$ and $p1$ (if they both exist, otherwise it will only have one child). The leaves of the trie are labeled by strings of S and the root is labeled by the empty string. A trie occupies $O(n\ell \log n)$ bits. In order to support predecessor searches, every internal node of the trie stores two elements of S. The two elements stored by a node labeled by binary string p are the

largest element prefixed by p and the predecessor of $p0^{w-|p|}$. A predecessor search on a compacted trie for a key y is then done by traversing the trie top-down, at level $i \in [1 \ldots \ell]$ following the edge labeled by character $y[i+1]$. The node at which the traversal stops is called the *locus* of y. The predecessor of y is then easily determined from its locus. If the locus is a leaf labeled by x, then necessarily $x = y$ and y is returned as the predecessor. Otherwise, the locus is some internal node and the predecessor is one of the two elements of S stored at that internal node. Suppose that the internal node is at level i and is labeled by string p. Then, if $x[i+1] = 1$, the predecessor is the largest element prefixed by p; otherwise, it is the predecessor of $p0^{w-p}$. In a *compacted trie* (*Patricia trie*), only leaves and internal nodes with degree 2 are kept, resulting in a tree of $2n-1$ nodes, n leaves, and $n-1$ internal nodes (see Fig. 1). The trie will then occupy only $O(n(\ell+\log n))$ bits. A predecessor search can be implemented on a compacted trie in a way similar to the non-compacted trie. The main difference is that the locus in a compacted trie is either a leaf or a location in the middle of a compacted edge.

Key Results

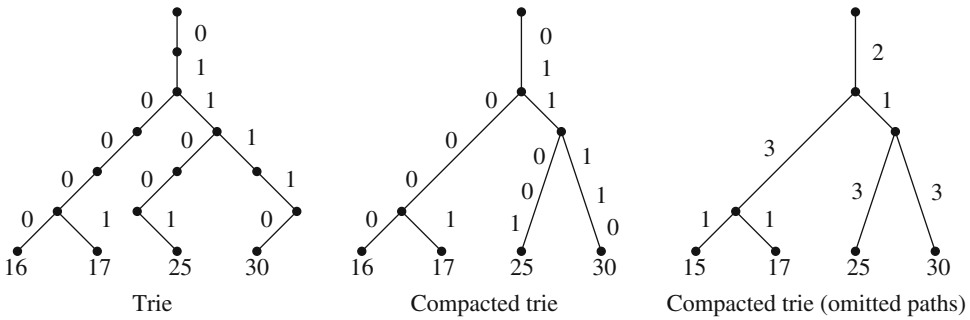
Van Emde Boas

The *Van Emde Boas tree* [17–19] is a compacted trie representation supporting predecessor search by doing a binary search on the trie levels. Since the number of levels is ℓ, the binary search takes time $O(\log \ell)$. The original structure used space $O(2^\ell)$. Later, Willard [20] showed how to use hashing to reduce the space usage to $O(n)$ while keeping the search time bounded by $O(\log \ell)$.

Searching a Compacted Trie (Fusion Trees)

The fusion tree reduces the predecessor search problem to the search on small compacted tries, each encoded in one memory word. The idea of the fusion tree dates back to a paper by Ajtai et al. [2], where it was shown how to implement predecessor search using a compacted trie in which the compacted paths are omitted and only their lengths are stored (the trie on the right in Fig. 1). This allows encoding a trie in $O(n(\log \ell + \log n))$ bits only compared to the $O(n(\ell + \log n))$ bits for the ordinary compacted trie. Then, a predecessor search for a key y is done by first doing a top-down traversal of the compacted trie, by always pretending that a comparison between the compacted paths and the bits of searched key is successful (only bits that label the edges are compared to bits of the searched key). At the end, the search terminates at a leaf that points to an integer $x \in S$ that is one of the elements that share the longest prefix with the searched key. Then, the locus (and hence the predecessor) is determined by filling the traversed compacted paths with bits from x and comparing those bits with the corresponding bits of y.

The main observation is that a predecessor search can be supported in constant time in the cell probe model whenever $n \log \ell \leq w$, since it



Predecessor Search, String Algorithms and Data Structures, Fig. 1 Three trie variants used for storing the integers 16, 17, 25, and 30. On the *left*, an ordinary trie; in the *middle*, a compacted trie; and on the *right*, a compacted trie in which the compacted paths are omitted and replaced by their lengths. Notice that the compacted trie has exactly $2 \cdot 4 - 1 = 7$ nodes

involves reading a constant number of memory locations corresponding to the trie encoded in a constant number of words and to two elements of S (the traversal of the trie is charged zero cost). Later, Fredman and Willard [11] invented the fusion node, where they implemented a predecessor search in constant time in the RAM model, when $n \leq w^{1/c}$ for $c = 6$. This allows searching the predecessors among a set of $w^{1/c}$ keys for $c = 6$ in constant time. By implementing a B-tree with block size $B = w^{1/c}$, one can achieve query time $O(\log_B n) = O(\log n / \log w)$. Finally, Pătraşcu and Thorup [15] have shown how to implement the approach with constant time updates and queries on $B = w^{1/c}$ keys for $c = 4$. This allows searches and dynamic updates in deterministic $O(\log n / \log w)$ time.

Beame and Fich

Beame and Fich [8] use a more advanced search that combines cardinality and length reductions. As a building block, they use a data structure that recursively reduces a search over n keys of length ℓ to a search over a group of n' keys of length ℓ' such that either $\ell' = \ell$ but $n' \leq q$ or $\ell' = \ell/h$ for some parameters h and q. This reduction technique was taken from an algorithm used for integer sorting [5]. Their search time is $O\left(\frac{\log \ell}{\log \log \ell}\right)$ and the space is quadratic. Combining with the fusion tree, this gives query time $O\left(\sqrt{\frac{\log n}{\log \log n}}\right)$ with quadratic space. This is achieved by using the fusion tree when $\log \ell \geq \sqrt{\log n \log \log n}$ and the new data structure when $\log \ell < \sqrt{\log n \log \log n}$. They also prove a matching lower bound, by showing that one cannot achieve space polynomial in n with query time $o\left(\frac{\log \ell}{\log \log \ell}\right)$ for all values of n and w or query time $o\left(\sqrt{\frac{\log n}{\log \log n}}\right)$ for all values of ℓ and w. Later, Sen and Venkatesh show that their lower bound holds even if randomization is allowed [16].

Exponential Search Trees

The *exponential search tree* [4] allows one to transform any predecessor data structure with polynomial space and preprocessing time, and query time $q(n, \ell, w)$, into a data structure with $O(n)$ space and preprocessing time, and query time at most $O(\log \log n \cdot q(n, \ell, w))$. Given some predecessor data structure P that supports queries in time $q(n, \ell, w)$ and uses space and preprocessing time $S(n) = O(n^c)$, the exponential search tree is a recursive data structure built from a sorted set $x_1 < \cdots < x_n$ of n keys as follows:

1. The root has degree $d = n^{1/(c+1)}$.
2. The n keys are partitioned into d blocks of sizes $b = \frac{n}{d}$ each and the data structure P is built on the set which consists in the first element of each of the blocks $2 \ldots d$ (the elements $x_{b+1}, \ldots, x_{(d-1)b+1}$).
3. The root has d children, where every child is itself an exponential search tree built on the $b = n^{c/(c+1)}$ elements of a block.

The recursion stops whenever we have a tree of constant size, in which the predecessor search is trivially supported in constant time. The construction time $C(n)$ follows the equation

$$C(n) = S(n^{1/(c+1)}) + n^{1/(c+1)} \cdot C(n^{c/(c+1)})$$

which gives $C(n) = O(n^{c/(c+1)}) + n^{1/(c+1)} \cdot C(n^{c/(c+1)})$. By iteratively expanding the term $C(n^{c/(c+1)})$, we get $C(n) = O(n)$.

A query is done by traversing the $\log \log n$ levels of the tree and doing predecessor searches at the structure P of each traversed node. The query time follows the equation $Q(n, \ell, w) = q(n^{1/(c+1)}, \ell, w) + Q(n^{c/(c+1)}, \ell, w)$, which solves to $Q(n, \ell, w) = O(\log \log n \cdot q(n, \ell, w))$. In the same paper [4], Andersson and Thorup show how to insert or delete an element in worst-case constant time, once a pointer to its predecessor (or to itself in case of a deletion) has been determined.

Deterministic Dynamic Bounds

When applied to Beame and Fich's solution with time $O\left(\frac{\log \ell}{\log \log \ell}\right)$, the exponential search tree gives $O(n)$ space with time $O\left(\log \log n \cdot \frac{\log \ell}{\log \log \ell}\right)$, and when applied to the

solution with $O\left(\sqrt{\frac{\log n}{\log\log n}}\right)$ time and quadratic space, it keeps the same time bound and achieves $O(n)$ space. By combining the two bounds with the bounds of the fusion tree [15], one gets the following time bounds which are the best known ones for dynamic deterministic predecessor search:

$$O\left(1+\min\left\{\begin{array}{c}\frac{\log n}{\log w}\\ \sqrt{\frac{\log n}{\log\log n}}\\ \log\log n\cdot\frac{\log \ell}{\log\log \ell}\end{array}\right\}\right) \quad (1)$$

The space is $O(n)$ for all the three branches. The bounds refer to the maximum of update and search times.

Optimal Static Bounds

Pătraşcu and Thorup [13] obtained optimal lower and upper bounds for the static case. They obtain optimal trade-offs between the time and the space usage. Define $a = \log\frac{S}{n} + \log w$, where S is the space usage. Then, the optimal time bound is

$$\Theta\left(1+\min\left\{\begin{array}{c}\frac{\log n}{\log w}\\ \log\frac{\ell-\log n}{\log w}\\ \frac{\log\frac{\ell}{a}}{\log\left(\frac{a}{\log n}\cdot\log\frac{\ell}{a}\right)}\\ \frac{\log\frac{\ell}{a}}{\log\left(\log\frac{\ell}{a}\Big/\log\frac{\log n}{a}\right)}\end{array}\right\}\right) \quad (2)$$

They later show that their lower bound holds even if randomization is allowed [14]. The first branch of the upper bound corresponds to the fusion tree. The second branch is obtained by first reducing the length from ℓ to $\ell - \log n$ bits, by dividing the universe into n buckets according to their most significant $\log n$ bits, and then by storing a separate Van Emde Boas structure for every bucket. The query time is then reduced from $O(\log(\ell - \log n))$ to $\log\frac{\ell-\log n}{\log w}$, by stopping the Van Emde Boas recursion when the key length gets to $\log w$ bits. Finally, the last two branches are implemented using a refinement of the technique by Beame and Fich.

Optimal Randomized Dynamic Bounds

When allowing randomization, optimal bounds can be achieved [15]. Again, the bounds are for the maximum of query and update times:

$$\Theta\left(1+\min\left\{\begin{array}{c}\frac{\log n}{\log w}\\ \log\left(\frac{\log(2^\ell-n)}{\log w}\right)\\ \frac{\log\frac{\ell}{\log w}}{\log\left(\log\frac{\ell}{\log w}/\log\frac{\log n}{\log w}\right)}\end{array}\right\}\right) \quad (3)$$

The space usage is linear ($O(n)$) or almost linear $O(nw^{O(1)})$.

The first branch of the upper bound corresponds to the dynamic version of the fusion tree [15] and the third branch to a dynamic version of the fourth branch of the optimal static upper bound. The second branch is similar to the second branch of the optimal static upper bound, with the difference that the term $\ell - \log n$ is replaced by $\log(2^\ell - n)$.

The first and third branches are trivially optimal, since the bounds are the same as the static ones and any lower bound that applies to the latter also applies to the former. The authors show that the second branch is also optimal by proving a corresponding lower bound that is stronger than the static one.

Applications

Range queries are very important in databases. Answering to range queries is an obvious and natural application of predecessor search. A query (in one dimension) asks, given a range $[a, b] \subseteq [1 \ldots 2^\ell]$, to return every element x in the set $S \cap [a, b]$. This can obviously be solved by doing two predecessor queries for a and b and then reporting all elements between the two predecessors (excluding the predecessor of a). In the comparison model and the external memory model, this is the best one can hope for, and the optimal time bounds are $O(\log n + |S \cap [a, b]|)$ and $O(\log_B n +$

$|S \cap [a,b]|/B$) respectively. Surprisingly, in the RAM model, there exists a linear-space static solution with $O(|S \cap [a,b]|)$ query time [3]. An important application of predecessor search is *IP forwarding problem*, which must be solved by every internet router. The router contains a database of subnetworks specified by their IP address prefixes, and each received packet has to be forwarded to the subnetwork with the longest matching prefix. The IP forwarding problem is an instance of the *longest common prefix problem*, which in the static case is equivalent to the predecessor problem.

The lower and upper bounds on predecessor search can be used to prove bounds for other problems through reductions. For example, predecessor search can be reduced to *two-dimensional range search*, allowing one to prove a lower bound of $\Omega(\log \log n)$ time for the two-dimensional range-emptiness problem on sets of n points on a grid of n rows by n columns. Optimal bounds can also be proved for rank queries on sequence representations through reduction to and from predecessor queries [9].

Open Problems

The deterministic complexity of the dynamic predecessor search is still open. Another open problem is whether updates can be supported faster than searches when the search time is optimal or near optimal (of course, one can always support constant update time when the query time is the trivial $\Theta(n)$). For the moment, this is not disallowed by any lower bound and has been achieved for the related *dynamic ranking problem* [10], in which a set $S \subset [1 \ldots 2^\ell]$ is maintained under updates and a query asks, given an integer $y \in S$ to count the number of elements of S smaller than y.

2005; Koutsoupias

Problem Definition

The *price of anarchy* captures the lack of coordination in systems where users are selfish and may have conflicted interests. It was first proposed by Koutsoupias and Papadimitriou in [8], where the term *coordination ratio* was used instead, but later Papadimitriou in [12] coined the term price of anarchy that finally prevailed in the literature.

Roughly, the price of anarchy is the system cost (e.g., makespan, average latency) of the worst-case Nash equilibrium over the optimal system cost that would be achieved if the players were forced to coordinate. Although it was originally defined in order to analyze a simple load-balancing game, it was soon applied to numerous variants and to more general games. The family of *(weighted) congestion games* [11, 13] is a nice abstract form to describe most of the alternative settings. (We focus our presentation on cost minimization problems in congestion games. We mention some utility maximization problems where price of anarchy analysis has been used in the Applications section.)

The price of anarchy may vary, depending on the

- Equilibrium solution concept *(e.g., pure, mixed, correlated equilibria)*
- Characteristics of the congestion game
  - Players Set *(e.g., atomic – non-atomic)*
  - Strategy Set *(e.g., symmetric asymmetric, parallel machines-network-general)*
  - Players' cost functions *(e.g., linear, polynomial)*
- Social cost *(e.g., maximum, sum, total latency)*

Notation

Let G be a (finite) game that is determined by the triple $(N, (\mathcal{S}_i)_{i\in N}, (c_i)_{i\in N})$. $N = \{1, \ldots, n\}$ is the set of the players that participate in the game. $\mathcal{S}_i$ is a *pure strategy set* for player i. An element $A_i \in \mathcal{S}_i$ is a *pure strategy* for player $i \in N$. A *pure strategy profile* $A = (A_1, \ldots, A_n)$ is a vector of pure strategies, one for each player. The set of all possible pure strategy profiles is denoted by $\mathcal{S} = \mathcal{S}_1 \times \cdots \times \mathcal{S}_n$. The *cost* of a player $i \in N$, for a pure strategy, is determined by a cost function $c_i : \mathcal{S} \mapsto \mathbb{R}$.

A pure strategy profile A is a *pure Nash equilibrium*, if none of the players $i \in N$ can benefit, by unilaterally deviating to another pure strategy $s_i \in \mathcal{S}_i$:

$$c_i(A) \leq c_i(A_{-i}, s_i) \qquad \forall i \in N, \quad \forall s_i \in \mathcal{S}_i,$$

where (A_{-i}, s_i) is the simple strategy profile that results when just the player i deviates from strategy $A_i \in \mathcal{S}_i$ to strategy $s_i \in \mathcal{S}_i$.

Similarly, a *mixed strategy* p_i for a player $i \in N$ is a probability distribution over her pure strategy set $\mathcal{S}_i$. A mixed strategy profile p is the tuple $p = (p_1, \ldots p_n)$, where player i chooses mixed strategy p_i. The expected cost of a player $i \in N$ with respect to the p is

$$c_i(p) = \sum_{A \in \mathcal{S}} p(A) c_i(A),$$

where $p(A) = \prod_{i \in N} p_i(A_i)$ is the probability that pure strategy A occurs, with respect to $(p_i)_{i \in N}$. A mixed strategy profile p is a *Nash equilibrium*, if and only if

$$c_i(p) \leq c_i(p_{-i}, s_i) \qquad \forall i \in N, \quad \forall s_i \in \mathcal{S}_i$$

The *social cost* of a pure strategy profile A, denoted by $\mathrm{SC}(A)$, is the maximum cost of a player $\textsc{Max}(A) = \max_{i \in N} c_i(A)$ or the average cost of a player. For simplicity, the sum of the players' cost is considered (i.e., n times the average cost) $\textsc{Sum}(A) = \sum_{i \in N} c_i(A)$. The same definitions extend naturally for the case of mixed strategies, but with expected costs in this case.

The (mixed) *price of anarchy* [8] for a game is the worst-case ratio, among all the (mixed) Nash equilibria, of the social cost over the optimal cost, $\textsc{Opt} = \min_{P \in \mathcal{S}} \mathrm{SC}(P)$.

$$\mathrm{PA} = \max_{p \text{ is N.E.}} \frac{\mathrm{SC}(p)}{\textsc{Opt}}$$

The price of anarchy for a class of games is the maximum (supremum) price of anarchy among all the games of this class.

Congestion Games Here, a general class of games is described that captures most of the games for which price of anarchy is studied in the literature. A *congestion game [11, 13]*, is defined by the tuple $(N, E, (\mathcal{S}_i)_{i \in N}, (f_e)_{e \in E})$, where $N = \{1, \ldots, n\}$ is a set of players, E is a set of *facilities*, $\mathcal{S}_i \subseteq 2^E$ is the pure strategy set for player i, a pure strategy $A_i \in \mathcal{S}_i$ is a subset of the facility set, and f_e is a *cost (or latency) function* (Unless otherwise stated, linear cost functions are only considered throughout this article. See [14] and references therein for results about more general cost functions, and for additional results see entries 00260, 00251, 00053.) with respect to the facility $e \in E$.

A pure strategy profile $A = (A_1, \ldots, A_n)$ is a vector of pure strategies, one for each player. The cost $c_i(A)$ of player i for the pure strategy profile A is given by

$$c_i(A) = \sum_{e \in A_i} f_e(n_e(A)),$$

where $n_e(A)$ is the number of the players that use facility e in A.

A congestion game is called *symmetric or single commodity*, if all the players have the same strategy set: $\mathcal{S}_i = \mathcal{C}$. The term *asymmetric or multi-commodity* is used to refer to all the games including the symmetric ones. A special class is the class of *network congestion games*. In these games, the facilities are edges of a (multi)graph $G(V, E)$. The pure strategy set for a player $i \in N$ is the simple paths set from a source $s_i \in V$ to a destination $t_i \in V$. In network symmetric congestion games, all the players have the same source and destination.

A natural generalization of congestion games are the *weighted congestion games*, where every player controls an amount of traffic w_i. The cost of each facility $e \in E$ depends on the total load of the facility. In this case, a well-studied social cost function is the weighted sum of players costs, or *total latency*.

In a congestion game with *splittable weights (divisible demands)*, every player $i \in N$, instead of fixing a single pure strategy, is allowed to distribute her demand among her pure strategy set.

Finally, in a *non-atomic congestion game*, there are k different player types $1 \ldots k$. Players are infinitesimal and for each player type i the continuum of the players is denoted by the interval $[0, n_i]$. In general, each player type contributes in a different way to the congestion on the facility $e \in E$, and this contribution is

determined by a positive *rate of consumption* $r_{s,e}$ for a strategy $s \in \mathcal{S}_i$ and a facility $e \in s$. Each player chooses a strategy that results in a *strategy distribution* $x = (x_s)_{s\in\mathcal{S}}$, with $\sum_{s\in S_i} x_s = n_i$.

Key Results

Maximum Social Cost

First, we review results on the price of anarchy w.r.t maximum social cost that was historically the first social cost considered in [8]. Formally, for a pure strategy profile A, the social cost is

$$\mathrm{SC}(A) = \textsc{Max}(A) = \max_{i\in N} c_i(A)$$

The definition naturally extends to mixed strategies.

Theorem 1 ([7–10]) *The price of anarchy for m identical machines is* $\Theta\left(\frac{\log m}{\log\log m}\right)$.

Theorem 2 ([7]) *The price of anarchy for m uniformly related machines with speeds* $s_1 \geq s_2 \geq \cdots \geq s_m$ *is*

$$\Theta\left(\min\left\{\frac{\log m}{\log\log\log m}, \frac{\log m}{\log\left(\frac{\log m}{\log(s_1/s_m)}\right)}\right\}\right).$$

Theorem 3 ([4]) *The price of anarchy for pure equilibria is* $\Theta(\sqrt{n})$ *for asymmetric but at most* $5/2$ *for symmetric congestion games.*

Average Social Cost: Total Latency

Here, we consider as social cost the (weighted) sum (total latency) of the players' cost for (weighted) congestion games, i.e.,

$$\mathrm{SC}(A) = \textsc{Sum}(A) = \sum_{i\in N} c_i(A),$$

$$\mathrm{SC}(A) = \mathrm{C}(A) = \sum_{i\in N} w_i c_i(A).$$

The definition naturally extends for mixed strategies.

Theorem 4 ([2–4]) *The price of anarchy is* $5/2$ *for asymmetric and* $\frac{5n-2}{2n+1}$ *for symmetric congestion games.*

Theorem 5 ([2, 3]) *The price of anarchy for weighted congestion games is* $1+\phi \approx 2.618$.

Theorem 6 ([6]) *The price of anarchy is at most* $3/2$ *for congestion games with splittable weights.*

Theorem 7 ([15, 16]) *The price of anarchy for non-atomic congestion games is* $4/3$.

Key Proof Technique: Smoothness Most of the above results on atomic congestion games have been generalized for polynomial latencies [1–3] and hold for various equilibrium concepts. Roughgarden's *smoothness* framework [14] distills the main ideas in these proofs and provides a general, canonical proof recipe to obtain price of anarchy bounds. He also shows how smoothness provides tight bounds for congestion games with general cost functions.

Applications

The efficiency of large-scale networks, in which selfish users interact, is highly affected due to the users' selfish behavior. The price of anarchy is a quantitative measure of the lack of coordination in such systems. It is a useful theoretical tool for the analysis and design of telecommunication and traffic networks, where selfish users compete on system's resources motivated by their atomic interests and are indifferent to the social welfare.

The price of anarchy has been also studied in utility maximization Problems; see, for example, Valid Utility Games [17]. Finally, a line of work shows that price of anarchy can be used to evaluate the performance of mechanisms; see, for example, [5] for an analysis of simultaneous Second-Price Auctions.

Problem Definition

This entry considers a selfish routing model formally introduced by Koutsoupias and Papadimitriou [10], in which the goal is to route the traffic on parallel links with linear latency functions. One can describe this model as a scheduling problem with m independent machines with speeds $s_1, \ldots, s_m$ and n independent tasks with weights $w_1, \ldots, w_n$. The goal is to allocate the tasks to the machines to minimize the maximum load of the links in the system.

It is assumed that all tasks are assigned by noncooperative agents. The set of *pure strategies* for task i is the set $\{1,\ldots,m\}$, and a *mixed strategy* is a distribution on this set.

Given a combination $(j_1,\ldots,j_n) \in \{1,\ldots,m\}^n$ of pure strategies, one for each task, the *cost* for task i is $\sum_{j_k=j_i} \frac{w_k}{s_{j_i}}$, which is the time needed for machine j_i chosen by task i to complete all tasks allocated to that machine. Similarly, for a combination of pure strategies $(j_1,\ldots,j_n) \in \{1,\ldots,m\}^n$, the *load* of machine j is defined as $\sum_{j_k=j} \frac{w_k}{s_j}$.

Given n tasks of length $w_1,\ldots,w_n$ and m machines with the speeds $s_1,\ldots,s_m$, let opt denote the *social optimum*, that is, the minimum cost over all combinations of pure strategies:

$$\mathsf{opt} = \min_{(j_1,\ldots,j_n)\in\{1,\ldots,m\}^n} \max_{1\le j\le m} \sum_{i:j_i=j} \frac{w_i}{s_j}.$$

For example, if all machines have the same unit speed ($s_j = 1$ for every j, $1 \le j \le m$) and all tasks have the same unit weight ($w_i = 1$ for every i, $1 \le i \le n$), then the social optimum is $\lceil \frac{n}{m} \rceil$.

It is also easy to see that in any system

$$\mathsf{opt} \ge \frac{\max_i w_i}{\max_j s_j}.$$

It is known that computing the social optimum is $\mathcal{NP}$-hard even for identical speeds (see [10]).

For mixed strategies, let p_i^j denote the probability that an agent i sends the entire traffic w_i to a machine j. Let ℓ_j denote the *expected load* on a machine j, that is,

$$\ell_j = \frac{1}{s_j} \cdot \sum_{i=1}^{n} w_i\, p_i^j.$$

For a task i, the *expected cost of task i on machine j* is equal to

$$c_i^j = \frac{w_i}{s_j} + \sum_{t\ne i} \frac{w_t\, p_t^j}{s_j} = \ell_j + (1 - p_i^j)\,\frac{w_i}{s_j}.$$

The expected cost c_i^j corresponds to the expected finish time of task i on machine j under the processor sharing scheduling policy. This is an appropriate cost model with respect to the underlying traffic routing application.

Definition 1 (Nash equilibrium) The probabilities $(p_i^j)_{1\le i\le n, 1\le j\le m}$ define a *Nash equilibrium* if and only if any task i will assign nonzero probabilities only to machines that minimize c_i^j, that is, $p_i^j > 0$ implies $c_i^j \le c_i^q$, for every q, $1 \le q \le m$.

As an example, in the system considered above in which all machines have the same unit speed and all weights are the same, the uniform probabilities $p_i^j = \frac{1}{m}$ for all $1 \le j \le m$ and $1 \le i \le n$ define a system in a Nash equilibrium.

The existence of a Nash equilibrium over mixed strategies for noncooperative games was shown by Nash [13]. In fact, the routing game considered here admits an equilibrium even if all players are restricted to pure strategies, what has been shown by Fotakis et al. [7].

Fix an arbitrary Nash equilibrium, that is, fix the probabilities $(p_i^j)_{1\le i\le n, 1\le j\le m}$ that define a Nash equilibrium. Consider the randomized allocation strategies in which each task i is allocated to a single machine chosen independently at random according to the probabilities p_i^j, that is, task i is allocated to machine j with probability p_i^j. Let C_j, $1 \le j \le m$, be the random variable indicating the *load of machine j* in our random experiment. Observe that C_j is the weighted sum of independent 0–1 random variables J_i^j, $\mathbf{Pr}[J_i^j = 1] = p_i^j$, such that

$$C_j = \frac{1}{s_j} \sum_{i=1}^{n} w_i \cdot J_i^j.$$

Let $\mathfrak{c}$ denote the *maximum expected load* over all machines, that is,

$$\mathfrak{c} = \max_{1\le j\le m} \ell_j.$$

Notice that $\mathbf{E}[C_j] = \ell_j$, and therefore, $\mathfrak{c} = \max_{1\le j\le m} \mathbf{E}[C_j]$.

Finally, let the *social cost* C be defined as the expected maximum load (instead of maximum expected load), that is,

$$\mathsf{C} = \mathbf{E}[\max_{1 \le j \le m} C_j].$$

Observe that $c \le C$ and possibly $c \ll C$. The goal is to estimate the *price of anarchy* (also called the *worst-case coordination ratio*) which is the worst-case ratio

$$R = \max \frac{\mathsf{C}}{\mathsf{opt}},$$

where the maximum is over all Nash equilibria.

Key Results

Early Work

The study of the price of anarchy has been initiated by Koutsoupias and Papadimitriou [10], who showed also some very basic results for this model. For example, they proved that for two identical machines, the price of anarchy is exactly $\frac{3}{2}$, and for two machines (with possibly different speeds), the price of anarchy is at least $\phi = \frac{1+\sqrt{5}}{2}$. Koutsoupias and Papadimitriou showed also that for m identical machines, the price of anarchy is $\Omega(\frac{\log m}{\log \log m})$ and it is at most $\mathcal{O}(\sqrt{m \ln m})$, and for m arbitrary machines, the price of anarchy is $\mathcal{O}(\sqrt{\frac{s_1}{s_m} \sum_{j=1}^{m} \frac{s_j}{s_m}} \sqrt{\log m})$, where $s_1 \ge s_2 \ge \cdots \ge s_m$ [10].

Koutsoupias and Papadimitriou [10] conjectured also that the price of anarchy for *m identical machines* is $\Theta(\frac{\log m}{\log \log m})$. In the quest to resolve this conjecture, Mavronicolas and Spirakis [12] considered the problem in the so-called fully mixed model, which is a special class of Nash equilibria in which all p_i^j are strictly positive. In this model, Mavronicolas and Spirakis [12] showed that for m identical machines in the fully mixed Nash equilibrium, the price of anarchy is $\Theta(\frac{\log m}{\log \log m})$. Similarly, they proved also that for m (not necessarily identical) machines and n identical weights in the fully mixed Nash equilibrium, if $m \le n$, then the price of anarchy is $\Theta(\frac{\log n}{\log \log n})$.

The motivation behind studying fully mixed equilibria is the so-called fully mixed Nash equilibrium conjecture stating that these equilibria maximize the price of anarchy because they maximize the randomization. The conjecture seems to be quite appealing as a fully mixed equilibrium can be computed in polynomial time, which led to numerous studies of this kind of equilibria with the hope to obtain efficient algorithms for computing or approximating the price of anarchy with respect to mixed equilibria. However, Fischer and Vöcking [6] disproved the fully mixed Nash equilibrium conjecture and showed that there is a mixed Nash equilibrium whose expected cost is larger than the expected cost of the fully mixed Nash equilibrium by a factor of $\Omega(\frac{\log m}{\log \log m})$. Furthermore, they presented polynomial time algorithms for approximating the price of anarchy for mixed equilibria on identical machines up to a constant factor.

Tight Bounds for the Price of Anarchy

Czumaj and Vöcking [4] entirely resolved the conjecture of Koutsoupias and Papadimitriou [10] and gave an exact description of the price of anarchy as a function of the number of machines and the ratio of the speed of the fastest machine over the speed of the slowest machine. (To simplify the notation, for any real $x \ge 0$, let $\log x$ denote $\log x = \max\{\log_2 x, 1\}$. Also, following standard convention, $\Gamma(N)$ is used to denote the *gamma (factorial) function*, which for any natural N is defined by $\Gamma(N+1) = N!$ and for an arbitrary real $x > 0$ is $\Gamma(x) = \int_0^\infty t^{x-1} e^{-t}\, dt$. For the inverse of the gamma function, $\Gamma^{(-1)}(N)$, it is known that $\Gamma^{(-1)}(N) = x$ such that $\lfloor x \rfloor ! \le N - 1 \le \lceil x \rceil !$. It is well known that $\Gamma^{(-1)}(N) = \frac{\log N}{\log \log N}(1 + o(1))$.)

Theorem 1 ([4] Upper bound)

The price of anarchy for m machines is bounded from above by

$$\mathcal{O}\left(\min\left\{\frac{\log m}{\log\log\log m}, \frac{\log m}{\log\left(\frac{\log m}{\log(s_1/s_m)}\right)}\right\}\right),$$

where it is assumed that the speeds satisfy $s_1 \ge \cdots \ge s_m$.

In particular, the price of anarchy for m machines is $\mathcal{O}\left(\frac{\log m}{\log\log\log m}\right)$.

The theorem follows directly from the following two results [4]: that the maximum expected load $\mathfrak{c}$ satisfies $\mathfrak{c} = \mathfrak{opt} \cdot \Gamma^{(-1)}(m) = \mathfrak{opt} \cdot \mathcal{O}\left(\min\left\{\frac{\log m}{\log\log m}, \log\left(\frac{s_1}{s_m}\right)\right\}\right)$ and that the social cost C satisfies $\mathsf{C} = \mathfrak{opt} \cdot \mathcal{O}\left(\frac{\log m}{\log\left(\frac{\mathfrak{opt}\cdot\log m}{c}\right)} + 1\right)$.

If one applied these results to systems in which all agents follow only *pure strategies*, then since then $\ell_j = C_j$ for every j, it holds that $\mathsf{C} = \mathfrak{c}$. This leads to the following result.

Corollary 1 ([4]) *For pure strategies the price of anarchy for m machines is upper bounded by*

$$\mathcal{O}\left(\min\left\{\frac{\log m}{\log\log m}, \log\left(\frac{s_1}{s_m}\right)\right\}\right),$$

where it is assumed that the speeds satisfy $s_1 \geq \cdots \geq s_m$.

Theorem 3 below proves that this corollary gives an asymptotically tight bound for the price of anarchy for pure strategies.

By Theorem 1, in the special case when all *machines are identical*, the price of anarchy is $\mathcal{O}\left(\frac{\log m}{\log\log m}\right)$; this result has been also obtained independently by Koutsoupias et al. [11]. However, in this special case one can get a stronger bound that is tight up to an additive constant.

Theorem 2 ([4]) *For m identical machines the price of anarchy is at most*

$$\Gamma^{(-1)}(m) + \Theta(1) = \frac{\log m}{\log\log m} \cdot (1 + o(1)).$$

One can obtain a lower bound for the price of anarchy for *m identical machines* by considering the system in which $p_i^j = \frac{1}{m}$ for every i, j. Gonnet [9] proved that then the price of anarchy is $\Gamma^{(-1)}(m) - \frac{3}{2} + o(1)$, which implies that Theorem 2 is tight up to an additive constant.

The next theorem shows that the upper bound in Theorem 1 is asymptotically tight.

Theorem 3 ([4] Lower bound) *The price of anarchy for m machines is lower bounded by*

$$\Omega\left(\min\left\{\frac{\log m}{\log\log\log m}, \frac{\log m}{\log\left(\frac{\log m}{\log(s_1/s_m)}\right)}\right\}\right).$$

In particular, the price of anarchy for m machines is $\Omega\left(\frac{\log m}{\log\log\log m}\right)$.

In fact, it can be shown [4] (analogously to the upper bound) that for every positive integer m, positive real r, and $S \geq 1$, there exists a set of m machines with $\frac{s_1}{s_m} = S$ being in a Nash equilibrium and satisfying $\mathfrak{opt} = r$, $\mathfrak{c} = \mathfrak{opt} \cdot \Omega\left(\min\left\{\frac{\log m}{\log\log m}, \log\left(\frac{s_1}{s_m}\right)\right\}\right)$, and $C = \mathfrak{opt} \cdot \Omega\left(\frac{\log m}{\log\left(\frac{\mathfrak{opt}\cdot\log m}{c}\right)}\right)$.

Applications

The model discussed here has been extended in the literature in numerous ways, in particular in [1,5,8]; see also survey presentations in [3,14].

Open Problems

An interesting attempt that adds an algorithmic or constructive element to the analysis of the price of anarchy is made in [2]. The idea behind "coordination mechanisms" is not to study the price of anarchy for a fixed system, but to design the system in such a way that the increase in cost or the loss in performance due to selfish behavior is as small as possible. This is a promising direction of research that might result in practical guidelines of how to build a distributed system that does not suffer from selfish behavior but might even exploit the selfishness of the agents.

Problem Definition

Let there be n agents and a set of feasible outcomes Ω. For concreteness, readers may think of Ω as the set of allocations of m items to n agents. Each agent has a private value function $v_i : \Omega \mapsto [0, 1]$ over feasible outcomes. We focus on direct revelation mechanisms, which first let each agent i report a value function $\bar{v}_i$, then choose a feasible outcome $\omega \in \Omega$ and a payment p_i for each agent i according to the reported value functions. Let $\omega(\bar{v})$ and $p(\bar{v})$ denote the outcome and payment vector chosen by the mechanism. Note that both $\omega(\bar{v})$ and $p(\bar{v})$ may be random variables.

We hope to achieve the following three objectives:

Objective 1: Maximizing Social Welfare

The social welfare of a feasible outcome $\omega \in \Omega$ is the sum of the agents' values for the outcome, namely, $\sum_{i=1}^{n} v_i(\omega)$. We hope to approximately maximize the expected social welfare of the chosen outcome over the randomness of the mechanism, a widely considered objective in mechanism design.

Approximately maximizing social welfare given the true value functions is a well-studied algorithmic problem (e.g., [4, 16]). In our mechanism design setting, agents may choose

not to report the true value if it fits their interests. So the mechanism has an additional challenge of motivating the agents to report truthfully.

Objective 2: Incentive Compatibility

We adopt the standard assumption that each agent i aims to maximize the expectation of his quasi-linear utility, which equals his value for the chosen outcome less his payment. A mechanism is *incentive compatible* if truth telling maximizes an agent's expected utility regardless of the reported values of other agents, that is, for any agent i, any true value v_i, reported value $\bar{v}_i$, and any reported values of other agents $\bar{v}_{-i}$, we have $\mathbb{E}[v_i(\omega(v_i, \bar{v}_{-i})) - p_i(v_i, \bar{v}_{-i})] \geq \mathbb{E}[v_i(\omega(\bar{v}_i, \bar{v}_{-i})) - p_i(\bar{v}_i, \bar{v}_{-i})]$. We also consider a relaxed notion called α-*incentive compatibility*, where an agent's expected utility of truth telling can be worst off by at most an α additive factor comparing to his utility of reporting any alternative value.

There is a vast literature on designing incentive compatible mechanisms with approximately optimal social welfare (see, e.g., [11] for a comprehensive survey). We remark the Vickrey-Clarke-Groves (VCG) mechanism [2, 5, 15], which chooses an outcome that maximizes the social welfare and uses payments to align the interests of the agents and the mechanism designer. When computational efficiency is not of concern, the VCG mechanism gives optimal social welfare and is incentive compatible for arbitrary problems. However, it does not achieve the next objective.

Objective 3: Protecting Agents' Privacy

Our last objective is to protect the agents' privacy by ensuring that the chosen outcome and payments do not reveal too much information about any individual agent' private value function. Agents may care about their privacy for both exogenous and endogenous reasons. On the one hand, privacy is a basic desideratum. On the other hand, violating an agent's privacy could explicitly hurt the agent's utility in the future, e.g., companies may post higher reserve prices based on an agent's past values if such information is revealed by previous mechanisms.

Definition 1 ([3]) A mechanism is (ϵ, δ)-differentially private if for any agent i, any value v_i, alternative value v_i', any values of other agents v_{-i}, and any subset of feasible outcome $S \subseteq \Omega$,

$$\Pr[\omega(v_i, v_{-i}) \in S] \leq e^{\epsilon} \cdot \Pr[\omega(v_i', v_{-i}) \in S] + \delta \ .$$

We remark that the payments may violate the agents' privacy as well. Nevertheless, we can make the prices privacy preserving without changing the agents' expected utilities by adding any scale of noise with expectation zero to the payments. (Having arbitrarily large variance in the payment and, thus, in the utility of an agent is an undesirable property. In some settings, it is possible to privately compute prices without having large variance. Readers are referred to Hsu et al. [6] for details, which we will omit due to space constraint.) So we focus on the privacy property of the outcome in the above definition.

We provide two informal interpretations of differential privacy (for sufficiently small δ). Information theoretically, a mechanism being (ϵ, δ)-differentially private implies that the outcome reveals at most $O(\epsilon^2)$ bits of information about any individual agent's private value. Game theoretically, it implies that truth telling may decrease an agent's future utility by at most a factor of $e^{-\epsilon} \approx 1 - \epsilon$.

For some mechanism design problems, such as auctioning m items to n agents, no (ϵ, δ)-differentially private mechanisms can approximately maximize social welfare. For such resource allocation problems, let ω_{-i} denote the allocation to all agents except agent i. We consider the following relaxed notion of privacy:

Definition 2 ([8]) A mechanism is (ϵ, δ)-jointly differentially private if for any agent i, any value v_i, alternative value v_i', any values of other agents v_{-i}, and any subset of feasible outcome $S \subseteq \Omega$,

$$\Pr[\omega_{-i}(v_i, v_{-i}) \in S] \leq e^{\epsilon} \cdot \Pr[\omega_{-i}(v_i', v_{-i}) \in S] + \delta \ .$$

In settings where each agent can see only his own allocation, a mechanism being (ϵ, δ)-jointly

differentially private also implies that it reveals at most $O(\epsilon^2)$ bits of information of an agent's value and that truth telling decreases an agent's future utility by at most $e^{-\epsilon}$, even if the adversary colludes with all other agents.

Related Work

The problem we consider in this article falls into the growing literature on the interface of game theory and differential privacy (see, e.g., Pai and Roth [14] for a survey). McSherry and Talwar [10] proposed using differentially private mechanisms to design auctions by pointing out that differential privacy implies approximate incentive compatibility and resilience to collusion. They also proposed the exponential mechanism, which is an important building block in one of the results we will discuss. Nissim et al. [13] showed how to convert differentially private mechanisms into exactly incentive compatible mechanisms in some settings, but the final mechanisms no longer protect agents' privacy. Xiao [17] proposed mechanisms that are both incentive compatible and differentially private in some special cases. Unfortunately, it does not seem possible to extend the results of Nissim et al. [13] and Xiao [17] to more general problems. Finally, Xiao [17], Chen et al. [1], and Nissim et al. [12] considered modeling the agents' concern for privacy in the utility functions and introduced incentive compatible mechanisms for some special cases in this model. In sum, most previous techniques apply only to special cases. In this article, we summarize two recent techniques for designing privacy-preserving auctions for a large family of mechanism design problems.

Key Results

Almost all mechanism design problems can be classified into two families: social choice problems and resource allocation problems. In a social choice problem, the set of feasible outcome is independent of the number of agents n. In particular, the number of feasible outcome is independent of n. For example, leader elections and choosing a subset of public projects subject a budget constraint fall into this family. In a resource allocation problem, such as allocating m items to n agents, the set of feasible outcome depends on the number of agents. In particular, the number of feasible outcome grows exponentially with n. Below we discuss two techniques by Huang and Kannan [7] and Hsu et al. [6] for designing privacy-preserving auctions for these two families of problems, respectively.

Social Choice Problems

Huang and Kannan [7] proposed a technique for designing incentive compatible and ϵ-differentially private mechanisms for arbitrary mechanism design problems. For social choice problems, in particular, this technique also gives nearly optimal social welfare.

Theorem 1 ([7]) *For any mechanism design problem, there is an incentive compatible and ϵ-differentially private mechanism that gives at least* $\mathrm{OPT} - \frac{2}{\epsilon}(\ln|\Omega| + \ln\frac{1}{\beta})$ *social welfare with probability at least* $1-\beta$.

This mechanism is based on the exponential mechanism by McSherry and Talwar [10], a general differentially private mechanism that can be applied to a large family of problems. The social welfare guarantee and ϵ-differential privacy in Theorem 1 follow directly from properties of the exponential mechanism. However, the exponential mechanism is not incentive compatible in general. Huang and Kannan [7] noticed that the exponential mechanism can be viewed as maximizing a linear combination of the social welfare and the Shannon entropy of the outcome distribution. Therefore, its allocation rule is equivalent to that of the VCG mechanism in a virtual market where the set of feasible outcomes are distributions over the original outcomes, the set of agents are the original n agents plus an additional agent whose value equals the entropy of the chosen distribution. As a result, using the payments in the virtual market along with the exponential mechanism achieves incentive compatibility.

In social choice problems, $\ln|\Omega|$ is a constant independent of n. So the loss in social welfare is a constant independent of n. On the other hand,

the social welfare is the sum of n agents' values, each of which is between 0 and 1. Hence, in a large market with many agents, it is reasonable to expect the optimal social welfare (if not of scale $\Theta(n)$) to be much larger than the additive loss in Theorem 1 in practical instances.

In resource allocation problems, however, $|\Omega|$ grows exponentially in n and, thus, $\ln|\Omega|$ is of scale $\Omega(n)$. For instance, consider matching $m = n$ items to n agents. Then, $|\Omega| = n!$ and $\ln|\Omega| = \Omega(n \ln n)$. Even if the optimal social welfare is of scale $\Theta(n)$, we would need ϵ to be at least $\Omega(\ln n)$ to have nontrivial social welfare guarantee in Theorem 1. This means that the mechanism would reveal $\Omega(\ln^2 n)$ bits of information of an agent's private value, and truth telling may decrease an agent's future utility by a poly(n) factor. Further, this is not only a limitation of the current technique. Huang and Kannan [7] showed that no ϵ-differentially private can give nontrivial social welfare guarantee for $\epsilon = o(\ln n)$, even without incentive compatibility.

Resource Allocation Problems

Given the obstacles for applying differential privacy to resource allocation problems, Hsu et al. [6] looked into a relaxed notion of privacy, namely, joint differential privacy. In particular, they considered matching m items to n agents where each item has a supply of at least s copies and then generalized the results to combinatorial auctions with gross substitute value functions (e.g., [9]). Their first result is a jointly differentially private (yet not incentive compatible) mechanism with nearly optimal social welfare when the supply s is poly-logarithmic in n and m. Their main technique is a noisy variant of the deferred-acceptance algorithm by Kelso and Crawford [9].

Theorem 2 ([6]) *For combinatorial auctions with gross substitute valuations, there is an ϵ-jointly differentially private algorithm that gives at least $OPT - \alpha n$ social welfare with probability at least $1-\beta$ if $s = \Omega(\frac{1}{\epsilon\alpha^3}\text{polylog}(n, m, \frac{1}{\alpha}, \frac{1}{\beta}))$.*

They also showed a supply of $\omega(1)$ is needed for a jointly differentially private mechanism to achieve $o(n)$ additive loss in social welfare. More precisely, they showed:

Theorem 3 ([6]) *No jointly differentially private algorithm can compute matchings with social welfare at least $OPT - \alpha n$ if $s \le O(\frac{1}{\sqrt{\alpha}})$.*

Their approach can also be used to design approximately incentive compatible and jointly differentially private mechanisms, but the supply needs to be polynomially large.

Theorem 4 (implicit in [6]) *For combinatorial auctions with gross substitute valuations, there is an α-incentive compatible and ϵ-jointly differentially private algorithm that gives at least $OPT - \alpha n$ social welfare with probability at least $1-\beta$ if $s = \Omega(m)$, where the constant depends on ϵ, δ, α, and β.*

Open Problems

The results of Huang and Kannan [7] and Hsu et al. [6] provided a preliminary step towards designing auctions that protect agents' privacy. There are still many open problems in this topic, some of which we sketch below.

First, the techniques of Hsu et al. [6] fundamentally rely on properties of gross substitute value functions and, thus, cannot be extended to more general value functions. Further, there are many important families of value functions beyond gross substitute, e.g., sub-modular functions, sub-additive functions, etc. So it is natural to seek for techniques that work for more general families of value functions.

Problem 1 Are there jointly differentially private mechanisms that achieve nearly optimal social welfare for arbitrary value functions?

Even if we restrict our attention to gross substitute value functions or even to matching markets, Theorems 2 and 3 leave a large gap between the upper and lower bounds on the supply needed by jointly differentially private mechanisms to get nearly optimal social welfare. Closing this gap would advance our understanding on joint differential privacy.

Problem 2 What is the minimal supply needed so that a jointly differentially private mechanism can achieve nearly optimal social welfare in combinatorial auctions? In particular, is the logarithmic dependency on n and m in Theorem 2 necessary?

Finally, the current technique for achieving both approximate incentive compatibility and joint differential privacy requires a polynomially large supply of items, much larger than the supply needed for achieving joint differential privacy alone. Does approximate incentive compatibility make the problem fundamentally harder? Or is it just a limitation of the current technique?

Problem 3 What is the minimal supply needed so that an approximately incentive compatible and jointly differentially private mechanism can achieve nearly optimal social welfare in combinatorial auctions? In particular, is the polynomial dependency on m in Theorem 4 necessary?

Problem Definition

Spectral analysis refers to a family of popular and effective methods that analyze an input matrix by exploiting information about its eigenvectors or singular vectors. Applications include principal component analysis, low-rank approximation, and spectral clustering. Many of these applications are commonly performed on data sets that feature sensitive information such as patient records in a medical study. In such cases privacy is a major concern. Differential privacy is a powerful general-purpose privacy definition. This entry explains how differential privacy may be applied to task of approximately computing the top singular vectors of a matrix.

Generally speaking, the input is a real-valued matrix $A \in \mathbb{R}^{m \times n}$ and a parameter $k \in \mathbb{N}$. We think of the input matrix as specifying n attributes for m individuals. The goal of the algorithm is to approximately compute the first $k \leq \min\{m, n\}$ singular vectors of A while achieving differential privacy. There are several notions of approximation as well as several variants of differential privacy that make sense in this context.

Approximation Guarantee

Let $A = U\Sigma V^\top$ denote the singular value decomposition of A with singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_{\max\{m,n\}} \geq 0$. Further, let U_k and V_k represent the first k columns of U and V, respectively. In other words, U_k consists of the first k left singular vectors of A and V_k consists of the first k right singular vectors.

Principal Angle

Principal angles are a useful tool for comparing the distance between subspaces. The sine of the largest principal angle between subspaces X, Y of equal dimension represented by orthonormal matrices is defined as $\sin\theta(X, Y) = \left\|(I - XX^\top)Y\right\|_2$, where the norm refers to the spectral norm (or ℓ_2-operator norm).

A natural objective is to require that the algorithm $\mathcal{M}$ outputs an orthonormal matrix $X \in \mathbb{R}^{m \times k}$ so as to minimize $\left\|(I - XX^\top)V_k\right\|$. We call this the *principal angle objective*. The angle is of course 0 when $X = V_k$. We will also be interested in the case where the rank of X is larger than the rank of V_k. Note that our objective is still well defined.

Expressed Variance

Another natural objective is to output an orthonormal matrix $X \in \mathbb{R}^{m \times k}$ so as to maximize the variance captured by the subspace spanned by the columns of X. A convenient way to express this objective is to maximize the quantity $\|AX\|_F^2$, where the norm refers to the Frobenius norm. It is not difficult to show that this objective is maximized for $X = V_k$. Again, the objective is still well defined when the rank of X is larger than that of X.

Privacy Guarantee

Differential privacy requires the definition of a *neighborhood relation* on matrices, denoted $A \sim A'$. Pairs of matrices in this relation are called *neighboring*. Differential privacy requires that the algorithm maps neighboring databases to nearly indistinguishable output distributions.

Definition 1 Given a neighborhood relation $\sim$, we say that a randomized algorithm $\mathcal{M}$ satisfies (ϵ, δ)-differential privacy if for all neighboring matrices $A \sim A'$ and for every measurable set S in the output space of the algorithm, we have that

$$\Pr\{\mathcal{M}(A) \in S\} \leq \exp(\epsilon)\Pr\left\{\mathcal{M}(A') \in S\right\} + \delta\,. \tag{1}$$

Neighborhood Relations. Typically in differential privacy, the neighborhood relation is chosen to be the set of all pairs of matrices that differ in at most one row. Unfortunately, this definition is unattainable in the spectral setting as the privacy definition is sensitive to the scale of the row vector that's being changed. Indeed, if we replace a single row of the matrix by a vector Δu of norm Δ, then as we let Δ tend to infinity, the top right singular vector of the matrix will tend to the vector u (say, in angle).

To circumvent this problem, we will generally specify a norm bound in each neighbor relation. It is important to note that the strength of privacy

definition then depends on the scaling of the matrix.

- We say that A, A' are *entry neighbors* if they differ by at most 1 in absolute value.
- We say that A, A' are *row neighbors* if they differ in at most one row by a vector whose Euclidean norm is bounded by 1.

All entry neighbors are of course also row neighbors so that the privacy definition based on row neighbors is stronger than that of entry neighbors. It is sometimes natural to scale the matrix such that either all entries have magnitude at most 1 or all rows have Euclidean norm at most 1. While this may strengthen the privacy guarantee, it also leads to a corresponding deterioration in the utility guarantee of the algorithm as the signal-to-noise ratio decreases. It is tempting to nonuniformly scale each row by a different factor. However, this can dramatically change the singular vector decomposition and does not in general lead to an easily interpretable guarantee.

Key Results

We describe two simple and effective methods that lead to nearly optimal approximation guarantees in various settings we introduced above. The first algorithm is based on the well-known power method. The other uses a simple Gaussian noise addition step (Fig. 1).

Noisy Power Method

For simplicity we describe the algorithm in the case where A is a symmetric $n \times n$ matrix. The algorithm extends straightforwardly to rectangular and asymmetric matrices as explained in [5]. We first state a general-purpose analysis of PPM.

Theorem 1 ([3]) *Let $k \leq p$. Then, the private power method satisfies (ϵ, δ)-differential privacy under the entry neighbor relation, and after $L = O(\frac{\sigma_k}{\sigma_k - \sigma_{k+1}} \log(n))$ iterations, we have with probability $9/10$ that*

$$\left\| (I - X_L X_L^\top) V_k \right\| \leq O\Big(\frac{\sigma \max_{\ell=0}^{L} \|X_\ell\|_\infty \sqrt{n \log L}}{\sigma_k - \sigma_{k+1}} \cdot \frac{\sqrt{p}}{\sqrt{p} - \sqrt{k-1}} \Big).$$

When $p = k + \Omega(k)$, the trailing factor becomes a constant. If $p = k$, it creates a factor k overhead. In the worst case we can always bound $\|X_\ell\|_\infty$ by 1 since X_ℓ is an orthonormal basis. However, in principle, we could hope that a much better bound holds provided that the target basis V_k has small coordinates. Hardt and Roth [4, 5] suggested a way to accomplish a stronger bound by considering a notion of *coherence* of A, denoted as $\mu(A)$. The coherence parameter varies between 1 and n but is often sublinear in n. Intuitively, the coherence measures the correlation between the singular vectors of the matrix with the standard basis. Low coherence means that the singular vectors have small coordinates in the standard basis. Many results on matrix completion and robust PCA crucially rely on such an assumption though the exact notion is somewhat different here. Specifically, if $A = V \Sigma V^\top$ is a singular vector decomposition of A, we define $\mu(A) \stackrel{\text{def}}{=} n \max_{i,j \in [n} |V_{ij}|^2$.

Theorem 2 ([3]) *Under the assumptions of Theorem 3, we have the conclusion*

Input: Symmetric $A \in \mathbb{R}^{n \times n}$, L, p, privacy parameters $\varepsilon, \delta > 0$
1. Let X_0 be a random orthonormal basis and put $\sigma = \varepsilon^{-1} \sqrt{4pL \log(1/\delta)}$
2. For $\ell = 1$ to L:
   a) $Y_\ell \leftarrow A X_{\ell-1} + G_\ell$ where $G_\ell \sim \mathrm{N}(0, \|X_{\ell-1}\|_\infty^2 \sigma^2)^{n \times p}$.
   b) Compute the QR-factorization $Y_\ell = X_\ell R_\ell$

Output: Matrix X_L

Private Spectral Analysis, Fig. 1 Private power method. Here $\|X\|_\infty = \max_{ij} |X_{ij}|$

Input: Matrix $A \in \mathbb{R}^{m \times n}$, privacy parameters $\varepsilon, \delta > 0$, parameter $p \in \mathbb{N}$
1. Let E be a symmetric matrix where the upper triangle (including the diagonal) is sampled i.i.d. from $N(0, \sigma^2)$ where $\sigma = \sqrt{2\ln(1.25/\delta)}/\varepsilon$
2. $C \leftarrow A^\top A + E$

Output: Top p singular vectors $X \in \mathbb{R}^{n \times p}$ of $\widetilde{C}$

Private Spectral Analysis, Fig. 2 Gaussian mechanism

$$\left\|(I - X_L X_L^\top) V_k\right\| \leq O\left(\frac{\sigma\sqrt{\mu(A)\log n \log L}}{\sigma_k - \sigma_{k+1}} \cdot \frac{\sqrt{p}}{\sqrt{p} - \sqrt{k-1}}\right).$$

Gaussian Mechanism

The Gaussian mechanism first appeared in [1] and was recently revisited [2]. The algorithm simply computes the covariance matrix of the data set and adds suitably scaled (symmetric) Gaussian noise to the covariance matrix. The result is differentially private, and the top singular vectors of the perturbed covariance matrix serve as an approximation of the true singular vectors (Fig. 2).

Theorem 3 ([2]) *Let $k \leq p$. .Then, the Gaussian mechanism satisfies (ϵ, δ)-differential privacy under the row neighbor relation, and with probability $1 - o(1)$, we have $\|AX\|_F^2 \geq \|AV_k\|_F^2 - O\left(\sigma k\sqrt{n}\right)$. Moreover, with probability $1 - o(1)$,*

$$\|AX\|_F^2 \geq \|AV_k\|_F^2 - O\left(\frac{\sigma^2 pn}{\sigma_k^2 - \sigma_{p+1}^2}\right).$$

Applications

Principal Component Analysis

In principal component analysis, the goal is to compute the top k singular vectors of the $n \times n$ matrix $A^\top A$. Recall that we identified data points with row vectors in A. The singular vectors of $A^\top A$ are identical to the right singular vectors of A. Hence, both algorithms we previously discussed immediately solve this problem.

Low-Rank Approximation

In low-rank approximation, the goal is to output a matrix B of rank k such that $\|A - B\|_\nu$ is small, where $\nu \in \{2, F\}$. For either norm, the optimal solution is given by the truncated singular value decomposition $B = U_k \Sigma_k V_k^\top$. In the context of privacy-preserving spectral analysis, a good approximation $\tilde{V}_k$ to V_k typically leads to a good low-rank approximation by performing a privacy-preserving multiplication step $\tilde{\Sigma}_k \tilde{U}_k = A\tilde{V}_k + N$, where N is suitably chosen noise matrix. See, for example, [5].

Open Problems

1. Is it possible to obtain an expressed variance guarantee for the noisy power method? For instance, can we match the bounds achieved by Gaussian noise addition via the power method? The problem with the Gaussian mechanism is that it computes the matrix $A^\top A$ which is impractical when n is large but A may be sparse. In this case, the power method is computationally far more efficient.
2. Can we weaken the incoherence assumption in Theorem 2?
3. Theorem 3 depends on the separation between σ_k and σ_{k+1} even when $p > k$. Is it possible to replace the dependence on $\sigma_k - \sigma_{k+1}$ with a dependence on $\sigma_k - \sigma_{p+1}$?

Problem Definition

An important problem in wireless sensor networks is that of *local detection and propagation*, i.e., the local sensing of a crucial event and the energy and time efficient propagation of data reporting its realization to a control center (for a graphical presentation, see Fig. 1). This center (called the *"sink"*) could be some human authorities responsible of taking action upon the realization of the crucial event. More formally:

Definition 1 Assume that a single sensor, E, senses the realization of a *local event* $\mathcal{E}$. Then the *propagation problem* is the following: "How can sensor P, via cooperation with the rest of the sensors in the network, efficiently propagate information reporting the realization of the event to the sink S?"

Note that this problem is in fact closely related to the more general problem of data propagation in sensor networks.

Wireless Sensor Networks

Recent dramatic developments in micro-electro-mechanical systems (MEMS), wireless communications and digital electronics have led to the development of small in size, low-power, low-cost sensor devices. Such extremely small (soon in the cubic millimetre scale) devices integrate sensing, data processing and wireless communication capabilities. Examining each such device individually might appear to have small utility, however the effective *distributed self-organization* of large numbers of such devices into an ad-hoc network may lead to the efficient accomplishment of large sensing tasks. Their wide range of applications is based on the use of various sensor types (i.e., thermal, visual, seismic, acoustic, radar, magnetic, etc.) to monitor a wide variety of conditions (e.g., temperature, object presence and movement, humidity, pressure, noise levels etc.). For a survey on wireless sensor networks see [1] and also [6, 9].

A Simple Model

Sensor networks are comprised of a vast number of ultra-small homogeneous sensors, which are called *"grain" particles*. Each grain particle is a fully-autonomous computing and communication device, characterized mainly by its available power supply (battery) and the energy cost of computation and transmission of data. Such particles (in the model here) do not move. Each particle is equipped with a set of monitors (sensors) for light, pressure, humidity, temperature etc. and has a *broadcast* (digital radio) *beacon mode*.

It is assumed that grain particles are *randomly deployed* in a given area of interest. Such a placement may occur e.g., when throwing sensors from an airplane over an area. A special case is considered, when the network being a lattice (or grid) deployment of sensors. This grid placement of grain particles is motivated by certain applications, where it is possible to have a pre-deployed sensor network, where sensors are put (possibly by a human or a robot) in a way that they form a *2-dimensional lattice*.

It is assumed that each particle has the following abilities: (i) It can estimate the direction of a received transmission (e.g., via the technology of direction-sensing antennae). (ii) It can estimate the distance from a nearby particle that did the transmission (e.g., via estimation of the attenuation of the received signal). (iii) It knows the direction towards the sink S. This can be implemented during a set-up phase, where the (powerful) sink broadcasts the information about itself to all particles. (iv) All particles have a common co-ordinates system. Notice that GPS information is not assumed. Also, there is no need to know the global structure of the network.

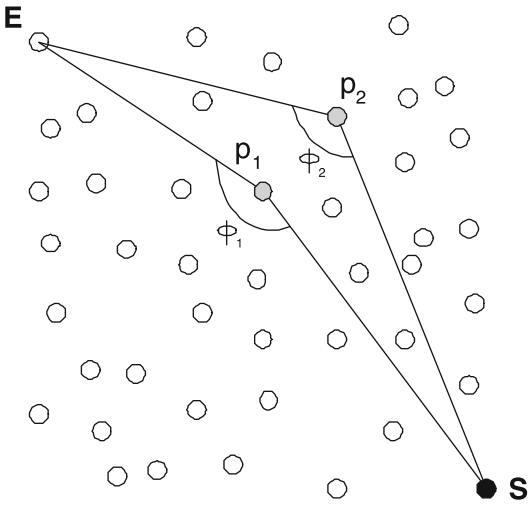
Key Results

The Basic Idea

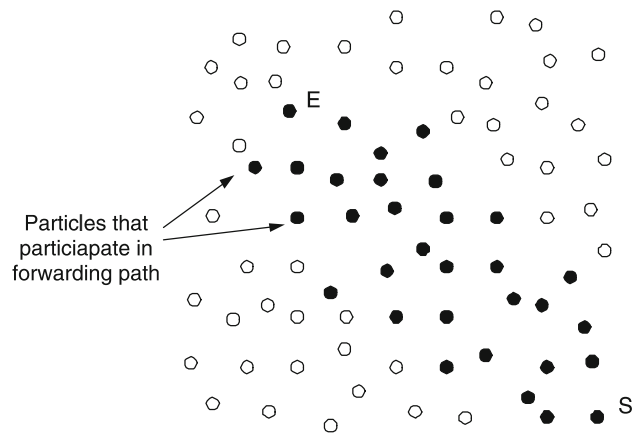
For the above problem [3] proposes a protocol which tries to minimize energy consumption by *probabilistically favoring certain paths of local data transmissions towards the sink*. Thus this protocol is called PFR (Probabilistic Forwarding Protocol). Its basic idea is to *avoid flooding* by favoring (in a probabilistic manner) data propagation along sensors which lie "close" to the (optimal) transmission line, ES, that connects the sensor node detecting the event, E, and the sink, S. This is implemented by locally calculating the angle $\phi = (\widehat{EPS})$, whose corner point P is the sensor currently running the local protocol, having received a transmission from a nearby sensor, previously possessing the event information (see Fig. 2). If φ is equal or greater to a predetermined threshold, then p will transmit (and thus propagate the information further). Else, it decides whether to transmit with probability equal to $\frac{\phi}{\pi}$. Because of the probabilistic nature of data propagation decisions and to prevent the propagation process from early failing, the protocol initially uses (for a short time period which is evaluated) a flooding mechanism that leads to a sufficiently large *"front"* of sensors possessing the data under propagation. When such a "front" is created, probabilistic Forwarding is performed.

The PFR Protocol

The protocol evolves in two phases:



Probabilistic Data Forwarding in Wireless Sensor Networks, Fig. 2 Angle φ and proximity to the optimal line



Probabilistic Data Forwarding in Wireless Sensor Networks, Fig. 3 Thin zone of particles

Phase 1: The "Front" Creation Phase

Initially the protocol builds (by using a limited, in terms of rounds, flooding) a sufficiently large "front" of particles, to guarantee the survivability of the data propagation process. During this phase, each particle having received the data to be propagated, deterministically forwards them towards the sink.

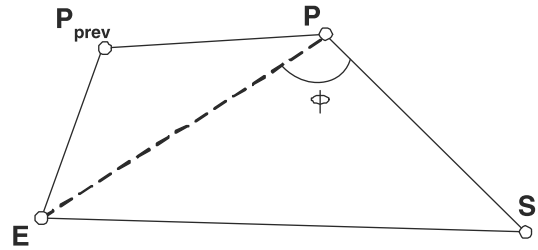
Phase 2: The Probabilistic Forwarding Phase

Each particle P possessing the information under propagation (called $info(\mathcal{E})$ hereafter), calculates an angle φ by calling the subprotocol "φ-calculation" (see description below) and broadcasts $info(\mathcal{E})$ to all its neighbors with probability $\mathbb{P}_{fwd}$ (or it does not propagate any data with probability $1 - \mathbb{P}_{fwd}$) as follows:

$$\mathbb{P}_{fwd} = \begin{cases} 1 & \text{if } \phi \geq \phi_{\text{threshold}} \\ \frac{\phi}{\pi} & \text{otherwise} \end{cases}$$

where φ is the $(\widehat{EPS})$ angle and $\phi_{\text{threshold}} = 134°$ (the selection reasons of this value are discussed in [3]).

If the density of particles is appropriately large, then for a line ES there is (with high probability) a sequence of points "closely surrounding ES" whose angles φ are larger than $\phi_{\text{threshold}}$ and so that successive points are within transmission range. All such points broadcast and thus essentially they follow the line ES (see Fig. 3).



Probabilistic Data Forwarding in Wireless Sensor Networks, Fig. 4 Angle φ calculation example

The φ-calculation Subprotocol (see Fig. 4)

Let P_{prev} the particle that transmitted $info(E)$ to P.

1. When P_{prev} broadcasts $info(E)$, it also attaches the info $|EP_{\text{prev}}|$ and the direction $\overrightarrow{P_{\text{prev}}E}$.
2. P estimates the direction and length of line segment $P_{\text{prev}}P$, as described in the model.
3. P now computes angle $(E\widehat{P_{\text{prev}}}P)$, and computes $|EP|$ and the direction of $\overrightarrow{PE}$ (this will be used in further transmission from P).
4. P also computes angle $(P_{\text{prev}}\widehat{P}E)$ and by subtracting it from $(P_{\text{prev}}\widehat{P}S)$ it finds φ.

Performance Properties of PFR

Any protocol Π solving the data propagation problem must satisfy the following three properties: **(a) Correctness**.Π must guarantee that data arrives to the position S, given that the whole network exists and is operational. **(b) Robustness**.

Π must guarantee that data arrives at enough points in a small interval around S, in cases where part of the network has become inoperative. **(c) Efficiency**. If Π activates k particles during its operation then Π should have a small ratio of the number of activated over the total number of particles $r = \frac{k}{N}$. Thus r is an energy efficiency measure of Π. It is shown that this is indeed the case for PFR.

Consider a partition of the network area into small squares of a fictitious grid G (see Fig. 5). When particle density is high enough, occupancy arguments guarantee that with very high probability (tending to 1) all squares get particles. All the analysis is conditioned on this event, call it F, of at least one particle in each square. Below only sketches of proofs are provided (full proofs can be found in [3]).

The Correctness of PFR

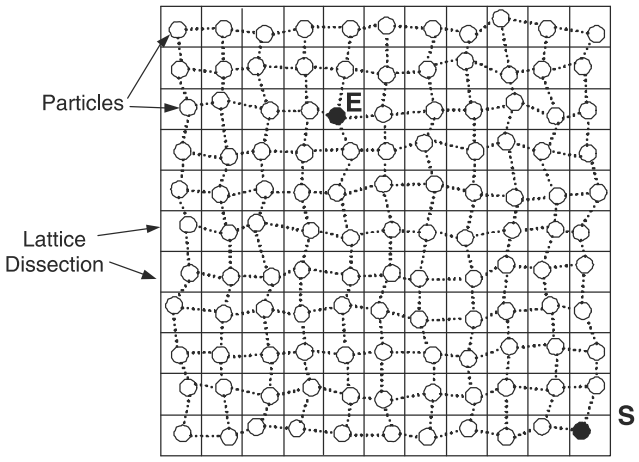
Consider any square Σ intersecting the ES line. By the occupancy argument above, there is w.h.p. a particle in this square. Clearly, the worst case is when the particle is located in one of the corners of Σ (since the two corners located most far away from the ES line have the smallest φ-angle among all positions in Σ). By geometric calculations, [3] proves that the angle φ of this particle is $\phi > 134°$. But the initial square (i.e., that containing E) always broadcasts and any intermediate intersecting square will be notified(by induction) and thus broadcast because of the argument above. Thus the sink will be reached if the whole network is operational:

Lemma 1 ([3]) *PFR succeeds with probability 1 given the event F.*

The Energy Efficiency of PFR

Consider a "lattice-shaped" network like the one in Fig. 5 (all results will hold for any random deployment "in the limit"). The analysis of the energy efficiency considers particles that are active but are as far as possible from ES. [3] estimates an upper bound on the number of particles in an $n \times n$ (i.e., $N = n \times n$) lattice. If k is this number then $r = \frac{k}{n^2}$ $(0 < r \leq 1)$ is the "energy efficiency ratio" of PFR. More specifically, in [3] the authors prove the (very satisfactory) result below. They consider the area around the ES line, whose particles participate in the propagation process. The number of active particles is thus, roughly speaking, captured by the size of this area, which in turn is equal to $|ES|$ times the maximum distance from $|ES|$. This maximum distance is clearly a random variable. To calculate the expectation and variance of this variable, the authors in [3] basically "upper bound" the stochastic process of the distance from ES by a random walk on the line, and subsequently "upper bound" this random walk by a well-known stochastic process (i.e., the "discouraged arrivals"

Probabilistic Data Forwarding in Wireless Sensor Networks, Fig. 5
A lattice dissection G



birth and death Markovian process. Thus they prove:

Theorem 2 ([3]) *The energy efficiency of the PFR protocol is* $\Theta\left(\left(\frac{n_0}{n}\right)^2\right)$ *where* $n_0 = |ES|$ *and* $n = \sqrt{N}$*, where N is the number of particles in the network. For* $n_0 = |ES| = o(n)$*, this is o(1).*

The Robustness of PFR

Consider particles "very near" to the *ES* line. Clearly, such particles have large φ-angles (i.e., $\phi > 134°$). Thus, even in the case that some of these particles are not operating, the probability that none of those operating transmits (during phase 2) is very small. Thus:

Lemma 3 ([3]) PFR *manages to propagate the crucial data across lines parallel to ES, and of constant distance, with fixed nonzero probability (not depending on n,* $|ES|$*).*

Applications

Sensor networks can be used for continuous sensing, event detection, location sensing as well as micro-sensing. Hence, sensor networks have several important applications, including (a) security (like biological and chemical attack detection), (b) environmental applications (such as fire detection, flood detection, precision agriculture), (c) health applications (like telemonitoring of human physiological data) and (d) home applications (e.g., smart environments and home automation). Also, sensor networks can be combined with other wireless networks (like mobile) or fixed topology infrastructures (like the Internet) to provide transparent wireless extensions in global computing scenaria.

Open Problems

It would be interesting to come up with formal models for sensor networks, especially with respect to energy aspects; in this respect, [10] models energy dissipation using stochastic methods. Also, it is important to investigate fundamental trade-offs, such as those between energy and time. Furthermore, the presence of mobility and/or multiple sinks (highly motivated by applications) creates new challenges (see e.g., [2, 11]). Finally, heterogeneity aspects (e.g., having sensors of various types and/or combinations of sensor networks with other types of networks like p2p, mobile and the Internet) are very important; in this respect see e.g., [5, 13].

Experimental Results

An implementation of the PFR protocol along with a detailed comparative evaluation (using simulation) with greedy forwarding protocols can be found in [4]; with clustering protocols (like LEACH, [7]) in [12]; with tree maintenance approaches (like Directed Diffusion, [8]) in [5]. Several performance measures are evaluated, like the success rate, the latency and the energy dissipation. The simulations mainly suggest that PFR behaves best in sparse networks of high dynamics.

Problem Definition

The virus identification is an important research topic in molecular biology. One method is using probes. A probe is a short oligonucleotide of size 8–25, which plays a role of ID when identify a virus in a biological sample through hybridization. If each probe hybridizes to a unique virus, then identification of virus is straightforward. However, unique probes are very hard to be obtained, especially for virus subtypes which are closely related. Therefore, how to identify virus with the minimum number of nonunique probes becomes an interesting problem.

Given a biological sample and a set of possibly nonunique probes, how to select a minimum subset of probes to identify viruses in the biological sample. This problem is called the *nonunique probe selection*.

Key Results

Suppose the biological sample contains only one virus. The problem is to determine what is this virus. To do so, it is sufficient to select probes satisfying the condition that different viruses hybridize different subsets of probes. This condition enables us to find the virus easily from a test outcome.

In general, suppose the biological sample contains at most d viruses. Then selected probes should satisfy the condition that different sets of at most d viruses should hybridize different subsets of selected probes. Schilep, Torney, and Rahman [9] first pointed out that this is actually a nongroup testing group testing problem [3].

Consider each virus as an item and each probe as a pool consisting of all viruses hybridized by the probe. A nonadaptive group testing with n items and t pools can be represented, and $t \times n$ binary matrix with rows labeled by pools and columns labeled by items and cell (i, j) contains 1-entry if and only if the ith pool contains item j. This binary matrix is called the incidence matrix of the nonadaptive group testing. In theory of nonadaptive group testing, the above condition means that the incidence matrix is $\bar{d}$-separable. Actually, a binary matrix is $\bar{d}$-separable if all Boolean sums of at most d columns are distinct. Here, by Boolean sum, we mean the following: If each column is seen as a set of rows corresponding to 1-entries in the column, then the Boolean sum can be seen as a union of columns. The Boolean sum is a classic statement in the study of group testing. With a $\bar{d}$-separable matrix, the test outcome can identify up to d viruses in biological sample.

In nonadaptive group testing, each test is on a pool. Thus, each probe can also be seen as a test. The test outcome is *positive* if the probe is hybridized by some virus in a biological sample and *negative* otherwise. Test outcomes for all selected probes can be written as a column vector which is exactly the union of columns corresponding viruses contained in the biological sample, where 1-entry denotes a positive outcome and 0-entry denotes a negative outcome. Therefore, the definition of $\bar{d}$-separable matrix means that different sets of at most d viruses receive different test-outcome t-dimensional vectors.

The nonunique probe selection problem can also be formulated as follows:

> MIN-$\bar{d}$-SS (Minimum $\bar{d}$-Separable Submatrix). Given a binary matrix $\boldsymbol{M}$, find the minimum of rows to form a $\bar{d}$-separable submatrix.

For any fixed d, MIN-$\bar{d}$-SS is NP-hard [3]. Moreover, from the test outcome obtained from $\bar{d}$-separable, it may take time $O(n^t)$ to find all existing viruses. This means that it is hard to decode the test outcome from a $\bar{d}$-separable matrix [3]. Therefore, Thai et al. [10] considered to use a d-disjunct matrix instead of $\bar{d}$-separable matrix. A binary matrix is *d-disjunct* if any union of d columns cannot contain the $(d + 1)$th column. Decoding test outcome from a d-disjunct matrix is very easy [3]. This introduces another minimization problem:

> MIN-d-DS (Minimum d-Disjunct Submatrix). Given a d-disjunct binary matrix $\boldsymbol{M}$, find a minimum subset of rows to form d-disjunct submatrix.

Theoretically, there is another similar problem as follows:

> MIN-d-SS (Minimum d-Separable Submatrix). Given a d-separable binary matrix $\boldsymbol{M}$, find a minimum subset of rows to form d-separable submatrix where a binary matrix is d-separable if all Boolean sums of exactly d columns are distinct.

For $d = 1$, MIN-d-SS is exactly the minimum test cover problem [5], also called the minimum test set problem [2] or the minimum test collection [6], which has a greedy approximation with performance $1 + 2 \ln n$ where n is the number of items [2]. This fact makes a suggestion that design greedy approximations for MIN-d-SS, MIN-$\bar{d}$-SS, and MIN-d-DS.

In fact, it is easy to construct greedy approximations with performance ratio $1 + 2d \ln n$ for MIN-d-SS, $1 + (d + 1) \ln n$ for MIN-d-DS, and $1 + 2d \ln(n + 1)$ for MIN-$\bar{d}$-SS. For example, let us study MIN-d-DS. Consider the collection $\mathcal{S}$ of all possible pairs (C, D) of one column

C and a submatrix D with d columns. Clearly $|\mathcal{S}| < n^{d+1}$. A row is said to *cover* such a pair (C, D) if and only if at this row, the entry of column C is 1 and all entries of columns in D are 0. Now, MIN-d-DS is equivalent to the problem of finding the minimum number of rows covering all such pairs. This is a special case of the set cover problem. It is well known that there is a greedy algorithm for the set cover problem with performance ratio $1 + \ln|\mathcal{S}| < 1 + (d+1)\ln n$.

This greedy algorithm works well only for small d because its running time is $O(n^{d+1})$. When d is large, it runs too slow. Therefore, we must look for other smart ways. Schilep, Torney, and Rahman [9] proposed an algorithm which adds probe one by one until the incidence matrix with considered viruses forms a $\bar{d}$-separable matrix. This does not work for large d, neither. In fact, if d is not bounded, then testing whether a binary matrix is d-separable, or $\bar{d}$-separable, or d-disjunct is co-NP-complete [3]. There exist more methods [8] in the literature, which work well for small d. However, no efficient method has been found to produce good solutions for larger d.

<?pag ?>In some applications, the pool size cannot be too big due to the sensitivity of tests. For example, UNH suggested in ADS testing, each pool should not contain more than five blood samples. When the pool size is bounded, the problem becomes easier. For instance, let us consider the case that every pool has size at most 2 so that all pools of size 2 together with items form a graph G where pools are edges and item are vertices. Halldórsson et al. [6] and De Bontridder et al. [2] proved that in this case, MIN-1-SS is still APX-hard, which means that there is no polynomial-time approximation scheme for it unless NP=P. They also showed that MIN-1-SS in this case has a polynomial-time approximation with performance ratio $7/6 + \varepsilon$ for any fixed $\varepsilon > 0$.

A surprising result was showed by Wang et al. [11] that a subgraph H of G represents a d-disjunct matrix if and only if every vertex in H has degree at least $d + 1$, and hence, finding such an H with minimum number of edges is polynomial-time solvable. What about the case that all pools have size 3 Wang et al. proved that in this case MIN-d-DS is still NP-hard. However, there exist polynomial-time approximations with better performance.

Applications

In practice, we may select nonunique probes in the following steps [9]:

Step 1. Estimate an upper bound d for the number of viruses existing in a given biological sample. Collect a large set of nonunique probes to form a $\bar{d}$-separable matrix.

Step 2. From this large set of probes, find a subset of probes to identify up to d viruses by computing an approximation solution for MIN-d-DS or MIN-$\bar{d}$-SS.

Step 3. Decode the presence or absence of viruses in the given biological sample from test outcome.

Open Problems

When d is not fixed, MIN-d-DS belongs to Σ_2^p and is conjectured to be Σ_2^p-complete [3].

Problem Definition

The topic of prophet inequality has been studied in optimal stopping theory since the 1970s [7, 9, 10] and more recently in computer science [1, 3, 6, 8]. In the prophet inequality setting, given (not necessary identical) independent distributions $D_1, \ldots, D_n$, a sequence of random variables $x_1, \ldots, x_n$ where x_i is drawn from D_i, a collection M of *feasible* subsets of $\{1, \ldots, n\}$, an onlooker has to choose from the succession of these values, where x_i is revealed to us at time step i. The onlooker starts with an empty set $S = \phi$. Upon the arrival of a value x_i, the onlooker can choose to either add x_i to the set S or discard it permanently. After the arrival of all values, the indices of values in S should form a feasible set in M. The revenue of the onlooker is the total value of variables in S. The onlooker's goal is to maximize his/her (expected) revenue compared to the hindsight expected revenue of a prophet who knows the drawn values in advance. The optimal offline solution (the prophet's revenue) is defined as $OPT = \mathrm{E}\left[\max_{I \in M} \sum_{i \in I} x_i\right]$. The *competitive ratio* of an algorithm for the onlooker is defined as the worst-case ratio of the expected revenue of the onlooker over OPT. This inequality ratio has been interpreted as meaning that a prophet with complete foresight has only a bounded advantage over an onlooker who observes the variables one by one, and this explains the name prophet inequality.

Different Variants

The *basic prophet inequality* discovered by Krengel, Sucheston, and Garling in the 1970s concerns the case in which the onlooker can only choose one value [9], i.e., M is the set of singletons. Decades later in 2007, Hajiaghayi, Kleinberg, and Sandholm [6] considered the *k-choice prophet secretary* variant in which sets with at most k elements are feasible. Later in 2012, Kleinberg and Weinberg [8] considered the more general *matroid prophet inequality*. In this variant the collection M contains the independent sets of a matroid.

Other prophet inequality settings (dependent D_i's, restricted prophets, etc.) have been considered in the literature as well. For an overview of these models, we refer the reader to [6, 8] and references therein.

Key Results

Krengel, Sucheston, and Garling [9] were first to consider basic prophet inequality. Using a very simple example, they showed no online algorithm can have a competitive ratio better than $\frac{1}{2}$: let

$q = \frac{1}{\epsilon}$. The first value, i.e., x_1 is always 1. The second value is either q with probability ϵ or 0 with probability $1 - \epsilon$. Observe that the expected revenue of any (randomized) online algorithm is at most $\max\left\{1, \epsilon\left(\frac{1}{\epsilon}\right)\right\} = 1$. However the prophet, i.e., the optimum offline solution, would choose x_2 if $x_2 = q$; otherwise he would choose the first value. Thus the optimum offline revenue is $(1-\epsilon) \times 1 + \epsilon\left(\frac{1}{\epsilon}\right) \approx 2$. We note that without considering stochastic assumptions, we cannot hope to get any constant competitive ratio.

An algorithm for the basic prophet inequality problem can be described by setting a threshold for every step: we stop at the first step that the arriving value is higher than the threshold of that step. The classical prophet inequality result [9] states that by choosing the same threshold $OPT/2$ for every step, one achieves the tight competitive ratio of $1/2$.

For the k-choice variant, Hajiaghayi et al. [6] show an algorithm with the competitive ratio $1 - O\left(\frac{\sqrt{\ln k}}{\sqrt{k}}\right)$. Later Alaei [1] improved this bound to $1 - \frac{1}{\sqrt{k+3}}$ using an involved randomized approach (gamma-conservative magician). Alaei, Hajiaghayi, and Liaghat simplified and generalized these results to the matching prophet inequality [2, 3]. Later they generalized their result to the *online stochastic generalized assignment problem* [4] (GAP) with slightly worse competitive ratio of $1 - \frac{1}{\sqrt{k}}$. In GAP, we have a set of items to be placed in a set of bins. The bins are known in advance, but the sequence of items arrives online; each item has a value and a size; upon arrival, an item can be placed in one of the bins or can be discarded permanently; the objective is to maximize the total value of the placement. Both value and size of an item may depend on the bin in which the item is placed; the size of an item is revealed only after it has been placed in a bin; distribution information is available about the value and size of each item in advance (not necessarily i.i.d.); however, items arrive in adversarial order (nonadaptive adversary). Alaei et al. [4] show an algorithm with the competitive ratio of $1 - \frac{1}{\sqrt{k}}$ where in this setting k is interpreted as the minimum number of items that can fill up the capacity of a bin.

Kleinberg and Weinberg [8] considered the matroid prophet inequality. They show an elegant algorithm that still achieves the competitive ratio of $1/2$. Generalizing their result still further, they show that under an intersection of p matroid constraints, the prophet's revenue exceeds the onlooker's by a factor of at most $O(p)$, and this factor is also tight. Kleinberg and Weinberg design the following algorithm for the matroid prophet inequality. The algorithm pretends that the online selection process is Phase 1 of a two-phase game; after each x_i has been revealed in Phase 1 and the algorithm has accepted some set A_1, Phase 2 begins. In Phase 2, a new weight will be sampled for every matroid element, independently of the Phase 1 weights, and the algorithm will play the role of the prophet on the Phase 2 weights, choosing the max-weight subset A_2 such that $A_1 \cup A_2$ is independent. However, the revenue for choosing an element in Phase 2 is only half of its value. When observing element i and deciding whether to select it, our algorithm can be interpreted as making the choice that would maximize its expected revenue if Phase 1 were to end immediately after making this decision and Phase 2 were to begin. Of course, Phase 2 is purely fictional: it never actually takes place, but it plays a key role in both the design and the analysis of the algorithm. The analysis of the algorithm is involved and relies on a careful analysis of the expected revenue at each step. For further intuitions about the analysis, we refer the reader to [8].

Applications

Beyond their interest as theorems about pure online algorithms or optimal stopping rules, prophet inequalities also have applications to mechanism design. Mechanism design has traditionally focused on the offline setting where all agents are present up front. However, many electronic commerce applications do not fit that model because the agents can arrive and depart dynamically. This is characteristic, for example, of online ticket auctions, search keyword auctions, Internet auctions, and scheduling computing jobs on a

cloud. The online aspect is characteristic of some important traditional applications as well, such as the sale of a house, where the buyers arrive and depart dynamically.

The pioneer work of Hajiaghayi, Kleinberg, and Sandholm [6] initiated the research on the relationship between algorithmic mechanism design and prophet inequalities. They observed that algorithms used in the derivation of prophet inequalities, owing to their monotonicity properties, could be interpreted as (temporarily) truthful online auction mechanisms and that the prophet inequality in turn could be interpreted as the mechanism's approximation guarantee. Indeed, Bayesian optimal mechanism design problems provide a compelling application of prophet inequalities in economics. In such a Bayesian market, we have a set of n agents with private types sampled from (not necessary identical) known distributions. Upon receiving the reported types, a seller has to allocate resources and charge prices to the agents. The goal is to maximize the seller's revenue in equilibrium. Chawla et al. [5] pioneered the study of the approximability of a special class of such mechanisms, *sequential posted pricing* (SPM): the seller makes a sequence of take-it-or-leave-it offers to agents, offering an item for a specific price. They show although simple, SPMs approximate the optimal revenue in many different settings. Therefore prophet inequalities directly translate to approximation factors for the seller's revenue in these settings through standard machineries. Indeed one can analyze the so-called *virtual values* of winning bids introduced by Roger Myerson [11], to prove via prophet inequalities that the expected virtual value obtained by the SPM mechanism approximates an offline optimum that is with respect to the exact types. Chawla et al. [5] provide a type of prophet inequality in which one can choose the ordering of agents. As mentioned before, Kleinberg and Weinberg [8] later improved their result by giving an algorithm with the tight competitive ratio of 0.5 for an adversarial ordering.

Problem Definition

The quadtree describes a class of data structures for geometric objects. A quadtree partitions space hierarchically using a stopping rule that decides when a region is small enough so that it does not need to be subdivided further. If the space is d dimensional, a quadtree recursively divides a d-dimensional hypercube containing the input data into 2^d hypercubes until each region satisfies the given stopping rule. In 2D, the hypercubes are squares. Three-dimensional quadtrees are also known as *octrees*. Quadtrees have been used for many types of data, such as points, line segments, polygons, rectangles, curves, and images, and for many types of applications. For a detailed presentation, we refer to the book by Samet [10]. While their worst-case behavior is good only in some simple cases, quadtrees perform well empirically in many applications.

A quadtree can be stored as a tree that corresponds to the hierarchical subdivision of the input region. A region that is subdivided further is then represented by a node with four children, one for each quadrant; the cells that are not subdivided further constitute the leaves of the tree and represent a subdivision of the input region. A quadtree with m leaves has exactly $(m-1)/3$ internal nodes and $4m/3 - 1/3$ nodes in total. Hence it can be described by a sequence of $4m/3 - 1/3$ bits representing the nodes of the tree in preorder, where each internal node is represented by a 1 (meaning that the next bit encodes its first child) and each leaf is represented by a 0. However, for efficient navigation one would typically use a pointer-based data structure. Alternatively, one may store only the leaves of the tree, ordered along a space-filling curve. This variant of the quadtree is called the *linear quadtree* and was introduced by Gargantini [3]. The linear quadtree has smaller memory requirements as it does not store the tree structure but only the data in the

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

leaves. This makes it particularly useful when dealing with large data.

In this entry we focus on quadtree construction algorithms that are efficient on very large data. To analyze these algorithms, we use the ▸ I/O-Model and the ▸ Cache-Oblivious Model. We'll use the terms linear quadtree and quadtree subdivision interchangeably. We define the size of a subdivision as the number of cells it contains and the size of a cell is the size of the data (points and edges) it contains/intersects.

The Complexity of Quadtrees for Points in the Plane

Let P be a set of n points in the plane and assume, for simplicity, that the points lie in the unit square. A quadtree for P corresponds to a recursive subdivision of the unit square into four equal regions, called canonical squares, quadrants, or cells, until each square contains at most one point. Following customary terminology in the computational geometry literature (and in deviation from Samet [10]), we refer to this generically as a *point quadtree*.

In the worst case, the size of a quadtree subdivision on P cannot be bounded by a function of n. If ϵ is the distance between the two closest points in P, the worst-case complexity is $\Theta(n \lg \frac{1}{\epsilon})$, and the corresponding tree may have a large number of empty nodes. A *compressed* quadtree is a quadtree where paths of nodes that each have three empty children are merged into a single node along with their empty children; the region corresponding to the merged node is called a *donut* and represents the difference between two canonical squares. A compressed quadtree for a set of n points in the plane such that each cell contains at most one point has size $\Theta(n)$ and height $\Theta(n)$ in the worst case.

The Complexity of Quadtrees for Line Segments in the Plane

Let $\mathcal{E}$ be a set of n non-intersecting line segments in the plane – for example, the edges of a planar subdivision – and assume, as above, that the edges lie in the unit square. We refer to a quadtree for $\mathcal{E}$ generically as an *edge quadtree* and assume that each edge is stored in all the cells that it intersects. The simplest way to define an edge quadtree may be to take a point quadtree on the endpoints of the edges and then store each edge with the leaves that correspond to the quadtree cells intersected by the edge. We denote by l the number of intersections between $\mathcal{E}$ and the cells in the subdivision. Even if we use a compressed quadtree, in the worst case, there can be $\Theta(n)$ cells that each intersects $\Theta(n)$ edges, so $l = \Theta(n^2)$, and the quadtree will have size $\Theta(n + l) = \Theta(n^2)$. Other edge quadtrees can be defined by formulating stopping criteria that allow subdividing cells further in order to limit the number of edges that intersect each cell; this will result in a subdivision with more cells but smaller number of edges per cell. However, obtaining a good trade-off between the size of a cell (number of points and edges inside or intersecting it) and the number of cells in the subdivision is not possible in the worst case. Note that an edge quadtree that splits a region until it intersects a single edge will result in a subdivision of unbounded size since the distance between two edges can be arbitrarily small.

Quadtrees and Morton Indexing

Quadtrees are often used in conjunction with a z-order space-filling curve. A z-order, or Morton order, can be understood as a mapping from two-dimensional (in general multidimensional) data to one dimension. We use a z-order curve that visits the four quadrants of the initial square, recursively, in the order top left, top right, bottom left, and bottom right. This order gives a well-defined ordering between any two canonical squares in the subdivision. If we define canonical squares to be closed on the top and left side and open on the bottom and right side, the z-order also gives a well-defined ordering between any two points in the input region. Let $p = (p_x, p_y)$ be a point in the unit square $[0, 1)^2$, with the x-axis oriented from left to right and the y-axis oriented from top to bottom. We define the z-index $Z(p)$ of p to be the value in the range $[0, 1)$ obtained by interleaving the bits in the fractional parts of p_x and p_y, starting with a bit from p_y. The value $Z(p)$ is sometimes called the *Morton block index* of p. The z-order of two points in the unit square

is the order of their z-indices. A crucial property is that the z-indices of all points in a canonical square σ form an interval $[z_1, z_2)$ of $[0, 1)$, where z_1 is the z-index of the top left corner of σ. A donut cell is the difference between two canonical squares $[z_1, z_2)$ and $[z_3, z_4)$, and thus, it is the union of two intervals $[z_1, z_3)$ and $[z_4, z_2)$.

With this notation, a (compressed) quadtree subdivision corresponds to a subdivision $\mathcal{Q}$ of the z-order curve and can be viewed as a set of consecutive, adjacent, nonoverlapping intervals, covering $[0, 1)$, in z-order: $\mathcal{Q} = \{[z_1 = 0, z_2), [z_2, z_3), \ldots\}$. Each interval $[z_i, z_{i+1})$ corresponds to a cell σ_i, which is either a canonical square or a part of a donut. We note that this representation does not make any assumptions on the stopping criterion used to generate the quadtree subdivision and thus works on any quadtree subdivision, no matter how many points are in a region and whether it is compressed or not. A linear edge quadtree can therefore be represented as a set of key-edge pairs, where each intersection of an edge e with a quadtree cell σ corresponding to an interval $[z_1, z_2)$ is represented by storing edge e with key z_1; thus each cell stores all edges that intersect it [2, 4].

Point Quadtrees

Agarwal et al. [1] described an algorithm for constructing a quadtree on a set of n points in the plane such that each cell contains $O(k)$ points; the algorithm runs in $O(\frac{n}{B}\frac{h}{\log M/B})$ I/O's, where h is the height of the quadtree. Effectively, this is $O(\text{sort}(n))$ I/O's only when $h = O(\log n)$, which is true when the points are nicely distributed. A bound on the size of the quadtree is not given, and the quadtree is not compressed, which means the quadtree size can be unbounded in the worst case. The algorithms were implemented and tested as part of an application to interpolate LIDAR datasets, which are nicely distributed and unlikely to cause worst-case behavior.

De Berg et al. [2] described an algorithm to construct a compressed quadtree subdivision with at most one point per cell in $O(\text{sort}(n))$ I/O's, as a step in the construction of their Guard-quadtree for edges which is discussed below. Haverkort et al. [4] describe a simple generalization of this algorithm which constructs a compressed quadtree subdivision of $O(n/k)$ cells with at most k points per cell in the same I/O-bound. Thus, compared to the algorithm by Agarwal et al., a stronger bound on the I/O-complexity is obtained, along with an upper bound on the number of cells in the subdivision.

PM Quadtrees

A variety of edge quadtrees were described by Samet and various co-authors [5–7, 9, 11, 12]. All of these solutions are aimed at subdividing the cells that intersect too many edges, while also limiting the total size of the quadtree and being able to construct it I/O-efficiently.

The *PM quadtree* [11] allows a region to contain more than one edge if the edges meet at a vertex inside the region; otherwise it keeps subdividing it. Variants of PM quadtrees differ in how to handle regions that contain no vertices (only edges). The *segment quadtree* [12] is a linear quadtree in which a leaf cell is either empty, contains one edge and no vertices, or contains precisely one vertex and its incident edges. The most versatile structure within the PM family is the *PMR quadtree* [9], a linear quadtree where each region may have a variable number of segments and regions are split if they contain more than a predetermined threshold of edges. The tree is built incrementally, by inserting each segment into all the regions that it intersects. When a region contains more segments than a predetermined splitting threshold, the region is split, once, into four quadrants. Improved algorithms for the construction (or *bulk loading*) of the PMR quadtree were described in [5–7]. These algorithms are developed and optimized with massive data in mind and use I/O-efficient sorting as one of the steps. It is reported that in many cases (although not in the worst case), the I/O-cost of the bulk-loading algorithm is the same as that of external sorting [5]. The algorithms are reported to perform well in practice, but there are several disadvantages: the the resulting quadtree depends on the insertion order; complexity is analyzed

in terms of various parameters that depend on the data; and the performance is not worst-case optimal. On the plus side, the algorithms can handle insertions and work in situations where the data is dynamic.

Star-Quadtrees

The Star-quadtree by De Berg et al. [2] is designed for fat triangulations (a triangulation is fat if every angle of every triangle is larger than some fixed positive constant δ). A Star-quadtree is a linear, uncompressed edge quadtree that splits a region until all edges intersecting a region are incident on one common endpoint (similar to the PM quadtree by Samet and Webber [11]). The Star-quadtree can be built on any set of edges in the plane, but, when the input is a fat triangulation, it can be shown that this stopping rule creates (1) a quadtree of $\Theta(n)$ size and (2) each leaf cell in the quadtree (each cell in the subdivision) intersecting $\Theta(1)$ edges. The height of the quadtree can still be $\Theta(n)$, which makes a top-down construction, such as that used by Agarwal et al. [1], height dependent and not optimal. The authors of the Star-quadtree describe a completely different algorithm for its construction that crucially exploits the stopping criterion and runs in $O(\text{sort}(n))$ I/O's if the input is a fat triangulation.

Guard-Quadtrees

The Guard-quadtree by De Berg et al. [2] is designed for sets of non-intersecting edges of low density – a set of edges has density λ if any disk D is intersected by at most λ edges whose length is at least the diameter of D. For a given set of n edges, the authors define a set of at most $4n$ *guards*, namely, the vertices of the minimum axis-parallel bounding rectangles of the individual edges. The Guard-quadtree is a linear, compressed edge quadtree that splits a region until it contains at most one *guard*. As the set of guards is a superset of the endpoints of the edges, this leads to a subdivision that is more refined than a quadtree built only on the endpoints of edges. The stopping rule, together with compression, leads to a quadtree subdivision that has $O(n)$ cells and each cell intersects $O(1)$ edges, provided the set of edges to be stored has low density. Furthermore, the quadtree can be constructed in $O(\text{sort}(n))$ I/O's in this case.

K-Quadtrees

Combining ideas from De Berg et al. [2] with packing more vertices in a region, Haverkort et al. [4] described an I/O-efficient edge quadtree referred to as a K-quadtree. For any $k \geq 1$, the K-quadtree is a compressed, linear quadtree built on the endpoints of the edges, with $O(n/k)$ cells in total and such that each cell contains $O(k)$ vertices (and such that each edge is stored in all cells that they intersect). Each cell in the subdivision can intersect $O(n)$ edges in the worst case. For $k = 1$, a K-quadtree is a linear, compressed edge quadtree with $O(n)$ cells and at most one vertex per cell. Larger values of k can be chosen to trade off between the number of cells $O(n/k)$ and the number of vertices in a cell $O(k)$.

The algorithm for building a K-quadtree has two steps: First it builds, in $O(\text{sort}(n))$ I/O's, a linear, compressed quadtree subdivision on the endpoints of $\mathcal{E}$ with $O(n/k)$ cells in total and such that each cell contains $O(k)$ vertices. This step is a simple generalization of the algorithm for building Guard-quadtrees from [2]. In the second step, the K-quadtree construction algorithm computes the intersections between the edges and the subdivision in $O(\text{sort}(n + l))$ I/O's, where $l = O(n^2/k)$ is the total number of intersections.

The main idea of the second step of the algorithm is to split the set of edges into edges of positive slope $\mathcal{E}_+$ and edges of negative slope $\mathcal{E}_-$ and compute the intersections of each set separately. The intersections of $\mathcal{E}_+$ with the subdivision are computed by *time-forward processing*, as follows. The cells of the quadtree subdivision are scanned in z-order. At any point during this scan, there is a *frontier*: an xy-monotone curve that constitutes the boundary between the cells that have already been scanned and the cells that are still to be scanned. The algorithm relies on the property that an edge of positive slope intersects the cells in the subdivision in z-order (a similar property holds for the edges of negative slope and a reflected version of the z-order). During the scan, each edge of $\mathcal{E}_+$ is passed on, from

each intersected quadtree cell to the next, through a supporting data structure that stores the edges intersecting the frontier.

Unlike standard instantiations of time-forward processing, the supporting data structure is not a priority queue, but it is a list, implemented as two stacks, containing the edges that intersect the frontier, in order along the frontier. At each point in time, the list starts at the bottom of one stack and goes up to the top and then down the other stack. The cutting point between the two stacks corresponds to the current scanning position in the list; scanning backward or forward in the list for lookups and updates is implemented by moving elements from one stack to another. The key to I/O-efficiency is that the total amount of scanning that is needed to maintain the supporting data structure is linear in the output size, incurring only $O(\text{scan}(l))$ I/Os.

As the algorithm relies only on the basic building blocks of I/O-efficient sorting, scanning, and stacks, it is also easy to implement cache obliviously.

Compared to a quadtree that employs a stopping criterion that aims to bound the number of edges intersecting a cell (like PMR, Star- and Guard-quadtrees), the simpler K-quadtree has a couple of advantages: (1) the resulting subdivision size is smaller; (2) the total size of the quadtree (the number of intersections between edges and the subdivisions) is also smaller since the size of the subdivision is smaller; and (3) the quadtree can be built in $O(\text{sort}(n + l))$ I/O's, without making any assumptions about the input.

Datasets

Common test datasets for 2D quadtrees are triangulated terrains and USA TIGER data. They represent relatively simple classes of inputs; however they arise frequently in practice and have been used extensively as test beds for spatial index structures. The TIGER dataset consists of 50 datasets, one for each state, containing roads, railways, boundaries, and hydrography in the state. The size of a dataset ranges from 115,626 edges (Delaware) to 40.4 million edges (Texas). The TIGER datasets can be downloaded from http://www.census.gov/cgi-bin/geo/shapefiles2013/main.

Experimental Results

Since many of the quadtree algorithms perform much better in practice than their theoretical worst-case bounds, experimental analysis is an important way to assess their merits. Some of the early experimental analysis of quadtrees performance on massive data was by Hjaltason and Samet [6]. They describe ample results concerning practical performance of PMR quadtrees in terms of construction time, insertions and bulk insertions, comparison with R-tree bulk-loading, and, as an application, performance of spatial join using quadtrees to store the datasets. Their test data consists of TIGER datasets ranging from 40K lines to approximately 260K edges on a machine with 64MB RAM.

Agarwal et al. [1] implemented and tested their I/O-efficient point quadtree part of an application to interpolate LIDAR datasets, where it was used specifically for batched neighbor finding (finding the points in all neighbor leaves for each quadtree leaf). The algorithms are scalable up to at least 500 million points (20GB raw data) (their platform was an Intel 3.4GHz machine with 1GB RAM running Linux).

Haverkort et al. [4] described an experimental analysis of K-quadtrees reporting on the construction time and size of the quadtree (number of cells and number of edge-cell intersections) for various values of k, as well as computing a spatial join using K-quadtrees. The K-quadtree construction algorithm is efficient and scalable, with the running time getting faster as more points are packed into a leaf. Even though the number of edges intersecting a cell may be large, the average size of a cell stays low and the total size of the quadtree is linear. Their tests use TIGER data with the largest bundle, corresponding to the entire USA, having approximately 427 million edges, on a machine with 512MB RAM. A comparison with the PMR quadtree results of

Hjaltason and Samet [6] is difficult because of the difference in platforms.

Extensions

A series of recent results have shown that compressed quadtrees and Delaunay triangulations are equivalent structures, in the sense that a compressed quadtree of a set of points P in the plane can be computed in linear time given the Delaunay triangulation $DT(P)$; and the other way around, the Delaunay triangulation $DT(P)$ can be computed in linear time given a compressed quadtree of P; see, for example, Löffler and Mulzer [8]. In the I/O-model, both problems can be solved in $O(\text{sort}(n))$ I/O's. This naturally brings the question of whether one can be computed from the other in $O(\text{scan}(n))$ I/O's.

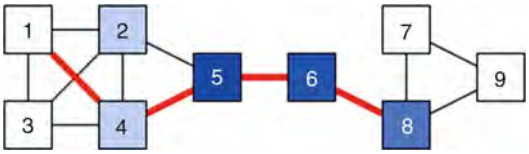
Problem Definition

A network representation of a complex system comprises nodes, which represent system elements, and edges, which represent interactions between the elements. Networks may be described in terms of their topology; for instance, some nodes may be connected to an atypically large number of other nodes, and some may act as bridge nodes that participate in paths between



Quantification of Regulation in Networks with Positive and Negative Interaction Weights, Fig. 1 Common network measures applied to a sample 9-node network with symmetric interactions. Darker nodes have higher betweenness centrality (i.e., they tend to act as a bridge between other pairs of nodes); note that even nodes with low degree (i.e., few connections) may have high betweenness centrality. Highlighted edges show a shortest path (length 4) between nodes 1 and 8

many other pairs of nodes (Fig. 1). For a review of topological network measures, see [1–3].

In some contexts, this topological structure serves as a basis for a dynamical description, where nodes are characterized by a dynamic variable that is regulated by the node's interactions. For instance, in the Boolean framework, nodes are either ON or OFF (1 or 0, respectively) [4]. In biological regulatory networks, where interactions between system elements can represent both upregulation and downregulation, one common dynamic scheme is summative [5]:

$$x_i\,(t+\tau) = \mathrm{sgn}\left(\sum_j E_{j,i}\,x_j\,(t)\right),$$

where $E_{j,i}$ is the weight of the interaction from node j to node i and absent interactions have a weight of 0 by definition. In such a framework, the state change of a node can propagate to the node(s) it directly regulates, then to the node(s) they regulate, and so on. This information flow across a network is sometimes referred to as network communicability [6]. A topological analysis of the network should, in principle, give insight into its dynamical structure and address questions such as, "Which nodes yield a strong influence on many other nodes?," "Which nodes are regulated in a complex way by many other nodes?," and "Which nodes seem to have a peripheral impact on the dynamics of the network?"

However, while networks have been used to explicate the structure and function of a large and diverse array of complex systems, most network measures consider the most general properties of networks and are therefore ill-suited for application to specialized networks. The positive and negative edge weights typically used in biological regulatory networks are one such specialization: standard network measures do not consider edge weights of opposite sign and are therefore ill-equipped to fully capture the dynamical implications of their topology.

Here, we address this shortcoming by developing a suite of topological measures that address the regulatory relationship between nodes that are connected by edges with both positive and negative edge weights. We first consider node-node interactions and then summarize those measures to quantify both the regulatory impact of a node on the entire network and of the entire network on a node.

Key Results

To first consider node-node relationships, we introduce two complementary measures. The **weighted node-node path count** from node i to node j considers both the number of paths from node i to node j and their length:

$$\omega_{ij} \equiv \sum_{l=1}^{l_{\max}} \frac{p_{lij}^{+} + p_{lij}^{-}}{l}$$

Here, p_{lij}^{+} and p_{lij}^{-} respectively indicate the number of positive and negative paths from node i to node j of length l. While we here consider a path to be positive if it contains 0 or an even number of negative edges, note that this measure effectively ignores the sign of the paths. To take this into consideration, we introduce the **node-node path influence**:

$$\pi_{ij} \equiv \sum_{l=1}^{l_{\max}} \frac{p_{lij}^{+} - p_{lij}^{-}}{l}$$

π_{ij} is therefore bounded by the range $[-\omega_{ij}, \omega_{ij}]$. ω_{ij} indicates the regulatory strength insofar as it is large when there are many short paths between the nodes and decreases when the paths are few and/or long; π_{ij} indicates the overall regulatory nature of those interactions. Values close to

0 relative to $|\omega_{ij}|$ indicate mixed (complex) regulation, while values close to $|\omega_{ij}|$ indicate overall positive or negative regulation.

Node-network relationships may be assessed by cumulating these measures with a fixed source or target node. The **node path influence**, ι_i, and **node path susceptibility**, σ_j, take this into account for a fixed source and target node, respectively:

$$\iota_i \equiv \sum_j \pi_{ij}\omega_{ij}$$

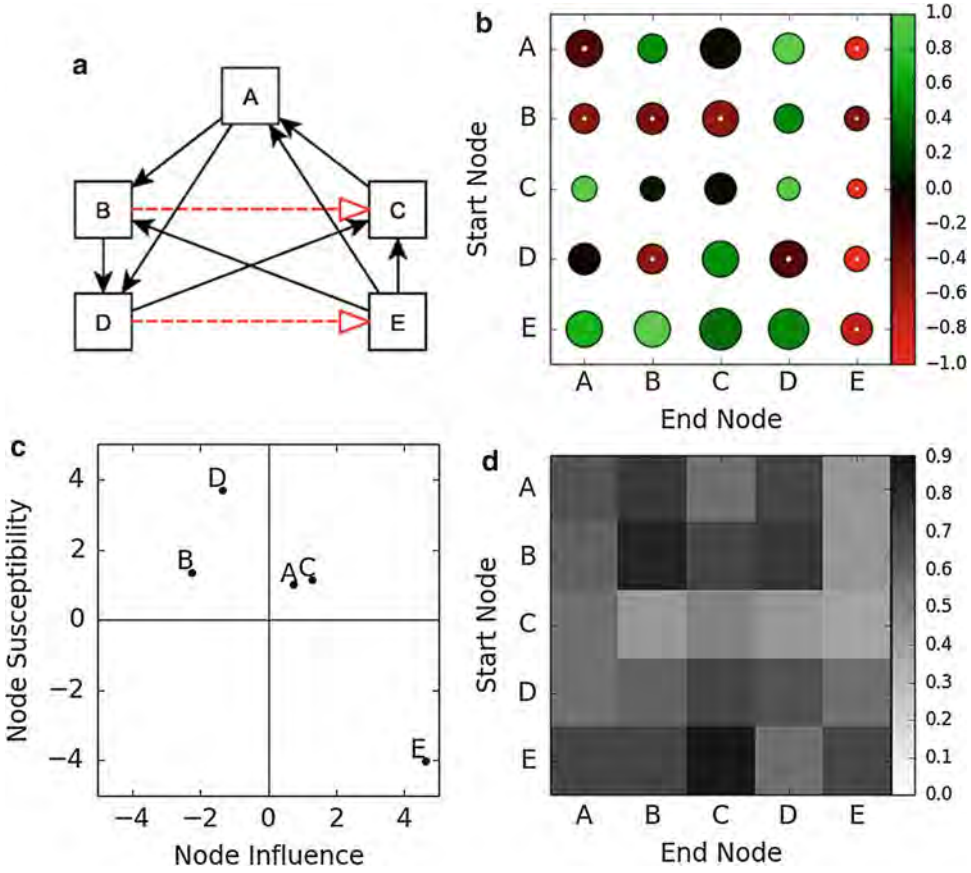
$$\sigma_j \equiv \sum_i \pi_{ij}\omega_{ij}.$$

The summative product results in large absolute values for these measures only when the regulation is both strong and consistent in sign. Nodes receiving low values are regulated weakly and/or in a complex way.

In cases where edge weights take on values other than ± 1, the p_{ijl} values may readily be modified to, for instance, the sum of the mean interaction weights of the pertinent paths. This modification reduces to the above definition when edge weights are restricted to ± 1. In both cases, however, the above measures are characterized by the parameter $l_{\max}$, which represents the longest path considered by the algorithm. Counting all paths of arbitrary length for all but the simplest networks is computationally intractable, and so in practice $l_{\max}$ must generally be a low number. We therefore introduce a complementary measure, **strength of connection**, which considers paths of arbitrary length through network erosion. The measure is determined for any two nodes i and j via a procedure that assigns every node a characteristic value. In the below pseudo-algorithm, these values are stored in a dictionary d.

```
N = number of nodes in graph
d = {}
for node in graph: d[node] = infinity

if i != j:
  while a path exists between i and j:
    SP = [nodes on the shortest path between i and j]
    SPL = length of shortest path between i and j
    if SPL == 1:
      delete edge between i and j
      d[i] = d[j] = SPL
    else:
      for node in SP:
        if d[node] == infinity: d[node] = SPL
        if (node != i and node != j): remove node from graph
  return sum(1/(values in d))/(N/2)
else:
    while a cycle containing i exists:
      SP = [nodes on the shortest cycle containing node i]
      SPL = length of shortest cycle containing node i
      if SPL == 1:
        delete self-edge
        d[i] = SPL
      else:
        for node in SP:
          if d[node] == infinity: d[node] = SPL
          if node != i: remove node from graph
  return sum(1/(values in d))/((N+2)/2)
```



Quantification of Regulation in Networks with Positive and Negative Interaction Weights, Fig. 2 Adapted from Figs. 1 and 2 of [7]. (**a**) A fully connected 5-node network. *Solid black arrows* indicate positive regulation, while *dashed*, *red arrows* indicate negative regulation. (**b**) A circle at position i, j has a size proportional to $\omega_{ij}\left(\max\left(\omega_{ij}\right) = 2.75\right)$ and color determined by π_{ij} / ω_{ij}, with positive, neutral, and negative sign corresponding to *green, black*, or *red* coloring, respectively. Circles are additionally identified with a small *white concentric circle* if $\pi_{ij} / \omega_{ij} \leq -0.2$. (**c**) A scatter plot of node path influence, ι, and node path susceptibility, σ. (**d**) The strength of connection measure indicates which node pairs remain well connected under network erosion; the values vary significantly despite each node having equal degree and the network being strongly connected

The normalization factors force the returned value to be bounded by 1 [7]. While this algorithm does not consider the sign of paths, it is straightforward to modify it to, e.g., include only those paths that are of the specified sign. Such a modification would then yield both a positive strength of connection and a negative strength of connection. We demonstrate the above-defined measures for a simple network in Fig. 2.

Applications

The analytical measures introduced above may be applied to any network with both positive and negative edge weights. Biological regulatory networks are a prime example of complex systems that are often modeled in this way. For example, the measures have been applied to explicate the regulatory cross talk of a network of the immune response responding

to both respiratory bacteria and allergen [7]. The measures stand to inform the dynamical regulation between nodes from a strictly topological perspective and thereby (1) provide insight into systems where the dynamic behavior is poorly understood and (2) complement dynamic analysis in systems where the regulatory behavior is understood.

Open Problems

The methodology discussed here considers the topology of a network with weighted positive and negative interactions. However, network analysis often involves an investigation of network dynamics, where the details of the interactions encoded in the network topology play a pivotal role. The role of network topology in constraining network dynamics is an active area of study (see, e.g., [8]).

Quantum Algorithm for Element Distinctness

Andris Ambainis
Faculty of Computing, University of Latvia, Riga, Latvia

Keywords

Element distinctness; Quantum algorithms; Quantum search; Quantum walks

Years and Authors of Summarized Original Work

2004; Ambainis

Problem Definition

In the *element distinctness* problem, one is given a list of N elements $x_1, \ldots, x_N \in \{1, \ldots, m\}$ and one must determine if the list contains two equal elements. Access to the list is granted by submitting queries to a black box, and there are two possible types of query.

Value Queries. In this type of query, the input to the black box is an index i. The black box outputs x_i as the answer. In the quantum version of this model, the input is a quantum state that may be entangled with the workspace of the algorithm. The joint state of the query, the answer register, and the workspace may be represented as $\sum_{i,y,z} a_{i,y,z}|i, y, z\rangle$, with y being an extra register which will contain the answer to the query and z being the workspace of the algorithm. The black box transforms this state into $\sum_{i,y,z} a_{i,y,z}|i, (y + x_i) \mod m, z\rangle$. The simplest particular case is if the input to the black box is of the form $\sum_i a_i|i, 0\rangle$. Then, the black box outputs $\sum_i a_i|i, x_i\rangle$. That is, a quantum state consisting of the index i is transformed into a quantum state, each component of which contains x_i together with the corresponding index i.

Comparison Queries. In this type of query, the input to the black box consists of two indices i, j. The black box gives one of the three possible answers: "$x_i > x_j$", "$x_i < x_j$," or "$x_i = x_j$." In the quantum version, the input is a quantum state consisting of basis states $|i, y, z\rangle$, with i, j being two indices and z being algorithm's workspace.

There are several reasons why the element distinctness problem is interesting to study. First of all, it is related to sorting. Being able to sort $x_1, \ldots, x_N$ enables one to solve the element distinctness by first sorting $x_1, \ldots, x_N$ in increasing order. If there are two equal elements $x_i = x_j$, then they will be the next one to another in the sorted list. Therefore, after one has sorted $x_1, \ldots, x_N$, one must only check the sorted list to see if each element is different from the next one. Because of this relation, the element distinctness problem captures some of the same difficulty as sorting. This has led to a long line of research on classical lower bounds for the element distinctness problem (cf. [5, 11, 21] and many other papers).

Second, the central concept of the algorithms for the element distinctness problem is the notion of a collision. This notion can be generalized in different ways, and its generalizations are useful for building quantum algorithms for various graph-theoretic problems (e.g., triangle finding [18]) and matrix problems (e.g., checking matrix identities [12]).

A generalization of element distinctness is element k-distinctness [3], in which one must determine if there exist k different indices $i_1, \ldots, i_k \in \{1, \ldots, N\}$ such that $x_{i1} = x_{i2} = \ldots = x_{ik}$. A further generalization is the k-subset finding problem [14], in which one is given a function $f(y_1, \ldots, y_k)$ and must determine whether there exist $i_1, \ldots, i_k \in \{1, \ldots, N\}$ such that $f(x_{i1}, x_{i2}, \ldots, x_{ik}) = 1$ (where $x_1, \ldots, x_N$ are the input data).

Key Results

Element Distinctness: Summary of Results

In the classical (non-quantum) context, the natural solution to the element distinctness problem is done by sorting, as described in the previous section. This uses $O(N)$ value queries (or $O(N \log N)$ comparison queries) and $O(N \log N)$ time. Any classical algorithm requires $\Omega(N)$ value or $\Omega(N \log N)$ comparison queries. If the algorithm is restricted to $o(N)$ space, stronger lower bounds are known [21].

In the quantum context, Buhrman et al. [13] gave the first nontrivial quantum algorithm, using $O(N^{3/4})$ queries. Ambainis [3] then designed a new algorithm, based on a novel idea using quantum walks. Ambainis' algorithm uses $O(N^{2/3})$ queries and is known to be optimal: Aaronson and Shi [1, 2, 15] have shown that any quantum algorithm for element distinctness must use $\Omega(N^{2/3})$ queries.

For quantum algorithms that are restricted to storing r values x_i (where $r < N^{2/3}$), the best algorithm runs in $O(N/\sqrt{r})$ time.

All of these results are for value queries. They can be adapted to the comparison query model, with a $\log N$ factor increase in the complexity. The time complexity is within a polylogarithmic $O(\log^c N)$ factor of the query complexity, as long as the computational model is sufficiently general [3]. (Random access quantum memory is necessary for implementing any of the known quantum algorithms.)

Using the quantum walk methods, one can also solve the k-distinctness problem [3]. This gives a quantum algorithm for k-distinctness (and k-subset finding) that uses $O(N^{k/(k+1)})$ value queries and $O(N^{k/(k+1)})$ memory. For the case when the memory is restricted to $r < N^{k/(k+1)}$ values of x_i, it suffices to use $O(r + (N^{k/2})/(r^{(k-1)/2}))$ value queries. The results generalize to comparison queries and time complexity, with a polylogarithmic factor increase in the time complexity (similarly to the element distinctness problem). For the k-subset finding problem, Belovs and Rosmanis [8] have shown that there is a function $f(y_1, \ldots, y_k)$ for which $\Omega(N^{k/(k+1)})$ queries are also necessary.

For the k-distinctness problem, a better quantum algorithm has been recently developed by Belovs [6], using the learning graph approach. It solves 3-distinctness using $O(N^{5/7})$ value

queries and k-distinctness using $O\left(N^{1-\frac{2^k-2}{2^k-1}}\right)$ value queries. The algorithm for 3-distinctness can be implemented so that it runs in time $O(N^{5/7}\log^c N)$ [9]. It is an open problem to construct a time-efficient implementation for $k > 3$.

Element Distinctness: The Methods

Ambainis' algorithm has the following structure. Its state space is spanned by basic states $|T\rangle$, for all sets of indices $T \subseteq \{1,\ldots,N\}$ with $|T| = r$. The algorithm starts in a uniform superposition of all $|T\rangle$ and repeatedly applies a sequence of two transformations:

1. Conditional phase flip: $|T\rangle \to -|T\rangle$ for all T such that T contains i, j with $x_i = x_j$, and $|T\rangle \to |T\rangle$ for all other T;
2. Quantum walk: perform $O(\sqrt{r})$ steps of quantum walk, as defined in [3]. Each step is a transformation that maps each $|T\rangle$ to a combination of basis states $|T'\rangle$ for T' that differ from T in one element.

The algorithm maintains another quantum register, which stores all the values of $x_i, i \in T$. This register is updated with every step of the quantum walk.

If there are two elements i, j such that $x_i = x_j$, repeating these two transformations $O(N/r)$ times increases the amplitudes of $|T\rangle$ containing i, j. Measuring the state of the algorithm at that point with high probability produces a set T containing i, j. Then, from the set T, we can find i and j.

The basic structure of [3] is similar to Grover's quantum search, but with one substantial difference. In Grover's algorithm, instead of using a quantum walk, one would use Grover's *diffusion transformation*. Implementing Grover's diffusion requires $\Omega(r)$ updates to the register that stores $x_i, i \in T$. In contrast to Grover's diffusion, each step of quantum walk changes T by one element, requiring just one update to the list of $x_i, i \in T$. Thus, $O(\sqrt{r})$ steps of quantum walk can be performed with $O(\sqrt{r})$ updates, quadratically better than Grover's diffusion. And, as shown in [3], the quantum walk provides a sufficiently good approximation of diffusion for the algorithm to work correctly.

This was one of the first uses of quantum walks to construct quantum algorithms. Ambainis, Kempe, and Rivosh [4] then generalized it to handle searching on grids (described in another entry of this encyclopedia). Their algorithm is based on the same mathematical ideas, but has a slightly different structure. Instead of alternating quantum walk steps with phase flips, it performs a quantum walk with two different walk rules – the normal walk rule and the "perturbed" one. (The normal rule corresponds to a walk without a phase flip and the "perturbed" rule corresponds to a combination of the walk with a phase flip.)

Generalization to Arbitrary Markov Chains

Szegedy [20] and Magniez et al. [19] have generalized the algorithms of [4] and [3], respectively, to speed up the search of an arbitrary Markov chain. The main result of [19] is as follows.

Let P be an irreducible Markov chain with state space X. Assume that some states in the state space of P are *marked*. Our goal is to find a marked state. This can be done by a classical algorithm that runs the Markov chain P until it reaches a marked state (Algorithm 1).

There are three costs that contribute to the complexity of Algorithm 1:

1. **Setup cost** S: the cost to sample the initial state x from the initial distribution.
2. **Update cost** U: the cost to simulate one step of a random walk.
3. **Checking cost** C: the cost to check if the current state x is marked.

The overall complexity of the classical algorithm is then $S + t_2(t_1 U + C)$. The required t_1 and t_2 can be calculated from the characteristics of the Markov chain P. Namely,

Proposition 1 ([19]) *Let P be an ergodic, yet symmetric Markov chain. Let $\delta > 0$ be the eigenvalue gap of P, and assume that whenever*

Algorithm 1: Search by a classical random walk

1. Initialize x to a state sampled from some initial distribution over the states of P.
2. t_2 times repeat:
   (a) If the current stage y is marked, output y and stop;
   (b) Simulate t_1 steps of random walk, starting with the current state y.
3. If the algorithm has not terminated, output "no marked state."

the set of marked states M is nonempty, we have $|M|/|X| \geq \epsilon$. Then there are $t_1 = O(1/\delta)$ and $t_2 = O(1/\epsilon)$ such that Algorithm 1 finds a marked element with high probability.

Thus, the cost of finding a marked element classically is $O(S + 1/\epsilon(1/\delta U + C))$. Magniez et al. [19] construct a quantum algorithm that finds a marked element in $O(S' + 1/\epsilon(1/\sqrt{\delta}U' + C'))$ steps, with S', U', and C' being quantum versions of the setup, update, and checking costs (in most of applications, these are of the same order as S, U, and C). This achieves a quadratic improvement in the dependence on both ε and δ.

The element distinctness problem is solved by a particular case of this algorithm: a search on the Johnson graph. The Johnson graph is the graph whose vertices v_T correspond to subsets $T \subseteq \{1, \ldots, N\}$ of size $|T| = r$. A vertex v_T is connected to a vertex v'_T, if the subsets T and T' differ in exactly one element. A vertex v_T is *marked* if T contains indices i, j with $x_i = x_j$.

Consider the following Markov chain on the Johnson graph. The starting probability distribution s is the uniform distribution over the vertices of the Johnson graph. In each step, the Markov chain chooses the next vertex v'_T from all vertices that are adjacent to the current vertex v_T, uniformly at random. While running the Markov chain, one maintains a list of all $x_i, i \in T$. This means that the costs of the classical Markov chain are as follows:

- Setup cost of $S = r$ queries (to query all $x_i, i \in T$ where v_T is the starting state).
- Update cost of $U = 1$ query (to query the value $x_i, i \in T' - T$, where v_T is the vertex before the step and v'_T is the new vertex).
- Checking cost of $C = 0$ queries (the values $x_i, i \in T$ are already known to the algorithm, and no further queries are needed).

The quantum costs S', U', and C' are of the same order as S, U, and C.

For this Markov chain, it can be shown that the eigenvalue gap is $\delta = O(1/r)$ and the fraction of marked states is $\epsilon = O((r^2)/(N^2))$. Thus, the quantum algorithm runs in time

$$O\left(S' + \frac{1}{\sqrt{\epsilon}}\left(\frac{1}{\sqrt{\delta}}U' + C'\right)\right) = O\left(S' + \sqrt{r}\left(\frac{N}{r}U' + C'\right)\right) = O\left(r + \frac{N}{\sqrt{r}}\right).$$

Learning Graphs

Another framework that generalizes the element distinctness is the learning graphs by Belovs [6]. A learning graph is a structure that describes algorithm's information about the input data. Using this approach, many quantum algorithms can be described as sequences of high-level instructions (which can be compiled into a standard quantum query algorithm). For example, the element distinctness algorithm corresponds to a sequence of three operations:

1. Load $O(N^{2/3})$ values x_i for randomly chosen $i \in \{1, 2, \ldots, N\}$.
2. Load one of the two equal elements x_i.
3. Load the other equal element x_j.

Belovs [6] describes rules for determining the complexity of each step. In the algorithm above, the complexities are $O(N^{2/3})$, $O(\sqrt{N})$, and $O(N^{2/3})$, respectively. This results in the same overall complexity of $O(N^{2/3})$.

The learning graph approach has been used to construct new quantum algorithms for k-distinctness [7], triangle-finding [6], and other tasks.

Q

Applications

Magniez et al. [19] showed how to use the ideas from the element distinctness algorithm as a subroutine to solve the *triangle problem*. In the triangle problem, one is given a graph G on n vertices, accessible by queries to an oracle, and they must determine whether the graph contains a triangle (three vertices v_1, v_2, v_3 with $v_1 v_2$, $v_1 v_3$, and $v_2 v_3$ all being edges). This problem requires $\Omega(n^2)$ queries classically. Magniez et al. [19] showed that it can be solved using $O(n^{1.3} \log^c n)$ quantum queries, with a modification of the element distinctness algorithm as a subroutine. This has been improved by several authors. Currently, the best quantum algorithm for triangle finding is by Le Gall [17] which uses $O(n^{1.25} \log^c n)$ queries. It is also based on the quantum walks but uses them in a much more complex way.

The methods of Szegedy [20] and Magniez et al. [19] can be used as subroutines for quantum algorithms for checking matrix identities [12,18].

Bernstein et al. [10] have used the element distinctness algorithm to design a quantum algorithm for the subset sum problem, by combining the element distinctness algorithm with ideas from classical algorithms for subset sum. The resulting algorithm solves the subset sum problem for n numbers in $2^{(0.241+o(1))n}$ time steps, under some heuristic assumptions that are similar to the ones that are assumed for classical subset sum algorithms. The best classical algorithm uses $2^{(0.291+o(1))n}$ time steps.

Open Problems

1. How many queries are necessary to solve the element distinctness problem if the memory accessible to the algorithm is limited to r items, $r < N^{2/3}$? The algorithm of [3] gives $O(N/\sqrt{r})$ queries, and the best lower bound is $\Omega(N^{2/3})$ queries.
2. Consider the following problem:

   Graph collision [18]. The problem is specified by a graph G (which is arbitrary but known in advance) and variables $x_1, \ldots, x_N \in \{0, 1\}$, accessible by queries to an oracle. The task is to determine if G contains an edge uv such that $x_u = x_v = 1$. How many queries are necessary to solve this problem?

   The element distinctness algorithm can be adapted to solve this problem with $O(N^{2/3})$ queries [18], but there is no matching lower bound. Is there a better algorithm? A better algorithm for the graph collision problem would immediately imply a better algorithm for the triangle problem.

Quantum Algorithm for Factoring

Sean Hallgren
Department of Computer Science and Engineering, The Pennsylvania State University, University Park, State College, PA, USA

Years and Authors of Summarized Original Work

1994; Shor

Problem Definition

Every positive integer n has a unique decomposition as a product of primes $n = p_1^{e_1} \cdots p_k^{e_k}$, for prime number p_i, and positive integer exponent e_i. Computing the decomposition $p_1, e_1, \ldots, p_k, e_k$ from n is the factoring problem.

Factoring has been studied for many hundreds of years, and exponential time algorithms for it were found to include trial division, Lehman's method, Pollard's ρ method, and Shank's class group method [1]. With the invention of the RSA public-key cryptosystem in the late 1970s, the problem became practically important and started receiving much more attention. The security of RSA is closely related to the complexity of factoring, and in particular, it is only secured if factoring does not have an efficient algorithm. The first subexponential-time algorithm is due to Morrison and Brillhard [4] using a continued fraction algorithm. This was succeeded by the quadratic sieve method of Pomerance and the elliptic curve method of Lenstra [5]. The number field sieve [2, 3], found in 1989, is the best-known classical algorithm for factoring and runs in time $\exp(c(\log n)^{1/3}(\log \log n)^{2/3})$ for some constant c. Shor's result is a polynomial-time quantum algorithm for factoring.

Key Results

Theorem 1 ([2, 3]) *There is a subexponential-time classical algorithm that factors the integer n in time* $\exp(c(\log n)^{1/3}(\log \log n)^{2/3})$.

Theorem 2 ([6]) *There is a polynomial-time quantum algorithm that factors integers. The algorithm factor n in time $O((\log n)^2(\log n \log n)(\log \log \log n))$ plus polynomial in $\log n$ post-processing which can be done classically.*

Applications

Computationally hard number theoretic problems are useful for public-key cryptosystems.

The RSA public-key cryptosystem, as well as others, requires that factoring not to have an efficient algorithm. The best-known classical algorithms for factoring can help determine how secure the cryptosystem is and what key sizes to choose. Shor's quantum algorithm for factoring can break these systems in polynomial time using a quantum computer.

Open Problems

It is open whether there is a polynomial-time classical algorithm for factoring.

Problem Definition

A *triangle* is a clique of size three in an undirected graph. Triangle finding has been the subject of extensive study as a basic search problem whose quantum query complexity is still open, in contrast to unstructured search [6] and element distinctness [1].

This survey concerns quantum query algorithms for triangle finding. A *quantum query algorithm* for a search problem $P = \{M_f\}_f$ is a sequence of unitary operators $Q_f = U_k O_f U_{k-1} O_f U_1 O_f U_0$ such that if $M_f \neq \emptyset$, measuring $|\psi_f\rangle = Q_f|0\rangle$ yields a member of M_f, the set of objects associated with input f, with probability $\geq 2/3$. The operators O_f are *oracle queries*, $O_f : |x\rangle|a\rangle \mapsto |x\rangle|a \oplus f(x)\rangle$, which yield information about f, whereas the U_j are independent of f. The quantum query complexity of P is the minimum number of

oracle queries required by a quantum query algorithm for P.

In the context of triangle finding, the function f is the adjacency matrix of an undirected graph on vertices $[n]$, $G \subseteq [n]^2$, with $m = |G|$ edges, where $(a, b) \in G \Rightarrow (b, a) \in G$, by convention. The associated set, M_G, is the set of triangles in G.

Problem 1 (Triangle finding)

INPUT: The adjacency matrix f of a graph G on n vertices.

OUTPUT: A triangle: $(a, b, c) \in [n]^3$ such that $(a, b), (b, c), (a, c) \in G$, if one exists.

A lower bound of $\Omega(n)$ on the quantum query complexity of the triangle finding problem follows from a reduction from search [5]. It is easy to see that the randomized query complexity of the triangle finding problem is $\Theta(n^2)$.

Key Results

Progress on the quantum query complexity of triangle finding has closely followed the development of quantum algorithmic techniques for search problems. The first upper bounds were based on increasingly clever use of the structure of the problem, combined with amplitude amplification [4]. The first bound to go beyond the amplitude amplification framework, achieving $\tilde{O}(n^{13/10})$ [10], was one of the first applications of the quantum walk search technique introduced by Ambainis in his element distinctness algorithm [1] and extended in [13] and [11]. The next bound of $O(n^{35/27})$ was the first application of a new quantum algorithmic technique, the learning graph framework [3]. This finding led to the development of extensions to the quantum walk search technique to give a $\tilde{O}(n^{35/27})$ quantum walk algorithm for triangle finding [7]. The next improvement to $O(n^{9/7})$ also used the learning graph framework [9], whereas the most recent upper bound of $O(n^{5/4})$ uses, once again, a quantum walk search algorithm [8].

An $O(n + \sqrt{nm})$ Algorithm Using Amplitude Amplification

A trivial application of Grover's quantum search algorithm solves the triangle finding problem with $O(n^{3/2})$ quantum queries by searching over $[n]^3$. Buhrman et al. [5] improved this upper bound in the special case where G is sparse (i.e., $m = o(n^2)$).

The algorithm searches for an edge $(a, b) \in G$ in $O(\sqrt{|[n]^2|/m}) = O(n/\sqrt{m})$ quantum queries and then for $c \in [n]$ such that (a, b, c) is a triangle in $O(\sqrt{n})$ quantum queries. The second step succeeds when (a, b) is a triangle edge, which happens with probability at least $1/m$ when G contains a triangle, so applying amplitude amplification to this procedure gives a $O(\sqrt{m}(n/\sqrt{m} + \sqrt{n})) = O(n + \sqrt{nm})$ upper bound:

Theorem 1 (Buhrman et al. [5]) *Using quantum amplitude amplification, the triangle finding problem can be solved in $O(n + \sqrt{nm})$ quantum queries.*

An $\tilde{O}(n^{10/7})$ Algorithm Using Amplitude Amplification

The algorithm of Szegedy et al. [10, 12] is also based on amplitude amplification; however, it exploits additional combinatorial structure in the triangle finding problem.

For $A \subseteq [n]$ and $w \in [n]$, define $\Delta_G(A, w) := \{(u, v) \in A^2 : (u, w), (v, w) \in G\}$. Choose a random subset $X \subseteq [n]$ of size $n^\chi \log n$, for $\chi = 3/7$. Query $X \times [n]$ and search for an edge in $E_X := \bigcup_{w \in X} \Delta_G([n], w)$, which can be determined from $G \cap (X \times [n])$, using $O(|X|n + \sqrt{|E_X|}) = \tilde{O}(n^{1+\chi})$ queries. Either a triangle is found, or $E_X \cap G = \emptyset$.

Let $G' := [n]^2 \setminus E_X$. If a triangle is not found in the first step, then $G \subseteq G'$. Fix $\alpha = \beta = 1/7$. Szegedy et al. show that for most X, G' can be partitioned into (T, E), such that T has $O(n^{3-\alpha})$ triangles and $|E \cap G| = O(n^{2-\beta} + n^{2-\chi+\alpha+\beta})$, in $\tilde{O}(n^{1+\alpha+\beta})$ queries (or a triangle is found in the process). If $G \subseteq G'$, any triangle in G either lies in T, in which case it can be found in $O(\sqrt{n^{3-\alpha}})$ queries using quantum search, or intersects E, in which case it can be found in

$O(n + \sqrt{n|G \cap E|})$ queries using the algorithm of Buhrman et al. This gives the following:

Theorem 2 (Szegedy; Magniez, Santha and Szegedy [10, 12]) *Using amplitude amplification, the triangle finding problem can be solved in* $\tilde{O}(n^{10/7})$ *quantum queries.*

An $\tilde{O}(n^{13/10})$ Algorithm Using Quantum Walks

A more efficient algorithm for the triangle finding problem was obtained by Magniez et al. [10], using the quantum walk search technique introduced by Ambainis [1].

Given oracle access to a function defining a relation $M \subseteq [n]^k$, Ambainis' quantum walk search procedure finds $(a_1, \ldots, a_k) \in M$ if $M \neq \emptyset$. The algorithm walks on sets $A \subseteq [n]$ of size n^α, keeping track of some data structure $D(A)$ for the current state A and transitioning, in superposition, from A to A' for $A' \subseteq [n]$ of size n^α such that $|A \setminus A'| = 1$. Assume access to a quantum procedure Φ that determines if $A^k \cap M \neq \emptyset$ using $D(A)$, with *checking cost* C queries. Suppose $D(A)$ can be constructed from scratch at *setup cost* S queries and modified from $D(A)$ to $D(A')$ when $|A \setminus A'| = 1$ at an *update cost* U. Then the procedure finds an element of M in $O(\mathsf{S} + (\frac{n}{n^\alpha})^{k/2}(\sqrt{n^\alpha}\mathsf{U} + \mathsf{C}))$ quantum queries. (For details, see the encyclopedia entry on element distinctness.)

For a fixed graph $G \subseteq [n]^2$, consider the *graph collision* problem on G, where an input f defines the binary relation $M_f \subseteq [n]^2$ satisfying $(u, u') \in M_f$ if $f(u) = f(u') = 1$ and $(u, u') \in G$. Setting $k = 2$, it is a simple exercise to see that a quantum walk search algorithm solves this problem with $O(n^\alpha + (\frac{n}{n^\alpha})(\sqrt{n^\alpha} \cdot 1 + 0)) = O(n^\alpha + n^{1-\alpha/2})$ queries. Setting $\alpha = 2/3$ gives an upper bound of $O(n^{2/3})$ quantum queries for graph collision.

Magniez et al. [10] solve triangle finding using a quantum walk algorithm whose checking subroutine is based on graph collision. Let M be the set of triangle edges. Define $D(A) = G \cap A^2$. Then $\mathsf{S} = n^{2\alpha}$ initial queries are needed to set up $D(A)$, and $\mathsf{U} = n^\alpha$ new queries are needed to update $D(A)$, where α is now $3/5$. The checking step consists of an algorithm that, given a known subgraph $H = G \cap A^2$ on n^α vertices, decides if H contains a triangle edge using $\mathsf{C} = \tilde{O}(\sqrt{n}n^{2/3\alpha})$ queries, as follows. For any $v \in [n]$, define f_v on A by $f_v(u) = 1$ if $(u, v) \in G$. An edge $(a, b) \in A^2$ is a graph collision in f_v on $G \cap A^2$ if and only if (a, b, v) is a triangle, so searching for $v \in [n]$ for which f_v has a graph collision, using $O(\sqrt{n}(n^\alpha)^{2/3})$ quantum queries, is equivalent to deciding if $G \cap A^2$ contains a triangle edge. Repeat $\Theta(\log n)$ times, to decrease the error to $1/n^{\Theta(1)}$, since the subroutine is called many times. This gives the following:

Theorem 3 (Magniez, Santha, and Szegedy [10]) *Using a quantum walk search procedure, the triangle finding problem can be solved in* $\tilde{O}(n^{13/10})$ *quantum queries.*

An $O(n^{35/27})$ Algorithm Using Learning Graphs

The learning graph framework, introduced by Belovs [3], allows for the construction of a quantum algorithm from a particular type of edge-weighted graph called a *learning graph*. For further details, refer to [3]. The first application of this framework was a new upper bound on the quantum query complexity of triangle finding.

A learning graph may be constructed in stages, corresponding to searching for more and more specialized structures, which will eventually contain a 1-certificate for the problem being solved. In Belovs' application to triangle finding, the first part of the learning graph corresponds to searching for an n^α-vertex subset of $[n]$, A, containing two triangle vertices a and b. The next two stages correspond to searching for an $n^{2\alpha-\sigma}$-edge graph on A, H, which contains the triangle edge $\{a, b\}$. The final stages correspond to the graph collision subroutine used in [10] to decide if any edge of the queried subgraph H is a triangle edge. Using $\alpha = 2/3$ and $\sigma = 1/27$ gives the following:

Theorem 4 (Belovs [3]) *Using a learning graph algorithm, the triangle finding problem can be solved in* $O(n^{35/27}) = O(n^{1.2963})$ *quantum queries.*

Additionally, a quantum walk search algorithm based on this learning graph construction solves triangle finding in $\tilde{O}(n^{35/27})$ queries [7].

An $O(n^{9/7})$ Algorithm Using Learning Graphs

The next upper bound on the quantum query complexity of triangle finding, due to Lee et al. [9], also uses a learning graph. The first part of their learning graph corresponds to searching for an n^{α}-vertex subset $A \subseteq [n]$, containing a triangle vertex a. The next part corresponds to searching for an n^{β}-vertex subset $B \subseteq [n]$, containing a vertex, b, from the same triangle as a. The final part corresponds to the graph collision subroutine used in [10], but optimized for an unbalanced bipartite graph, used to decide if any edge of $G \cap (A \times B)$ is a triangle edge. Using $\alpha = 4/7$ and $\beta = 5/7$ gives the following:

Theorem 5 (Lee, Magniez and Santha [9]) *Using a learning graph algorithm, the triangle finding problem can be solved in* $O(n^{9/7}) = O(n^{1.2858})$ *quantum queries.*

As with the previous algorithm, there exists a quantum walk search algorithm based on this learning graph construction that solves triangle finding in $\tilde{O}(n^{9/7})$ queries [7].

An $\tilde{O}(n^{5/4})$ Algorithm Using Quantum Walks

The best known upper bound on the quantum query complexity of triangle finding is an algorithm by Le Gall [8]. Le Gall's algorithm uses the quantum walk search technique, as in the $\tilde{O}(n^{13/10})$-query algorithm, combined with a more clever utilization of the combinatorial structure of triangle finding, similar to that of the $\tilde{O}(n^{10/7})$-query algorithm, and a quantum search algorithm of Ambainis that finds an x such that $\Phi(x) = 1$ in cost $O(\sqrt{\sum_x C(x)^2})$, where $C(x)$ is the cost to compute $\Phi(x)$ [2].

The algorithm begins, like the $\tilde{O}(n^{10/7})$ algorithm, by choosing a random $X \subseteq [n]$ of size $n^{\chi} \log n$ and searching for a triangle in $X \times [n]^2$. This is done by quantum search on $X \times [n]^2$, using $O(\sqrt{|X \times [n]^2|}) = \tilde{O}(n^{1+\chi/2})$ quantum queries. If no triangle is found, as in the $\tilde{O}(n^{10/7})$ algorithm, the rest of the algorithm will make use of the fact that $E_X \cap G = \emptyset$, although in this case, since $X \times [n]$ is not queried, E_X is not known.

The rest of the algorithm consists of the following four levels of recursion:

1. Using a quantum walk search algorithm, search for a set $A \subseteq [n]$ of size n^{α} such that A^2 contains a triangle edge. Maintain a data structure, $D(A)$, encoding $G \cap (A \times X)$.
2. For any $A \subseteq [n]$, to check if A^2 contains a triangle edge, search for a vertex $c \in [n]$ such that $A^2 \times \{c\}$ contains a triangle.
3. For any $A \subseteq [n]$ and $c \in [n]$, to check if $A^2 \times \{c\}$ contains a triangle, use a quantum walk search algorithm to search for a set $B \subseteq A$ of size n^{β} such that $B^2 \times \{c\}$ contains a triangle. Maintain a data structure, $D^c(B)$, encoding $G \cap (B \times \{c\})$.
4. For any $B \subseteq [n]$ and $c \in [n]$, to check if $B^2 \times \{c\}$ contains a triangle, search for an edge in $\Delta_G(B, c) \setminus E_X$. Here the algorithm exploits the fact that there is no edge in E_X. The set $E_X \cap B^2$ can be determined from $G \cap (A \times X)$.

Constructing $D(A)$ costs $\mathsf{S} = |A \times X| = \tilde{O}(n^{\alpha+\chi})$ queries. Mapping $D(A)$ to $D(A')$ costs $\mathsf{U} = 2|X| = \tilde{O}(n^{\chi})$ queries. Let $\Phi(A) = 1$ if A^2 has a triangle edge. Then if C is the quantum query complexity of computing $\Phi(A)$, the quantum query complexity of finding a triangle in $G \setminus E_X$ is $O\left(\mathsf{S} + \frac{n}{n^{\alpha}}\left(\sqrt{n^{\alpha}}\mathsf{U} + \mathsf{C}\right)\right) = \tilde{O}\left(n^{\alpha+\chi} + n^{1+\chi-\alpha/2} + n^{1-\alpha}\mathsf{C}\right)$.

Let $\Phi_A(c) = 1$ if $A^2 \times \{c\}$ contains a triangle. To compute $\Phi(A)$, search for $c \in [n]$ such that $\Phi_A(c) = 1$. Let $\mathsf{C}'(c)$ be the cost of computing $\Phi_A(c)$, which will vary in c. Then by [2], $\mathsf{C} = O\left(\sqrt{\sum_{c \in [n]} \mathsf{C}'(c)}\right)$.

Let $\Phi^c(D^c(B)) = 1$ if $B^2 \times \{c\}$ has a triangle. To compute $\Phi_A(c)$, search for $B \subseteq A$ such that $\Phi^c(D^c(B)) = 1$. Creating $D^c(B)$ costs $\mathsf{S}'' = |B \times \{c\}| = n^{\beta}$ queries. Mapping $D^c(B)$ to $D^c(B')$ costs $\mathsf{U}'' = 2$ queries. If computing $\Phi^c(D^c(B))$ costs $\mathsf{C}''(c)$, computing $\Phi_A(c)$ costs $\mathsf{C}'(c) = \mathsf{S}'' + \frac{n^{\alpha}}{n^{\beta}}\left(\sqrt{n^{\beta}}\mathsf{U}'' + \mathsf{C}''(c)\right) = O\left(n^{\beta} + n^{\alpha-\beta/2} + n^{\alpha-\beta}\mathsf{C}''(c)\right)$ queries.

Observe that $\Phi^c(D^c(B)) = 1$ if and only if $\Delta_G(B,c)$ contains an edge. Since $G \cap E_X = \emptyset$, one need only search $\Delta_G(B,c) \setminus E_X$ for an edge. The set $\Delta_G(B,c)$ can be determined from $D^c(B)$, and $E_X \cap A^2$ can be determined from $D(A)$, so $\Delta_G(B,c) \setminus E_X$ is known. Thus, $\mathsf{C}''(c) = O(\sqrt{|\Delta_G(B,c) \setminus E_X|})$.

Using combinatorial arguments, Le Gall proves an upper bound on $|\Delta_G(B,c) \setminus E_X|$ relative to $|\Delta_G(A,c) \setminus E_X|$ for *most* B, allowing him to use further combinatorial arguments to show an upper bound on $\mathsf{C} = \sqrt{\sum_{c\in[n]} \mathsf{C}'(c)^2}$ of $O(n^{1/2+\chi} + n^{1/2+\beta} + n^{1/2+\alpha-\beta/2} + n^{1/2+\alpha-\chi/2})$. Setting $\chi = \beta = 1/2$ and $\alpha = 3/4$ then gives the following:

Theorem 6 (Le Gall [8]) *Using a quantum walk search algorithm, the triangle finding problem can be solved in $\tilde{O}(n^{5/4})$ quantum queries.*

The quantum query complexity of triangle finding is still open, as the best known lower bound is $\Omega(n)$.

Quantum Algorithm for Search on Grids

Andris Ambainis
Faculty of Computing, University of Latvia, Riga, Latvia

Keywords

Spatial search

Years and Authors of Summarized Original Work

2005; Ambainis, Kempe, Rivosh

Problem Definition

Consider an $\sqrt{N} \times \sqrt{N}$ grid, with each location storing a bit that is 0 or 1. The locations on the grid are indexed by (i, j), where $i, j \in$

$\{0, 1, \ldots, \sqrt{N}-1\} \cdot a_{i,j}$ denotes the value stored at the location (i, j).

The task is to find a location storing $a_{i,j} = 1$. This problem is as an abstract model for search in a two-dimensional database, with each location storing a variable $x_{i,j}$ with more than two values. The goal is to find $x_{i,j}$ that satisfies certain constraints. One can then define new variables $a_{i,j}$ with $a_{i,j} = 1$ if $x_{i,j}$ satisfies the constraints and search for i, j satisfying $a_{i,j} = 1$.

The grid is searched by a "robot," which at any moment of time is at one location i, j. In one time unit, the robot can either examine the current location or move one step in one of the four directions (left, right, up, or down).

In a probabilistic version of this model, the robot is probabilistic. It makes its decisions (querying the current location or moving) randomly according to prespecified probability distributions. At any moment of time, such a robot is at a probability distribution over the locations of the grid. In the quantum case, one has a "quantum robot" [5] which can be in a quantum superposition of locations (i, j) and is allowed to perform transformations that move it at most one step at a time.

There are several ways to make this model of a "quantum robot" precise [1] and they all lead to similar results.

The simplest to define is the Z-local model of [1]. In this model, the robot's state space is spanned by states $|i, j, a\rangle$ with i, j representing the current location and a being the internal memory of the robot. The robot's state $|\psi\rangle$ can be any quantum superposition of those: $|\psi\rangle = \sum_{i,j,a} \alpha_{i,j,a} |i, j, a\rangle$, where $\alpha_{i,j,a}$ are complex numbers such that $\sum_{i,j,a} |\alpha_{i,j,a}|^2 = 1$. In one step, the robot can either perform a query of the value at the current location or a Z-local transformation.

A query is a transformation that leaves i, j parts of a state $|i, j, a\rangle$ unchanged and modifies the a part in a way that depends only on the value $a_{i,j}$. A Z-local transformation is a transformation that maps any state $|i, j, a\rangle$ to a superposition that involves only states with robot being either at the same location or at one of the four adjacent locations ($|i, j, b\rangle$, $|i-1, j, b\rangle$, $|i+1, j, b\rangle$, $|i, j-1, b\rangle$ or $|i, j+1, b\rangle$ where the content of the robot's memory b is arbitrary).

The problem generalizes naturally to d-dimensional grid of size $N^{1/d} \times N^{1/d} \times \ldots \times N^{1/d}$, with robot being allowed to query or move one step in one of the d directions in one unit of time.

Key Results

Early Results

This problem was first studied by Benioff [5] who considered the use of the usual quantum search algorithm by Grover [9] in this setting. Grover's algorithm allows to search a collection of N items $a_{i,j}$ with $O(\sqrt{N})$ queries. However, it does not respect the structure of a grid. Between any two queries, it performs a transformation that may require the robot to move from any location (i, j) to any other locations (i', j'). In the robot model, where the robot in only allowed to move one step in one time unit, such transformation requires $O(\sqrt{N})$ steps to perform. Implementing Grover's algorithm, which requires $O(\sqrt{N})$ such transformations, therefore, takes $O(\sqrt{N}) \times O(\sqrt{N}) = O(N)$ time, providing no advantage over the naive classical algorithm.

The first algorithm improving over the naive use of Grover's search was proposed by Aaronson and Ambainis [1] who achieved the following results:

- Search on $\sqrt{N} \times \sqrt{N}$ grid, if it is known that the grid contains exactly one $a_{i,j} = 1$ in $O(\sqrt{N} \log^{3/2} N)$ steps.
- Search on $\sqrt{N} \times \sqrt{N}$ grid, if the grid may contain an arbitrary number of $a_{i,j} = 1$ in $O(\sqrt{N} \log^{5/2} N)$ steps.
- Search on $N^{1/d} \times N^{1/d} \times \ldots \times N^{1/d}$ grid, for $d \geq 3$, in $O(\sqrt{N})$ steps.

They also considered a generalization of the problem, search on a graph G, in which the robot moves on the vertices v of the graph G and searches for a variable $a_v = 1$. In one step, the

robot can examine the variable a_v corresponding to the current vertex v or move to another vertex w adjacent to v. Aaronson and Ambainis [1] gave an algorithm for searching an arbitrary graph with grid-like expansion properties in $O(N^{1/2+o(1)})$ steps. The main technique in those algorithms was the use of Grover's search and its generalization, amplitude amplification [6], in combination with "divide-and-conquer" methods recursively breaking up a grid into smaller parts.

Quantum Walks

The next algorithms were based on quantum walks [3,7,8]. Ambainis, Kempe, and Rivosh [3] presented an algorithm, based on a discrete time quantum walk, which searches the two-dimensional $\sqrt{N} \times \sqrt{N}$ in $O(\sqrt{N} \log N)$ steps, if the grid is known to contain exactly one $a_{i,j} = 1$ and in $O(\sqrt{N} \log^2 N)$ steps in the general case. Childs and Goldstone [8] achieved a similar performance, using continuous time quantum walk. Curiously, it turned out that the performance of the walk crucially depended on the particular choice of the quantum walk, both in the discrete and continuous time, and some very natural choices of quantum walk (e.g., one in [7]) failed.

Besides providing an almost optimal quantum speedup, the quantum walk algorithms also have an additional advantage: their simplicity. The discrete quantum walk algorithm of [3] uses just two bits of quantum memory. Its basis states are $|i, j, d\rangle$, where (i, j) is a location on the grid and d is one of the four directions: $\leftarrow$, $\rightarrow$, $\uparrow$, and $\downarrow$. The basic algorithm consists of the following simple steps:

1. Generate the state $\sum_{i,j,d} \frac{1}{2\sqrt{N}} |i, j, d\rangle$.
2. $O(\sqrt{N \log N})$ times repeat
   1. Perform the transformation

$$C_0 = \begin{pmatrix} -\frac{1}{2} & \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} \end{pmatrix}$$

   2. On the states $|i, j, \leftarrow\rangle$, $|i, j, \rightarrow\rangle$, $|i, j, \uparrow\rangle$, $|i, j, \downarrow\rangle$, if $a_{i,j} = 0$ and the transformation $C_1 = -I$ on the same four states if $a_{i,j} = 1$.
   3. Move one step according to the direction register and reverse the direction:

$$|i, j, \rightarrow\rangle \rightarrow |i + 1, j, \leftarrow\rangle,$$
$$|i, j, \leftarrow\rangle \rightarrow |i - 1, j, \rightarrow\rangle,$$
$$|i, j, \uparrow\rangle \rightarrow |i, j - 1, \downarrow\rangle,$$
$$|i, j, \downarrow\rangle \rightarrow |i, j + 1, \uparrow\rangle.$$

In case, if $a_{i,j} = 1$ for one location (i, j), a significant part of the algorithm's final state will consist of the four states $|i, j, d\rangle$ for the location (i, j) with $a_{i,j} = 1$. This can be used to detect the presence of such location. More precisely, if we run the algorithm for $O(\sqrt{N \log N})$ steps and measure the state, we obtain one of the four states $|i, j, d\rangle$ with probability $\Theta(1/\log N)$.

We can increase the probability of algorithm finding the right location *(i, j)* by either repeating the algorithm or using quantum amplitude amplification. Quantum amplitude amplification [6] takes a quantum algorithm that succeeds with a small probability ε and increases the success probability to 3/4, by repeating the quantum algorithm $O(1/\sqrt{\epsilon})$ times. In our case, $\epsilon = \Theta(1/\log N)$ which means that it suffices to repeat the basic algorithm $O(\sqrt{\log N})$ times. This increases the running time from $O(\sqrt{N \log N})$ for the basic algorithm to $O(\sqrt{N} \log N)$.

A quantum algorithm for search on a grid can be also derived by designing a classical algorithm that finds $a i, j = 1$ by performing a random walk on the grid and then applying Szegedy's general translation of classical random walks to quantum random chains, with a quadratic speedup over the classical random walk algorithm [15]. The resulting algorithm is similar to the algorithm of [3] described above and has the same running time.

For an overview on related quantum algorithms using similar methods, see [2,10].

Further Developments

The running time of the algorithm has been improved to $O(\sqrt{N \log N})$ time steps if the grid is known to contain exactly one *(i, j)* with $a_{i,j} = 1$ and $O(\sqrt{N} \log^{1.5} N)$ steps in the general case. This can be achieved in two different ways. First, Tulsi [16] showed how to modify the quantum walk so that, after $O(\sqrt{N \log N})$ steps, it finds the right *(i, j)* with a constant probability. This eliminates the need to use amplitude amplification.

Second, Ambainis et al. [4] showed that the same result can be achieved without modifying the quantum walk, by a simple classical postprocessing. That is, even if the quantum walk does not find the right *(i, j)*, its final state is much more likely to be (i', j') that is close to *(i, j)*. One can then run the quantum walk for $O(\sqrt{N \log N})$ steps once, measure the result, obtain a location (i', j'), and search the nearby locations for *(i, j)* with $a_{i,j} = 1$.

Search algorithms similar to the original 2D search algorithm have been analyzed for a number of other graphs (e.g., for hierarchical networks [12]).

Applications

The quantum algorithm for search on the grid by Ambainis, Kempe, and Rivosh [3] has been generalized by Szegedy [15], obtaining a general procedure for speeding up classical Markov chains (described in more detail in the article on Quantization of Markov Chains). Szegedy's generalization concerns a class of algorithms called *Search by Random Walk* in which one performs a random walk on some search space until finding an element with a certain property. Szegedy [15] showed that if a classical random walk finds a marked element in T steps (on average), there is a quantum algorithm that detects the existence of a marked element in $O(\sqrt{T})$ steps.

It is an open problem to extend Szegedy's algorithm so that it not only detects the existence of an element with the desired property but also finds it in $O(\sqrt{T})$ time steps. (This is known as the "finding problem".) A step in this direction was made by Magniez et al. [11] who generalized Tulsi's algorithm for search on the grid [16] to solve the finding problem in $O(\sqrt{T})$ steps whenever the classical random walk is vertex transitive and the search space has a unique element with the desired property.

Quantum algorithms for spatial search are also useful for designing quantum communication protocols for the set disjointness problem. In the set disjointness problem, one has two parties holding inputs $x \in \{0,1\}^N$ and $y \in \{0,1\}^N$ and they have to determine if there is $i \in \{1, \ldots, N\}$ for which $x_i = y_i = 1$. (One can think of x and y as representing subsets $X, Y \subseteq \{1, \ldots, N\}$ with $x_i = 1 (y_i = 1)$ if $i \in X (i \in Y)$. Then, determining if $x_i = y_i = 1$ for some i is equivalent to determining if $X \cap Y \neq \emptyset$.)

The goal is to solve the problem, communicating as few bits between the two parties as possible. Classically, $\Omega(N)$ bits of communication are required [13]. The optimal quantum protocol [1] uses $O(\sqrt{N})$ quantum bits of communication and its main idea is to reduce the problem to spatial search. As shown by the $\Omega(\sqrt{N})$ lower bound of [14], this algorithm is optimal.

Quantum Algorithm for Solving Pell's Equation

Sean Hallgren
Department of Computer Science and Engineering, The Pennsylvania State University, University Park, State College, PA, USA

Years and Authors of Summarized Original Work

2002; Hallgren

Problem Definition

Pell's equation is one of the oldest studied problem in number theory. For a positive square-free integer d, Pell's equation is $x^2 - dy^2 = 1$, and the problem is to compute integer solutions x, y of the equation [8, 10]. The earliest algorithm for it uses the continued fraction expansion of $\sqrt{d}$ and dates back to 1000 a.d. by Indian mathematicians. Lagrange showed that there are an infinite number of solutions of Pell's equation. All solutions are of the form $x_n + y_n\sqrt{d} = (x_1 + y_1\sqrt{d})^n$, where the smallest solution, (x_1, y_1), is called the fundamental solution. The solution (x_1, y_1) may have exponentially many bits in general in terms of the input size, which is $\log d$, and so cannot be written down in polynomial time. To resolve this difficulty, the computational problem is recast as computing the integer closest to the regulator $R = \ln(x_1 + y_1\sqrt{d})$. In this representation, solutions of Pell's equation are positive integer multiples of R.

Solving Pell's equation is a special case of computing the unit group of number field. For a positive non-square integer Δ congruent to 0 or 1 mod 4, $K = \mathbb{Q}(\sqrt{\Delta})$ is a real quadratic number field. Its subring $\mathcal{O} = \mathbb{Z}\left[\frac{\Delta+\sqrt{\Delta}}{2}\right] \subseteq Q(\sqrt{\Delta})$ is called the quadratic order of discriminant Δ. The unit group is the set of invertible elements of $\mathcal{O}$. Units have the form $\pm\varepsilon^k$, where $k \in \mathbb{Z}$, for some $\varepsilon > 1$ called the fundamental unit. The fundamental unit ε can have exponentially many bits, so an approximation of the regulator $R = \ln\varepsilon$ is computed. In this representation the unit group consists of integer multiples of R. Given the integer closest to R there are classical polynomial-time algorithms to compute R to any precision. There are also efficient algorithms to test if a given number is a good approximation to an integer multiple of a unit or to compute the least significant digits of $\varepsilon = e^R$ [1, 3].

Two related and potentially more difficult problems are the principal ideal problem and computing the class group of a number field. In the principal ideal problem, a number field and an ideal I of $\mathcal{O}$ are given, and the problem is to decide if the ideal is principal, i.e., whether

there exists α such that $I = \alpha\mathcal{O}$. If it is principal, then one can ask for an approximation of $\ln\alpha$. There are efficient classical algorithms to verify that a number is close to $\ln\alpha$ [1, 3]. The class group of a number field is the finite abelian group defined by taking the set of fractional ideals modulo the principal fractional ideals. The class number is the size of the class group. Computing the unit group, computing the class group, and solving the principal ideal problems are three of the main problems of computational algebraic number theory [3]. Assuming the GRH, they are in NP ∩ CoNP [9].

Key Results

The best known classical algorithms for the problems defined in the last section take subexponential time, but there are polynomial-time quantum algorithms for them [5, 7].

Theorem 1 *Given a quadratic discriminant Δ, there is a classical algorithm that computes an integer multiple of the regulator to within one. Assuming the GRH, this algorithm computes the regulator to within one and runs in expected time* $\exp\left(\sqrt{(\log\Delta)\log\log\Delta}\right)^{O(1)}$.

Theorem 2 *There is a polynomial-time quantum algorithm that, given a quadratic discriminant Δ, approximates the regulator to within δ of the associated order $\mathcal{O}$ in time polynomial in* $\log\Delta$ *and* $\log\delta$ *with probability exponentially close to one.*

Corollary 1 *There is a polynomial-time quantum algorithm that solves Pell's equation.*

The quantum algorithm for Pell's equation uses the existence of a periodic function on the reals which has period R and is one-to-one within each period [5, 7]. There is a discrete version of this function that can be computed efficiently. This function does not have the same periodic property since it cannot be evaluated at arbitrary real numbers such as R, but it does approximate the situation well enough for the quantum algorithm. In particular, computing the approximate period of this function gives R to the closest integer or, in other words, computes a generator for the unit group.

Theorem 3 *There is a polynomial-time quantum algorithm that solves the principal ideal problem in real quadratic number fields.*

Corollary 2 *There is a polynomial-time quantum algorithm that can break the Buchmann-Williams key-exchange protocol in real quadratic number fields.*

Theorem 4 *The class group and class number of a real quadratic number field can be computed in quantum polynomial time assuming the GRH.*

In general, one can ask to find the unit group of an arbitrary degree number field $\mathbb{Q}(\theta)$, where θ is the root of a polynomial with rational coefficients. There are two parameters associated with this problem. The first is the discriminant, which generalizes parameter above. The second is the degree n of the number field as a vector space over the rational numbers. In the above example the degree is fixed at 2. The unit group of an arbitrary degree number can also be computed efficiently by a quantum algorithm.

Theorem 5 ([4]) *The unit group of a number field can be computed by a quantum algorithm in time polynomial in log the discriminant, and the degree n.*

This last result uses a major generalization of the hidden subgroup problem to continuous functions. A new method is used to compute the function that is polynomial time in the degree of the number field and solves the hidden subgroup problem for continuous groups.

Applications

Computationally hard number theoretic problems are useful for public key cryptosystems. There are reductions from factoring to Pell's equation and Pell's equation to the principal ideal problem, but no reductions are known in the opposite direction. The principal ideal problem forms the basis of the Buchmann-Williams key-exchange protocol

[2]. Identification schemes based on this problem have been proposed by Hamdy and Maurer [6]. The classical exponential-time algorithms help determine which parameters to choose for the cryptosystem. The best known algorithm for Pell's equation is exponentially slower than the best factoring algorithm. Systems based on these harder problems were proposed as alternatives in case factoring turns out to be polynomial time solvable. The efficient quantum algorithms can break these cryptosystems.

Open Problems

Lattice-based cryptography is the leading class of candidates for primitives secure against quantum computers. Recent systems have used lattices from number fields in order to make them more efficient. It is an open question whether lattice-based systems are secure against quantum computers, given that quantum computers have an exponential advantage over classical computers for some problems in number fields.

Quantum Algorithm for the Collision Problem

Gilles Brassard[1], Peter Høyer[2], and Alain Tapp[1]
[1]Université de Montréal, Montréal, QC, Canada
[2]University of Calgary, Calgary, AB, Canada

Keywords

Collision; Grover's algorithm; Quantum algorithm

Years and Authors of Summarized Original Work

1998; Brassard, Høyer, Tapp

Problem Definition

A function F is said to be *r-to-one* if every element in its image has exactly r distinct preimages.

Input : an r-to-one function F.
Output : x_1 and x_2 such that $F(x_1) = F(x_2)$.

Key Results

The algorithm presented here finds collisions in arbitrary r-to-one functions F after only $O(\sqrt[3]{N/r})$ expected evaluations of F. The algorithm uses the function as a black box, that is, the only thing the algorithm requires is the capacity to evaluate the function. Again assuming the function is given by a black box, the algorithm is optimal [1], and it is more efficient than the best *possible* classical algorithm which has query complexity $\Omega(\sqrt{N/r})$. The result is stated precisely in the following theorem and corollary.

Theorem 1 *Given an r-to-one function $F:X\to Y$ with $r\geq 2$ and an integer $1\leq k\leq N=|X|$, algorithm* **Collision**(F,k) *returns a collision after an expected number of $O(k+\sqrt{N/(rk)})$ evaluations of F and uses space $\Theta(k)$. In particular, when $k=\sqrt[3]{N/r}$, then* **Collision**(F,k) *uses an expected number of $O(\sqrt[3]{N/r})$ evaluations of F and space $\Theta(\sqrt[3]{N/r})$.*

Corollary 1 *There exists a quantum algorithm that can find a collision in an arbitrary r-to-one function $F:X\to Y$, for any $r\geq 2$, using space S and an expected number of $O(T)$ evaluations of F for every $1\leq S\leq T$ subject to $ST^2\geq |F(X)|$ where $F(X)$ denotes the image of F.*

The algorithm uses as a procedure a version of Grover's search algorithm. Given a function H with domain size n and a target y, **Grover**(H,y) returns an x such that $H(x)=y$ in expected $O(\sqrt{n})$ evaluations of H.

Collision(F,k):

1. Pick an arbitrary subset $K\subseteq X$ of cardinality k. Construct a table L of size k where each item in L holds a distinct pair $(x,F(x))$ with $x\in K$.
2. Sort L according to the second entry in each item of L.
3. Check if L contains a collision, that is, check if there exist distinct elements $(x_0,F(x_0))$, $(x_1,F(x_1))\in L$ for which $F(x_0)=F(x_1)$. If so, go to step 6.
4. Compute $x_1=$ **Grover**$(H,1)$ where $H:X\to\{0,1\}$ denotes the function defined by $H(x)=1$ if and only if there exists $x_0\in K$ so that $(x_0,F(x))\in L$ but $x\neq x_0$. (Note that x_0 is unique if it exists since we already checked that there are no collisions in L.)
5. Find $(x_0,F(x_1))\in L$.
6. Output the collision $\{x_0,x_1\}$.

Applications

This problem is of particular interest for cryptology because some functions known as *hash functions* are used in various cryptographic protocols. The security of these protocols crucially depends on the presumed difficulty of finding collisions in such functions.

Quantum Algorithm for the Discrete Logarithm Problem

Pranab Sen
School of Technology and Computer Science,
Tata Institute of Fundamental Research,
Mumbai, India

Keywords

Logarithms in groups

Years and Authors of Summarized Original Work

1994; Shor

Problem Definition

Given positive real numbers $a \neq 1, b$, the logarithm of b to base a is the unique real number s such that $b = a^s$. The notion of the *discrete logarithm* is an extension of this concept to general groups.

Problem 1 (Discrete logarithm)

INPUT: Group $G, a, b \in G$ such that $b = a^s$ for some positive integer s.

OUTPUT: The smallest positive integer s satisfying $b = a^s$, also known as the *discrete logarithm* of b to the base a in G.

The usual logarithm corresponds to the discrete logarithm problem over the group of positive reals under multiplication. The most common case of the discrete logarithm problem is when the group $G = \mathbb{Z}_p^*$, the multiplicative group of integers between 1 and $p-1$ modulo p, where p is a prime. Another important case is when the group G is the group of points of an elliptic curve over a finite field.

Key Results

The discrete logarithm problem in $\mathbb{Z}_p^*$, where p is a prime, as well as in the group of points of an elliptic curve over a finite field is believed to be intractable for randomized classical computers. That is, any, possibly randomized, algorithm for the problem running on a classical computer will take time that is superpolynomial in the number of bits required to describe an input to the problem. The best classical algorithm for finding discrete logarithms in $\mathbb{Z}_p^*$, where p is a prime, is Gordon's [4] adaptation of the number field sieve which runs in time $\exp(O((\log p)^{1/3}(\log\log p)^{2/3}))$.

In a breakthrough result, Shor [9] gave an efficient quantum algorithm for the discrete logarithm problem in any group G; his algorithm runs in time that is polynomial in the bit size of the input.

Result 1 ([9]) There is a quantum algorithm solving the discrete logarithm problem in any group G on n-bit inputs in time $O(n^3)$ with probability at least 3/4.

Description of the Discrete Logarithm Algorithm

Shor's algorithm [9] for the discrete logarithm problem makes essential use of an efficient quantum procedure for implementing a unitary transformation known as the *quantum Fourier transform*. His original algorithm gave an efficient procedure for performing the quantum Fourier transform only over groups of the form $\mathbb{Z}_r$, where r is a "smooth" integer, but nevertheless, he showed that this itself sufficed to solve the discrete logarithm in the general case. In this article, however, a more modern description of Shor's algorithm is given. In particular, a result by Hales and Hallgren [5] is used which shows that the quantum Fourier transform over any finite cyclic group $\mathbb{Z}_r$ can be

efficiently approximated to inverse-exponential precision.

A description of the algorithm is given below. A general familiarity with quantum notation on the part of the reader is assumed. A good introduction to quantum computing can be found in the book by Nielsen and Chuang [8]. Let $(G, a, b, \bar{r})$ be an instance of the discrete logarithm problem, where $\bar{r}$ is a supplied upper bound on the order of a in G. That is, there exists a positive integer $r \leq \bar{r}$ such that $a^r = 1$. By using an efficient quantum algorithm for order finding also discovered by Shor [9], one can assume that the order of a in G is known, that is, the smallest positive integer r satisfying $a^r = 1$. Shor's order-finding algorithm runs in time $O((\log \bar{r})^3)$. Let $\epsilon > 0$. The discrete logarithm algorithm works on three registers, of which the first two are each t qubits long, where $t := O(\log r + \log(1/\epsilon))$, and the third register is big enough to store an element of G. Let U denote the unitary transformation

$$U : |x\rangle|y\rangle|z\rangle \mapsto |x\rangle|y\rangle|z \otimes (b^x a^y)\rangle,$$

where $\otimes$ denotes bitwise XOR. Given access to a reversible oracle for group operations in G, U can be implemented reversibly in time $O(t^3)$ by repeated squaring.

Let $\mathbb{C}[\mathbb{Z}_r]$ denote the Hilbert space of functions from $\mathbb{Z}_r$ to complex numbers. The computational basis of $\mathbb{C}[\mathbb{Z}_r]$ consists of the delta functions $\{|l\rangle\}_{0 \leq l \leq r-1}$, where $|\rangle$ is the function that sends the element l to 1 and the other elements of $\mathbb{Z}_r$ to 0. Let $\mathrm{QFT}_{\mathbb{Z}_r}$ denote the *quantum Fourier transform* over the cyclic group $\mathbb{Z}_r$ defined as the following unitary operator on $\mathbb{C}[\mathbb{Z}_r]$:

$$\mathrm{QFT}_{\mathbb{Z}_r} : |x\rangle \mapsto r^{-1/2} \sum_{y \in \mathbb{Z}_r} e^{-2\pi i x y / r} |y\rangle.$$

It can be implemented in quantum time $O(t \log(t/\epsilon) + \log^2(1/\epsilon))$ up to an error of ϵ using one t-qubit register [5]. Note that for any $k \in \mathbb{Z}_r$, $\mathrm{QFT}_{\mathbb{Z}_r}$ transforms the state $r^{-1/2} \sum_{x \in \mathbb{Z}_r} e^{-2\pi i k x / r} |x\rangle$ to the state $|k\rangle$. For any integer $l, 0 \leq l \leq r-1$, define

$$|\hat{l}\rangle := r^{-1/2} \sum_{k=0}^{r-1} e^{-2\pi i l k / r} |a^k\rangle. \qquad (1)$$

Observe that $\{|\hat{l}\rangle\}_{0 \leq l \leq r-1}$ forms an orthonormal basis of $\mathbb{C}[\langle a \rangle]$, where $\langle a \rangle$ is the subgroup generated by a in G and is isomorphic to $\mathbb{Z}_r$, and $\mathbb{C}[\langle a \rangle]$ denotes the Hilbert space of functions from $\langle a \rangle$ to complex numbers.

Algorithm 1 (Discrete logarithm)

INPUT: Elements $a, b \in G$, a quantum circuit for U, the order r of a in G.

OUTPUT: With constant probability, the discrete logarithm s of b to the base a in G.

RUNTIME: A total of $O(t^3)$ basic gate operations, including four invocations of $\mathrm{QFT}_{\mathbb{Z}_r}$ and one of U.

PROCEDURE:

1. Repeat Steps (a)–(e) twice, obtaining $(sl_1 \bmod r, l_1)$ and $(sl_2 \bmod r, l_2)$.
   (a) $|0\rangle|0\rangle|0\rangle$
   (b) $\mapsto r^{-1} \sum_{x,y \in \mathbb{Z}_r} |x\rangle|y\rangle|0\rangle$
   Apply $\mathrm{QFT}_{\mathbb{Z}_r}$ to the first two registers:
   (c) $\mapsto r^{-1} \sum_{x,y \in \mathbb{Z}_r} |x\rangle|y\rangle|b^x a^y\rangle$
   Apply U
   (d) $\mapsto r^{-1/2} \sum_{l=0}^{r-1} |sl \mod r\rangle|l\rangle|\hat{l}\rangle$
   Apply $\mathrm{QFT}_{\mathbb{Z}_r}$ to the first two registers:
   (e) $\mapsto (sl \mod r, l)$
   Measure the first two registers:
2. If l_1 is not coprime to l_2, abort.
3. Let k_1, k_2 be integers such that $k_1 l_1 + k_2 l_2 = 1$. Then, output $s = k_1(sl_1) + k_2(sl_2) \bmod r$.

The working of the algorithm is explained below. From Eq. (1), it is easy to see that

$$|b^x a^y\rangle = r^{-1/2} \sum_{l=0}^{r-1} e^{2\pi i l(sx+y)/r} |\hat{l}\rangle.$$

Thus, the state in Step 1(c) of the above algorithm can be written as

$$
\begin{aligned}
& r^{-1} \sum_{x,y \in \mathbb{Z}_r} |x\rangle|y\rangle|b^x a^y\rangle \\
& \quad = r^{-3/2} \sum_{l=0}^{r-1} \sum_{x,y \in \mathbb{Z}_r} \mathrm{e}^{2\pi i l(sx+y)/r} |x\rangle|y\rangle|\hat{l}\rangle \\
& \quad = r^{-3/2} \sum_{l=0}^{r-1} \left[\sum_{x \in \mathbb{Z}_r} e^{2\pi i s l x/r} |x\rangle \right] \cdot \left[\sum_{y \in \mathbb{Z}_r} e^{2\pi i l y/r} |y\rangle \right] |\hat{l}\rangle .
\end{aligned}
$$

Now, applying $\mathrm{QFT}_{\mathbb{Z}_r}$ to the first two registers gives the state in Step 1(d) of the above algorithm. Measuring the first two registers gives ($sl \bmod r, l$) for a uniformly distributed $l, 0 \le l \le r-1$ in Step 1(e). By elementary number theory, it can be shown that if integers l_1, l_2 are uniformly and independently chosen between 0 and $l-1$, they will be coprime with constant probability. In that case, there will be integers k_1, k_2 such that $k_1 l_1 + k_2 l_2 = 1$, leading to the discovery of the discrete logarithm s in Step 3 of the algorithm with constant probability. Since actually only an ϵ-approximate version of $\mathrm{QFT}_{\mathbb{Z}_r}$ can be applied, ϵ can be set to be a sufficiently small constant, and this will still give the correct discrete logarithm s in Step 3 of the algorithm with constant probability. The success probability of Shor's algorithm for the discrete logarithm problem can be boosted to at least 3/4 by repeating it a constant number of times.

Generalizations of the Discrete Logarithm Algorithm

The discrete logarithm problem is a special case of a more general problem called the *hidden subgroup problem* [8]. The ideas behind Shor's algorithm for the discrete logarithm problem can be generalized in order to yield an efficient quantum algorithm for hidden subgroups in Abelian groups (see [1] for a brief sketch). It turns out that finding the discrete logarithm of b to the base a in G reduces to the hidden subgroup problem in the group $\mathbb{Z}_r \times \mathbb{Z}_r$ where r is the order of a in G. Besides the discrete logarithm problem, other cryptographically important functions like integer factoring, finding the order of permutations, as well as finding self-shift-equivalent polynomials over finite fields can be reduced to instances of a hidden subgroup in Abelian groups.

Applications

The assumed intractability of the discrete logarithm problem lies at the heart of several cryptographic algorithms and protocols. The first example of public-key cryptography, namely, the Diffie-Hellman key exchange [2], uses discrete logarithms, usually in the group $\mathbb{Z}_p^*$ for a prime p. The security of the US national standard Digital Signature Algorithm (see [7] for details and more references) depends on the assumed intractability of discrete logarithms in $\mathbb{Z}_p^*$, where p is a prime. The ElGamal public-key cryptosystem [3] and its derivatives use discrete logarithms in appropriately chosen subgroups of $\mathbb{Z}_p^*$, where p is a prime. More recent applications include those in elliptic curve cryptography [6], where the group consists of the group of points of an elliptic curve over a finite field.

Quantum Algorithm for the Parity Problem

Yaoyun Shi
Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MI, USA

Keywords

Deutsch algorithm; Deutsch-Jozsa algorithm; Parity

Years and Authors of Summarized Original Work

1985; Deutsch

Problem Definition

The *parity* of n bits $x_0, x_1, \cdots, x_{n-1} \in \{0,1\}$ is

$$x_0 \oplus x_1 \oplus \cdots \oplus x_{n-1} = \sum_{i=0}^{n-1} x_i \mod 2.$$

As an elementary Boolean function, parity is important not only as a building block of digital logic but also for its instrumental roles in several areas such as error correction, hashing, discrete Fourier analysis, pseudorandomness, communication complexity, and circuit complexity. The feature of parity that underlies its many applications is its maximum sensitivity to the input: flipping any bit in the input changes the output. The computation of parity from its input bits is quite straightforward in most computation models. However, two settings deserve attention.

The first is the circuit complexity of parity when the gates are restricted to AND, OR, and NOT gates. It is known that parity cannot be computed by such a circuit of a polynomial size and a constant depth, a groundbreaking result proved independently by Furst, Saxe, and Sipser [7] and Ajtai [1] and improved by several subsequent works.

The second, and the focus of this article, is in the decision tree model (also called the query model or the black-box model), where the input bits $x = x_0 x_1 \cdots x_{n-1} \in \{0,1\}^n$ are known to an oracle only, and the algorithm needs to ask questions of the type "x_i =?" to access the input. The complexity is measured by the number of queries. Specifically, a quantum query is the application of the following query gate:

$$O_x : |i, b\rangle \mapsto |i, b \oplus x_i\rangle,$$
$$i \in \{0, \cdots, n-1\}, b \in \{0,1\}.$$

Key Results

Proposition 1 *There is a quantum query algorithm computing the parity of 2 bits with probability 1 using 1 query.*

Proof Denote by $|\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$. The initial state of the algorithm is

$$\frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \otimes |-\rangle.$$

Apply a query gate, using the first register for the index slot and the second register for the answer slot. The resulting state is

$$\frac{1}{\sqrt{2}}((-1)^{x_0}|0\rangle + (-1)^{x_1}|1\rangle) \otimes |-\rangle.$$

Applying a Hadamard gate $H = |+\rangle\langle 0| + |-\rangle\langle 1|$ on the first register brings the state to

$$(-1)^{x_0}|x_0 + x_1\rangle \otimes |-\rangle.$$

Thus measuring the first register gives $x_0 + x_1$ with certainty.

Corollary 1 *There is a quantum query algorithm computing the parity of n bits with probability 1 using $\lceil n/2 \rceil$ queries.*

The above quantum upper bound for parity is tight, even if the algorithm is allowed to err with a probability bounded away from 1/2 [6]. In contrast, any classical randomized algorithm with bounded error probability requires n queries. This follows from the fact that on a random input, any classical algorithm not knowing all the input bits is correct with precisely 1/2 probability.

Applications

The quantum speedup for computing parity was first observed by Deutsch [4]. His algorithm uses $|0\rangle$ in the answer slot, instead of $|-\rangle$. After one query, the algorithm has 3/4 chance of computing the parity, better than any classical algorithm (1/2 chance). The presented algorithm is actually a special case of the Deutsch-Jozsa Algorithm, which solves the following problem now referred to as the Deutsch-Jozsa Problem.

Problem 1 (Deutsch-Jozsa Problem) Let $n \geq 1$ be an integer. Given an oracle function $f : \{0,1\}^n \to \{0,1\}$ that satisfies either (a) $f(x)$ is constant on all $x \in \{0,1\}^n$ or (b) $|\{x : f(x) = 1\}| = |\{x : f(x) = 0\}| = 2^{n-1}$, determine which case it is.

When $n = 1$, the above problem is precisely parity of 2 bits. For a general n, the Deutsch-Jozsa Algorithm solves the problem using only once the following query gate:

$$O_f : |x, b\rangle \mapsto |x, f(x) \oplus b\rangle,\ x \in \{0,1\}^n,\ b \in \{0,1\}.$$

The algorithm starts with

$$|0^n\rangle \otimes |-\rangle.$$

It applies $H^{\otimes n}$ on the index register (the first n qubits), changing the state to

$$\frac{1}{2^{n/2}} \sum_{x \in \{0,1\}^n} |x\rangle \otimes |-\rangle.$$

The oracle gate is then applied, resulting in

$$\frac{1}{2^{n/2}} \sum_{x \in \{0,1\}^n} (-1)^{f(x)}|x\rangle \otimes |-\rangle.$$

For the second time, $H^{\otimes n}$ is applied on the index register, bringing the state to

$$\sum_{y \in \{0,1\}^n} \left(\frac{1}{2^n} \sum_{x \in \{0,1\}^n} (-1)^{f(x)+x\cdot y} \right) |y\rangle \otimes |-\rangle. \tag{1}$$

Finally, the index register is measured in the computational basis. The Algorithm returns "Case (a)" if 0^n is observed, otherwise returns "Case (b)."

By direct inspection, the amplitude of $|0^n\rangle$ is 1 in Case (a) and 0 in Case (b). Thus the algorithm is correct with probability 1. It is easy to see that any deterministic algorithm requires $n/2 + 1$ queries in the worst case; thus the algorithm provides the first exponential quantum versus deterministic speedup.

Note that $O(1)$ expected a number of queries are sufficient for randomized algorithms to solve the Deutsch-Jozsa Problem with a constant success probability arbitrarily close to 1. Thus the Deutsch-Jozsa Algorithm does not have much advantage compared with error-bounded random-

ized algorithms. One might also feel that the saving of one query for computing the parity of 2 bits by Deutsch-Jozsa Algorithm is due to the artificial definition of one quantum query. Thus the significance of the Deutsch-Jozsa Algorithm is not in solving a practical problem, but in its pioneering use of quantum Fourier transform (QFT), of which $H^{\otimes n}$ is one, in the pattern

$$\text{QFT} \rightarrow \text{Query} \rightarrow \text{QFT}.$$

The same pattern appears in many subsequent quantum algorithms, including those found by Bernstein and Vazirani [2], Simon [9], and Shor [8].

The Deutsch-Jozsa Algorithm is also referred to as Deutsch Algorithm. The algorithm as presented above is actually the result of the improvement by Cleve, Ekert, Macchiavello, and Mosca [3] and independently by Tapp (unpublished) on the algorithm in [5].

Quantum Algorithms for Class Group of a Number Field

Sean Hallgren
Department of Computer Science and Engineering, The Pennsylvania State University, University Park, State College, PA, USA

Years and Authors of Summarized Original Work

2005; Hallgren

Problem Definition

Associated with each number field is a finite abelian group called the class group. The order of the class group is called the class number. Computing the class number and the structure of the class group of a number field is among the main tasks in computational algebraic number theory [4].

A number field F can be defined as a subfield of the complex numbers $\mathbb{C}$ which is generated over the rational numbers $\mathbb{Q}$ by an algebraic number, i.e., $F = \mathbb{Q}(\theta)$ where θ is the root of a polynomial with rational coefficients. The ring of integers $\mathcal{O}$ of F is the subset consisting of all elements that are roots of monic polynomials with integer coefficients. The ring $\mathcal{O} \subseteq F$ can be thought of as a generalization of $\mathbb{Z}$, the ring of integers in $\mathbb{Q}$. In particular, one can ask whether $\mathcal{O}$ is a principal ideal domain and whether elements in $\mathcal{O}$ have unique factorization. Another interesting problem is computing the unit group $\mathcal{O}^*$, which is the set of invertible algebraic integers inside F, that is, elements $\alpha \in \mathcal{O}$ such that α^{-1} is also in $\mathcal{O}$.

Ever since the class group was discovered by Gauss in 1798, it has been an interesting object of study. The class group of F is the set of equivalence classes of fractional ideals of F, where two ideals I and J are equivalent if there exists $\alpha \in F^*$ such that $J = \alpha I$. Multiplication of two ideals I and J is defined as the ideal generated by all products ab, where $a \in I$ and $b \in J$. Much is still unknown about number fields, such as whether there exist infinitely many number fields with trivial class group. The question of the class group being trivial is equivalent to asking whether the elements in the ring of integers $\mathcal{O}$ of the number field have unique factorization.

In addition to computing the class number and the structure of the class group, computing the unit group and determining whether given ideals are principal, called the principal ideal problem, are also central problems in computational algebraic number theory.

Key Results

The best known classical algorithms for the class group take subexponential time [1, 2, 4]. Assuming the GRH, computing the class group, the unit group, and solving the principal ideal problem are in NP ∩ CoNP [10].

The following theorems state that the three problems defined above have efficient quantum algorithms [7, 9].

Theorem 1 *There is a polynomial-time quantum algorithm that computes the unit group of a constant degree number field.*

Theorem 2 *There is a polynomial-time quantum algorithm that solves the principal ideal problem in constant degree number fields.*

Theorem 3 *The class group and class number of a constant degree number field can be computed in quantum polynomial time assuming the GRH.*

Computing the class group means computing the structure of a finite abelian group given a set of generators for it. When it is possible to efficiently multiply group elements (including computing large powers of elements) and efficiently compute unique representations of each group element, then this problem reduces to the standard hidden subgroup problem over the integers and therefore has an efficient quantum algorithm. Ideal multiplication is efficient in number fields. For imaginary number fields, there are efficient classical algorithms for computing group elements with a unique representation, and therefore there is an efficient quantum algorithm for computing the class group.

For real number fields, there is no known way to efficiently compute unique representations of class group elements. As a result, the classical algorithms typically compute the unit group and class group at the same time. A quantum algorithm [7] is able to efficiently compute the unit group of a number field and then use the principal ideal algorithm to compute a unique quantum representation of each class group element. Then the standard quantum algorithm can be applied to compute the class group structure and class number.

Applications

There are factoring algorithms based on computing the class group of an imaginary number field. One is exponential time and the other is subexponential time [4].

Computationally hard number theoretic problems are useful for public key cryptosystems. Pell's equation reduces to the principal ideal problem, which forms the basis of the Buchmann-Williams key-exchange protocol [3]. Identification schemes have also been based on this problem by Hamdy and Maurer [8]. The classical exponential-time algorithms help determine which parameters to choose for the cryptosystem. Factoring reduces to Pell's equation, and the best known algorithm for it is exponentially slower than the best factoring algorithm. Systems based on these harder problems were proposed as alternatives in case factoring turns out to be polynomial time solvable. The efficient quantum algorithms can break these cryptosystems.

Open Problems

The unit group of an arbitrary degree number field has an efficient quantum algorithm [6], and computing the class group and solving the principal ideal problem are related to this problem. One open problem is to compute certain towers of number fields with special properties, such as an infinite family with constant root discriminant [5].

Problem Definition

The input is an undirected simple graph G on n vertices. The graph is given by its adjacency matrix: For any two vertices u and v, one can query whether u and v are connected by an edge. (Note that classical algorithms usually have access to G in the form of incidence lists. However, specification of the input graph in the form of adjacency matrix is standard in quantum algorithms.) Two special vertices of the graph, s and t, are selected. The task is to detect whether s and t lie in the same connected component of G. Quantum algorithms for this problem are described.

Classically, this problem can be solved in quadratic time by a variety of algorithms. It is easy to see that this is optimal. Also, the st-connectivity problem is a canonical example of a problem in RL (the class of problems solvable

in randomized logspace) [1]. Later, it was shown to be in L (deterministic logspace) [8].

Key Results

Previous Algorithm

Dürr et al. [5] gave a quantum algorithm with the following properties. Its query complexity is $O(n^{3/2})$, and its time complexity is the same up to logarithmic factors. The algorithm repeatedly executes a quantum subroutine that uses $O(\log n)$ qubits and requires quantum read-only access to $O(n \log n)$ classical bits. This memory is changed between the runs of the quantum subroutine.

The algorithm is based on Borůvka's algorithm [4]. It solves a more general problem of finding a minimum spanning tree of G. In particular, the algorithm outputs a list of the connected components of G.

Main Algorithm

Theorem 1 ([3]) *Consider the st-connectivity problem on an n-vertex graph G with the additional promise: Either s and t lie in different components of G, or they are connected by a path of length at most d. The above problem can be solved by a quantum algorithm in $\tilde{O}(n\sqrt{d})$ time, $O(n\sqrt{d})$ queries, and $O(\log n)$ space.*

Thus, in the worst case of $d = n - 1$, the complexity of the algorithm is the same as of the algorithm by Dürr et al. But if d is small, this algorithm performs better. This promise appears quite naturally in practice.

The algorithm is based on the quantum algorithm for evaluating span programs [6, 7].

Applications

The st-connectivity algorithm or its modifications can be used as a quantum version of dynamic programming. In general, quantum algorithms provide no advantage in implementing dynamic programming. The algorithm of Theorem 1, although it does not have the full power of dynamic programming, attains a quadratic speedup (for small values of d). In [3], this algorithm is combined with the color-coding approach [2] to solve the problem of finding small subgraphs.

For example, consider the problem of detecting the presence of a k-path in an input graph G given by its adjacency matrix. (We assume that $k = O(1)$.) Color each vertex of G in a color from $\{0, 1, \ldots k\}$ independently and uniformly at random. Leave only those edges of G that connect vertices whose colors differ by exactly 1. Add two new vertices s and t, connect s to all vertices of color 0, and connect t to all vertices of color k. Denote the resulting graph by G'.

We say that a k-path in G is colored correctly, if the colors of its vertices go from 0 to k starting with one of its end points. Thus, for any k-path of G, the probability it is colored correctly is $\Omega(1)$.

Execute the algorithm of Theorem 1 on G' with $d = k + 2$. If G contains a correctly colored k-path, then G' has a path of length $k+2$ from s to t; hence, the algorithm accepts. On the other hand, if s and t are connected by a path in G', then G contains a k-path (not necessary correctly colored). Hence, if there is no k-path in G, the algorithm rejects for any coloring of G. By repeating the algorithm constant a number of times with different colorings, it is possible to distinguish these two cases.

Classically, color coding is capable of finding a subgraph H in the input graph, if H is an arbitrary fixed tree. In the quantum case, the class of graphs is narrower.

Problem 1 (Subgraph/not-a-minor promise problem) Let H be a fixed simple graph. The input is a graph G given by its adjacency matrix. The task is to distinguish two cases:

- The graph G contains H as a subgraph.
- The graph G does not contain H as a minor.

Classically, this problem requires $\Omega(n^2)$ queries even if H is a single edge. The quantum query lower bound is $\Omega(n)$.

Theorem 2 ([3]) *Assume that H is a triangle or an edge-subdivision of a star. The subgraph/not-a-minor promise problem for H on an n-vertex input graph can be solved by a quantum algorithm in $\tilde{O}(n)$ time. The algorithm uses $O(n)$ queries. If H is an edge-subdivision of a star, the algorithm uses $O(\log n)$ space.*

Corollary 1 *Assume that H is a path or an edge-subdivision of a claw (a 3-star). There exists a quantum algorithm that detects whether an n-vertex input graph contains H as a subgraph in $\tilde{O}(n)$ time. The algorithm uses $O(n)$ queries and $O(\log n)$ space.*

2012; Jeffery, Kothari, Magniez

Problem Definition

Let S be any algebraic structure over which matrix multiplication is defined, such as a field (e.g., real numbers), a ring (e.g., integers), or a semiring (e.g., the Boolean semiring). If we use $+$ and $\cdot$ to denote the addition and multiplication operations over S, then the matrix product C of two $n \times n$ matrices A and B is defined as $C_{ij} := \sum_{k=1}^{n} A_{ik} \cdot B_{kj}$ for all $i, j \in \{1, 2, \ldots, n\}$. Over the Boolean semiring, the addition and multiplication operations are the logical OR and logical AND operations, respectively, and thus, the matrix product C is defined as $C_{ij} := \bigvee_{k=1}^{n} (A_{ik} \wedge B_{kj})$. In this article we consider the following problems.

Problem 1 (Matrix multiplication)

INPUT: Two $n \times n$ matrices A and B with entries from S.
OUTPUT: The matrix $C := AB$.

Problem 2 (Matrix product verification)

INPUT: Three $n \times n$ matrices A, B, and C with entries from S.
OUTPUT: A bit indicating whether or not $C = AB$.

The matrix multiplication problem is a well-studied problem in classical computer science. The straightforward algorithm for matrix multiplication that computes each entry separately using its definition uses $O(n^3)$ operations. In 1969, Strassen [17] presented an algorithm that multiplies matrices over any ring using only $O(n^{2.807})$ operations, showing that the straightforward approach was suboptimal. Since then there have been many improvements and the complexity of matrix multiplication remains an area of active research.

Surprisingly, the matrix product verification problem can be solved faster. In 1979, Freivalds [6] presented an optimal $O(n^2)$ time bounded-error probabilistic algorithm to solve the matrix product verification problem over any ring using a randomized fingerprinting technique, which has found numerous other applications in theoretical computer science (see, e.g., Ref. [15]).

In the quantum setting, these problems are traditionally studied in the model of quantum query complexity, where we assume the entries of the input matrices are provided by a black box or an oracle. The query complexity of an algorithm is the number of queries made to the oracle. The bounded-error quantum query complexity of a problem is the minimum query complexity of any quantum algorithm that solves the problem with bounded error, i.e., it outputs the correct answer with probability greater than (say) $2/3$. The time complexity of an algorithm refers to the time required to implement the remaining non-query operations. In this article we only consider bounded-error quantum algorithms.

Key Results

It is not known if quantum algorithms can improve the time complexity of the general matrix multiplication problem compared to classical algorithms. Improvements are possible for matrix product verification and special cases of the matrix multiplication problem, as described below.

Matrix Product Verification over Rings

According to Buhrman and Špalek [3], matrix product verification was first studied (in an unpublished paper) by Ambainis, Buhrman, Høyer, Karpinski, and Kurur. Using a recursive application of Grover's algorithm [7], they gave an $O(n^{7/4})$ query algorithm for the problem. The first published work on the topic is due to Buhrman and Špalek [3], who gave an $O(n^{5/3})$ query algorithm for matrix product verification over any ring using a generalization of Ambainis' element distinctness algorithm [1]. This algorithm also achieves the same query complexity over semirings and more general algebraic structures. The algorithm can easily be cast in the quantum walk search framework of Magniez, Nayak, Roland, and Santha [14] as explained in the survey by Santha [16]. More interestingly, they presented an algorithm with time complexity $\tilde{O}(n^{5/3})$ for the problem over fields and integral domains. Their algorithm uses the same technique used by Freivalds [6] and is therefore also time efficient over arbitrary rings. Buhrman and Špalek also proved a lower bound showing that any bounded-error quantum algorithm must make at least $\Omega(n^{3/2})$ queries to solve the problem over the field $\mathbb{F}_2$. This lower bound can be extended to all rings [10].

Theorem 1 (Matrix product verification over rings) *The matrix product verification problem over any ring can be solved by a quantum algorithm with query complexity $O(n^{5/3})$ and time complexity $\tilde{O}(n^{5/3})$. Furthermore, any quantum algorithm must make $\Omega(n^{3/2})$ queries to solve the problem over a ring.*

Buhrman and Špalek also studied the relationship between the complexity of their algorithm and the number of incorrect entries in the purported product, C, and showed that their algorithm performs better when C has a large number of incorrect entries [3].

Matrix Multiplication over Rings

The quantum query complexity of multiplying two $n \times n$ matrices is easy to characterize in terms of the input size. Clearly the query complexity is upper bounded by the input size, $O(n^2)$. On the other hand, if A equals the identity matrix, then $C = B$ and in this case the matrix multiplication problem is equivalent to learning all the bits of an input of size n^2, which requires $\Omega(n^2)$ queries. This follows, for example, from the fact that computing the parity of n^2 bits requires $\Omega(n^2)$ queries [2, 5]. This shows that the quantum query complexity of matrix multiplication is $\Theta(n^2)$, which is the same as the classical query complexity. Similarly, no quantum algorithm is known to improve the time complexity of matrix multiplication over rings compared to classical algorithms.

Buhrman and Špalek [3] studied the matrix multiplication problem in terms of n and an additional parameter ℓ, the number of nonzero entries in the output matrix C, and showed the following result.

Theorem 2 *The matrix multiplication problem over any ring can be solved by a quantum algorithm with query and time complexity upper bounded by*

$$\begin{array}{ll} \tilde{O}(n^{5/3}\ell^{2/3}) & \text{when } 1 \le \ell \le \sqrt{n}, \\ \tilde{O}(n^{3/2}\ell) & \text{when } \sqrt{n} \le \ell \le n, \text{ and} \\ \tilde{O}(n^2\sqrt{\ell}) & \text{when } n \le \ell \le n^2, \end{array}$$

where ℓ is the number of nonzero entries in the output matrix C.

When ℓ is small, this algorithm achieves subquadratic time complexity and when ℓ approaches n^2, its time complexity is close to $O(n^3)$, which is trivial and slower than known classical algorithms. A detailed comparison of this quantum algorithm with classical algorithms may be found in Ref. [3].

Boolean Matrix Product Verification

Buhrman and Špalek [3] also studied the matrix product verification problem over the Boolean semiring and showed that the problem can be solved with query and time complexity $O(n^{3/2})$. On the other hand, the best known lower bound is only $\Omega(n^{1.055})$ queries due to Childs, Kimmel, and Kothari [4].

Theorem 3 (Boolean matrix product verification) *The Boolean matrix product verification problem can be solved by a quantum algorithm with query complexity $O(n^{3/2})$ and time complexity $\tilde{O}(n^{3/2})$. Furthermore, any quantum algorithm must make $\Omega(n^{1.055})$ queries to solve the problem.*

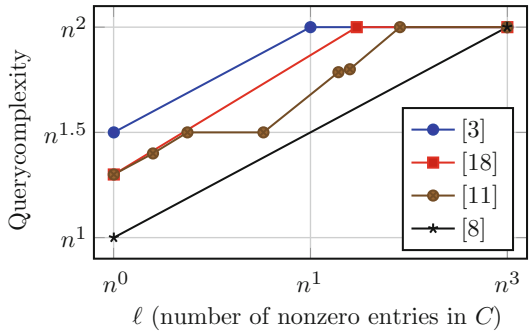
Boolean Matrix Multiplication

As before, the quantum query complexity of multiplying two $n \times n$ Boolean matrices is $\Theta(n^2)$, since it is at least as hard as learning n^2 input bits. The time complexity of Boolean matrix multiplication can be improved to $\tilde{O}(n^{2.5})$ by observing that the inner product of two Boolean vectors of length n can be computed with $O(\sqrt{n})$ queries using Grover's algorithm [7]. This observation also speeds up matrix multiplication over some other semirings.

Similar to the matrix multiplication problem over rings, Boolean matrix multiplication can be studied in terms of an additional parameter ℓ, the number of nonzero entries in the output matrix. Indeed, the problem has been extensively studied in this setting.

Buhrman and Špalek [3] observed that two Boolean matrices can be multiplied with query complexity $O(n^{3/2}\sqrt{\ell})$. This upper bound was improved by Vassilevska Williams and Williams [18], who presented an algorithm with query complexity $\tilde{O}(\min\{n^{1.3}\ell^{17/30}, n^2 + n^{13/15}\ell^{47/60}\})$, which was then improved by Le Gall [11]. Finally, Jeffery, Kothari, and Magniez [8] presented a quantum algorithm for Boolean matrix multiplication that makes $\tilde{O}(n\sqrt{\ell})$ queries. These upper bounds are depicted in Fig. 1. The log factors present in their algorithm were later removed to yield an algorithm with query complexity $O(n\sqrt{\ell})$ [9]. Jeffery, Kothari, and Magniez [8] also proved a matching lower bound of $\Omega(n\sqrt{\ell})$ when $\ell \le \epsilon n^2$ for any constant $\epsilon < 1$. Their algorithm can also be modified to achieve time complexity $\tilde{O}(n\sqrt{\ell} + \ell\sqrt{n})$ [12].

Q



Quantum Algorithms for Matrix Multiplication and Product Verification, Fig. 1 Upper bounds on the quantum query complexity of Boolean matrix multiplication

Theorem 4 (Boolean matrix multiplication) *The Boolean matrix multiplication problem can be solved by a quantum algorithm with query complexity* $O(n\sqrt{\ell})$. *Furthermore, any quantum algorithm that solves the problem must make* $\Omega(n\sqrt{\ell})$ *queries when* $\ell \leq \epsilon n^2$ *for any constant* $\epsilon < 1$. *Boolean matrix multiplication can be solved in time* $\tilde{O}(n\sqrt{\ell} + \ell\sqrt{n})$.

Recently the problem has also been studied in terms of the sparsity of the input matrix. Le Gall and Nishimura [13] present algorithms with improved time complexity in this case. Their algorithm's time complexity is a complicated function of the parameters and the reader is referred to Ref. [13] for details.

Matrix Multiplication over Other Semirings

Le Gall and Nishimura [13] recently initiated the study of matrix multiplication over semirings other than the Boolean semiring and presented algorithms with improved time complexity for the (max, min)-semiring and related semirings.

Open Problems

Several open problems remain in the time and query complexity settings. In the time complexity setting, a major open problem is whether quantum algorithms can solve the matrix multiplication problem faster than classical algorithms over any ring. In the query complexity setting, the complexity of matrix product verification over rings and the Boolean semiring remains open. The best upper and lower bounds are presented in Theorems 1 and 3. A more comprehensive survey of the quantum query complexity of matrix multiplication and its relation to other problems studied in quantum query complexity such as triangle finding and graph collision can be found in the first author's PhD thesis [10], which also contains additional open problems.

Problem Definition

This problem is concerned with the development of quantum methods to speed up classical algorithms based on simulated annealing (SA).

SA is a well-known and powerful strategy to solve discrete combinatorial optimization problems [1]. The search space $\Sigma = \{\sigma_0, \ldots, \sigma_{d-1}\}$ consists of d configurations σ_i, and the goal is to find the (optimal) configuration that corresponds to the global minimum of a given cost function $E : \Sigma \to \mathbf{R}$. Monte Carlo implementations of SA generate a stochastic sequence of configurations via a sequence of Markov processes that converges to the low-temperature Gibbs (probability) distribution, $\pi_{\beta_m}(\Sigma) \propto \exp(-\beta_m E(\Sigma))$. If β_m is sufficiently large, sampling from the Gibbs distribution outputs an optimal configuration with large probability, thus solving the combinatorial optimization problem. The annealing process depends on the choice of an annealing schedule, which consists of a sequence of $d \times d$ stochastic matrices (transition rules) $S(\beta_1)$, $S(\beta_2), \ldots,$ $S(\beta_m)$. Such matrices are determined, e.g., by using Metropolis-Hastings [2]. The real parameters β_j denote a sequence of "inverse temperatures." The implementation complexity of SA is given by m, the number of times that transition rules must be applied to converge to the desired Gibbs distribution (within arbitrary precision). Commonly, the stochastic matrices are sparse, and each list of nonzero conditional probabilities and corresponding configurations, $\{\Pr_\beta(\sigma_j|\sigma_i), j : \Pr_\beta(\sigma_j|\sigma_i) > 0\}$, can be efficiently computed on input (i, β). This implies an efficient Monte Carlo implementation of each Markov process. When a lower bound on the spectral gap of the stochastic matrices (i.e., the difference between the two largest eigenvalues)

is known and given by $\Delta > 0$, one can choose $(\beta_{k+1} - \beta_k) \propto \Delta / E_{\max}$ and $\beta_0 = 0$, $\beta_m \propto \log \sqrt{d}$. $E_{\max}$ is an upper bound on $\max_\sigma |E(\sigma)|$. The constants of proportionality depend on the error probability ϵ, which is the probability of not finding an optimal solution after the transition rules have been applied. These choices result in a complexity $m \propto E_{\max} \log \sqrt{d}/\Delta$ for SA [3].

Quantum computers can theoretically solve some problems, such as integer factorization, more efficiently than classical computers [4]. This work addresses the question of whether quantum computers could also solve combinatorial optimization problems more efficiently or not. The answer is satisfactory in terms of Δ (Section "Key Results"). The complexity of a quantum algorithm is determined by the number of elementary steps needed to prepare a quantum state that allows one to sample from the Gibbs distribution after measurement. Similar to SA, such a complexity is given by the number of times a unitary corresponding to the stochastic matrix is used. For simplicity, we assume that the stochastic matrices are sparse and disregard the cost of computing each list of nonzero conditional probabilities and configurations, as well as the cost of computing $E(\sigma)$. We also assume $d = 2^n$ and the space of configurations Σ is represented by n-bit strings. Some assumptions can be relaxed.

Problem

INPUT: *An objective function* $E : \Sigma \to \mathbf{R}$, *sparse stochastic matrices* $S(\beta)$ *satisfying the detailed balance condition, a lower bound* $\Delta > 0$ *on the spectral gap of* $S(\beta)$, *an error probability* $\epsilon > 0$.

OUTPUT: *A random configuration* $\sigma_i \in \Sigma$ *such that* $\Pr(\sigma_i \in S_0) \geq 1 - \epsilon$, *where* S_0 *is the set of optimal configurations that minimize* E.

Key Results

The main result is a quantum algorithm, referred to as quantum simulated annealing (QSA), that solves a combinatorial optimization problem with high probability using $m_Q \propto E_{\max} \log \sqrt{d}/\sqrt{\Delta}$ unitaries corresponding to the stochastic matrices [5]. The quantum speedup is in the spectral gap, as $1/\sqrt{\Delta} \ll 1/\Delta$ when $\Delta \ll 1$.

Computationally hard combinatorial optimization problems are typically manifest in a spectral gap that decreases exponentially fast in $\log d$, the problem size. The quadratic improvement in the gap is then most significant in hard instances. The QSA algorithm is based on ideas and techniques from quantum walks and the quantum Zeno effect. The quantum Zeno effect can be implemented by evolution randomization [6]. Nevertheless, recent results on "spectral gap amplification" allow for other quantum algorithms that result in a similar complexity scaling [7].

Quantum Walks for QSA

A quantization of the classical random walk is obtained by first defining a $d^2 \times d^2$ unitary matrix that satisfies [8–10]

$$X|\sigma_i\rangle|\mathbf{0}\rangle = \sum_{j=0}^{d-1} \sqrt{\Pr_\beta(\sigma_j|\sigma_i)}|\sigma_i\rangle|\sigma_j\rangle \ . \quad (1)$$

The configuration $\mathbf{0}$ represents a simple configuration, e.g., $\mathbf{0} \equiv \sigma_0 = 0 \ldots 0$ (the n-bit string), and $\Pr_\beta(\sigma_j|\sigma_i)$ are the entries of the stochastic matrix $S(\beta)$. The other $d^2 \times d^2$ unitary matrices used by QSA are P, the permutation (swap) operator that transforms $|\sigma_i\rangle|\sigma_j\rangle$ into $|\sigma_j\rangle|\sigma_i\rangle$, and $R = \mathbb{1} - 2|\mathbf{0}\rangle\langle\mathbf{0}|$, the reflection operator over $|\mathbf{0}\rangle$.

The quantum walk is $W = X^\dagger PXPRPX^\dagger PXR$, and the detailed balance condition implies [5]

$$W \sum_{i=0}^{d-1} \sqrt{\pi_\beta(\sigma_i)}|\sigma_i\rangle|\mathbf{0}\rangle = \sum_{i=0}^{d-1} \sqrt{\pi_\beta(\sigma_i)}|\sigma_i\rangle|\mathbf{0}\rangle \ , \quad (2)$$

where $\pi_\beta(\sigma_i)$ are the probabilities given by the Gibbs distribution. (X, $X^\dagger$, and W also depend on β.) The goal of QSA is to prepare the corresponding eigenstate of W in Eq. 2, within certain precision $\epsilon > 0$, and for inverse temperature $\beta_m \propto \log d$. A projective quantum measurement

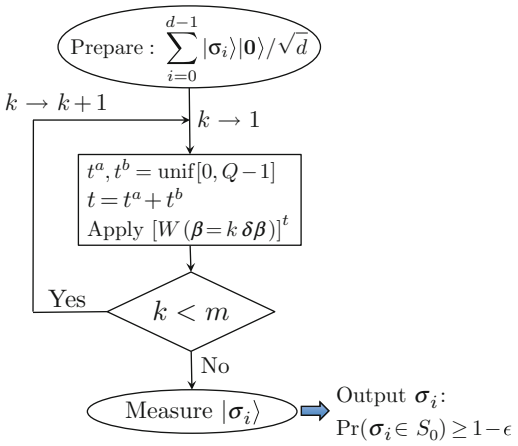
of $|\sigma_i\rangle$ on such a state outputs an optimal solution in the set S_0 with probability $\Pr(S_0) \geq 1 - \epsilon$.

Evolution Randomization and QSA Implementation

The QSA is based on the idea of adiabatic state transformations [6, 11]. For $\beta = 0$, the initial eigenstate of W is $\sum_{i=0}^{d-1} |\sigma_i\rangle|\mathbf{0}\rangle/\sqrt{d}$, which can be prepared easily on a quantum computer. The purpose of QSA is then to drive this initial state towards the eigenstate of W for inverse temperature β_m, within given precision. This is achieved by applying the sequence of unitary operations $[W(\beta_m)]^{t_m} \ldots [W(\beta_2)]^{t_2}[W(\beta_1)]^{t_1}$ to the initial state (Fig. 1). In contrast to SA, $(\beta_{k+1} - \beta_k) \propto 1/E_{\max}$ [11], but the initial and final inverse temperatures are also $\beta_0 = 0$ and $\beta_m \propto \log\sqrt{d}$. This implies that the number of different inverse temperatures in QSA is $m \propto E_{\max} \log\sqrt{d}$, where the constant of proportionality depends on ϵ. The nonnegative integers t_k can be sampled randomly according to several distributions [6]. One way is to obtain t_k after sampling multiple (but constant) times from a uniform distribution on integers between 0 and $Q - 1$, where $Q = \lceil 2\pi/\sqrt{\Delta}\rceil$. The average cost of QSA is then $m\langle t_k\rangle \propto E_{\max} \log\sqrt{d}/\sqrt{\Delta}$. One can use Markov's inequality to avoid those (improbable) instances where the cost is significantly greater than the average cost. The QSA and the values of the constants are given in detail in Fig. 1.

Analytical Properties of W

The quantum walk W has eigenvalues $e^{\pm i\phi_j}$, for $j = 0, \ldots, d-1$, in the relevant subspace. In particular, $\phi_0 = 0 < \phi_1 \leq \ldots \leq \phi_{d-1}$ and $\phi_1 \geq \sqrt{\Delta}$ [5, 7–9]. This implies that the relevant spectral gap for methods based on quantum adiabatic state transformations is of order $\sqrt{\Delta}$. The quantum speedup follows from the fact that the complexity of such methods, recently discussed in [6, 11–13], depends on the inverse of the relevant gap.



Quantum Algorithms for Simulated Annealing, Fig. 1 Flow diagram for the QSA. Under the assumptions, the input state can be easily prepared on a quantum computer by applying a sequence of n Hadamard gates on n qubits. unif$[0, Q-1]$ is the uniform distribution on nonnegative integers in that range and $Q = \lceil 2\pi/\sqrt{\Delta}\rceil$. $\delta\beta = \beta_{k+1} - \beta_k = \epsilon/(2E_{\max})$ and $m = \lceil 2\beta_m E_{\max}/\epsilon\rceil$. Like SA, the final inverse temperature is $\beta_m = (\gamma/2)\log(2\sqrt{d}/\epsilon)$, where γ is the gap of E, that is, $\gamma = \min_{\sigma\notin S_0} E(\sigma) - E(S_0)$. The average cost of the QSA is then $mQ = \lceil 2\pi\gamma E_{\max}\log(2\sqrt{d}/\epsilon)/(\epsilon\sqrt{\Delta})\rceil$, and dependence on ϵ can be made fully logarithmic by repeated executions of the algorithm. A quantum computer implementation of W can be efficiently done by using the algorithm that computes the nonzero conditional probabilities of the stochastic matrix $S(\beta)$

Applications

Like SA, QSA can be applied to solve general discrete combinatorial optimization problems [14]. QSA is often more efficient than exhaustive search in finding the optimal configuration. Examples of problems where QSA can be powerful include the simulation of equilibrium states of Ising spin glasses or Potts models, solving satisfiability problems or solving the traveling salesman problem.

Open Problems

Some (classical) Monte Carlo implementations do not require varying an inverse temperature and apply the same (time-independent) transition rule

S to converge to the Gibbs distribution. The number of times the transition rule must be applied is the so-called mixing time, which depends on the inverse spectral gap of S [15]. The development of quantum algorithms to speed up this type of Monte Carlo algorithms remains open. Also, the technique of spectral gap amplification outputs a Hamiltonian $H(\beta)$ on input $S(\beta)$. The relevant eigenvalue of such a Hamiltonian is zero, and the remaining eigenvalues are $\pm\sqrt{\lambda_i}$, where $\lambda_i \geq \Delta$. This opens the door to a quantum adiabatic version of the QSA, in which $H(\beta)$ is changed slowly and the quantum system remains in an "excited" eigenstate of eigenvalue zero at all times. The speedup is also due to the increase in the eigenvalue gap. Nevertheless, finding a different Hamiltonian path with the same gap, where the adiabatic evolution occurs within the lowest energy eigenstates of the Hamiltonians, is an open problem.

Problem Definition

The problem is to find a vector $x \in \mathbb{C}^N$ such that $Ax = b$, for some given inputs $A \in \mathbb{C}^{N\times N}$ and $b \in \mathbb{C}^N$. Several variants are also possible, such as rectangular matrices A, including overdetermined and underdetermined systems of equations.

Unlike in the classical case, the output of this algorithm is a quantum state on $\log(N)$ qubits whose amplitudes are proportional to the entries of x, along with a classical estimate of $\|x\| :=$

$\sqrt{\sum_i |x_i|^2}$. Similarly, the input b is given as a quantum state. The matrix A is specified implicitly as a row-computable matrix. Specifying the input and output in this way makes it possible to find x in time sublinear, or even polylogarithmic, in N. The next section has more discussion of the relation of this algorithm to classical linear systems solvers.

Key Results

Suppose that:

- $A \in \mathbb{C}^{N \times N}$ is Hermitian, has all eigenvalues in the range $[-1, -1/\kappa] \cup [1/\kappa, 1]$ for some known $\kappa \geq 1$, and has $\leq s$ nonzero entries per row. The parameter κ is called the *condition number* (defined more generally to be the ratio of the largest to the smallest singular value) and s is the *sparsity*.
- There is a quantum algorithm running in time T_A that takes an input $i \in [N]$ and outputs the nonzero entries of the ith row, together with their location.
- Assume that $\|b\| = 1$ and that there is a corresponding quantum state to produce the state $|b\rangle$ that runs in time T_B.

Define $x' := A^{-1}|b\rangle$ and $x = \frac{x'}{\|x'\|}$.

We use the notation x to refer to the vector as a mathematical object and $|x\rangle$ to refer to the corresponding quantum state on $\log(N)$ qubits. For a variable T, let $\tilde{O}(T)$ denote a quantity upper bounded by $T \cdot \text{poly}\log(T)$. The norm of a vector $\|x\|$ is the usual Euclidean norm $\sqrt{\sum_i |x_i|^2}$, while for a matrix $\|A\|$ is the operator norm $\max_{\|x\|=1} \|Ax\|$, or equivalently the largest singular value of A.

Quantum Algorithm for Linear Systems

The main result is that $|x\rangle$ and $\|x'\|$ can be produced, both up to error ϵ, in time $\text{poly}(\kappa, s, \epsilon^{-1}, \log(N), T_A, T_B)$. More precisely, the following run-times are known:

$$\tilde{O}(\kappa T_B + \log(N) s^2 \kappa^2 T_A / \epsilon) \quad [5] \quad (1a)$$

$$\tilde{O}(\kappa T_B + \log(N) s^2 \kappa T_A / \epsilon^3) \quad [1] \quad (1b)$$

A key subroutine is Hamiltonian simulation, and the run-times in (1) are based on the recent improvements in this component due to [3].

Hardness Results and Comparison to Classical Algorithms

These algorithms are analogous to classical algorithms for solving linear systems of equations, but do not achieve exactly the same thing. Most classical algorithms output the entire vector x as a list of N numbers, while the quantum algorithms output the state $|x\rangle$, i.e., a superposition on $\log(N)$ qubits whose N amplitudes equal x. This allows potentially faster algorithms but for some tasks will be weaker. This resembles the difference between the Quantum Fourier Transform and the classical Fast Fourier Transform.

To compare the classical and quantum complexities for this problem, we should consider classical tasks (with classical output) that can be solved with the help of quantum linear equations algorithms. One can show that better classical algorithms for such tasks exist only if *all* quantum algorithms could be simulated more quickly by classical algorithms. This is because the linear systems problem is BQP-complete, i.e., solving large sparse well-conditioned linear systems of equations is equivalent in power to general purpose quantum computing.

To make this precise, define LinearSystemSample$(N, \kappa, \epsilon, T_A)$ to be the problem of producing a sample $i \in [N]$ from a distribution p satisfying $\sum_{i=1}^{N} |p_i - |x_i|^2| \leq \epsilon$, where $x = x'/\|x'\|$, $x' = A^{-1}b$, and $b = e_1$ (i.e., one in the first entry and zero elsewhere). Additionally the eigenvalues of A should have absolute value between $1/\kappa$ and 1, and there should exist a classical algorithm for computing the entries of a row of A that runs in time T_A. This problem differs slightly from the version described above, but only in ways that make it easier, so that it still makes sense to talk about a matching hardness result.

Theorem 1 *Consider a quantum circuit on n qubits that applies two-qubit unitary gates $U_1, \ldots, U_T$ to the $|0\rangle^{\otimes n}$ state and concludes by outputting the result of measuring the first qubit. It is possible to simulate this measurement outcome up to error ϵ by reducing to* LinearSystemSample$(N, \kappa, \epsilon/2, T_A)$ *with* $N = O(2^n T/\epsilon)$, $\kappa = O(T/\epsilon)$, *and* $T_A = \text{poly}\log(N)$.

In other words, LinearSystemSample is at least as hard to solve as any quantum computation of the appropriate size. This result is nearly tight. In other words, when combined with the algorithm of [1], the relation between N, κ (for linear system solving) and n, T (for quantum circuits) is known to be nearly optimal, while the correct ϵ dependence is known up to a polynomial factor.

Theorem 1 can also rule out classical algorithms for LinearSystemSample$(N, \kappa, \epsilon, T_A)$. Known algorithms for the problem (assuming for simplicity that A is s-sparse) run in time $\text{poly}(N)\,\text{poly}\log(\kappa/\epsilon) + NT_A$ (direct solvers), $N\,\text{poly}(\kappa)\,\text{poly}\log(1/\epsilon)T_A$ (iterative methods), or even $s^{\kappa \ln(1/\epsilon)}\,\text{poly}\log(N)$ (direct expansion of $x \approx \sum_{n \le \kappa \ln(1/\epsilon)} (I - A)^n b$, assuming A is positive semidefinite). Depending on the parameters N, κ, ϵ, s, a different one of these may be optimal. And from Theorem 1 it follows (a) that any nontrivial improvement in these algorithms would imply a general improvement in the ability of classical computers to simulate quantum mechanics and (b) that such improvement is impossible for algorithms that use the function describing A in a black-box manner (i.e., as an oracle).

Applications and Extensions

Linear system solving is usually a subroutine in a larger algorithm, and the following algorithms apply it to a variety of settings. Complexity analyses can be found in the cited papers, but since hardness results are not known for them, we cannot say definitively whether they outperform all possible classical algorithms.

Machine Learning

A widely used application of linear systems of equations is to performing least-squares estimation of a model [6]. In this problem, we are given a matrix $A \in \mathbb{R}^{n \times p}$ with $n \ge p$ (for an overdetermined model) along with a vector $b \in \mathbb{R}^n$, and we wish to compute $\arg\min_{x \in \mathbb{R}^p} \|Ax - b\|$. If A is well conditioned, sparse, and implicitly specified, then the state $|x\rangle$ can be found quickly [6], and from this features of x can be extracted by measurement.

Differential Equations

Consider the differential equation [2]

$$\dot{x}(t) = A(t)x(t) + b(t) \qquad x(t) \in \mathbb{R}^N. \quad (2)$$

One of the simplest ways to solve this is to discretize time to take values $t_1 < \ldots < t_m$ and approximate

$$x(t_{i+1}) \approx x(t_i) + (A(t_i)x(t_i) + b(t_i))(t_{i+1} - t_i). \quad (3)$$

By treating $(x(t_1), \ldots, x(t_m))$ as a single vector of size Nm, we can find this vector as a solution of the linear system of equations specified by (3). More sophisticated higher-order solvers can also be made quantum; see [2] for details.

Boundary-Value Problems

The solution to PDEs can also be expressed in terms of the solution to a linear system of equations [4]. For example, in Poisson's equation we are given a function $Q : \mathbb{R}^3 \to \mathbb{R}$ and want to find $u : \mathbb{R}^3 \to \mathbb{R}$ such that $-\nabla^2 u = Q$. By defining x and b to be discretized versions of u, Q, this PDE becomes an equation of the form $Ax = b$. One challenge is that if A is the finite-difference operator (i.e., discretized second derivative) for an $L \times L \times L$ box, then its condition number will scale as L^2. Since the total number of points is $O(L^3)$, this means the quantum algorithm cannot achieve a substantial speedup. Classically this condition number is typically reduced by using preconditioners. A method for using preconditioners with the quantum linear system solver was presented in [4], along with an application to an electromagnetic scattering

problem. The resulting complexity is still not known.

Problem Definition

Spatial Search and Walk Processes

Spatial search by *quantum walk* is database search with the additional constraint that one is required to move through the search space that obeys some locality structure. For example, the data items may be stored at the vertices of a two-dimensional grid. The requirement of moves along the edges of the grid captures the cost of accessing different items starting from some fixed position in the database.

One of possible ways of carrying out spatial search is by performing a random walk on the search space or its quantum analog, a quantum walk. The complexity of spatial search by quantum walk is strongly tied to the *quantum hitting time* [19] of the walk.

Let S, with $|S| = n$, be a finite set of *states*. Assume that a subset $M \subseteq S$ of states are *marked*. We are given a procedure $\mathcal{C}$ that, on input $x \in S$ and an associated data structure $d(x)$, checks whether the state x is marked. The goal is either to find a marked state when promised that $M \neq \emptyset$ (*search version*) or to determine whether M is nonempty (*decision version*).

The algorithm progresses in stages. In the *setup stage*, we access some state of S (usually a random state). In the walk stage we move from state to state, performing a spatial walk as described below. The moves are called *updates*. In addition, in the walk stage we perform *checks* to see if the current state is marked at steps selected by the algorithm.

In the classical setting, the *transition probabilities* of the spatial walk are described by a stochastic matrix $P = (p_{x,y})_{x,y \in S}$. This makes the walk a *Markov chain*. In every move the

algorithm *must perform* a random transition according to P. The possible $x \to y$ moves, i.e., those with $p_{x,y} \neq 0$, form the edges of a (directed) graph G, and we say that the Markov chain P has *locality structure* G.

We define the search problem in the classical setting, which carries over to the quantum case with little modification:

INPUT: Markov chain P on set S, marked subset $M \subseteq S$ that is implicitly specified by a checking procedure $\mathcal{C}$, and the associated costs:

Cost type	Setup	Update	Checking
Notation	S	U	C

OUTPUT: a marked state if one exists (search version) or a Boolean return value that indicates whether M is empty or not (decision version).

The algorithm is required to be correct with probability at least $2/3$ in either case, the search or the decision problem. The significance of the setup cost, which is incurred only once, will be clearer when we see some applications. Often we can choose between several competing walks, and we would like to design the one with minimum total cost.

In the *quantum* case, the random process P is replaced by a *quantum walk* W_P that has the same locality structure as P. The costs $\mathsf{S}, \mathsf{U}, \mathsf{C}$ reflect the costs of quantum operations.

The Quantum Walk Algorithm

Designing a quantum analog of P is not so straightforward, since stochastic matrices have no immediate unitary equivalents. One either needs to abandon the discrete-time nature of the walk [15] or define the walk operator on a space other than $\mathbb{C}^S$. Here we take the second route.

We say that a Markov chain P is *irreducible* if its underlying digraph is strongly connected. Let P be an irreducible Markov chain, let π be its unique stationary distribution, and let P^* (with $P^* = (p^*_{x,y})$) denote the *time-reversed Markov chain*, where $p^*_{x,y} := \pi_y p_{y,x}/\pi_x$. Define the following vectors in the vector space $\mathbb{C}^S$:

$$|p_x\rangle := \sum_{y \in X} \sqrt{p_{x,y}}\,|y\rangle \qquad \text{and}$$

$$|p^*_y\rangle := \sum_{x \in X} \sqrt{p^*_{y,x}}\,|x\rangle \ .$$

Define the unitary operator $W_P := R_1 R_2$ on $\mathbb{C}^{S \times S}$ as the product of the two reflections $R_2 := \sum_{x \in S} |x\rangle\langle x| \otimes (2|p_x\rangle\langle p_x| - \mathrm{I})$ and $R_1 := \sum_{y \in S} (2|p^*_y\rangle\langle p^*_y| - \mathrm{I}) \otimes |y\rangle\langle y|$. The operator W_P is called the *quantum analog* of P, or the *discrete-time quantum walk operator* arising from P, and may be viewed as a walk on the *edges* of the underlying graph G. We define a "checking" operator on $\mathbb{C}^S$, based on whether or not the current state is marked: $O_M := \sum_{x \notin M} |x\rangle\langle x| - \sum_{x \in M} |x\rangle\langle x|$.

In the above description, we have suppressed the data structure associated with a state in the Markov chain for the sake of simplicity. The precise description of the operators can be derived via the isometry $|x\rangle \mapsto |x\rangle|d(x)\rangle$ between the appropriate spaces (see, e.g., Refs. [28, 29]). The data structure becomes especially significant in the context of the complexity of the operators.

A search algorithm by quantum walk is described by a quantum circuit that acts on "registers" or "wires" which are associated with the space $\mathbb{C}^S \otimes \mathbb{C}^S \otimes \mathbb{C}^k$, for some $k \geq 0$. We again suppress the registers carrying the data structure. The first two registers hold the current edge, and the last register holds auxiliary information, or work space, that drives the quantum walk. The quantum circuit implements the composition $X := X_t X_{t-1} \cdots X_1$, where each X_i is either W_P or O_M acting on the edge registers, possibly controlled by the auxiliary register, or a unitary operator independent of P and M acting on any of the registers. The circuit X is applied to a suitably constructed initial state $|\phi_0\rangle$.

We associate a cost with each operator as a measure of its complexity, with respect to a resource of interest. The resource could be circuit size or in the query model (which is the more typical application) the number of queries. We denote the cost of implementing W_P as a quantum circuit in the units of the resource of interest by U (*update cost*), the cost of construct-

ing O_M by C (*checking cost*), and the cost of preparing the initial state, $|\phi_0\rangle$, of the algorithm by S (*setup cost*). Every time an operator is used, we incur the cost associated with it. This abstraction, implicit in Ref. [3] and made explicit in Ref. [28], allows W_P and O_M to be treated as black-box operators and provides a convenient way to capture *time complexity* or, in the quantum query model, *query complexity*. The cost of the sequence $X_t X_{t-1} \cdots X_1$ is the sum of the costs of the individual operators. The *observation probability* is the probability that we observe an element of M on measuring the first register of the final state, $|\phi_t\rangle := X|\phi_0\rangle$, in the standard basis $(|x\rangle)_{x\in S}$. In the decision version of the problem, we measure a fixed single qubit of the auxiliary register in the standard basis to obtain the output of the algorithm.

Key Results

Walk Definitions

Quantum walks were first introduced by David Meyer and John Watrous to study quantum cellular automata and quantum logspace, respectively. Discrete-time quantum walks were investigated for their own sake by Ambainis, Bach, Nayak, Vishwanath, and Watrous [4, 32] and Aharonov, Ambainis, Kempe, and Vazirani [2] on the infinite line and the n-cycle, respectively. The central issues in the early development of quantum walks included the definition of the walk operator, notions of mixing and hitting times, and the speedup achievable compared to the classical setting.

Hitting Time

Exponential quantum speedup of the hitting time between antipodes of the hypercube was shown by Kempe [19]. Childs, Cleve, Deotto, Farhi, Gutmann, and Spielman [13] presented the first oracle problem solvable exponentially faster by a quantum walk-based algorithm than by any (not necessarily walk-based) classical algorithm.

The first systematic studies of quantum hitting time on the hypercube and the d-dimensional torus were conducted by Shenvi, Kempe, and Whaley [34] and Ambainis, Kempe, and Rivosh [5]. Improving upon the Grover search-based spatial search algorithm of Aaronson and Ambainis, Ambainis et al. [5] showed that the d-dimensional torus with n nodes can be searched by quantum walk in $\sqrt{n}$ steps with observation probability $\Omega(1)$ for $d \geq 3$ and in $\sqrt{n \log n}$ in steps and observation probability $\Omega(1/\log n)$ for $d = 2$ (see also Ref. [11]). Combining the algorithm for $d = 2$ with amplitude amplification [9], we get an algorithm with observation probability $\Omega(1)$, at a cost that is a multiplicative factor of $\sqrt{\log n}$ larger.

In the results in Refs. [13, 19], the algorithm has implicit knowledge of the target state, as the walk starts from a state whose location is "related" to that of the target. It is not known if we can achieve an exponential speedup when the walk starts in a state that is independent of the target.

Element Distinctness

The first result that used a quantum walk to solve a natural algorithmic problem, the so-called *element distinctness problem*, was due to Ambainis [3]. The problem is to find out if among the set of s elements of a database, two are identical. Ambainis constructed a walk on the *Johnson graph* $J(r, s)$ whose vertices are the r-size subsets of a universe of size s (in his case the universe corresponds to the set of all database elements), with two subsets connected iff their symmetric difference has size two. A subset is marked, i.e., it is an element of M, if it captures two identical database elements. In the quantum (but also the classical) query model, the setup cost is r, which stands for the cost of downloading r (random) database elements. Update incurs a constant cost, as it requires reading a new database element and forgetting an old one. Furthermore, since we are in the query model, the checking cost is zero, since whether a state is marked can be deduced from the currently held database elements without any further download. Ambainis ingeniously balanced the costs of S and U finding that in the quantum case, the optimum choice for r is $s^{2/3}$, leading to a query complexity of $s^{2/3}$ (this is a nontrivial balance: in the classical case, the same walk gives no speedup).

In contrast, the Grover algorithm, the inspiration behind Ambainis' work, has no balancing option: its setup and update costs are zero in the query model. (The Grover search may be viewed as a quantum walk on the complete graph.) It turns out that the above walk-based quantum query algorithm with complexity $O(s^{2/3})$ matches the lower bound due to Aaronson and Shi [1].

General Markov Chains

Ambainis's result is based on the quantum hitting time of $J(r,s)$ for a marked set of relative size $\left(\frac{r}{s}\right)^2$. In Ref. [35], Szegedy investigates the hitting time of quantum walks arising from general Markov chains. His definitions (walk operator, hitting time) are abstracted directly from Ref. [3] and are consistent with prior literature, although slightly different in presentation.

For a Markov chain P, the (classical) *average hitting time* of M can be expressed in terms of the *leaking walk matrix* P_M, which is obtained from P by deleting all rows and columns indexed by states of M. Let $v_1, \ldots, v_{n-m}$, be the normalized eigenvectors of P_M, and let $\lambda_1, \ldots, \lambda_{n-m}$ be the associated eigenvalues, where $m = |M|$. Let $h(x, M)$ denote the expected time to reach M from x. Let $\mu : S \to \mathbb{R}^+$ be the initial distribution from which we start and μ' its restriction to $S \setminus M$. Denote the vector $(\sqrt{\mu'(x)})_{x \in S \setminus M}$ by u. Then the average hitting time of M is $h := \sum_{x \in S} \mu(x)\, h(x, M) = \sum_{k=1}^{n-m} \frac{|(v_k, u)|^2}{1-\lambda_k}$. Although the leaking walk matrix P_M is not stochastic, one can consider the *absorbing walk* matrix $P' = \left[\begin{smallmatrix} P_M & P'' \\ 0 & I \end{smallmatrix}\right]$, where P'' is the matrix obtained from P by deleting the rows indexed by M and the columns indexed by $S \setminus M$. The walk P' behaves like P but is absorbed by the first marked state it hits. Consider the quantum analog $W_{P'}$ of P' and $|\phi_0\rangle := \sum_{x \in S} \sqrt{\pi(x)}|x\rangle|p_x\rangle$, where π is the stationary distribution of P. The state $|\phi_0\rangle$ is stationary for W_P, i.e., an eigenvector with eigenvalue 1. Define the *quantum hitting time*, H, of set M to be the smallest t for which $\|W_{P'}^t|\phi_0\rangle - |\phi_0\rangle\| \geq 0.1$. Note that the cost of $W_{P'}$ is proportional to $\mathsf{U} + \mathsf{C}$.

The motivation behind this definition of quantum hitting time is the following. The classical hitting time measures the number of iterations of the absorbing walk P' required to noticeably skew the uniform starting distribution. Similarly, the quantum hitting time bounds the number of iterations of the following quantum algorithm for detecting whether M is nonempty: At each step, apply operator $W_{P'}$. If M is empty, then $P' = P$ and the starting state is left invariant. If M is nonempty, then the angle between $W_{P'}^t|\phi_0\rangle$ and $W_P^t|\phi_0\rangle$ gradually increases (for t not too large). Using an additional *control register* to apply either $W_{P'}$ or W_P with quantum control, the divergence of these two states (should M be nonempty) can be detected. The required number of iterations is characterized by H.

It remains to compute H. When P is symmetric and *ergodic*, the expression for the classical hitting time has a quantum analog [35] (we assume $m \leq n/2$ for technical reasons):

$$H \leq \sum_{k=1}^{n-m} \frac{v_k^2}{\sqrt{1-\lambda_k}}, \tag{1}$$

where $v_k = (v_k, u)$. Note that $u = \frac{1}{\sqrt{n}}(1, \ldots, 1)$, since P is symmetric, so v_k sum of the coordinates of v_k divided by $1/\sqrt{n}$. From (1) and the expression for h, one can derive an amazing connection between the classical and quantum hitting times:

Theorem 1 (Szegedy [35]) *Let P be symmetric and ergodic, and let h be the classical hitting time for marked set M and uniform starting distribution. Then the quantum hitting time of M is at most $\sqrt{h}$. Therefore, the cost of solving the decision version of the problem is of order $\mathsf{S} + \sqrt{h}(\mathsf{U} + \mathsf{C})$.*

One can further show:

Theorem 2 (Szegedy [35]) *If P is state-transitive and $|M| = 1$, then the marked state is observed with probability at least n/h with cost $O(\mathsf{S} + \sqrt{h}(\mathsf{U} + \mathsf{C}))$.*

The observation probability n/h can be increased to $\Theta(1)$ with $\sqrt{h/n}$ iterations of the

algorithm from Theorem 2, using amplitude amplification [9]. Theorems 1 and 2 imply most quantum hitting time results of the previous section *directly*, relying only on estimates of the corresponding classical hitting times. Expression (1) is based on a fundamental connection between the eigenvalues and eigenvectors of P and W_P. Notice that $p^*_{y,x} = p_{y,x}$ for symmetric P, so $|p^*_y\rangle = |p_y\rangle$. So R_1 and R_2 are reflections through the subspaces generated by $\{|p_x\rangle \otimes |x\rangle |\ x \in S\}$ and $\{|x\rangle \otimes |p_x\rangle |\ x \in S\}$, respectively. The eigenvalues of $R_1 R_2$ can be expressed in terms of the eigenvalues of the mutual Gram matrix $D(P)$ of these systems. This matrix $D(P)$, the *discriminant matrix* of P, equals P when P is symmetric. The formula remains fairly simple even when P is not symmetric. In particular, the absorbing walk P' has discriminant matrix $\left[\begin{smallmatrix} P_M & 0 \\ 0 & 1 \end{smallmatrix}\right]$. Finally, the relation between $D(P)$ and the spectral decomposition of W_P is given by:

Theorem 3 (Szegedy [35]) *Let P be an arbitrary Markov chain on a finite state space S and let $\cos\theta_1 \geq \cdots \geq \cos\theta_l$ be those singular values of $D(P)$ lying in the open interval $(0, 1)$, with associated singular vector pairs v_j, w_j for $1 \leq j \leq l$. Then the nontrivial eigenvalues of W_P (namely, those other than 1 and -1) and their corresponding eigenvectors are $(e^{-2i\theta_j}, R_1 w_j - e^{-i\theta_j} R_2 v_j)$ and $(e^{2i\theta_j}, R_1 w_j - e^{i\theta_j} R_2 v_j)$ for $1 \leq j \leq l$.*

Subsequent Developments

Magniez, Nayak, Roland, and Santha [29] used the Szegedy quantum analog W_P of an ergodic walk P, rather than that of its absorbing version P', to develop a *search* algorithm in the style of Ambainis [3].

Theorem 4 (Magniez, Nayak, Roland, Santha [29]) *Let P be reversible and ergodic with spectral gap $\delta > 0$. Let M have probability either zero or $\varepsilon > 0$ under the stationary distribution of P. There is a quantum algorithm solving the search problem with cost $\mathsf{S} + \frac{1}{\sqrt{\varepsilon}}(\frac{1}{\sqrt{\delta}}\mathsf{U} + \mathsf{C})$.*

The main idea here is to apply quantum phase estimation [14, 21] to the quantum walk W_P in order to implement an approximate reflection operator about the initial state. This operator is then used along with the checking operator O_M in an amplitude amplification scheme to get the final algorithm.

The average classical hitting time h may be bounded by $1/\delta\varepsilon$ (with δ, M, ε as in Theorem 4), and this bound is tight for most known applications. In these applications, the above algorithm *finds* marked elements with complexity at most that of the Szegedy algorithm. In other applications, for instance, Triangle Finding [28], where the checking cost C is much larger than the update cost U, the complexity of the algorithm in Theorem 4 is asymptotically smaller.

In the case of the two-dimensional square grid with n vertices, the average classical hitting time h is $n \log n$. This is asymptotically lesser than $1/\delta\varepsilon$ when there is a single marked element. (In this case, $1/\delta\varepsilon = n^2$.) Algorithms due to Ambainis et al. [5] and Szegedy [35] find a unique marked state with $O(\sqrt{n}\ \log n)$ steps of quantum walk, a $\sqrt{\log n}$ factor larger than $\sqrt{h}$. Tulsi [36] showed how we may find a unique marked element in $O(\sqrt{h})$ steps. Magniez, Nayak, Richter, and Santha [30] extended this result to show that for any state-transitive Markov chain, a unique marked state can be found in $O(\sqrt{h})$ steps. They also devised a detection algorithm that solves the decision version of the problem for any reversible Markov chain and any number of marked elements, in $O(\sqrt{h})$ steps (thus extending Theorem 1).

Krovi, Magniez, Ozols, and Roland [23] presented a different quantum algorithm for finding multiple marked elements in any *reversible* Markov chain. They introduced a notion of interpolation between any reversible chain P and its absorbing counterpart P' and used the quantum analog of the interpolated walk. In the case of a unique marked element, the resulting algorithm solves the search version of the problem with cost $\mathsf{S} + \sqrt{h}(\mathsf{U} + \mathsf{C})$. The precise relationship between the number of steps of the quantum walk taken by the algorithm in the case of more than one marked element and the corresponding

Q

classical hitting time remains open. It is known that for certain choices of P and M, the former may be asymptotically larger than $\sqrt{h}$.

The schema due to Magniez et al. [29] described above has been extended in different ways. Jeffery, Kothari, and Magniez [17] use a *quantum state* as the data structure $d(x)$ associated with a state $x \in S$ in quantum algorithms with nested walks. In this manner, they avoid the repeated overhead of setup cost in the inner quantum walks used for checking marked states. They solve several problems, including Triangle Finding, with query as well as time complexity matching, up to polylogarithmic factors, the performance of algorithms previously derived from *learning graphs* [7, 26]. Childs, Jeffery, Kothari, and Magniez [8] introduced the use of a data structure that depends on the state transition in the walk. Using this, they develop quantum algorithms with nested walks, where the recursion occurs in the update operation. The cost incurred is essentially what we would expect from Theorem 4. This extension leads to algorithms that are as efficient in *time* as in query complexity, for applications such as 3-Distinctness. Independently, Belovs designed a different quantum walk algorithm [8], which leads to a similar result for 3-Distinctness.

Applications

We list some quantum walk-based results for search problems that represent speedups over Grover search-based solutions. All are inspired by Ambainis' algorithm for element distinctness.

Triangle Finding

Suppose we are given the adjacency matrix A of a graph on n vertices and are required to determine if the graph contains a triangle (i.e., a clique of size 3), using as few queries as possible to the entries of A. The classical query complexity of this problem is $\Theta(n^2)$. Magniez, Santha, and Szegedy [28] gave an $\tilde{O}(n^{1.3})$ algorithm. This upper bound has been improved by a sequence of results [7, 25, 26, 29] (see also Ref. [17]) to $\tilde{O}(n^{5/4})$. Several of these algorithms, including the current best algorithm due to Le Gall [25], are based on the quantum walk search framework.

Matrix Product Verification and Matrix Multiplication

Suppose we are given three $n \times n$ matrices A, B, C over a ring and are required to determine if $AB \neq C$, i.e., if there exist i, j such that $\sum_k A_{ik} B_{kj} \neq C_{ij}$. We would like to make as few queries as possible to the entries of A, B, and C. This problem has classical query complexity $\Theta(n^2)$. Buhrman and Špalek [10] gave an $O(n^{5/3})$ quantum query algorithm. They also observed that two Boolean matrices can be multiplied with query complexity $O(n^{3/2}\sqrt{\ell})$, where ℓ is the number of nonzero entries in the product. This has since been improved in a sequence of results [16, 24, 37] to $O(n\sqrt{\ell})$. The algorithm due to Le Gall [24] builds upon quantum walk algorithms. We refer the reader to Ref. [22] for further work on this topic.

Group Commutativity Testing

Suppose we are presented with a black-box group specified by its k generators and are required to determine if the group commutes using as few queries as possible to the group product operation (i.e., queries of the form "What is the product of elements g and h?"). The classical query complexity is $\Theta(k)$ group operations. Magniez and Nayak [27] gave an (essentially optimal) $\tilde{O}(k^{2/3})$ quantum query algorithm for this problem. The algorithm involves a quantum walk on the product of two graphs whose vertices are ordered l-tuples of distinct generators.

Forbidden Subgraph Property

A property of graphs is called *minor closed* when the following condition holds: if a graph has the property, then all its minors also possess the property. A graph property (which need not be minor closed) is called a *forbidden subgraph property* (FSP) if it can be described by a finite set of forbidden subgraphs. Suppose we are given the adjacency matrix A of a graph on n vertices and are required to determine if the graph has a minor closed property Π, using as few queries as possible to the entries of A. Childs and Kothari [12]

show that if Π is nontrivial and is *not* FSP, then it has query complexity in $\Theta(n^{3/2})$. They complement this with a more efficient algorithm for any minor closed property Π that *is* FSP. The algorithm has query complexity $O(n^{\alpha})$ for some $\alpha < 3/2$ and is based on the quantum walk search framework.

3-Distinctness

This is a generalization of the element distinctness problem. Suppose we are given elements $x_1, \ldots, x_m \in \{1, \ldots, m\}$ and are asked if there exist *three* distinct indices i, j, k such that $x_i = x_j = x_k$. The Ambainis quantum walk algorithm achieves query and time complexity $O(m^{3/4})$. The *query* complexity was improved to $O(m^{5/7})$ by Belovs [6] using a new technique – learning graphs, while the best time complexity remained unchanged. Childs et al. [8] later designed *time*-efficient query algorithms with complexity $\tilde{O}(m^{5/7})$, using extensions of the quantum walk search framework.

Open Problems

Many issues regarding quantum analogs of Markov chains remain unresolved, both for the search problem and the closely related mixing problem.

Search Problem

Can the quadratic quantum speedup of hitting time for the decision version of the problem be extended from all reversible Markov chains to all *ergodic* ones? Can quantum walks also *find* marked elements quadratically faster than classical walks, in the case of reversible Markov chains with *multiple* marked states? What other algorithmic applications of search by quantum walk can be found?

Sampling Problem

Another wide use of Markov chains in classical algorithms is in generating samples from certain probability distributions. In particular, *Markov chain Monte Carlo* algorithms work by running a carefully designed ergodic Markov chain. After a number of steps given by the *mixing time* of P, the distribution over states is guaranteed to be ϵ-close to its stationary distribution π. Such algorithms form the basis of most randomized algorithms for approximating #P-complete problems (see, e.g., Ref. [18]). The sampling problem may be formalized as follows:

INPUT: Markov chain P, tolerance $\epsilon \in (0, 1)$.
OUTPUT: A sample from a distribution that is ϵ-close to π in total variation distance.

Notions of quantum mixing time were first proposed and analyzed on the line, the cycle, and the hypercube [2,4,31,32]. Kendon and Tregenna [20] and Richter [33] have investigated the use of decoherence in improving mixing of quantum walks. Two fundamental questions about quantum mixing time remain open: What is the "most natural" definition? And when is there a quantum speedup over the classical mixing time?

Problem Definition

A knot invariant is a function on knots (or links – i.e., circles embedded in R^3) which is invariant under isotopy of the knot, i.e., it does not change under stretching, moving, tangling, etc. (cutting the knot is not allowed). In low dimensional topology, the discovery and use of *knot invariants* is of central importance. In 1984, Jones [12] discovered a new knot invariant, now called the Jones polynomial $V_L(t)$, which is a Laurent polynomial in $\sqrt{t}$ with integer coefficients and which is an invariant of the link L. In addition to the important role it has played in low dimensional topology, the Jones polynomial has found applications in numerous fields, from *DNA* recombination [16] to statistical physics [20].

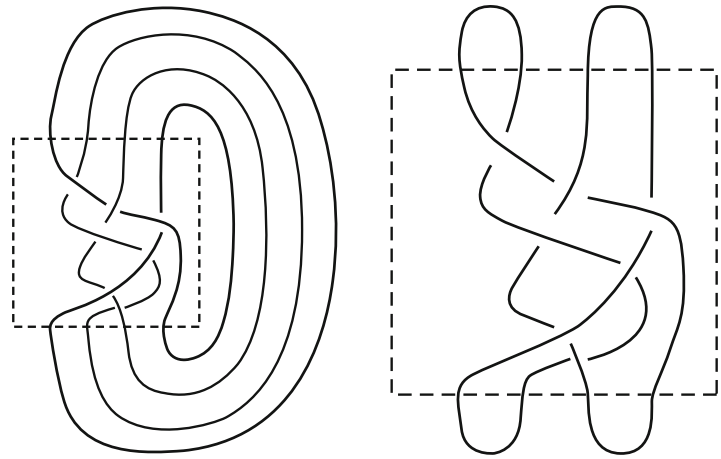
From the moment of the discovery of the Jones polynomial, the question of how hard it is to compute became important. There is a very simple inductive algorithm (essentially due to Conway [5]) to compute it by changing crossings in a link diagram, but, naively applied, this takes exponential time in the number of crossings. It was shown [11] that the computation of $V_L(t)$ is #P-hard for all but a few values of t where $V_L(t)$ has an elementary interpretation. Thus, a polynomial time algorithm for computing $V_L(t)$ for any value of t other than those elementary ones is unlikely. Of course, the #P-hardness of the problem does not rule out the possibility of good approximations. Still, the best classical algorithms to approximate the Jones polynomial at all but trivial values are exponential. Simply stated, the problem becomes:

Problem 1 For what values of t and for what level of approximation can the Jones polynomial $V_L(t)$ be approximated in time polynomial in the number of crossings and links of the link L?

Key Results

As mentioned above, exact computation of the Jones polynomial for most t is #P-hard, and the best known classical algorithms to approximate the Jones polynomial are exponential. The key results described here consider the above problem in the context of quantum rather than classical computation.

The results concern the approximation of links that are given as closures of braids. (All links can be described this way.) Briefly, a braid of n strands and m crossings is described pictorially by n strands hanging alongside each other, with m crossings, each of two adjacent strands. A braid B may be "closed" to form a link by tying its ends together in a variety of ways, two of which are the *trace closure* (denoted by B^{tr}) which joins the ith strand from the top right to the ith strand from the bottom right (for each i) and the *plat closure* (denoted by B^{pl}) which is defined only for braids with an even number of strands by connecting pairs of adjacent strands (beginning at the rightmost strand) on both the top and bottom.



Quantum Approximation of the Jones Polynomial, Fig. 1 The trace closure (*left*) and plat closure (*right*) of the same 4-strand braid

Examples of the trace and plat closure of the same 4-strand braid are given in Fig. 1.

For such braids, the following results have been shown by Aharonov, Jones, and Landau:

Theorem 1 ([2]) *For a given braid B in B_n with m crossings and a given integer k, there is a quantum algorithm which with probability $1 - c^{\Omega(n+m+k)}$ outputs a complex number r with $|r - V_{B^{\text{tr}}}(e^{2\pi i/k})| < \epsilon d^{n-1}$ where $d = 2\cos(\pi/k)$ and ϵ is inverse polynomial in n, k, m, using time that is polynomial in n, m, k.*

Theorem 2 ([2]) *For a given braid B in B_n with m crossings and a given integer k, there is a quantum algorithm which with probability $1 - c^{\Omega(n+m+k)}$ outputs a complex number r with $|r - V_{B^{\text{pl}}}(e^{2\pi i/k})| < \epsilon d^{n-1}$ where $d = 2\cos(\pi/k)$ and ϵ is inverse polynomial in n, k, m, using time that is polynomial in n, m, k.*

The original connection between quantum computation and the Jones polynomial was made earlier in the series of papers [6–9]. A model of quantum computation based on Topological Quantum Field Theory (*TQFT*) and Chern-Simons theory was defined in [6, 9], and Kitaev, Larsen, Freedman, and Wang showed that this model is polynomially equivalent in computational power to the standard quantum computation model in [7, 8]. These results, combined with a deep connection between *TQFT* and the value of the Jones polynomial at particular roots of unity discovered by Witten 13 years earlier [18], implicitly implied (without explicitly formulating) an efficient quantum algorithm for the approximation of the Jones polynomial at the value $e^{2\pi i/5}$.

The approximation given by the above algorithms are additive, namely, the result lies in a given window, whose size is independent of the actual value being approximated. The formulation of this kind of additive approximation was given in [4]; this is much weaker than a multiplicative approximation, which is what one might desire (again, see discussion in [4]). One might wonder if under such weak requirements, the problem remains meaningful at all. It turns out that, in fact, this additive approximation problem is hard for quantum computation, a result originally shown by Freedman, Kitaev, and Wang:

Theorem 3 (Adapted from [8]) *The problem of approximating the Jones polynomial of the plat closure of a braid at $e^{2\pi i/k}$ for constant k, to within the accuracy given in Theorem 2, is BQP-hard.*

A different proof of this result was given in [19], and the result was strengthened by Aharonov and Arad [1] to any k which is polynomial in the size of the input, namely, for all the plat closure cases for which the algorithm is polynomial in the size of the braid.

Understanding the Algorithm

The structure of the solution described by Theorems 1 and 2 consists of four steps:

1. *Mapping the Jones polynomial computation to a computation in the Temperley-Lieb algebra.* There exists a homomorphism of the braid group inside the so-called Temperley-Lieb algebra (this homomorphism was the connection that led to the original discovery of the Jones polynomial in [12]). Using this homomorphism, the computation of the Jones polynomial of either the plat or trace closure of a braid can be mapped to the computation of a particular linear functional (called the Markov trace) of the image of the braid in the Temperley-Lieb algebra (for an essential understanding of a geometrical picture of the Temperley-Lieb algebra, see [14]).
2. *Mapping the Temperley-Lieb algebra calculation into a linear algebra calculation.* Using a representation of the Temperley-Lieb algebra, called the path model representation, the computation in step 1 is shown to be equal to a particular weighted trace of the matrix corresponding to the Temperley-Lieb algebra element coming from the original braid.
3. *Choosing the parameter t corresponding to unitary matrices.* The matrix in step 2 is a product of basic matrices corresponding to individual crossings in the braid group; an important characteristic of these basic matrices is that they have a local structure. In addition, by choosing the values of t as in Theorems 1 and 2, the matrices corresponding to individual crossings become unitary. The result is that the original problem has been turned into a weighted trace calculation of a matrix formed from a product of local unitary matrices – a problem well suited to a quantum computer.
4. *Implementing the quantum algorithm.* Finally the weighted trace calculation of a matrix described in step 3 is formally encoded into a calculation involving local unitary matrices and qubits.

A nice exposition of the algorithm is given in [15].

Applications

Since the publication [2], a number of interesting results have ensued investigating the possibility of quantum algorithms for other combinatorial/topological questions. Quantum algorithms have been developed for the case of the HOMFLY-PT two-variable polynomial of the trace closure of a braid at certain pairs of values [19]. (This entry also extends the results of [2] to a class of more generalized braid closures; it is recommended reading as a complement to [2] or [15] as it gives the representation theory of the Jones-Wenzl representations, thus putting the path model representation of the Temperley-Lieb algebra in a more general context.) A quantum algorithm for the colored Jones polynomial is given in [10].

Significant progress was made on the question of approximating the partition function of the Tutte polynomial of a graph [3]. This polynomial, at various parameters, captures important combinatorial features of the graph. Intimately associated to the Tutte polynomial is the Potts model, a model originating in statistical physics as a generalization of the Ising model to more than 2 states [17,20]; approximating the partition function of the Tutte polynomial of a graph is a very important question in statistical physics. The work of [3] develops a quantum algorithm for additive approximation of the Tutte polynomial for all planar graphs at all points in the Tutte plane and shows that for a significant set of these points (though not those corresponding to the Potts model) the problem of approximating is a complete problem for a quantum computer. Unlike previous results, these results use non-unitary representations.

Open Problems

There remain many unanswered questions related to the computation of the Jones polynomial from both a classical and quantum computational point of view.

From a classical computation point of view, the originally stated Problem 1 remains

wide open for all but trivial choices of t. A result as strong as Theorem 2 for a classical computer seems unlikely since it would imply (via Theorem 3) that classical computation is as strong as quantum computation. A result by Jordan and Shor [13] shows that the approximation given in Theorem 1 solves a complete problem for a presumed (but not proven) weaker quantum model called the one-clean-qubit model. Since this model seems weaker than the full quantum computation model, a classical result as strong as Theorem 1 for the trace closure of a braid is perhaps in the realm of possibility.

From a quantum computational point of view, various open directions seem worthy of pursuit. Most of the quantum algorithms known as of the writing of this entry are based on the quantum Fourier transform and solve problems which are algebraic and number theoretical in nature. Arguably, the greatest challenge in the field of quantum computation (together with the physical realization of large scale quantum computers) is the design of new quantum algorithms based on substantially different techniques. The quantum algorithm to approximate the Jones polynomial is significantly different from the known quantum algorithms in that it solves a problem which is combinatorial in nature, and it does so without using the Fourier transform. These observations suggest investigating the possibility of quantum algorithms for other combinatorial/topological questions. Indeed, the results described in the applications section above address questions of this type. Of particular interest would be progress beyond [3] in the direction of the Potts model, specifically either showing that the approximation given in [3] is non-trivial or providing a different non-trivial algorithm.

Problem Definition

Quantum information theory distinguishes classical bits from quantum bits or qubits. The quantum state of n qubits is represented by a complex vector in $(\mathbb{C}^2)^{\otimes n}$, where $(\mathbb{C}^2)^{\otimes n}$ is the tensor product of n 2-dimensional complex vector spaces. Classical n-bit strings form a basis for the vector space $(\mathbb{C}^2)^{\otimes n}$. Column vectors in $(\mathbb{C}^2)^{\otimes n}$ are denoted as $|\psi\rangle$ and row vectors are denoted as $|\psi\rangle^\dagger = |\psi\rangle^{*T} \equiv \langle\psi|$. The complex inner product between vectors $|\psi\rangle$ and $|\phi\rangle$ is conveniently written as $\langle\psi|\phi\rangle$.

Entangled quantum states $|\psi\rangle \in (\mathbb{C}^2)^{\otimes n}$ are those quantum states that cannot be written as a product of some vectors $|\psi_i\rangle \in \mathbb{C}^2$, that is, $|\psi\rangle \neq \bigotimes_i |\psi_i\rangle$. The Bell states are four orthogonal (maximally) entangled states defined as

$$|\Psi_{00}\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle),$$
$$|\Psi_{10}\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle),$$
$$|\Psi_{01}\rangle = \frac{1}{\sqrt{2}}(|01\rangle + |10\rangle),$$
$$|\Psi_{11}\rangle = \frac{1}{\sqrt{2}}(|01\rangle + |10\rangle).$$

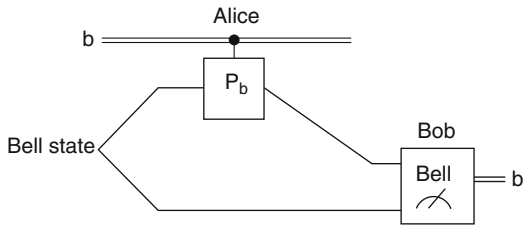
The Pauli matrices X, Y, and Z are three unitary, Hermitian 2×2 matrices. They are defined as $X = |0\rangle\langle 1| + |1\rangle\langle 0|$, $Z = |0\rangle\langle 0| - |1\rangle\langle 1|$ and $Y = iXZ$.

Quantum states can evolve dynamically under inner product preserving unitary operations $U(U^{-1} = U^\dagger)$. Quantum information can be mapped onto observable classical information through the formalism of quantum measurements. In a quantum measurement on a state $|\psi\rangle$ in $(\mathbb{C}^2)^{\otimes n}$, a basis $\{|x\rangle\}$ in $(\mathbb{C}^2)^{\otimes n}$ is chosen. This basis is made observable through an interaction of the qubits with a macroscopic measurement system. A basis vector x is thus observed with probability $\mathbb{P}(x) = |\langle x|\psi\rangle|^2$.

Quantum information theory or more narrowly quantum Shannon theory is concerned with protocols which enable distant parties to efficiently transmit quantum or classical information, possibly aided by the sharing of quantum entanglement between the parties. For a detailed introduction to quantum information theory, see the book by Nielsen and Chuang [12].

Key Results

Superdense coding [3] is the protocol in which two classical bits of information are sent from sender Alice to receiver Bob. This is accomplished by sharing a Bell state $|\Psi_{00}\rangle_{AB}$ between Alice and Bob and the transmission of one qubit. The protocol is illustrated in Fig. 1. Given two bits b_1 and b_2, Alice performs the following unitary transformation on her half of the Bell state:



Quantum Dense Coding, Fig. 1 Dense coding. Alice and Bob use a shared Bell state to transmit two classical bits $b = (b_1, b_2)$ by sending one qubit. *Double lines* are classical bits and *single lines* represent quantum bits

$$P_{b_1 b_2} \otimes I_{\mathrm{B}} |\Psi_{00}\rangle = |\Psi_{b_1 b_2}\rangle, \qquad (1)$$

i.e., one of the four Bell states. Here $P_{00} = I$, $P_{01} = X$, $P_{10} = Z$, and $P_{11} = XZ = -iY$. Alice then sends her qubit to Bob. This allows Bob to do a measurement in the Bell basis. He distinguishes the four states $|\Psi_{b1b2}\rangle$ and learns the value of the two bits b_1 and b_2.

The protocol demonstrates the interplay between classical information and quantum information. No information can be communicated by merely sharing an entangled state such as $|\Psi_{00}\rangle$ without the actual transmission of physical information carriers. On the other hand, it is a consequence of Holevo's theorem [10] that one qubit can encode at most one classical bit of information. The protocol of dense coding shows that the two resources of entanglement and qubit transmission *combined* give rise to a *superdense coding* of classical information. Dense coding is thus captured by the following resource inequality:

$$1 \text{ ebit} + 1 \text{ qubit} \geq 2 \text{ cbits}. \qquad (2)$$

In words, one bit of quantum entanglement (one ebit) in combination with the transmission of one qubit is sufficient for the transmission of two classical bits or cbits.

Dense coding can be generalized to the encoding of continuous variables, namely, the encoding of quadrature variables (x, p) of an electromagnetic field into one half of a two-mode squeezed state [2]. Such a two-mode squeezed state approximates the two-mode EPR state – in which both quadrature variables are perfectly correlated, i.e., $\mathrm{x}_1 = \mathrm{x}_2$ and $\mathrm{p}_1 = -\mathrm{p}_2$ – in the limit of large squeezing. The authors in [2] show that the information transmission capacity through the EPR state is, in the limit of large squeezing, twice that of a direct encoding using a single transmitted mode. The scheme thus exemplifies the notion of dense coding through the use of quantum entanglement.

Quantum teleportation [4] is a protocol that is dual to dense coding. In quantum teleportation, 1 ebit (a Bell state) is used in conjunction with the transmission of two classical bits to send one qubit from Alice to Bob. Thus, the resource relation for quantum teleportation is

$$1 \text{ ebit} + 2 \text{ cbits} \geq 1 \text{ qubit}. \qquad (3)$$

The relation with quantum teleportation allows one to argue that dense coding is optimal. It is not possible to encode $2k$ classical bits in less than $m < k$ quantum bits even in the presence of shared quantum entanglement. Let us assume the opposite and obtain a contradiction. One uses quantum teleportation to convert the transmission of k quantum bits into the transmission of $2k$ classical bits. Then one can use the assumed superdense coding scheme to encode these $2k$ bits into $m < k$ qubits. As a result one can send k quantum bits by effectively transmitting $m < k$ quantum bits (and sharing quantum entanglement) which is known to be impossible.

Applications

Harrow [8] has introduced the notion of a coherent bit or cobit. The notion of a cobit is useful in understanding resource relations and trade-offs between quantum and classical information. The noiseless transmission of a qubit from Alice to Bob can be viewed as the linear map $S_q : |x\rangle_{\mathrm{A}} \rightarrow |x\rangle_{\mathrm{B}}$ for a set of basis states $\{|x\rangle\}$. The transmission of a classical bit can be viewed as the linear map $S_c : |x\rangle_{\mathrm{A}} \rightarrow |x\rangle_{\mathrm{B}} |x\rangle_E$ where E stands for the environment Eve. Eve's copy of every basis state $|x\rangle$ can be viewed as the output of a quantum

measurement, and thus, Bob's state is classical. The transmission of a cobit corresponds to the linear map $S_{co} : |x\rangle_A \to |x\rangle_A|x\rangle_B$. Since Alice keeps a copy of the transmitted data, Bob's state is classical. On the other hand, the cobit can also be used to generate a Bell state between Alice and Bob. Since no qubit can be transmitted via a cobit, a cobit is weaker than a qubit. A cobit is stronger than a classical bit since entanglement can be generated using a cobit.

One can define a *coherent* version of superdense coding and quantum teleportation in which measurements are replaced by unitary operations. In this version of dense coding, Bob replaces his Bell measurement by a rotation of the states $|\Psi_{b1b2}\rangle$ to the states $|b_1 b_2\rangle_B$. Since Alice keeps her input bits, the coherent protocol implements the map $|x_1 x_2\rangle_A \to |x_1 x_2\rangle_A|x_1 x_2\rangle_B$. Thus, one can strengthen the dense coding resource relation to

$$1 \text{ ebit} + 1 \text{ qubit} \geq 2 \text{ cobits}. \tag{4}$$

Similarly, the coherent execution of quantum teleportation gives rise to the modified relation 2 cobits + 1 ebit $\geq$ 1 qubit + 2 ebits. One can omit 1 ebit on both sides of the inequality by using ebits catalytically, i.e., they can be borrowed and returned at the end of the protocol. One can then combine both coherent resource inequalities and obtain a resource *equality*:

$$2 \text{ cobits} = 1 \text{ qubit} + 1 \text{ ebit}. \tag{5}$$

A different extension of dense coding is the notion of superdense coding of quantum states proposed in [9]. Instead of dense coding classical bits, the authors in [9] propose to code quantum bits *whose quantum states are known to the sender Alice*. This last restriction is usually referred to as the remote preparation of qubits, in contrast to the transmission of qubits whose states are unknown to the sender. In remote preparation of qubits, the sender Alice can use the additional knowledge about her states in the choice of encoding. In [9] it is shown that one can obtain the asymptotic resource relation

$$1 \text{ ebit} + 1 \text{ qubit} \geq 2 \text{ remotely prepared qubit(s)}. \tag{6}$$

Such relation would be impossible if the r.h.s. were replaced by 2 qubits. In that case the inequality could be used repeatedly to obtain that 1 qubit suffices for the transmission of an arbitrary number of qubits which is impossible.

The "non-oblivious" superdense coding of quantum states should be compared with the non-oblivious and asymptotic variant of quantum teleportation which was introduced in [5]. In this protocol, referred to as remote state preparation (using classical bits), the quantum teleportation inequality, Eq. (3), is tightened to

$$1 \text{ ebit} + 1 \text{ cbit} \geq 1 \text{ remotely prepared qubit(s)}. \tag{7}$$

These various resource (in)equalities and their underlying protocols can be viewed as the first in a comprehensive theory of resources inequalities. The goal of such theory [6] is to provide a unified and simplified approach to quantum Shannon theory.

Experimental Results

In [11] a partial realization of dense coding was given using polarization states of photons as qubits. The Bell state $|\Psi_{01}\rangle$ can be produced by parametric down-conversion; this state was used in the experiment as the shared entanglement between Alice and Bob. With current experimental techniques, it is not possible to carry out a low-noise measurement in the Bell basis which uniquely distinguishes the four Bell states. Thus, in [11] one of three messages, *a trit*, is encoded into the four Bell states. Using two-particle interferometry, Bob learns the value of the trit by distinguishing two of the four Bell states uniquely and obtaining a third measurement signal for the two other Bell states.

In perfect dense coding, the channel capacity is 2 bits. For the trit-scheme of [11], the ideal channel capacity is $\log 3 \approx 1.58$. Due to the noise in the operations and measurements, the authors

of [11] estimate the experimentally achieved capacity as 1.13 bits. In [1] it is shown how the presence of additional entanglement of the polarized photons in their orbital momentum degree of freedom (hyperentanglement) can assist in distinguishing all 4 Bell states in a modified Bell state analyzer. A capacity of 1.63 bits is reported.

In [13] the complete protocol of dense coding was carried out using two $^9Be^+$ ions confined to an electromagnetic trap. A qubit is formed by two internal hyperfine levels of the $^9Be^+$ ion. Single-qubit and two-qubit operations are carried out using two polarized laser beams. A single qubit measurement is performed by observing a weak/strong fluorescence of $|0\rangle$ and $|1\rangle$. The authors estimate that the noise in the unitary transformations and measurements leads to an overall error rate on the transmission of the bits b of 15 %. This results in an effective channel capacity of 1.16 bits.

In [7] dense coding was carried out using NMR spectroscopy. The two qubits were formed by the nuclear spins of ^1H and ^{13}C of chloroform molecules $^{13}CHCL_3$ in liquid solution at room temperature. The full dense coding protocol was implemented using the technique of temporal averaging and the application of coherent RF pulses; see [12] for details. The authors estimate an overall error rate on the transmission of the bits b of less than 10 %.

Quantum Error Correction

Martin Roetteler
Microsoft Research, Redmond, WA, USA

Keywords

Quantum codes; Quantum error-correcting codes; Stabilizer codes

Years and Authors of Summarized Original Work

1995; Shor

Problem Definition

A quantum system can never be seen as being completely isolated from its environment, thereby permanently causing disturbance to the state of the system. The resulting noise problem

threatens quantum computers and their great promise, namely, to provide a computational advantage over classical computers for certain problems (see also the cross-references in the section "Cross-References"). Quantum noise is usually modeled by the notion of a *quantum channel* which generalizes the classical case and, in particular, includes scenarios for communication (space) and storage (time) of quantum information. For more information about quantum channels and quantum information in general, see [19]. A basic channel is the quantum mechanical analog of the classical binary symmetric channel [17]. This quantum channel is called the *depolarizing channel* and depends on a real parameter $p \in [0, 1]$. Its effect is to randomly apply one of the Pauli spin matrices X, Y, and Z to the state of the system, mapping a quantum state ρ of one qubit to $(1 - p)\rho + p/3(X\rho X + Y\rho Y + Z\rho Z)$. It should be noted that it is always possible to map any quantum channel to a depolarizing channel by twirling operations. The basic problem of quantum error correction is to devise a mechanism that allows to recover quantum information that has been sent through a quantum channel, in particular the depolarizing channel.

Key Results

For a long time, it was not known whether it would be possible to protect quantum information against noise. Even some indication in the form of the no-cloning theorem was put forward to support the view that it might be impossible. The no-cloning theorem essentially says that an unknown quantum state cannot be copied perfectly. This dashes hopes that, similar to the classical case, a simple triple-replication and majority voting mechanism may be used in the quantum case as well. Therefore, it came as a surprise when Shor [20] found a quantum code which encodes one qubit into nine qubits in such a way that the resulting state has the ability to be protected against arbitrary single-qubit errors on each of these nine qubits. The idea is to use a concatenation of two threefold repetition codes. One of them protects against bit-flip errors while the other protects against phase-flip errors. The quantum code is a two-dimensional subspace of the 2^9 dimensional Hibert space $(\mathbb{C}^2)^{\otimes 9}$. Two orthogonal basis vectors of this space are identified with the logical 0 and 1 states, respectively, usually called $|0\rangle$ and $|1\rangle$. Explicitly, the code is given by

$$|\underline{0}\rangle = \frac{1}{2\sqrt{2}}(|000\rangle + |111\rangle) \otimes (|000\rangle + |111\rangle) \otimes (|000\rangle + |111\rangle),$$

$$|\underline{1}\rangle = \frac{1}{2\sqrt{2}}(|000\rangle + |111\rangle) \otimes (|000\rangle - |111\rangle) \otimes (|000\rangle + |111\rangle).$$

The state $\alpha|0\rangle + \beta|1\rangle$ of one qubit is encoded to the state $\alpha|\underline{0}\rangle + \beta|\underline{1}\rangle$ of the nine-qubit system. The reason why this code can correct one arbitrary quantum error is as follows.

First, suppose that a bit-flip error has happened, which in quantum mechanical notation is given by the operator X. Then a majority vote of each block of three qubits 1–3, 4–6, and 7–9 can be computed and the bit flip can be corrected. To correct against phase-flip errors, which are given by the operator Z, the fact is used that the code can be written as $|\underline{0}\rangle = |+++\rangle + |---\rangle$, $|\underline{1}\rangle = |+++\rangle - |---\rangle$, where $|\pm\rangle = \frac{1}{\sqrt{2}}(|000\rangle + |111\rangle)$. By measuring each block of three in the basis $\{|+\rangle, |-\rangle\}$, the majority of the phase flips can be detected and one phase-flip error can be corrected. Similarly, it can be shown that Y, which is a combination of a bit flip and a phase flip, can be corrected.

Discretization of Noise

Even though the above procedure seemingly only takes care of bit-flips and phase-flip errors, it actually is true that an *arbitrary* error affecting a single qubit out of the nine qubits can be corrected. In particular, and perhaps surprisingly, this is also the case if one of the nine qubits is completely destroyed. The linearity of quantum mechanics allows this method to work. Linearity implies that whenever operators A and B can be

corrected, so can their sum $A + B$ [8, 20, 22]. Since the (finite) set $\{1_2, X, Y, Z\}$ forms a vector space basis for the (continuous) set of all one-qubit errors, the nine-qubit code can correct an arbitrary single-qubit error.

Syndrome Decoding and the Need for Fresh Ancillas

A way to do the majority vote quantum-mechanically is to introduce two new qubits (also called ancillas) that are initialized in $|0\rangle$. Then, the results of the two parity checks for the repetition code of length three can be computed into these two ancillas. This syndrome computation for the repetition code can be done using the so-called controlled not (CNOT) gates [19] and Hadamard gates. After this, the qubits holding the syndrome will factor out (i.e., they have no influence on future superpositions or interferences of the computational qubits) and can be discarded. Quantum error correction demands a large supply of fresh qubits for the syndrome computations which have to be initialized in a state $|0\rangle$. The preparation of many such states is required to fuel active quantum error-correcting cycles, in which syndrome measurements have to be applied repeatedly. This poses great challenges to any concrete physical realization of quantum error-correcting codes.

Conditions for General Quantum Codes

Soon after the discovery of the first quantum code, general conditions required for the existence of codes, which protect quantum systems against noise, were sought after. Here the noise is modeled by a general quantum channel, given by a set of error operators E_i. The Knill-Laflamme conditions [13] yield such a characterization. Let C be the code subspace and let P_C be an orthogonal projector onto C. Then the existence of a recovery operation for the channel with error operators E_i is equivalent to the equation

$$P_C E_i^\dagger E_j P_C = \lambda_{i,j} P_C,$$

for all i and j, where $\lambda_{i,j}$ are some complex constants. This recently has been extended to the more general framework of subsystem codes (also called operator quantum error-correcting codes) [16].

Constructing Quantum Codes

The problem of deriving general constructions of quantum codes was addressed in a series of groundbreaking papers by several research groups in the mid-1990s. Techniques were developed which allow classical coding theory to be imported to an extent that is enough to provide many families of quantum codes with excellent error correction properties.

The IBM group [3] investigated quantum channels, placed bounds on the quantum channels' capacities, and showed that for some channels, it is possible to compute the capacity (such as for the quantum erasure channel). Furthermore, they showed the existence of a five-qubit quantum code that can correct an arbitrary error, thereby being much more efficient than Shor's code. Around the same time, Calderbank and Shor [4] and Steane [21] found a construction of quantum codes from any pair C_1, C_2 of classical linear codes satisfying $C_2^\perp \subseteq C_1$. Named after their inventors, these codes are known as CSS codes.

The AT&T group [5] found a general way of defining a quantum code. Whenever a classical code over the finite field $\mathbb{F}_4$ exists that is additively closed and self-orthogonal with respect to the Hermitian inner product, they were able to find even more examples of codes. Independently, D. Gottesman [8,9] developed the theory of stabilizer codes. These are defined as the simultaneous eigenspaces of an abelian subgroup of the group of tensor products of Pauli matrices on several qubits. Soon after this, it was realized that the two constructions are equivalent.

A stabilizer code which encodes k qubits into n qubits and has distance d is denoted by $[n, k, d]$. It can correct up to $\lfloor (d-1)/2 \rfloor$ errors of the n qubits. The rate of the code is defined as $r = k/n$. Similar to classical codes, bounds on quantum error-correcting codes are known, i.e., the Hamming, Singleton, and linear programming bounds.

Asymptotically Good Codes

Matching the developments in classical algebraic coding theory, an interesting question deals with the existence of asymptotically good codes, i.e., families of quantum codes with parameters $[[n_i, k_i, d_i]]$, where $i \geq 0$, which have asymptotically nonvanishing rate $\lim_{i\to\infty} k_i/n_i > 0$ and nonvanishing relative distance $\lim_{i\to\infty} d_i/n_i > 0$. In [4], the existence of asymptotically good codes was established using random codes. Using algebraic geometry (Goppa) codes, it was later shown by Ashikhmin, Litsyn, and Tsfasman that there are also explicit families of asymptotically good quantum codes [2]. Currently, most constructions of quantum codes are from the abovementioned stabilizer/additive code construction, with notable exception of a few nonadditive codes and some codes which do not fit into the framework of Pauli error bases.

Applications

Besides their canonical application to protect quantum information against noise, quantum error-correcting codes have been used for other purposes as well. The Preskill/Shor proof of the security of the quantum key distribution scheme BB84 relies on an entanglement purification protocol, which in turn uses CSS codes [19]. Furthermore, quantum codes have been used for quantum secret sharing, quantum message authentication, and secure multiparty quantum computations. Properties of stabilizer codes are also germane for the theory of fault-tolerant quantum computation.

Open Problems

The literature of quantum error correction is fast growing, and the list of open problems is certainly too vast to be surveyed here in detail. The following short list is highly influenced by the preference of the author.

1. It is desirable to find quantum codes for which all stabilizer generators have low weight and which at the same time allow for efficient fault-tolerant quantum computation with the encoded data. These requirements correspond to a quantum equivalent to low-density parity check (LDPC) codes. So far only a few constructions are known, but recent progress was made by Gottesman [10] who used quantum LDPC codes to show that universal fault-tolerant quantum computing with constant overhead is possible. See also [11,15] for recent progress on quantum LDPC codes.
2. It is an open problem to find new families of quantum codes that improve on the currently best known estimates for the threshold for fault-tolerant quantum computing, in particular for codes that can be implemented on a two-dimensional fabric of qubits. An advantage might be had by using subsystem codes since they allow for simple error correction circuits. For more information about noise thresholds, see also the entry on ▸ Fault-Tolerant Quantum Computation.
3. Many quantum codes are designed for the depolarizing channel, where – roughly speaking – the error probability is improved from p to $p^{d/2}$ for a distance d code. The independence assumption underlying this model might not always be justified, and therefore, it seems imperative to consider other channels, e.g., non-Markovian local error models. Under some assumptions on the decay of the interaction strengths, threshold results for such channels have been shown [1]. However, it remains open to find constructions of good codes for non-Markovian noise and in general for noise models that are more realistic than the depolarizing channel.

Experimental Results

Active quantum error-correcting codes, such as those codes which require syndrome measurements and correction operations, as well as passive codes (i.e., codes in which the system stays in a simultaneous invariant subspace of all error operators for certain types of noise), have been

demonstrated for various physical systems. First, this was shown in nuclear magnetic resonance (NMR) experiments [14]. The three-qubit repetition code, which protects one qubit against phase-flip error Z, was then demonstrated in an ion trap for beryllium ion qubits [6].

Subsequently, architectures have been proposed [18] that would in principle allow to construct scalable quantum computers based on ion traps and concatenated coding, e.g., based on the [1, 3, 7] Steane code. In superconducting qubit systems, using an architecture that supports nine physical qubits, high gate fidelities have been reported [12]. This suggests that it might be possible in this architecture to achieve error rates that are below the threshold for the surface code, which is known to be around 1 % [7].

Data Sets

Markus Grassl maintains http://www.codetables.de, which contains tables of the best known quantum codes, some entries of which extend ([5], Table III). It also contains bounds on the minimum distance of quantum codes for given lengths and dimensions and contains information about the construction of the codes. In principle, this can be used to get explicit generator matrices (see also the following section "URL to Code").

URL to Code

The computer algebra system Magma (http://magma.maths.usyd.edu.au/magma/) has functions and data structures for defining and analyzing quantum codes. Several quantum codes are already defined in a database of quantum codes. For instance, the command *BestKnownQuantumCode(F, n, k)* returns the best known quantum code (i.e., one of the highest known minimum weight) over the field F, of length n, and dimension k. It allows the user to define new quantum codes and to study its properties such as the weight distribution, automorphism, and several predefined methods for obtaining new codes from a set of given ones.

Problem Definition

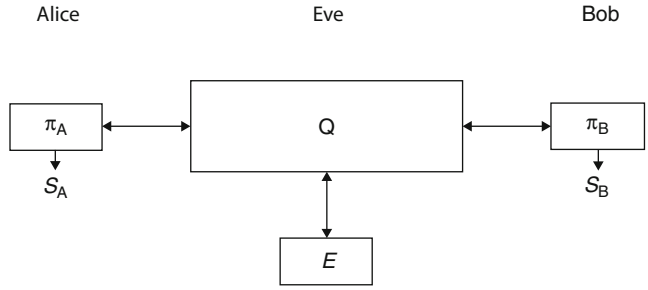
Secret keys, i.e., random bitstrings not known to an adversary, are a vital resource in cryptography (they can be used, e.g., for message encryption or authentication). The *distribution* of secret keys among distant parties, possibly only connected by insecure communication channels, is thus a fundamental cryptographic problem. *Quantum key distribution (QKD)* is a method to solve this problem using quantum communication. It relies on the fact that any attempt of an adversary to wiretap the communication would, by the laws of quantum mechanics, inevitably introduce disturbances which can be detected.

For the technical definition, consider a setting consisting of two honest parties, called *Alice* and *Bob*, as well as an adversary, *Eve*. Alice and Bob are connected by a quantum channel $\mathcal{Q}$ which might be coupled to a (quantum) system E controlled by Eve (see Fig. 1). In addition, it is assumed that Alice and Bob have some means to exchange classical messages *authentically*, that is, they can make sure that Eve is unable to (undetectably) alter classical messages during transmission. If only insecure communication channels are available, Alice and Bob can achieve this using an *authentication scheme* [19]. The scheme requires that Alice and Bob have a short initial key or at least some initial common randomness that is not entirely known to Eve [17]. This is why QKD is sometimes called *quantum key growing*.

A *QKD protocol* $\pi = (\pi_A, \pi_B)$ is a pair of algorithms for Alice and Bob, producing classical outputs S_A and S_B, respectively. S_A and S_B take values in $\mathcal{S} \cup \{\perp\}$ where $\mathcal{S}$ is called *key space* and $\perp$ is a symbol (not contained in $\mathcal{S}$) indicating that no key can be generated. A QKD protocol π with key space $\mathcal{S}$ is said to be *perfectly secure on a channel* $\mathcal{Q}$ if, after its execution using communication over $\mathcal{Q}$, the following holds:

- $S_A = S_B$;
- if $S_A \neq \perp$, then S_A and S_B are uniformly distributed on $\mathcal{S}$ and independent of the state of E.

More generally, π is said to be ε-*secure on* $\mathcal{Q}$ if it satisfies the above conditions except with probability (at most) ε. Furthermore, π is



Quantum Key Distribution, Fig. 1 A QKD protocol π consists of algorithms π_A and π_B for Alice and Bob, respectively. The algorithms communicate over a quantum channel $\mathcal{Q}$ that might be coupled to a system E controlled by an adversary. The goal is to generate identical keys S_A and S_B which are independent of E

said to be ε-*robust on* $\mathcal{Q}$ if the probability that $S_A = \perp$ is at most ε. These definitions may be extended to sets of channels $\mathcal{Q}$, i.e., one demands that the conditions hold for any member of the set.

In the standard literature on QKD, protocols are typically parametrized by some positive number k quantifying certain resources needed for its execution (e.g., the amount of communication). A protocol $\pi = (\pi_k)_{k\in\mathbb{N}}$ is said to be *secure* (*robust*) on a set of channels if there exists a sequence $(\varepsilon_k)_{k\in\mathbb{N}}$ which approaches zero exponentially fast such that π_k is ε_k-secure (ε_k-robust) on this set for any $k \in \mathbb{N}$. Moreover, if the key space of π_k is denoted by $\mathcal{S}_k$, the *key rate* of $\pi = (\pi_k)_{k\in\mathbb{N}}$ is defined by $r = \lim_{k\to\infty} \frac{l_k}{k}$ where $l_k := \log_2 |\mathcal{S}_k|$ is the key length.

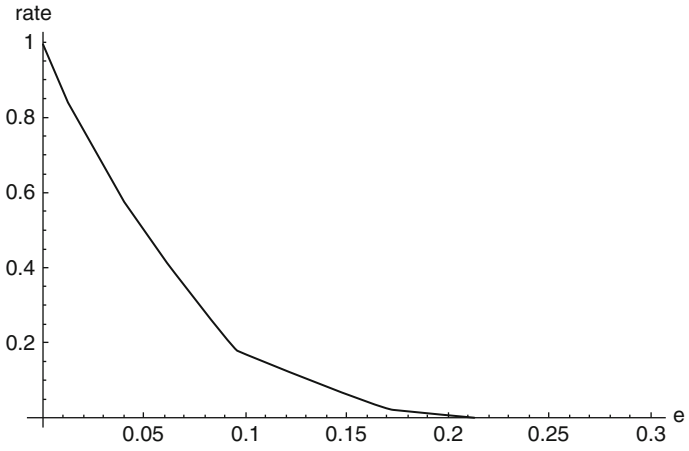
The ultimate goal is to construct QKD protocols π which are secure against general attacks, i.e., secure on the set of *all* possible channels $\mathcal{Q}$. This ensures that an adversary cannot get any information on the generated key even if she fully controls the communication between Alice and Bob. At the same time, a protocol π should be robust on a set of realistic channels, corresponding to a situation where the noise of the channel is below a given threshold and no adversary is present. Note that, in contrast to security, robustness cannot be guaranteed on the set of all possible channels. Indeed, an adversary could, for instance, interrupt the entire communication between Alice and Bob (in which case key generation is obviously impossible).

Key Results

Protocols

On the basis of the pioneering work of Wiesner [20], Bennett and Brassard, in 1984, invented QKD and proposed a first protocol, known today as the *BB84 protocol* [3]. In 1991, Ekert invented entanglement-based QKD. His protocol is commonly referred to as E91 [8] and provides an additional level of security, termed *device independence* [1, 9]. Later, in an attempt to increase the efficiency and practicability of QKD, various extensions to the BB84 and E91 protocols as well as alternative schemes have been proposed.

QKD protocols can generally be subdivided into (at least) two subprotocols. The purpose of the first, called *distribution protocol*, is to generate a *raw key pair*, i.e., a pair of correlated classical values X and Y known to Alice and Bob, respectively. In many protocols (including BB84), Alice chooses $X = (X_1, \ldots, X_k)$ at random, encodes each of the X_i into the state of a quantum particle, and then sends the k particles over the quantum channel to Bob. Upon receiving the particles, Bob applies a measurement to each of them, resulting in $Y = (Y_1, \ldots, Y_k)$. The crucial idea now is that, by virtue of the laws of quantum mechanics, the secrecy of the raw key is a function of the strength of the correlation between X and Y; in other words, the more information about the (raw) key an adversary tries to acquire, the more disturbances she introduces.



Quantum Key Distribution, Fig. 2 Key rate of an extended version of the BB84 QKD protocol depending on the maximum tolerated channel noise (measured in terms of the bit-flip probability e) [14]

This is exploited in the second subprotocol, called *distillation protocol*. Roughly speaking, Alice and Bob estimate the statistics of the raw key pair (X, Y). If the correlation between their respective parts is sufficiently strong, they use classical techniques such as *information reconciliation* (error correction) and *privacy amplification* (see [4] for the case of a classical adversary which is relevant for the analysis of security against individual attacks and [14, 16] for the quantum-mechanical case which is relevant in the context of collective and general attacks; cf. the characterization below) to turn (X, Y) into a pair (S_A, S_B) of identical and secret keys.

Key Rate as a Function of Robustness and Security

The performance (in terms of the key rate) of a QKD protocol strongly depends on the desired level of security and robustness, as illustrated in Fig. 2. (The robustness is typically measured in terms of the *maximum tolerated channel noise*, i.e., the maximum noise of a channel $\mathcal{Q}$ such that the protocol is still robust on $\mathcal{Q}$.) The results summarized below apply to protocols of the form described above where, for the analysis of robustness, it is assumed that the quantum channel $\mathcal{Q}$ connecting Alice and Bob is *memoryless* and *time invariant*, i.e., each transmission is subject to the same type of disturbances. Formally, such channels are denoted by $\mathcal{Q} = \bar{\mathcal{Q}}^{\otimes k}$ where $\bar{\mathcal{Q}}$ describes the action of the channel in a single transmission.

Security Against Individual Attacks

A QKD protocol π is said to be *secure against individual attacks* if it is secure on the set of channels $\mathcal{Q}$ of the form $\bar{\mathcal{Q}}^{\otimes k}$ under the constraint that the coupling to E is purely classical. Note that this notion of security is relatively weak. Essentially, it only captures attacks where the adversary applies identical and independent measurements to each of the particles sent over the channel.

The following statement can be derived from a classical argument due to Csiszár and Körner [6]. Let τ be a distribution subprotocol as described above, i.e., τ generates a raw key pair (X, Y). Moreover, let $\mathcal{S}$ be a set of quantum channels $\bar{\mathcal{Q}}$ suitable for τ. Then there exists a QKD protocol π (parametrized by k) consisting of k executions of the subprotocol τ followed by an appropriate distillation subprotocol such that the following holds: π is robust on $\mathcal{Q} = \bar{\mathcal{Q}}^{\otimes k}$ for any $\bar{\mathcal{Q}} \in \mathcal{S}$, is secure against individual attacks, and has key rate at least

$$r \geq \min_{\bar{\mathcal{Q}} \in \mathcal{S}} H(X|Z) - H(X|Y), \qquad (1)$$

where the conditional Shannon entropies on the r.h.s. are evaluated for the joint distribution $P^{\bar{\mathcal{Q}}}_{XYZ}$ of the raw key (X, Y) and the (classical) state Z of Eve's system E after one execution of τ on the channel $\mathcal{Q}$. Evaluating the right hand side for the BB84 protocol on a channel with bit-flip probability e shows that the rate is non-negative if $e \leq 14.6\,\%$ [10].

Security Against Collective Attacks

A QKD protocol π is said to be *secure against collective attacks* if it is secure on the set of channels $\mathcal{Q}$ of the form $\bar{\mathcal{Q}}^{\otimes k}$ with arbitrary coupling to E. This notion of security is strictly stronger than security against individual attacks, but it still relies on the assumption that an adversary does not apply joint operations to the particles sent over the channel.

As shown by Devetak and Winter [7], the above statement for individual attacks extends to collective attacks when replacing inequality (1) by

$$r \geq \min_{\bar{\mathcal{Q}} \in \mathcal{S}} S(X|E) - H(X|Y), \qquad (2)$$

where $S(X|E)$ is the conditional von Neumann entropy evaluated for the classical value X and the quantum state of E after one execution of τ on $\bar{\mathcal{Q}}$. For the standard BB84 protocol, the rate is positive as long as the bit-flip probability e of the channel satisfies $e \leq 11.0\,\%$ [18] (see Fig. 2 for a graph of the performance of an extended version of the protocol).

Security Against General Attacks

A QKD protocol π is said to be *secure against general attacks* if it is secure on the set of all channels $\mathcal{Q}$. This type of security is sometimes also called *full* or *unconditional security* as it does not rely on any assumptions on the type of attacks (as long as they are constrained to the communication channel) or the resources needed by an adversary.

The first QKD protocol to be proved secure against general attacks was the BB84 protocol. The original argument by Mayers [13] was followed by various alternative proofs. Most notably, based on a connection to the problem of entanglement purification [5] established by Lo and Chau [12], Shor and Preskill [18] presented a general argument which applies to various versions of the BB84 protocol.

Later it has been shown that, for virtually *any* QKD protocol, security against collective attacks implies security against general attacks [14, 15]. In particular, the above statement about the security of QKD protocols against collective attacks, including formula 2 for the key rate, extends to security against general attacks.

Applications

Because the notion of security described above is *composable* [16] (see [2, 14] for a general discussion of composability of QKD), the key generated by a secure QKD protocol can in principle be used within any application that requires a secret key (such as one-time pad encryption). More precisely, let $\mathcal{A}$ be a scheme which, when using a *perfect* key S (i.e., a uniformly distributed bitstring which is independent of the adversary's knowledge), has some failure probability δ (according to some arbitrary failure criterion). Then, if the perfect key S is replaced by the key generated by an ε-secure QKD protocol, the failure probability of $\mathcal{A}$ is bounded by $\delta + \varepsilon$ [14].

Experimental Results

Most known QKD protocols (including BB84 and E91) only require relatively simple quantum operations on Alice and Bob's side (e.g., preparing a two-level quantum system in a given state or measuring the state of such a system). This makes it possible to realize them with today's technology. Experimental implementations of QKD protocols usually use photons as carriers of quantum information, because they can easily be transmitted (e.g., through optical fibers or free space). A main limitation, however, is noise in the transmission, which, with increasing distance between Alice and Bob, reduces the performance of the protocol (see Fig. 2). We refer to [11] for an overview on quantum cryptography with a focus on experimental aspects.

Problem Definition

Brief Description

The search problem can be described informally as finding an item possessing a specific property, in a given set of N items. Each item either does or does not possess the specified property, and that can be checked by a binary query. The complexity of the problem is the number of such queries required to find the desired item (also called the *target* item). The items are often collected in a

database and sorted to simplify the subsequent searches. When they are not sorted, there is no shortcut to the brute force method of checking each item one by one until the desired item is found. A familiar example of a database is a telephone directory. Its entries are sorted according to the names of persons but not according to the telephone numbers. Hence, it is easy to find the telephone number of a particular person, but difficult to find the name of a person to whom a particular telephone number belongs (i.e., a lookup is difficult when it is not in the same order in which the database is sorted).

The $\Omega(N)$ lower bound on search speed, based on inspection of one item at a time, is correct only for classical computers. Quantum computers can be in a superposition of multiple states, however, and so can inspect multiple items at the same time. There is no obvious lower bound on how fast a quantum search can be, nor is there an obvious technique faster than the brute force search. It turns out, though, that there is an efficient and optimal quantum search algorithm that requires only $O(\sqrt{N})$ queries [15].

This quantum algorithm is very different from the search on a classical computer [8]. The optimal classical strategy is to check the items one at a time in a random order, avoiding in later trials the items that have already been checked earlier. After η items have been checked from a uniform distribution, the probability that the search hasn't yet succeeded is $(1 - 1/N)(1 - 1/(N-1)) \cdots (1 - 1/(N - \eta + 1))$. For $\eta \ll N$, the success probability is therefore roughly $1 - (1 - 1/N)^{\eta} \approx \eta/N$. Increasing this success probability to $\Theta(1)$ requires the number of items checked, η, to be $\Theta(N)$.

In contrast to classical computation, quantum computation is formulated in terms of wavelike complex amplitudes, whose interference can be used to cancel undesirable components and boost the desired component. Quantum search is then analogous to the design of a multi-element antenna array, where a careful choice of phases can boost the radiation in a particular direction. The analysis of such structures is carried out using the algebra of unitary transformations, and absolute-value squares of the amplitudes give the observation probabilities. Unitary transformations include rotations and reflections (about various directions) in the space of amplitudes, as well as local phase shifts. Rotations and reflections redistribute the amplitudes and are similar to classical transformations. On the other hand, the phase shifts are uniquely quantum; they do not alter probabilities of individual components, but affect their subsequent interference pattern. The challenge of quantum computation is to find a sequence of elementary unitary operations (i.e., quantum logic gates) that solve the given computer science problem, while ensuring that the input and the output of the quantum algorithm have clear classical interpretations.

The quantum search algorithm steadily increases the amplitude of the desired item through a series of quantum operations. Starting with an initial amplitude $1/\sqrt{(N)}$, in η steps, the amplitude increases to roughly $\eta/\sqrt{N}$, and hence, the success probability (on observation of the state) increases to η^2/N. Boosting this to $\Theta(1)$ requires only $O(\sqrt{N})$ steps, approximately the square root of the number of steps required by the best classical algorithm.

The quantum search algorithm is of wide interest because of its versatility; it can be adapted to different settings in a variety of fields, giving a new class of quantum algorithms extending well beyond the search problems. Since its discovery, it has been incorporated in solutions of many quantum problems – several of them are mentioned later in this article. Even now, two decades after the algorithm's discovery, new applications and extensions keep on appearing regularly.

Formal Construction

Let the items in the set be labeled by an index $i = 1, 2, \ldots, N$. Let the binary query be represented by an oracle $f(i)$, such that $f(i) = 1$ when i represents a desired item and $f(i) = 0$ otherwise. The quantum algorithm works in an N-dimensional vector space with complex coordinates, known as the Hilbert space. We use Dirac's notation, which is standard in the literature of quantum mechanics and quantum computation. Then the items are mapped to the N orthogonal basis vectors $|i\rangle$ of the Hilbert space, and the bi-

nary query is mapped to the selective phase-shift operator defined by $U_f|i\rangle = (-1)^{f(i)}|i\rangle$. Given the binary query $f(i)$, it is easy to construct the operator U_f using an ancilla qubit.

The problem is to start from a specific initial state $|s\rangle$ and evolve to a target state satisfying $U_f|t\rangle = -|t\rangle$, by applying a sequence of unitary operations. The number of times U_f is used in the algorithm is its query complexity. This search problem is *unstructured* because nothing is known about the solution, except the information available from the oracle that can tell whether or not a specific state is the target state.

NP-complete problems can be represented as exhaustive search problems. For example, let ϕ be a 3-SAT formula on n Boolean variables. Then the search problem is to find an assignment for the variables, $i \in \{1, 2, \ldots, N = 2^n\}$, that satisfy ϕ. This example does not involve a database and so bypasses concerns regarding how the items are stored in a physical memory device and the spatial relationship among them.

Key Results

Grover [15] showed that there indeed exists a quantum search algorithm that provides a square-root speedup over the optimal classical randomized algorithm. The algorithm has its simplest form when there is only one target item. Then the algorithm starts with an unbiased uniform superposition state $|s\rangle = (1/\sqrt{N}) \sum_{i=1}^{N} |i\rangle$ and performs $Q = O(\sqrt{N})$ iterations to evolve to the state $(U_D U_f)^Q |s\rangle$. Each iteration consists of two reflection operations:

1. $U_f = 1 - 2|t\rangle\langle t|$ is a reflection along $|t\rangle$. It uses the binary query to flip the sign of the amplitude of the target state.
2. $U_D = 2|s\rangle\langle s| - 1$ is reflection about $|s\rangle$. It can be carried out without any information about the target state. Since the action of $|s\rangle\langle s|$ gives the average amplitude state, U_D amounts to inversion about the average or overrelaxation.

At the end, the final state is measured in the $\{|i\rangle\}$ basis that encodes the item labels, and i is output.

There are several ways of analyzing the algorithm, and the geometric picture is perhaps the simplest. We observe that throughout the evolution, the quantum state stays in the two-dimensional subspace (of the Hilbert space) spanned by $|s\rangle$ and $|t\rangle$. Initially, the amplitude of the state along $|t\rangle$ is $\langle t|s\rangle = 1/\sqrt{N}$, and the angle between $|t\rangle$ and $|s\rangle$ is $\pi/2 - \theta$ with $\sin\theta = 1/\sqrt{N}$. It is a general property of linear transformations in two dimensions that a pair of reflections about two distinct axes produces a rotation, and the amount of rotation is twice the angle between the two axes. The quantum search algorithm is an alternating sequence of reflections about two different axes. Each application of the operator $U_D U_f$ rotates the quantum state from $|s\rangle$ toward $|t\rangle$ by angle 2θ. The number of iterations $\tilde{Q}$ required to exactly reach the target state is therefore given by $(2\tilde{Q} + 1)\theta = \pi/2$. In practice, we have to truncate to integer $Q = \lfloor \tilde{Q} + 0.5 \rfloor$, introducing a small error. The success probability still remains at least $\cos^2\theta = 1 - 1/N$. Asymptotically, $Q = (\pi/4)\sqrt{N}$.

The reflection about the uniform superposition state, U_D, is known as the Grover diffusion operation. When the indices are represented in binary notation, with $N = 2^n$, we have $|s\rangle = H^{\otimes n}|0\rangle^{\otimes n}$ in terms of the Hadamard operator $H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$. Then $U_D = H^{\otimes n} U_0 H^{\otimes n}$, with $U_0 = 2|0\rangle^{\otimes n}\langle 0|^{\otimes n} - 1$ being the reflection about the $|0\rangle^{\otimes n}$ state, and it can be implemented using $O(n)$ qubit-level operations. In this case, the full quantum search algorithm evolves the state $|0\rangle^{\otimes n}$ to the state $(H^{\otimes n} U_0 H^{\otimes n} U_f)^Q H^{\otimes n}|0\rangle^{\otimes n}$.

When there are M target items, instead of just one, all that is required is to replace $|t\rangle$ by $\sum_{j=1}^{M} |t_j\rangle/\sqrt{M}$ in the algorithm. The final measurement then yields one of the target items after $O\left(\sqrt{N/M}\right)$ queries. Thus, we have [15]:

Theorem 1 (Grover search) *There is a quantum black-box unstructured search algorithm*

with success probability $\Theta(1)$*, which finds any one of the* M *target items in a set of* N *items, using* $O\left(\sqrt{N/M}\right)$ *queries.*

This algorithm has several noteworthy properties:

- The algorithm is optimal. It saturates the $\Omega\left(\sqrt{N}\right)$ lower bound [5] on the number of queries required for an unstructured quantum search. The evolution from $|s\rangle$ to $|t\rangle$ follows the shortest geodesic route in the Hilbert space at constant speed. A variational analysis shows that the algorithm cannot be improved by even a single query [43].
- The best classical search algorithm has to walk randomly through all the items, while the quantum search algorithm performs a directed walk in the Hilbert space. The square-root speedup of the quantum search algorithm can therefore be understood as the well-known result that directed walk provides a square-root speedup over random walk while covering the same distance.
- The algorithm can be looked upon as evolution of the quantum state from $|s\rangle$ to $|t\rangle$, governed by a Hamiltonian containing two terms, $|t\rangle\langle t|$ and $|s\rangle\langle s|$. The former represents a potential energy attracting the state toward $|t\rangle$, and the latter represents a kinetic energy diffusing the state throughout the Hilbert space. The algorithm is then the discrete Trotter's formula, generated by exponentiating the two terms in the Hamiltonian [17].
- Grover search does not require the full power of quantum dynamics and can be implemented using any system that obeys the superposition principle. Explicit examples using classical waves in the form of coupled oscillators have been constructed [20, 29]. In these mechanical systems, the role of the uniform superposition state is played by the center-of-mass mode, and the search problem becomes the energy focusing problem. The classical wave implementation requires the same number of queries as the quantum algorithm. The difference is that to represent N items, we need N wave modes but only $n = \log_2 N$ qubits.
- Grover search finds with certainty a single target state out of four possibilities using a single binary query, i.e., $Q = 1$ for $N = 4$. The best classical Boolean algorithm can distinguish only two items with a single binary query, and so it needs two binary queries to carry out the same task. When the query can be factored into subqueries, e.g., the item label is searched for one digit at a time and not as a whole, the best quantum (or wave) arrangement for a database is a quaternary tree. Then every subquery reduces the search space by a factor of 4, which is a factor-of-2 advantage over the classically optimal binary tree. An additional advantage following from commutativity of superposition is that, unlike the classical case, the quantum tree does not require sorting of the database [28].
- The quantum search algorithm is robust against changes in the initial state and the operators, in sharp contrast to many other quantum processes that are highly sensitive to errors. The initial state and the diffusion operator are related in Grover search, but can be separated in a more general context [2, 40]. Let $\tilde{U}_D$ be the modified diffusion operator with $|s\rangle$ as an eigenstate with eigenvalue 1, i.e., the diffusion is translationally invariant. The algorithm then succeeds with $\Theta(1)$ probability, provided $\alpha = |\langle t|s\rangle|$ as well as the angular spectral gap of $\tilde{U}_D$ in the vicinity of identity (say $\tilde{\theta}$) are bounded away from zero. The number of queries required is $O(B^3/\alpha)$, where B^2 is related to the second moment of the eigenvalue distribution of $\tilde{U}_D$ and obeys $B^2 < 1 + (4/\tilde{\theta}^2)$, in contrast to the classical result $O(1/\alpha^2)$. Grover search, therefore, can be generalized to an entire class of algorithms that use different diffusion operators. This flexibility is one of the reasons why Grover search ideas appear frequently in quantum algorithms.
- Quantum search can be implemented so as to be robust also against faulty queries, a problem known as *bounded-error search*. When the query has a bounded coherent

error, say $\tilde{U}_f|i\rangle|1\rangle = \sqrt{p_i}(-1)^{f(i)}|i\rangle|1\rangle + \sqrt{1-p_i}|\tilde{i}\rangle|0\rangle$ with each $p_i \geq 0.9$ ($|\tilde{i}\rangle$ are arbitrary states and the last qubit is a witness for the fault), quantum search can still be implemented using $O\left(\sqrt{N}\right)$ queries [22]. The deterioration of the search algorithm depends on p_i, but that is only in the scaling constant for the number of queries.

A useful generalization of the quantum search algorithm is the *amplitude amplification* technique [10, 16], which can be applied on top of nearly any quantum algorithm for any problem. It says that given a quantum algorithm that solves a problem with a small success probability ϵ, the success probability can be increased to roughly $m^2\epsilon$ using $O(m)$ calls to that algorithm. (Classically, the success probability can be increased to only about $m\epsilon$.) For the standard search problem, the simple algorithm that picks a random item has success probability $\epsilon = 1/N$, which the quantum search algorithm increases to $\Theta(1)$.

More formally, let V be the unitary operator corresponding to an algorithm that evolves the initial state $|s\rangle$ to $V|s\rangle$. Its success probability is $\epsilon = |\langle t|V|s\rangle|^2 = |V_{ts}|^2$. The algorithm obtained by replacing $|s\rangle$ by $V|s\rangle$ in Grover search, i.e., replacing U_D by $VU_DV^\dagger$, then increases the success probability to $\Theta(1)$ in $O\left(1/\sqrt{|V_{ts}|}\right)$ iterations. In particular, this algorithm evolves the quantum state in the two-dimensional subspace spanned by $|t\rangle$ and $V|s\rangle$, rotating it by angle $2\sin^{-1}|V_{ts}|$ at every iteration. In order to implement U_f, the algorithm needs a witness for the correctness of the output. Thus, we have [10, 16]:

Theorem 2 (Amplitude amplification) *Let $\mathcal{A}$ be a quantum algorithm that outputs a correct answer with witness, with known probability $\epsilon = \sin^2\theta$. Furthermore, let $m = \lfloor \pi/(4\theta) \rfloor$. Then there is an algorithm $\mathcal{A}'$ that uses $2m+1$ calls to $\mathcal{A}$ and $\mathcal{A}^{-1}$ and outputs a correct answer with probability $\epsilon' \geq 1-\epsilon$.*

Depending on the actual implementation, it is possible to vary the quantum search algorithm somewhat from the preceding deterministic and optimal approach and obtain small improvements:

- The algorithm needs $O\left(\sqrt{N}\log N\right)$ qubit-level operations in order to implement $H^{\otimes n}$ and U_0. The $\log N$ factor in this count can be suppressed by adding a small number of queries to the algorithm. A simple scheme divides the n qubits into k sets of n/k qubits each and uses the Grover diffusion operators ${U_D}^{(i)} = H^{\otimes(n/k)}{U_0}^{(i)}H^{\otimes(n/k)}$ that act only on one set at a time leaving the other sets unchanged [18]. Sequentially going through all the sets generates the transformation $V = \prod_{i=1}^{k}(U_D^{(i)}U_f)H^{\otimes n}$, which is then used for amplitude amplification with the initial state $|0\rangle^{\otimes n}$. Overall, the number of qubit-level operations reduce by a factor $\Theta(k)$, while the number of queries go up by a factor $1+\Theta(kN^{-1/k})$, provided $kN^{-1/k} = o(1)$. The choice $k = \Theta(n/\log n)$ reduces the qubit-level operations to $O\left(\sqrt{N}\log n\right)$, at the cost of increasing the queries by a factor $1+\Theta(1/\log n)$.
- Consider the partial search problem where the items are separated into N/b blocks of size b each, and only the block containing the desired item is to be located using the same U_f. In that case, the number of queries can be reduced by $0.34\sqrt{b}$ for large b [25]. The procedure first uses Grover search to make the amplitudes of nontarget blocks sufficiently small, then applies Grover search in parallel within each block to make the amplitudes of the target block sufficiently negative (amplitudes of nontarget blocks remain unchanged in this step), and then executes a final U_D operation to reduce the amplitudes of nontarget blocks to zero.
- Though Grover search proceeds from $|s\rangle$ to $|t\rangle$ with uniform speed in the Hilbert space, it slows down in terms of the success probability as it nears the target state. So one can reduce the expected number of queries, by stopping the algorithm before reaching the target state and then looking for the desired

item probabilistically. That amounts to minimizing $(Q+1)/p$, with the success probability $p = \sin^2\left((2Q+1)\sin^{-1}(1/\sqrt{N})\right)$. This probabilistic search reduces the required number of queries asymptotically to $0.6900\sqrt{N}$ [14].

- Consider the search problem where the times required for querying different items are not the same. This can happen when the query is an algorithm $\mathcal{A}$ acting on different input states $|i\rangle$. When the query for the i^{th} item takes time t_i to execute, unstructured quantum search can be accomplished in time $O\left(T = \left(\sum_{i=1}^{N} t_i^2\right)^{1/2}\right)$ when t_i are known apriori [3]. The strategy is to divide the items into multiple groups so that items in every group have query times within a constant factor, apply Grover search within each group, and then query the groups sequentially. The number of groups needed is $O(\log N)$, and the result improves upon the global Grover search bound $O\left(\sqrt{N}t_{\max}\right)$. Amplitude amplification can be used when $\mathcal{A}$ is probabilistic, and a polylogarithmic overhead in T is required when t_i are not known in advance.

Applications

NP-Complete Problems

Even though NP-complete problems have some structure, there are few known algorithms that exploit this structure to solve them, and often the only recourse left is to solve them as exhaustive search problems. Since quantum search does not assume any structure or pattern in the input data, it provides a square-root speedup in such cases.

Quantum Counting

The counting problem is to find the number of items in a set that satisfy the given query. Its quantum solution is based on the fact that the iterative evolution in Grover search is periodic, with angular frequency $\omega = 2\sin^{-1}\left(\sqrt{M/N}\right)$. The phase estimation procedure (based on quantum Fourier transform) [24] can therefore determine M approximately, up to error $\sqrt{M}$, using $O\left(\sqrt{N}\right)$ queries. Then, using the property that ω differs by $1/\sqrt{M(N-M)}$ between adjacent values of M, M can be determined exactly using $O/\sqrt{M(N-M)}$ queries [27]. For $M = o(N)$, this quantum result is a power-law improvement over the classical result of $\Theta(N)$ queries, although not as good as a square-root speedup.

Element Distinctness

An early application of Grover search was to find collisions, i.e., given oracle access to a 2-to-1 function f, find distinct arguments x, y such that $f(x) = f(y)$. The quantum *collision problem* has an $O(N^{1/3})$ algorithm [9]. The more general *element distinctness problem* is to find distinct x, y such that $f(x) = f(y)$, for an unknown function f that can be accessed only by an oracle. Ambainis discovered an optimal $O(N^{2/3})$ quantum algorithm for this problem [2]. It searches a suitably constructed graph, with the Grover diffusion operation replaced by a certain quantum walk. The vertices of the graph correspond to various subsets of items $S_j \subseteq \{1, 2, \ldots, N\}$, each of size $N^{2/3}$, two vertices are connected by an edge when the corresponding subsets differ by only one item, and the target vertices are the subsets S_j that solve the element distinctness problem.

Distributed Search

Grover search is also useful in improving communication complexity. For example, a straightforward distributed implementation of the quantum search algorithm solves the *set intersection problem* or the *appointment problem*. The result is, when A and B have respective data strings $x, y \in \{0,1\}^N$, and they want to find an index i such that $x_i = y_i = 1$, only $O\left(\sqrt{N}\log N\right)$ qubits of communication is necessary [11]. This result has led to an exponential classical/quantum separation in the memory required to evaluate a certain total function with a streaming input [26].

Fixed-Point Search

The iterative evolution in Grover's search algorithm is cyclic, and knowledge of N is necessary

to stop it at the right time to find the target item. In contrast, fixed-point search algorithms converge monotonically to the target state. For a long time, a fixed-point quantum algorithm was considered unlikely, since any iterative unitary evolution is periodic. Surprisingly, a way out was provided by recursive unitary evolution. When the reflection operations in the amplitude amplification algorithm are replaced by selective phase shifts of $\pi/3$ (e.g., $R_i = 1 + (e^{i\pi/3} - 1)|i\rangle\langle i|$ for the state $|i\rangle$), $|\langle t|V|s\rangle|^2 = 1 - \epsilon$ implies $|\langle t|VR_sV^\dagger R_tV|s\rangle|^2 = 1 - \epsilon^3$ [19]. So each recursive substitution of the operator V by the operator $VR_sV^\dagger R_tV$ reduces the deviation of the final state from the target state to the cube of what it was before. (The corresponding best classical reduction is $O(\epsilon^2)$, e.g., by majority rule selection after three trials.) This technique does not give a square-root speedup for search, but it is useful when ϵ is small, for instance, in error correction. It has been used to design composite pulse sequences for reducing systematic errors [35]. An iterative quantum search algorithm with similar properties has been obtained combining reflection operations with non-unitary projective measurements [41]. Another recent construction is a bounded-error quantum search algorithm (i.e., success probability $p \geq 1 - \delta$) that varies the phase shifts between π and $\pi/3$ as a function of the iteration number [42]. It exhibits square-root speedup as well as convergence to the target state, provided that both δ and $|\langle t|s\rangle|$ are bounded away from zero.

Spatial Search

This is the search problem where the items belonging to a database are spread over distinct physical locations, say a d-dimensional lattice, and there is a restriction that one can proceed from any location to only its neighbors while searching for the target item. Its quantum solution replaces the global Grover diffusion operator by a local quantum walk, and Grover search becomes the $d \to \infty$ limit. The required number of queries has to obey the double lower bound $\Omega\left(dN^{1/d}, \sqrt{N}\right)$; the former arises from the finite speed of movement on the lattice and the latter from the optimality of Grover search. The best algorithms are found in the framework of relativistic quantum mechanics. They use $O\left(\sqrt{N}\right)$ queries for $d > 2$, with the scaling constant approaching $\pi/4$ from above as $d \to \infty$ [1, 33]. In the critical dimension $d = 2$, the algorithms are slowed down by logarithmic factors arising from the infrared divergence, and the best known algorithm requires $O\left(\sqrt{N \log N}\right)$ queries [39]. For non-integer values of d, the scaling behavior of the algorithm has been verified using numerical simulations on fractal lattices [32].

Markov Chain Evolution

Generic stationary stochastic processes (e.g., random walks) are defined in terms of transition matrices that encode the possible evolutionary changes at each step. Many properties of the resulting evolution (e.g., hitting time, detection, mixing, escape time) scale as negative powers of the spectral gap of the transition matrix. For Markovian evolution on bipartite graphs, the transition matrix can be separated into two disjoint parts, say $\{x\} \to \{y\}$ and $\{y\} \to \{x\}$. Szegedy constructed two reflection operators from these parts and defined a quantum evolution operator as their product [38] (classical Markov chain evolution does not allow such reflection operators). The spectral gap of this quantum evolution operator scales as the square root of the spectral gap of the original transition matrix and so speeds up the evolution the same way as Grover search does.

Recursive Search

Game-tree evaluation, which is a recursive search problem, is an extension of unstructured search. Classically, using the alpha-beta pruning technique, the value of a balanced binary AND-OR tree can be computed with $o(1)$ error in expected time $O\left(N^{\log_2[(1+\sqrt{33})/4]}\right) = O(N^{0.754})$ [36]. This is optimal even for bounded-error algorithms [37]. By applying quantum search recursively, a depth-d regular AND-OR tree can be evaluated with constant error in time $\sqrt{N} \cdot O(\log N)^{d-1}$. The log factors come from amplifying the success probability of inner searches to

be close to one. Bounded-error quantum search eliminates these log factors, reducing the time to $O\left(\sqrt{N}\cdot c^{d}\right)$ for some constant c. Recently, an $O(N^{0.5+o(1)})$ time algorithm has been discovered for evaluating an arbitrary AND-OR tree on N variables [4, 13].

Open Problems

In several applications of the quantum search algorithm, only the leading asymptotic behavior of the query complexity is known, and attempts to suppress logarithmic corrections (when they appear) and reduce the scaling constants continue [34]. In this section, we point out some other offbeat applications.

Hamiltonian Evolution

Many conventional algorithms for simulations of quantum systems with sparse Hamiltonians use the Trotter formula with a small step size. They have a power-law dependence of the computational complexity on the simulation error and hence are not efficient. In contrast, Grover search amounts to a Trotter formula with the largest possible step size, given the projection operator nature of the terms in the Hamiltonian. A recent exciting realization is that this feature leads to only logarithmic dependence of the computational complexity on the simulation error, which is an exponential improvement. The general strategy is to decompose the sparse Hamiltonian as a sum of projection operators, formulate the evolution problem as a multi-query search problem, and then use a large step size Trotter formula to simulate it [7, 31]. This framework can also readily benefit classical simulations of quantum systems.

Molecular Biology

Many molecular processes of metabolism occur at scales, nanometer and picosecond, where quantum dynamics is relevant. They frequently involve unstructured search and transport, in the sense that correct ingredients for the processes have to be found from the mixture of molecules floating around. Evolution over billions of years has certainly produced complex machinery to carry out these searches efficiently, although we do not fully comprehend their optimization criteria. Attempts to understand some of these processes suggest that Grover search may have played a role in their design, quite likely exploiting coherent coupled vibrational modes and not quantum superposition. An intriguing example is that the universal genetic language uses an alphabet of four letters, while a binary alphabet would be sufficient and simpler to construct during evolution [30]. Coherent vibrational dynamics of molecules also contributes to efficient energy transport during photosynthesis and to the detection of smell [23].

Ordered Search

A sequentially ordered database can be easily searched by factoring $f(i)$ into subqueries for individual digits of i. An alternative is to use a different oracle $g(i)$, such that $g(i) = 0$ when i represents items before the desired item and $g(i) = 1$ otherwise. Classically, binary search is the optimal algorithm given either $f(i)$ or $g(i)$ and requires $\lceil \log_2 N \rceil$ queries. The optimal quantum algorithm for $f(i)$ is quaternary search with $0.5\lceil \log_2 N \rceil$ queries, but surprisingly a quantum algorithm using $g(i)$ can do better. In case of $g(i)$, though the optimal solution is unknown, the query complexity for an exact algorithm has a lower bound of $0.221 \log_2 N$ [21] and a known solution of $0.433 \log_2 N$ [12] (there also exists a quantum stochastic Las Vegas algorithm with $0.32 \log_2 N$ expected queries and $o(1)$ error [6]).

Search with Additional Structure

It may be possible to speed up a search process beyond the square-root speedup of Grover search, when the problem has extra structure beyond the minimal information provided by the oracle $f(i)$. The details of the algorithm and the extent of speedup would then depend on the extra structure, and the possibilities are open to explorations. Some examples are symmetries among the items, associative memory recall with connections, and patterns in the Boolean function

to be evaluated. Another problem of interest is determination of the complete path (with certain properties) from the initial to the target state instead of locations of just the end points.

Perspective

In a lecture at the Bell Labs in 1985, Richard Feynman made an interesting observation. In the 1940s when airplanes were being developed, aeronautical engineers had proved bounds and theorems about why planes would never be able to fly faster than the speed of sound. For several years, this speed was regarded as fundamentally a bound for flights as the speed of light is for communications. However, gradually just by using intelligent design, it was discovered that airplanes could indeed fly faster than the speed of sound – only the rules of design in the new regime were very different. The question is whether the bounds on quantum computation (specifically the $\Omega\left(\sqrt{N}\right)$ bound for search) will continue to hold, or by making the rules of design very different, just as in the case of supersonic airplanes, someone will find a way around these bounds. No one has found any loophole in the arguments in the 20 years since the lower bound for quantum search was discovered, despite numerous scientists from different fields having tried their hand at it. On the other hand, even though this bound has been derived over and over again using different methods, no one has come up with a simple and short physical explanation for it, which would give one the assurance that one really understood it.

Problem Definition

Our goal is to design differentially private algorithms to answer *statistical queries* on a sensitive database. We model the database $D = (x_1, \ldots, x_n) \in (\{0,1\}^d)^n$ as a collection of n records – one per individual – each consisting

of d binary attributes. A differentially private algorithm is a randomized algorithm whose output distribution does not depend "significantly" on any one record of the database. The formal definition is as follows:

Definition 1 ([8]) An algorithm $\mathcal{A}:(\{0,1\}^d)^n \to \mathcal{R}$ is (ε, δ)-*differentially private* if for every pair of databases $D, D' \in (\{0,1\}^d)^n$ that differ on at most one row and every $S \subseteq \mathcal{R}$,

$$\mathbb{P}[\mathcal{A}(D) \in S] \leq e^{\varepsilon}\mathbb{P}[\mathcal{A}(D') \in S] + \delta.$$

Henceforth, we will say $\mathcal{A}$ is *differentially private* if it satisfies $(1, 1/n^2)$-differential privacy. (The choice of $\varepsilon = 1$ and $\delta = 1/n^2$ is arbitrary and can be replaced with $\varepsilon = c$ and $\delta = 1/n^{1+c'}$ for any constants $c, c' > 0$ without affecting any stated results).

A *statistical query* (henceforth, simply *query*) is specified by a Boolean predicate $q : \{0,1\}^d \to \{0,1\}$. The answer to a query is the expected value of the predicate over records in the database. Abusing notation, we write

$$q(D) = \frac{1}{n}\sum_{i=1}^{n} q(x_i).$$

We wish to design a differentially private algorithm $\mathcal{A}$ that takes a database and a set of statistical queries and outputs an approximate answer to each query.

Definition 2 An algorithm $\mathcal{A}$ is α-*accurate* for a query q if $\mathcal{A}(D)$ outputs $a \in [0,1]$ such that $|a - q(D)| \leq \alpha$, with probability at least 99/100. An algorithm $\mathcal{A}$ is α-*accurate* for a set of queries $Q = \{q_1, q_2, \ldots\}$ if $\mathcal{A}(D)$ outputs $(a_q)_{q\in Q}$ such that for every $q \in Q$, $|a_q - q(D)| \leq \alpha$ with probability at least 99/100.

The goal is to design differentially private algorithms that are α-accurate for sets of queries Q as large as possible. As privacy is easier to achieve when the number of records n is large, we will seek to obtain privacy and accuracy for n as small as possible. Lastly, we seek to make the algorithms as computationally efficient as possible.

Key Results

As a baseline, we will consider simple *additive perturbation* [2, 6–8], which answers each query by independently perturbing the answer with noise from a suitable distribution.

Theorem 1 *There is a differentially private algorithm $\mathcal{A}$ that takes a database $D \in (\{0,1\}^d)^n$ and a set of queries $Q = \{q_1, \ldots, q_k\}$ as input, runs in time* $\mathrm{poly}(n, d, |q_1| + \cdots + |q_k|)$, *and is α-accurate for Q so long as $n \geq \tilde{O}(|Q|^{1/2}/\alpha)$.*

Here, $|q|$ represents the time complexity of evaluating the predicate on a single row of the database. Typically, this it is assumed to be $\mathrm{poly}(d)$.

Additive perturbation is differentially private and computationally efficient, but requires that the size of the database be polynomial in the number of queries, and thus is restricted to answering at most about n^2 queries. As we will see, it is possible to accurately answer *exponentially* more queries under differential privacy.

Answering Many Queries via No-Regret Learning

The first algorithm that improved on additive perturbation for answering arbitrary queries was given by Blum, Ligett, and Roth [3]. Surprisingly, they showed for the first time that it was possible to answer *exponentially many* queries under differential privacy. Subsequent to their work, there were several improvements in the computational efficiency, functionality, and quantitative guarantees of their algorithm. This work led to the *private multiplicative weights algorithm* of Hardt and Rothblum [10]. We summarize the capabilities of this algorithm in the following theorem.

Theorem 2 ([10]) *There is a differentially private algorithm $\mathcal{A}$ that takes a database $D \in (\{0,1\}^d)^n$ and a set of queries $Q = \{q_1, \ldots, q_k\}$ as input, runs in time* $\mathrm{poly}(n, 2^d, |q_1| + \cdots + |q_k|)$, *and is α-accurate for $|Q|$ so long as $n \geq \tilde{O}(\sqrt{d}\log|Q|/\alpha^2)$.*

The private multiplicative weights algorithm is based on the following surprisingly simple

framework: Begin with a "crude approximation" of the database D^1. Then, for $t = 1, \ldots, T$, find (in a differentially private manner) a query $q^t \in Q$ such that the approximation D^t does not give an accurate answer. That is, $|q^t(D) - q^t(D^t)| > \alpha$. Use q^t to "update" D^t into a better approximation D^{t+1}. Finally, output the answers to Q given by D^T.

Remarkably, it is possible to find a query $q^t \in Q$ such that D^t is inaccurate (or conclude that none exists) using much less data than would be required to simply answer all the queries in Q using additive perturbation. Perhaps even more surprisingly, it can be shown that if the updates are performed using the *multiplicative weights update rule*, then after $T = O(d/\alpha^2)$ iterations (independent of $|Q|$!), the database D^T will give an accurate answer to *every* $q \in Q$. This argument makes use of the guarantee that multiplicative weights update rule is a "no-regret learning algorithm" (cf. the survey of Arora, Hazan, and Kale [1] for more information about the multiplicative weights update rule). This fast convergence makes it possible to argue that the algorithm can give accurate and differentially private answers with much less data than would be required by simple additive perturbation.

Computational Complexity and Optimality

When $|Q|$ is large, the private multiplicative weights algorithm requires many fewer records n than additive perturbation (when $|Q| \gg d/\alpha^2$). One might ask whether even fewer records suffices. Bun, Ullman, and Vadhan [4] gave a negative answer to this question, and showed that the private multiplicative weights algorithm uses essentially the fewer records possible.

Theorem 3 ([4]) *There is no (even computationally inefficient) differentially private algorithm $\mathcal{A}$ that takes an arbitrary set of queries $Q = \{q_1, \ldots, q_k\}$ with $k \gg d/\alpha^2$ and a database $D \in (\{0,1\}^d)^n$ with $n \leq \tilde{\Omega}(\sqrt{d} \log |Q|/\alpha^2)$ as input and is α-accurate for the set of queries Q.*

A drawback of the private multiplicative weights algorithm (and all known algorithms with similar properties), when compared to additive perturbation, is computational complexity. Even when answering a polynomial number of efficiently computable queries, the running time of private multiplicative weights is dominated by the factor of 2^d, which is exponential in the number of attributes in the database. Ullman [13] showed that this is inherent, and (under a widely believed cryptographic assumption) improving on additive perturbation requires exponential running time.

Theorem 4 ([13]) *Assuming the existence of one-way functions, there is no differentially private algorithm $\mathcal{A}$ that takes an arbitrary set of queries $Q = \{q_1, \ldots, q_k\}$ database $D \in (\{0,1\}^d)^n$ with $n \leq \tilde{\Omega}(|Q|^{1/2})$ as input, runs in time* $\mathrm{poly}(n, d, |q_1| + |q_k|)$*, and is* $1/3$*-accurate for the set of queries Q.*

Together, these negative results show the private multiplicative weights algorithm is nearly optimal for answering large sets of arbitrary statistical queries under differential privacy.

Faster Algorithms for Marginal Queries via Efficient Learning

Given the hardness of answering arbitrary queries, there has been a significant effort to design faster differentially private algorithms that improve on additive noise for natural restricted set of queries. One such set of queries is *k-way marginals*. These queries are specified by a subset of attributes $S \subseteq [d]$ of size at most k and a pattern $t \in \{0,1\}^{|S|}$ and asks for the fraction of records in D that have each attribute $j \in S$ set to t_j. Note that there are $\mathrm{poly}(d^k)$ such queries, and thus, additive perturbation would require running time $\mathrm{poly}(d^k)$ and $n \geq \mathrm{poly}(d^k)$. On the other hand, private multiplicative weights would require running time $\mathrm{poly}(2^d)$, but $n \geq \tilde{O}(k\sqrt{d})$ would suffice.

Most of the more effective algorithms for answering k-way marginal queries are based on the following technique, introduced by Gupta et al. [9]: View the database D as specifying a function $f_D(q) = q(D)$ that maps a query to its answer on D, and then attempt to "learn" a differentially private approximation $g_D \approx f_D$. Intuitively, the value of this approach is that learning algorithms see the evaluation of f_D on a small

number of queries and then are able to predict the value of f_D on new queries. Since the learning algorithm only needs a small number of examples, it is easier to ensure differential privacy. If the queries q are "simple," then good learning algorithms may exist for the function f_D. In the case of k-way marginal queries, it turns out that f is in fact (an average of) *conjunctions*, and there are learning algorithms for this class of functions that satisfy various interesting parameter trade-offs. This technique underlies the following two results:

Theorem 5 ([12], building on [11]) *For every $k \in \mathbb{N}$, there is a differentially private algorithm $\mathcal{A}$ that takes a database $D \in (\{0,1\}^d)^n$ as input and runs in time $\mathrm{poly}(n, d^{\sqrt{k}})$, and if $n \geq \mathrm{poly}(d^{\sqrt{k}})$, $\mathcal{A}$ outputs a summary of the database that yields $1/100$-accurate answers to every k-way marginal query. That is, for every k-way marginal query q, one can obtain a $1/100$-accurate answer to q in time $\mathrm{poly}(n, d^{\sqrt{k}})$.*

Theorem 6 ([5]) *For every $k \in \mathbb{N}$, there is a differentially private algorithm $\mathcal{A}$ that takes a database $D \in (\{0,1\}^d)^n$ as input and runs in time $\mathrm{poly}(n, 2^{d^{1-1/100\sqrt{k}}})$, and if $n \geq kd^{.51}$, $\mathcal{A}$ outputs $1/100$-accurate answers to every k-way marginal query.*

We remark that there are many other algorithms for answering k-way marginal queries based on this learning approach, each achieving different parameter trade-offs and guarantees of accuracy. At the time of writing, improving these algorithms and extending these techniques to richer classes of queries remains an active area of research.

Problem Definition

Quorum systems are tools for increasing the availability and efficiency of replicated services. A *quorum system* for a universe of servers is a collection of subsets of servers, each pair of which intersect. Intuitively, each quorum can operate on behalf of the system, thus increasing its availability and performance, while the intersection property guarantees that operations done on distinct quorums preserve consistency.

The motivation for quorum systems stems from the need to make critical missions performed by machines that are reliable. The only way to increase the reliability of a service, aside from using intrinsically more robust hardware, is via replication. To make a service robust, it can be installed on multiple identical servers, each one of which holds a copy of the service state and performs read/write operations on it. This allows the system to provide information and perform operations even if some machines fail or communication links go down. Unfortunately, replication incurs a cost in the need to maintain the servers consistent. To enhance the availability and performance of a replicated service, Gifford and Thomas introduced in 1979 [3, 14] the usage of *votes* assigned to each server, such that a majority of the sum of votes is sufficient to perform operations. More generally, quorum systems are defined formally as follows:

Quorum system: Assume a *universe* U of servers, $|U| = n$, and an arbitrary number of clients. A *quorum system* $\mathcal{Q} \subseteq 2^U$ is a set of subsets of U, every pair of which intersect. Each $Q \in \mathcal{Q}$ is called a *quorum*.

Access Protocol

To demonstrate the usability of quorum systems in constructing replicated services, quorums are used here to implement a multi-writer multi-reader atomic shared variable. Quorums have also been used in various *mutual exclusion* protocols, to achieve Consensus, and in commit protocols.

In the application, clients perform read and write operations on a variable x that is replicated at each server in the universe U. A copy of the variable x is stored at each server, along with a timestamp value t. Timestamps are assigned by a client to each replica of the variable when the client writes the replica. Different clients choose distinct timestamps, e.g., by choosing integers appended with the name of c in the low-order bits. The read and write operations are implemented as follows.

Write: For a client c to write the value v, it queries each server in some quorum Q to obtain a set of value/timestamp pairs $A = \{\langle v_u, t_u\rangle\}_{u\in Q}$; chooses a timestamp $t \in T_c$ greater than the highest timestamp value in A; and updates x and the associated timestamp at each server in Q to v and t, respectively.

Read: For a client to read x, it queries each server in some quorum Q to obtain a set of value/timestamp pairs $A = \{\langle v_u, t_u\rangle\}_{u\in Q}$. The client then chooses the pair $\langle v, t\rangle$ with the highest timestamp in A to obtain the result of the read operation. It writes back $\langle v, t\rangle$ to each server in some quorum Q'.

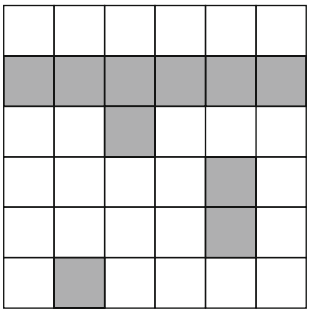
In both read and write operations, each server updates its local variable and timestamp to the received values $\langle v, t\rangle$ only if t is greater than the timestamp currently associated with the variable. The above protocol correctly implements the semantics of a multi-writer multi-reader atomic variable (see ▸ Linearizability).

Key Results

Perhaps the two most obvious quorum systems are the singleton, and the set of majorities, or more generally, weighted majorities suggested by Gifford [3].

Singleton: The set system $\mathcal{Q} = \{\{u\}\}$ for some $u \in U$ is the singleton quorum system.

Weighted Majorities: Assume that every server s in the universe U is assigned a number of votes w_s. Then, the set system $\mathcal{Q} = \{Q \subseteq U : \sum_{q\in Q} w_q > (\sum_{q\in U} w_q)/2\}$ is a quorum system called Weighted Majorities. When all the weights are the same, simply call this the system of Majorities.



Quorums, Fig. 1 The Grid quorum system of 6×6, with one quorum shaded

An example of a quorum system that cannot be defined by voting is the following Grid construction:

Grid: Suppose that the universe of servers is of size $n = k^2$ for some integer k. Arrange the universe into a $\sqrt{n} \times \sqrt{n}$ grid, as shown in Fig. 1. A quorum is the union of a full row and one element from each row below the full row. This yields the Grid quorum system, whose quorums are of size $O(\sqrt{n})$.

Maekawa suggests in [6] a quorum system that has several desirable symmetry properties, and in particular, that every pair of quorums intersect in exactly one element:

FPP: Suppose that the universe of servers is of size $n = q^2 + q + 1$, where $q = p^r$ for a prime p. It is known that a finite projective plane exists for n, with $q + 1$ pairwise intersecting subsets, each subset of size $q + 1$, and where each element is contained in $q + 1$ subsets. Then the set of finite projective plane subsets forms a quorum system.

Voting and Related Notions

Since generally it would be senseless to access a large quorum if a subset of it is a quorum, a good definition may avoid such anomalies. Garcia-Molina and Barbara [2] call such well-formed systems *coteries*, defined as follows:

Coterie: A *coterie* $\mathcal{Q} \subseteq 2^U$ is a quorum system such that for any $Q, Q' \in \mathcal{Q} : Q \not\subseteq Q'$.

Of special interest are quorum systems that cannot be reduced in size (i.e., that no quorum in the system can be reduced in size). Garcia-Molina and Barbara [2] use the term "dominates" to mean that one quorum system is always superior to another, as follows:

Domination: Suppose that $\mathcal{Q}, \mathcal{Q}'$ are two coteries, $\mathcal{Q} \neq \mathcal{Q}'$, such that for every $Q' \in \mathcal{Q}'$, there exists a $Q \in \mathcal{Q}$ such that $Q \subseteq Q'$. Then $\mathcal{Q}$ *dominates* $\mathcal{Q}'$.$\mathcal{Q}'$ is *dominated* if there exists a coterie $\mathcal{Q}$ that dominates it, and is *non-dominated* if no such coterie exists.

Voting was mentioned above as an intuitive way of thinking about quorum techniques. As it turns out, vote assignments and quorums are not equivalent. Garcia-Molina and Barbara [2] show that quorum systems are strictly more general than voting, i.e., each vote assignment has some corresponding quorum system but not the other way around. In fact, for a system with n servers, there is a double-exponential ($2^{2^{cn}}$) number of non-dominated coteries, and only $O(2^{n^2})$ different vote assignments, though for $n \leq 5$, voting and non-dominated coteries are identical.

Measures

Several measures of quality have been identified to address the question of which quorum system works best for a given set of servers; among these, *load* and *availability* are elaborated on here.

Load

A measure of the inherent performance of a quorum system is its *load*. Naor and Wool define in [10] the load of a quorum system as the probability of accessing the busiest server in the *best* case. More precisely, given a quorum system $\mathcal{Q}$, an *access strategy* w is a probability distribution on the elements of $\mathcal{Q}$; i.e., $\sum_{Q \in \mathcal{Q}} w(Q) = 1$. $w(Q)$ is the probability that quorum Q will be chosen when the service is accessed. Load is then defined as follows:

Load: Let a strategy w be given for a quorum system $\mathcal{Q} = \{Q_1, \ldots, Q_m\}$ over a universe U. For an element $u \in U$, the load induced by w on u is $l_w(u) = \sum_{Q_i \ni u} w(Q_i)$. The load induced by a strategy w on a quorum system $\mathcal{Q}$ is

$$L_w(\mathcal{Q}) = \max_{u \in U} \{l_w(u)\}.$$

The *system load* (or just *load*) on a quorum system $\mathcal{Q}$ is

$$L(\mathcal{Q}) = \min_{w}\{L_w(\mathcal{Q})\},$$

where the minimum is taken over all strategies.

The load is a best-case definition, and will be achieved only if an optimal access strategy is used, and only in the case that no failures occur. A strength of this definition is that load is a property of a quorum system, and not of the protocol using it.

The following theorem was proved in [10] for all quorum systems.

Theorem 1 *Let $\mathcal{Q}$ be a quorum system over a universe of n elements. Denote by $c(\mathcal{Q})$ the size of the smallest quorum of $\mathcal{Q}$. Then $L(\mathcal{Q}) \geq \max\{\frac{1}{c(\mathcal{Q})}, \frac{c(\mathcal{Q})}{n}\}$. Consequently, $L(\mathcal{Q}) \geq \frac{1}{\sqrt{n}}$.*

Availability

The resilience f of a quorum system provides one measure of how many crash failures a quorum system is *guaranteed* to survive.

Resilience: The *resilience* f of a quorum system $\mathcal{Q}$ is the largest k such that for every set $K \subseteq U$, $|K| = k$, there exists $Q \in \mathcal{Q}$ such that $K \cap Q = \emptyset$.

Note that, the resilience f is at most $c(\mathcal{Q}) - 1$, since by disabling the members of the smallest quorum every quorum is hit. It is possible, however, that an f-resilient quorum system, though vulnerable to a few failure configurations of $f + 1$ failures, can survive many configurations of more than f failures. One way to measure this property of a quorum system is to assume that each server crashes independently with probability p and then to determine the probability F_p that no quorum remains completely alive. This is known as *failure probability* and is formally defined as follows:

Failure probability: Assume that each server in the system crashes independently with probability p. For every quorum $Q \in \mathcal{Q}$ let $\mathcal{E}_Q$ be the event that Q is *hit*, i.e., at least one element $i \in Q$ has crashed. Let crash $(\mathcal{Q})$ be the event that all the quorums $Q \in \mathcal{Q}$ were hit, i.e., crash $(\mathcal{Q}) = \bigwedge_{Q \in \mathcal{Q}} \mathcal{E}_Q$. Then the system failure probability is $F_p(\mathcal{Q}) = \Pr(\text{crash } (\mathcal{Q}))$.

Peleg and Wool study the availability of quorum systems in [11]. A good failure probability $F_p(\mathcal{Q})$ for a quorum system $\mathcal{Q}$ has $\lim_{n\to\infty} F_p(\mathcal{Q}) = 0$ when $p < \frac{1}{2}$. Note that, the failure probability of any quorum system whose resilience is f is at least $e^{-\Omega(f)}$. Majorities has the best availability when $p < \frac{1}{2}$; for $p = \frac{1}{2}$, there exist quorum constructions with $F_p(\mathcal{Q}) = \frac{1}{2}$; for $p > \frac{1}{2}$, the singleton has the best failure probability $F_p(\mathcal{Q}) = p$, but for most quorum systems, $F_p(\mathcal{Q})$ tends to 1.

The Load and Availability of Quorum Systems

Quorum constructions can be compared by analyzing their behavior according to the above measures. The singleton has a load of 1, resilience 0, and failure probability $F_p = p$. This system has the best failure probability when $p > \frac{1}{2}$, but otherwise performs poorly in both availability and load.

The system of Majorities has a load of $\lceil \frac{n+1}{2n} \rceil \approx \frac{1}{2}$. It is resilient to $\lfloor \frac{n-1}{2} \rfloor$ failures, and its failure probability is $e^{-\Omega(n)}$. This system has the highest possible resilience and asymptotically optimal failure probability, but poor load.

Grid's load is $O(\frac{1}{\sqrt{n}})$, which is within a constant factor from optimal. However, its resilience is only $\sqrt{n} - 1$ and it has poor failure probability which tends to 1 as n grows.

The resilience of a FPP quorum system is $q \approx \sqrt{n}$. The load of FPP was analyzed in [10] and shown to be $L(\text{FPP}) = \frac{q+1}{n} \approx 1/\sqrt{n}$, which is optimal. However, its failure probability tends to 1 as n grows.

As demonstrated by these systems, there is a tradeoff between load and fault tolerance in quorum systems, where the resilience f of a quorum system $\mathcal{Q}$ satisfies $f \leq nL(\mathcal{Q})$. Thus, improving one must come at the expense of the other, and it is in fact impossible to simultaneously achieve both optimally. One might conclude that good load conflicts with low failure probability, which is not necessarily the case. In fact, there exist quorum systems such as the

Paths system of Naor and Wool [10] and the Triangle Lattice of Bazzi [1] that achieve asymptotically optimal load of $O(1/\sqrt{n})$ and have close to optimal failure probability for their quorum sizes. Another construction is the CWlog system of Peleg and Wool [12], which has unusually small quorum sizes of $\log n - \log\log n$, and for systems with quorums of this size, has optimal load, $L(\text{CWlog}) = O(1/\log n)$, and optimal failure probability.

Byzantine Quorum Systems

For the most part, quorum systems were studied in environments where failures may simply cause servers to become unavailable (benign failures). But what if a server may exhibit arbitrary, possibly malicious behavior? Malkhi and Reiter [7] carried out a study of quorum systems in environments prone to arbitrary (Byzantine) behavior of servers. Intuitively, a quorum system tolerant of Byzantine failures is a collection of subsets of servers, each pair of which intersect in a set containing sufficiently many *correct* servers to mask out the behavior of faulty servers. More precisely, Byzantine quorum systems are defined as follows:

Masking quorum system

A quorum system $\mathcal{Q}$ is a *b-masking quorum system* if it has resilience $f \geq b$, and each pair of quorums intersect in at least $2b + 1$ elements.

The masking quorum system requirements enable a client to obtain the correct answer from the service despite up to b Byzantine server failures. More precisely, a write operation remains as before; to obtain the correct value of x from a read operation, the client reads a set of value/timestamp pairs from a quorum Q and sorts them into clusters of identical pairs. It then chooses a value/timestamp pair that is returned from at least $b + 1$ servers, and therefore must contain at least one correct server. The properties of masking quorum systems guarantee that at least one such cluster exists. If more than one such cluster exists, the client chooses the one with the highest timestamp. It is easy to see that any value so obtained was written before, and moreover, that the most recently written value is obtained. Thus, the semantics of a multi-writer multi-reader safe variable are obtained (see ▸ Linearizability) in a Byzantine environment.

For a b-masking quorum system, the following lower bound on the load holds:

Theorem 2 *Let $\mathcal{Q}$ be a b-masking quorum system. Then $L(\mathcal{Q}) \geq \max\{\frac{2b+1}{c(\mathcal{Q})}, \frac{c(\mathcal{Q})}{n}\}$, and consequently $L(\mathcal{Q}) \geq \sqrt{\frac{2b+1}{n}}$.*

This bound is tight, and masking quorum constructions meeting it were shown.

Malkhi and Reiter explore in [7] two variations of masking quorum systems. The first, called *dissemination quorum systems*, is suited for services that receive and distribute *self-verifying* information from correct clients (e.g., digitally signed values) that faulty servers can fail to redistribute but cannot undetectably alter. The second variation, called *opaque masking quorum systems*, is similar to regular masking quorums in that it makes no assumption of self-verifying data, but it differs in that clients do not need to know the failure scenarios for which the service was designed. This somewhat simplifies the client protocol and, in the case that the failures are maliciously induced, reveals less information to clients that could guide an attack attempting to compromise the system. It is also shown in [7] how to deal with faulty clients in addition to faulty servers.

Probabilistic Quorum Systems

The resilience of any quorum system is bounded by half of the number of servers. Moreover, as mentioned above, there is an inherent tradeoff between low load and good resilience, so that it is in fact impossible to simultaneously achieve both optimally. In particular, quorum systems over n servers that achieve the optimal load of $\frac{1}{\sqrt{n}}$ can tolerate at most $\sqrt{n}$ faults.

To break these limitations, Malkhi et al. propose in [8] to relax the intersection property of a quorum system so that "quorums" chosen according to a specified strategy intersect only with very high probability. They accordingly name

these *probabilistic quorum systems*. These systems admit the possibility, albeit small, that two operations will be performed at non-intersecting quorums, in which case consistency of the system may suffer. However, even a small relaxation of consistency can yield dramatic improvements in the resilience and failure probability of the system, while the load remains essentially unchanged. Probabilistic quorum systems are thus most suitable for use when availability of operations despite the presence of faults is more important than certain consistency. This might be the case if the cost of inconsistent operations is high but not irrecoverable, or if obtaining the most up-to-date information is desirable but not critical, while having no information may have heavier penalties.

The family of constructions suggested in [8] is as follows:

W(n, ℓ) Let U be a universe of size n. $W(n, \ell)$, $\ell \geq 1$, is the system $\langle \mathcal{Q}, w \rangle$ where $\mathcal{Q}$ is the set system $\mathcal{Q} = \{Q \subseteq U : |Q| = \ell\sqrt{n}\}$; w is an access strategy w defined by $\forall Q \in \mathcal{Q}$, $w(Q) = \frac{1}{|\mathcal{Q}|}$.

The probability of choosing according to w two quorums that do not intersect is less than $e^{-\ell^2}$, and can be made sufficiently small by appropriate choice of ℓ. Since every element is in $\binom{n-1}{\ell\sqrt{n}-1}$ quorums, the load $L(W(n, \ell))$ is $\frac{\ell}{\sqrt{n}} = O(\frac{1}{\sqrt{n}})$. Because only $\ell\sqrt{n}$ servers need be available in order for some quorum to be available, $W(n, \ell)$ is resilient to $n - \ell\sqrt{n}$ crashes. The failure probability of $W(n, \ell)$ is less than $e^{-\Omega(n)}$ for all $p \leq 1 - \frac{\ell}{\sqrt{n}}$, which is asymptotically optimal. Moreover, if $\frac{1}{2} \leq p \leq 1 - \frac{\ell}{\sqrt{n}}$, this probability is provably better than any (non-probabilistic) quorum system.

Relaxing consistency can also provide dramatic improvements in environments that may experience Byzantine failures. More details can be found in [8].

Applications

Just about any fault tolerant distributed protocol, such as Paxos [5] or consensus [1] implicitly builds on quorums, typically majorities. More concretely, scalable data repositories were built, such as Fleet [9], Rambo [4], and Rosebud [13].

Problem Definition

Consider a graph $G(V, E)$. For any two vertices $u, v \in V$, $d(u, v)$ denotes the distance of u, v in G. The general problem concerns a coloring of the graph G and it is defined as follows:

Definition 1 (k-coloring problem)
INPUT: A graph $G(V, E)$.
OUTPUT: A function $\phi : V \to \{1, \ldots, \infty\}$, called k *-coloring of* G such that $\forall u, v \in V$, $x \in \{0, 1, \ldots, k\}$: if $d(u, v) \geq k - x + 1$ then $|\phi(u) - \phi(v)| = x$.

OBJECTIVE: Let $|\phi(V)| = \lambda_\phi$. Then λ_ϕ is the *number of colors* that φ actually uses (it is usually called *order* of G under φ). The number $v_\phi = max_{v \in V}\phi(v) - min_{u \in V}\phi(u) + 1$ is usually called the *span* of G under φ. The function φ satisfies one of the following objectives:

- minimum span: λ_ϕ is the minimum possible over all possible functions φ of G;
- minimum order: v_ϕ is the minimum possible over all possible functions φ of G;
- Min span order: obtains a minimum span and moreover, from all minimum span assignments, φ obtains a minimum order.
- Min order span: obtains a minimum order and moreover, from all minimum order assignments, φ obtains a minimum span.

Note that the case $k = 1$ corresponds to the well known problem of *vertex graph coloring*. Thus, k-coloring problem (with k as an input) is $\mathcal{NP}$-complete [4]. The case of k-coloring problem where $k = 2$, is called the *Radiocoloring problem*.

Definition 2 (Radiocoloring Problem (RCP) [7])
INPUT: A graph $G(V, E)$.
OUTPUT: A function $\Phi : V \to N^*$ such that $|\Phi(u) - \Phi(v)| \geq 2$ if $d(u, v) = 1$ and $|\Phi(u) - \Phi(v)| \geq 1$ if $d(u, v) = 2$.
OBJECTIVE: The least possible number (order) needed to radiocolor G is denoted

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

by $X_{\text{order}}(G)$. The least possible number $\max_{v \in V} \Phi(v) - \min_{u \in V} \Phi(u) + 1$ (span) needed for the radiocoloring of G is denoted as $X_{\text{span}}(G)$. Function Φ satisfies one of the followings:

- Min span RCP: Φ obtains a minimum span, i.e., $\lambda_\Phi = X_{span}(G)$;
- Min order RCP: Φ obtains a minimum order $\nu_\Phi = X_{\text{order}}(G)$;
- Min span order RCP: obtains a minimum span and moreover, from all minimum span assignments, Φ obtains a minimum order.
- Min order span RCP: obtains a minimum order and moreover, from all minimum order assignments, Φ obtains a minimum span.

A related to the RCP problem concerns to the square of a graph G, which is defined as follows:

Definition 3 Given a graph $G(V, E)$, G^2 is the graph having the same vertex set V and an edge set $E' : \{u, v\} \in E'$ iff $d(u, v) \leq 2$ in G.

The related problem is to color the square of a graph G, G^2 so that no two neighbor vertices (in G^2) get the same color. The objective is to use a minimum number of colors, denoted as $\chi(G^2)$ and called *chromatic number of the square of the graph G*. Fotakis et al. [5, 6] first observed that for any graph G, $X_{\text{order}}(G)$ is the same as the (vertex) chromatic number of G^2, i.e., $X_{\text{order}}(G) = \chi(G^2)$.

Key Results

Fotakis et al. [5, 6] studied *min span order*, *min order* and *min span* RCP in *planar* graph G. A planar graph, is a graph for which its edges can be embedded in the plane without crossings. The following results are obtained:

- It is first shown that the number of colors used in the *min span order RCP* of graph G is different from the chromatic number of the square of the graph, $\chi(G^2)$. In particular, it may be greater than $\chi(G^2)$.
- It is then proved that the radiocoloring problem for general graphs is hard to approximate (unless $\mathcal{NP} = ZPP$, the class of problems with polynomial time zero-error randomized algorithms) within a factor of $n^{1/2-\epsilon}$ (for any $\epsilon > 0$), where n is the number of vertices of the graph. However, when restricted to some special cases of graphs, the problem becomes easier.

  It is shown that the *min span RCP*and *min span order RCP* are $\mathcal{NP}$ *-complete* for planar graphs. Note that few combinatorial problems remain hard for *planar* graphs and their proofs of hardness are not easy since they have to use planar gadgets which are difficult to find and understand.
- It presents a $O(n\Delta(G))$ time algorithm that *approximates* the min order of RCP, X_{order}, of a planar graph G *by a constant ratio which tends to 2* as the maximum degree $\Delta(G)$ of G increases.

  The algorithm presented is motivated by a constructive coloring theorem of Heuvel and McGuiness [9]. The construction of [9] can lead (as shown) to an $O(n^2)$ technique assuming that a planar embedding of G is given. Fotakis et al. [5, 6] improves the time complexity of the approximation, and presents a much more simple algorithm to verify and implement. The algorithm does not need any planar embedding as input.
- Finally, the work considers the problem of *estimating the number of different radiocolorings* of a planar graph G. This is a $\#\mathcal{P}$-complete problem (as can be easily seen from the completeness reduction presented there that can be done parsimonious). They authors employ here standard techniques of rapidly mixing Markov Chains and the *new method of coupling* for purposes of proving *rapid convergence* (see e.g., [10]) and present *a fully polynomial randomized approximation scheme* for estimating the number of radiocolorings with λ colors for a planar graph G, when $\lambda \geq 4\Delta(G) + 50$.

In [8] and [7] it has been proved that the problem of min span RCP is $\mathcal{NP}$-complete, even

for graphs of diameter 2. The reductions use highly non-planar graphs. In [11] it is proved that the problem of coloring the square of a general graph is $\mathcal{NP}$-complete.

Another variation of RCP for planar graphs, called *distance-2-coloring* is studied in [12]. This is the problem of coloring a given graph G with the minimum number of colors so that the vertices of distance *at most* two get different colors. Note that this problem is equivalent to coloring the square of the graph G, G^2. In [12] it is proved that the distance-2-coloring problem for planar graphs is $\mathcal{NP}$-complete. As it is shown in [5, 6], this problem is different from the min span order RCP. Thus, the $\mathcal{NP}$-completeness proof in [12] certainly does not imply the $\mathcal{NP}$-completeness of min span order RCP proved in [5, 6]. In [12] a 9-approximation algorithm for the distance-2-coloring of planar graphs is also provided.

Independently and in parallel, Agnarsson and Halldórsson in [1] presented approximations for the chromatic number of square and power graphs (G^k). In particular they presented an 1.8-approximation algorithm for coloring the square of a planar graph of large degree ($\Delta(G) \geq 749$). Their method utilizes the notion of *inductiveness* of the square of a planar graph.

Bodlaender et al. in [2] proved also independently and and in parallel that the min span RCP, called λ-labeling there, is $\mathcal{NP}$-complete for planar graphs, using a similar to the approach used in [5, 6]. In the same work the authors presented approximations for the problem for some interesting families of graphs: outerplanar graphs, graphs of bounded treewidth, permutation and split graphs.

Applications

The Frequency Assignment Problem (FAP) in radio networks is a well-studied, interesting problem, aiming at assigning frequencies to transmitters exploiting frequency reuse while keeping signal interference to acceptable levels. The interference between transmitters are modeled by an interference graph $G(V, E)$, where V ($|V| = n$) corresponds to the set of transmitters and E represents distance constraints (e.g., if two neighbor nodes in G get the same or close frequencies then this causes unacceptable levels of interference). In most real life cases the network topology formed has some special properties, e.g., G is a lattice network or a planar graph. Planar graphs are mainly the object of study in [5, 6].

The FAP is usually modeled by variations of the graph coloring problem. The set of colors represents the available frequencies. In addition, each color in a particular assignment gets an integer value which has to satisfy certain inequalities compared to the values of colors of nearby nodes in G (frequency-distance constraints). A discrete version of FAP is the k-coloring problem, of which a particular instance, for $k = 2$, is investigated in [5, 6].

Real networks reserve bandwidth (range of frequencies) rather than distinct frequencies. In this case, an assignment seeks to use as small range of frequencies as possible. It is sometimes desirable to use as few distinct frequencies of a given bandwidth (span) as possible, since the unused frequencies are available for other use. However, there are cases where the primary objective is to minimize the number of frequencies used and the span is a secondary objective, since we wish to avoid reserving unnecessary large span. These realistic scenaria directed researchers to consider optimization versions of the RCP, where one aims in minimizing the span (bandwidth) or the order (distinct frequencies used) of the assignment. Such optimization problems are investigated in [5, 6].

2003; Flaxman

Problem Definition

This classic problem in complexity theory is concerned with efficiently finding a satisfying assignment to a propositional formula. The input is a formula with n Boolean variables which is expressed as an AND of ORs with 3 variables in each OR clause (a *3-CNF formula*). The goal is to (1) find an assignment of variables to TRUE and FALSE so that the formula has value TRUE or (2) prove that no such assignment exists. Historically, recognizing satisfiable 3-CNF formulas was the first "natural" example of an NP-complete problem, and, because it is NP-complete, no polynomial-time algorithm can succeed on all 3-CNF formulas unless P = NP [4, 10]. Because of the numerous practical applications of 3-SAT, and also due to its position as the canonical NP-complete problem, many heuristic algorithms have been developed for solving3-SAT, and some of these algorithms have been analyzed rigorously on random instances.

Notation

A 3-CNF formula over variables $x_1, x_2, \ldots, x_n$ is the conjunction of m clauses $C_1 \wedge C_2 \wedge \ldots \wedge C_m$, where each clause is the disjunction of 3 literals, $C_i = \ell_{i_1} \vee \ell_{i_2} \vee \ell_{i_3}$, and each literal ℓ_{i_j} is either a variable or the negation of a variable (the negation of the variable x is denoted by $\bar{x}$). A 3-CNF formula is *satisfiable* if and only if there is an assignment of variables to truth values so that every clause contains at least one true literal. Here, all asymptotic analysis is in terms of n, the number of variables in the 3-CNF formula, and a sequence of events $\{\mathcal{E}_n\}$ is said to hold *with high probability* (abbreviated **whp**) if $\lim_{n\to\infty} \Pr[\mathcal{E}_n] = 1$.

Distributions

There are many distributions over 3-CNF formulas which are interesting to consider, and this

chapter focuses on dense satisfiable instances. Dense satisfiable instances can be formed by conditioning on the event $\{I_{n,m}$ is satisfiable$\}$, but this conditional distribution is difficult to sample from and to analyze. This has led to research in "planted" random instances of 3-SAT, which are formed by first choosing a truth assignment φ uniformly at random and then selecting each clause independently from the triples of literals where at least one literal is set to TRUE by the assignment φ. The clauses can be included with equal probabilities in analogy to the $\mathbb{I}_{n,p}$ or $\mathbb{I}_{n,m}$ distributions above [8, 9], or different probabilities can be assigned to the clauses with one, two, or three literals set to TRUE by φ, in an effort to better hide the satisfying assignment [2, 7].

Problem 1 (3-SAT)

INPUT: *3-CNF Boolean formula* $F = C_1 \wedge C_2 \wedge \cdots \wedge C_m$*, where each clause* C_i *is of the form* $C_i = \ell_{i_1} \vee \ell_{i_2} \vee \ell_{i_3}$ *and each literal* ℓ_{i_j} *is either a variable or the negation of a variable.*

OUTPUT: *A truth assignment of variables to Boolean values which makes at least one literal in each clause TRUE or a certificate that no such assignment exists.*

Key Results

A line of basic research dedicated to identifying hard search and decision problems, as well as the potential cryptographic applications of planted instances of 3-SAT, has motivated the development of algorithms for 3-SAT which are known to work on planted random instances.

Majority Vote Heuristic: If every clause consistent with the planted assignment is included with the same probability, then there is a bias towards including the literal satisfied by the planted assignment more frequently than its negation. This is the motivation behind the majority vote heuristic, which assigns each variable to the truth value which will satisfy the majority of the clauses in which it appears. Despite its simplicity, this heuristic has been proven successful **whp** for sufficiently dense planted instances [8].

Theorem 1 *When* c *is a sufficiently large constant and* $I \sim \mathbb{I}^{\phi}_{n,cn\log n}$*,* ***whp*** *the majority vote heuristic finds the planted assignment* φ*.*

When the density of the planted random instance is lower than $c \log n$*, then the majority vote heuristic will fail, and if the relative probability of the clauses satisfied by one, two, and three literals is adjusted appropriately, then it will fail miserably. But there are alternative approaches.*

For planted instances where the density is a sufficiently large constant, the majority vote heuristic provides a good starting assignment, and then the k-OPT heuristic can finish the job. The k-OPT heuristic of [6] is defined as follows: Initialize the assignment by majority vote. Initialize k to 1. While there exists a set of k variables for which flipping the values of the assignment will (1) make false clauses true and (2) will not make true clauses false, flip the values of the assignment on these variables. If this reaches a local optimum that is not a satisfying assignment, increase k and continue.

Theorem 2 *When* c *is a sufficiently large constant and* $I \sim I^{\phi}_{n,cn}$*, the k-OPT heuristic finds a satisfying assignment in polynomial time* ***whp****. The same is true even in the semi-random case, where an adversary is allowed to add clauses to* I *that have all three literals set to TRUE by* φ *before giving the instance to the k-OPT heuristic.*

A related algorithm has been shown to run in expected polynomial time in [9], and a rigorous analysis of *warning propagation (WP)*, a message passing algorithm related to survey propagation, has shown that WP is successful **whp** on planted satisfying assignments, provided that the clause density exceeds a sufficiently large constant [5].

When the relative probabilities of clauses containing one, two, and three literals are adjusted carefully, it is possible to make the majority vote assignment very different from the planted assignment. A way of setting these relative probabilities that is predicted to be difficult is discussed in [2]. If the density of these instances is high

enough (and the relative probabilities are anything besides the case of "Gaussian elimination with noise"), then a spectral heuristic provides a starting assignment close to the planted assignment and local reassignment operations are sufficient to recover a satisfying assignment [7].

More formally, consider instance $I = I_{n,p1,p2,p3}$, formed by choosing a truth assignment φ on n variables uniformly at random and including in I each clause with exactly i literals satisfied by φ independently with probability p_i. By setting $p_1 = p_2 = p_3$, this reduces to the distribution mentioned above.

Setting $p_1 = p_2$ and $p_3 = 0$ yields a natural distribution on 3CNFs with a planted not-all-equal assignment, a situation where the greedy variable assignment rule generates a random assignment. Setting $p_2 = p_3 = 0$ gives 3CNFs with a planted exactly-one-true assignment (which succumb to the greedy algorithm followed by the nonspectral steps below). Also, correctly adjusting the ratios of p_1, p_2, and p_3 can obtain a variety of (slightly less natural) instance distributions which thwart the greedy algorithm. Carefully selected values of p_1, p_2, and p_3 are considered in [2], where it is conjectured that no algorithm running in polynomial time can solve $I_{n,p1,p2,p3}$ **whp** when $p_i = c_i\alpha/n^2$ and

$$0.007 < c_3 < 0.25 \qquad c_2 = (1-4c_3)/6$$
$$c_1 = (1+2c_3)/6 \quad \alpha > \frac{4.25}{7}.$$

The *spectral heuristic* modeled after the coloring algorithms of [1, 3] was developed for such planted distributions in [7]. This polynomial time algorithm which returns a satisfying assignment to $I_{n,p1,p2,p3}$ **whp** when $p_1 = d/n^2$, $p_2 = \eta_2 d/n^2$, and $p_3 = \eta_3 d/n^2$, for $0 \le \eta_2, \eta_3 \le 1$, and $d \ge d_{\min}$, where $d_{\min}$ is a function of η_2, η_3. The algorithm is structured as follows:

1. Construct a graph G from the 3CNF.
2. Find the most negative eigenvalue of a matrix related to the adjacency matrix of G.
3. Assign a value to each variable based on the signs of the eigenvector corresponding to the most negative eigenvalue.
4. Iteratively improve the assignment.
5. Perfect the assignment by exhaustive search over a small set containing all the incorrect variables.

A more elaborate description of each step is the following:

Step (1): Given 3CNF $I = I_{n,p1,p2,p3}$, where $p_1 = d/n^2$, $p_2 = \eta_2 d/n^2$, and $p_3 = \eta_3 d/n^2$, the graph in step (1), $G = (V, E)$, has $2n$ vertices, corresponding to the literals in I, and labeled $\{x_1, \bar{x}_1, \ldots x_n, \bar{x}_n\}$. G has an edge between vertices ℓ_i and ℓ_j if I includes a clause with both ℓ_i and ℓ_j (and G does not have multiple edges).

Step (2): Consider $G' = (V, E')$, formed by deleting all the edges incident to vertices with degree greater than $180d$. Let A be the adjacency matrix of G'. Let λ be the most negative eigenvalue of A and $\mathbf{v}$ be the corresponding eigenvector.

Step (3): There are two assignments to consider, π_+, which is defined by

$$\pi_+(x_i) = \begin{cases} T, \text{ if } \mathbf{v}_i \ge 0; \\ F, \text{ otherwise;} \end{cases}$$

and π_-, which is defined by

$$\pi_-(x) = \neg\pi_+(x).$$

Let π_0 be the better of π_+ and π_- (i.e., the assignment which satisfies more clauses). It can be shown that π_0 agrees with φ on at least $(1 - C/d)n$ variables for some absolute constant C.

Step (4): For $i = 1, \ldots, \log n$, do the following: for each variable x, if x appears in $5\varepsilon d$ clauses unsatisfied by π_{i-1}, then set $\pi_i(x) = \neg\pi_{i-1}(x)$, where ε is an appropriately chosen constant (taking $\varepsilon = 0.1$ works); otherwise set $\pi_i(x) = \pi_{i-1}(x)$.

Step (5): Let $\pi'_0 = \pi_{\log n}$ denote the final assignment generated in step (4). Let $\mathcal{A}_4^{\pi'_0}$ be

the set of variables which do not appear in $(3 \pm 4\varepsilon)d$ clauses as the only true literal with respect to assignment π'_0, and let $\mathcal{B}$ be the set of variables which do not appear in $(\mu_D \pm \varepsilon)d$ clauses, where $\mu_D d = (3+6)d + (6+3)\eta_2 d + 3\eta_3 d + \mathcal{O}(1/n)$ is the expected number of clauses containing variable x. Form partial assignment π'_1 by unassigning all variables in $\mathcal{A}_4^{\pi'_0}$ and $\mathcal{B}$. Now, for $i \geq 1$, if there is a variable x_i which appears in less than $(\mu_D - 2\varepsilon)d$ clauses consisting of variables that are all assigned by π'_i, then let π'_{i+1} be the partial assignment formed by unassigning x_i in π'_i. Let π' be the partial assignment when this process terminates. Consider the graph Γ with a vertex for each variable that is unassigned in π' and an edge between two variables if they appear in a clause together. If any connected component in Γ is larger than $\log n$, then fail. Otherwise, find a satisfying assignment for I by performing an exhaustive search on the variables in each connected component of Γ.

Theorem 3 *For any constants* $0 \leq \eta_2, \eta_3 \leq 1$, *except* $(\eta_2, \eta_3) = (0, 1)$, *there exists a constant* $d_{\min}$ *such that for any* $d \geq d_{\min}$, *if* $p_1 = d/n^2$, $p_2 = \eta_2 d/n^2$, *and* $p_3 = \eta_3 d/n^2$, *then this polynomial-time algorithm produces a satisfying assignment for random instances drawn from* $I_{n,p1,p2,p3}$ ***whp***.

Applications

3-SAT is a universal problem, and due to its simplicity, it has potential applications in many areas, including proof theory and program checking, planning, cryptanalysis, machine learning, and modeling biological networks.

Open Problems

An important direction is to develop alternative models of random distributions which more accurately reflect the type of instances that occur in the real world.

Data Sets

Sample instances of satisfiability and 3-SAT are available on the web at http://www.satlib.org/.

Problem Definition

This problem is concerned with using the multi-writer multi-reader register primitive in the shared memory model to design a fast, wait-free implementation of consensus. Below are detailed descriptions of each of these terms.

Consensus Problems

There are n processors and the goal is to design distributed algorithms to solve the following two consensus problems for these processors.

Problem 1 (Binary consensus)
INPUT: Processor i has input bit b_i.
OUTPUT: Each processor i has output bit b'_i such that: (1) all the output bits b'_i equal the same value v; and (2) $v = b_i$ for some processor i.

Problem 2 (Id consensus)
INPUT: Processor i has a unique id u_i.
OUTPUT: Each processor i has output value u'_i such that: (1) all the output values u'_i equal the same value u; and (2) $u = u_i$ for some processor i.

Wait-Free

This result builds on extensive previous work on the shared memory model of parallel computing. Shared object types include data structures such as read/write registers and synchronization primitives such as "test and set". A shared object is said to be *wait-free* if it ensures that every invocation on the object is guaranteed a response in finite time even if some or all of the other processors in the system crash. In this problem, the existence of wait-free registers is assumed and the goal is to create a fast wait-free algorithm to solve the consensus problem. In the rest of this summary, "wait-free implementations" will be referred to simply as "implementations" i.e., the term wait-free will be omitted.

Multi-writer Multi-reader Register

Many past results on solving consensus in the shared memory model assume the existence of a single writer multi-reader register. For such a register, there is a single writer client and multiple reader clients. Unfortunately, it is easy to show that the per processor step complexity of any implementation of consensus from single writer multi-reader registers will be at least linear in the number of processors. Thus, to achieve a time efficient implementation of consensus, the more powerful primitive of a multi-writer multi-reader register must be assumed. A multi-writer multi-reader register assumes the clients of the register are multiple writers and multiple readers. It is well known that it is possible to implement such a register in the shared memory model.

The Adversary

Solving the above problems is complicated by the fact that the programmer has little control over the rate at which individual processors execute. To model this fact, it is assumed that the schedule at which processors run is picked by an adversary.

It is well-known that there is no deterministic algorithm that can solve either Binary consensus or ID consensus in this adversarial model if the number of processors is greater than 1 [6, 7]. Thus, researchers have turned to the use of randomized algorithms to solve this problem [1]. These algorithms have access to random coin flips. Three types of adversaries are considered for randomized algorithms. The *strong adversary* is assumed to know the outcome of a coin flip immediately after the coin is flipped and to be able to modify its schedule accordingly. The *oblivious adversary* has to fix the schedule before any of the coins are flipped. The *intermediate adversary* is not permitted to see the outcome of a coin flip until some process makes a choice based on that coin flip. In particular, a process can flip a coin and write the result in a global register, but the intermediate adversary does not know the outcome of the coin flip until some process reads the value written in the register.

Key Results

Theorem 1 *Assuming the existence of multi-writer multi-reader registers, there exists a randomized algorithm to solve binary consensus against an intermediate adversary with O(1) expected steps per processor.*

Theorem 2 *Assuming the existence of multi-writer multi-reader registers, there exists a randomized algorithm to solve id-consensus against an intermediate adversary with* $O(\log^2 n)$ *expected steps per processor.*

Both of these results assume that every processor has a unique identifier. Prior to this result, the fastest known randomized algorithm for binary consensus made use of single writer multiple reader registers, was robust against a strong adversary, and required $O(n \log^2 n)$ steps per processor [2]. Thus, the above improvements are obtained at the cost of weakening the adversary and strengthening the system model when compared to [2].

Applications

Binary consensus is one of the most fundamental problems in distributed computing. An example of its importance is the following result shown by Herlihy [8]: If an abstract data type X together with shared memory is powerful enough to implement wait-free consensus, then X together with shared memory is powerful enough to implement in a wait-free manner any other data structure Y. Thus, using this result, a wait-free version of any data structure can be created using only wait-free multi-writer multi-reader registers as a building block.

Binary consensus has practical applications in many areas including: database management, multiprocessor computation, fault diagnosis, and mission-critical systems such as flight control. Lynch contains an extensive discussion of some of these application areas [9].

Open Problems

This result leaves open several problems. First, it leaves open a gap on the number of steps per process required to perform randomized consensus using multi-writer multi-reader registers against the *strong* adversary. A recent result by Attiya and Censor shows an $\Omega(n^2)$ lower bound on the total number of steps for all processors with multi-writer multi-reader registers (implying $\Omega(n)$ steps per process) [3]. They also show a matching upper bound of $O(n^2)$ on the total number of steps. However, closing the gap on the per-process number of steps is still open.

Another open problem is whether there is a randomized implementation of id consensus using multi-reader multi-writer registers that is robust to the intermediate adversary and whose expected number of steps per processor is better than $O(\log^2 n)$. In particular, is a constant run time possible? Aumann in follow up work to this result was able to improve the expected run time per process to $O(\log n)$ [4]. However, to the best of the reviewer's knowledge, there have been no further improvements.

A third open problem is to close the gap on the time required to solve binary consensus against the strong adversary with a single writer multiple reader register. The fastest known randomized algorithm in this scenario requires $O(n \log^2 n)$ steps per processor [2]. A trivial lower bound on the number of steps per processor when single-writer registers are used is $\Omega(n)$. However, to the best of this reviewers knowledge, a $O(\log^2 n)$ gap still remains open.

A final open problem is to close the gap on the total work required to solve consensus with single-reader single-writer registers against an oblivious adversary. Aumann and Kapah-Levy describe algorithms for this scenario that require $O(n \log n \exp(2\sqrt{\ln n \ln(c \log n \log^* n)})$ expected total work for some constant c [5]. In particular, the total work is less than $O(n^{1+\epsilon})$ for any $\epsilon > 0$. A trivial lower bound on total work is $\Omega(n)$, but a gap remains open.

Problem Definition

This entry investigates deterministic and randomized protocols for achieving broadcast (dis-

tributing a message from a source to all other nodes) in arbitrary multi-hop synchronous radio networks.

The model consists of an arbitrary (undirected) network, with processors communicating in synchronous time-slots subject to the following rules. In each time-slot, each processor acts either as a *transmitter* or as a *receiver*. A processor acting as a receiver is said to receive a message in time-slot t if exactly one of its neighbors transmits in that time-slot. The message received is the one transmitted. If more than one neighbor transmits in that time-slot, a *conflict* occurs. In this case, the receiver may either get a message from one of the transmitting neighbors or get no message. It is assumed that conflicts (or "collisions") are not detected, hence a processor cannot distinguish the case in which no neighbor transmits from the case in which two or more of its neighbors transmits during that time-slot. The processors are not required to have IDs nor do they know their neighbors; in particular, the processors do not know the topology of the network.

The only inputs required by the protocol are the number of processors in the network – n, Δ – an a priori known upper bound on the maximum degree in the network, and the error bound $-\epsilon$. (All bounds are a priori known to the algorithm.)

Broadcast is a task initiated by a single processor, called the *source*, transmitting a single *message*. The goal is to have the message reach all processors in the network.

Key Results

The main result is a randomized protocol that achieves broadcast in time which is optimal up to a logarithmic factor. In particular, with probability $1-\epsilon$, the protocol achieves broadcast within $O((D+\log n/\epsilon)\cdot\log n)$ time-slots.

On the other hand, a linear lower bound on the deterministic time-complexity of broadcast is proved. Namely, any deterministic broadcast protocol requires $\Omega(n)$ time-slots, even if the network has diameter 3, and n is known to all processors. These two results demonstrate an exponential gap in complexity between randomization and determinism.

Randomized Protocols

The Procedure *Decay*

The basic idea used in the protocol is to resolve potential conflicts by randomly eliminating half of the transmitters. This process of "cutting by half" is repeated each time-slot with the hope that there will exist a time-slot with a single active transmitter. The "cutting by half" process is easily implemented distributively by letting each processor decide randomly whether to eliminate itself. It will be shown that if all neighbors of a receiver follow the elimination procedure, then, with positive probability, there exists a time slot in which exactly one neighbor transmits.

What follows is a description of the procedure for sending a message m, that is executed by each processor after receiving m:

procedure *Decay*(k, m);
repeat at most k times (but at least once!)
send m to all neighbors;
set *coin*←0 or 1 with equal probability.
until *coin* = 0.

By using elementary probabilistic arguments, one can prove:

Theorem 1 *Let y be a vertex of G. Also let $d \geq 2$ neighbors of y execute Decay during the time interval [0,k) and assume that they all start the execution at Time = 0. Then $P(k,d)$, the probability that y receives a message by Time = k, satisfies:*

1. $\lim_{k\to\infty} P(k,d) \geq \frac{2}{3}$;
2. *For* $k \geq 2\lceil \log d \rceil$, $P(k,d) > \frac{1}{2}$.

(All logarithms are to base 2.)

The expected termination time of the algorithm depends on the probability that coin = 0. Here, this probability is set to be one half. An analysis of the merits of using other probabilities was carried out by Hofri [4].

The Broadcast Protocol

The broadcast protocol makes several calls to *Decay* (k, m). By Theorem 1 (2), to ensure that the probability of a processor y receiving the message be at least 1/2, the parameter k should be at least $2\log d$ (where d is the number of neighbors sending a message to y). Since d is not known, the parameter was chosen as $k = 2\lceil \log \Delta \rceil$ (recall that Δ was defined to be an upper bound on the in-degree). Theorem 1 also requires that all participants start executing *Decay* at the same time-slot. Therefore, *Decay* is initiated only at integer multiples of $2\lceil \log \Delta \rceil$.

procedure *Broadcast*;
$k = 2\lceil \log \Delta \rceil$;
$t = 2\lceil \log(N/\epsilon) \rceil$;
Wait until receiving a message, say m;
do t times {
Wait until $(Time \bmod k) = 0$;
Decay(k, m) ;
}

A network is said to execute the *Broadcast_scheme* if some processor, denoted s, transmits an initial message and each processor executes the abovementioned *Broadcast* procedure.

Theorem 2 *Let* $T = 2D + 5\max\{\sqrt{D}, \sqrt{\log(n/\epsilon)} \cdot \sqrt{\log(n/\epsilon)}$. *Assume that Broadcast_scheme starts at Time* $= 0$. *Then, with probability* $\geq 1 - 2\epsilon$, *by time* $2\lceil \log \Delta \rceil \cdot T$ *all nodes will receive the message. Furthermore, with probability* $\geq 1 - 2\epsilon$, *all the nodes will terminate by time* $2\lceil \log \Delta \rceil \cdot (T + \lceil \log(N/\epsilon) \rceil)$.

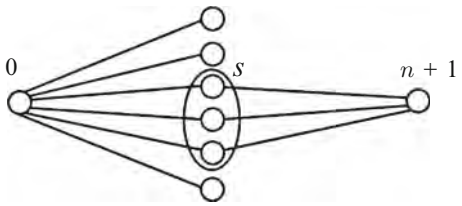
The bound provided by Theorem 2 contains two additive terms: the first represents the diameter of the network, and the second represents delays caused by conflicts (which are rare, yet they exist).

Additional Properties of the Broadcast Protocol

- **Processor IDs** – The protocol does not use processor IDs, and thus does not require that the processors have distinct IDs (or that they know the identity of their neighbors). Furthermore, a processor is not even required to know the number of its neighbors. This property makes the protocol adaptive to changes in topology which occur throughout the execution and resilient to non-malicious faults.
- **Knowing the size of the network** – The protocol performs almost as well when given instead of the actual number of processors (i.e., n), a "good" upper bound on this number (denoted N). An upper bound polynomial in n yields the same time-complexity, up to a constant factor (since complexity is logarithmic in N).
- **Conflict detection** – The algorithm and its complexity remain valid even if no messages can be received when a conflict occurs.
- **Simplicity and fast local computation** – In each time slot, each processor performs a constant amount of local computation.
- **Message complexity** – Each processor is active for $\lceil \log(N/\epsilon) \rceil$ consecutive phases, and the average number of transmissions per phase is at most 2. Thus, the expected number of transmissions of the entire network is bounded by $2n \cdot \lceil \log(N/\epsilon) \rceil$.
- **Adaptiveness to changing topology and fault resilience** – The protocol is resilient to some changes in the topology of the network. For example, edges may be added or deleted at any time, provided that the network of unchanged edges remains connected. This corresponds to fail/stop failure of edges, thus demonstrating the resilience to some non-malicious failures.
- **Directed networks** – The protocol does not use acknowledgments. Thus it may be applied even when the communication links are not symmetric, i.e., the fact that processor v can transmit to u does not imply that u can transmit to v. (The appropriate network model is, therefore, a directed graph.) In real life this situation occurs, for instance, when v has a stronger transmitter than u.

A Lower Bound on Deterministic Algorithms

For deterministic algorithms, one can show a lower bound: for every n, there exist a family of n-node networks such that every



Randomized Broadcasting in Radio Networks, Fig. 1 The network used for the lower bound

deterministic broadcast scheme requires $\Omega(n)$ time. For every **non-empty** subset $S \subseteq \{1, 2, \ldots, n\}$, consider the following network G_S (Fig. 1).

Node 0 is the *source* and node $n + 1$ the *sink*. The source initiates the message and the problem of broadcast in G_S is to reach the sink. The difficulty stems from the fact that the partition of the middle layer (i.e., S) is not known a priori. The following theorem can be proved by a series of reductions to a certain "hitting game":

Theorem 3 *Every deterministic broadcast protocol that is correct for all n-node networks requires time* $\Omega(n)$.

The result of [2] depends crucially on the assumption that the nodes do not know the number and IDs of their neighbors. If this restriction is lifted, Kowalski and Pelc [5] showed how to broadcast in logarithmic time on all networks of type G_S. Moreover, they show how to broadcast in sublinear time on all n-node graphs of diameter o (log log n).

Kowalski and Pelc also constructed a class of graphs of diameter 4, such that every broadcasting algorithm requires time $\boldsymbol{\Omega}\left(\sqrt[4]{n}\right)$ on one of these graphs. Thus they showed an exponential gap for their model too.

Applications

The procedure *Decay* has been used to resolve contention in radio and cellular phone networks.

Recommended Reading

Subsequent papers showed the optimality of the randomized algorithm:

- Alon et al. [1] showed the existence of a family of radius-2 networks on n vertices for which any broadcast schedule requires at least $\Omega(\log^2 n)$ time slots.
- Kushilevitz and Mansour [7] showed that for any randomized broadcast protocol, there exists a network in which the expected time to broadcast a message is $\Omega(D \log(N/D))$.
- Bruschi and Del Pinto [3] showed that for any deterministic distributed broadcast algorithm, any n and $D \leq n/2$ there exists a network with n nodes and diameter D such that the time needed for broadcast is $\Omega(D \log n)$.
- Kowalski and Pelc [6] discussed networks in which collisions are indistinguishable from the absence of transmission. They showed an $\Omega(n \log n / \log(n/D))$ lower bound and an $O(n \log n)$ upper bound. For this model, they also showed an $O(D \log n + \log^2 n)$ randomized algorithm, thus matching the lower bound of [1] and improving the bound of [2] for graphs for which $D = \theta(n/\log n)$.

Randomized Contraction

Marek Cygan
Institute of Informatics, University of Warsaw, Warsaw, Poland

Keywords

Cuts; Graphs; Parameterized complexity; Randomization

Years and Authors of Summarized Original Work

2012; Chitnis, Cygan, Hajiaghayi, Pilipczuk, Pilipczuk

Problem Definition

The randomized contractions framework is often useful when designing fixed-parameter-tractable (FPT) algorithms for graph cut problems. Let us assume that we are given an undirected graph G with n vertices and m edges together with an integer k. The goal is to remove at most k edges or at most k vertices, in the edge- and vertex-deletion variants of a problem, respectively, to satisfy some problem-specific constraints. In this entry, for the sake of simplicity, we restrict our attention to edge-deletion variants only.

Examples of problems that fit in the above graph cut problem class include:

Multiway Cut
Input: an undirected graph G, a set of terminals $T \subseteq V(G)$, and an integer k.
Question: is there a set $X \subseteq E(G)$ of at most k edges of G, so that in $G \setminus X$, no connected component contains more than one terminal from T?

Steiner Cut
Input: an undirected graph G, a set of terminals $T \subseteq V(G)$, and integers k, s.
Question: is there a set $X \subseteq E(G)$ of at most k edges of G, so that in $G \setminus X$, at least s connected components contain at least one terminal from T?

Multiway Cut-Uncut
Input: an undirected graph G, a set of terminals $T \subseteq V(G)$, an equivalence relation $\mathcal{R}$ on the set T, and an integer k.
Question: is there a set $X \subseteq E(G)$ of at most k edges of G, so that for any $u, v \in T$, vertices u, v are in the same connected component of $G \setminus X$ iff $\mathcal{R}(u, v)$?

Unique Label Cover
Input: an undirected graph G, a finite alphabet Σ of size s, an integer k, for each vertex $v \in V(G)$ a set $\phi_v \subseteq \Sigma$, and for each edge $e \in E(G)$ and each its endpoint v, a partial permutation $\psi_{e,v}$ of Σ, such that if $e = uv$ then $\psi_{e,u} = \psi_{e,v}^{-1}$.
Question: is there a set $X \subseteq E(G)$ of at most k edges of G and a function $\Psi : V(G) \to \Sigma$ such that for any $v \in V(G)$ we have $\Psi(v) \in \phi_v$ and for any $uv \in E(G) \setminus X$, we have $(\Psi(u), \Psi(v)) \in \psi_{uv,u}$?

Key Results

The randomized contractions framework was obtained by Chitnis et al. [2]; however, it was inspired by an earlier work of Kawarabayashi and Thorup [4], who have shown that the k-way cut problem is fixed parameter tractable. Randomized contractions were used to obtain the first FPT algorithm for unique label cover parameterized by both the cut size and the alphabet size, as well as to improve the dependency on k in the FPT algorithms for Steiner cut and multiway cut-uncut.

To exemplify usage of randomized contractions, we use the multiway cut problem. Multiway cut is known to be FPT for a long time [5] and it admits efficient FPT algorithms with $f(k) = 4^k$ dependency on k by using important separators [1] as well as $f(k) = 2^k$ by LP-branching [3]. We use multiway cut as an illustration of usage of randomized contractions to simplify the description and magnify the most important parts of the technique.

High-Level Intuition

From now on, we assume that the given undirected graph G is connected, as otherwise one can solve the problem independently for each connected component of G. Observe that this guarantees that after removing k edges, the graph contains at most $k + 1$ connected components.

On a high level, the technique works in two phases. In the first phase, as long as the graph admits a certain type of a good edge separation, we proceed recursively and simplify the instance.

On the other hand, if the graph is well connected and does not contain a cut we are looking for, then in the second phase, we solve the problem directly, by exploiting the high connectivity of G.

Recursive Understanding

Assume that we have a set of vertices $V_1 \subseteq V(G)$, such that $G[V_1]$ is connected, V_1 contains at least $k \cdot k! + 2$ vertices, and there are at most k edges between V_1 and $V_2 = V(G) \setminus V_1$ in G. Let $B \subseteq V_1$ be the set of vertices in V_1 having at least one neighbor in V_2. In such a setting, one can show that by looking at $G[V_1]$ only (in particular without looking at $G[V_2]$), one can find an edge of $G[V_1]$ which can be safely contracted, i.e., which is not part of some solution for the whole graph G. The reason is that any solution $X \subseteq E(G)$ gives some partition of B by looking at the set of connected components o $G[V_2 \cup B] \setminus X$. There are at most $k!$ partitions of B as $|B| \leq k$. Imagine that for any such partition, we mark a set of at most k edges, which would extend the partial solution under consideration, i.e., extend $X \cap E(G[B \cup V_2])$. In total, this marking procedure would select $k \cdot k!$ edges, leaving at least one edge unmarked, as $E(G[V_1]) \geq |V_1| - 1 \geq k \cdot k! + 1$. Such an unmarked edge can be safely contracted. The intuition behind this reasoning leads to the following definition:

Definition 1 Let G be a connected graph. A partition (V_1, V_2) of $V(G)$ is called a (q, k)-*good edge separation*, if

- $|V_1|, |V_2| > q$;
- $|E(V_1, V_2)| \leq k$;
- $G[V_1]$ and $G[V_2]$ are connected.

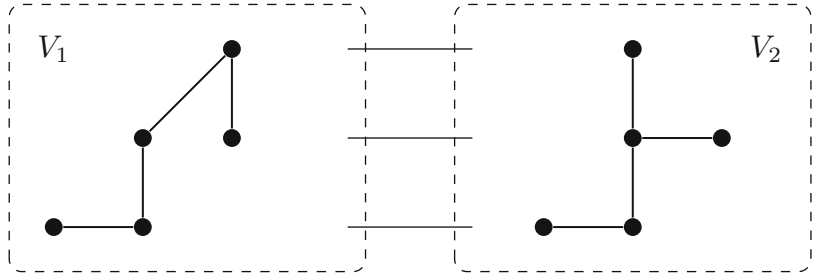
For the multiway cut problem, we would set $q = k \cdot k! + 1$. The following lemma states that we can find a (q, k)-good edge separation, if it exists:

Lemma 1 *There exists a deterministic algorithm that, given an undirected, connected graph G on n vertices along with integers q and k, in time $\mathcal{O}(2^{\mathcal{O}(\min(q,k)\log(q+k))} n^3 \log n)$ either finds a (q, k)-good edge separation or correctly concludes that no such separation exists.*

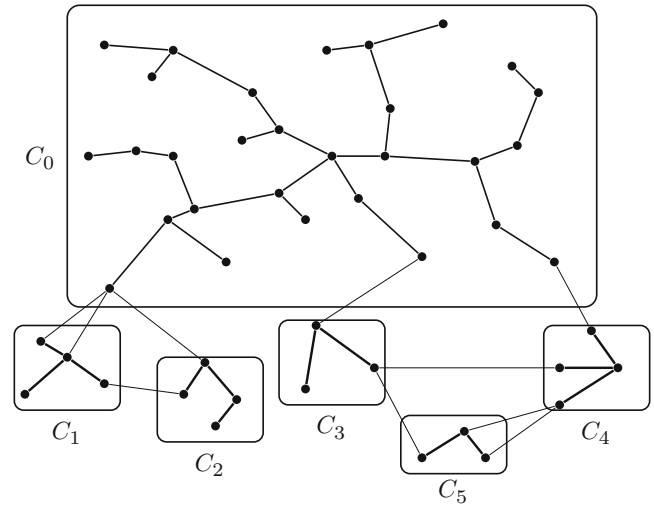
A rough sketch of the proof follows. Assume that a (q, k)-good edge separation (V_1, V_2) exists. Let E_1 be the set of edges of some subtree of $G[V_1]$ with exactly q edges; similarly let E_2 be the set of edges of some subtree of $G[V_2]$ with exactly q edges. By the definition of a (q, k)-good separation, such sets E_1, E_2 exist. Contract each edge of the graph with probability $1/2$ independently from other edges. With probability at least $1/f(k, q) = 2^{-(2q+k)}$, the following event happens (see Fig. 1):

(i) No edge between V_1 and V_2 is contracted,
(ii) All edges of $E_1 \cup E_2$ are contracted.

If we are lucky and such an event occurs, then by looking for a minimum cut between each two vertices onto which at least $q + 1$ vertices of G were contracted, we can find a (q, k)-good separation. By a better choice of contraction probability, we can improve the probability of success, whereas by using splitters [6], we can derandomize the procedure.



Randomized Contraction, Fig. 1 A (q, k)-good separation. In the randomized routine, we hope the thick edges to be contracted and the thin edges not to be contracted



Randomized Contraction, Fig. 2 Structure of a connected graph G that does not admit a (q, k)-good separation. After removing at most k edges, only one big connected component, C_0, remains

Summarizing this phase of the algorithm, we look for a (q, k)-good edge separation. If it does not exist, then we proceed to the second – high connectivity – phase of the algorithm. However, if a (q, k)-good edge separation exists, then we proceed recursively. Clearly, we are omitting some important details in this description. The most important of them is that when recursing, some vertices play a special role, as they are *border terminals* – vertices which have neighbors outside of the part of the graph under consideration. For this reason, to make the induction work, we need a stronger definition of a problem, called its border version, which for multiway cut is as follows:

Border Multiway Cut

Input: a connected, undirected graph G, a set of terminals $T \subseteq V(G)$, an integer k, and a set $T_b \subseteq V(G)$ of at most $2k$ terminals.

Output: for each partition $\mathcal{P}$ of T_b output, a set $X_{\mathcal{P}}$ of size at most k (if it exists), such that in the graph $G_{\mathcal{P}} \setminus X$, no two terminals from T are in the same connected component, where $G_{\mathcal{P}} = (V(G), E(G) \cup E_{\mathcal{P}})$ and $E_{\mathcal{P}}$ contains pairs of vertices which are in the same block of $\mathcal{P}$.

High-Connectivity Phase

The second phase of the approach is usually problem specific; however, its main idea is the following. Since we know that G does not admit a (q, k)-good edge separation, if we remove any set X of at most k edges, there is at most one connected component of $G \setminus X$ containing more than q vertices (see Fig. 2). Therefore, if we independently contract each edge at random, then with good enough probability, no solution edge

will be contracted and all connected components of $G \setminus X$ except possibly one will be contracted onto single vertices (again, see Fig. 2). In such a case, one can show that we can solve a cut problem under consideration either greedily or by dynamic programming.

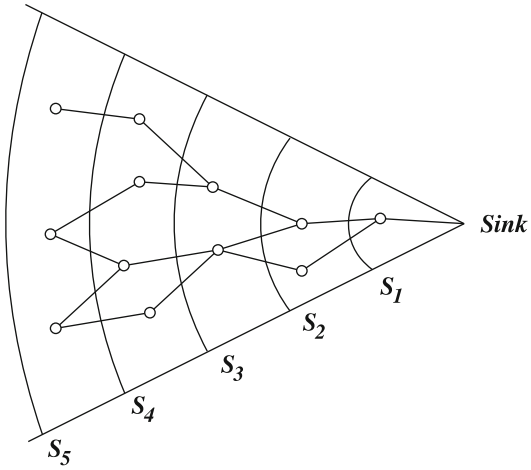
Problem Definition

Recent developments in wireless communications and digital electronics have led to the development of extremely small in size, low-power, low-cost sensor devices (often called smart dust). Such tiny devices integrate sensing, data processing and wireless communication capabilities. Examining each such resource constraint device individually might appear to have small utility; however, the distributed self-collaboration of large numbers of such devices into an ad hoc network may lead to the efficient accomplishment of large sensing tasks i.e., reporting data about the realization of a local event happening in the network area to a faraway control center.

The problem considered is the development of a randomized algorithm to balance energy among sensors whose aim is to detect events in the network area and report them to a sink. The network is sliced by the algorithm into layers composed of sensors at approximately equal distances from the



Randomized Energy Balance Algorithms in Sensor Networks, Fig. 1 The sink and five slices $S_1, \ldots, S_5$

sink [1, 2, 8] (Fig. 1). The slicing of the network depends on the communication distance. The sink initiates the process by sending a control message containing a counter, the value of which is initially 1. Sensors receiving the message assign themselves to a slice number corresponding to the counter, increment the counter and propagate the message in the network. A sensor already assigned to a slice ignores subsequent received control messages.

The strategy suggested to balance the energy among sensors consists in allowing a sensor to probabilistically choose between either sending data to a sensor in the next layer towards the sink or sending the data directly to the sink. The difference between the two choices is the energy consumption, which is much higher if the sensor decides to report to the sink directly. The energy consumption is modeled as a function of the transmission distance by assuming that the energy necessary to send data up to a distance d is proportional to d^2. Actually, more accurate models can be considered, in which the dependence is of the form d^α, with $2 \leq \alpha \leq 5$ depending on the particular environmental conditions. Although the model chosen determines the parameters of the algorithm, the particular shape of the function describing the relationship between the distance of transmission and energy consumption is not relevant except that it might increase with distance. The distance between two successive slices is normalized to be 1. Hence, a sensor sending data to one of its neighbors consumes one unit of energy and a sensor located in slice i consumes i^2 units of energy to report to the sink directly. Small hop transmissions are cheap (with respect to energy consumption) but pass through the critical region around the sink and might strain sensors in that region, while expensive direct transmissions bypass that critical area.

Energy balance is defined as follows:

Definition 1 The network is energy-balanced if the average per sensor energy dissipation is the same for all sectors, i.e., when

$$\frac{E[\mathcal{E}_i]}{S_i} = \frac{E[\mathcal{E}_j]}{S_j}, \quad i, j = 1, \ldots, n \qquad (1)$$

where $\mathcal{E}_i$ is the total energy available and S_i is the number of nodes in slice number i.

The dynamics of the network is modeled by assigning probabilities $\lambda_i, i = 1, \ldots, N$, $\sum \lambda_i = 1$, of the occurrence of an event in slice i. The protocol consists in transmitting the data to a neighbor slice with probability p_i and with probability $1 - p_i$ to the sink, for a sensor belonging to slice i. Hence, the mean energy consumption per data unit is $p_i + (1 - p_i)i^2$. A central assumption in the following is that the events are evenly generated in a given slice. Then, denoting by e_i the energy available per node in slice i (i.e., $e_i = \mathcal{E}_i / S_i$), the problem of energy-balanced data propagation can be formally stated as follows:

Given $\lambda_i, e_i, S_i, i = 1, \ldots, N$, find p_i, λ such that

$$\underbrace{\left(\lambda_i + \lambda_{i+1} p_{i+1} + \ldots + \lambda_n p_n p_{n-1} \cdots p_{i+1}\right)}_{=:x_i} \cdot \left(p_i \frac{1}{S_i} + (1 - p_i)\frac{i^2}{S_i}\right) = \lambda e_i, \quad i = 1, \ldots, N. \qquad (2)$$

```
Initialize x̃_0 = λ, ..., x̃_n
Initialize NbrLoop=1
repeat forever
   Send x̃_i and λ values to the stations which compute
                                        their p_i probability
    wait for a data
   for i=0 to n
      if the data passed through slice i then
         X ← 1
      else
         X ← 0
      end if
      Generate R a x̃_i-Bernoulli random variable
      x̃_i    x̃_i + 1/NbrLoop (X − R)
      Increment NbrLoop by one.
   end for
end repeat
```

Randomized Energy Balance Algorithms in Sensor Networks, Fig. 2 Pseudo-code for estimation of the x_i value by the sink

Equation (2) amounts to ensuring that the mean energy dissipation for all sensors is proportional to the available energy. In turn, this ensures that sensors might, on average, run out of energy all at the same time. Notice that (2) contains the definitions of the x_i. They are the ones estimated in the pseudo-code in Fig. 2, the successive estimations being denoted as $\tilde{x}_i$. These variables are proportional to the number of messages handled by slice i.

Key Results

In [1, 2] recursive equations similar to (2) were suggested and solved in closed form under adequate hypotheses. The need for a priori knowledge of the probability of occurrence of the events, the λ_i parameters, was considered in [7], in which these parameters were estimated by the sink on the basis of the observations of the various paths the data follow. The algorithm suggested is based on recursive estimation, is computationally not expensive and converges with rate $\mathcal{O}(1/\sqrt{n})$. One might argue that the rate of convergence is slow; however, it is numerically observed that relatively quickly compared with the convergence time, the algorithm finds an estimation close enough to the final value. The estimation algorithm run by the sink (which has no energy constraints) is given in Fig. 2.

Results taken from [1, 2, 7] all assume the existence of an energy-balance solution. However, particular distributions of the events might prevent the existence of such a solution and the relevant question is no longer the computation of an energy-balance algorithm. For instance, assuming that $\lambda_N = 0$, sensors in slice N have no way of balancing energy. In [9] the problem was reformulated as finding the probability distribution $\{p_i\}_{i=1,\ldots,N}$ which leads to the maximal functional lifetime of the networks. It was proved that if an energy-balance strategy exists, then it maximizes the lifetime of the network establishing formally the intuitive reasoning which was the motivation to consider energy-balance strategies. A centralized algorithm was presented to compute the optimal parameters. Moreover, it was observed numerically that the interslice energy consumption is prone to be uneven and a spreading technique was suggested and numerically validated as being efficient to overcome this limitation of the probabilistic algorithm.

The communication graph considered is a restrictive subset of the complete communication graph and it is legitimate to wonder whether one can improve the situation by extending it. For instance, by allowing data to be sent two hops or more away. In [3, 6] it was proved that the topology in which sensors communicate only to neighbor slices and the sink is the one which maximizes the flow of data in the network. Moreover, the communication graph in which sensors send data only to their neighbors and the sink leads to a completely distributed algorithm balancing energy [6]. Indeed, as a sensor sends data to a neighbor slice, the neighbor must in turn send the data and can attach information concerning its own energy level. This information might be captured by the initial sensor since it belongs to the communication range of its neighbor (this does not hold any longer if multiple hops are allowed). Hence, a distributed strategy consists in

sending data to a particular neighbor only if its energy level consumption is lower, otherwise the data are sent directly to the sink.

Applications

Among the several constraints sensor networks designers have to face, energy management is central since sensors are usually battery powered, making the lifetime of the networks highly sensitive to the energy management. Besides the traditional strategy consisting in minimizing the energy consumption at sensor nodes, energy-balance schemes aim at balancing the energy consumption among sensors. The intuitive function of such schemes is to avoid energy depletion holes appearing as some sensors that run out of their available energy resources and are no longer able to participate in the global function of the networks. For instance, routing might be no longer possible if a small number of sensors run out of energy, leading to a disconnected network. This was pointed out in [5] as well as the need to develop application-specific protocols. Energy balancing is suggested as a solution in order to make the global functional lifetime of the network longer. The earliest development of dedicated protocols ensuring energy balance can be found in [4, 10, 11].

A key application is to maximize the lifetime of the network while gathering data to a sink. Besides increasing the lifetime of the networks, other criteria have to be taken into account. Indeed, the distributed algorithm might be as simple as possible owing to limited computational resources, might avoid collisions or limit the total number of transmissions, and might ensure a large enough flow of data from the sensors toward the sink. Actually, maximizing the flow of data is equivalent to maximizing the lifetime of sensor networks if some particular realizable conditions are fulfilled. Besides the simplicity of the distributed algorithm, the network deployment and the self-realization of the network structure might be possible in realistic conditions.

2001; Chrobak, Gąsieniec, Rytter

Problem Definition

The two classical problems of disseminating information in computer networks are *broadcasting* and *gossiping*. In broadcasting, the goal is to distribute a message from a distinguished *source* node to all other nodes in the networks. In gossiping, each node v in the network initially contains a message m_v, and the task is to distribute each message m_v to all nodes in the network.

The radio network abstraction captures the features of distributed communication networks with multi-access channels, with minimal assumptions on the channel model and processors' knowledge. Directed edges model unidirectional links, including situations in which one of two adjacent transmitters is more powerful than the other. In particular, there is no feedback mechanism (see, for example, [6]). In some applications, collisions may be difficult to distinguish from the noise that is normally present in the channel, justifying the need for protocols that do not depend on the reliability of the collision detection mechanism (see [3, 4]). Some network configurations are subject to frequent changes. In other networks, a network topology could be unstable or dynamic, for example, when mobile users are present. In such situations, algorithms that do not assume any specific topology are more desirable.

More formally a radio network is a directed graph $G = (V, E)$, where by $|V| = n$, we denote the number of nodes in this graph. Individual nodes in V are denoted by letters $u, v, \ldots$. If there is an edge from u to v, i.e., $(u, v) \in E$, then we say that v is an *out-neighbor* of u and u is an *in-neighbor* of v. Messages are denoted by letter m, possibly with indices. In particular, the message originating from node v is denoted by m_v . The whole set of initial messages is $M = \{m_v : v \in V\}$. During the computation, each node v holds a set of messages M_v that have been received by v so far. Initially, each node v does not possess any information apart from $M_v = \{m_v\}$. Without loss of generality, whenever a node is in the transmitting mode, one can assume that it transmits the whole content of M_v.

The time is divided into discrete time steps. All nodes start simultaneously, have access to a common clock, and work synchronously. A gossiping algorithm is a protocol that for each node u, given all past messages received by u, specifies, for each time step t, whether u will transmit a message at time t, and if so, it also specifies the message. A message M transmitted at time t from a node u is sent instantly to all its out-neighbors. An out-neighbor v of u receives M at time step t only if no collision occurred, that is, if the other in-neighbors of v do not transmit

at time t at all. Further, collisions cannot be distinguished from background noise. If v does not receive any message at time t, it knows that either none of its in-neighbors transmitted at time t or that at least two did, but it does not know which of these two events occurred. The *running time* of a gossiping algorithm is the smallest t such that for any network topology, and any assignment of identifiers to the nodes, all nodes receive messages originating in every other node no later than at step t.

Limited Broadcast $_v$ (k) Given an integer k and a node v, the goal of *limited broadcasting* is to deliver the message m_v (originating in v) to at least k other nodes in the network.

Distributed Coupon Collection The set of network nodes V can be interpreted as a set of n bins and the set of messages M as a set of n coupons. Each coupon has at least k copies, each copy belonging to a different bin. M_v is the set of coupons in bin v. Consider the following process. At each step, one opens every bin at random, independently, with probability $1/n$. If no bin is opened, or if two or more bins are opened, a failure occurs and no coupons are collected. If exactly one bin, say v, is opened, all coupons from M_v are collected. The task is to establish how many steps are needed to collect (a copy of) each coupon.

Key Results

Theorem 1 ([1]) *There exists a deterministic $O(k \log^2 n)$-time algorithm for limited broadcasting from any node in radio networks with an arbitrary topology.*

Theorem 2 ([1]) *Let δ be a given constant, $0 < \delta < 1$, and $s = (4n/k)\ln(n/\delta)$. After s steps of the distributed coupon collection process, with probability at least $1 - \delta$, all coupons will be collected.*

Theorem 3 ([1]) *Let ϵ be a given constant, where $0 < \epsilon < 1$. There exists a randomized $O(n \log^3 n \log(n/\epsilon))$-time Monte Carlo-type algorithm that completes radio gossiping with probability at least $1 - \epsilon$.*

Theorem 4 ([1]) *There exists a randomized Las Vegas-type algorithm that completes radio gossiping with expected running time $O(n \log^4 n)$.*

Applications

Further work on efficient randomized radio gossiping include the $O(n \log^3 n)$-time algorithm by Liu and Prabhakaran; see [5], where the deterministic procedure for limited broadcasting is replaced by its $O(k \log n)$-time randomized counterpart. This bound was later reduced to $O(n \log^2 n)$ by Czumaj and Rytter in [2], where a new randomized limited broadcasting procedure with an expected running time $O(k)$ is proposed.

Open Problems

The exact complexity of randomized radio gossiping remains an open problem. All three gossiping algorithms [1, 2, 5] are based on the concepts of limited broadcast and distributed coupon collection. The two improvements [2, 5] refer solely to limited broadcasting. Thus, very likely further reduction of the time complexity must coincide with more accurate analysis of the distributed coupon collection process or with development of a new gossiping procedure.

Randomized Minimum Spanning Tree

Vijaya Ramachandran
Computer Science, University of Texas, Austin, TX, USA

Keywords

Linear time; Minimum spanning tree; Minimum spanning tree verification; Randomized algorithm

Years and Authors of Summarized Original Work

1995; Karger, Klein, Tarjan

Problem Definition

The input to the problem is a connected undirected graph $G = (V, E)$ with a weight $w(e)$ on each edge $e \in E$. The goal is to find a spanning tree of minimum weight, where for any subset of edges $E' \subseteq E$, the *weight of* E' is defined to be $w(E') = \sum_{e \in E'} w(e)$.

If the graph G is not connected, the goal of the problem is to find a *minimum spanning forest*, which is defined to be a minimum spanning tree in each connected component of G. Both problems will be referred to as the *MST* problem.

The randomized MST algorithm by Karger, Klein, and Tarjan [9] which is considered here will be called the *KKT algorithm*. Also it will be assumed that the input graph $G = (V, E)$ has n vertices and m edges and that the edge weights are distinct.

The MST problem has been studied extensively prior to the KKT result, and several very efficient, deterministic algorithms are available from these studies. All of these are deterministic and are based on a method that greedily adds an edge to a forest that is a subgraph of the minimum spanning tree at all times. The early algorithms in this class are already efficient with a running time of $O(m \log n)$. These include the algorithms of Borůvka [1], Jarník [8] (later rediscovered by Dijkstra and Prim [5]), and Kruskal [5].

The fastest algorithm known for MST prior to the KKT algorithm runs in time $O(m \log \beta(m, n))$ [7], where $\beta(m, n) = \min\{i \mid \log^{(i)} n \leq m/n\}$ [7]; here $\log^{(i)} n$ is defined as $\log n$ if $i = 1$ and as $\log \log^{(i-1)} n$ if $i > 1$. Although this running time is close to linear, it is not linear time if the graph is very sparse.

The problem of finding the minimum spanning tree efficiently is an important and fundamental problem in graph algorithms and combinatorial optimization.

Background

Some relevant background is summarized here.

- The basic step in Borůvka's algorithm [1] is the *Borůvka step*, which picks the minimum edge-weight incident on each vertex, adds it to the minimum spanning tree, and then contracts these edges. This step runs in linear time and also very efficiently in parallel. It is the backbone of the most efficient parallel algorithms for minimum spanning tree and is also used in the KKT algorithm.
- A related and simpler problem is that of *minimum spanning tree verification*. Here, given a spanning tree T of the input edge-weighted graph, one needs to determine if T is its minimum spanning tree. An algorithm that solves this problem with a linear number of edge-weight comparisons was shown by Kom-

lós [13], and later a deterministic linear-time algorithm was given in [6] (see also [12] for a simpler algorithm).

Key Results

The main result in [9] is a randomized algorithm for the minimum spanning tree problem that runs in expected linear time. The only operations performed on the edge weights are pairwise comparisons. The algorithm does not assume any particular representation of the edge weights (i.e., integer or real values) and only assumes that any comparison between a pair of edge weights can be performed in unit time. The entry also shows that the algorithm runs in $O(m+n)$ time with the exponentially high probability $1 - \exp(-\Omega(m))$ and that its worst-case running time is $O(n + m \log n)$.

The simple and elegant *MST sampling lemma* given in Lemma 1 below is the key tool used to derive and analyze the KKT algorithm. This lemma needs a couple of definitions and facts:

1. The well-known *cycle property* for the minimum spanning tree states that the heaviest edge in any cycle in the input graph G *cannot* be in the minimum spanning tree.
2. Let F be a forest of G (i.e., an acyclic subgraph of G). An edge $e \in E$ is *F-light* if $F \cup \{e\}$ either continues to be a forest of G, or the heaviest edge in the cycle containing e is *not* e. An edge in G that is not F-light is *F-heavy*. Note that by the cycle property, an F-heavy edge cannot be in the minimum spanning tree of G, *no matter what forest F is used*. Given a forest F of G, the set of F-heavy edges can be determined in linear time by a simple modification to existing linear-time minimum spanning tree verification algorithms [6, 12].

Lemma 1 (MST Sampling Lemma) *Let $H = (V, E_H)$ be formed from the input edge-weighted graph $G = (V, E)$ by including each edge with probability p independent of the other edges. Let F be the minimum spanning forest of H. Then, the expected number of F-light edges in G is $\leq n/p$.*

The KKT algorithm identifies edges in the minimum spanning tree of G only using Borůvka steps. However, after every two Borůvka steps, it removes F-heavy edges using the minimum spanning forest F of a subgraph obtained through sampling edges with probability $p = 1/2$. As mentioned earlier, these F-heavy edges can be identified in linear time. The minimum spanning forest of the sampled graph is computed recursively.

The correctness of the KKT algorithm is immediate since every F-heavy edge it removes cannot be in the MST of G since F is a forest of G, and every edge it adds to the minimum spanning tree is in the MST since it is added through a Borůvka step.

The expected running time analysis as well as the exponentially high probability bound for the running time are surprisingly simple to derive using the MST Sampling Lemma (Lemma 1).

In summary, the entry [9] proves the following results.

Theorem 1 *The KKT algorithm is a randomized algorithm that finds a minimum spanning tree of an edge-weighted undirected graph on n nodes and m edges in $O(n + m)$ time with probability at least $1 - \exp(-\Omega(m))$. The expected running time is $O(n+m)$ and the worst-case running time is $O(n + m \log n)$.*

The model of computation used in [9] is the unit-cost RAM model since the known MST verification algorithms were for this model and not the more restrictive *pointer machine* model. More recently the MST verification result and hence the KKT algorithm have been shown to work on the pointer machine as well [2].

Lemma 1 is proved in [9] through a simulation of Kruskal's algorithm along with an analysis of the probability with which an F-light edge is not sampled. Another proof that uses a backward analysis is given in [3].

Further Comments

- Recently (and since the appearance of the KKT algorithm in 1995), two new deterministic algorithms for MST have appeared, due to Chazelle [4] and Pettie and Ramachandran [14]. The former [4] runs in $O(n + m\alpha(m, n))$ time, where α is an inverse of the Ackermann's function, whose growth rate is even smaller than the β function mentioned earlier for the best result that was known prior to the KKT algorithm [7]. The latter algorithm [14] provably runs in time that is within a constant factor of the decision-tree complexity of the MST problem and hence is optimal; its time bound is $O(n + m\alpha(m, n))$ and $\Omega(n + m)$, and the exact bound remains to be determined.
- Although the KKT algorithm runs in expected linear time (and with exponentially high probability), it is not the last word on randomized MST algorithms. A randomized MST algorithm that runs in expected linear time and uses only $O(\log^* n)$ random bits is given in [16, 17]. In contrast, the KKT algorithm uses a linear number of random bits.

Applications

The minimum spanning tree problems has a large number of applications, which are discussed in minimum spanning trees.

Open Problems

Some open problems that remain are the following:

1. Can randomness be removed in the KKT algorithm? A hybrid algorithm that uses the KKT algorithm within a modified version of the Pettie-Ramachandran algorithm [14] is given in [16, 17] that achieves expected linear time while reducing the number of random bits used to only $O(\log^* n)$. Can this tiny amount of randomness be removed as well? If all randomness can be removed from the KKT algorithm, that will establish a linear time bound for the Pettie-Ramachandran algorithm [14] and also provide another optimal deterministic MST algorithm, this one based on the KKT approach.
2. Can randomness be removed from the work-optimal *parallel algorithms* [10] for MST? A linear-work, expected logarithmic-time parallel MST algorithm for the EREW PRAM is given in [15]. This parallel algorithm is both work and time optimal. However, it uses a linear number of random bits. Another work-optimal parallel algorithm is given in [16, 17] that runs in expected polylog time using only polylog random bits. This leads to the following open questions regarding parallel algorithms for the MST problem:
   - To what extent can dependence on random bits be reduced (from the current linear bound) in a time- and work-optimal parallel algorithm for MST?
   - To what extent can the dependence on random bits be reduced (from the current polylog bound) in a work-optimal parallel algorithm with reasonable parallelism (say polylog parallel time)?

Experimental Results

Katriel, Sanders, and Träff [11] performed an experimental evaluation of the KKT algorithm and showed that it has good performance on moderately dense graphs.

Randomized Parallel Approximations to Max Flow

Maria Serna
Department of Language and System Information, Technical University of Catalonia, Barcelona, Spain

Keywords

Approximate maximum flow construction

Years and Authors of Summarized Original Work

1991; Serna, Spirakis

Problem Definition

The work of Serna and Spirakis provides a parallel approximation schema for the Maximum Flow problem. An approximate algorithm provides a solution whose cost is within a factor of the optimal solution. The notation and definitions are the standard ones for networks and flows (see for example [2, 7]).

A *network* $N = (G, s, t, c)$ is a structure consisting of a directed graph $G = (V, E)$, two distinguished vertices, $s, t \in V$ (called the *source* and the *sink*), and $c : E \to \mathbb{Z}^+$, an assignment of an integer capacity to each edge in E. A *flow function* f is an assignment of a non-negative number to each edge of G (called the flow into the edge) such that first at no edge does the flow exceed the capacity, and second for every vertex except s and t, the sum of the flows on its incoming edges equals the sum of the flows on its outgoing edges. The *total flow* of a given flow function f is defined as the net sum of flow into the sink t. The Maximum Flow problem can be stated as

Name	Maximum Flow
Input	A network $N = (G, s, t, c)$
Output	Find a flow f for N for which the total flow is maximum.

Maximum Flows and Matchings

The Maximum Flow problem is closely related to the Maximum Matching problem on bipartite graphs.

Given a graph $G = (V, E)$ and a set of edges $M \subseteq E$ is a *matching* if in the subgraph (V, M) all vertices have degree at most one. A *maximum matching* for G is a matching with a maximum number of edges. For a graph $G = (V, E)$ with weight $w(e)$, the *weight* of a matching M is the sum of the weights of the edges in M. The problem can be stated as follows:

Name	Maximum Weight Matching
Input	A graph $G = (V, E)$ and a weight $w(e)$ for each edge $e \in E$
Output	Find a matching of G with the maximum possible weight.

There is a standard reduction from the Maximum Matching problem for bipartite graphs to the Maximum Flow problem [7, 8]. In the general weighted case one has just to look at each edge with capacity $c > 1$ as c edges joining the same points each with capacity one, and transform the multigraph obtained as shown before. Notice that to perform this transformation a c value is required which is polynomially bounded. The whole procedure was introduced by Karp, Upfal, and Wigderson [5] providing the following results

Theorem 1 *The Maximum Matching problem for bipartite graphs is NC equivalent to the Maximum Flow problem on networks with polynomial capacities. Therefore, the Maximum Flow with polynomial capacities problem belongs to the class RNC.*

Key Results

The first contribution is an extension of Theorem 1 to a generalization of the problem, namely the Maximum Flow on networks with polynomially bounded maximum flow. The proof is based on the construction (in NC) of a second network which has the same maximum flow but for which the maximum flow and the maximum capacity in the network are polynomially related.

Lemma 2 *Let $N = (G, s, t, c)$. Given any integer k, there is an NC algorithm that decides whether $f(N) \geq k$ or $f(N) < km$.*

Since Lemma 2 applies even to numbers that are exponential in size, they get

Lemma 3 *Let $N = (G, s, t, c)$ be a network, there is an NC algorithm that computes an integer value k such that $2^k \leq f(N) < m\ 2^{k+1}$.*

The following lemma establishes the NC-reduction from the Maximum Flow problem with polynomial maximum flow to the Maximum Flow problem with polynomial capacities.

Lemma 4 *Let $N = (G, s, t, c)$ be a network, there is an NC algorithm that constructs a second network $N_1 = (G, s, t, c_1)$ such that*

$$\log(\mathrm{Max}(N_1)) \leq \log(f(N_1)) + O(\log n)$$

and $f(N) = f(N_1)$.

Lemma 4 shows that the Maximum Flow problem restricted to networks with polynomially bounded maximum flow is NC-reducible to the Maximum Flow problem restricted to polynomially bounded capacities, the latter problem is a simplification of the former one, so the following results follow.

Theorem 5 *For each polynomial p, the problem of constructing a maximum flow in a network N such that $f(N) \leq p(n)$ is NC-equivalent to the problem of constructing a maximum matching in a bipartite graph, and thus it is in RNC.*

Recall that [5] gave us an $O(\log^2 n)$ randomized parallel time algorithm to compute a maximum matching. The combination of this with the reduction from the Maximum Flow problem to the Maximum Matching leads to the following result.

Theorem 6 *There is a randomized parallel algorithm to construct a maximum flow in a directed network, such that the number of processors is*

bounded by a polynomial in the number of vertices and the time used is $O((\log n)^{\alpha} \log f(N))$ *for some constant* $\alpha > 0$.

The previous theorem is the first step towards finding an approximate maximum flow in a network N by an RNC algorithm. The algorithm, given N and an $\varepsilon > 0$, outputs a solution f' such that $f(N)/f' \leq 1 + 1/\varepsilon$. The algorithm uses a polynomial number of processors (independent of ε) and parallel time $O(\log^{\alpha} n(\log n + \log \varepsilon))$, where α is independent of ε. Thus, the algorithm is an RNC one as long as ε is at most polynomial in n. (Actually ε can be $O(n^{\log^{\beta} n})$ for some β.) Thus, being a Fully RNC approximation scheme (FRNCAS).

The second ingredient is a rough NC approximation to the Maximum Flow problem.

Lemma 7 *Let* $N = (G, s, t, c)$ *be a network. Let* $k \geq 1$ *be an integer, then there is an NC algorithm to construct a network* $M = (G, s, t, c_1)$ *such that* $k\ f(M) \leq f(N) \leq k\ f(M) + km$.

Putting all together and allowing randomization the algorithm can be sketched as follows:

FAST-FLOW($N = (G, s, t, c), \varepsilon$)

1. Compute k such that $2^k \leq F(N) \leq 2^{k+1}m$.
2. Construct a network N_1 such that

$$\log(\text{Max}(N_1)) \leq \log(F(N_1)) + O(\log n).$$

3. If $2^k \leq (1 + \varepsilon)m$ then $F(N) \leq (1 + \varepsilon)m^2$ so use the algorithm given in Theorem 6 to solve the Maximum Flow problem in N as a Maximum Matching and **return**
4. Let $\beta = \lfloor (2^k)/((1 + \varepsilon)m) \rfloor$. Construct N_2 from N_1 and β using the construction in Lemma 7.
5. Solve the Maximum Flow problem in N_2 as a Maximum Matching.
6. Output $F' = \beta F(M_2)$ and for all $e \in E$, $f'(e) = \beta f(e)$.

Theorem 8 *Let* $N = (G, s, t, c)$ *be a network. Then, algorithm FAST-FLOW is an RNC algorithm such that for all* $\varepsilon > 0$ *at most polynomial in the number of network vertices, the algorithm computes a legal flow of value* f' *such that*

$$\frac{f(N)}{f'} \leq 1 + \frac{1}{\varepsilon}.$$

Furthermore, the algorithm uses a polynomial number of processors and runs in expected parallel time $O(\log^{\alpha} n(\log n + \log \varepsilon))$, *for some constant* α, *independent of* ε.

Applications

The *rounding/scaling* technique is used in general to deal with problems that are hard due to the presence of large weights in the problem instance. The technique modifies the problem instance in order to produce a second instance that has no large weights, and thus can be solved efficiently. The way in which a new instance is obtained consists of computing first an estimate of the optimal value (when needed) in order to discard unnecessary high weights. Then the weights are modified, scaling them down by an appropriate factor that depends on the estimation and the allowed error. The rounding factor is determined in such a way that the so-obtained instance can be solved efficiently. Finally, a last step consisting of scaling up the value of the "easy" instance solution is performed in order to meet the corresponding accuracy requirements.

It is known that in the sequential case, the only way to construct FPTAS uses rounding/scaling and interval partition [6]. In general, both techniques can be paralyzed, although sometimes the details of the parallelization are non-trivial [1].

The Maximum Flow problem has a long history in Computer Science. Here are recorded some results about its parallel complexity. Goldschlager, Shaw, and Staples showed that the Maximum Flow problem is P-complete [3]. The P-completeness proof for Maximum Flow uses large capacities on the edges; in fact the values of some capacities are exponential in the number of network vertices. If the capacities are constrained

to be no greater than some polynomial in the number of network vertices the problem is in ZNC. In the case of planar networks it is known that the Maximum Flow problem is in NC, even if arbitrary capacities are allowed [4].

Open Problems

The parallel complexity of the Maximum Weight Matching problem when the weight of the edges are given in binary is still an open problem. However, as mentioned earlier, there is a randomized NC algorithm to solve the problem in $O(\log^2 n)$ parallel steps, when the weights of the edges are given in unary. The scaling technique has been used to obtain fully randomized NC approximation schemes, for the Maximum Flow and Maximum Weight Matching problems (see [10]). The result appears to be the best possible in regard of full approximation, in the sense that the existence of an FNCAS for any of the problems considered is equivalent to the existence of an NC algorithm for perfect matching which is also still an open problem.

Randomized Rounding

Rajmohan Rajaraman
Department of Computer Science, Northeastern University, Boston, MA, USA

Years and Authors of Summarized Original Work

1987; Raghavan, Thompson

Problem Definition

Randomized rounding is a technique for designing approximation algorithms for NP-hard optimization problems. Many combinatorial optimization problems can be represented as 0-1 integer linear programs; that is, integer linear programs in which variables take values in $\{0, 1\}$. While 0-1 integer linear programming is NP-hard, the rational relaxations (also referred to as fractional relaxations) of these linear programs are solvable in polynomial time [12, 13]. Randomized rounding is a technique to construct a provably good solution to a 0-1 integer linear program from an optimum solution to its rational relaxation by means of a randomized algorithm.

Let Π be a 0-1 integer linear program with variables $x_i \in \{0, 1\}$, $1 \leq i \leq n$. Let Π_R be the rational relaxation of Π obtained by replacing the $x_i \in \{0, 1\}$ constraints by $x_i \in [0, 1]$, $1 \leq i \leq n$. The randomized rounding approach consists of two phases:

1. Solve Π_R using an efficient linear program solver. Let the variable x_i take on value $x_i^* \in [0, 1]$, $1 \leq i \leq n$.
2. Compute a solution to Π by setting the variables x_i randomly to one or zero according to the following rule:

$$\Pr[x_i = 1] = x_i^* .$$

For several fundamental combinatorial optimization problems, the randomized rounding technique yields simple randomized approximation algorithms that yield solutions provably close to optimal. Variants of the basic approach outlined above, in which the rounding of variable x_i in the second phase is done with a probability that is some appropriate function of x_i^*, have also been studied. The analyses of algorithms based on randomized rounding often rely on Chernoff–Hoeffding bounds from probability theory [5, 11].

The work of Raghavan and Thompson [14] introduced the technique of randomized rounding for designing approximation algorithms for NP-hard optimization problems. The randomized rounding approach also implicitly proves the existence of a solution with certain desirable properties. In this sense, randomized rounding can be viewed as a variant of the probabilistic method, due to Erdös [1], which is widely used for various existence proofs in combinatorics.

Raghavan and Thompson illustrate the randomized rounding approach using three optimization problems: VLSI routing, multicommodity flow, and k-matching in hypergraphs.

Definition 1 In the **VLSI Routing** problem, we are given a two-dimensional rectilinear lattice L_n over n nodes and a collection of m *nets* $\{a_i : 1 \leq i \leq m\}$, where net a_i, is a set of nodes to be connected by means of a Steiner tree in L_n. For each net a_i, we are also given a set $\mathcal{A}_i$ of *allowed* trees that can be used for connecting the nodes in that set. A solution to the problem is a set $\mathcal{T}$ of trees $\{T_i \in \mathcal{A}_i : 1 \leq i \leq m\}$. The *width* of solution $\mathcal{T}$ is the maximum, over all edges e, of the number of trees in $\mathcal{T}$ that contain the edge. The goal of the VLSI routing problem is to determine a solution with minimum width.

Definition 2 In the **Multicommodity Flow Congestiom Minimization** problem (or simply, the Congestion Minimization problem), we are given a graph $G = (V, E)$, and a set of source-destination pairs $\{(s_i, t_i) : 1 \leq i \leq k\}$. For each pair (s_i, t_i), we would like to route one unit of demand from s_i to t_i. A solution to the problem is a set $\mathcal{P} = \{P_i : 1 \leq i \leq k\}$ such that P_i is a path from s_i to t_i in G. We define the *congestion* of $\mathcal{P}$ to be the maximum, over all edges e, of the number of paths containing e. The goal of the undirected multicommodity flow problem is to determine a path set $\mathcal{P}$ with minimum congestion.

In their original work [14], Raghavan and Thompson studied the above problem for the case of undirected graphs and referred to it as the Undirected Multicommodity Flow problem. Here, we adopt the more commonly-used term of Congestion Minimization and consider both undirected and directed graphs since the results of [14] apply to both classes of graphs. Researchers have studied a number of variants of the multicommodity flow problem, which differ in various aspects of the problem such as the nature of demands (e.g., uniform vs. non-uniform), the objective function (e.g., the total flow vs. the maximum fraction of each demand), and edge capacities (e.g., uniform vs. non-uniform).

Definition 3 In the **Hypergraph Simple k-Matching** problem, we are given a hypergraph H over an n-element vertex set V. A k-matching of H is a set M of edges such that each vertex in V belongs to at most k of the edges in M. A k-matching M is simple if no edge in H occurs more than once in M. The goal of the problem is to determine a maximum-size simple k-matching of a given hypergraph H.

Key Results

Raghavan and Thompson present approximation algorithms for the above three problems using randomized rounding. In each case, the algorithm is easy to present: write a 0-1 integer linear program for the problem, solve the rational relaxation of this program, and then apply randomized rounding. They establish bounds on the quality of the solutions (i.e., the approximation ratios of the algorithm) using Chernoff–Hoeffding bounds on the tail of the sums of bounded and independent random variables [5, 11].

The VLSI Routing problem can be easily expressed as a 0-1 integer linear program, say Π_1. Let W^* denote the width of the optimum solution to the rational relaxation of Π_1.

Theorem 1 *For any ε such that $0 < \varepsilon < 1$, the width of the solution produced by randomized rounding does not exceed*

$$W^* + \left[3W^* \ln \frac{2n(n-1)}{\varepsilon}\right]^{1/2}$$

with probability at least $1 - \varepsilon$, provided $W^* \geq 3\ln(2n(n-1)/\varepsilon)$.

Since W^* is a lower bound on the width of an optimum solution to Π_1, it follows that the randomized rounding algorithm has an approximation ratio of $1 + o(1)$ with high probability as long as W^* is sufficiently large.

The Congestion Minimization problem can be easily expressed as a 0-1 integer linear program, say Π_2. Let C^* denote the congestion of the optimum solution to the linear relaxation of Π_2. This optimum solution yields a set of flows, one for each commodity i. The flow for commodity i can be decomposed into a set Γ_i of at most $|E|$ paths from s_i to t_i. The randomized rounding algorithm selects, for each commodity i, one path P_i at random from Γ_i according to the flow values determined by the flow decomposition.

Theorem 2 *For any ε such that $0 < \varepsilon < 1$, the capacity of the solution produced by randomized rounding does not exceed*

$$C^* + \left[3C^* \ln \frac{|E|}{\varepsilon}\right]^{1/2}$$

with probability at least $1 - \varepsilon$, provided $C^* \geq 2\ln|E|$.

Since C^* is a lower bound on the width of an optimum solution to Π_1, it follows that the randomized rounding algorithm achieves a constant approximation ratio with probability $1 - 1/n$ when C^* is $\Omega(\log n)$.

For both the VLSI Routing and the Congestion Minimization problems, slightly worse approximation ratios are achieved if the lower bound condition on W^* and C^*, respectively, is removed. In particular, the approximation ratio achieved is $O(\log n/\log\log n)$ with probability at least $1 - n^{-c}$ for a constant $c > 0$ whose value depends on the constant hidden in the big-Oh notation.

The hypergraph k-matching problem is different than the above two problems in that it is a packing problem with a maximization objective while the latter are covering problems with a minimization objective. Raghavan and Thompson show that randomization rounding, in conjunction with a scaling technique, yields good approximation algorithms for the hypergraph k-matching problem. They first express the matching problem as a 0-1 integer linear program, solve its rational relaxation Π_3, and then round the optimum rational solution by using appropriately scaled values of the variables as probabilities. Let S^* denote the value of the optimum solution to Π_3.

Theorem 3 *Let δ_1 and δ_2 be positive constants such that $\delta_2 > n \cdot e^{-k/6}$ and $\delta_1 + \delta_2 < 1$. Let $\alpha = 3\ln(n/\delta_2)/k$ and*

$$S' = S^*\left(1 - \frac{(\alpha^2 + 4\alpha)^{1/2} - \alpha}{2}\right).$$

Then, there exists a simple k-matching for the given hypergraph with size at least

$$S' - \left(2S' \ln \frac{1}{\delta_1}\right)^{1/2}.$$

Note that the above result is stated as an existence result. It can be modified to yield a randomized algorithm that achieves essentially the same bound with probability $1 - \varepsilon$ for a given failure probability ε.

Applications

Randomized rounding has found applications for a wide range of combinatorial optimization problems. Following the work of Raghavan and Thompson [14], Goemans and Williamson showed that randomized rounding yields an $e/(e-1)$-approximation algorithm for MAXSAT, the problem of finding an assignment that satisfies the maximum number of clauses of a given Boolean formula [7]. For the set cover problem, randomized rounding yields an algorithm with an asymptotically optimal approximation ratio of $O(\log n)$, where n is the number of elements in the given set cover instance [10]. Srinivasan has developed more sophisticated randomized rounding approaches for set cover and more general covering and packing problems [15]. Randomized rounding also yields good approximation algorithms for several flow and cut problems, including variants of undirected multicommodity flow [9] and the multiway cut problem [4].

While randomized rounding provides a unifying approach to obtain approximation algorithms for hard optimization problems, better approximation algorithms have been designed for specific problems. In some cases, randomized rounding has been combined with other algorithms to yield better approximation ratios than previously known. For instance, Goemans and Williamson showed that the better of two solutions, one obtained by randomized rounding and the other obtained by an earlier algorithm due to Johnson, yields a 4/3 approximation for MAXSAT [7].

The work of Raghavan and Thompson applied randomized rounding to a solution obtained for the relaxation of a 0-1 integer program for a given problem. In recent years, more sophisticated approximation algorithms have been obtained by applying randomized rounding to semidefinite program relaxations of the given problem. Examples include the 0.87856-approximation algorithm for MAXCUT due to Goemans and Williamson [8] and an $O(\sqrt{\log n})$-approximation algorithm for the sparsest cut problem, due to Arora, Rao, and Vazirani [3].

An excellent reference for the above and other applications of randomized rounding in approximation algorithms is the text by Vazirani [16].

Open Problems

While randomized rounding has yielded improved approximation algorithms for a number of NP-hard optimization problems, the best approximation achievable by a polynomial-time algorithm is still open for most of the problems discussed in this article, including MAXSAT, MAXCUT, the sparsest cut, the multiway cut, and several variants of the congestion minimization problem. For directed graphs, it has been shown that best approximation ratio achievable for congestion minimization in polynomial time is $\Omega(\log n / \log\log n)$, unless NP $\subset$ ZPTIME($n^{O(\log\log n)}$), matching the upper bound mentioned in section "Key Results" up to constant factors [6]. For undirected graphs, the best known inapproximability lower bound is $\Omega(\log\log n / \log\log\log n)$ [2].

Randomized Searching on Rays or the Line

Stephen R. Tate
Department of Computer Science, University of North Carolina, Greensboro, NC, USA

Keywords

Cow-path problem; Online navigation

Years and Authors of Summarized Original Work

1993; Kao, Reif, Tate

Problem Definition

This problem deals with finding a point at an unknown position on one of a set of w rays which extend from a common point (the origin). In this problem there is a *searcher*, who starts at the origin, and follows a sequence of commands such as "explore to distance d on ray i." The searcher detects immediately when the target point is crossed, but there is no other information provided from the search environment. The goal of the searcher is to minimize the distance traveled.

There are several different ways this problem has been formulated in the literature, including one called the "cow-path problem" that involves a cow searching for a pasture down a set of paths. When $w = 2$, this problem is to search for a point on the line, which has also been described as a robot searching for a door in an infinite wall or a shipwreck survivor searching for a stream after washing ashore on a beach.

Notation

The problem is as described above, with w rays. The position of the target point (or goal) is denoted (g, i) if it is at distance g on ray $i \in \{0, 1, \ldots, w-1\}$. The standard notion of *competitive ratio* is used when analyzing algorithms for this problem: An algorithm that knows which ray the goal is on will simply travel distance g down that ray before stopping, so search algorithms are compared to this optimal, omniscient strategy.

In particular, if $\mathcal{R}$ is a randomized algorithm, then the distance traveled to find a particular goal position is a random variable denoted *distance* $(\mathcal{R}, (g, i))$, with expected value $E[\text{distance}(\mathcal{R}, (g, i))]$. Algorithm $\mathcal{R}$ has competitive ratio c if there is a constant a such that, for all goal positions (g, i),

$$E[\text{distance}(\mathcal{R}, (g, i))] \leq c.g + a. \quad (1)$$

Key Results

This problem is solved optimally using a randomized geometric sweep strategy: Search through the rays in a random (but fixed) order, with each search distance a constant factor longer than the preceding one. The initial search distance is picked from a carefully selected probability distribution, giving the following algorithm:

RAYSEARCH $_{r,w}$
$\sigma \leftarrow$ A random permutation of $\{0,1,2,\ldots,w-1\}$;
$\epsilon \leftarrow$A random real uniformly chosen from $[0,1)$;
$d \leftarrow r^{\epsilon}$;
$p \leftarrow 0$;
repeat
Explore path $\sigma(p)$ up to distance d;
if goal not found then return to origin;
$d \leftarrow d \cdot r$;
$p \leftarrow (p+1) \bmod w$;
until goal found;

The following theorems give the competitive ratio of this algorithm, show how to pick the best r, and establish the optimality of the algorithm.

Theorem 1 ([9]) *For any fixed $r > 1$, Algorithm* RAYSEARCH $_{r,w}$ *has competitive ratio*

$$R(r,w) = 1 + \frac{2}{w} \cdot \frac{1 + r + r^2 + \cdots + r^{w-1}}{\ln r},$$

Theorem 2 ([9]) *The unique solution of the equation*

$$\ln r = \frac{1 + r + r^2 + \cdots + r^{w-1}}{r + 2r^2 + 3r^3 + \cdots + (w-1)r^{w-1}} \tag{2}$$

for $r > 1$, denoted by r_w^*, gives the minimum value for $R(r,w)$.

Theorem 3 ([8, 9, 12]) *The optimal competitive ratio for any randomized algorithm for searching on w rays is*

$$\min_{r>1} \left\{ 1 + \frac{2}{w} \cdot \frac{1 + r + r^2 + \cdots + r^{w-1}}{\ln r} \right\}.$$

Corollary 1 *Algorithm* RAYSEARCH $_{r,w}$ *is optimally competitive.*

Using Theorem 2 and standard numerical techniques, $r_w{}^*$ can be computed to any required degree of precision. The following table shows, for small values of w, approximate values for $r_w{}^*$ and the corresponding optimal competitive ratio (achieved by RAYSEARCH$_{r,w}$) – the optimal deterministic competitive ratio (see [1]) is also shown for comparison (Table 1):

Theorem 4 ([9]) *The competitive ratio for algorithm* RAYSEARCH $_{r,w}$ *(with $r = r_w{}^*$) is $\kappa w + o(w)$, where*

$$k = \min_{s>0} \left[2\frac{e^s - 1}{s^2} \right] \approx 3.088.$$

Applications

The most direct applications of this problem are in geometric searching, such as robot navigation problems. For example, when a robot is traveling in an unknown area and encounters an obstacle, a typical first step is to find the nearest corner to go around [2, 3], which is just an instance of the ray searching problem (with $w = 2$).

In addition, any abstract search problem with a cost function that is linear in the distance to the goal reduces to ray searching. This includes applications in artificial intelligence that search for a goal in a largely unknown search space

Randomized Searching on Rays or the Line, Table 1 The asymptotic growth of the competitive ratio with w is established in the following theorem

w	r_w^*	Optimal randomized ratio	Optimal deterministic ratio

[11] and the construction of hybrid algorithms [8]. In hybrid algorithms, a set of algorithms $A_1, A_2, \ldots, A_w$ for solving a problem is considered – algorithm A_1 is run for a certain amount of time, and if the algorithm is not successful algorithm A_1 is stopped and algorithm A_2 is started, repeating through all algorithms as many times as is necessary to find a solution. This notion of hybrid algorithms has been used successfully for several problems (such as the first competitive algorithm for the online k-server problem [4]), and the ray search algorithm gives the optimal strategy for selecting the trial running times of each algorithm.

Open Problems

Several natural extensions of this problem have been studied in both deterministic and randomized settings, including ray searching when an upper bound on the distance to the goal is known (i.e., the rays are not infinite but are line segments) [5, 10, 12], or when a probability distribution of goal positions is known [7]. Other variations of this basic searching problem have been studied for deterministic algorithms only, such as when the searcher's control is imperfect (so distances cannot be specified precisely) [6] and for more general search spaces like points in the plane [1]. A thorough study of these variants with randomized algorithms remains an open problem.

Problem Definition

We use the abstract tile assembly model of Winfree [6], which models the aggregation of monomers called *tiles* that attach one at a time to a growing structure, starting from a single *seed* tile, in which bonds ("glues") on the tile are specific (glues only stick to glues of the same type on other tiles) and cooperative (so that multiple weak glues are necessary to attach a tile). The general idea of *randomized* self-assembly is to use the inherent randomness of self-assembly to help the assembly process. If multiple types of tiles are able to bind to a single binding site, then we assume that their relative concentrations determine the probability that each succeeds. With careful design, we can use the same tile set to create different structures, by changing the concentrations to affect what is likely to assemble. Another use of randomness is in reducing the number of different tile types required to assemble a shape.

Definitions

A *shape* is a finite, connected subset of $\mathbb{Z}^2$. A *tile type* is a unit square with four sides, each side consisting of a *glue label* (finite string) and a non-negative integer *strength*. We assume a finite set T of tile types, but an infinite number of copies of each tile type, each copy referred to as a *tile*. An *assembly* is a positioning of tiles on the integer lattice $\mathbb{Z}^2$; i.e., a partial function $\alpha : \mathbb{Z}^2 \dashrightarrow T$. Write $\alpha \sqsubseteq \beta$ to denote that α is a *subassembly* of β, which means that $\mathrm{dom}\ \alpha \subseteq \mathrm{dom}\ \beta$ and $\alpha(p) = \beta(p)$ for all points $p \in \mathrm{dom}\ \alpha$. In this case, say that β is a *superassembly* of α. Two adjacent tiles in an assembly *interact* if the glue labels on their abutting sides are equal and have positive strength. Each assembly induces a *binding graph*, a grid graph whose vertices are tiles, with an edge between two tiles if they interact. The assembly is τ-*stable* if every cut of its binding graph has strength at least τ, where the weight of an edge is the strength of the glue it represents (energy τ is required to separate the assembly). The τ-*frontier* $\partial^\tau \alpha \subset \mathbb{Z}^2 \setminus \mathrm{dom}\ \alpha$ of α (or *frontier* $\partial\alpha$ when τ is clear from context) is the set of empty locations adjacent to α at which a single tile could bind stably.

A *tile system* is a triple $\mathcal{T} = (T, \sigma, \tau)$, where T is a finite set of tile types, $\sigma : \mathbb{Z}^2 \dashrightarrow T$ is a *seed assembly* consisting of a single tile (i.e., $|\mathrm{dom}\ \sigma| = 1$), and $\tau \in \mathbb{N}$ is the *temperature*. An assembly α is *producible* if either $\alpha = \sigma$ or if β is a producible assembly and α can be obtained from β by the stable binding of a single tile. In this case, write $\beta \to_1 \alpha$ (α is producible from β by the attachment of one tile), and write $\beta \to \alpha$ if $\beta \to_1^* \alpha$ (α is producible from β by the attachment of zero or more tiles). If α is producible, then there is an *assembly sequence* $\boldsymbol{\alpha} = (\alpha_i \mid 1 \leq i \leq k)$ such that $\alpha_1 = \sigma$, $\alpha_k = \alpha$, and, for each $i \in \{1, \ldots, k-1\}$, $\alpha_i \to_1 \alpha_{i+1}$. An assembly is *terminal* if no tile can be τ-stably attached to it. Write $\mathcal{A}[\mathcal{T}]$ to denote the set of all producible assemblies of $\mathcal{T}$, and write $\mathcal{A}_\square[\mathcal{T}]$ to denote the set of all producible, terminal assemblies of $\mathcal{T}$. We also speak of *shapes* assembled by tile assembly systems, by which we mean $\mathrm{dom}\ \alpha$ if $\alpha \in \mathcal{A}_\square[\mathcal{T}]$, and we consider shapes to be equivalent up to translation.

We now define the semantics of incorporating randomization into self-assembly. Intuitively, there are two sources of nondeterminism in the model as defined: (1) if $|\partial\alpha| > 1$, then there are multiple binding sites, one of which is nondeterministically selected as the next site to receive a tile, and (2) if multiple tile types could bind to a *single* binding site, then one of them is nondeterministically selected. Both concepts are handled by assigning positive real-valued concentrations to each tile type; Ref. [3] gives a full definition that accounts for both of these. However, in the results we discuss, only the latter source of nondeterminism will actually af-

fect the probabilities of various terminal assemblies being produced; the binding sites themselves can be picked in an arbitrary order without affecting these probabilities. Thus we state here a simpler definition based on this assumption.

A *tile concentration assignment* on $\mathcal{T}$ is a function $\rho : T \to [0, \infty)$. If $\rho(t)$ is not specified explicitly for some $t \in T$, then $\rho(t) = 1$. If α is a τ-stable assembly such that $t_1, \ldots, t_j \in T$ are the tiles capable of binding to the same position $\mathbf{m} \in \partial\alpha$, then for $1 \leq i \leq j$, t_i binds at position $\mathbf{m}$ with probability $\frac{\rho(t_i)}{\rho(t_1)+\cdots+\rho(t_j)}$. ρ induces a probability measure on $\mathcal{A}_\square[T]$ in a straightforward way. Formally, let $\alpha \in \mathcal{A}_\square[T]$ be a producible terminal assembly. Let $A(\alpha)$ be the set of all assembly sequences $\boldsymbol{\alpha} = (\alpha_i \mid 1 \leq i \leq k)$ such that $\alpha_k = \alpha$, with $p_{\boldsymbol{\alpha},i}$ denoting the probability of attachment of the tile added to α_{i-1} to produce α_i (noting that $p_{\boldsymbol{\alpha},i} = 1$ if the ith tile attached without contention). Then $\Pr[\alpha] = \sum_{\boldsymbol{\alpha} \in A(\alpha)} \prod_{i=2}^{k} \frac{1}{|\partial\alpha_i|} p_{\boldsymbol{\alpha},i}$. Write $\mathcal{T}(\rho)$ to denote the random variable representing the producible, terminal assembly produced by $\mathcal{T}$ when using tile concentration assignment ρ.

Problems

The general problem is this: given a shape $X \subset \mathbb{Z}^2$ (a connected, finite set), set the concentrations of tile types in some tile system $\mathcal{T}$ so that $\mathcal{T}$ is likely to create a terminal assembly with shape X or "close to it." We now state formal problems that are variations on this theme. The first four problems use "concentration programming": varying the concentrations of tile types in a single tile system $\mathcal{T}$ to get it to assemble different shapes. The last two problems concern a tile system that only does one thing – assemble a line of a desired expected length – because in this setting we will require all concentrations to be equal. However, the tile system uses randomized self-assembly to do this with far fewer tile types than are needed to accomplish the same task in a deterministic tile system.

The first three problems concern the self-assembly of squares, and the problems are listed in order of increasing difficulty. The first asks for a square with a desired expected width, the second for a guarantee that the actual width is likely to be *close* to the expected width, and finally, for a guarantee that the actual width is likely to be *exactly* the expected width.

Formally, design a tile system $\mathcal{T} = (T, \sigma, \tau)$ such that, for any $n \in \mathbb{Z}^+$, there exists a tile concentration assignment $\rho : T \to [0, \infty)$ such that…

Problem 1 …dom $\mathcal{T}(\rho)$ is a square with expected width n.

Problem 2 …with probability at least $1 - \delta$, dom $\mathcal{T}(\rho)$ is a square whose width is between $(1 - \epsilon)n$ and $(1 + \epsilon)n$.

Problem 3 …with probability at least $1 - \delta$, dom $\mathcal{T}(\rho)$ is a square of width n.

The next problem generalizes the previous problems to arbitrary shapes, while making one relaxation: allowing a scaled-up version of a shape to be assembled instead of the exact shape. Formally, for $c \in \mathbb{Z}^+$ and shape $S \subset \mathbb{Z}^2$ (finite and connected), define $S^c = \left\{ (x, y) \in \mathbb{Z}^2 \;\middle|\; (\lfloor x/c \rfloor, \lfloor y/c \rfloor) \in S \right\}$ to be S *scaled by factor* c.

Problem 4 Let $\delta > 0$. Design a tile system $\mathcal{T} = (T, \sigma, \tau)$ such that, for any shape $S \subset \mathbb{Z}^2$, there exists a tile concentration assignment $\rho : T \to [0, \infty)$ and $c \in \mathbb{Z}^+$ so that, with probability at least $1 - \delta$, dom $\mathcal{T}(\rho)$ is S^c.

It is easy to see that for a deterministic tile system to assemble a length n, height 1 line requires n tile types. The next problem concerns using randomization to reduce the number of tile types required, subject to the constraint that all tile type concentrations are equal. (Without this constraint, a solution to Problem 1 would trivially be a solution to the next problem, with optimal $O(1)$ tile types, but since the solution to Problem 1 uses different tile type concentrations to achieve its goal, it cannot be used directly for this purpose.)

Problem 5 Let $n \in \mathbb{Z}^+$. Design a tile system $\mathcal{T} = (T, \sigma, \tau)$ such that, with tile concentration

assignment $\rho : T \to [0, \infty)$ defined by $\rho(t) = 1$ for all $t \in T$, dom $\mathcal{T}(\rho)$ is a height 1 line of expected length n.

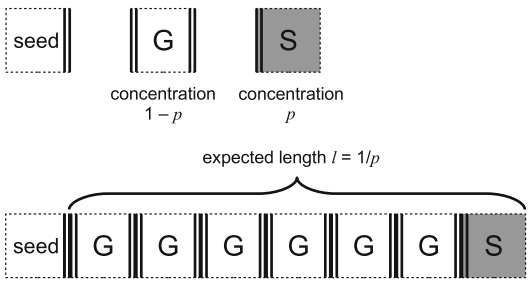
As with the case of concentration programming, it is desirable for the line to have length likely to be close to its expected length.

Problem 6 Let $n \in \mathbb{Z}^+$ and $\delta, \epsilon > 0$. Design a tile system $\mathcal{T} = (T, \sigma, \tau)$ such that, with tile concentration assignment $\rho : T \to [0, \infty)$ defined by $\rho(t) = 1$ for all $t \in T$, dom $\mathcal{T}(\rho)$ is a height 1 line whose length is between $(1 - \epsilon)n$ and $(1 + \epsilon)n$ with probability at least $1 - \delta$.

Key Results

The solutions to Problems 1–4 use temperature 2 tile systems. The solutions to Problems 5 and 6 use a temperature 1 tile system (there is no need for cooperative binding in one dimension).

Figure 1 shows a simple tile system with three tile types that can grow a line of any desired expected length to the right of the seed tile; this is the basis for the solutions to Problems 1–4. The length of the line has a geometric distribution, with expected value controlled by the ratio of the concentrations of G and S. Figure 2 shows the solution to Problem 1, due to Becker, Remilá, and Rapaport [1]. It is essentially the tile system from Fig. 1 (tile types A and B are analogous to G and S in Fig. 1) augmented with a constant number of extra tiles that can assemble the square to be as high as the line is long.



Randomized Self-Assembly, Fig. 1 A randomized temperature $\tau = 2$ tile system that can grow a line of any desired expected length l by setting $p = \frac{1}{l}$. Two tiles compete nondeterministically to bind to the right of the line (using strength 2 glues, indicated by *double black lines*), one of which stops the growth, while the other continues, giving the length of the line (not counting the seed) a geometric distribution with expected value l

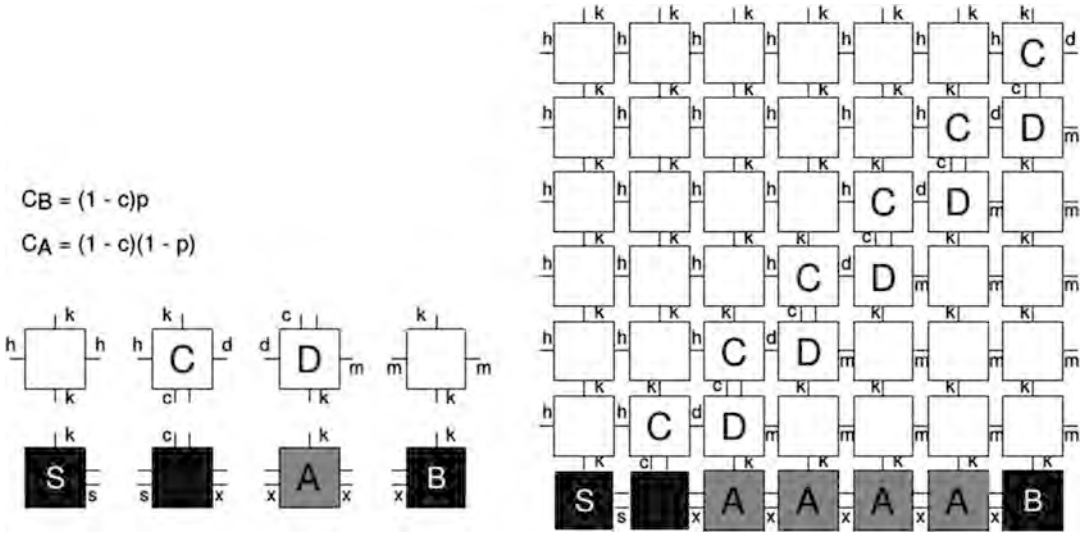
Kao and Schweller [4] showed a solution to Problem 2, and Doty [3] improved their construction to show a solution to Problem 3. Here, we describe only the latter construction, since the two share similar ideas, and the latter construction solves both problems.

Figure 3 shows an improvement to the tile system of Fig. 1, which will be the starting point for the solution. It also can grow a line of any desired expected length. However, by using multiple independent "stages" of growth, each stage having a geometric distribution, the resulting assembly is more likely to have a length that is close to its expected length. More tile types are needed for more stages, but only a constant number of stages are required.

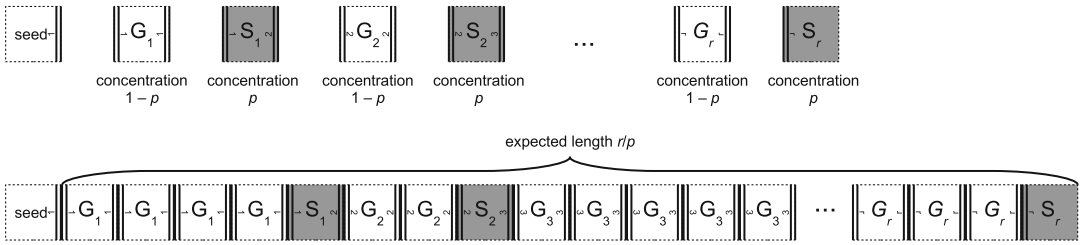
In particular, if the expected length is chosen to be midway between any two consecutive powers of two, i.e., midway in the interval $[2^{a-1}, 2^a)$ for arbitrary $a \in \mathbb{N}$, with $r = 113$ stages, the probability is at most 0.0025 that the actual length is outside the interval $[2^{a-1}, 2^a)$. So although the length is not controlled with exact precision, the number of bits needed to represent the length is controlled with exact precision (with high probability), using a constant number of tile types.

Figure 4 shows a tile system $\mathcal{T}$ with the following property: for any bit string s (equivalently, any natural number m if we assume the most significant bit of s is 1), there is a tile concentration assignment that causes $\mathcal{T}$ to grow an assembly of height $O(\log m)$, width $O(m^2)$, such that the tile types in the upper-right corner of the assembly encode s. The bottom row is the tile system from Fig. 3, with identical strength 2 glues on the north of the tiles (other than the final stop tile on the right).

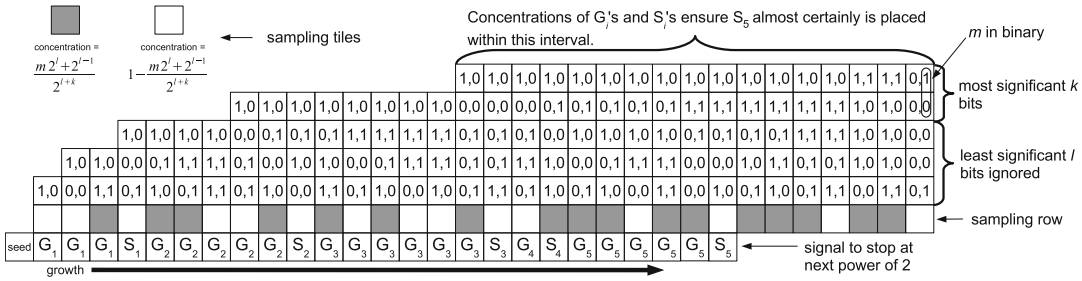
Figure 5 shows a high-level overview of the entire tile system that assembles an $n \times n$ square, solving Problem 3. Using similar ideas to Fig. 4, one can encode three different numbers $m_1, m_2, m_3 \in \mathbb{N}$ into the tile concentrations. We choose these numbers to be such that each $m_i = O(n^{1/3})$, and each of their binary



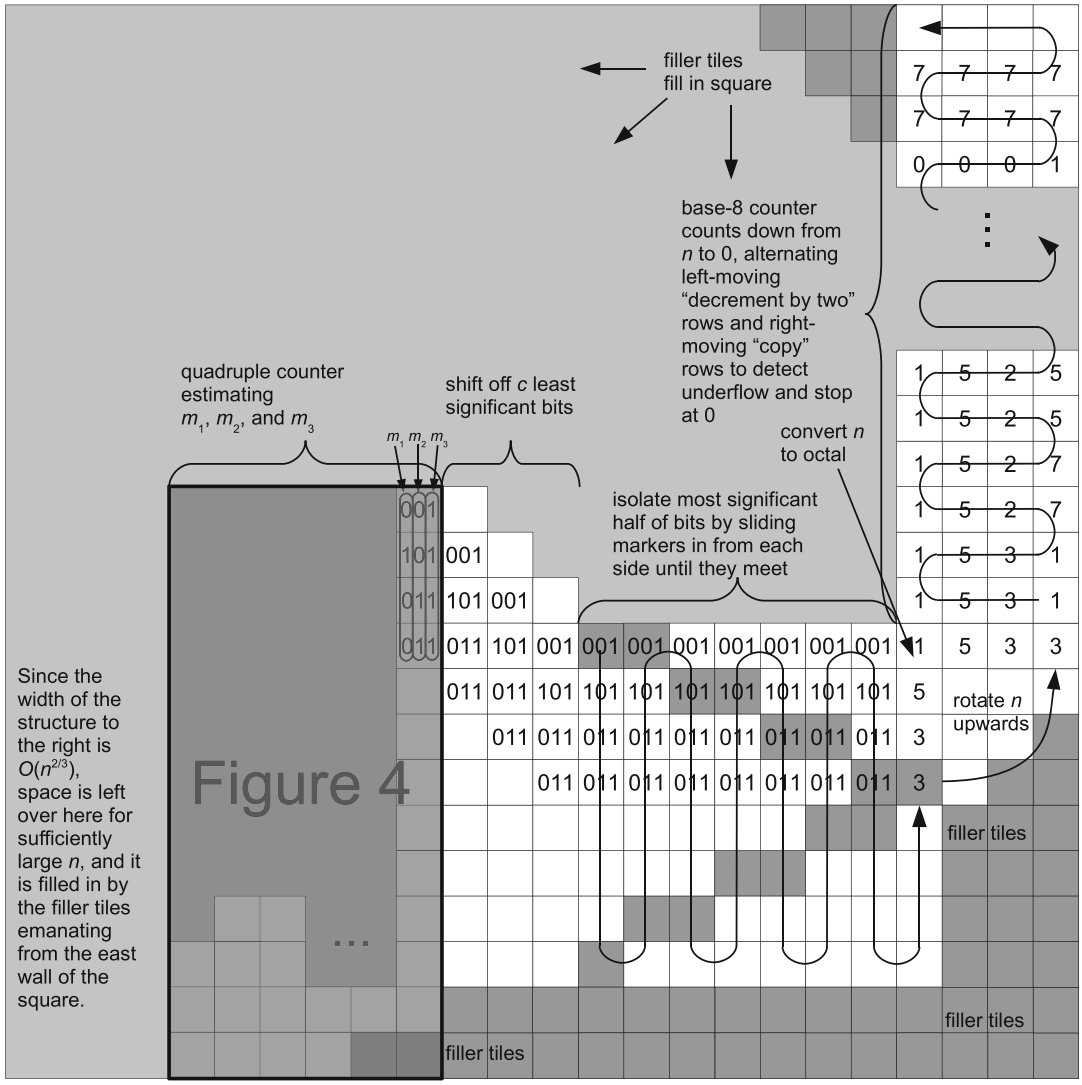
Randomized Self-Assembly, Fig. 2 A tile system that grows a square of any desired expected width (Figure taken from [4]); strength 2 glues are indicated by *two lines* between the tiles. The seed is labeled S, and C_A and C_B respectively represent the concentrations of A and B. p is used the same way as in Fig. 1, and c represents total concentration of all other tile types, since [4] assumed that concentrations of all tile types must sum to 1



Randomized Self-Assembly, Fig. 3 A tile system that grows a line of a given length with greater precision than in Fig. 1. r stages each have expected length $1/p$, making the expected total length r/p, but more tightly concentrated about that expected length than in the case of one stage

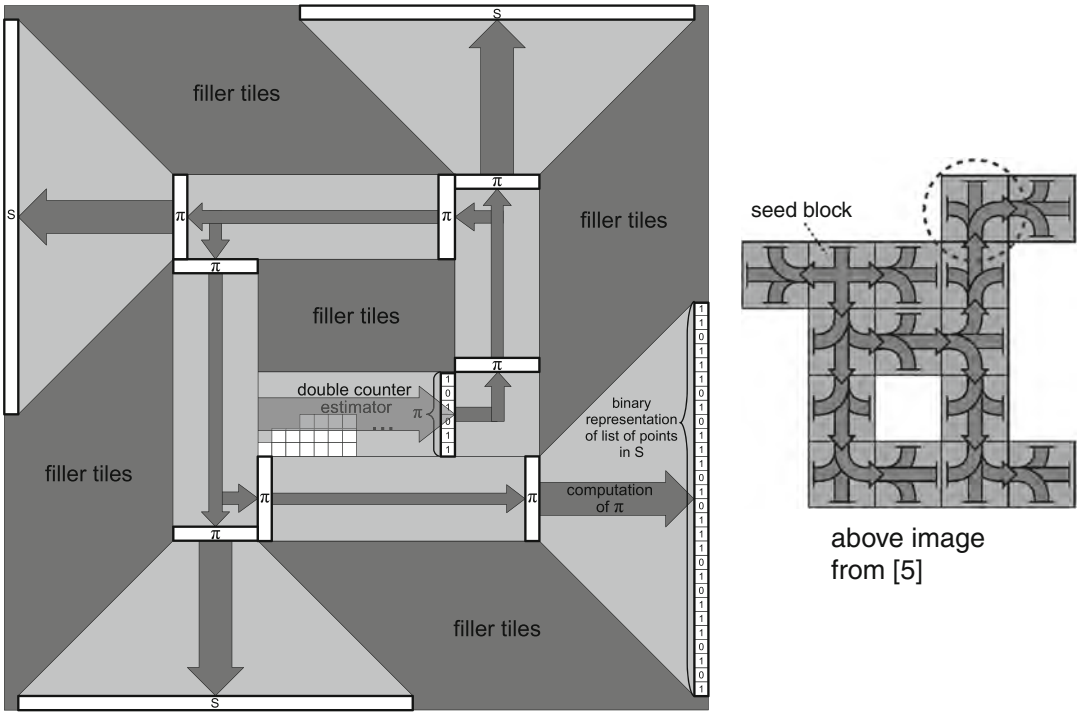


Randomized Self-Assembly, Fig. 4 Computing the binary string 10 (equivalently, the natural number $m = 2$) from tile concentrations. For brevity, glue strengths and labels are not shown. Each column increments the primary counter, represented by the bits on the left of each tile, and each *gray tile* increments the sampling counter, represented by the bits on the right of each tile. The number of bits at the end is $l + k$, where c is a constant coded into the tile set and k depends on m, and $l = k+c$. The most significant k bits of the sampling counter encode m. In this example, $k = 2$ and $c = 1$



Randomized Self-Assembly, Fig. 5 High-level overview of the entire construction solving Problem 3, not at all to scale. For brevity, glue strengths and labels are not shown. The double counter number estimator of Fig. 4 is embedded with two additional counters to create a quadruple counter estimating m_1, m_2, and m_3, shown as a box labeled as "Fig. 4" in the above figure. In this example, $m_1 = 4$, $m_2 = 3$, and $m_3 = 15$, represented vertically in binary in the most significant 4 tiles at the end of the quadruple counter. Concatenating the bits of the tiles results in the string 001101011011, the binary representation of 859, which equals $n - 2k - 4$ for $n = 871$, so this example builds an 871×871 square. Once the counter ends, c tiles ($c = 3$ in this example) are shifted off the bottom, and the top half of the tiles are isolated ($k = 4$ in this example). Each remaining tile represents 3 bits of n, which are converted into octal digits, rotated to face upwards, and then used to initialize a base-8 counter that builds the east wall of the square. Filler tiles cover the remaining area of the square

expansions, interwoven into a single bit string, is the binary expansion of n. Then each tile at the upper right of Fig. 4 encodes not one but 3 bits of n, or equivalently each encodes an octal digit of n. These bits are then used to assemble a counter that counts from n down to 0 as it grows north, and a constant set of tiles (similar to Fig. 2) expand this counter to grow about as far east as the counter grows north, creating an $n \times n$ square that surrounds the assembly of Fig. 4.



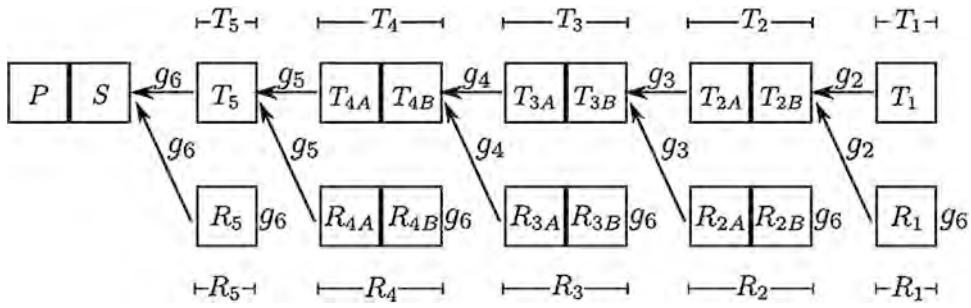
Randomized Self-Assembly, Fig. 6 On the *left* is the seed block used to replace the seed block of [5], from which the construction of [5] can assemble a scaled version of the shape S (encoded by a binary string representing the list of coordinates, also labeled "S" in the figure). S is output by the single-tape Turing machine program π. π is estimated from tile concentrations as in Fig. 4, then four copies of it are propagated to each side of the block, where it is executed in four rotated, but otherwise identical, computation regions. When completed, four copies of the binary representation of S border the seed block, which is sufficient for the construction of [5] to assemble a scaled version of S using a spanning tree of S as shown on the *right*

Since $m_i = O(n^{1/3})$, and the tiles of Fig. 4 create a structure of height $O(\log m_i)$ and width $O(m_i^2) = O(n^{2/3})$, the square is sufficiently large to contain the tiles of Fig. 4.

Finally, the tiles of Fig. 4 are used in a different way to solve Problem 4, shown in Fig. 6. Given a finite shape S, Soloveichik and Winfree [5] use an intricate construction of a "seed block" that "unpacks," from a set of tile types that depend on S, a single-tape Turing machine program $\pi \in \{0,1\}^*$ that outputs a binary string bin(S) representing a list of the coordinates of S.

The width of the seed block is then c, chosen to be large enough to do the unpacking and also large enough to accommodate the simulation of π by a tile set that simulates single-tape Turing machines. Once this seed block is in place, a tile set then assembles the scaled shape by carrying bin(S) through each block. The order in which blocks are assembled is determined by a spanning tree of S, so that any blocks with an ancestor relationship have a dependency, in that the ancestor must be (mostly) assembled before the descendant, whereas blocks without an ancestor relationship can potentially assemble in parallel.

We replace the seed block tiles of [5], which depend on S, with a single tile system that produces the program π from tile concentrations, and use the remainder of the tile set of [5] unchanged. This is illustrated in Fig. 6. Choose c to be sufficiently large that π can be simulated within the trapezoidal region of the $c \times c$ block of Fig. 6 and also sufficiently large that the construction of Fig. 4 has sufficient room to estimate the binary string π from tile concentrations in the center region (the



Randomized Self-Assembly, Fig. 7 Example of solution to Problem 5 for the case of expected length 92

"double counter estimator") of Fig. 6. Once this is done, the construction of [5] can take over and assemble the entire scaled shape S^c. The portion of the construction of [5] that achieves this is a constant-size tile set, so combined with the presented construction remains constant. This solves Problem 4.

Finally, Problems 5 and 6 have solutions due to Chandran, Gopalkrishnan, and Reif [2], which we now explain intuitively (the actual analysis is a bit trickier but is close to the following intuitive argument). Figure 7 shows an example of a solution to Problem 5 for the case of expected length $n = 92$. Each T_{iB} tile type has an east glue, g_i, that matches two tile types $T_{(i-1)A}$ and $R_{(i-1)A}$. There are $O(\log n)$ "stages" (five stages in this case). Each stage has probability $\frac{1}{2}$ to either decrement the stage or reset back to the highest stage. The number n is programmed into the system by choosing each stage to have either 1 or 2 tiles. Given that we are in stage i, to make it from stage i to stage 1 without resetting means that i consecutive unbiased coin flips must come up "heads," which we expect to take 2^i flips before happening. Thus we expect stage i to appear 2^i times; this means that stage i's expected contribution to the total length is either 2^i or $2 \cdot 2^i$, depending on whether it has 1 or 2 tiles. The reason this works to encode arbitrary natural numbers n is that every natural number can be expressed as $n = \sum_{i=0}^{\approx \log n} b_i 2^i$, where $b_i \in \{1, 2\}$. Since there are a constant number of tile types per stage, this implies that the number of tile types required is $O(\log n)$.

This solves Problem 5. To solve Problem 6, it suffices to concatenate k independent assemblies of the kind shown in Fig. 7, where k is a constant that, if chosen sufficiently large based on δ (the desired error probability), solves Problem 6 since it increases the number of tile types required. In addition to proving that this works, Chandran, Gopalkrishnan, and Reif [2] also show a more complex construction with even sharper bounds on the probability that the length differs very much from its expected value.

Open Problems

The construction resolving Problem 3 shows that for every $\delta, \epsilon > 0$, a tile set exists such that, for every $n \in \mathbb{N}$, appropriately programming the tile concentrations results in the self-assembly of a structure of size $O(n^\epsilon) \times O(\log n)$ whose rightmost tiles represent the value n with probability at least $1-\delta$. (In the tile system described, $\epsilon = 2/3$, and it could be made arbitrarily close to 0 by estimating more than 3 numbers at once.) Is this optimal?

Formally, say that a tile assembly system $\mathcal{T} = (T, \sigma, 2)$ is *δ-concentration programmable* (for $\delta > 0$) if there is a (total) computable function $r : \mathcal{A}_\square[\mathcal{T}] \to \mathbb{N}$ (the *representation function*) such that, for each $n \in \mathbb{N}$, there is a tile concentration assignment $\rho : T \to [0, \infty)$ such that $\Pr[r(\mathcal{T}(\rho)) = n] \geq 1 - \delta$. In other words, $\mathcal{T}$, programmed with concentrations ρ, almost certainly self-assembles a structure that "represents" n, according to the representation

function r, and such a ρ can be found to create a high-probability representation of *any* natural number.

Question 1 Is the following statement true? For each $\delta > 0$, there is a tile assembly system $\mathcal{T}$ and a representation function $r : \mathcal{A}_{\square}[\mathcal{T}] \to \mathbb{N}$ such that $\mathcal{T}$ is δ-concentration programmable and, for each $\epsilon > 0$ and all but finitely many $n \in \mathbb{N}$, $\Pr[|\text{dom } \mathcal{T}(\rho)| < n^{\epsilon}] \geq 1 - \delta$. If so, what is the smallest bound that can be written in place of n^{ϵ}?

Problem Definition

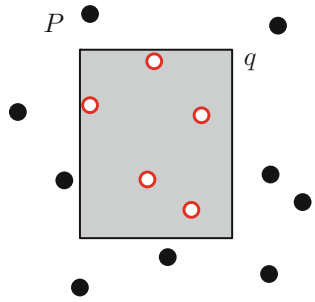
Generally speaking, data structures come in two types: those that represent data and those that allow efficient searching. The collection of results in the area of *range searching* belongs to the latter type. We distinguish two computation phases: during the *preprocessing phase*, data is stored in some suitable structure, so that during the *query phase*, all data that lies inside a query range can be found and reported efficiently.

In the most basic form of range searching, the data consists of points in a one-, two-, or higher-dimensional space, and the query range is a simple shape like a rectangle, triangle, or circle. Even for this basic form, there are many different data structures and corresponding query algorithms.

Problem 1 (Range Searching)

INPUT: Set P of n points in $\mathbb{R}^d$.
OUTPUT: Description of a data structure storing P and query algorithm that will report, for any given query d-rectangle (d-

simplex, d-sphere) q, all points of P that lie inside q.

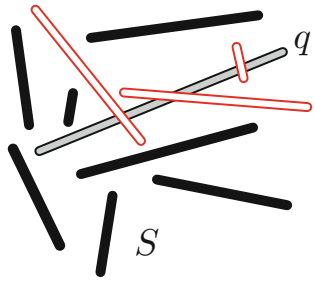


When the data is not a set of points but a set of more complex objects, such as line segments, triangles, circles, or other geometric shapes, we may not be interested in only the objects that lie completely within a query range but also all objects that *intersect* the range.

Problem 1 (Intersection Searching)

INPUT: *Set S of n non-crossing line segments in $\mathbb{R}^2$ (triangles in $\mathbb{R}^3$).*

OUTPUT: *Description of a data structure storing S and query algorithm that will report, for any given query line segment q, all line segments (triangles) of S that intersect q.*



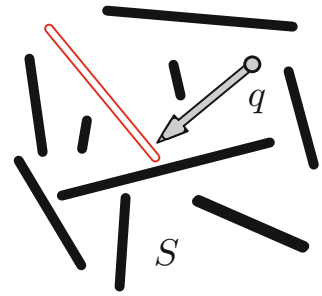
For both range searching and intersection searching, we may be interested in different types of queries. In a *counting query*, we report the number of objects in P or S that lie in the range or intersect the query object. A reporting query must spend time at least linear in the number of objects reported, whereas a counting query returns a single value. Usually, small variations of a data structure for reporting can be used for the counting version.

Ray shooting is closely related to intersection searching. We are not interested in all objects intersected by a line segment but only the first along a directed ray.

Problem 2 (Ray Shooting)

INPUT: *Set S of n non-crossing line segments in $\mathbb{R}^2$ (triangles in $\mathbb{R}^3$).*

OUTPUT: *Description of a data structure storing S and query algorithm that will report, for any given query point q and direction in $\mathbb{R}^2$ ($\mathbb{R}^3$), the first line segment (triangle) of S that is reached when q moves in the query direction.*



A combination of a data structure and a query algorithm forms a solution to a range-searching problem. The most important aspects of efficiency are the storage requirements of the data structure and the query time. Sometimes, preprocessing time and update time are also important. If the data structure is so large that it must be stored on background storage, I/O complexity becomes relevant.

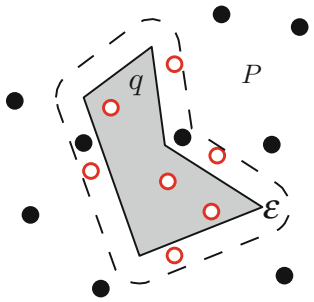
We can distinguish solutions with guaranteed efficiency and heuristics. The heuristic solutions used in practice nearly always have linear size but often have no guaranteed worst-case query time bounds. For example, R-trees [14] are among the most used data structures for range searching in practice.

One of the most interesting practical approaches for range searching with provable bounds is approximate range searching.

Problem 3 (Approximate Range Searching)

INPUT: *Set P of n points in $\mathbb{R}^d$.*

OUTPUT: *Description of a data structure storing P and query algorithm that will report, for any given query d-polyhedron q of constant complexity, all points of P that lie inside q, possibly but not necessarily some points that lie within distance ε from q, and no points that lie farther than ε from q.*



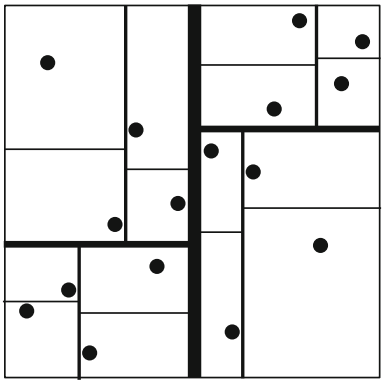
In this entry we concentrate on algorithmic results that have provable worst-case bounds for both the storage requirements and the query time.

Key Results

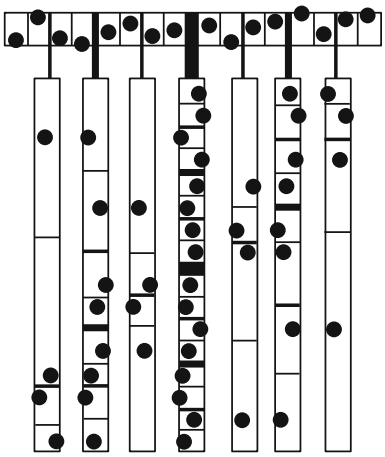
Orthogonal Range Searching

Range searching in one dimension is just searching in a sorted sequence of values. Standard binary search trees for one-dimensional searching can be extended in several ways to allow rectangular range-searching queries. For example, a *kd-tree* [4] is a balanced binary tree on a set of points in $\mathbb{R}^d$ that splits the point set on different coordinates in different nodes: the root splits on x_1-coordinate, its two children on x_2-coordinate, their four children on x_3-coordinate, and so on; after the splitting on the x_d-coordinate, the tree starts over by splitting on x_1-coordinate again. As soon as there is a single point left, it is stored in a leaf.

An *(orthogonal) range tree* [5, 10, 15] uses *associated structures*, a technique that has proved to be very powerful for solving various kinds of query problems. It refers to the fact that the structure has a main tree, and each internal node



v of the tree stores – besides two pointers to children – an extra pointer to a different data structure. Suppose that in the main tree, node v is root of a subtree storing a subset S_v of the whole set S. Then the associated structure of v also stores S_v, but in a different manner.



A range tree for a set S of points in d-space consists of a main tree that is a balanced binary search tree on x_d-coordinate. The leaves of the main tree store the points of S sorted on x_d-coordinate in the leaves. If $d > 1$, then each internal node v stores a pointer to a $(d-1)$-dimensional range tree that stores S_v restricted to their first $d-1$ coordinates.

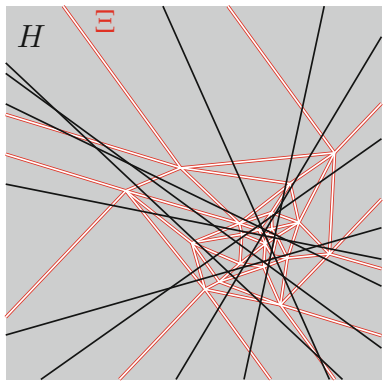
The performance of kd-trees and range trees is given in Table 1. To achieve the stated query time for range trees, an additional technique

called *fractional cascading* is needed [7]. The table also shows that in special cases, like 2-dimensional range queries in which one side of the query rectangle is unbounded (a 3-sided range), better results can be obtained using priority search trees. Other small improvements can be obtained, also depending on the machine model.

Simplex Range Searching

The range-searching problem with d-simplices is considerably harder than when the query shape is an axis-aligned d-box. There are two types of solutions: solutions with near-linear-size data structures and solutions with near-logarithmic query time. The results for d-simplex and d-half-space searching are given in Table 2.

Between the extremes of space-efficient data structures and query-efficient data structures, many other results "in between" can be obtained. For example, if for a problem in the plane one knows that a linear number of triangle range queries are needed, then one can use a data structure of size $O(n^{4/3})$ and query time close to $O(n^{1/3} + k)$, because this balances the preprocessing time (roughly the same as the size) and total query time (without the time for reporting) to something close to $O(n^{4/3})$.



A $(1/r)$-*cutting* of a set H of hyperplanes is a set Ξ of (relatively open) disjoint simplices covering $\mathbb{R}^d$ so that each simplex intersects at most n/r hyperplanes of H. Cutting trees are based on this concept. We state the main result on cuttings as a theorem, because it has implications to multidimensional divide-and-conquer schemes as well.

Theorem 1 ([6]) *Let H be a set of n hyperplanes and $r \leq n$ a parameter. Set $k = \lceil \log_2 r \rceil$. There exist k cuttings $\Xi_1, \ldots, \Xi_k$ so that Ξ_i is a $(1/2^i)$-cutting of size $O(2^{id})$, each simplex of Ξ_i is contained in a simplex of Ξ_{i-1}, and each simplex of Ξ_{i-1} contains a constant number of simplices of Ξ_i. Moreover, $\Xi_1, \ldots, \Xi_k$ can be computed in time $O(nr^{d-1})$.*

Data structures for range searching with curved boundaries can be obtained by linearization techniques. For example, range searching with a d-ball can be done by mapping each point $(x_1, \ldots, x_d)$ from the set to a point $(x_1, \ldots, x_d, x_1^2 + \cdots + x_d^2)$ in $\mathbb{R}^{d+1}$ and storing these points in a $(d+1)$-dimensional half-space range query structure. A d-ball with center $(b_1, \ldots, b_d)$ and radius r is mapped to the half-space $x_{d+1} \leq b_1(2x_1 - b_1) + \cdots + b_d(2x_d - b_d) + r^2$, and now the mapped points inside the mapped half-space correspond exactly to the original points inside the d-ball.

Intersection searching and ray shooting data structures are often based on the technique of associated structures mentioned before. Depending on the type of stored objects and the type of query objects (or query rays), different main trees and associated structures are combined into efficient solutions.

Approximate Range Searching

Many of the given data structures are not very useful in practice, especially in higher dimensions. One of the more interesting approaches toward a practical data structure for range searching that has performance guarantees is the approximate approach. The idea is that the query range is considered a shape with an inner boundary and a buffer zone around it. All points inside the inner boundary must be reported, all points outside the inner boundary but inside the buffer zone may

Range Searching, Table 1 Results on orthogonal range searching. n is the number of points stored and k is the number of points reported

Query range	Storage	Query time	Reference
d-box	$O(n)$	$O(n^{1-\frac{1}{d}} + k)$	kd-tree [4]
d-box	$O(n \log^{d-1} n)$	$O(\log^{d-1} n + k)$	Range tree [10]
3-sided rectangle	$O(n)$	$O(\log n + k)$	Priority search tree [13]

Range Searching, Table 2 Results on simplex and half-space range searching. n is the number of points stored, k is the number of points reported, c is some constant, and $\varepsilon > 0$ is an arbitrarily small constant

Query range	Storage	Query time	Reference
d-simplex	$O(n)$	$O(n^{1-\frac{1}{d}} + k)$	Partition trees [11]
d-simplex	$O(n^{d+\varepsilon})$	$O(\log n + k)$	Cutting trees [8]
d-half-space	$O(n \log \log n)$	$O(n^{1-\frac{1}{\lfloor d/2 \rfloor}} \log^c n + k)$	[12]
d-half-space	$O(n^{\lfloor d/2 \rfloor} \log^c n)$	$O(\log n + k)$	[2, 12]

but need not be reported, and all points outside the buffer zone may not be reported. A query will specify the inner boundary and a distance to the inner boundary that is the width of the buffer zone.

Assuming that the inner boundary has constant complexity and the buffer zone has width $\varepsilon \cdot D$, where D is the diameter of the inner boundary (ε is any positive constant), an approximate range query can be answered in $O(\log n + 1/\varepsilon^d)$ time, where d is the dimension of the space [3]. When the inner boundary is convex, the query time can be improved slightly.

Problem Definition

Given a static bit string $\boldsymbol{b} = b_1 \ldots b_m$, the objective is to preprocess $\boldsymbol{b}$ and to create a space-efficient data structure that supports the following operations rapidly:

$\mathsf{rank}_1(i)$ takes an index i as input, $1 \leq i \leq m$, and returns the number of **1**s among $b_1 \ldots b_i$.
$\mathsf{select}_1(i)$ takes an index $i \geq 1$ as input and returns the position of the i-th **1** in $\boldsymbol{b}$, and -1 if i is greater than the number of **1**s in $\boldsymbol{b}$.

A data structure that supports the operations above will be called a *bit vector*. The operations rank_0 and select_0 are defined analogously for the **0**s in $\boldsymbol{b}$. As $\mathsf{rank}_0(i) = i - \mathsf{rank}_1(i)$, one considers just rank_1 (abbreviated to rank) and refers to select_0 and select_1 collectively as select. In what follows, $|\boldsymbol{x}|$ denotes the length of a bit string $\boldsymbol{x}$ and $w(\boldsymbol{x})$ denotes the number of **1**s in it. $\boldsymbol{b}$ is always used to denote the input bit string, m to denote $|\boldsymbol{b}|$ and n to denote $w(\boldsymbol{b})$.

Memory Usage Models

In terms of space usage, we aim not only to store $\boldsymbol{b}$ in the minimum amount of space but also to minimize any additional space (called the *redundancy*) needed to support rank and select. The notion of redundancy can be formalized in two different ways.

In the *succinct index* model (also known as the *systematic* model), the bit vector does not have direct access to $\boldsymbol{b}$, but can obtain $O(\log m)$ consecutive bits of $\boldsymbol{b}$ in $O(1)$ time. During preprocessing, one can create additional data structures (called *succinct indices*) to allow rapid rank and select queries. Indices allow the representation of $\boldsymbol{b}$ to be decoupled from the auxiliary data structure, e.g., $\boldsymbol{b}$ can be stored (in a potentially highly compressed form) in a data structure such as that of [6]. The redundancy in the succinct index model is the space usage of the index.

In the *unrestricted* model, we give a "space budget" for storing $\boldsymbol{b}$, based upon some compressibility measure (the data structure is usually designed to target a particular measure). We now give some examples of space budgets:

- The obvious space budget for $\boldsymbol{b}$ is m bits, and this is used if $\boldsymbol{b}$ is believed to be incompressible.
- Recalling that $n = w(\boldsymbol{b})$, we define the space budget $B(m,n) = \lceil \log_2 \binom{m}{n} \rceil$, which is the information-theoretic minimum number of bits to store a bit string of length m with n **1**s. Using standard approximations of the factorial function, one can show [17] that $B(m,n) = n \log_2(m/n) + n \log_2 e + O(n^2/m)$. In particular, if $n = o(m)$, then $B(m,n) = o(m)$.
- Yet another space budget is obtained from the *k-th-order empirical entropy*, denoted by $H_k(\boldsymbol{b})$. For any bit string s, define $\#(s)$ as the number of (possibly overlapping) contiguous occurrences of the bit string s in $\boldsymbol{b}$. Then, for any $k \geq 0$,

$$H_k(\boldsymbol{b}) = -\frac{1}{m} \sum_{s \in \{0,1\}^k} \left(\#(s\mathbf{0}) \log_2 \frac{\#(s\mathbf{0})}{\#(s)} + \#(s\mathbf{1}) \log_2 \frac{\#(s\mathbf{1})}{\#(s)} \right) \quad (1)$$

(take $\log_2(0/0) = 0 \log_2 0 = 0$ and $\#(s) = m$ when s is the empty string). $H_k(\boldsymbol{b})$ gives the information content per bit in $\boldsymbol{b}$, when conditioned upon the previous k bits as context. The space budget is therefore $mH_k(\boldsymbol{b})$. Note that $mH_0(\boldsymbol{b}) \sim B(m,n)$, but even $H_1(\boldsymbol{b})$ can be much smaller than $H_0(\boldsymbol{b})$, and in general $H_{k+1} \leq H_k$. For example, if $\boldsymbol{b} = (\mathbf{01})^{m/2}$, then $H_0(\boldsymbol{b}) \sim m$ but $mH_1(\boldsymbol{b})$ vanishes.

The redundancy in the unrestricted model is the difference between the space usage of the data structure and the space budget.

Models of Computation

Three models of computation are commonly considered. One is the *word RAM* model with word size $O(\log m)$ bits [13]. The other models, which are particularly useful for proving lower bounds, are the *cell probe* and *bit probe* models. In the cell probe model, the time complexity of answering a query is the worst-case number of words of $O(\log m)$ consecutive bits of the data structure that are read by the algorithm to answer that query. All other computation is "free." The bit probe model is similar, except that we only count the number of bits of the data structure that are read when answering a query. Clearly, $O(\log m)$ bit probes can be more useful than reading $O(1)$ consecutive words, so $O(\log m)$ bit probes are more powerful than $O(1)$ cell probes. Also, $O(1)$ cell probes are more powerful than $O(1)$ time on the word RAM, since computation on values read into registers is for free in the cell probe model. Thus, an $O(t)$ upper bound in the word RAM is stronger than $O(t)$ upper bound in the cell probe model, which is stronger than an $O(t \log m)$ upper bound in the bit probe model. For lower bounds, the situation is of course reversed, with cell probe lower bounds being stronger than equivalent word RAM lower bounds.

Key Results

Relation to Predecessor Search

Given a static set $S \subseteq \{0, \ldots, m-1\}$, $|S| = n$, the *predecessor search* problem is to preprocess S to answer the query $\mathsf{pred}(x, S) = \max\{y \in S | y \leq x\}$. The predecessor search can easily be solved using a bit vector: we simply create a bit string $\boldsymbol{b}$ that is the characteristic vector of S, and note that (i) $|\boldsymbol{b}| = m$, (ii) $w(\boldsymbol{b}) = n = |S|$, and (iii) $\mathsf{pred}(x, S) = \mathsf{select}_1(\mathsf{rank}_1(x))$.

Clearly, if we are interested in highly space-efficient solutions, space usages of significantly more than $O(n \log m)$ bits are not of interest, since any bit string $\boldsymbol{b}$ can be represented as a set using $O(n \log m)$ bits by enumerating the positions of its **1**s. However, this close connection of the bit vector problem to the predecessor search problem means that lower bounds for the predecessor search problem also apply to the bit vector problem. In particular, if rank should take $O(1)$ time and the space should be at most $O(n \log m)$ bits, then this is only possible if $n = m/(\log m)^{O(1)}$ [19]. Since constant-time rank (and select) is taken by the succinct data structure community to be a "standard" expectation, this lower bound means that we only consider moderately sparse bit strings $\boldsymbol{b}$ in this entry.

Reductions

It has been already noted that rank_0 and rank_1 reduce to each other and that operations on sets reduce to select operations on a bit string. Some other reductions, whereby one can support operations on $\boldsymbol{b}$ by performing operations on bit strings derived from $\boldsymbol{b}$, are:

Theorem 1 *(a)* rank *reduces to* select_0 *on a bit string* $\boldsymbol{c}$ *such that* $|\boldsymbol{c}| = m + n$ *and* $w(\boldsymbol{c}) = n$.
(b) If $\boldsymbol{b}$ *has no consecutive* **1***s, then* select_0 *on* $\boldsymbol{b}$ *can be reduced to* rank *on a bit string* $\boldsymbol{c}$ *such that* $|\boldsymbol{c}| = m - n$ *and* $w(\boldsymbol{c})$ *is either* $n-1$ *or* n.
(c) From $\boldsymbol{b}$*, one can derive two-bit string* $\boldsymbol{b_0}$ *and* $\boldsymbol{b_1}$ *such that* $|\boldsymbol{b_0}| = m - n$, $|\boldsymbol{b_1}| = n$, $w(\boldsymbol{b_0}), w(\boldsymbol{b_1}) \leq \min\{m-n, n\}$, *and* select_0 *and* select_1 *on* $\boldsymbol{b}$ *can be supported by supporting* select_1 *and* rank *on* b_0 *and* b_1.

Parts (a) and (b) follow from Elias's observations on multiset representations, specialized to sets. For part (a), create $\boldsymbol{c}$ from $\boldsymbol{b}$ by adding a **0** after every **1**. For example, if $\boldsymbol{b} = \mathbf{01100100}$, then $\boldsymbol{c} = \mathbf{01}0\mathbf{1}0\mathbf{00}1\mathbf{0}0\mathbf{0}$. Then, $\mathsf{rank}_1(i)$ on $\boldsymbol{b}$ equals

$\mathsf{select}_0(i) - i$ on $\boldsymbol{c}$. For part (b), essentially invert the mapping of part (a). Part (c) is shown in [3].

Succinct Indices for Bit Vectors

The following is known about the sizes of succinct indices for bit vectors:

Theorem 2 ([11]) *Given a bit string $\boldsymbol{b}$ with $|\boldsymbol{b}| = m$, $w(\boldsymbol{b}) = n$, and $m/n = (\log m)^{O(1)}$, there is an index of size*

$$\begin{cases} O(m' \log(n/m')) & \text{if } n = \omega(m') \\ O(n(1 + \max\{0, \log(m'/n)\})) & \text{if } n = O(m') \end{cases} \text{bits},$$

where $m' = m/\log m$, that supports rank, select_0, *and* select_1 *in $O(1)$ time. This index size is optimal for any data structure that makes $O(\log m)$ bit probes to $\boldsymbol{b}$.*

This result generalizes an earlier result by Golynski, who showed that the index size must be $\Theta(m \log\log m/\log m)$ bits for $O(1)$ time operations [9]. The bound of Theorem 2 is asymptotically the same when n is relatively close to m, e.g., when $n = \Omega(m/(\log m)^{1/2})$, but is smaller thereafter, e.g., for $n = \Theta(m/(\log m)^2)$ the index size implied by Theorem 2 $O(m \log\log m/(\log m)^2)$ bits, which is a $\Theta(\log m)$ factor better than that given by [9].

Elias [5] previously gave an $o(m)$-bit index that supported select in $O(\log m)$ bit probes on average (where the average was computed across all select queries). Jacobson [14] gave $o(m)$-bit indices that supported rank and select in $O(\log m)$ bit probes in the worst case. Clark and Munro [2] gave the first $o(m)$-bit indices that support both rank and select in $O(1)$ time on the RAM.

Bit Vectors in the Unrestricted Model

In the unrestricted model, the best redundancy, if one is targeting the $B(m,n)$ space budget, is given by the following result due to Pătraşcu:

Theorem 3 ([18]) *A bit string $\boldsymbol{b}$ with $|\boldsymbol{b}| = m$ and $w(\boldsymbol{b}) = n$ can be represented using $B(m,n) + m/((\log m)/t)^t + m^{3/4}(\log m)^{O(1)}$ bits of memory, supporting* rank *and* select_1 *queries in $O(t)$ time.*

Earlier results, with a significantly higher redundancy, were given by [17, 21]. Thus, for $t = O(1)$, the redundancy is $m/(\log m)^{O(1)}$. There is an almost matching lower bound:

Theorem 4 ([20]) *Any representation of a bit string $\boldsymbol{b}$ with $|\boldsymbol{b}| = m$ and $w(\boldsymbol{b}) = n$ that answers* rank *or* select_1 *queries in $O(t)$ time on the cell probe model must use $B(m,n) + m/(\log m)^t$ bits of memory.*

The case where we aim for higher-order entropy appears to be less well studied. The best-known result is as follows:

Theorem 5 ([10]) *A bit string $\boldsymbol{b}$ with $|\boldsymbol{b}| = m$ can be represented using $mH_k(\boldsymbol{b}) + O(mk/\log m)$ bits of memory, supporting* rank *and* select *queries in $O(1)$ time, for any $k \geq 1$.*

Applications

Bit vectors are fundamental building blocks in a huge number of space-efficient data structures, in real-world and theoretical applications such as XML document representation [1, 4, 7], text retrieval [16], bioinformatics [15], and data mining [22], to name but a few. In the Cross-References, we list the various succinct data structures that build on or are related to bit vectors.

Experimental Results

Bit vectors have been extensively experimentally evaluated. Mature implementations are available in the libraries `SDSL` [8] and `Succinct` [12]. Other libraries of note are Vigna's `Sux4J` (http://

sux.di.unimi.it) and Claude's `libcds` (https://github.com/fclaude/libcds).

Problem Definition

The query $S.\text{rank}_a(i)$ on a sequence S is defined to return the number of occurrences of the distinct character a among the first i characters of S, and the query $S.\text{select}_a(j)$ is defined to return the position of the jth occurrence of a in S (if it exists). Since rank and select queries are fundamental to the field of succinct and compressed data structures, researchers have proposed several data structures that answer them quickly while using little space. Most of these data structures also support fast random access to S, and a few of them support fast insertions and deletions of characters in S. Some of them return $S.\text{rank}_a(i)$ more quickly when the ith character of S is itself an a; the query is then called partial rank.

Key Results

While considering how to store trees and graphs in small space while supporting fast navigation, Jacobson [16] considered the problem of supporting rank and select on binary sequences. He showed how to store an n-bit binary sequence using $o(n)$ bits in addition to the sequence itself, such that we can answer rank and select using $O(\log n)$ bit probes. Later authors have considered the problem in the word-RAM model with $\Omega(\log n)$-bit words, in which Jacobson's implementation of rank takes $O(1)$ time; they showed how to answer also select in this model in $O(1)$ time while still using $o(n)$ extra bits. Pătraşcu [20] showed how we can store an n-bit binary sequence containing m 1s in a total of $\lg \binom{n}{m} + O(n/\log^c n)$ bits, where c is any constant, and still answer rank and select in $O(1)$ time.

Grossi, Gupta, and Vitter [12] described a data structure, called a wavelet tree, that uses rank and select on several binary sequences to answer access, rank, and select on sequences over larger alphabets. If S is a sequence of length n over an alphabet of size σ and a wavelet tree for S is implemented with uncompressed data structures for rank and select on the binary sequences, then it takes $n \log \sigma + o(n \log \sigma)$ bits and answers access, rank, and select in $O(\log \sigma)$ time. With instances of Pătraşcu's data structure, the space becomes $nH_0(S) + o(n)$ bits, where $H_0(S)$ is the 0th-order empirical entropy of S. To simplify, we assume throughout that $\sigma = o(n/\log n)$.

Ferragina, Manzini, Mäkinen, and Navarro [7] described a multiary version of the wavelet tree that uses only $O\left(\frac{\log \sigma}{\log \log n} + 1\right)$ time for access, rank, and select, which is $O(1)$ when $\sigma = \lg^{O(1)} n$. Their implementation takes $nH_0(S) + o(n)$ bits when $\sigma = \lg^{O(1)} n$ and $nH_0(S) + o(n \log \sigma)$ bits otherwise. Golynski, Raman, and Rao [11] reduced the space to $nH_0(S) + o(n)$ bits in the general case.

Golynski, Munro, and Rao [10] described a data structure that takes $n \lg \sigma + o(n \lg \sigma)$ bits

and either answers select in $O(1)$ time and access and rank in $O(\log\log\sigma)$ time, or answers access in $O(1)$ time, rank in $O(\log\log(\sigma)\log\log\log\sigma)$ time, and select in $O(\log\log\sigma)$ time. If the space is increased to $(1+\epsilon)n\lg\sigma$ bits, where ϵ is any positive constant, then both access and select take $O(1)$ time and rank takes $O(\log\log\sigma)$ time. Golynski [9] showed that the product of the query times for access and select and the per-character redundancy in bits must be $\Omega\left(\frac{\log^2\sigma}{w}\right)$ in general, where w is the length of a machine word.

Barbay, He, Munro, and Rao [1] described a data structure that takes $nH_k(S) + o(n\log\sigma)$ bits, where $H_k(S)$ is the kth-order empirical entropy of S, and answers access in $O(1)$ time, rank in $O(\log\log\sigma(\log\log\log\sigma)^2)$ time, and select in $O(\log\log(\sigma)\log\log\log\sigma)$ time. We assume throughout that $k = o(\log_\sigma n)$. They also reduced to $nH_0(S)+o(n\log\sigma)$ bits, the space for the version of Golynski, Munro, and Rao's data structure with $O(1)$-time select and $O(\log\log\sigma)$-time access and rank. Grossi, Orlandi, and Raman [13] reduced the space of the version with $O(1)$-time access and $O(\log\log\sigma)$-time select to $nH_k(S) + o(n\log\sigma)$ bits and reduced the time for rank to $O(\log\log\sigma)$.

Barbay, Claude, Gagie, Navarro, and Nekrich [2] combined multiary wavelet trees with the versions of Golynski, Munro and, Rao's data structure, to obtain a data structure that takes $nH_0(S) + o(n)(H_0(S) + 1)$ bits and answers one of access and select in $O(1)$ time and the other in $O(\log\log\sigma)$ time, and rank also in $O(\log\log\sigma)$ time. If the space is increased to $(1+\epsilon)nH_0(S) + o(n)$ bits, then both access and select take $O(1)$ time. They partition the alphabet into sub-alphabets such that all the characters in each sub-alphabet have roughly the same frequency, and then store a data structure that answers access, rank, and select queries on the subsequence of characters in S from that sub-alphabet.

Belazzougui and Navarro [3, 4] showed that any data structure that takes $n \cdot w^{O(1)}$ space must use $\Omega\left(\log\frac{\log\sigma}{\log w}\right)$ time for rank. They also gave the following upper bounds:

- We can store S in $nH_0(S) + o(n)$ bits and answer access, rank, and select in $O\left(\frac{\log\sigma}{\log w} + 1\right)$ time, which is $O(1)$ when $\sigma = \lg^{O(1)} n$.
- We can store S in $nH_0(S) + o(n)(H_0(S) + 1)$ bits and answer access in $O(1)$ time and select in $O(f(n,\sigma))$ time or vice versa, where $f(n,\sigma)$ is any function in $\omega(1)$, and answer rank in $O\left(\log\frac{\log\sigma}{\log w}\right)$ time.
- We can store S in $nH_k(S) + o(n\log\sigma)$ bits and answer access in $O(1)$ time, select in $O(f(n,\sigma))$ time, and rank in $O\left(\log\frac{\log\sigma}{\log w}\right)$ time in general and in $O(f(n,\sigma))$ time when $\sigma = w^{O(1)}$.

These and the other bounds described above are summarized in Table 1. In another paper [5], Belazzougui and Navarro showed how we can add $o(n)(H_0(S) + 1)$ bits to any of these representations and answer partial rank queries in the same time as access.

Dynamic Sequences

Several authors have described data structures that store binary sequences in succinct or compressed space and support fast rank, select, and update operations, typically insertions and deletions of bits. In particular, Navarro and Sadakane [19] described data structures that store a binary sequence B in $|B|H_0(B) + o(|B|)$ bits and support rank, select, insert, and delete in $O\left(\frac{\log|B|}{\log\log|B|}\right)$ time, which is optimal [8]. These can be used in wavelet trees to obtain data structures that support rank and select on dynamic sequences over larger alphabets. Navarro and Sadakane [19] and He and Munro [15] described data structures that store a sequence S in $nH_0(S) + o(n\log\sigma)$ bits, where n is the current length of S, and support access, rank, and select queries and insertions and deletions of characters in $O\left(\frac{\log n}{\log\log n}\left(\frac{\log\sigma}{\log\log n} + 1\right)\right)$ time, which is $O\left(\frac{\log n}{\log\log n}\right)$ when $\sigma = \lg^{O(1)} n$.

Navarro and Nekrich [17, 18] recently described a data structure that stores S in $nH_0(S) + o(n\log\sigma)$ bits and supports access,

Rank and Select Operations on Sequences, Table 1 A summary of previous and current upper bounds for rank and select on a sequence S of length n over an alphabet of size $\sigma = o(n/\log n)$, with ϵ a positive constant, $k = o(\log_\sigma n)$, and $f(n,\sigma) = \omega(1)$. The bounds in the second row hold when $\sigma = \lg^{O(1)} n$ and those in the last row hold when $\sigma = w^{O(1)}$, with w the word length

Source	Space (bits)	Access	Rank	Select
[12]	$nH_0(S) + o(n)$	$O(\log\sigma)$	$O(\log\sigma)$	$O(\log\sigma)$
[7]	$nH_0(S) + o(n)$	1	1	1

[2]	$nH_0(S) + o(n)(H_0(S)+1)$	$O(\log\log\sigma)$	$O(\log\log\sigma)$	1
[2]	$(1+\epsilon)nH_0(S) + o(n)$	1	$O(\log\log\sigma)$	1
[3,4]	$nH_0(S) + o(n)$	$O\left(\frac{\log\sigma}{\log w} + 1\right)$	$O\left(\frac{\log\sigma}{\log w} + 1\right)$	$O\left(\frac{\log\sigma}{\log w} + 1\right)$
[3,4]	$nH_0(S) + o(n)(H_0(S)+1)$	1	$O\left(\log\frac{\log\sigma}{\log w}\right)$	$O(f(n,\sigma))$
[3,4]	$nH_0(S) + o(n)(H_0(S)+1)$	$O(f(n,\sigma))$	$O\left(\log\frac{\log\sigma}{\log w}\right)$	1
[3,4]	$nH_k(S) + o(n\log\sigma)$	1	$O\left(\log\frac{\log\sigma}{\log w}\right)$	$O(f(n,\sigma))$
[3,4]	$nH_k(S) + o(n\log\sigma)$	1	$O(f(n,\sigma))$	$O(f(n,\sigma))$

rank, select, insert, and delete in $O\left(\frac{\log n}{\log\log n}\right)$ time. This time bound is worst-case for the queries and amortized for the updates; the update times can be made worst-case as well at the cost of increasing the times for rank, insert, and delete from $O\left(\frac{\log n}{\log\log n}\right)$ to $O(\log n)$. Their structure is essentially a multiary wavelet tree built using rank and select data structures for dynamic sequences over sublogarithmic alphabets, much like He and Munro's or Navarro and Sadakane's, but they divide those component sequences into polylogarithmic-sized blocks and augment them with pointers such that they can ascend and descend the tree using only the pointers and rank and select on individual blocks.

Grossi, Raman, Rao, and Venturini [14] later reduced the time for access to $O(1)$ while using $nH_k(S) + o(n\log\sigma)$ bits but at the cost of being able only to replace characters instead of inserting and deleting them. The time for rank and select is the same.

Applications

Jacobson [16] first studied rank and select for representing unlabeled trees succinctly and planar graphs almost succinctly, while supporting fast navigation queries. Since then, rank and select on binary sequences have been used in succinct and compressed representations of several other combinatorial objects, such as binary relations and general graphs. Rank and select on sequences over larger alphabets have been used in succinct and compressed representations of labeled trees and permutations and in compressed full-text indexes such as compressed suffix arrays. Notice that with a data structure for rank and select that achieves compression in terms of 0th-order empirical entropy, we can build a full-text index that achieves compression in terms of kth-order empirical entropy.

Open Problems

The current main open problems regarding rank and select on static sequences are to answer access and select in $O(1)$ time while storing S in $nH_0(S) + o(n \log \sigma)$ bits when $\lg \sigma = o(w)$, to answer select in constant time and access in almost constant time while storing S in $nH_k(S) + o(n \log \sigma)$ bits when $k > 0$, and to answer access, rank, and select queries in $O(1)$ time while storing S in $nH_k(S) + o(n)$ bits when $\sigma = \lg^{O(1)} w$.

The current main open problems regarding rank and select on dynamic sequences are to achieve $O\left(\frac{\log n}{\log \log n}\right)$ worst-case time for all operations while still using compressed space, to achieve a similar space bound in terms of $H_k(S)$ instead of $H_0(S)$ while supporting the same operations, and to support a wider range of updates.

Experimental Results

The most recent experimental results for rank and select on static sequences are by Barbay et al. [2] and Claude, Navarro, and Ordóñez [6]. These results show that rank and select data structures can be implemented in a time- and space-efficient way in practice, even when the alphabet size is large. There are no current experimental results for rank and select on succinct or compressed dynamic sequences.

Ranked Matching

Kavitha Telikepalli
CSA Department, Indian Institute of Science, Bangalore, India

Keywords

Popular matching

Years and Authors of Summarized Original Work

2005; Abraham, Irving, Kavitha, Mehlhorn

Problem Definition

This problem is concerned with matching a set of *applicants* to a set of *posts*, where each applicant has a *preference list*, ranking a non-empty subset of posts in order of preference, possibly involving ties. Say that a matching M is *popular* if there is no matching M' such that the number of applicants preferring M' to M exceeds the number of applicants preferring M to M'. The ranked matching problem is to determine if the given instance admits a popular matching and if so, to compute one. There are many practical situations that give rise to such large-scale matching problems involving two sets of participants – for example, pupils and schools, doctors and hospitals – where participants of one set express preferences over the participants of the other set; an allocation determined by a popular matching can be regarded as an optimal allocation in these applications.

Notations and Definitions

An instance of the *ranked matching problem* is a bipartite graph $G = (\mathcal{A} \cup \mathcal{P}, E)$ and a partition $E = E_1 \dot\cup E_2 \ldots \dot\cup E_r$ of the edge set. Call the nodes in $\mathcal{A}$ *applicants*, the nodes in $\mathcal{P}$ *posts*, and the edges in E_i the edges of rank i. If $(a, p) \in E_i$ and $(a, p') \in E_j$ with $i < j$, say that a prefers p to p'. If $i = j$, say that a is indifferent between p and p'. An instance is *strict* if the degree of every applicant in every E_i is at most one.

A matching M is a set of edges, no two of which share an endpoint. In a matching M, a node $u \in \mathcal{A} \cup \mathcal{P}$ is either *unmatched*, or *matched* to some node, denoted by $M(u)$. Say that an applicant a *prefers* matching M' to M if (i) a is matched in M' and unmatched in M, or (ii) a is matched in both M' and M, and a prefers $M'(a)$ to $M(a)$.

Definition 1 M' is *more popular than* M, denoted by $M' \succ M$, if the number of applicants preferring M' to M exceeds the number of applicants preferring M to M'. A matching M is popular if and only if there is no matching M' that is more popular than M.

Figure 1 shows an instance with $A = \{a_1, a_2, a_3\}$, $P = \{p_1, p_2, p_3\}$, and each applicant prefers p_1 to p_2, and p_2 to p_3 (assume throughout that preferences are transitive). Consider the three symmetrical matchings $M_1 = \{(a_1, p_1), (a_2, p_2), (a_3, p_3)\}$, $M_2 = \{(a_1, p_3), (a_2, p_1), (a_3, p_2)\}$ and $M_3 = \{(a_1, p_2), (a_2, p_3), (a_3, p_1)\}$. It is easy to verify that none of these matchings is popular, since $M_1 \prec M_2$, $M_2 \prec M_3$, and $M_3 \prec M_1$. In fact, this instance admits no popular matching – the problem being, of course, that the *more popular than* relation is not acyclic, and so there need not be a maximal element.

The *ranked matching problem* is to determine if a given instance admits a popular matching, and to find such a matching, if one exists. Popular matchings may have different sizes, and a largest such matching may be smaller than a maximum-

$$\begin{array}{lccc} a_1: & p_1 & p_2 & p_3 \\ a_2: & p_1 & p_2 & p_3 \\ a_3: & p_1 & p_2 & p_3 \end{array}$$

Ranked Matching, Fig. 1 An instance for which there is no popular matching

cardinality matching. The *maximum-cardinality popular matching problem* then is to determine if a given instance admits a popular matching, and to find a *largest* such matching, if one exists.

Key Results

First consider *strict instances*, that is, instances $(\mathcal{A} \cup \mathcal{P}, E)$ where there are no ties in the preference lists of the applicants. Let n be the number of vertices and m be the number of edges in G.

Theorem 1 *For a strict instance $G = (\mathcal{A} \cup \mathcal{P}, E)$, it is possible to determine in $O(m + n)$ time if G admits a popular matching and compute one, if it exists.*

Theorem 2 *Find a maximum-cardinality popular matching of a strict instance $G = (\mathcal{A} \cup \mathcal{P}, E)$, or determine that no such matching exists, in $O(m + n)$ time.*

Next consider the general problem, where preference lists may have ties.

Theorem 3 *Find a popular matching of $G = (\mathcal{A} \cup \mathcal{P}, E)$, or determine that no such matching exists, in $O(\sqrt{n}m)$ time.*

Theorem 4 *Find a maximum-cardinality popular matching of $G = (\mathcal{A} \cup \mathcal{P}, E)$, or determine that no such matching exists, in $O(\sqrt{n}m)$ time.*

Techniques

Our results are based on a novel characterization of popular matchings. For exposition purposes, create a unique *last resort* post $l(a)$ for each applicant a and assign the edge $(a, l(a))$ a rank higher than any edge incident on a. In this way, assume that every applicant is matched, since any unmatched applicant can be allocated to his/her last resort. From now on then, matchings are *applicant-complete*, and the size of a matching is just the number of applicants not matched to their last resort. Also assume that instances have no gaps, i.e., if an applicant has a rank i edge incident to it then it has edges of all smaller ranks incident to it. First outline the characterization in strict instances and then extend it to general instances.

Strict Instances

For each applicant a, let $f(a)$ denote the most preferred post on a's preference list. That is, $(a, f(a)) \in E_1$. Call any such post p an *f-post*, and denote by $f(p)$ the set of applicants a for which $f(a) = p$.

For each applicant a, let $s(a)$ denote the most preferred non-f-post on a's preference list; note that $s(a)$ must exist, due to the introduction of $l(a)$. Call any such post p an *s-post*, and remark that f-posts are disjoint from s-posts.

Using the definitions of f-posts and s-posts, show three conditions that a popular matching must satisfy.

Lemma 1 *Let M be a popular matching.*

1. *For every f-post p, (i) p is matched in M, and (ii) $M(p) \in f(p)$.*
2. *For every applicant a, $M(a)$ can never be strictly between $f(a)$ and $s(a)$ on a's preference list.*
3. *For every applicant a, $M(a)$ is never worse than $s(a)$ on a's preference list.*

It is then shown that these three necessary conditions are also sufficient. This forms the basis of the following preliminary characterization of popular matchings.

Lemma 2 *A matching M is popular if and only if (i)* every *f-post is matched in M, and (ii) for each applicant a, $M(a) \in \{f(a), s(a)\}$.*

Given an instance graph $G = (\mathcal{A} \cup \mathcal{P}, E)$, define the *reduced graph* $G' = (\mathcal{A} \cup \mathcal{P}, E')$

as the subgraph of G containing two edges for each applicant a: one to $f(a)$, the other to $s(a)$. The authors remark that G' need not admit an applicant-complete matching, since $l(a)$ is now isolated whenever $s(a) \neq l(a)$. Lemma 2 shows that a matching is popular if and only if it belongs to the graph G' and it matches every f-post. Recall that all popular matchings are applicant-complete through the introduction of last resorts. Hence, the following characterization is immediate.

Theorem 5 *M is a popular matching of G if and only if (i) every f-post is matched in M, and (ii) M is an applicant-complete matching of the reduced graph G'.*

The characterization in Theorem 5 immediately suggests the following algorithm for solving the popular matching problem. Construct the reduced graph G'. If G' does not admit an applicant-complete matching, then G admits no popular matching. If G' admits an applicant-complete matching M, then modify M so that every f-post is matched. So for each f-post p that is unmatched in M, let a be any applicant in $f(p)$; remove the edge $(a, M(a))$ from M and instead match a to p. This algorithm can be implemented in $O(m + n)$ time. This shows Theorem 1.

Now, consider the maximum-cardinality popular matching problem. Let $\mathcal{A}_1$ be the set of all applicants a with $s(a) = l(a)$. Let $\mathcal{A}_1$ be the set of all applicants with $s(a) = l(a)$. Our target matching must satisfy conditions (i) and (ii) of Theorem 5, and among all such matchings, allocate the fewest $\mathcal{A}_1$-applicants to their last resort. This scheme can be implemented in $O(m + n)$ time. This proves Theorem 2.

General Instances

For each applicant a, let $f(a)$ denote the *set* of first-ranked posts on a's preference list. Again, refer to all such posts p as *f-posts*, and denote by $f(p)$ the set of applicants a for which $p \in f(a)$. It may no longer be possible to match *every* f-post p with an applicant in $f(p)$ (as in Lemma 1), since, for example, there may now be more f-posts than applicants. Let M be a popular matching of some instance graph $G = (\mathcal{A} \cup \mathcal{P}, E)$. Define the *first-choice graph* of G as $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$, where E_1 is the set of all rank one edges. Next the authors show the following lemma.

Lemma 3 Let M be a popular matching. Then $M \cap E_1$ is a maximum matching of G_1.

Next, work towards a generalized definition of $s(a)$. Restrict attention to rank-one edges, that is, to the graph G_1 and using M_1, partition $\mathcal{A} \cup \mathcal{P}$ into three disjoint sets. A node v is *even* (respectively *odd*) if there is an even (respectively odd) length alternating path (with respect to M_1) from an unmatched node to v. Similarly, a node v is *unreachable* if there is no alternating path (w.r.t. M_1) from an unmatched node to v. Denote by $\mathcal{E}$, $\mathcal{O}$, and $\mathcal{U}$ the sets of even, odd, and unreachable nodes, respectively. Conclude the following facts about $\mathcal{E}$, $\mathcal{O}$, and $\mathcal{U}$ by using the well-known Gallai–Edmonds decomposition theorem.

(a) $\mathcal{E}$, $\mathcal{O}$, and $\mathcal{U}$ are pairwise disjoint. Every maximum matching in G_1 partitions the vertex set into the same partition of even, odd, and unreachable nodes.

(b) In any maximum-cardinality matching of G_1, every node in $\mathcal{O}$ is matched with some node in $\mathcal{E}$, and every node in $\mathcal{U}$ is matched with another node in $\mathcal{U}$. The size of a maximum-cardinality matching is $|\mathcal{O}| + |\mathcal{U}|/2$.

(c) No maximum-cardinality matching of G_1 contains an edge between two nodes in $\mathcal{O}$, or a node in $\mathcal{O}$ and a node in $\mathcal{U}$. And there is no edge in G_1 connecting a node in $\mathcal{E}$ with a node in $\mathcal{U}$.

The above facts motivate the following definition of $s(a)$: let $s(a)$ be the set of most preferred posts in a's preference list that are *even* in G_1 (note that $s(a) \neq \emptyset$, since $l(a)$ is always even in G_1). Recall that our original definition of $s(a)$ led to parts (2) and (3) of Lemma 1 which restrict the set of posts to which an applicant can be matched in a popular matching. This shows that the generalized definition leads to analogous results here.

Lemma 4 *Let M be a popular matching. Then for every applicant a, $M(a)$ can never be strictly*

between f(a) and s(a) on a's preference list and M(a) can never be worse than s(a) in a's preference list.

The following characterization of popular matchings is formed.

Lemma 5 *A matching M is popular in G if and only if (i) $M \cap E_1$ is a maximum matching of G_1, and (ii) for each applicant a, $M(a) \in f(a) \cup s(a)$.*

Given an instance graph $G = (\mathcal{A} \cup \mathcal{P}, E)$, we define the *reduced graph* $G' = (\mathcal{A} \cup \mathcal{P}, E')$ as the subgraph of G containing edges from each applicant a to posts in $f(a) \cup s(a)$. The authors remark that G' need not admit an applicant-complete matching, since $l(a)$ is now isolated whenever $s(a) \neq \{l(a)\}$. Lemma 11 tells us that a matching is popular if and only if it belongs to the graph G' and it is a maximum matching on rank one edges. Recall that all popular matchings are applicant-complete through the introduction of last resorts. Hence, the following characterization is immediate.

Theorem 6 *M is a popular matching of G if and only if (i) $M \cap E_1$ is a maximum matching of G_1, and (ii) M is an applicant-complete matching of G'.*

Using the characterization in Theorem 6, the authors now present an efficient algorithm for solving the ranked matching problem.

Popular-Matching ($G = (\mathcal{A} \cup \mathcal{P}, E)$)

1. Construct the graph $G' = (\mathcal{A} \cup \mathcal{P}, E')$, where $E' = \{(a, p) \mid p \in f(a) \cup s(a), a \in \mathcal{A}\}$.
2. Compute a maximum matching M_1 on rank one edges i.e., M_1 is a maximum matching in $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$.
   (M_1 is also a matching in G' because $E' \supseteq E_1$)
3. Delete all edges in G' connecting two nodes in the set $\mathcal{O}$ or a node in $\mathcal{O}$ with a node in $\mathcal{U}$, where $\mathcal{O}$ and $\mathcal{U}$ are the sets of odd and unreachable nodes of $G_1 = (\mathcal{A} \cup \mathcal{P}, E_1)$.
   Determine a maximum matching M in the modified graph G' by augmenting M_1.
4. If M is not applicant-complete, then declare that there is no popular matching in G. Else return M.

The matching returned by the algorithm Popular-Matching is an applicant-complete matching in G' and it is a maximum matching on rank one edges. So the correctness of the algorithm follows from Theorem 6. It is easy to see that the running time of this algorithm is $O(\sqrt{n}m)$. The algorithm of Hopcroft and Karp [7] is uesd to compute a maximum matching in G_1 and identify the set of edges E' and construct G' in $O(\sqrt{n}m)$ time. Repeatedly augment M_1 (by the Hopcroft–Karp algorithm) to obtain M. This proves Theorem 3.

It is now a simple matter to solve the maximum-cardinality popular matching problem. Assume that the instance $G = (\mathcal{A} \cup \mathcal{P}, E)$ admits a popular matching. (Otherwise, the process is done.) In order to compute an applicant-complete matching in G' that is a maximum matching on rank one edges and which maximizes the number of applicants not matched to their last resort, first compute an arbitrary popular matching M' and remove all edges of the form $(a, l(a))$ from M' and from the graph G'. Call the resulting subgraph of G' as H. Determine a maximum matching N in H by augmenting M'. N need not be a popular matching, since it need not be a maximum matching in the graph G'. However, this is easy to mend. Determine a maximum matching M in G' by augmenting N. It is easy to show that M is a popular matching which maximizes the number of applicants not matched to their last resort. Since the algorithm takes $O(\sqrt{n}m)$ time, Theorem 4 is shown.

Applications

The bipartite matching problem with a graded edge set is well-studied in the economics literature, see for example [1, 10, 12]. It models some important real-world problems, including the allocation of graduates to training positions [8], and families to government-owned housing [11]. The concept of a popular matching was first

introduced by Gardenfors [5] under the name *majority assignment* in the context of the stable marriage problem [4, 6].

Various other definitions of optimality have been considered. For example, a matching is *Pareto-optimal* [1, 2, 10] if no applicant can improve his/her allocation (say by exchanging posts with another applicant) without requiring some other applicant to be worse off. Stronger definitions exist: a matching is *rank-maximal* [9] if it allocates the maximum number of applicants to their first choice, and then subject to this, the maximum number to their second choice, and so on. A matching is *maximum utility* if it maximizes $\sum_{(a,p)\in M} u_{a,p}$, where $u_{a,p}$ is the utility of allocating post p to applicant a. Neither rank-maximal nor maximum-utility matchings are necessarily popular.

Problem Definition

Liu and Layland [11] introduced rate-monotonic scheduling in the context of the scheduling of recurrent real-time processes upon a computing platform comprising a single preemptive processor.

The Periodic Task Model

The *periodic task* abstraction models real-time processes that make repeated requests for computation. As defined by Liu and Layland [11], each periodic task τ_i is characterized by an ordered pair of positive real-valued parameters (C_i, T_i), where C_i is the *worst-case execution requirement* and T_i the *period* of the task. The requests for computation that are made by task τ_i (subsequently referred to as *jobs* that are *generated* by τ_i) satisfy the following assumptions:

A1: τ_i's first job arrives at system start time (assumed to equal time zero), and subsequent jobs arrive every T_i time units, i.e., one job arrives at time instant $k \times T_i$ for all integer $k \geq 0$.

A2: Each job needs to execute for at most C_i time units, i.e., C_i is the maximum amount of time that a processor would require to execute each job of τ_i, without interruption.

A3: Each job of τ_i must complete before the next job arrives. That is, each job of task τ_i must complete execution by a *deadline* that is T_i time units after its arrival time.

A4: Each task is *independent* of all other tasks – the execution of any job of task τ_i is not contingent on the arrival or completion of jobs of any other task τ_j.

A5: A job of τ_i may be *preempted* on the processor without additional execution cost. In other words, if a job of τ_i is currently executing, then it is permitted that this execution be halted and a job of a different task τ_j begins execution immediately.

A periodic task system $\tau \stackrel{\text{def}}{=} \{\tau_1, \tau_2, \ldots, \tau_n\}$ is a collection of n periodic tasks. The *utilization* $U(\tau)$ is defined as follows:

$$U(\tau) \stackrel{\text{def}}{=} \sum_{i=1}^{n} C_i / T_i \ . \tag{1}$$

Intuitively, this denotes the fraction of time that may be spent by the processor executing jobs of tasks in τ, in the worst case.

The Rate-monotonic Scheduling Algorithm

A (uniprocessor) scheduling algorithm determines which task executes on the shared processor at each time instant. If a scheduling algorithm is guaranteed to always meet all deadlines when scheduling a task system τ, then τ is said to be *schedulable* with respect to that scheduling algorithm.

Many scheduling algorithms work as follows: at each time instant, they assign a priority to each job and select for execution the greatest-priority job with remaining execution. A *static -priority* (often called *fixed-priority*) scheduling algorithm for scheduling periodic tasks is one in which it is required that all the jobs of each periodic task be assigned the same priority.

Liu and Layland [11] proposed the *rate-monotonic* (RM) static-priority scheduling algorithm, which assigns priority to jobs according to the period parameter of the task that generates them: *the smaller the period, the higher the priority*. Hence, if $T_i < T_j$ for two tasks τ_i and τ_j, then each job of τ_i has higher priority than all jobs of τ_j and hence any executing job of τ_j will be preempted by the arrival of one of τ_i's jobs. Ties may be broken arbitrarily, but consistently – if $T_i = T_j$, then either all jobs of τ_i are assigned higher priority than all jobs of τ_j or all jobs of τ_j are assigned higher priority than all jobs of τ_i.

Key Results

First, key results from the original paper by Liu and Layland [11] are presented. Following this, results extending the work of Liu and Layland [11] are summarized.

Results from [11]

Optimality. Liu and Layland were concerned with designing "good" static- priority scheduling algorithms. They defined a notion of optimality for such algorithms: a static-priority algorithm $\mathcal{A}$ is *optimal* if any periodic task system that is

schedulable with respect to some static-priority algorithm is also schedulable with respect to $\mathcal{A}$.

Liu and Layland obtained the following result for the rate-monotonic scheduling algorithm (RM):

Theorem 1 *For periodic task systems,* RM *is an optimal static-priority scheduling algorithm.*

Schedulability testing. A *schedulability test* for a particular scheduling algorithm determines, for any periodic task system τ, whether τ is schedulable with respect to that scheduling algorithm. A schedulability test is said to be *exact* if it is the case that it correctly identifies all schedulable task systems and *sufficient* if it identifies some, but not necessarily all, schedulable task systems.

In order to derive good schedulability tests for the rate-monotonic scheduling algorithm, Liu and Layland considered the concept of *response time*. The response time of a job is defined as the elapsed time between the arrival of a job and its completion time in a schedule; the response time of a task is defined to be the largest response time that may be experienced by one of its jobs. For static- priority scheduling, Liu and Layland obtained the following result on the response time:

Theorem 2 *The maximum response time for a periodic task τ_i occurs when a job of τ_i arrives simultaneously with jobs of all higher-priority tasks. Such a time instant is known as the* critical instant *for task τ_i.*

Observe that the critical instant of the lowest-priority task in a periodic task system is also a critical instant for all tasks of higher priority. An immediate consequence of the previous theorem is that the response time of each task in the periodic task system can be obtained by simulating the scheduling of the periodic task system starting at the critical instant of the lowest-priority task. If the response time for each task τ_i obtained from such simulation does not exceed T_i, then the task system will always meet all deadlines when scheduled according to the given priority assignment. This argument immediately gives rise to a schedulability analysis test [9] for any static-priority scheduling algorithm. Since the simulation may need to be carried out until $\max_{i=1}^{n}\{T_i\}$, this schedulability test has run-time pseudo-polynomial in the representation of the task system:

Theorem 3 (Lehoczky, Sha, and Ding [9]) *Exact rate-monotonic schedulability testing of a periodic task system may be done in time pseudo-polynomial in the representation in the task system.*

Liu and Layland also derived a polynomial-time sufficient (albeit not exact) schedulability test for RM, based upon the utilization of the task system:

Theorem 4 *Let n denote the number of tasks in periodic task system τ. If $U(\tau) \leq n(2^{1/n} - 1)$, then τ is schedulable with respect to the* RM *scheduling algorithm.*

Results Since [11]

The utilization-bound sufficient schedulability test (Theorem 4) was shown to be tight in the sense that for all n, there are unschedulable task systems comprising n tasks with utilization exceeding $n(2^{1/n} - 1)$ by an arbitrarily small amount. However, tests have been devised that exploit more knowledge about tasks' period parameters. For instance, Kuo and Mok [8] provide a potentially superior utilization bound for task systems in which the task period parameters tend to be harmonically related – exact multiples of one another. Suppose that a collection of numbers is said to comprise a *harmonic chain* if for every two numbers in the set, it is the case that one is an exact multiple of the other. Let $\tilde{n}$ denote the minimum number of harmonic chains into which the period parameters $\{T_i\}_{i=1}^{n}$ of tasks in τ may be partitioned; a sufficient condition for task system τ to be RM schedulable is that

$$U(\tau) \leq \tilde{n}(2^{1/\tilde{n}} - 1) .$$

Since $\tilde{n} \leq n$ for all task systems τ, this utilization bound above is never inferior to the one in Theorem 4 and is superior for all τ for which $\tilde{n} < n$.

A different polynomial-time schedulability test was proposed by Bini, Buttazzo, and Buttazzo [4]: they showed that

$$\Pi_{i=1}^{n}((C_i/T_i)+1) \leq 2$$

is sufficient to guarantee that the periodic task system $\{\tau_1, \tau_2, \ldots, \tau_n\}$ is rate-monotonic schedulable. This test is commonly referred to as the *hyperbolic* schedulability test for rate-monotonic schedulability. The hyperbolic test is in general known to be superior to the utilization-based test of Theorem 4 – see [4] for details.

Other work done since the seminal paper of Liu and Layland has focused on relaxing the assumptions of the periodic task model. The (implicit-deadline) *sporadic* task model relaxed assumption A17 by allowing T_i to be the *minimum* (rather than exact) separation between arrivals of successive jobs of task τ_i. It turns out that the Theorems 1–4 continue to hold for systems of such tasks as well.

A more general sporadic task model has also been studied that relaxes assumption A17 in addition to assumption A17, by allowing for the explicit specification of a deadline parameter for each task (which may differ from the task's period). The *deadline-monotonic* scheduling algorithm [10] generalizes rate-monotonic scheduling to such task systems.

Work has also been done [2, 12] in removing the independence assumption of A4, by allowing for different tasks to use critical sections to access non-preemptable serially reusable resources.

Applications

The periodic task model has been invaluable for modeling several different types of systems. For control systems, the periodic task model is well suited for modeling the periodic requests and computations of sensors and actuators. Multimedia and network applications also typically involve computation of periodically arriving packets and data.

Many of the results described in section "Key Results" above have been integrated into powerful tools, techniques, and methodologies for the design and analysis of real-time application systems [1, 7]. The general methodology framework is commonly referred to as the *rate-monotonic analysis* (RMA) methodology. Furthermore, most operating systems provide standard primitives for supporting rate-monotonic scheduling.

Open Problems

There are plenty of interesting and challenging open problems in real-time scheduling theory; however, most of these are concerned with extensions to the basic task and scheduling model considered in the original Liu and Layland paper [11]. Perhaps the most interesting open problem with respect to the task model in [11] is regarding the computational complexity of schedulability analysis of static-priority scheduling. Recent research by Eisenbrand and Rothvoß [5] has shown that determining the maximum response time of any periodic task is NP-hard. This result shows that any exact schedulability test that utilizes response time cannot run in polynomial time (unless P = NP); however, it does not settle the open question of whether there are polynomial-time schedulability tests for static-priority periodic task systems that do not (implicitly or explicitly) calculate task response time.

URLs to Code and Data Sets

Research efforts have been made to develop a standardized methodology for evaluating the efficacy and efficiency of algorithms and analysis proposed for rate-monotonic scheduling problems. Bini and Buttazzo [3] derived an unbiased method for synthetically generating random periodic task systems (http://retis.sssup.it/~bini/publications/2005BinBut.html). Additionally, researchers have proposed suites of benchmarks as representative of embedded and real-time applications in practice. Notably, the Mälardalen WCET benchmarks [6] (http://

www.mrtc.mdh.se/projects/wcet/benchmarks.html) maintain a collection of programs that are typical for real-time applications.

Electrical Engineering and Computer Science (EECS) Department, Northwestern University, Evanston, IL, USA

Keywords

Metric minimum spanning tree; Rectilinear spanning graph

Years and Authors of Summarized Original Work

2001; Zhou, Shenoy, Nicholls

Problem Definition

Given a set of n points in a plane, a spanning tree is a set of edges that connects all the points and contains no cycles. When each edge is weighted using some distance metric of the incident points, the *metric minimum spanning tree* is a tree whose sum of edge weights is minimum. If the Euclidean distance (L_2) is used, it is called the *Euclidean minimum spanning tree*; if the rectilinear distance (L_1) is used, it is called the *rectilinear minimum spanning tree*.

Since the minimum spanning tree problem on a weighted graph is well studied, the usual approach for metric minimum spanning tree is to first define a weighted graph on the set of points and then to construct a spanning tree on it.

Much like a connection graph is defined for the maze search [4], a spanning graph can be defined for the minimum spanning tree construction.

Definition 1 Given a set of points V in a plane, an undirected graph $G = (V, E)$ is called a *spanning graph* if it contains a minimum spanning tree of V in the plane.

Since spanning graphs with fewer edges give more efficient minimum spanning tree construction, the *cardinality* of a spanning graph is defined as its number of edges. It is easy to see that a complete graph on a set of points contains all spanning trees, thus is a spanning graph. However, such a graph has a cardinality of $O(n^2)$. A rectilinear spanning graph of cardinality $O(n)$ can be constructed within $O(n \log n)$ time [6] and will be described here.

Minimum spanning tree algorithms usually use two properties to infer the inclusion and exclusion of edges in a minimum spanning tree. The first property is known as the *cut property*. It states that an edge of smallest weight crossing any partition of the vertex set into two parts belongs to a minimum spanning tree. The second property is known as the *cycle property*. It says that an edge with largest weight in any cycle in the graph can be safely deleted. Since the two properties are stated in connection with the construction of a minimum spanning tree, they are useful for a spanning graph.

Key Results

Using the terminology given in [3], the *uniqueness property* is defined as follows.

Definition 2 Given a point s, a region R has the *uniqueness property* with respect to s if for every pair of points $p, q \in R$, $||pq|| < \max(||sp||, ||sq||)$. A partition of space into a finite set of disjoint regions is said to have the uniqueness property with respect to s if each of its regions has the uniqueness property with respect to s.

The notation $||sp||$ is used to represent the distance between s and p under the L_1 metric. Define the *octal partition* of the plane with respect to s as the partition induced by the two rectilinear lines and the two 45° lines through s, as shown in Fig. 1a. Here, each of the regions R_1 through R_8 includes only one of its two bounding half lines as shown in Fig. 1b. It can be shown that the octal partition has the uniqueness property.

Lemma 1 *Given a point s in the plane, the octal partition with respect to s has the uniqueness property.*

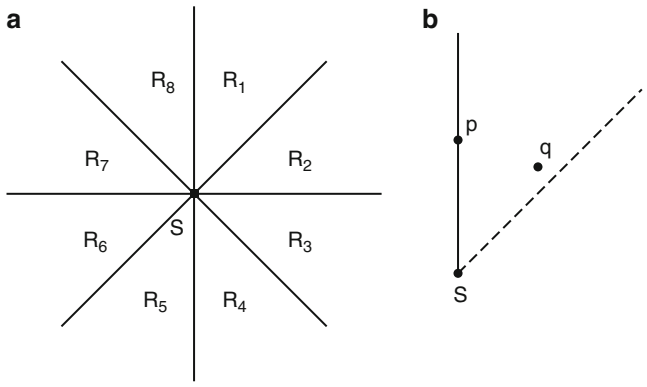
Proof To show a partition has the uniqueness property, it needs to prove that each region of the partition has the uniqueness property. Since the regions R_1 through R_8 are similar to each other, a proof for R_1 will be sufficient.

The points in R_1 can be characterized by the following inequalities:

$$x \geq x_s,$$

$$x - y < x_s - y_s.$$

Suppose there are two points p and q in R_1. Without loss of generality, it can be assumed $x_p \leq x_q$. If $y_p \leq y_q$, then $||sq|| = ||sp|| +$



Rectilinear Spanning Tree, Fig. 1 Octal partition and the uniqueness property

$||pq|| > ||pq||$. Therefore it only needs to consider the case when $y_p > y_q$. In this case,

$$\begin{aligned}\|pg\| &= |x_p - x_q| + |y_p - y_p| \\ &= x_q - x_p + y_p - y_q \\ &= (x_q - y_q) + y_p - x_p \\ &< (x_s - y_s) + y_p - x_s \\ &= y_p - y_s \\ &\leq x_p - x_s + y_p - y_s \\ &= \|sp\|.\end{aligned}$$

Given two points p, q in the same octal region of point s, the uniqueness property says that $||pq|| < \max(||sp||, ||sq||)$. Consider the cycle on points s, p, and q. Based on the cycle property, only one point with the minimum distance from s needs to be connected to s. An interesting property of the octal partition is that the contour of equidistant points from s forms a line segment in each region. In regions R_1, R_2, R_5, and R_6, these segments are captured by an equation of the form $x + y = c$; in regions R_3, R_4, R_7, and R_8, they are described by the form $x - y = c$.

From each point s, the closest neighbor in each octant needs to be found. It will be described how to efficiently compute the neighbors in R_1 for all points. The case for other octant is symmetric. For the R_1 octant, a sweep line algorithm will run on all points according to nondecreasing $x + y$. During the sweep, maintained will be an *active* set consisting of points whose nearest neighbors in R_1 are yet to be discovered. When a point p is processed, all points in the active set that have p in their R_1 regions will be found. If s is such a point in the active set, since points are scanned in nondecreasing $x + y$, then p must be the nearest point in R_1 for s. Therefore, the edge sp will be added and s will be deleted from the active set. After processing those active points, the point p will be added into the active set. Each point will be added and deleted at most once from the active set.

A fundamental operation in the sweep line algorithm is to find a subset of active points such that a given point p is in their R_1 regions. Based on the observation that point p is in the R_1 region of point s if and only if s is in the R_5 region of p, it needs to find the subset of active points in the R_5 region of p. Since R_5 can be represented as a two-dimensional range $(-\infty, x_p] \times (x_p - y_p, +\infty)$ on $(x, x - y)$, a priority search tree [1] can be used to maintain the active point set. Since each of the insertion and deletion operations takes $O(\log n)$ time, and the query operation takes $O(\log n + k)$ time where k is the number of objects within the range, the total time for the sweep is $O(n \log n)$. Since other regions can be processed in the similar way as in R_1, the algorithm is running in $O(n \log n)$ time. Priority search tree is a data structure that relies on maintaining a balanced structure for the fast query time. This works well for static input sets. When the input set is dynamic, rebalancing the tree can be quite challenging. Fortunately, the active set has a structure that can be explored for an alternate representation. Since a point is deleted from the active set if a point in its R_1 region is found, no point in the active set can be in the R_1 region of another point in the set.

Lemma 2 *For any two points p, q in the active set, it must be* $x_p \neq x_q$, *and if* $x_p < x_q$, *then* $x_p - y_p \leq x_q - y_q$.

Based on this property, the active set can be ordered in increasing order of x. This implies a nondecreasing order on $x - y$. Given a point s, the points which have s in their R_1 region must obey the following inequalities:

$$\begin{aligned}x &\leq x_s, \\ x - y &> x_s - y_s.\end{aligned}$$

To find the subset of active points which have s in their R_1 regions, it can first find the largest x such that $x \leq x_s$ and then proceed in decreasing order of x until $x - y \geq x_s - y_s$. Since the ordering is kept on only one dimension, using any binary search tree with $O(\log n)$ insertion, deletion, and query time will also give us an $O(n \log n)$ time algorithm. Binary search trees also need to be balanced. An alternative is to use

skip lists [2] which use randomization to avoid the problem of explicit balancing but provide $O(\log n)$ expected behavior.

A careful study also shows that after the sweep process for R_1, there is no need to do the sweep for R_5, since all edges needed in that phase are either connected or implied. Moreover, based on the information in R_5, the number of edge connections can be further reduced. When the sweep step processes point s, it finds a subset of active points which have s in their R_1 regions. Without lost of generality, suppose p and q are two of them. Then p and q are in the R_5 region of s, which means $||pq|| < \max(||sp||, ||sq||)$. Therefore, it needs only to connect s with the nearest active point.

Since R_1 and R_2 have the same sweep sequence, they can be processed together in one pass. Similarly, R_3 and R_4 can be processed together in another pass. Based on the above discussion, the pseudo-code of the algorithm is presented in Fig. 2.

The correctness of the algorithm is stated in the following theorem.

Theorem 1 *Given n points in the plane, the rectilinear spanning graph algorithm constructs a spanning graph in $O(n \log n)$ time, and the number of edges in the graph is $O(n)$.*

Proof The algorithm can be considered as deleting edges from the complete graph. As described, all deleted edges are redundant based on the cycle property. Thus, the output graph of the algorithm will contain at least one rectilinear minimum spanning tree.

In the algorithm, each given point will be inserted and deleted at most once from the active set for each of the four regions R_1 through R_4. For each insertion or deletion, the algorithm requires $O(\log n)$ time. Thus, the total time is upper bounded by $O(n \log n)$. The storage is needed only for active sets, which is at most $O(n)$.

Applications

Rectilinear minimum spanning tree problem has wide applications in VLSI CAD. It is frequently used as a metric of wire length estimation during placement. It is often constructed to approximate a minimum Steiner tree and is also a key step in many Steiner tree heuristics. It is also used in an approximation to the traveling salesperson problem which can be used to generate scan chains in testing. It is important to emphasize that for real- world applications, the input sizes are usually very large. Since it is a problem that will be computed hundreds of thousands times and many of them will have very large input sizes, the rectilinear minimum spanning tree problem needs a very efficient algorithm.

Experimental Results

The experimental results using the rectilinear spanning graph (RSG) followed by Kruskal's algorithm for a rectilinear minimum spanning tree were reported in Zhou et al. [5]. Two other approaches were compared. The first approach used

the complete graph on the point set as the input to Kruskal's algorithm. The second approach is an implementation of concepts described in [3]; namely, for each point, scan all other points but only connect the nearest one in each quadrant region. With sizes ranging from 1,000 to 20,000, randomly generated point sets were used in the experiments. The results are reproduced here in Table 1. The first column gives the number of generated points; the second column gives the number of distinct points. For each approach, the number of edges in the given graph and the total running time are reported. For input size larger than 10,000, the complete graph approach simply runs out of memory.

Problem Definition

Given n points on a plane, a Steiner minimal tree connects these points through some extra points (called Steiner points) to achieve a minimal total

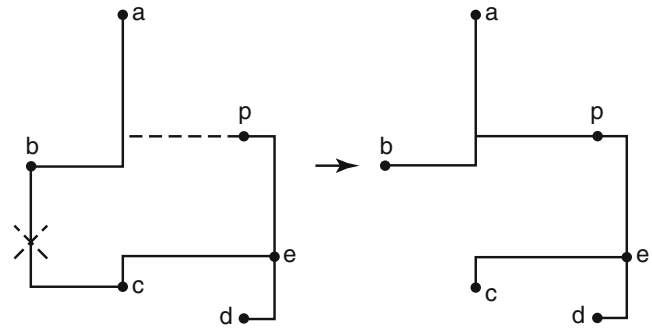
length. When the length between two points is measured by the rectilinear distance, the tree is called a rectilinear Steiner minimal tree.

Because of its importance, there is much previous work to solve the SMT problem. These algorithms can be grouped into two classes: exact algorithms and heuristic algorithms. Since SMT is NP-hard, any exact algorithm is expected to have an exponential worst-case running time. However, two prominent achievements must be noted in this direction. One is the *GeoSteiner* algorithm and implementation by Warme, Winter, and Zacharisen [14, 15], which is the current fastest exact solution to the problem. The other is a Polynomial Time Approximation Scheme (PTAS) by Arora [1], which is mainly of theoretical importance. Since exact algorithms have long running time, especially on large input sizes, much more previous efforts were put on heuristic algorithms. Many of them generate a Steiner tree by improving on a minimal spanning tree topology [7], since it was proved that a minimal spanning tree is a 3/2 approximation of a SMT [8]. However, since the backbones are restricted to the minimal spanning tree topology in these approaches, there is a reported limit on the improvement ratios over the minimal spanning trees. The iterated 1-Steiner algorithm by Kahng and Robins [10] is an early approach to deviate from that restriction, and an improved implementation [6] is a champion among such programs in public domain. However, the implementation in [10] has a running time of $O(n^4 \log n)$, and the implementation in [6] has a running time of $O(n^3)$. A much more efficient approach was later proposed by Borah et al. [2]. In their approach, a spanning tree is iteratively improved by connecting a point to an edge and deleting the longest edge on the created circuit. Their algorithm and implementation had a worst-case running time of $\Theta(n^2)$, even though an alternative $O(n \log n)$ implementation was also proposed. Since the backbone is no longer restricted to the minimal spanning tree topology, its performance was reported to be similar to the iterated 1-Steiner algorithm [2]. A recent effort in this direction is a new heuristic by Mandoiu et al. [11] which is based on a 3/2 approximation algorithm of the metric Steiner tree problem on quasi-bipartite graphs [12]. It performs slightly better than the iterated 1-Steiner algorithm, but its running time is also slightly longer than the iterated 1-Steiner algorithm (with the empty rectangle test [11] used). More recently, Chu [3] and Chu and Wong [4] proposed an efficient lookup table- based approach for rectilinear Steiner tree construction.

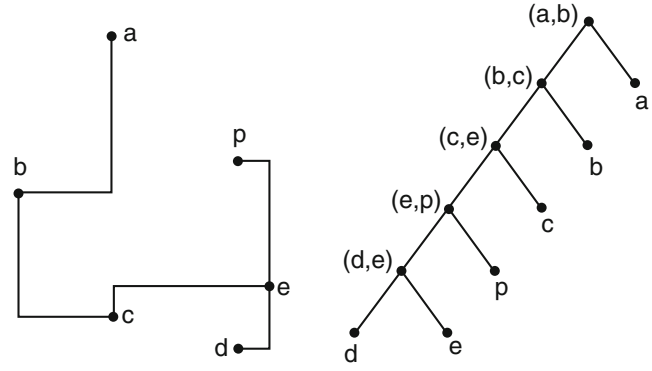
Key Results

The presented algorithm is based on the edge substitution heuristic of Borah et al. [2]. The heuristic works as follows. It starts with a minimal spanning tree and then iteratively considers connecting a point (e.g., p in Fig. 1) to a nearby edge (e.g., (a, b)) and deleting the longest edge $((b, c))$ on the circuit thus formed. The algorithm employs the spanning graph [17] as a backbone of the computation: it is first used to generate the initial minimal spanning tree and then to generate point-edge pairs for tree improvements. This kind of unification happens also in the spanning tree computation and the longest edge computation for each point-edge pair: using Kruskal's algorithm with disjoint set operations (instead of Prim's algorithm) [5] will unify these two computations.

In order to reduce the number of point-edge pair candidates from $O(n^2)$ to $O(n)$, Borah et al. suggested to use the visibility of a point from an edge, that is, only a point visible from an edge can be considered to connect to that edge. This requires a sweep line algorithm to find visibility relations between points and edges. In order to skip this complex step, the geometrical proximity information embedded within the spanning graph is leveraged. Since a point has eight nearest points connected around it, it is observed that if a point is visible to an edge, then the point is *usually* connected in the graph to at least one end point. In the algorithm, the spanning graph is used to generate point-edge pair candidates. For each edge in the current tree, all points that are neighbors of either of the end points will be considered to form point-edge pairs with the edge. Since the cardinality



Rectilinear Steiner Tree, Fig. 1 Edge substitution by Borah et al.



Rectilinear Steiner Tree, Fig. 2 A minimal spanning tree and its merging binary tree

of the spanning graph is $O(n)$, the number of possible point-edge pairs generated in this way is also $O(n)$.

When connecting a point to an edge, the longest edge on the formed circuit needs to be deleted. In order to find the corresponding longest edge for each point-edge pair efficiently, it explores how the spanning tree is formed through Kruskal's algorithm. This algorithm first sorts the edges into nondecreasing lengths, and each edge is considered in turn. If the end points of the edge have been connected, then the edge will be excluded from the spanning tree; otherwise, it will be included. The structure of these connecting operations can be represented by a binary tree, where the leaves represent the points and the internal nodes represent the edges. When an edge is included in the spanning tree, a node is created representing the edge and has as its two children the trees representing the two components connected by this edge. To illustrate this, a spanning tree with its representing binary tree is shown in Fig. 2. As can be seen, the longest edge between two points is the least common ancestor of the two points in the binary tree. For example, the longest edge between p and b in Fig. 2 is (b, c), which is the least common ancestor of p and b in the binary tree. To find the longest edge on the circuit formed by connecting a point to an edge, it needs to find the longest edge between the point and one end point of the edge that are in the same component before connecting the edge. For example, consider the pair p and (a, b); since p and b are in the same component before connecting (a, b), the edge that needs to be deleted is the longest between p and b.

Based on the above discussion, the pseudocode of the algorithm can be described in Fig. 3. At the beginning of the algorithm, Zhou et al.'s rectilinear spanning graph algorithm [17] is used to generate the spanning graph G for the given set of points. Then, Kruskal's algorithm is used on the graph to generate a minimal spanning tree. The data structure of disjoint sets [5] is used to merge components and check whether two points are in the same component (the first **for** loop). During this process, the merging binary tree and

    s1 = find_set(u); s2 = find_set(v);
    if (s1 ! = s2) {
        add (u, v) in tree T;
        for (each neighbor w of u, v in G)
            if (s1 == find_set(w))
                lca_add_query(w, v, (u, v));
            else lca_add_query(w, v, (u, v));
        lca_tree_edge((u, v), s1.edge);
        lca_tree_edge((u, v), s2.edge);
        s = union_set(s1, s2); s.edge = (u, v) ;
    }
}
generate point-edge pairs by lca_answer_queries;
for (each pair (p, (a, b), (c, d)) in non-increasing positive gains)
    if ((a, b), (c, d) has not been deleted from T) {
        connect p to (a, b) by adding three edges to T;
        delete (a, b), (c, d) from T;
    }
```

the queries for least common ancestors of all point-edge pairs are also generated. Here, s, $s1$, and $s2$ represent disjoint sets, and each records the root of the component in the merging binary tree. For each edge (u, v) adding to T, each neighbor w of either u or v will be considered to connect to (u, v). The longest edge for this pair is the least common ancestor of w, u or w, v depending on which point is in the same component as w. The procedure *lca_add_query* is used to add this query. Connecting the two components by (u, v) will also be recorded in the merging binary tree by the procedure *lca_tree_edge*. After generating the minimal spanning tree, it also has the corresponding merging binary tree and the least common ancestor queries ready. Using Tarjan's off-line least common ancestor algorithm [5] (represented by *lca_answer_queries*), it can generate all longest edges for the pairs. With the longest edge for each point-edge pair, the gain of connecting the point to the edge can be calculated. Then, each of the point to edge connections will be realized in a nonincreasing order of their gains. A connection can only be realized if both the connection edge and deletion edge have not been deleted yet.

The running time of the algorithm is dominated by the spanning graph generation and edge sorting, which take $O(n \log n)$ time. Since the number of edges in the spanning graph is $O(n)$, both Kruskal's algorithm and Tarjan's off-line least common ancestor algorithm take $O(n\alpha(n))$ time, where $\alpha(n)$ is the inverse of Ackermann's function, which grows extremely slow.

Applications

The Steiner minimal tree (SMT) problem has wide applications in VLSI CAD. A SMT is generally used in initial topology creation for noncritical nets in physical synthesis. For timing

critical nets, minimization of wire length is generally not enough. However, since most nets are noncritical in a design and a SMT gives the most desirable route of such a net, it is often used as an accurate estimation of congestion and wire length during floor planning and placement. This implies that a Steiner tree algorithm will be invoked millions of times. On the other hand, there exist many large pre-routes in modern VLSI design. The pre-routes are generally modeled as large sets of points, thus increasing the input sizes of the Steiner tree problem. Since the SMT is a problem that will be computed millions of times and many of them will have very large input sizes, highly efficient solutions with good performance are desired.

Experimental Results

As reported in [16], the first set of experiments were conducted on a Linux system with a 928 MHz Intel Pentium III processor and 512 M memory. The *RST* algorithm was compared with other publicly available programs: the exact algorithm *GeoSteiner* (version 3.1) by Warme, Winter, and Zacharisen [14]; the Batched Iterated 1-Steiner (*BI1S*) by Robins; and the Borah et al.'s algorithm implemented by Madden (*BOI*).

Table 1 gives the results of the first set of experiments. For each input size ranging from 100 to 5,000, 30 different test cases are randomly generated through the *rand_points* program in *GeoSteiner*. The improvement ratios of a Steiner tree *St* over its corresponding minimal spanning tree *MST* are defined as `100 × (MST - St)/MST`. For each input size, the average of the improvement ratios and the average running time (in seconds) on each of the programs are reported. As can be seen, *RST* always gives better improvements than *BOI* with less running times.

The second set of experiments compared *RST* with Borah's implementation of Borah et al.'s algorithm (*Borah*), Rohe's Prim-based algorithm (*Rohe*) [13], and Kahng et al.'s Batched Greedy Algorithm (*BGA*) [9]. They were run on a different Linux system with a 2.4 GHz Intel Xeon processor and 2 G memory. Besides the randomly generated test cases, the VLSI industry test cases used in [9] were also used. The results are reported in Table 2.

Problem Definition

Graph decompositions are the basis for many divide-and-conquer algorithms. Two main properties make a decomposition useful. The first is *balance*, namely, that the parts of the decomposition have roughly the same size. Balanced decompositions lead to logarithmic depth recursion. The second is small *overlap* between the parts of the decomposition. The overlap affects the time it takes to combine solutions of different parts into a solution for the union of the parts.

A decomposition of a graph G is a collection of subgraphs of G, called *regions*, whose union is G. A *decomposition tree* of G is a tree $\mathcal{T}$ whose nodes correspond to subgraphs of G. The root of $\mathcal{T}$ consists of the entire graph G. For a node v of $\mathcal{T}$ that corresponds to a subgraph R, the children $v_1, v_2, \ldots, v_k$ of v correspond to subgraphs of R whose union is R. Every maximal set D of nodes of $\mathcal{T}$, such that no node in D is an ancestor of another (i.e., every maximal antichain in $\mathcal{T}$ with respect to the ancestry partial order), corresponds to a decomposition of G.

A vertex v of G that belongs to a unique region R in a decomposition is called an *interior* vertex (of R). A vertex v that belongs to more than one region is called a *boundary* vertex.

Let G be a graph with n vertices. Given a parameter $r < n$, an *r-division* of G is a decomposition of G into $\Theta(n/r)$ regions, each with at most r vertices and $O(\sqrt{r})$ boundary vertices. The bounds on the number of regions and on the number of vertices in each region imply that an r-division is a balanced decomposition of G. The $O(\sqrt{r})$ bound on the number of boundary vertices immediately implies the same bound for the overlap between different regions in the decomposition. For an increasing sequence $\mathbf{r} = r_1, r_2, \ldots$, a *recursive* $\mathbf{r}$*-division* is a decomposition tree $\mathcal{T}$ in which the nodes at height i form an r_i-division.

For various applications it is useful to impose additional requirements, such as requiring regions to be connected, requiring that each region share vertices with a constant number of other regions, etc. One particularly useful requirement that is relevant to planar graphs is that the boundary vertices of each region lie on a small number of faces. Formally, every region R inherits its embedding from that of the planar graph G. A hole of R is a face of R that is not a face of G. An *r-division with few holes* is an r-division in which each region has a constant number of holes.

Key Results

Balanced graph decompositions with small overlap are based on small balanced separators. An n-vertex graph G has a $f(n)$-separator if there exists a partition A, B, S of the vertices of G, such that the size of S is at most $f(n)$, the sizes of A and B are at most $2n/3$, and no edge exists between A and B. The set S is called a *separator*. The subgraphs induced on $A \cup S$ and $B \cup S$ form a balanced decomposition of G into 2 regions with $f(n)$ boundary vertices.

The best-known separator result for planar graphs is the $O(\sqrt{n})$ vertex separator of Lipton and Tarjan [16]. Consider a breadth-first-search tree T of a planar graph G. Each BFS level (i.e., the set of vertices at a specific distance from the root) is a separator of G, albeit not necessarily a small or a balanced one. Lipton and Tarjan's separator is based on the observation that it is possible to construct an $O(\sqrt{n})$ balanced separator by combining two appropriately chosen BFS levels with a fundamental cycle with respect to the BFS tree T.

Theorem 1 (Lipton-Tarjan separator) *Let G be an n-vertex planar graph, equipped with non-negative vertex weights summing to one. There exists a linear-time algorithm that returns a separation A, B, S of G such that S consists of at*

most $2\sqrt{2n}$ *vertices, and neither* A *nor* B *has total weight exceeding* $2/3$.

Note that the formulation of the theorem allows for a balanced separation with respect to a general weight function, rather than just with respect to the number of vertices.

Miller gave an $O(\sqrt{n})$ simple cycle separator [19] for planar graphs. Miller's result can be viewed as a version of Lipton and Tarjan's separator applied to the planar dual of G.

Theorem 2 (Miller's cycle separator) *Let* G *be an* n*-vertex 2-connected planar graph, equipped with nonnegative face weights summing to 1, such that no face weighs more than 2/3. Let* d *denote the maximum over all face sizes in* G*. There exists a linear-time algorithm that returns a simple cycle* C *with at most* $2\sqrt{2\lfloor d/2 \rfloor n}$ *vertices, such that neither the interior of* C *nor the exterior of* C *has total weight exceeding* $2/3$.

Similar formulations exist for vertex and edge weights.

$O(\sqrt{n})$ separators are known for other families of sparse graphs, such as graphs excluding a fixed minor [1, 11]. However, some sparse graphs (e.g., expanders) do not have small separators.

By applying a separator recursively, Frederickson [6] showed that r-divisions exist for graphs with $O(\sqrt{n})$ separators. Frederickson's construction generates a decomposition tree whose leaves correspond to the regions of an r-division. It consists of two phases. In the first phase, the separator theorem is applied to each region consisting of more than r vertices. This results in $\Theta(n/r)$ regions, each with at most r vertices and $\sqrt{r}$ boundary vertices *on average*. In a second phase, the separator theorem is applied to each region with more than $\sqrt{r}$ boundary vertices, assigning weight only to boundary vertices. Frederickson proves that this two-phase process results in an r-division. A naïve implementation of Frederickson's approach to construct an r-division takes $O(n \log n)$ time. By applying this approach to a contracted graph, and then further subdividing some of the resulting regions, an r-division can be constructed in $O(n \log r + (n/\sqrt{r}) \log n)$ time [6].

Goodrich [7] showed that for planar graphs an entire binary decomposition tree whose leaves correspond to regions with a constant number of vertices can be computed in $O(n)$ time. This is achieved by showing that, after linear time preprocessing, each invocation of Lipton and Tarjan's separator theorem can be implemented in sublinear time in the number of vertices of a region. The key components of Goodrich's algorithm are the use of a tree-cotree pair of spanning trees of G and of its planar dual to facilitate the search for balanced fundamental cycles, representing these trees using dynamic trees [22], and the use of balanced binary search trees to maintain BFS levels. At each recursive iteration a separator is found in a region with n' vertices in $O(\sqrt{n'} \log n')$ time. This leads to a total linear running time for computing a complete decomposition tree.

Subramanian and Klein [12] were the first to suggest r-divisions with few holes in planar graphs. The idea for achieving a constant number of holes is to use Miller's simple cycle separator instead of Lipton and Tarjan's. To keep the number of holes constant, one needs to alternate the separation criterion between balance with respect to the number of vertices and balance with respect to the number of holes [5]. Since a cycle separator introduces at most one new hole into each of the resulting two regions, reducing the number of holes by a constant factor every constant number of iterations ensures that the number of holes in each region is bounded by a (small) constant. Using Frederickson's approach, an r-division with few holes can be constructed in $O(n \log r + (n/\sqrt{r}) \log n)$ [9].

Klein, Mozes, and Sommer [14] presented a modified version of Miller's cycle separator and used it to obtain a linear-time algorithm for computing r-divisions with few holes in planar graphs (see also [2] for a similar result). Following Miller, their cycle separator algorithm uses BFS levels in the planar dual of G. They show a choice of a spanning tree T of G that makes their cycle separator algorithm very similar to Lipton and Tarjan's vertex separator. Using a technique similar to that of Goodrich, they use this cycle separator algorithm to generate an entire decom-

position tree of G in linear time. They show that alternating between three balance criteria (number of vertices, number of boundary vertices, and number of holes) results in a decomposition tree that contains an r-division for any value of r. This is in contrast with Frederickson's two-phase construction which targets a specific value of r. As a consequence, the resulting decomposition tree also contains a recursive **r**-division, for practically any choice of **r**.

Theorem 3 *There exists a linear-time algorithm that, given a planar graph G and an increasing sequence* **r***, computes a recursive* **r***-division with few holes of G.*

Applications

Separator-based decompositions are wildly used in divide-and-conquer algorithms. Lipton and Tarjan [17] used their separator theorem to show a variety of approximation algorithms and subexponential-time algorithms for NP-hard problems such as the maximum independent set, as well as $O(n^{3/2})$-time algorithms for problems such as maximum matching and Gaussian elimination [18]. These recursive algorithms implicitly generate a complete binary decomposition tree of the input graph. Typically, such algorithms only use the existence of small balanced separators and do not rely on planarity. Hence, they are applicable to families of graphs other than planar graphs.

Frederickson introduced r-divisions for computing shortest paths in a planar graph with nonnegative arc lengths in $O(n\sqrt{\log n})$ time and for finding a minimum st-cut or a maximum st-flow in undirected planar graphs in $O(n \log n)$ time. Since then r-divisions were used, along with Goodrich's linear-time construction, in many algorithms and in different settings (sequential, parallel, dynamic graph problems). A very partial list includes dynamic planar graph algorithms [4], Laplacian solvers and electrical flow algorithms [15, 20], and parallel algorithms in computational geometry [7]. Henzinger et al. [8] used a recursive **r**-division with roughly $\log^* n$ levels to compute shortest paths with nonnegative arc lengths in linear time.

Decompositions based on simple cycle separators are also wildly used in efficient algorithms for planar graphs. Examples include maximum flow [3, 10], shortest paths [13], and many others. These algorithms typically rely on additional structural properties specific to planar graphs, such as non-crossing of shortest paths (also known as the Monge property). Decompositions with few holes were introduced by Klein and Subramanian [12] to construct approximate dynamic distance oracles for planar graphs. Fakcharoenphol and Rao [5] used a complete decomposition with few holes for computing shortest paths with negative lengths in planar graphs in $O(n \log^3 n)$-time. The currently fastest algorithm for this problem uses r-divisions with few holes and runs in $O(n \log^2 n / \log\log n)$ time [21]. Italiano et al. [9] used an r-division with few holes to find a min st-cut and max st-flow in $O(n \log\log n)$ time.

Problem Definition

The goal is to design algorithms that succeed in models where input is reported by strategic agents (henceforth referred to as *strategic input*), as opposed to standard models where the input is directly given (henceforth referred to as *honest input*). For example, consider a resource allocation problem where a single user has m jobs to process on n self-interested machines. Each machine i can process job j in time t_{ij}, and this is privately known only to the machine. Each machine reports some processing times $\hat{t}_{ij}$ to the user, who then runs some algorithm to determine where to process the jobs. Good approximation algorithms are known when machines are honest (i.e., $\hat{t}_{ij} = t_{ij}$ for all i, j) if the user's goal is to minimize the *makespan*, the time elapsed until all jobs are completed, going back to seminal work of Lenstra, Shmoys, and Tardos [13]. However, such algorithms do not account for the strategic nature of the machines, which may want to minimize their own work: why would they report honestly their processing time for each job if they can elicit a more favorable schedule by lying? To accommodate such challenges, new algorithmic tools must be developed that draw inspiration from Game Theory.

Requiring solutions that are robust against potential strategic manipulation potentially increases the computational difficulty of whatever problem is at hand. The discussed works provide a framework with which to design such solutions (henceforth called *mechanisms*) and address the following important question.

Question 1 How much (computationally) more difficult is mechanism design than algorithm design?

Using this framework, we resolve this question with an answer of "not at all" for several important problems including job scheduling and fair allocation. Another application of our framework provides efficient algorithms and structural characterization results for multi-item revenue-optimal auction design, a central open problem in mathematical economics.

Model

Environment

1. Set $\mathcal{F}$ of feasible outcomes. Interpret $\mathcal{F}$ as the set of all (feasible) allocations of jobs to machines, allocations of items to bidders, etc.
2. n agents who all care about which outcome is chosen.

Strategic Agents

1. Each agent i has a value $t_i(x)$ for each outcome $x \in \mathcal{F}$. t_i induces a function from $\mathcal{F} \to \mathbb{R}$ and is called the agent's *type*.
2. Each t_i is drawn *independently* from some distribution $\mathcal{D}_i$ of finite support.
3. Agent i knows t_i; all other agents and the designer know only $\mathcal{D}_i$.
4. Agents are *quasi-linear* and *risk neutral*. That is, the utility of an agent of type t for a randomized outcome (distribution over outcomes) $X \in \Delta(\mathcal{F})$, when he is charged price p, is $\mathbb{E}_{x \leftarrow X}[t(x)] - p$.
5. Agents behave in a way that maximizes utility, taking into consideration beliefs about the behavior of other agents.

Designer

1. Designs an *allocation rule* A and *price rule* P. A takes as input a type profile $(t_1, \ldots, t_n)$ and outputs (possibly randomly) an outcome $A(\mathbf{t}) \in \mathcal{F}$. P takes as input a type profile and outputs (possibly randomly) a price vector $P(\mathbf{t})$. The pair (A, P) is called a (direct) *mechanism*. Note that it is without loss of generality to consider only the design of direct mechanisms by the revelation principle [14].
2. Announces A and P to agents. Invites agents to report a type. When $\mathbf{t}$ is reported, selects the outcome $A(\mathbf{t})$ and charges agent i price $P_i(\mathbf{t})$.
3. Has some objective function $\mathcal{O}$ to optimize. $\mathcal{O}$ may depend on the agents' types, the outcome selected, and the prices charged, so we write $\mathcal{O}(\mathbf{t}, x, \mathbf{P})$. Examples include:
   - Social welfare: $\mathcal{O}(\mathbf{t}, x, \mathbf{P}) = \sum_i t_i(x)$.
   - Revenue: $\mathcal{O}(\mathbf{t}, x, \mathbf{P}) = \sum_i P_i(\mathbf{t})$.
   - Makespan: $\mathcal{O}(\mathbf{t}, x, \mathbf{P}) = \max_i \{-t_i(x)\}$ (In job scheduling, agents' values from alloca-

tions are nonpositive, since they have cost for processing jobs. An agent's cost for allocation x is then $-t_i(x)$.).

- Fairness: $\mathcal{O}(\mathbf{t}, x, \mathbf{P}) = \min_i \{t_i(x)\}$.

Game Theoretic Definitions

1. The *interim rule* of a mechanism is a function that takes as input an agent i and type t_i and outputs the distribution of allocations and prices that agent i sees when reporting type t_i over the randomness of the mechanism and the other agents' types, assuming they tell the truth. So the interim allocation rule $(\boldsymbol{\pi}, \mathbf{p})$ of the mechanism (A, P) satisfies:

$$\Pr[x \leftarrow \pi_i(t_i)] = \mathbb{E}_{\mathbf{t}_{-i} \leftarrow \mathcal{D}_{-i}} [\Pr[A(t_i; \mathbf{t}_{-i}) = x]] .$$

$$\Pr[p \leftarrow p_i(t_i)] = \mathbb{E}_{\mathbf{t}_{-i} \leftarrow \mathcal{D}_{-i}} [\Pr[P_i(t_i; \mathbf{t}_{-i}) = p]].$$

2. A mechanism is *Bayesian Incentive Compatible (BIC)* if every agent receives at least as much utility by reporting their true type as any other type (assuming other agents report truthfully). Formally, $t_i(\pi_i(t_i)) - p_i(t_i) \geq t_i(\pi_i(t_i')) - p_i(t_i')$ for all i, t_i, t_i' (We use the shorthand $t_i(\pi_i(t_i'))$ to denote the expected value of t_i for the random allocation drawn from $\pi_i(t_i')$. Formally, $t_i(\pi_i(t_i')) = \mathbb{E}_{x \leftarrow \pi_i(t_i')}[t_i(x)]$.). A commonly used relaxation of BIC is called *ϵ-Bayesian Incentive Compatible (ϵ-BIC)*. A mechanism is ϵ-BIC if every agent derives at most ϵ less utility by reporting their true type comparing to any other type (assuming other agents report truthfully). Formally, $t_i(\pi_i(t_i)) - p_i(t_i) \geq t_i(\pi_i(t_i')) - p_i(t_i') - \epsilon$ for all i, t_i, t_i'.
3. A mechanism is *individually rational (IR)* if every agent has nonnegative expected utility by participating in the mechanism (assuming other agents report truthfully). Formally, $t_i(\pi_i(t_i)) - p_i(t_i) \geq 0$ for all i, t_i.

Bayesian Mechanism Design (BMeD)

Here we describe formally the mechanism design problem we study. BMeD is parameterized by a set of feasible outcomes $\mathcal{F}$, objective function $\mathcal{O}$, and set of possible types $\mathcal{V}$. Both $\mathcal{V}$ and $\mathcal{F}$ can be discrete or continuous. We assume that every element $v \in \mathcal{V}$ and $x \in \mathcal{F}$ can be represented by a finite bit string $\langle v \rangle$ and $\langle x \rangle$. $\mathcal{V}$ and $\mathcal{F}$ also specify how those bit strings are interpreted. For instance, $\mathcal{V}$ might be the class of all submodular functions, and the bit strings used to represent them may be interpreted as indexing a black-box value oracle. Or $\mathcal{V}$ might be the class of all subadditive functions, and the bit strings used to represent them may be interpreted as an explicit circuit. Or $\mathcal{V}$ could be the class of all additive functions, and the bit strings used to represent them may be interpreted as a vector containing values for each item. So we are parameterizing our problems both by the actual classes $\mathcal{V}$ and $\mathcal{F}$ but also by how elements of these classes are represented. Now, we are ready to formally discuss the problem BMeD$(\mathcal{F}, \mathcal{V}, \mathcal{O})$.

BMeD$(\mathcal{F}, \mathcal{V}, \mathcal{O})$:

INPUT*: For each agent $i \in [n]$, a discrete distribution $\mathcal{D}_i$ over types in $\mathcal{V}$, described* explicitly *by listing the support of $\mathcal{D}_i$ and the corresponding probabilities.*

OUTPUT*: A BIC, IR mechanism.*

GOAL*: Find the mechanism that optimizes $\mathcal{O}$ in expectation, with respect to all BIC, IR mechanisms (when n bidders with types drawn from $\times_i \mathcal{D}_i$ report truthfully).*

APPROXIMATION*: A mechanism is said to be an (ϵ, α)-approximation to BMeD if it outputs an ϵ-BIC mechanism whose expected value of $\mathcal{O}$ (when n bidders with types drawn from $\times_i \mathcal{D}_i$ report truthfully) is at least $\alpha\mathrm{OPT} - \epsilon$ (or at most $\alpha\mathrm{OPT} + \epsilon$ for minimization problems).*

Generalized Objective Optimization Problem (GOOP)

Here we describe formally the algorithmic problem we show has strong connections to BMeD. GOOP is parameterized by a set of feasible outcomes $\mathcal{F}$, objective function $\mathcal{O}$, and set of possible types $\mathcal{V}$. We therefore formally discuss the problem GOOP$(\mathcal{F}, \mathcal{V}, \mathcal{O})$. Below, $\mathcal{V}^{\times}$ denotes the closure of $\mathcal{V}$ under linear combinations. Functions in $\mathcal{V}^{\times}$ are represented by a finite list of elements of $\mathcal{V}$, along with (possibly negative) scalar multipliers.

GOOP$(\mathcal{F}, \mathcal{V}, \mathcal{O})$:

INPUT: *For each agent* $i \in [n]$*, a type* $g_i \in \mathcal{V}$*, multiplier* $m_i \in \mathbb{R}$*, and cost function* $f_i \in \mathcal{V}^\times$*. Additionally, an indicator bit* b *(The indicator bit* b *is included so that the optimization of just* $\sum_i f_i(x)$ *(without price multipliers or* $\mathcal{O}$*) is formally a special case of* GOOP$(\mathcal{F}, \mathcal{V}, \mathcal{O})$*.).*

OUTPUT: *An allocation* $x \in \mathcal{F}$*, and price vector* $\mathbf{p} \in \mathbb{R}^n$*.*

GOAL: *Find* $\arg\max_{x \in \mathcal{F}, \mathbf{p}} \{b \cdot \mathcal{O}(\mathbf{g}, x, \mathbf{p}) + \sum_i m_i p_i + \sum_i f_i(x)\}$ *(or* $\arg\min$*, if* $\mathcal{O}$ *is a minimization objective like makespan).*

APPROXIMATION: $(x, \mathbf{p})$ *is said to be an* (α, β)*-approximation to GOOP if* $\beta \cdot b \cdot \mathcal{O}(\mathbf{g}, x, \mathbf{p}) + \sum_i m_i p_i + \sum_i f_i(x)$ *is at least/most* $\alpha \cdot OPT$*. Note that a* $(\alpha, 1)$*-approximation is the standard notion of an* α*-approximation. Allowing* $\beta \neq 1$ *boosts/discounts the value of* $\mathcal{O}$ *(the objective) before comparing to* $\alpha \cdot OPT$*. Note also that allowing* $\beta \neq 1$ *provides no benefit if* $b = 0$*.*

Key Results

We provide a poly-time black-box reduction from BMeD$(\mathcal{F}, \mathcal{V}, \mathcal{O})$ to GOOP$(\mathcal{F}, \mathcal{V}, \mathcal{O})$. That is, we provide a reduction from Bayesian mechanism design to traditional algorithm design.

Theorem 1 *Let* G *be an* (α, β)*-approximation algorithm for* GOOP$(\mathcal{F},\mathcal{V},\mathcal{O})$*. Then for all* $\epsilon > 0$*, there is an* $(\epsilon, \alpha/\beta)$*-approximation algorithm for* BMeD$(\mathcal{F},\mathcal{V},\mathcal{O})$*. If* ℓ *is the length of the input to a* BMeD$(\mathcal{F},\mathcal{V},\mathcal{O})$ *instance, the algorithm succeeds with probability* $1 - \exp(-\text{poly}(\ell, 1/\epsilon))$*, makes* $\text{poly}(\ell, 1/\epsilon)$ *black-box calls to* G *on inputs of size* $\text{poly}(\ell, 1/\epsilon)$*, and terminates in time* $\text{poly}(\ell, 1/\epsilon)$ *(times the running time of each oracle call to* G*).*

This reduction is developed in a recent series of papers by the authors [4–7, 9]. The possibility of failure and additive error is due to a sampling procedure in the reduction. In addition to the computational aspect provided in Theorem 1, our reduction also has a structural aspect. Namely, we provide a characterization of the optimal mechanism in Bayesian settings.

Theorem 2 *For all objectives* $\mathcal{O}$*, feasibility constraints* $\mathcal{F}$*, set of possible types* $\mathcal{V}$*, and inputs* $\mathcal{D}$ *to* BMeD$(\mathcal{F}, \mathcal{V}, \mathcal{O})$*, the optimal mechanism is a distribution over generalized objective maximizers. Formally, there exists a joint distribution* Δ *over an indicator bit* b^δ *and mappings* $(f_1^\delta, \ldots, f_n^\delta)$*, where each* f_i^δ *maps types* t_i *to multipliers* $m_i^\delta(t_i) \in \mathbb{R}$ *and cost functions* $\phi_i^\delta(t_i) \in \mathcal{V}^\times$*, such that the optimal mechanism first samples* $(b^\delta, \mathbf{f}^\delta)$ *from* Δ *then maps the type profile* $\mathbf{t}$ *to the allocation and price vector* $(x(\mathbf{t}), \mathbf{p}(\mathbf{t})) = \arg\max_{x \in \mathcal{F}, \mathbf{p}} \{b^\delta \cdot \mathcal{O}(\mathbf{t}, x, \mathbf{p}) + \sum_i m_i^\delta(t_i) p_i + \sum_i \phi_i^\delta(t_i)(x)\}$.

Perhaps the most interesting case of Theorem 2 is when the objective is revenue. In this case, we may interpret the cost functions $\phi_i^\delta \in \mathcal{V}^\times$ as the *virtual valuation function* of bidder i. By virtual valuations, we do *not* mean Myerson's specific virtual valuation functions [14], which aren't even defined for multi-item instances. Instead we simply mean *some* virtual valuation functions that may or may not be the same as the types/valuations reported by the agents. We include this and other applications of Theorems 1 and 2 below.

Applications

In this section, we apply Theorem 1 to the objectives of revenue, makespan, and fairness.

Revenue Maximization

We apply Theorem 1 to reduce the BMeD problem of optimizing revenue in multi-item settings to GOOP. In [7], it is shown that for this case, one need only consider instances of GOOP with $b = m_1 = \ldots = m_n = 0$, so the GOOP instances that must be solved require just optimization of the cost function (which we call *virtual welfare* for this application). We obtain the following computational and structural results on optimal auction design in general multi-item settings, addressing a long-standing open question following Myerson's seminal work on single-item auctions [14].

Theorem 3 (Revenue Maximization, Computational) *Let G be an α-approximation algorithm for maximizing virtual welfare over $\mathcal{F}$ when all virtual types are from $\mathcal{V}^{\times}$. Then for all $\epsilon > 0$, there is an (ϵ, α)-approximation algorithm for the problem* BMeD($\mathcal{F}, \mathcal{V}$, REVENUE) *that makes polynomially many black-box calls to G. If ℓ is the length of the input to a* BMeD($\mathcal{F}$,$\mathcal{V}$,REVENUE) *instance, the algorithm succeeds with probability $1 - \exp(-\text{poly}(\ell, 1/\epsilon))$, makes $\text{poly}(\ell, 1/\epsilon)$ black-box calls to G on inputs of size $\text{poly}(\ell, 1/\epsilon)$, and terminates in time $\text{poly}(\ell, 1/\epsilon)$ (times the running time of each oracle call to G).*

Theorem 4 (Revenue Maximization, Structural) *In any multi-item setting with arbitrary feasibility constraints and possible agent types, the allocation rule of the revenue-optimal auction is a distribution over virtual welfare maximizers. Formally, there exists a distribution Δ over mappings $(\phi_1, \ldots, \phi_n)$, where each ϕ_i maps types t_i to cost functions $f_i \in \mathcal{V}^{\times}$, such that the allocation rule for the optimal mechanism first samples $\boldsymbol{\phi}$ from Δ then maps type profile $\mathbf{t}$ to the allocation* $\arg\max_{x \in \mathcal{F}} \{\sum_i \phi_i(t_i)(x)\}$.

We further consider the following important special case: There are m items for sale to n buyers. Any allocation of items to buyers is feasible (that is, each item can be awarded to at most one buyer), so we can denote the set of feasible allocations as $\mathcal{F} = [n+1]^m$. Furthermore, each buyer i has a value v_{ij} for item j and is *additive* across items, meaning that their value for a set S of items is $\sum_{j \in S} v_{ij}$. So we can denote the set of possible types as $\mathbb{R}_+^m$ (and have types represented as such).

Theorem 5 (Revenue Maximization for Additive Buyers, Computational) *There is a poly-time algorithm for* GOOP($[n+1]^m$, $\mathbb{R}_+^m$, REVENUE). *Therefore, there is a poly-time algorithm for* BMeD($[n+1]^m, \mathbb{R}_+^m$, REVENUE) *(In this special case, no sampling is required in the reduction, so the theorem holds even for $\epsilon = 0$. Formally, this is a $(0, 1)$-approximation (an exact algorithm). See [4] for details.).*

Theorem 6 (Revenue Maximization for Additive Buyers, Structural) *In any multi-item setting with n additive buyers and m items for sale, the allocation rule of the revenue-optimal auction is a distribution over virtual welfare maximizers. Formally, there exists a distribution Δ over mappings $(\phi_1, \ldots, \phi_n)$, where each ϕ_i maps types t_i to cost functions $f_i \in \mathbb{R}^m$, such that the allocation rule for the optimal mechanism first samples $\boldsymbol{\phi}$ from Δ then awards every item j to a buyer in* $\arg\max_i \{\phi_{ij}(\mathbf{v}_i)\}$ *if their virtual value for item j is nonnegative and does not allocate the item otherwise.*

Job Scheduling on Unrelated Machines

The problem of job scheduling on unrelated machines consists of m jobs and n machines, with machine i able to process job j in time t_{ij}. The goal is to find a schedule (that assigns each job to exactly one machine) minimizing the *makespan*. Specifically, if S_i are the jobs assigned to machine i, the makespan is $\max_i \{\sum_{j \in S_i} t_{ij}\}$. As a mechanism design problem, one considers the machines to be strategic agents who know their processing time for each job (but the designer and other machines do not). In the language of BMeD, we can denote the feasibility constraints as $[n]^m$, the set of possible types as $\mathbb{R}_+^m$, and the objective as MAKESPAN. Theorem 1 reduces BMeD($[n]^m, \mathbb{R}_+^m$, MAKESPAN) to GOOP($[n]^m, \mathbb{R}_+^m$, MAKESPAN). It is shown in [7] that for objectives that don't depend on the prices charged at all (called "allocation-only"), only instances of GOOP with $m_i = 0 \ \forall i$ need be considered. It is further shown in [9] that GOOP($[n]^m, \mathbb{R}_+^m$, MAKESPAN) can be interpreted as a job scheduling problem with costs. Specifically, GOOP($[n]^m, \mathbb{R}_+^m$, MAKESPAN) takes as input a processing time $t_{ij} \geq 0$, and monetary cost $c_{ij} \in \mathbb{R}$ for all machines i and jobs j. The goal is to find a schedule that minimizes the makespan plus cost. Formally, partition the jobs into disjoint sets S_i to minimize $\max_i \{\sum_{j \in S_i} t_{ij}\} + \sum_i \sum_j c_{ij}$. While it is NP-hard to approximate GOOP($[n]^m, \mathbb{R}_+^m$, MAKESPAN) within any finite factor, a result of Shmoys and Tardos from the early 1990s obtains a polynomial time $(1, 1/2)$-

approximation algorithm [15]. In combination with Theorem 1, this yields the following theorem:

Theorem 7 (Job Scheduling on Unrelated Machines) *For all $\epsilon > 0$, there is a poly-time $(\epsilon, 2)$-approximation algorithm for* BMeD($[n]^m, \mathbb{R}_+^m$, MAKESPAN)*. If ℓ is the length of the input to a* BMeD($[n]^m, \mathbb{R}_+^m$, MAKESPAN) *instance, the algorithm succeeds with probability $1 - \exp(-\text{poly}(\ell, 1/\epsilon))$ and terminates in time $\text{poly}(\ell, 1/\epsilon)$.*

Fair Allocation of Indivisible Goods

The problem of fairly allocating indivisible goods consists of m indivisible goods and n children, with child i receiving value v_{ij} for good j. The goal is to find an allocation of goods (that assigns each good to at most one child) maximizing the *fairness*. Specifically, if S_i are the goods allocated to child i, the fairness is $\min_i\{\sum_{j\in S_i} v_{ij}\}$. As a mechanism design problem, one considers the children to be strategic agents who know their own value for each good (but the designer and other children do not). In the language of BMeD, we can denote the feasibility constraints as $[n+1]^m$, the set of possible types as $\mathbb{R}_+^m$, and the objective as FAIRNESS. Theorem 1 reduces BMeD($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS) to GOOP($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS), which can be interpreted as a fair allocation problem with costs (again, because FAIRNESS is allocation only) [7,9]. Specifically, GOOP($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS) takes as input a value $v_{ij} \geq 0$ and monetary cost $c_{ij} \in \mathbb{R}$ for all children i and goods j. The goal is to find an allocation that maximizes the fairness minus cost. Formally, allocate the goods into disjoint sets S_i to maximize $\min_i\{\sum_{j\in S_i} v_{ij}\} - \sum_i \sum_j c_{ij}$. While it is NP-hard to approximate GOOP($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS) within any finite factor, we develop poly-time $(1, m-n+1)$- and $(1/2, \tilde{O}(\sqrt{n}))$-approximation algorithms for fair allocation with costs, based on algorithms of Bezáková and Dani [2] and Asadpour and Saberi [1] for fair allocation (without costs).

Theorem 8 (Fair Allocation of Indivisible Goods) *There are poly-time $(1, m-n+1)$- and $(1/2, \tilde{O}(\sqrt{n}))$-approximation algorithms for* GOOP($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS)*. Therefore, for all $\epsilon > 0$, there is a $(\epsilon, \min\{\tilde{O}(\sqrt{n}), m-n+1\})$-approximation algorithm for* BMeD($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS)*. If ℓ is the length of the input to a* BMeD($[n+1]^m, \mathbb{R}_+^m$, FAIRNESS) *instance, the algorithm succeeds with probability $1 - \exp(-\text{poly}(\ell, 1/\epsilon))$ and terminates in time $\text{poly}(\ell, 1/\epsilon)$.*

Tools for Convex Optimization

We prove Theorems 1 and 2 by solving a linear program over the space of possible interim allocation rules and generalizations of interim allocation rules that we do not discuss here. In doing so, we also develop new tools applicable for general convex optimization that we discuss here. We omit full details of the approach and refer the reader to a series of papers by the authors [5–7, 9] for specifics of the linear program solved and why it addresses BMeD. Seminal works of Khachiyan [12], Grötschel, Lovász, and Schrijver [10], and Karp and Papadimitriou [11] study the problems of optimization and separation over a close, convex region $P \subseteq \mathbb{R}^d$ (Below, we denote by $\alpha P = \{\alpha \mathbf{x} | \mathbf{x} \in P\}$. Also, for simplicity of exposition, we only consider P that contain the origin, so that $\alpha P \subseteq P$ for all $\alpha \leq 1$, but our results extend to all closed, convex P. See [9] for our most general results.). Formally, these problems are:

Optimize(P):

INPUT*: A direction* $\mathbf{c} \in \mathbb{R}^d$.
OUTPUT*: A point* $\mathbf{x} \in P$.
GOAL*: Find* $\mathbf{x}^* \in \arg\max_{\mathbf{x}\in P}\{\mathbf{c}\cdot\mathbf{x}\}$.

Separate(P):

INPUT*: A point* $\mathbf{x} \in \mathbb{R}^d$.
OUTPUT*: "Yes," or a direction* $\mathbf{c} \in \mathbb{R}^d$.
GOAL*: If* $\mathbf{x} \in P$*, output "yes." Otherwise, output any* $\mathbf{c}$ *such that* $\mathbf{c}\cdot\mathbf{x} > \max_{\mathbf{y}\in P}\{\mathbf{c}\cdot\mathbf{y}\}$.

Khachiyan's Ellipsoid algorithm shows that if one can solve the problem Separate(P) in time $\text{poly}(d)$, then one can also solve Optimize(P) in

time poly(d). Grötschel, Lovász, and Schrijver and independently Karp and Papadimitriou show that the other direction holds as well: if one can solve Optimize(P) in time poly(d), then one can also solve Separate(P) in time poly(d). This is colloquially called "the equivalence of separation and optimization." While separation as a means for optimization has obvious uses, optimization as a means for separation is more subtle. Still, numerous applications exist (including our results) and we refer the reader to [10, 11] for several others, including the first poly-time algorithm for submodular minimization.

In order to provide our guarantees with respect to approximation, we develop further the equivalence of separation and optimization to accommodate approximation. Specifically, consider the following problems, further parameterized by some $\alpha < 1$:

α-Optimize(P):

INPUT: *A direction* $\mathbf{c} \in \mathbb{R}^d$.
OUTPUT: *A point* $\mathbf{x} \in P$.
GOAL: *Find* $\mathbf{x}$ *satisfying* $\mathbf{c} \cdot \mathbf{x} \geq \alpha \max_{\mathbf{y} \in P} \{\mathbf{c} \cdot \mathbf{y}\}$.

α-Separate(P):

INPUT: *A point* $\mathbf{x} \in \mathbb{R}^d$.
OUTPUT: *"Yes" and a proof that* $\mathbf{x} \in P$, *or a direction* $\mathbf{c} \in \mathbb{R}^d$ *(For formal details on exactly what constitutes a proof, we refer the reader to [6, 7, 9]. Roughly speaking,* $\mathbf{x}$ *is written as a convex combination of points* known *to be in* P*.).*
GOAL: *If* $\mathbf{x} \in \alpha P$, *output "yes" and a proof that* $\mathbf{x} \in P$. *If* $\mathbf{x} \notin P$, *output a direction* $\mathbf{c}$ *such that* $\mathbf{c} \cdot \mathbf{x} > \alpha \max_{\mathbf{y} \in P} \{\mathbf{c} \cdot \mathbf{y}\}$. *If* $\mathbf{x} \in P \backslash \alpha P$, *either is acceptable.*

Theorem 9 (Approximate Equivalence of Separation and Optimization) *For all* $\alpha \leq 1$, *the problems* α-Optimize(P) *and* α-Separate(P) *are computationally equivalent. That is, if one can solve one in time* poly(d), *one can solve the other in time* poly(d) *as well.*

We also extend these results to accommodate bi-criterion approximation, via the problems below, further parameterized by some $\beta > 1$ and subset $S \subseteq [d]$ of coordinates (Below, when we write $(\beta \mathbf{x}_S, \mathbf{x}_{-S})$, we mean to take $\mathbf{x}$ and multiply each $x_i, i \in S$ by β.).

(α, β, S)-Optimize(P):

INPUT: *A direction* $\mathbf{c} \in \mathbb{R}^d$.
OUTPUT: *A point* $\mathbf{x} \in P$.
GOAL: *Find* $\mathbf{x}$ *satisfying* $\mathbf{c} \cdot (\beta \mathbf{x}_S, \mathbf{x}_{-S}) \geq \alpha \max_{\mathbf{y} \in P} \{\mathbf{c} \cdot \mathbf{y}\}$.

(α, β, S)-Separate(P):

INPUT: *A point* $\mathbf{x} \in \mathbb{R}^d$.
OUTPUT: *"Yes" and a proof that* $\mathbf{x} \in P$, *or a direction* $\mathbf{c} \in \mathbb{R}^d$.
GOAL: *If* $(\beta \mathbf{x}_S, \mathbf{x}_{-S}) \in \alpha P$, *output "yes" and a proof that* $\mathbf{x} \in P$. *If* $\mathbf{x} \notin P$, *output a direction* $\mathbf{c}$ *such that* $\mathbf{c} \cdot (\beta \mathbf{x}_S, \mathbf{x}_{-S}) > \alpha \max_{\mathbf{y} \in P} \{\mathbf{c} \cdot \mathbf{y}\}$. *If* $(\beta \mathbf{x}_S, \mathbf{x}_{-S}) \notin \alpha P$ *and* $\mathbf{x} \in P$, *either is acceptable (An astute reader might worry that for some* α, β, S, P, *the problem* (α, β, S)*-Separate(*P*) is impossible, due to the existence of an* $\mathbf{x} \notin P$ *such that* $(\beta \mathbf{x}_S, \mathbf{x}_{-S}) \in \alpha P$. *For some* α, β, S, P, *this is indeed the case, but we show that* (α, β, S)*-Optimize(*P*) is impossible in these cases as well.).*

Theorem 10 (Bi-Criterion Approximate Equivalence of Separation and Optimization) *For all* $\alpha \leq 1, \beta \geq 1, S \subseteq [d]$, *the problems* (α, β, S)-Optimize(P) *and* (α, β, S)-Separate(P) *are computationally equivalent. That is, if one can solve one in time* poly(d), *one can solve the other in time* poly(d) *as well.*

More formal statements and how we apply these theorems to yield our main result can be found in [9]. Finally, the theorems hold for minimization as well as maximization and without the restriction that P contains the origin (but the theorem statements are more technical).

Open Problems

Our work provides a novel computational framework for solving Bayesian mechanism design problems. We have applied our framework to solve several specific important problems, such as computing revenue-optimal auctions in multi-item settings and approximately optimal BIC mechanisms for job scheduling, but numerous

R

important settings and objectives remain unresolved. Theorem 1 provides a concrete approach for tackling such problems, via the design of (α, β)-approximations for the purely algorithmic Generalized Objective Optimization Problem. Therefore, one important direction following our work is to apply our framework to novel settings and design algorithms for the resulting GOOP instances.

Keywords

Asynchronous communication hardware; Shared-memory (wait-free); Wait-free registers; Wait-free shared variables

Years and Authors of Summarized Original Work

1986; Lamport, Vitanyi, Awerbuch

Problem Definition

Consider a system of asynchronous processes that communicate among themselves by only executing read and write operations on a set of shared variables (also known as shared *registers*). The system has no global clock or other synchronization primitives. Every shared variable is associated with a process (called *owner*) which writes it and the other processes may read it. An execution of a write (read) operation on a shared variable will be referred to as a *Write* (*Read*) on that variable. A Write on a shared variable puts a value from a pre-determined finite domain into the variable, and a Read reports a value from the

domain. A process that writes (reads) a variable is called a *writer* (*reader*) of the variable.

The goal is to construct shared variables in which the following two properties hold. (1) Operation executions are not necessarily atomic, that is, they are not indivisible but rather consist of atomic sub-operations, and (2) every operation finishes its execution within a bounded number of its own steps, irrespective of the presence of other operation executions and their relative speeds. That is, operation executions are *wait-free*. These two properties give rise to a classification of shared variables, depending on their output characteristics. Lamport [8] distinguishes three categories for 1-writer shared variables, using a precedence relation on operation executions defined as follows: for operation executions A and B, A *precedes* B, denoted $A \longrightarrow B$, if A finishes before B starts; A and B *overlap* if neither A precedes B nor B precedes A. In 1-writer variables, all the Writes are totally ordered by "$\longrightarrow$". The three categories of 1-writer shared variables defined by Lamport are the following.

1. A *safe* variable is one in which a Read not overlapping any Write returns the most recently written value. A Read that overlaps a Write may return any value from the domain of the variable.
2. A *regular* variable is a safe variable in which a Read that overlaps one or more Writes returns either the value of the most recent Write preceding the Read or of one of the overlapping Writes.
3. An *atomic* variable is a regular variable in which the Reads and Writes behave as if they occur in some total order which is an extension of the precedence relation.

A shared variable is *boolean* (Boolean variables are referred to as *bits*.) or *multivalued* depending upon whether it can hold only one out of two or one out of more than two values. A *multiwriter* shared variable is one that can be written and read (concurrently) by many processes. If there is only one writer and more than one reader it is called a *multireader* variable.

Key Results

In a series of papers starting in 1974, for details see [4], Lamport explored various notions of concurrent reading and writing of shared variables culminating in the seminal 1986 paper [8]. It formulates the notion of wait-free implementation of an atomic multivalued shared variable – written by a single writer and read by (another) single reader – from safe 1-writer 1-reader 2-valued shared variables, being mathematical versions of physical *flip-flops*, later optimized in [13]. Lamport did not consider constructions of shared variables with more than one writer or reader.

Predating the Lamport paper, in 1983 Peterson [10] published an ingenious wait-free construction of an atomic 1-writer, n-reader m-valued atomic shared variable from $n + 2$ safe 1-writer n-reader m-valued registers, $2n$ 1-writer 1-reader 2-valued atomic shared variables, and 2 1-writer n-reader 2-valued atomic shared variables. He presented also a proper notion of the wait-freedom property. In his paper, Peterson didn't tell how to construct the n-reader boolean atomic variables from flip-flops, while Lamport mentioned the open problem of doing so, and, incidentally, uses a version of Peterson's construction to bridge the algorithmically demanding step from atomic shared bits to atomic shared multivalues. On the basis of this work, N. Lynch, motivated by concurrency control of multi-user data-bases, posed around 1985 the question of how to construct wait-free multiwriter atomic variables from 1-writer multireader atomic variables. Her student Bloom [1] found in 1985 an elegant 2-writer construction, which, however, has resisted generalization to multiwriter. Vitányi and Awerbuch [14] were the first to define and explore the complicated notion of wait-free constructions of general multiwriter atomic variables, in 1986. They presented a proof method, an unbounded solution from 1-writer 1-reader atomic variables, and a bounded solution from 1-writer n-reader atomic variables. The bounded solution turned out not to be atomic, but only achieved regularity ("Errata" in [14]). The paper introduced important notions and techniques

in the area, like (bounded) vector clocks, and identified open problems like the construction of atomic wait-free bounded multireader shared variables from flip-flops, and atomic wait-free bounded multiwriter shared variables from the multireader ones. Peterson who had been working on the multiwriter problem for a decade, together with Burns, tried in 1987 to eliminate the error in the unbounded construction of [14] retaining the idea of vector clocks, but replacing the obsolete-information tracking technique by repeated scanning as in [10]. The result [11] was found to be erroneous in the technical report (R. Schaffer, On the correctness of atomic multiwriter registers, Report MIT/LCS/TM-364, 1988). Neither the re-correction in Schaffer's Technical Report, nor the claimed re-correction by the authors of [11] has appeared in print. Also in 1987 there appeared at least five purported solutions for the implementation of 1-writer n-reader atomic shared variable from 1-writer 1-reader ones: [2, 7, 12] (for the others see [4]) of which [2] was shown to be incorrect (S. Haldar, K. Vidyasankar, *ACM Oper. Syst. Rev*, 26:1(1992), 87–88) and only [12] appeared in journal version. The paper [9], initially a 1987 Harvard Tech Report, resolved all multiuser constructions in one stroke: it constructs a bounded n-writer n-reader (multiwriter) atomic variable from $O(n^2)$ 1-writer 1-reader safe bits, which is optimal, and $O(n^2)$ bit-accesses per Read/Write operation which is optimal as well. It works by making the unbounded solution of [14] bounded, using a new technique, achieving a robust proof of correctness. "Projections" of the construction give specialized constructions for the implementation of 1-writer n-reader (multireader) atomic variables from $O(n^2)$ 1-writer 1-reader ones using $O(n)$ bit accesses per Read/Write operation, and for the implementation of n-writer n-reader (multiwriter) atomic variables from n 1-writer n-reader (multireader) ones. The first "projection" is optimal, while the last "projection" may not be optimal since it uses $O(n)$ control bits per writer while only a lower bound of $\Omega(\log n)$ was established. Taking up this challenge, the construction in [6] claims to achieve this lower bound.

Timestamp System

In a multiwriter shared variable it is only required that every process keeps track of which process wrote last. There arises the general question whether every process can keep track of the order of the last Writes by all processes. A. Israeli and M. Li were attracted to the area by the work in [14], and, in an important paper [5], they raised and solved the question of the more general and universally useful notion of a bounded timestamp system to track the order of events in a concurrent system. In a timestamp system every process owns an *object*, an abstraction of a set of shared variables. One of the requirements of the system is to determine the temporal order in which the objects are written. For this purpose, each object is given a *label* (also referred to as a *timestamp*) which indicates the latest (relative) time when it has been written by its owner process. The processes assign labels to their respective objects in such a way that the labels reflect the real-time order in which they are written to. These systems must support two operations, namely *labeling* and *scan*. A labeling operation execution (Labeling, in short) assigns a new label to an object, and a scan operation execution (Scan, in short) enables a process to determine the ordering in which all the objects are written, that is, it returns a set of labeled-objects ordered temporally. The concern is with those systems where operations can be executed *concurrently*, in an overlapped fashion. Moreover, operation executions must be *wait-free*, that is, each operation execution will take a bounded number of its own steps (the number of accesses to the shared space), irrespective of the presence of other operation executions and their relative speeds. Israeli and Li [5] constructed a bit-optimal bounded timestamp system for *sequential* operation executions. Their sequential timestamp system was published in the above journal reference, but the preliminary concurrent timestamp system in the conference proceedings, of which a more detailed version has been circulated in manuscript form, has not been published in final form. The first generally accepted solution of the *concurrent* case of the bounded timestamp system was from Dolev and Shavit [3]. Their construction is of the type presented in [5]

and uses shared variables of size $O(n)$, where n is the number of processes in the system. Each Labeling requires $O(n)$ steps, and each Scan $O(n^2 \log n)$ steps. (A 'step' accesses an $O(n)$ bit variable.) In [4] the unbounded construction of [14] is corrected and extended to obtain an efficient version of the more general notion of a bounded concurrent timestamp system.

Applications

Wait-free registers are, together with message-passing systems, the primary interprocess communication method in distributed computing theory. They form the basis of all constructions and protocols, as can be seen in the textbooks. Wait-free constructions of concurrent timestamp systems (CTSs, in short) have been shown to be a powerful tool for solving concurrency control problems such as various types of mutual exclusion, multiwriter multireader shared variables [14], and probabilistic consensus, by synthesizing a "wait-free clock" to sequence the actions in a concurrent system. For more details see [4].

Open Problems

There is a great deal of work in the direction of register constructions that use less constituent parts, or simpler parts, or parts that can tolerate more complex failures, than previous constructions referred to above. Only, of course, if the latter constructions were not yet optimal in the parameter concerned. Further directions are work on wait-free higher-typed objects, as mentioned above, hierarchies of such objects, and probabilistic constructions. This literature is too vast and diverse to be surveyed here.

Experimental Results

Register constructions, or related constructions for asynchronous interprocess communication, are used in current hardware and software.

Problem Definition

Given a *text string* T of length n and a *regular expression* R, the **regular expression matching** problem **(REM)** is to find all text positions at which an occurrence of a string in $L(R)$ ends (see below for definitions).

For an alphabet Σ, a *regular expression* R over Σ consists of elements of $\Sigma \cup \{\varepsilon\}$ (ε denotes the empty string) and operators $\cdot$ (concatenation), $|$ (union), and $*$ (iteration, i.e., repeated concatenation); the set of strings $L(R)$ represented by R is defined accordingly; see [7]. It is important to distinguish two measures for the size of a regular expression: the *size*, m, which is the total number of characters from $\Sigma \cup \{\cdot, |, *\}$, and Σ-*size*, m_Σ, which counts only the characters in Σ. As an example, for $R = \texttt{(A|T)((C|CG)*)}$, the set $L(R)$ contains all strings that start with an `A` or a `T` followed by zero or more strings in the set $\{\texttt{C}, \texttt{CG}\}$; the size of R is $m = 8$ and the Σ-size is $m_\Sigma = 5$. Any regular expression can be processed in linear time so that $m = \mathcal{O}(m_\Sigma)$ (with a small constant); the difference becomes important when the two sizes appear as exponents.

Key Results

Finite Automata

The classical solutions for the REM problem involve finite automata which are directed graphs with the edges labelled by symbols from $\Sigma \cup \{\varepsilon\}$; their nodes are called states; see [7] for details. Unrestricted automata are called *nondeterministic finite automata (NFA)*. *Deterministic finite automata (DFA)* have no ε-labels and require that no two outgoing edges of the same state have the same label. Regular expressions and DFAs are equivalent, that is, the sets of strings represented are the same, as shown by Kleene [11]. There are two classical ways of computing an NFA from a regular expression. Thompson's construction [17] builds an NFA with up to $2m$ states and up to $4m$ edges whereas Glushkov-McNaughton-Yamada's automaton [5, 12] has the minimum number of states, $m_\Sigma + 1$, and $\mathcal{O}(m_\Sigma^2)$ edges; see Fig. 1. Any NFA can be converted into an equivalent DFA by the *subset construction*: each subset of the set of states of the NFA becomes a state of the DFA. The problem is that the DFA can have exponentially more states than the NFA.

Classical Solutions

A regular expression is first converted into an NFA or DFA which is then simulated on the text. In order to be able to search for a match starting anywhere in the text, a loop labelled by all elements of Σ is added to the initial state; see Fig. 1.

Searching with an NFA requires linear space, but many states can be active at the same time, and to update them all we need, for Thompson's NFA, $\mathcal{O}(m)$ time for each letter of the text; this gives Theorem 1. On the other hand, DFAs allow searching time that is linear in n but require more space for the automaton. Theorem 2 uses the DFA obtained from Glushkov-McNaughton-Yamada's NFA.

Theorem 1 (Thompson [17]) *The REM problem can be solved with an NFA in $\mathcal{O}(mn)$ time and $\mathcal{O}(m)$ space.*

Theorem 2 (Kleene [11]) *The REM problem can be solved with a DFA in $\mathcal{O}(n + 2^{m\Sigma})$ time and $\mathcal{O}(2^{m\Sigma})$ space.*

Lazy Construction and Modules

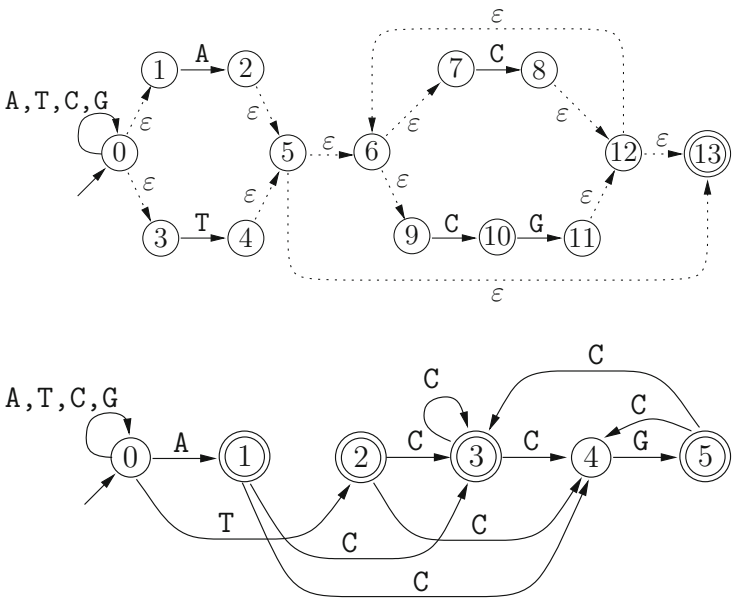
One heuristic to alleviate the exponential increase in the size of DFA is to build only the states reached while scanning the text, as implemented in *Gnu Grep*. Still, the space needed for the DFA remains a problem. A four-Russians approach was presented by Myers [13] where a trade-off between the NFA and DFA approaches is proposed. The syntax tree of the regular expression is divided into modules which are implemented as DFAs and are thereafter treated as leaf nodes in the syntax tree. The process continues until a single module is obtained. An $\mathcal{O}(mn/\log n)$ time and space algorithm is obtained. This bound was recently improved by Bille and Thorup [2].

Theorem 3 (Bille and Thorup [2]) *The REM problem can be solved in linear space and $\mathcal{O}\left(mn/(\log n)^{3/2}\right)$ time.*

The same authors showed in [3] that the length m of the regular expression can be essentially replaced in the complexity bounds by the number of strings (concatenations of characters) that appear in the regular expression.

Bit Parallelism

The simulation of the abovementioned modules is done by encoding all states as bits of a single computer word (called *bit mask*) so that all can be updated in a single operation. The method can be used without modules to simulate directly an NFA as done in [20] and implemented in the



Regular Expression Matching, Fig. 1 Thompson's NFA (*left*) and Glushkov-McNaughton-Yamada's NFA (*right*) for the regular expression `(A|T)((C|CG)*)`; the initial loops labelled `A,T,C,G` are not part of the construction; they are needed for REM

Agrep software [19]. Note that, in fact, the DFA is also simulated: a whole bit mask corresponds to a subset of states of the NFA, that is, one state of the DFA.

The bit-implementation of Wu and Manber [20] uses the property of Thompson's automaton that all Σ-labelled edges connect consecutive states, that is, they carry a bit 1 from position i to position $i+1$. This makes it easy to deal with the Σ-labelled edges, but the ε-labelled ones are more difficult. A table of size linear in the number of states of the DFA needs to be precomputed to account for the ε-closures (set of states reachable from a given state by ε-paths).

Note that in Theorems 1, 2, and 3, the space complexity is given in words. In Theorems 4 and 5 below, for a more practical analysis, the space is given in bits and the alphabet size is also taken into consideration. For comparison, the space in Theorem 2, given in bits, is $\mathcal{O}(|\Sigma| m_\Sigma 2^{m_\Sigma})$.

Theorem 4 (Wu and Manber [20]) *Thompson's automaton can be implemented using* $2m(2^{2m+1} + |\Sigma|)$ *bits.*

Glushkov-McNaughton-Yamada's automaton has different structural properties. First, it is ε-free, that is, there are no ε-labels on edges. Second, all edges incoming to a given state are labelled the same. These properties are exploited by Navarro and Raffinot [16] to construct a bit-parallel implementation that requires less space. The result is a simple algorithm for regular expression searching which uses less space and usually performs faster than any existing algorithm.

Theorem 5 (Navarro and Raffinot [16]) *Glushkov-McNaughton-Yamada's automaton can be implemented using* $(m_\Sigma + 1)(2^{m_\Sigma+1} + |\Sigma|)$ *bits.*

All algorithms in this category run in $\mathcal{O}(n)$ time, but smaller DFA representation implies more locality of reference and thus faster algorithms in practice. An improvement of any algorithm using Glushkov-McNaughton-Yamada's automaton can be done by reducing first the automaton by merging some of its states, as done by Ilie et al. [8, 9]. The reduction can be performed in such a way that all useful properties of the automaton are preserved. The search becomes faster due to the reduction in size.

Filtration

The above approaches examine every character in the text. In [18] a multipattern search algorithm is used to search for strings that must appear inside any occurrence of the regular expression. Another technique is used in *Gnu Grep*; it extracts the longest string that must appear in any match (it can be used only when such a string exists). In [16], bit-parallel techniques are combined with a reverse factor search approach to obtain a very fast character-skipping algorithm for regular expression searching.

Related Problems

Regular expressions with *backreference* have a feature that helps remembering what was matched to be used later; the matching problem becomes NP-complete; see [1]. *Extended* regular expressions involve adding two extra operators, intersection and complement, which do not change the expressive power. The corresponding matching problem can be solved in $\mathcal{O}((n+m)^4)$ time using dynamic programming; see [7, Exercise 3.23].

Concerning finite automata construction, recall that Thompson's NFA has $\mathcal{O}(m)$ edges, whereas the ε-free Glushkov-McNaughton-Yamada's NFA can have a quadratic number of edges. It has been shown in [4] that one can always build an ε-free NFA with $\mathcal{O}(m \log m)$ edges (for fixed alphabets). However, it is the number of states which is more important in the searching algorithms.

Applications

Regular expression matching is a powerful tool in text-based applications, such as text retrieval and text editing, and in computational biology to find various motifs in DNA and protein sequences. See [6] for more details.

Open Problems

The most important theoretical problem is whether linear time and linear space can be achieved simultaneously. Characterizing the regular expressions that can be searched for using a linear-size equivalent DFA is also of interest. The expressions consisting of a single string are included here – the algorithm of Knuth, Morris, and Pratt is based on this. Also, it is not clear how much we can reduce an NFA efficiently (as done by [8, 9]); the problem of finding a minimal NFA is PSPACE-complete; see [10]. Finally, for testing, it is not clear how to define random regular expressions.

Experimental Results

A disadvantage of the bit-parallel technique compared with the classical implementation of a DFA is that the former builds all possible subsets of states whereas the latter builds only the states that can be reached from the initial one (the other ones are useless). On the other hand, bit-parallel algorithms are simpler to code and more flexible (they allow also approximate matching), and there are techniques for reducing the space required. Among the bit-parallel versions, Glushkov-McNaughton-Yamada-based algorithms are better than Thompson-based ones. Modules obtain essentially the same complexity as bit-parallel ones but are more complicated to implement and slower in practice. As the number of computer words increases, bit-parallel algorithms slow down and modules may become attractive. Note also that technological progress has more impact on the bit-parallel algorithms, as opposed to classical ones, since the former depend very much on the machine word size. For details on comparison among various algorithms (including filtration based), see [15]; more recent comparisons are in [16], including the fastest algorithms to date.

URLs to Code and Data Sets

Many text editors and programming languages include regular expression search features. They are, as well, among the tools used in protein databases, such as PROSITE and SWISS-PROT, which can be found at www.expasy.org. The package *agrep* [20] can be downloaded from webglimpse.net and *nrgrep* [14] from www.dcc.uchile.cl/gnavarro/software.

Keywords

Neuro-dynamic programming

Years and Authors of Summarized Original Work

1992; Watkins

Problem Definition

Many sequential decision problems ranging from dynamic resource allocation to robotics can be formulated in terms of stochastic control and solved by methods of reinforcement learning. Therefore, reinforcement learning (a.k.a neuro-dynamic programming) has become one of the major approaches to tackling real-life problems.

In reinforcement learning, an agent wanders in an unknown environment and tries to maximize its long-term return by performing actions and receiving rewards. The most popular mathematical models to describe reinforcement learning problems are the Markov Decision Process (MDP) and its generalization, the partially observable MDP. In contrast to supervised learning, in reinforcement learning, the agent is learning through interaction with the environment and thus influences the "future." One of the challenges that arises in such cases is the exploration-exploitation dilemma. The agent can choose either to exploit its current knowledge and perhaps not learn anything new or to explore and risk missing considerable gains.

While reinforcement learning contains many problems, due to lack of space, this entry focuses on the basic ones. For a detailed history of the development of reinforcement learning, see [1, Chapter 1]. The focus of this entry is on Q-learning and Rmax.

Notation

Markov Decision Process

A Markov decision process (MDP) formalizes the following problem. An agent is in an environment, which is composed of different states. In each time step, the agent performs an action and as a result observes a signal. The signal is composed from the reward to the agent and the state it reaches in the next time step. More formally the MDP is defined as follows:

Definition 1 A Markov decision process (MDP) M is a 4-tuple (S,A,P,R), where S is a set of states, A is a set of actions, $P_{s,s'}{}^{a}$ is the transition probability from state s to state s' when performing action $a \in A$ in state s, and $R(s,a)$ is the reward distribution when performing action a in state s.

A strategy for an MDP assigns, at each time t, for each state s a probability for performing action $a \in A$, given a history $F_{t-1} =$

$\{s_1, a_1, r_1, \ldots, s_{t-1}, a_{t-1}, r_{t-1}\}$ which includes the states, actions, and rewards observed until time $t-1$. While executing a strategy π, an agent performs at time t action a_t in state s_t and observes a reward r_t (distributed according to $R(s_t, a_t)$), and a next state s_{t+1} (distributed according to $P_{s_t,\cdot}^{a_t}$). The sequence of rewards is combined into a single value called the *return*. The agent's goal is to maximize the return. There are several natural ways to define the return.

- *Finite horizon:* The return of policy π for a given horizon H is $\sum_{t=0}^{H} r_t$.
- *Discounted return:* For a discount parameter $\gamma \in (0,1)$, the discounted return of policy π is $\sum_{t=0}^{\infty} \gamma^t r_t$.
- *Undiscounted return:* The return of policy π is $\lim_{t\to\infty} \frac{1}{t+1} \sum_{i=0}^{t} r_i$.

Due to lack of space, only discounted return, which is the most popular approach mainly due to its mathematical simplicity, is considered. The value function for each state s, under policy π, is defined as $V^{\pi}(s) = E^{\pi}[\sum_{i=0}^{\infty} r_i \gamma^i]$, where the expectation is over a run of policy π starting at state s. The state-action value function for using action a in state s and then following π is defined as $Q^{\pi}(s,a) = R(s,a) + \gamma \sum_{s'} P_{s,s'}^{a} V^{\pi}(s')$.

There exists a stationary deterministic optimal policy, π^*, which maximizes the return from any start state [11]. This implies that for any policy π and any state s, $V^{\pi *}(s) \geq V^{\pi}(s)$, and $\pi^*(s) = \text{argmax}_a(Q^{\pi *}(s,a))$. A policy π is ε-optimal if $\|V^{\pi *} - V^{\pi}\|_{\infty} \leq \epsilon$.

Problems Formulation

The reinforcement learning problems are divided into two categories, planning and learning.

Planning

Given an MDP in its tabular form, compute the optimal policy. An MDP is given in its tabular form if the 4-tuple, (A, S, P, R) is given explicitly.

The standard methods for the planning problem in MDP are given below.

Value Iteration

Value iteration is defined as follows. Start with some initial value function, C_s, and then iterate using the Bellman operator, $TV(s) = \max_a R(s,a) + \gamma \sum_{s' \in S} P_{s,s'}^{a} V(s')$.

$$V_0(s) = C_s$$

$$V_{t+1}(s) = TV_t(s),$$

This method relies on the fact that the Bellman operator is contracting. Therefore, the distance between the optimal value function and current value function contracts by a factor of γ with respect to max norm (L_∞) in each iteration.

Policy Iteration

This algorithm starts with initial policy π_0 and iterates over polices. The algorithm has two phases for each iteration. In the first phase, the *value evaluation step*, a value function for π_t is calculated, by finding the fixed point of $T_{\pi t} V_{\pi t} = V_{\pi t}$, where $T_{\pi t} V = R(S, \pi_t(s)) + \gamma \sum_{s' \in S} P_{s,s'}^{\pi_t(s)} V(s')$. The second phase, *policy improvement step*, is taking the next policy π_{t+1} as a greedy policy with respect to $V_{\pi t}$. It is known that policy iteration converges with fewer iterations than value iteration. In practice the convergence of policy iteration is very fast.

Linear Programming

This approach formulates and solves an MDP as a linear program (LP). The LP variables are $V_1, \ldots, V_n$, where $V_i = V(s_i)$. The definition is:

Variables: $V_1, \ldots, V_n$
Minimize: $\sum_i V_i$
Subject to: $V_i \geq [R(s_i, a) + \gamma \sum_j P_{s_i, s_j}(a) V_j]$

$$\forall a \in A, s_i \in S.$$

Learning

Given the states and action identities, learn an (almost) optimal policy through interaction with

the environment. The methods are divided into two categories: model-free learning and model-based learning.

The widely used Q-learning [16] is a model-free algorithm. This algorithm belongs to the class of temporal difference algorithms [12]. Q-learning is an off-policy method, i.e., it does not depend on the underlying policy but, as can immediately be seen, depends on the trajectory and not on the policy generating the trajectory.

Q-Learning

The algorithm estimates the state-action value function (for discounted return) as follows:

$$Q_0(s,a) = 0$$
$$Q_{t+1}(s,a) = (1-\alpha_t(s,a))Q_t(s,a) + \alpha_t(s,a)(r_t(s,a) + \gamma V_t(s'))$$

where s' is the state reached from state s when performing action a at time t, and $V_t(s) = \max_a Q_t(s,a)$. Assume that $\alpha_t(s',a') = 0$ if at time t action a' was not performed at state s'. A learning rate α_t is *well behaved* if for every state action pair (s,a): (1) $\sum_{t=1}^{\infty} \alpha_t(s,a) = \infty$ and (2) $\sum_{t=1}^{\infty} \alpha_t^2(s,a) = \infty$. As will be seen, this is necessary for the convergence of the algorithm.

The model-based algorithms are very simple to describe; they simply build an empirical model and use any of the standard methods to find the optimal policy in the empirical (approximate) model. The main challenge in these methods is in balancing exploration and exploitation and having an appropriate stopping condition. Several algorithms give a nice solution for this [3, 7]. A version of these algorithms appearing in [6] is described below.

On an intuitive level, a state will become known when it was visited "enough" times and one can estimate with high probability its parameters with good accuracy. The modified empirical model is defined as follows. All states that are not in K are represented by a single absorbing state in which the reward is maximal (which causes exploration). The probability to move to the absorbing state from a state $s \in K$ is the empirical probability to move out of K from s and the probability to move between states in K is the empirical probability.

Algorithm 1: A model-based algorithm

```
Rmax
Set K = ∅;
if s ∈ K? then
   Execute π̂(s)
else
   Execute a random action;
   if s becomes known then
      K = K ∪ {s};
      Compute optimal policy, π̂ for
      the modified empirical model
   end
end
```

Sample complexity [6] measures how many samples an algorithm needs in order to learn. Note that the sample complexity translates into the time needed for the agent to wander in the MDP.

Key Results

The first Theorem shows that the planning problem is easy as long as the MDP is given in its tabular form, and one can use the algorithms presented in the previous section.

Theorem 1 ([10]) *Given an MDP, the planning problem is P-complete.*

The learning problem can be done also efficiently using the $R_{\max}$ algorithm as is shown below.

Theorem 2 ([3, 7]) *$R_{\max}$ computes an ε-optimal policy from state s with probability at least $1-\delta$ with sample complexity polynomial in $|A|, |S|, \frac{1}{\epsilon}$ and $\log \frac{1}{\delta}$, where s is the state in which the algorithm halts. Also the algorithm's computational complexity is polynomial in $|A|$ and $|S|$.*

The fact that Q-learning converges in the limit to the optimal Q function (which guarantees that the greedy policy with respect to the Q function will be optimal) is now shown.

Theorem 3 ([17]) *If every state-action is visited infinitely often and the learning rate is well behaved, then Q_t converges to Q^* with probability one.*

The last statement is regarding the convergence rate of Q-learning. This statement must take into consideration some properties of the underlying policy, and assume that this policy covers the entire state space in reasonable time. The next theorem shows that the convergence rate of Q-learning can vary according to the tuning of the algorithm parameters.

Theorem 4 ([4]) *Let L be the time needed for the underlying policy to visit every state action with probability 1/2. Let T be the time until $||Q^* - Q_T|| \leq \epsilon$ with probability at least $1 - \delta$ and $\#(s,a,t)$ be the number of times action a was performed at state s until time t. Then if $\alpha_t(s,a) = 1/\#(s,a,t)$, then T is polynomial in $L, \frac{1}{\epsilon}, \log\frac{1}{\delta}$ and exponential in $\frac{1}{1-\gamma}$. If $\alpha_t(s,a) = 1/\#(s,a,t)^{\omega}$ for $\omega \in (1/2, 1)$, then T is polynomial $L, \frac{1}{\epsilon}, \log\frac{1}{\delta}$ and $\frac{1}{1-\gamma}$.*

Applications

The biggest successes of reinforcement learning so far are mentioned here. For a list of successful applications of reinforcement learning, see http://neuromancer.eecs.umich.edu/cgi-bin/twiki/view/Main/SuccessesOfRL.

Backgammon Tesauro [14] used temporal difference learning combined with neural networks to design a player that learned to play backgammon by playing itself and resulted in a player at the level of the world's top players.

Helicopter control Ng et al. [9] used inverse reinforcement learning for autonomous helicopter flight.

Open Problems

While in this entry only MDPs given in their tabular form were discussed, much current research is dedicated to two major directions: large state space and partially observable environments.

In many real-world applications, such as robotics, the agent cannot observe the state she is in and can only observe a signal which is correlated with it. In such scenarios, the MDP framework is no longer suitable, and another model is in order. The most popular reinforcement learning for such environments is the partially observable MDP. Unfortunately, for POMDP even the planning problems are intractable (and not only for the optimal policy which is not stationary but even for the optimal stationary policy); the learning contains even more obstacles as the agent cannot repeat the same state twice with certainty, and thus, it is not obvious how she can learn. An interesting open problem is trying to characterize when a POMDP is "solvable" and when it is hard to solve according to some structure.

In most applications, the assumption that the MDP can be represented in its tabular form is not realistic and approximate methods are in order. Unfortunately not much theoretically is known under such conditions. Here are a few of the prominent directions to tackle large state space.

Function Approximation

The term "function approximation" is due to the fact that this approach takes examples from a desired function (e.g., a value function) and constructs an approximation of the entire function. Function approximation is an instance of supervised learning, which is studied in machine learning and other fields. In contrast to the tabular representation, this time a parameter vector Θ represents the value function. The challenge will be to learn the optimal vector parameter in the sense of minimum square error, i.e.,

$$\min_{\Theta} \sum_{s \in S} (V^{\pi}(s) - V(s,\Theta))^2,$$

where $V(s,\Theta)$ is the approximation function. One of the most important function approximations is the linear function approximation,

$$V_t(s,\Theta) = \sum_{i=1}^{T} \phi_s(i)\Theta_t(i),$$

where each state has a set of vector features, ϕ_s. A feature-based function approximation was analyzed and demonstrated in [2, 15]. The main goal here is designing algorithms which converge to almost optimal polices under realistic assumptions.

Factored Markov Decision Process

In an FMDP, the set of states is described via a set of random variables $X = \{X_1, \ldots, X_n\}$, where each X_i takes values in some finite domain $Dom(X_i)$. A state s defines a value $x_i \in Dom(X_i)$ for each variable X_i. The transition model is encoded using a dynamic Bayesian network. Although the representation is efficient, not only is finding an ε-optimal policy intractable [8], but it cannot be represented succinctly [1]. However, under assumptions on the FMDP structure, there exist algorithms such as [5] that have both theoretical guarantees and nice empirical results.

1990; Attiya, Bar-Noy, Dolev, Peleg, Reischuk

Problem Definition

Consider a system in which $n + 1$ processes $P_0, \ldots, P_n$ communicate either by message-

passing or by reading and writing a shared memory. Processes are *asynchronous*: there is no upper or lower bounds on their speeds, and up to t of them may fail undetectably by halting. In the *renaming task* proposed by Attiya, Bar-Noy, Dolev, Peleg, and Reischuk [1], each process is given a unique *input name* taken from a range $0, \ldots, N$, and chooses a unique *output name* taken from a strictly smaller range $0, \ldots, K$. To rule out trivial solutions, a process's decision function must depend only on input names, not its preassigned identifier (so that P_i cannot simply choose output name i). Attiya et al. showed that the task has no solution when $K = n$, but does have a solution when $K = N + t$. In 1993, Herlihy and Shavit [2] showed that the task has no solution when $K < N + t$.

Vertexes, simplexes, and complexes model decision tasks.(See the companion article entitled ▸ Topology Approach in Distributed Computing). A process's state at the start or end of a task is represented as a vertex $\mathbf{v}$ labeled with that process's identifier, and a value, either input or output: $\mathbf{v} = \langle P, v_i \rangle$. Two such vertexes are *compatible* if (1) they have distinct process identifiers, and (2) those process can be assigned those values together. For example, in the renaming task, input values are required to be distinct, so two input vertexes are compatible only if they are labeled with distinct process identifiers and distinct input values.

Figure 1 shows the output complex for the three-process renaming task using four names. Notice that the two edges marked A are identical, as are the two edges marked B. By identifying these edges, this task defines a simplicial complex that is topologically equivalent to a torus. Of course, after changing the number of processes or the number of names, this complex is no longer a torus.

Key Results

Theorem 1 *Let S^n be an n-simplex, and S^m a face of S^n. Let S be the complex consisting of all faces of S^m, and $\dot{S}$ the complex consisting of all proper faces of S^m (the boundary complex of S). If $\sigma(\dot{S})$ is a subdivision of $\dot{S}$, and $\phi: \sigma(\dot{S}) \to \mathcal{F}(S)$ a simplicial map, then there exists a subdivision $\tau(S)$ and a simplicial map $\psi: \tau(S) \to \mathcal{F}(S)$ such that $\tau(\dot{S}) = \sigma(\dot{S})$, and ϕ and ψ agree on $\sigma(\dot{S})$.*

Informally, any simplicial map of an m-sphere to $\mathcal{F}$ can be "filled in" to a simplicial map of the $(m+1)$-disk. A *span* for $\mathcal{F}(S^n)$ is a subdivision σ of the input simplex S^n together with a simplicial map $\phi: \sigma(S^n) \to \mathcal{F}(S^n)$ such that for every face S^m of S^n, $\phi: \sigma(S^m) \to \mathcal{F}(S^m)$. Spans are constructed one dimension at a time. For each $\mathbf{s} = \langle P_i, v_i \rangle \in S^n, \phi$ carries $\mathbf{s}$ to the solo execution by P_i with input $\mathbf{v}_i$. For each $S^1 = (\mathbf{s}_0, \mathbf{s}_1)$, Theorem 1 implies that $\phi(\mathbf{s}_0)$ and $\phi(\mathbf{s}_1)$ can be joined by a path in $\mathcal{F}(S^1)$. For each $S^2 = (\mathbf{s}_0, \mathbf{s}_1, \mathbf{s}_2)$, the inductively constructed spans define each face of the boundary complex $\phi: \sigma(S^1_{ij}) \to \mathcal{F}(S^1)_{ij}$, for $i, j \in \{0, 1, 2\}$. Theorem 1 implies that one can "fill in" this map, extending the subdivision from the boundary complex to the entire complex.

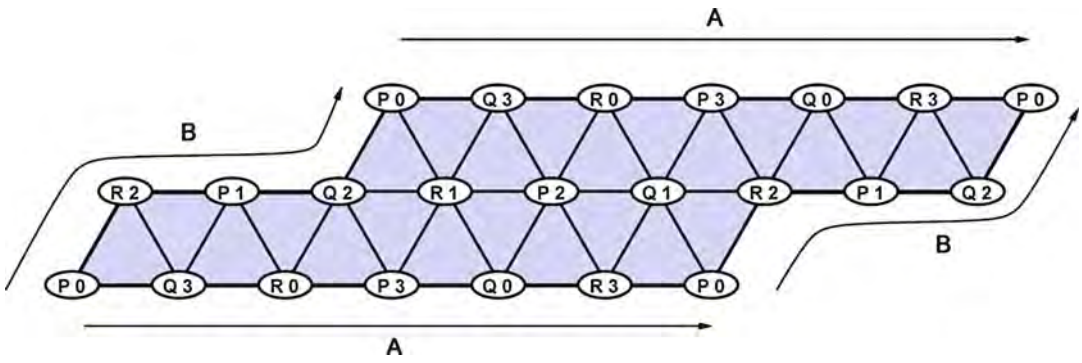
Theorem 2 *If a decision task has a protocol in asynchronous read/write memory, then each input simplex has a span.*

One can restrict attention to protocols that have the property that any process chooses the same name in a solo execution.

Definition 1 A protocol is *comparison-based* if the only operations a process can perform on processor identifiers is to test for equality and order; that is, given two P and Q, a process can test for $P = Q, P \leq Q$, and $P \geq Q$, but cannot examine the structure of the identifiers in any more detail.

Lemma 1 *If a wait-free renaming protocol for K names exists, then a comparison-based protocol exists.*

Proof Attiya et al. [1] give a simple comparison-based wait-free renaming protocol that uses $2n + 1$ output names. Use this algorithm to assign each



Renaming, Fig. 1 Output complex for 3-process renaming with 4 names

process an *intermediate* name, and use that intermediate name as input to the K-name protocol.□

Comparison-based algorithms are *symmetric* on the boundary of the span. Let S^n be an input simplex, $\phi: \sigma(S^n) \to \mathcal{F}(S^n)$ a span, and $\mathcal{R}$ the output complex for $2n$ names. Composing the span map ϕ and the decision map δ yields a map $\sigma(S^n) \to \mathcal{R}$. This map can be simplified by replacing each output name by its parity, replacing the complex $\mathcal{R}$ with the binary n-sphere $\mathcal{B}^n$.

$$\mu: \sigma(S^n) \to \mathcal{B}^n \ . \tag{1}$$

Denote the simplex of $\mathcal{B}^n$ whose values are all zero by 0^n, and all one by 1^n.

Lemma 2 $\mu^{-1}(0^n) = \mu^{-1}(1^n) = \emptyset$.

Proof The range $0, \ldots, 2n-1$ does not contain $n+1$ distinct even names or $n+1$ distinct odd names. □

The *n-cylinder* C^n is the binary n-sphere without 0^n and 1^n. Informally, the rest of the argument proceeds by showing that the boundary of the span is "wrapped around" the hole in C^n a non-zero number of times.

The span $\sigma(S^n)$ (indeed any any subdivided n-simplex) is a (combinatorial) *manifold with boundary*: each $(n-1)$-simplex is a face of either one or two n-simplexes. If it is a face of two, then the simplex is an *internal simplex*, and otherwise it is a *boundary* simplex. An orientation of S^n induces an orientation on each n-simplex of $\sigma(S^n)$ so that each internal $(n-1)$-simplex inherits opposite orientations. Summing these oriented simplexes yields a chain, denoted $\sigma_*(S^n)$, such that

$$\partial\sigma_*(S^n) = \sum_{i=0}^{n} (-1)^i \sigma_*(face_i(S^n)) \ .$$

The following is a standard result about the homology of spheres.

Theorem 3 *Let the chain 0^n be the simplex 0^n oriented like S^n. (1) For $0 < m < n$, any two m-cycles are homologous, and (2) every n-cycle C^n is homologous to $k \cdot \partial 0^n$, for some integer k. C^n is a boundary if and only if $k = 0$.*

Let S^m be the face of S^n spanned by solo executions of $P_0, \ldots, P_m$. Let 0^m denote some m-simplex of C^n whose values are all zero. Which one will be clear from context.

Lemma 3 *For every proper face S^{m-1} of S^n, there is an m-chain $\alpha(S^{m-1})$ such that*

$$\mu_*(\sigma_*(S^m)) - 0^m - \sum_{i=0}^{m} (-1)^i \alpha(face_i(S^m))$$

is a cycle.

Proof By induction on m. When $m=1$, $ids(S^1) = \{i, j\}$. 0^1 and $\mu_*(\sigma_*(S^1))$ are

1-chains with a common boundary $\langle P_i, 0\rangle - \langle P_j, 0\rangle$, so $\mu_*(\sigma_*(S^1)) - 0^1$ is a cycle, and $\alpha(\langle P_i, 0\rangle) = \emptyset$.

Assume the claim for $m, 1 \geq m < n-1$. By Theorem 3, every m-cycle is a boundary (for $m < n-1$), so there exists an $(m+1)$-chain $\alpha(S^m)$ such that

$$\mu_*(\sigma_*(S^m)) - 0^m - \sum_{i=0}^{m} (-1)^i \alpha(face_i(S^m)) = \partial\alpha(S^m) .$$

Taking the alternating sum over the faces of S^{m+1}, the $\alpha(face_i(S^m))$ cancel out, yielding

$$\mu_*(\partial\sigma_*(S^{m+1})) - \partial 0^{m+1} = \sum_{i=0}^{m+1} (-1)^i \partial\alpha(face_i(S^{m+1})) .$$

Rearranging terms yields

$$\partial \left(\mu_*(\sigma_*(S^{m+1})) - 0^{m+1} - \sum_{i=0}^{m+1} (-1)^i \alpha(face_i(S^{m+1})) \right) = 0 ,$$

implying that

$$\mu_*(\sigma_*(S^{m+1})) - 0^{m+1} - \sum_{i=0}^{m+1} (-1)^i \alpha(face_i(S^{m+1}))$$

is an $(m+1)$-cycle. □

Theorem 4 *There is no wait-free renaming protocol for $(n+1)$ processes using $2n$ output names.*

Proof Because

$$\mu_*(\sigma_*(S^{n-1})) - 0^{n-1} - \sum_{i=0}^{n} (-1)^i \alpha(face_i(S^{n-1}))$$

is a cycle, Theorem 3 implies that it is homologous to $k \cdot \partial 0^n$, for some integer k. Because μ is symmetric on the boundary of $\sigma(S^n)$, the alternating sum over the $(n-1)$-dimensional faces of S^n yields:

$$\mu_*(\partial\sigma_*(S^n)) - \partial 0^n \sim (n+1)k \cdot \partial 0^n$$

or

$$\mu_*(\partial\sigma_*(S^n)) \sim (1 + (n+1)k) \cdot \partial 0^n .$$

Since there is no value of k for which $(1 + (n+1)k)$ is zero, the cycle $\mu_*(\partial\sigma_*(S^n))$ is not a boundary, a contradiction. □

Applications

The renaming problem is a key tool for understanding the power of various asynchronous models of computation.

Open Problems

Characterizing the full power of the topological approach to proving lower bounds remains an open problem.

Algorithmic Game Theory; Approximation; Electronic Commerce; Incentive compatibility; Mechanism Design; Price of revenue monotonicity; Revenue monotonicity; Social welfare

Introduction

Fueled by the growth of Internet and advancements in online advertising techniques, today more and more online firms rely on advertising revenue for their business. Some of these firms include news agencies, media outlets, search engines, social and professional networks, etc. Much of this online advertising business is moving to what's called *programmatic* buying where an advertiser bids for each single impression, sometimes in real time, depending on how he values the ad opportunity. This work is motivated by the need of a desired property in the auction mechanisms that are used in these bid-based advertising systems.

A standard mechanism for most auction scenarios is the famous Vickrey-Clarke-Groves (VCG) mechanism. VCG is *incentive compatible* (IC) and maximizes *social welfare*. Incentive compatibility guarantees that the best response for each advertiser is to report its true valuation. This makes the mechanism transparent and removes the load from the advertisers to calculate the best response. *Social welfare* is the sum of the valuations of the winners. This value is treated as a proxy for how much all the participants gain from the transaction. What makes VCG mechanism versatile is that it reduces the mechanism design problem into an optimization problem for any scenario.

Even though this versatility of VCG mechanism makes it a popular choice mechanism, however, it doesn't satisfy an important property, namely, that of *revenue monotonicity*. Revenue monotonicity says that if one increases the bid values or add new bidders, the total revenue should not go down. To see that VCG is not revenue monotone, consider a simple example of two items and three bidders (A, B, and C). Say, bidder A wants only the first item and has a bid of 2. Similarly bidder B wants only the second item and has a bid of 2. Bidder C wants both the items or nothing and has a bid of 2. Now if only bidders A and B participate in the auction, then VCG gives a revenue of 2; however, if all the three bidders participate, then the revenue goes down to 0.

This lack of revenue monotonicity (which has been noted several times in the literature) is one of the serious practical drawbacks of the celebrated VCG mechanism. To think of it, an online firm that depends on advertising revenue puts significant resources in its sales efforts to attract more bidders as the general belief is that more bidders imply more competition which should lead to higher prices. Now to tell this firm that their revenue can go down if they get more bidders can be strategically very confusing for them. To see this from another perspective, say, in a search engine firm, there is a team which makes a UI change that increases the click-through probability (CTR) of the search ads. These changes are thought of as good changes in the firm as they increase the effective bid of the bidders (the effective bid of a bidder in search advertising is a function of its cost-per-click bid and the CTR of its ad). Now if after making the change, the revenue goes down, what was supposed to be a good change may seem like a bad change. The point we are trying to make is that there are many teams in a firm, and for these teams to function properly, it is important that the auction mechanisms satisfy *revenue monotonicity*.

In this entry, with a focus on auctions arising in advertising scenarios, we seek to understand mechanisms that satisfy this additional property

of revenue monotonicity (RM). It is well known that for various settings (including ours), no mechanism can satisfy both IC and RM properties while attaining optimal social welfare. In fact it is known that one cannot even hope to get Pareto-optimality in social welfare while attaining both IC and RM [10]. Thus to overcome this bottleneck and develop an understanding of RM mechanisms, we relax the requirement of attaining full social welfare and define the notion of *price of revenue monotonicity* (PoRM). Price of revenue monotonicity of an IC and RM mechanism M is the ratio of optimal social welfare to the social welfare attained by the mechanism M. The goal is to design mechanisms that satisfy IC and RM properties and at the same time achieve low price of revenue monotonicity. To the best of our knowledge, this is the first work that defines and studies this notion of price of revenue monotonicity.

We study two different advertising settings in this entry. The first setting we study is the *image-text* auction. In image-text auction there is a special box designated for advertising in a publisher's website which can be filled by either k text ads or a single image ad. The second setting is the *video-pod* auction where an advertising break of a certain duration in a video content can be filled with multiple video ads of possibly different durations.

We note that revenue monotonicity is an *across-instance* constraint as it requires total revenue to behave in a certain manner across different instances, where a single instance is defined by fixing the *type* of the buyers. Note that incentive compatibility is also an across-instance constraint. A lot of research effort has gone into understanding incentive compatibility, which has resulted in useful tools for designing incentive-compatible mechanisms. Surprisingly, hardly any work has gone into understanding and building tools for designing mechanisms which satisfy the desired property of revenue monotonicity. We believe that understanding revenue monotonicity will shed new fundamental insights into the design of mechanisms for many practical scenarios.

Related Work

Ausubel and Milgrom [1] show that VCG satisfies RM if bidders' valuations satisfy *bidder submodularity*. Bidders' valuations satisfy bidders submodularity if and only if for any bidder i and any two sets of bidders S, S' with $S \subseteq S'$ we have $\text{WF}(S \cup \{i\}) - \text{WF}(S) \geq \text{WF}(S' \cup \{i\}) - \text{WF}(S')$, where $\text{WF}(S)$ is the maximum social welfare achievable using only S. Note that this is a general tool one can use to design revenue-monotone mechanisms – restrict the range of the possible allocations such that we get bidder submodularity when we run VCG on this range. However, we can show that this general tool is not so powerful by showing that for our auction scenarios, it is not possible to get a mechanism with PoRM better than $\Omega(k)$ by using the above tool.

Ausubel and Milgrom [1] also show that bidder submodularity is guaranteed when the goods are substitutes, i.e., the valuation function of each bidder is submodular over the goods. However, for many practical scenarios, including ours, the valuation function of the bidders is not submodular. Ausubel and Milgrom [1] design mechanisms which select allocations that are in the core of the exchange economy for combinatorial auctions. Here an allocation is in the core if there is no coalition of bidders and the seller to trade with each other in a way which is preferred by all the members of the coalition to the allocation. Day and Milgrom [3] show that core-selecting mechanisms that choose a core allocation which minimizes the seller's revenue satisfy RM given bidders follow so-called *best-response truncation strategy*. Therefore the core-selecting mechanism designed by [1] satisfies RM if the participants play such best-response strategy, although this mechanism is not incentive compatible.

Rastegari et al. [10] prove that no mechanism for general combinatorial auctions which satisfies IC and RM can achieve weakly maximal social welfare. An allocation is weakly maximal if it cannot be modified to make at least one participant better off without hurting anyone else. In another work [9] they design a randomized mech-

anism for combinatorial auctions which achieves weak maximality and expected revenue monotonicity.

Another related work is around the characterization of mechanisms that achieve the IC property. The classic result of Roberts [11] states that affine maximizers are the only social choice functions that can be implemented using IC mechanisms when bidders have unrestricted quasi-linear valuations. Subsequent works study the restricted cases [2, 6, 12, 13].

There is also an extensive body of research around designing mechanisms with good bounds on the revenue. Myerson [7] designs a mechanism which achieves the optimal expected revenue in the single parameter Bayesian setting. Goldbert et al. consider optimizing revenue in prior-free settings (see [8] for a survey on this).

Our Results

As mentioned earlier, we study two settings: (1) image-text auction and (2) video-pod auction. Both these settings can be described using the following abstract model. Say, there is a seller selling k identical items to n participants/buyers. Participant i wants either d_i items or nothing and has a valuation of v_i if it gets d_i items or 0 otherwise. Demand d_i is assumed to be public knowledge, and valuation v_i is assumed to be the private information of the participant i. We want to design a mechanism that is incentive compatible, individually rational (IR), and revenue monotone and maximizes social welfare.

For the image-text auction, the demand $d_i \in \{1, k\}$, i.e., each participant wants either 1 item (text ads) or k items (image ad). For the video-pod auction, an item corresponds to a unit time interval (say, one second), and the demand d_i could be any number between 1 and k, i.e., $d_i \in [k]$.

The first result of this entry is the following theorem.

Theorem 1 *We design a deterministic mechanism for image-text auction (*MITA*) which satisfies individual rationality (IR), IC, and RM with* PoRM *of at most* $\sum_{i=1}^{k} \frac{1}{i} \simeq \ln(k)$*, i.e., the ratio of* MITA*'s welfare over the optimal welfare is at most* $\ln(k)$.

The proof of Theorem 1 appears in section "Image-Text Auctions." We outline our mechanism over here: Let $v_1 \geq \ldots \geq v_{n_1}$ be the valuations of text participants and V_1 be the maximum valuation of the image participants. If $\max_{j \in [k]} j \cdot v_j$ is less than V_1, MITA gives all the items to the image participant who has valuation V_1; otherwise MITA picks the highest j^* text participants as the winners where j^* is the maximum number in $[k]$ such that $j^* \cdot v_{j^*} \geq V_1$. Note that the j that maximizes $j \cdot v_j$ might be less than the $j*$ which is the largest j such that $j \cdot v_j \geq V_1$. Also note that MITA sometimes picks less than k text ads as the winner (even if there are k or more text ads). VCG always picks the maximum number of text ads (if it decides to allocate the slot to text ads); this is one of the reasons why VCG fails to satisfy RM. When we allow lesser number of text ads to be declared as winners, intuitively, this increases the competition which boosts the revenue and thus helps in achieving RM, although this comes with a loss in social welfare.

Surprisingly, we can also show that the above mechanism achieves the optimal PoRM for the image-text auction by proving a matching lower bound. We show that a mechanism that satisfies IR, IC, RM, and two additional mild assumptions of anonymity (AM) and independence of irrelevant alternatives (IIA) cannot achieve a PoRM better than $\sum_{i=1}^{k} \frac{1}{i}$. Anonymity means that the auction mechanism doesn't depend on the identities of the participants (a formal definition appears in section "Image-Text Auctions"). IIA means that decreasing the bid of a losing participant shouldn't hurt any winner. Note that our mechanism satisfies both AM and IIA as well. Formally, we prove the following theorem whose proof appears in section "Image-Text Auctions."

Theorem 2 *There is no deterministic mechanism which satisfies IR, IC, RM, AM, and IIA and has* PoRM *less than* $\sum_{i=1}^{k} \frac{1}{i}$.

Finally we prove the following theorem for video-pod auctions.

Theorem 3 *We design a mechanism for video-pod auction (*MVPA*) which satisfies IR, IC, and RM with* PoRM *of at most* $(\lfloor \log k \rfloor + 1) \cdot (2 + \ln k)$.

We give the formal proof of Theorem 3 in section "Video-Pod Auctions" and outline the mechanism here. MVPA partitions the participants into $(\lfloor \log k \rfloor + 1)$ groups where each group $g \in [\log k]$ contains only the participants whose demands are in the range $[2^{g-1}, 2^g)$. MVPA selects winners only from one group. We round up the size of each participant in group g to 2^g; thus we can have at most $\frac{k}{2^g}$ number of winners from the group g. Let $v_1^{(g)} \geq \ldots \geq v_p^{(g)}$ be the sorted valuations of all the participants in group g. We define the max possible revenue of group g (MPRG(g)) to be

$$\text{MPRG}(g) = \max_{j \in [k/2^g]} j \cdot v_j^{(g)}.$$

As the name of MPRG(g) suggests, its value captures the maximum revenue we can truthfully obtain from group g without violating revenue monotonicity. Let g^* be the group with the highest MPRG value and group g' be the group whose MPRG is the second highest. The set of winners are the first j participants from group g^* where j is the largest number in $[k/2^g]$ such that $j \cdot v_j^{(g^*)}$ is greater than or equal MPRG(g'). We show that PoRM of MVPA is $(\lfloor \log k \rfloor + 1) \cdot (2 + \ln k)$.

Preliminaries

Let $N = \{1, \ldots, n\}$ be the set of all participants and k be the number of identical items. We denote the type of participant i by $\theta_i = (d_i, v_i) \in [k] \times \mathbb{R}^+$, where d_i is the number of items participant i demands and v_i is her valuation for getting d_i items. Note that the valuation of player i for getting less than d_i items is 0. Now in the image-text auction, participants have demand of either 1 or k. In the video-pod auction, participants can have arbitrary demands in $\{1, \ldots, k\}$. Let's denote the set of all possible types $[k] \times \mathbb{R}^+$ by Θ and the set of all type profiles of n participants by $\Theta^n = \underbrace{\Theta \times \ldots \times \Theta}_{n}$.

A deterministic mechanism $\mathcal{M}$ consists of an allocation rule $x : \Theta^n \to 2^n$ which maps each type profile to a subset of participants as the winners and payment rule $p : \Theta^n \to \left(\mathbb{R}^+\right)^n$ which maps each type profile to the payments of each participant.

Let $\theta = (\theta_1, \theta_2, \ldots, \theta_n) \in \Theta^n$ be a specific type profile. Also let $\mathcal{A}_\theta$ be the set of all feasible solutions, i.e.,

$$\mathcal{A}_\theta = \left\{ S \subseteq N \middle| \sum_{i \in S} d_i \leq k \right\}.$$

For each feasible solution $A \in \mathcal{A}_\theta$, the social welfare of A (denoted by WF(A)) is equal to $\sum_{\theta_i \in A} v_i$. To evaluate the social welfare of a mechanism $\mathcal{M}$ on a type profile θ, we compare the welfare of its solution to the optimal solution.

Definition 1 The welfare ratio of mechanism $\mathcal{M} = (x, p)$ on type profile $\theta \in \Theta^n$ (denoted by WFR$(\mathcal{M}, \theta)$) is the following:

$$\text{WFR}(\mathcal{M}, \theta) = \frac{\max_{A \in \mathcal{A}_\theta} \text{WF}(A)}{\text{WF}(x(\theta))}$$

To capture the worst-case loss in social welfare across all type profiles, we define the notion of *price of revenue monotonicity*.

Definition 2 The Price of Revenue Monotonicity of a mechanism $\mathcal{M}$ (denoted by PoRM$(\mathcal{M})$) is defined as follows:

$$\text{PoRM}(\mathcal{M}) = \max_{\theta \in \Theta^n} \text{WFR}(\mathcal{M}, \theta)$$

The desired goal is to design mechanisms which have low PoRM value, where the best possible value is 1.

Note that since we are interested in mechanisms with bounded PoRM, we restrict ourselves to mechanisms that satisfy consumer sovereignty. Consumer sovereignty says that any participant can be a winner as long as he bids high enough.

Now we will define a weakly monotone allocation rule which is used in the characterization of deterministic IC mechanisms. Let function $x_i : \Theta^n \to \{0, 1\}$ be the restriction of function x to participant i. Here $x_i(.)$ is one if participant i is a winner and zero otherwise.

Definition 3 We call allocation function x is weakly monotone if for any type profile $\theta \in \Theta^n$ and any participant $i \in [n]$ with demand

R

d_i, function $x_i((d_i, v_i), \theta_{-i})$ is a non-decreasing function in v_i.

Note that if a deterministic mechanism $\mathcal{M}$ satisfies consumer sovereignty and has a weakly monotone allocation function, then function $x_i((d_i, v_i), \theta_{-i})$ is a single-step function. The value at which the function $x_i((d_i, v_i), \theta_{-i})$ jumps from zero to one, i.e., the smallest value at which the participant i becomes a winner, is called *critical value*.

Definition 4 Let $\mathcal{M} = (x, p)$ be a deterministic mechanism that satisfies consumer sovereignty and has a weakly monotone allocation function; the critical value of participant i in type profile θ is $v_i^* = sup\{v_i | x_i((d_i, v_i), \theta_{-i}) = 0\}$.

The following lemma characterizes deterministic IC mechanisms (first given by [7]). We provide a proof sketch for the sake of completeness (for a complete proof, see, e.g., [8]).

Lemma 1 *Let $\mathcal{M} = (x, p)$ be a mechanism which satisfies IR. Mechanism $\mathcal{M}$ is truthful (IC) if and only if the following hold:*

1. *x is weakly monotone.*
2. *If participant i is a winner, then its payment is its critical value (v_i^*).*

Proof First we prove that if $\mathcal{M}$ is truthful, then it satisfies both conditions 1 and 2. We prove the first condition by contradiction. If x is not monotone, then there exist participant i, type profile θ, and two values $v_i^{(1)} > v_i^{(2)}$ such that i wins in type profile $\left((d_i, v_i^{(2)}), \theta_{-i}\right)$ but loses in type profile $\left((d_i, v_i^{(1)}), \theta_{-i}\right)$. This makes incentive for participant i to lie for type profile $\left((d_i, v_i^{(1)}), \theta_{-i}\right)$ and announce its valuation as $v_i^{(2)}$.

Consider an arbitrary participant i who is a winner; now we prove that the payment of participant i is its critical value. Assume for contradiction that mechanism $\mathcal{M}$ charges participant i amount c_i where $c_i < v_i^*$ in a type profile $((d_i, v_i), \theta_{-i})$. In this case, if participant i had type $(d_i, \hat{v_i})$ where $c_i < \hat{v_i} < v_i^*$, then i is not a winner in $((d_i, \hat{v_i}), \theta_{-i})$ as v_i^* is the critical value. Therefore, if the real type of participant i is $(d_i, \hat{v_i})$, she has incentive to lie her type as (d_i, v_i), become a winner, and pay c_i. Hence, the payment cannot be less than v_i^*. Now suppose that there exists value v_i for which mechanism $\mathcal{M}$ charges i amount c_i which is more than v_i^*. In this case, if participant i had type $(d_i, \hat{v_i})$ where $v_i^* < \hat{v_i} < c_i$, then i is still a winner (as v_i^* is the critical value) and pays at most $\hat{v_i}$ (as $\mathcal{M}$ satisfies IR). Therefore, she has an incentive to lie her type as $(d_i, \hat{v_i})$, become a winner, and pay at most $\hat{v_i}$. Hence, the payment cannot be more than v_i^* for any winning valuation v_i.

For the other direction, it is easy to check that any IR mechanism that satisfies conditions 1 and 2 is truthful. □

Image-Text Auctions

In this section we give our *mechanism for image-text auction* (MITA) which satisfies IR, IC, RM, and PoRM(MITA) $\leq \ln k$. Recall that in the image-text auction we have k identical items to sell and there are two groups of participants: the ones who want all the k items which we call *image participants* and the ones who want only one item which we refer to as *text participants*. As a result there are also two possible types of outcome: MITA gives all the items to an image participant; or it gives an item to each member of a subset of the text participants.

We start with explaining why VCG fails to satisfy RM and how we address this issue in MITA. Consider the type profile where we have one image participant with type $(k, 1)$ and one text participant with type $(1, 1)$. In this case either of the participants can be the winner. The payment of the winner in VCG is her critical value which is one. However if we add one more text participant with the same type $(1, 1)$, the two text participants win and each of them pays zero. The reason for the payment drop is that VCG always selects k winners from the text participants. This decreases the critical value of each text participant as the valuation of the other text participants helps her to win against image participants. In our mechanism we overcome this issue by not guaranteeing that the maximal number of text

participants can win an item. In other words, in our mechanism it is possible that less than k text participants win an item even if there are more than k text participants. This way, intuitively, even if the number of text participants increases, it potentially creates more competition and hence increases the payments.

Let θ be an arbitrary-type profile where there are n_1 text participants with types $(1, v_1), \ldots, (1, v_{n_1})$ and n_2 image participants with types $(k, V_1), \ldots, (k, V_{n_2})$. We define mechanism $\text{MITA} = (x^{\text{MITA}}, p^{\text{MITA}})$ by giving allocation function x^{MITA} which is weakly monotone. Given the allocation function, we obtain payment function p^{MITA} using the critical values defined in Lemma 1 which makes the mechanism truthful.

Allocation rule of MITA. Without loss of generality, we assume that $v_1 \geq v_2 \geq \ldots \geq v_{n_1}$ and $V_1 \geq V_2 \geq \ldots \geq V_{n_2}$. Also, we assume that $n_1 \geq k$; if not, we add fake text participants with value 0. For each $j \in [k]$, we consider value $j \cdot v_j$. Let candidate set C_θ contain all the values $j \in [k]$ such that $j \cdot v_j$ is greater than or equal to V_1, i.e., $C_\theta = \{j \in [k] | j \cdot v_j \geq V_1\}$. If C_θ is empty, the image participant with type (k, V_1) wins. If C_θ is nonempty, then let j^* be the maximum member of C_θ, i.e., $j^* = \max_{j \in C_\theta} j$. In this case the first j^* text participants win.

Observation 1 *Allocation function x^{MITA} is weakly monotone.*

Proof Recall from Definition 3, in order to prove that x^{MITA} is weakly monotone, we have to show that for any participant $i \in [n]$ with demand d_i, function $x_i\left((d_i, v_i), \theta_{-i}\right)$ is a non-decreasing function in v_i.

If i is an image participant, then i wins if its valuation is larger than $\max(W, \max_{j \in [k]} j \cdot v_j)$ where W is the largest valuation of the image participants in θ_{-i}. Moreover, bidder i loses for any value smaller than or equal to $\max(W, \max_{j \in [k]} j \cdot v_j)$. Therefore x_i is weakly monotone.

If i is a text participant, then let $v'_1 \geq v'_2 \geq \ldots$ be the sorted valuations of the text participants and V_1 be the largest valuation of image participants in θ_{-i}. Let t be the smallest value such that there exist $j \in [k-1]$ where $v'_{j+1} \leq t \leq v'_j$ and $(j+1) \cdot t$ is greater than or equal to V_1. If the valuation of bidder i is larger than or equal to t, then she wins since $(j+1) \cdot t \geq V_1$; otherwise she does not win since t is the smallest value for which there exist $j \in [k-1]$ such that $(j+1) \cdot t \geq V_1$. Therefore x_i is weakly monotone. □

In the following lemma we obtain the critical value (or truthful payments) of the winners in x^{MITA} using Lemma 1. The lemma also gives an intuition to why we select j^* text participants to win, which is the maximum j such that $j \cdot v_j \geq V_1$.

Lemma 2 *If C_θ, where $C_\theta = \{j \in [k] | j \cdot v_j \geq V_1\}$, is empty, then the first image participant wins all the items with critical value $\max(V_2, \max_{j \in [k]} j \cdot v_j)$. If C_θ is not empty, the first j^* text participants win the items where $j^* = max_{j \in C_\theta} j$ and all of them have critical value $\max(v_{k+1}, \frac{V_1}{j^*})$.*

Proof We find the critical value (Definition 4) of a winner by showing that if she has any valuation larger than the critical value she wins and for any valuation less than the critical value she doesn't.

If C_θ is empty, then the first image participant (with type (k, V_1)) wins all the items. As long as V_1 is larger than $\max(V_2, \max_{j \in [k]} j \cdot v_j)$, participant (k, V_1) wins. If V_1 is less than $\max(V_2, \max_{j \in [k]} j \cdot v_j)$, then she loses to the image participant (k, V_2) if $\max(V_2, \max_{j \in [k]} j \cdot v_j) = V_2$ or loses to the text participants if $\max(V_2, \max_{j \in [k]} j \cdot v_j) = \max_{j \in [k]} j \cdot v_j$. This means that the critical value of the first image participant is $\max(V_2, \max_{j \in [k]} j \cdot v_j)$ if she is the winner.

If C_θ is nonempty, then the first j^* text participants win. Let $i \in [j^*]$ be an arbitrary winner. First we observe that for any valuation v'_i greater than or equal to $\max\left(v_{k+1}, \frac{V_1}{j^*}\right)$, participant i remains as a winner in type profile $\theta' = ((1, v'_i), \theta_{-i})$. This is because for any such change in valuation of participant i number j^* remains in set $C_{\theta'}$. Moreover, this change does not add any new number j' to $C_{\theta'}$ such that $j' > j^*$ because the valuations of the text participants with index greater than j^* are not changed in θ'.

R

In order to prove that for any valuation v_i' less than critical value $\max\left(v_{k+1}, \frac{V_1}{j^*}\right)$, participant i is not a winner we consider two cases: (A) when the critical value is equal to $\frac{V_1}{j^*}$ and (B) when the critical value is equal to v_{k+1}.

Case (A): We prove this case by contradiction. Let v_i' be a valuation less than $\frac{V_1}{j^*}$ for which participant i is in the set of winners in type profile $\theta' = ((1, v_i'), \theta_{-i})$. Because v_i' is less than $\frac{V_1}{j^*}$, the number of winners which contains participant i cannot be less than or equal to j^* in type profile θ'. Let $j' \in [k]$ which is greater than j^* be the number of winners in θ'. This means that there are at least j' participants whose valuation is larger than $\frac{V_1}{j'}$ in θ'. Note that all the valuations in θ are the same as θ' except v_i which is decreased to v_i'; therefore, there are also at least j' participants whose valuation is larger than $\frac{V_1}{j'}$ in θ and hence j' is in set C_θ. This contradicts with the fact that j^* is the largest member of C_θ.

Case (B): In case (B) we have $\max\left(v_{k+1}, \frac{V_1}{j^*}\right) = v_{k+1}$ which implies that $k \cdot v_{k+1}$ is larger than V_1 as $j^* \in [k]$. Therefore Case (B) can only happen when $j^* = k$. Now consider participant i decreases its valuation to value v_i' that is less than v_{k+1}; then it cannot be a winner as there are k other participants whose valuations are more than v_i' while we have only k items. □

The payment function of MITA is set to the critical values of the winners as specified in Lemma 2 which by using Observation 1 and Lemma 1 implies MITA satisfies IC. Moreover, as the payments are always less than the participants' bid, IR property of MITA follows. Finally in the following lemma, we show that MITA is revenue monotone.

Lemma 3 *Let θ' be the type profile obtained by either increasing the valuation of a participant or adding a new participant to the type profile θ; then we have* $\text{REVENUE}(\text{MITA}, \theta') \geq \text{REVENUE}(\text{MITA}, \theta)$.

Proof Let $v_1 \geq v_2 \geq \ldots$ be the valuations of text participants and $V_1 \geq V_2 \geq \ldots$ be the valuations of image participants in θ. Similarly let $v_1' \geq v_2' \geq \ldots$ be the valuations of text participants and $V_1' \geq V_2' \geq \ldots$ be the valuations of image participants in θ'. Note that for any i we have $v_i \leq v_i'$ and $V_i \leq V_i'$ as we have onemore participant or a higher valuation in θ'. Let x be the new added participant or the participant which has higher valuation in θ'.

We prove this lemma by considering the value of $\text{REVENUE}(\text{MITA}, \theta)$ for the case when text participants win and the case when an image participant wins. If an image participant wins, then it means that $V_1 > \max_{j\in[k]} j \cdot v_j$ and she pays $\max(V_2, \max_{j\in[k]} j \cdot v_j)$ which is the total revenue.

If text participants win, then it means $V_1 \leq \max_{j\in[k]} j \cdot v_j$ and there are j^* winners where each of them pays $\max(v_{k+1}, \frac{V_1}{j^*})$. If $\max(v_{k+1}, \frac{V_1}{j^*}) = \frac{V_1}{j^*}$, then the total revenue is V_1. If $\max(v_{k+1}, \frac{V_1}{j^*}) = v_{k+1}$, it implies that $k \cdot v_{k+1}$ is larger than V_1. Remember that $C_\theta = \{j \in [k] | j \cdot v_j \geq V_1\}$ and $j^* = \max_{j\in C_\theta} j$; therefore $j^* = k$ and hence the total payment of the winners is $k \cdot v_{k+1}$.

In summary the total revenue for type profile θ is the following:

$$\text{REVENUE}(\text{MITA}, \theta) = \begin{cases} \max(V_2, \max_{j\in[k]} j \cdot v_j) & V_1 > \max_{j\in[k]} j \cdot v_j \ (A) \\ \max(V_1, k \cdot v_{k+1}) & V_1 \leq \max_{j\in[k]} j \cdot v_j \ (B) \end{cases}$$

Similarly the total revenue for type profile θ' is the following:

$$\text{REVENUE}(\text{MITA}, \theta') = \begin{cases} \max(V_2', \max_{j\in[k]} j \cdot v_j') & V_1' > \max_{j\in[k]} j \cdot v_j' \ (A) \\ \max(V_1', k \cdot v_{k+1}') & V_1' \leq \max_{j\in[k]} j \cdot v_j' \ (B) \end{cases}$$

Note that because for any i we have $v_i \leq v'_i$ and $V_i \leq V'_i$ the following inequalities are straightforward:

$$V_1 \leq V'_1 \tag{1}$$

$$V_2 \leq V'_2 \tag{2}$$

$$\max_{j\in[k]} j \cdot v_j \leq \max_{j\in[k]} j \cdot v'_j \tag{3}$$

$$k \cdot v_{k+1} \leq k \cdot v'_{k+1} \tag{4}$$

If both REVENUE(MITA, θ) and REVENUE(MITA, θ') take their value from Case (A), then the proof of the lemma follows from Eqs. (2) and (3). Similarly if both REVENUE(MITA, θ) and REVENUE(MITA, θ') take their value from Case (B), then the proof of the lemma follows from Eqs. (1) and (4).

If REVENUE(MITA, θ) takes its value from Case (A) and REVENUE(MITA, θ') takes from Case (B), then it means that participant x is a text participant which causes $\max_{j\in[k]} j \cdot v'_j$ to be larger than V'_1. The following proves the theorem for this case:

REVENUE(MITA, θ)	
$= \max(V_2, \max_{j\in[k]} j \cdot v_j)$	
$< V_1$	REVENUE(MITA, θ) takes its value from Case (A)
$= V'_1$	participant x is a text-participant
$\leq \max(V'_1, k \cdot v'_{k+1})$	
$=$ REVENUE(MITA, θ')	

If REVENUE(MITA, θ) takes its value from Case (B) and REVENUE(MITA, θ') takes from Case (A), then it means that participant x is an image participant. The following proves the theorem for this case:

REVENUE(MITA, θ)	
$= \max(V_1, k \cdot v_{k+1})$	
$< \max_{j\in[k]} j \cdot v_j$	REVENUE(MITA, θ) takes its value from Case (B) and the fact that $v_k \geq v_{k+1}$
$= \max_{j\in[k]} j \cdot v'_j$	x is an image participant
$\leq \max(V'_2, \max_{j\in[k]} j \cdot v'_j)$	
$=$ REVENUE(MITA, θ')	

□

In the above we proved that MITA satisfies IR, IC, and RM. In the following theorem we bound the PoRM of MITA and finish this section.

Theorem 4 $\text{PoRM}(\text{MITA}) \leq \ln k$.

Proof Let A be the set of winner(s) which realizes the maximum social welfare in type profile θ. If A contains only one image participant with valuation V_1, then we also have $V_1 \geq \max_{j\in[k]} j \cdot v_j$. Mechanism MITA also selects an image participant with the same valuation if $V_1 > \max_{j\in[k]} j \cdot v_j$ and hence PoRM(MITA) is 1. Otherwise we have $V_1 = \max_{j\in[k]} j \cdot v_j$ where MITA selects a set of text participants which overall gives social welfare V_1 and hence again the PoRM(MITA) is 1.

Now we consider the case when A contains text participants. By adding enough dummy participants with value zero, and without loss of generality, we assume that set A contains the first k text participants with highest valuations $v_1 \geq v_2 \geq \ldots \geq v_k$. Mechanism MITA selects either the first j^* text participants with highest valuations ($v_1 \geq v_2 \geq \ldots \geq v_{j^*}$) or selects an image participant with valuation V_1. Remember that j^* is the greatest number in set $C_\theta = \{j \,|\, j \in [k] \wedge j \cdot v_j \geq V_1\}$ which implies the following:

$$\forall j' \in \{j^*+1, \ldots, k\} \quad v_{j'} < \frac{V_1}{j'} \tag{5}$$

Note that if MITA selects an image participant, then Eq. (5) holds for $j^* = 0$.

Now we consider the following two cases to prove the theorem:

If MITA selects an image participant, then we have the following:

$$\begin{aligned}\text{PoRM}(\text{MITA}) &= \frac{\sum_{j\in[k]} v_j}{V_1} \\ &\leq \frac{\sum_{j\in[k]} V_1/j}{V_1} \qquad \text{Eq. (5)} \\ &\leq \ln k\end{aligned}$$

If MITA selects the first j^* text participants, then we have the following:

$$\begin{aligned}\text{PoRM}(\text{MITA}) &= \frac{\sum_{j\in[k]} v_j}{\sum_{j\in[j^*]} v_j} \\ &\leq \frac{\sum_{j\in[j^*]} v_j + \sum_{j=j^*+1}^{k} v_j}{\sum_{j\in[j^*]} v_j} \\ &\leq \frac{\sum_{j\in[j^*]} v_j + \sum_{j=j^*+1}^{k} V_1/j}{\sum_{j\in[j^*]} v_j} \\ &\qquad \text{Eq. (5)} \\ &\leq \frac{\sum_{j\in[j^*]} v_j + \sum_{j=j^*+1}^{k} \left(\sum_{j\in[j^*]} v_j\right)/j}{\sum_{j\in[j^*]} v_j} \\ &\qquad \text{because } V_1 \leq \sum_{j\in[j^*]} v_j \\ &\leq \ln k\end{aligned}$$

□

Video-Pod Auctions

In this section we design a mechanism for video-pod auction (MVPA) which satisfies IR, IC, and RM whose PoRM is at most $(\lfloor \log k \rfloor + 1) \cdot (2 + \ln k)$. Note that all the log functions are in base 2. Let $\theta = ((d_1, v_1), \ldots, (d_n, v_n)) \in \Theta^n$ be an arbitrary-type profile of n participants. We define the allocation and payment function of MVPA for this type profile.

Mechanism MVPA partitions the participants into $\lfloor \log k \rfloor + 1$ groups $G^{(1)}, \ldots, G^{(\lfloor \log k \rfloor + 1)}$ where group $G^{(g)}$ contains all the participants whose demand is in the range $[2^{g-1}, 2^g)$. Mechanism MVPA selects winners only from one group $G^{(g)}$.

Definition 5 Let $M^{(g)}$ be equal to $\max\left(\lfloor \frac{k}{2^g} \rfloor, 1\right)$ which is the maximum number of winners MVPA selects from group $G^{(g)}$.

Note that we can select at least $\lfloor \frac{k}{2^g} \rfloor$ winners from $G^{(g)}$ since there are k items and the demand of each participant is at most 2^g. Moreover, from the last group $G^{(\lfloor \log k \rfloor + 1)}$ we can select at least one winner although $\lfloor \frac{k}{2^{(\lfloor \log k \rfloor + 1)}} \rfloor = 0$, since we assume the demand of all the participants is from set $[k]$.

Let $\left(d_1^{(g)}, v_1^{(g)}\right), \ldots, \left(d_p^{(g)}, v_p^{(g)}\right)$ be the types of all the participants in group g where $p = |G^{(g)}|$. Here by adding enough dummy participants, we assume p is always larger than $M^{(g)}$. Also, without loss of generality we assume $v_1^{(g)} \geq v_2^{(g)} \geq \ldots \geq v_p^{(g)}$. We define the max possible revenue of group g (MPRG(g)) to be the following:

$$\text{MPRG}(g) = \max_{j \in [M^{(g)}]} j \cdot v_j^{(g)}$$

As the name MPRG suggests, we will see that its value captures the maximum revenue can be truthfully obtained from group g. Let $G^{(g^*)}$ be a group with the maximum MPRG and $G^{(g')}$ be a group with the second maximum MPRG breaking the ties arbitrarily.

The set of winners selected by MVPA is

$$\left\{\left(d_1^{(g^*)}, v_1^{(g^*)}\right), \ldots, \left(d_j^{(g^*)}, v_j^{(g^*)}\right)\right\}$$

where j is the largest number in $[M^{(g^*)}]$ for which $j \cdot v_j^{(g^*)}$ is larger than or equal to $\text{MPRG}(g')$. In other words, the number of winners (j) is the largest number in $[M^{(g^*)}]$ for which $j \cdot v_j^{(g^*)} \geq \text{MPRG}(g')$.

Now we use Lemma 1 to show that MVPA is truthful and obtain the payments of winners.

Observation 2 *Allocation function x^{MVPA} is weakly monotone.*

Proof Note that MVPA sorts the participants according to their valuation and selects the first j participants. Therefore if any participant i increases its valuation, it only helps her to enter the winning set. Hence, the observation follows: □

In the rest of this section, we drop the group identifier of $M^{(g^*)}$ and simply use M unless it is about another group.

In the following lemma we find the critical value of each winner i which is actually equal to its payment $\left(p_i^{\text{MVPA}}\right)$.

Lemma 4 *Let set of winners $x^{\text{MVPA}}(\theta)$ contain the first j participants with highest valuations from $G^{(g^*)}$ and $v_{M+1}^{(g^*)}$ be the $(M+1)$th highest valuation in group $G^{(g^*)}$ which is zero if it does not exist. Then, the payment of participant i is the following:*

$$p_i^{\text{MVPA}}(\theta) = \begin{cases} \max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right) & i \in x^{\text{MVPA}}(\theta) \\ 0 & i \notin x^{\text{MVPA}}(\theta) \end{cases}$$

R

Proof If participant i is not a winner, then its payment is zero. When participant i is a winner, then we prove that its payment is equal to its critical value (Definition 4). In order to prove that value $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$ is the critical value of participant i, we show that for any value larger than $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$ participant i still wins and for any value less than it she loses.

Remember that $v_1^{(g^*)} \geq v_2^{(g^*)} \geq \ldots \geq v_p^{(g^*)}$ are the valuations of participants in group $G^{(g^*)}$ and $v_1^{(g^*)}, v_2^{(g^*)}, \ldots, v_j^{(g^*)}$ are the valuations of the winners. Because group $G^{(g^*)}$ is the group with the maximum MPRG, we have $v_j^{(g^*)} \geq \frac{\text{MPRG}(g')}{j}$. As there can be at most M winners from group $G^{(g^*)}$, we have $v_j^{(g^*)} \geq v_{M+1}^{(g^*)}$. Therefore we have

$$v_j^{(g^*)} \geq \max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right). \quad (6)$$

Let participant i with type profile $\left(d_i^{(g^*)}, v_i^{(g^*)}\right)$ be the ith winner in group g^* where $i \in [j]$. We show that for any valuation greater than or equal to $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$ participant i remains in the winning set. Equation (6) implies that there are j participants in group $G^{(g^*)}$ whose valuations are larger than $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$. If we decrease the valuation of participant i to $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$, we still have j participants in group $G^{(g^*)}$ with valuations at least $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$. Therefore, the value $\text{MPRG}(g^*)$ will be at least $\text{MPRG}(g')$ and group $G^{(g^*)}$ remains the winning group: hence participant i remains in the winning set.

Now we prove that if the valuation of participant i is less than the $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$, she cannot be in the winning set. In order to prove this, we consider two cases: (A) when $\max(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)})$ is equal to $v_{M+1}^{(g^*)}$ and (B) when $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$ is equal to $\frac{\text{MPRG}(g')}{j}$.

Case (A): If $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right) = v_{M+1}^{(g^*)}$ and the valuation of participant i is less than $v_{M+1}^{(g^*)}$, then it means that there are M participants who have valuations greater than the valuation of participant i. As there can be at most M winners from group $G^{(g^*)}$, participant i cannot be a winner.

Case (B): We prove this case by contradiction. Suppose $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right) = \frac{\text{MPRG}(g')}{j}$ and $\theta' = \left((d_i^{(g^*)}, v_i^{(g^*)'}), \theta_{-i}\right)$ be a type profile in which the valuation of participant i is less than $\frac{\text{MPRG}(g')}{j}$ while she is still winner. Because the valuation of participant i $\left(v_i^{(g^*)'}\right)$ is less than $\frac{\text{MPRG}(g')}{j}$ and i is in the winning set, in order for $\text{MPRG}(g^*)$ to be larger than $\text{MPRG}(g')$, there has to be more than j winners. Let $j' > j$ be the number of winners in θ'. Having j' winners in θ' and in order for $G^{(g^*)}$ to be the group with the highest MPRG, we conclude that there are j' participants with valuation greater than $\frac{\text{MPRG}(g')}{j'}$. Note that the only difference between θ and θ' is that the valuation of participant i is higher in θ. Therefore, there are also at least j' participants with valuation greater than $\frac{\text{MPRG}(g')}{j'}$ in θ. This contradicts with the way we select the number of winners (j) in θ which is the maximum number for which $j \cdot v_j^{(g^*)}$ is larger than $\text{MPRG}(g')$. □

The allocation function x^{MVPA} is weakly monotone (Observation 2) and the payments of the winners are their critical values (Lemma 4); therefore by Lemma 1 we conclude that MVPA satisfies IC.

In the rest of this section, first we prove that MVPA satisfies RM and then bounds its PoRM.

Proposition 1 *The total revenue of mechanism* MVPA *for type profile* θ *(*$\text{REVENUE}(\text{MVPA}, \theta)$*) is the following:*

$$\text{REVENUE}(\text{MVPA}, \theta) = \max\left(\text{MPRG}(g'), M \cdot v_{M+1}^{(g^*)}\right)$$

where g' is a group with the second highest MPRG.

Proof From Lemma 4 we know that there are j winners and each of them pays $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$. Therefore the sum of payments or the revenue of MVPA is $j \cdot \max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$. The proof of the proposition follows if we show that when $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$ is equal to $v_{M+1}^{(g^*)}$, then the number of winners (j) is equal to M.

If $\max\left(\frac{\text{MPRG}(g')}{j}, v_{M+1}^{(g^*)}\right)$ is equal to $v_{M+1}^{(g^*)}$, then as $v_{M+1}^{(g^*)} \leq v_M^{(g^*)}$, we have $M \cdot v_M^{(g^*)} \geq \frac{\text{MPRG}(g')}{j}$. Remember that j is the maximum number in the set $[M]$ for which $j \cdot v_j^{(g^*)}$ is larger than $\text{MPRG}(g')$. Therefore j is equal to M. □

Lemma 5 *Let θ' be the type profile obtained by either adding a new participant or increasing the valuation of a participant in θ. Then,*

$$\text{REVENUE}(\text{MVPA}, \theta') \geq \text{REVENUE}(\text{MVPA}, \theta).$$

Proof Let x be the new added participant or the participant which has the increased valuation in θ'. Throughout the proof we show MPRG of each group g in type profile θ by $\text{MPRG}_\theta(g)$ and in type profile θ' by $\text{MPRG}_{\theta'}(g)$. Similarly, we show the jth highest valuation of the participants of group g by $v_j^{(g^*,\theta)}$ in type profile θ and by $v_j^{(g^*,\theta')}$ in type profile θ'.

As the jth highest valuation of the participants of each group can only increase by adding participant x, we conclude

$$\forall g, \forall j \quad v_j^{(g,\theta')} \geq v_j^{(g,\theta)}. \tag{7}$$

Remember that MPRG_θ of each group g is $\max_{j \in [M^{(g)}]} j \cdot v_j^{(g,\theta)}$ and using Eq. (7) we get

$$\forall g \quad \text{MPRG}_{\theta'}(g) \geq \text{MPRG}_\theta(g). \tag{8}$$

In order to prove this lemma we consider two cases: (A) adding participant x does not change the winning group $G^{(g^*)}$ and (B) adding x changes the winning group.

Case (A): Let g'' be a group with the second highest MPRG in θ'; it is possible that g' is equal to g''.

$$\begin{aligned}
\text{REVENUE}(\text{MVPA}, \theta') &= \max\left(\text{MPRG}_{\theta'}(g''), M \cdot v_{M+1}^{(g^*,\theta')}\right) \\
&\quad \text{Proposition 1} \\
&\geq \max\left(\text{MPRG}_{\theta'}(g'), M \cdot v_{M+1}^{(g^*,\theta')}\right) \\
&\quad \text{definition of } g'' \\
&\geq \max\left(\text{MPRG}_{\theta}(g'), M \cdot v_{M+1}^{(g^*,\theta)}\right) \\
&\quad \text{Eqs. (7) and (8)} \\
&= \text{REVENUE}(\text{MVPA}, \theta)
\end{aligned}$$

Case (B): Let $G^{(g'')}$ be a group with the highest MPRG in θ'. We have

$$\text{MPRG}_\theta(g^*) \geq \text{MPRG}_\theta(g') \tag{9}$$

as g^* has the highest and g' has the second highest MPRG in θ.

$$\begin{aligned} \text{MPRG}_\theta(g^*) &\geq M \cdot v_M^{(g^*,\theta)} && \text{As } \text{MPRG}_\theta(g^*) = \max_{j\in[M]} j \cdot v_j^{(g^*,\theta)} \\ &\geq M \cdot v_{M+1}^{(g^*,\theta)} && \text{As } v_M^{(g^*,\theta)} \geq v_{M+1}^{(g^*,\theta)} \end{aligned} \tag{10}$$

Let $\hat{g}$ be the group with second highest MPRG in θ'. Because g^* is no longer the winning group in θ', it can be a candidate for the group with the second highest MPRG in θ' and hence we have the following:

$$\text{MPRG}_\theta(g^*) \leq \text{MPRG}_{\theta'}(g^*) \leq \text{MPRG}_{\theta'}(\hat{g}) \tag{11}$$

The following equations conclude the proof of this case:

$$\begin{aligned} \text{REVENUE}(\text{MVPA}, \theta) &= \max\left(\text{MPRG}_\theta(g'), M \cdot v_{M+1}^{(g^*,\theta)}\right) \\ &\leq \text{MPRG}_\theta(g^*) \\ &\quad \text{by Eqs. (9) and (10)} \\ &\leq \text{MPRG}_{\theta'}(\hat{g}) \\ &\quad \text{by Eq. (11)} \\ &\leq \max\left(\text{MPRG}_{\theta'}(\hat{g}), M^{(g'')} \cdot v_{M^{(g'')}+1}^{(g'',\theta)}\right) \\ &= \text{REVENUE}(\text{MVPA}, \theta') \end{aligned}$$

□

The following lemma which bounds PoRM of MVPA finishes this section:

Theorem 5 $\text{PoRM}(\text{MITA}) \leq (\lfloor \log k \rfloor + 1) \cdot (2 + \ln k)$

Proof Let $\text{WF}(g)$ to be the maximum social welfare achievable if we select the winners only from group $G^{(g)}$. Let A be a set of winner(s) which realizes the maximum welfare in type profile θ. Note that as there are $\lfloor \log k \rfloor + 1$ groups, one group $(\hat{g})$ has a subset of participants from A whose social welfare is at least $\frac{\text{WF}(A)}{\lfloor \log k \rfloor + 1}$ and hence the following:

$$\text{WF}(\hat{g}) \geq \frac{\text{WF}(A)}{\lfloor \log k \rfloor + 1} \tag{12}$$

Now we prove the following claim about $\text{MPRG}(\hat{g})$:

Claim 1 $\text{MPRG}(\hat{g}) \geq \frac{\text{WF}(\hat{g})}{2+\ln k}$

Proof Let B be the set of participants from group $G^{(\hat{g})}$ which give the maximum social welfare. Because the demands of all the participants of $G^{(\hat{g})}$ are in range $[2^{\hat{g}-1}, 2^{\hat{g}})$, size of B is at most $\lfloor k/2^{\hat{g}-1} \rfloor$. Remember from Definition 5 that $M^{(\hat{g})} = \max\left(\lfloor k/2^{(\hat{g})} \rfloor, 1\right)$ is the maximum number of winners that MVPA potentially selects from group $G^{(\hat{g})}$. Therefore, we have $|B| \leq 2 \cdot M^{(\hat{g})} + 1$.

Throughout the proof, we drop the superscript from $M^{(\hat{g})}$ and simply refer to it as M.

Let $v_1 \geq v_2 \geq \ldots \geq v_{2\cdot M+1}$ be the valuations of the participants in B; if B has less than $2\cdot M+1$ participants, we add enough dummy participants with valuations zero. Remember that $\text{MPRG}(\hat{g}) = \max_{j\in[M]} j \cdot v_j^{(\hat{g})}$ where M is at least 1 (see Definition 5) which implies

$$v_i \leq \frac{\text{MPRG}(\hat{g})}{i} \quad \forall i \in [M] \tag{13}$$

The following equations conclude the proof of the claim:

$$\begin{aligned}
\text{WF}(\hat{g}) &= \sum_{i=1}^{2\cdot M+1} v_i \\
&= \sum_{i=1}^{M} v_i + \sum_{i=M+1}^{2\cdot M+1} v_i \\
&\le \sum_{i=1}^{M} v_i + \sum_{i=M+1}^{2\cdot M+1} v_M \\
&\quad \text{replacing } v_i \text{ with } v_M \text{ for } i > M \\
&\le \sum_{i=1}^{M} \frac{\text{MPRG}(\hat{g})}{i} + \sum_{i=M+1}^{2\cdot M+1} \frac{\text{MPRG}(\hat{g})}{M} \\
&\quad \text{by Eq. (13)} \\
&\le (2 + \ln k)\text{MPRG}(\hat{g})
\end{aligned}$$

□

Remember $G^{(g^*)}$ is the group with maximum MPRG value. Let j be the number for which $\text{MPRG}(g^*)$ is equal to $j \cdot v_j^{(g^*)}$. Allocation function x^{MVPA} selects the first j^* participants from group $G^{(g^*)}$ where j^* is the maximum number for which $j^* \cdot v_{j^*}^{(g^*)}$ is larger than $\text{MPRG}(g')$. Therefore we can conclude that $j \le j^*$ and hence

$$\text{WF}\left(x^{\text{MVPA}}(\theta)\right) \ge \text{MPRG}(g^*). \tag{14}$$

The following equations conclude the proof of the theorem:

$$\begin{aligned}
\text{WF}\left(x^{\text{MVPA}}(\theta)\right) &\ge \text{MPRG}(g^*) \\
&\quad \text{by Eq. (14)} \\
&\ge \text{MPRG}(\hat{g}) \\
&\quad G^{(g^*)} \text{ has the highest MPRG} \\
&\ge \frac{\text{WF}(\hat{g})}{2 + \ln k} \\
&\quad \text{Claim 1} \\
&\ge \frac{\text{WF}(A)}{(\lfloor \log k \rfloor + 1) \cdot (2 + \ln k)} \\
&\quad \text{by Eq. (12)}
\end{aligned}$$

□

Lower Bound

In this section we prove Theorem 2. As mentioned earlier we need two additional mild assumptions of *anonymity* and *independence of irrelevant alternatives* (which we define below) on the class of mechanisms for which we prove our lower bound.

Definition 6 A mechanism $(\mathcal{M} = (x, p))$ is anonymous (AM) if the following holds: Suppose $\theta_1, \theta_2 \in \Theta^n$ are two type profiles which are permutations of each other (i.e., the set of type profiles are same just that the identities of participants to whom those types belongs are different). Say, $\theta_2 = \pi(\theta_1)$. Also say $x(\theta_1) = S_1$ and $x(\theta_2) = S_2$. Then $S_2 = \pi(S_1)$.

Definition 7 Let $\theta \in \Theta^n$ be an arbitrary-type profile and $i \in N$ be an arbitrary participant with type $\theta_i = (d_i, v_i)$. A mechanism $(\mathcal{M} = (x, p))$ satisfies independence of irrelevant alternatives (IIA) that if we decrease the bid of a losing participant, say, participant i, to $\hat{v}_i < v_i$, then the new set of winners is a super set of the previous one, i.e., $x(\theta) \subseteq x((d_i, \hat{v}_i), \theta_{-i})$. In other words, decreasing the bid of a losing participant does not hurt any winner.

The proof outline of Theorem 2 is the following. Let $\mathcal{M}^* = (x^*, p^*)$ be a mechanism which satisfies all the five properties and has the optimal PoRM OPT (i.e., $\text{OPT} = \text{PoRM}(\mathcal{M}^*)$). We study the behavior of $\mathcal{M}^*$ in a few type profiles. Let ϵ be an arbitrary small positive real value. First we show that when there are only two participants with types $(k, 1)$ and $(k, 1 + \epsilon)$, $\mathcal{M}^*$ gives all the k items to the participant with type $(k, 1 + \epsilon)$. The revenue of $\mathcal{M}^*$ from these two participants is 1. Then, we add k

more participants to create type profile $\theta = \big((1, 1-\epsilon), (1, \frac{1}{2}-\epsilon), \ldots, (1, \frac{1}{k}-\epsilon), (k, 1), (k, 1+\epsilon)\big)$. The RM property requires $\mathcal{M}^*$ to make at least the same revenue for θ. From this constraint we are able to show that $\mathcal{M}^*$ assigns all the items to participant $k+2$ with type $(k, 1+\epsilon)$ and hence gets social welfare $1+\epsilon$. Note that the maximum social welfare happens when the set of winners is $\{1, \ldots, k\}$ which implies $\text{WFR}(\mathcal{M}^*, \theta) \geq \sum_{i=1}^{k} \frac{1}{i} - k \cdot \epsilon$ (see Definition 1). Because $\text{PoRM}(\mathcal{M}^*) \geq \text{WFR}(\mathcal{M}^*, \theta)$ for any $\theta \in \Theta^n$, we conclude that $\text{OPT} \geq \sum_{i=1}^{k} \frac{1}{i}$.

First we study the behavior of $\mathcal{M}^*$ when we have only two participants with types $(k, 1)$ and $(k, 1+\epsilon)$.

Lemma 6 *Mechanism $\mathcal{M}^*$ in type profile $((k, 1), (k, 1+\epsilon))$ gives all k items to the second participant and make one unit of revenue, i.e., $x^*\left((k, 1), (k, 1+\epsilon)\right) = \{2\}$ and $p^*\left((k, 1), (k, 1+\epsilon)\right) = (0, 1)$.*

Proof First we study type profile $((k, v_1), (k, v_2))$ for general values $v_1, v_2 \in \mathbb{R}^+$ where $v_1 < v_2$. We prove that $\mathcal{M}^*$ gives all the items to the second participant.

Claim 2 $x^*\left((k, v_1), (k, v_2)\right) = \{2\}$ for any $v_1, v_2 \in \mathbb{R}^+$ where $v_1 < v_2$.

Proof First note that M^* has to have a winner for this type profile because otherwise its social welfare will be zero while the maximum social welfare is v_2. This makes the social welfare ratio of $\mathcal{M}^*$ to be undefined.

Now we prove that if $x^*\left((k, v_1), (k, v_2)\right) = \{1\}$, then $\mathcal{M}^*$ either violates IC or AM. Let call type profile $((k, v_1), (k, v_2))$ by $\theta^{(1)}$ and suppose for the sake of contradiction $x^*(\theta^{(1)}) = \{1\}$. From Lemma 1 we know that if participant 1 increases his bid to v_2, she still wins; hence $x^*(\theta^{(2)}) = \{1\}$ where $\theta^{(2)} = ((k, v_2), (k, v_2))$. Now if in type profile $\theta^{(2)}$ participant 2 decrease his bid to v_1, again from Lemma 1 we conclude that she cannot win, i.e., $x^*(\theta^{(3)}) = \{1\}$ where $\theta^{(3)} = ((k, v_2), (k, v_1))$. Type profile $\theta^{(1)}$ is $\theta^{(3)}$ with participant 1 swapped with participant 2 but in both of them the first participant wins which contradicts with AM. □

Claim 2 directly proves that the winner in type profile $((k, 1), (k, 1+\epsilon))$ is the second participant. The only thing remains is to show that her payment (p_2) is 1. Note that payment p_2 cannot be less than one because otherwise by Lemma 1 participant 2 wins all the items in type profile $((k, 1), (k, p_2))$ which contradicts with Claim 2. Payment p_2 cannot be larger than one because otherwise for any value $1 < v_2 < p_2$ participant 2 wins all the items in type profile $((k, 1), (k, v_2))$. This contradicts with Lemma 1 which states that the payment p_2 is the smallest value for which participant 2 wins the items. □

Now we add k more participants, each of which wants only one item. In the following lemma we prove that RM forces $\mathcal{M}^*$ to assign all of the items to one of the participants who want all the items.

Lemma 7 *For the set of $k+2$ participants with type profile $\theta^{(0)} = \big((1, 1-\epsilon), (1, \frac{1}{2}-\epsilon), \ldots, (1, \frac{1}{k}-\epsilon), (k, 1), (k, 1+\epsilon)\big)$, mechanism $\mathcal{M}^*$ assigns all the k items to either participant $k+1$ or participant $k+2$, i.e., $x^*\left(\theta^{(0)}\right) = \{k+1\}$ or $x^*\left(\theta^{(0)}\right) = \{k+2\}$.*

Proof We prove the lemma by contradiction that if $\mathcal{M}^*$ assigns the items to a subset of the first k participants, it satisfies RM. We consider a class of k type profiles $(\theta^{(1)}, \ldots, \theta^{(k)})$ where $\theta^{(i)}$ is built from $\theta^{(i-1)}$. The only possible difference between $\theta^{(i)}$ and $\theta^{(i-1)}$ is in the valuation of participant i. If participant i is a winner in $\theta^{(i-1)}$, then we obtain $\theta^{(i)}$ by increasing the valuation of the ith participant from $\frac{1}{i} - \epsilon$ to $1 - \epsilon$. Note that the payment of participant i in $\theta^{(i-1)}$ is at most her valuation which is $\frac{1}{i} - \epsilon$ and in $\theta^{(i)}$ it remains the same by Lemma 1. If participant i is not a winner in $\theta^{(i-1)}$, then we obtain $\theta^{(i)}$ by decreasing his valuation to zero. Note that by IIA, no winner turns to a loser in $\theta^{(i)}$.

Let $j \in \{1, \ldots, k\}$ be the largest number for which participant j is a winner in $\theta^{(j-1)}$ and we increase his valuation to $1-\epsilon$ in $\theta^{(j)}$. Note that at the start in type profile $\theta^{(0)}$, the set of winners is a nonempty subset of $\{1, \ldots, k\}$. Therefore there is at least one such j for which participant j is a

winner in $\theta^{(j)}$ since decreasing the non-winners valuation does not reduce the size of the winners.

Now we prove that there is no winner in the set of participants $\{j+1,\ldots,k\}$ in type profile $\theta^{(j)}$. Assume otherwise and let $p \in \{j+1,\ldots,k\}$ be the smallest number for which participant p is a winner in $\theta^{(j)}$. Note that when we decrease the valuation of each participant $j < p' < p$ to zero to obtain $\theta^{(p')}$, participant p remains as a winner in all of them by IIA. Therefore, participant p is a winner in type profile $\theta^{(p-1)}$ and we increase his valuation in $\theta^{(p)}$ which contradicts with the fact that j is the largest number for which participant j is a winner in $\theta^{(j-1)}$.

The payment of participant j in $\theta^{(j-1)}$ is at most its valuation which is $\frac{1}{j}-\epsilon$. When we increase his bid to $1-\epsilon$ in type profile $\theta^{(j)}$, its payment remains the same by Lemma 1. Note that by construction of $\theta^{(j)}$, the valuation of all participants in $\{1,\ldots,j\}$ is either zero or $1-\epsilon$. If the valuation of them is $1-\epsilon$ and they are winner, by AM their payment is $\frac{1}{j}-\epsilon$. Therefore the total payments or revenue of $\mathcal{M}^*$ in $\theta^{(j)}$ is at most $j\cdot(\frac{1}{j}-\epsilon) = 1-j\cdot\epsilon$ since there is no other winner in set of participants $\{j+1,\ldots,k\}$ in type profile $\theta^{(j)}$.

Note that type profile $\theta^{(j)}$ is obtained from type profile $((k,1),(k,1+\epsilon))$ by adding k more participants. However the revenue of $\theta^{(j)}$ is $1-j\cdot\epsilon$ that is strictly less than 1 which is the revenue of $((k,1),(k,1+\epsilon))$ by Lemma 6. This contradicts with the RM property of $\mathcal{M}^*$; hence $\mathcal{M}^*$ has to assign the items to either participant $k+1$ or $k+2$. □

Now we show how from Lemma 7 we can derive Theorem 2. Note that the maximum welfare for type profile $\theta^{(0)} = \big((1,1-\epsilon),(1,\frac{1}{2}-\epsilon),\ldots,(1,\frac{1}{k}-\epsilon),(k,1),(k,1+\epsilon)\big)$ realized when we give one item to each of the first k participants for which we get the total social welfare $\sum_{i=1}^{k}\frac{1}{i}-k\cdot\epsilon$, i.e., the nominator of Definition 1 for this type profile is $\sum_{i=1}^{k}\frac{1}{i}-k\cdot\epsilon$. The denominator of Definition 1 is at most $1+\epsilon$ by Lemma 7. Therefore the ratio of the welfare for this type profile is at least $\frac{\sum_{i=1}^{k}1/i-k\cdot\epsilon}{1+\epsilon}$. Because OPT is the maximum ratio over all type profiles (see Definition 2), we have $\text{OPT} \geq \frac{\sum_{i=1}^{k}1/i-k\cdot\epsilon}{1+\epsilon}$ which results in $\text{OPT} \geq \sum_{i=1}^{k}\frac{1}{i}-\epsilon'$ where $\epsilon' = \frac{\epsilon(k-\sum_{i=1}^{k}1/i)}{1+\epsilon}$.

Note that the value ϵ' can be made arbitrarily small by selecting a sufficiently small value for ϵ. Therefore we prove that for any positive small real value ϵ', we have $\text{OPT} \geq \sum_{i=1}^{k}\frac{1}{i}-\epsilon'$ which implies Theorem 2.

Acknowledgments The first author would like to thank Vasilis Gkatzelis for some initial fruitful discussions on this topic.

Problem Definition

We will consider enumeration problems, i.e., we want to list all the objects that satisfy given conditions (e.g., vertices of a polytope $\{\boldsymbol{x} \mid A\boldsymbol{x} \geq \boldsymbol{b}\}$ or maximal cliques in a given graph). One object should not be listed twice or more.

Introduction

In this entry, we consider an enumeration scheme called *reverse search* developed by Avis and Fukuda [1]. The scheme was originally developed to enumerate all the vertices of a given polytope represented by the intersection of half spaces [1]. The scheme is very powerful, and quite many kinds of objects such as arrangements in a hyperplane, triangulations of a polygon, bases of a matroid, spanning trees, trees, or maximal cliques in a graph, plane graphs of given number of vertices, etc., can be enumerated with it [1–4, 6].

Think of a problem to enumerate (or visit) all the vertices of a given connected graph G. Most of the readers may use depth-first search or breadth-first search algorithms. The two algorithms dynamically find tree structures in G and traverse them. Given an enumeration problem, reverse search scheme also finds some kind of tree structure on objects to enumerate dynamically and traverse it. To execute depth-first search or breadth-first search, a graph G should be given explicitly, and we have to remember which vertices have been visited. However, in most of enumeration problems, the objects that we want to enumerate are, of course, not explicitly given, nor we cannot remember all the objects that we have already output in the execution of an algorithm. For example, if we want to enumerate all the vertices of a polytope represented by the intersection of half spaces, the vertices are not given explicitly. If we want to enumerate plane graphs of 100 vertices, the number is quite large, and we do not want to remember every obtained graph. So, the scheme is designed to treat implicitly given objects and run with small amount of memory.

Key Results

When we develop an algorithm for enumerating some objects with reverse search scheme, we first think of an implicit connected graph G_{rs} of the objects. For example, when enumerating all the vertices of a given polytope, we think of a graph whose vertices correspond to the vertices of the polytope and whose edges correspond to the edges of the polytope. When enumerating spanning trees in a graph G, we think of a graph G_{rs} whose vertices correspond to the spanning trees of G, and $\{i, j\} \in E(G_{\mathrm{rs}})$ if and only if spanning tree T_j of G corresponding to vertex j of G_{rs} can be obtained from spanning tree T_i of G corresponding to vertex i of G_{rs} by removing an edge and adding an edge. Of course, we cannot make such a graph G_{rs} explicitly without enumerating the vertices of the polytope or the spanning trees of G. However, given an object x, we can easily generate every object whose corresponding vertex is adjacent to x's corresponding vertex in G_{rs}. To put it the other way around, we require G_{rs} this property. In the above examples, G_{rs} are undirected. However, G_{rs} is sometimes di-

rected. When enumerating (not necessarily maximal) cliques in a graph, $(i, j) \in E(G_{\mathrm{rs}})$ if and only if the clique corresponding to j is a proper subset of the clique corresponding to i.

Now we have a connected graph G_{rs} of objects to enumerate. Then for every vertex $v \in V(G_{\mathrm{rs}})$ except for a special vertex r called *root*, we define a *parent* vertex u of v such that u is adjacent to v, and no vertex of G_{rs} is a proper ancestor of itself, i.e., by iteratively moving from a vertex v to the parent of v, to the parent of the parent of v, and so on, we never come to the start vertex v again. Then we easily come to the following lemma.

Lemma 1 *For every vertex v of G_{rs}, v is a descendant of r.*

Proof Since every vertex of G_{rs} cannot be an ancestor of itself and the number of vertices in G_{rs} is bounded, every vertex of G_{rs} has its oldest ancestor. Since a vertex of G_{rs} except for r has its parent, it cannot be the oldest ancestor. Therefore, r is the oldest ancestor of every vertex of G_{rs}. □

By the lemma above, edges in G_{rs} corresponding to the "parent-child" relations clearly induce a spanning tree (or arborescence) T_{rs} of G_{rs}. Therefore, we can enumerate every object by traversing T_{rs} from r in the depth-first manner. The whole scheme is shown below.

```
Procedure ENUMERATE_SUBTREE(v)
  output v
  for all w satisfying (w, v) ∈ E(G_rs) do
    if v is the parent of w then
        ENUMERATE_SUBTREE(w)
    end if
  end for
end procedure
```

```
Procedure ENUMERATE
  find r
  ENUMERATE_SUBTREE(r)
end procedure
```

If the depth of T_{rs} is very deep, using a recursion needs a big amount of memory. However, since we can find the parent of each vertex of G_{rs}, we actually do not need to use a recursion. Even if we do not remember the previously visited vertices in G_{rs}, we can go back in the tree search by finding the parents. If the time complexity for finding the parent is relatively high, the total time complexity gets high. Therefore, there is a time-space trade-off.

Examples

For enumerating all the vertices of a given polytope $P = \{A\boldsymbol{x} \geq \boldsymbol{b}\}$, we use G_{rs} described in the previous section. For the sake of simplicity, we assume that P is not degenerated. First, we find a vertex $\boldsymbol{x}^*$ of P by the simplex method or the interior point method. Then, find an objective vector $\boldsymbol{c}$ such that the unique optimal solution of the linear programming problem $\min \boldsymbol{c}^\top \boldsymbol{x}$, s. t. $A\boldsymbol{x} \geq \boldsymbol{b}$ is $\boldsymbol{x}^*$. We define a parent vertex $\overline{\boldsymbol{x}}$ of a vertex $\boldsymbol{x}$ as the vertex corresponding to the basis of P obtained from the basis corresponding to $\boldsymbol{x}$ by a single pivot in the simplex method minimizing $\boldsymbol{c}^\top \boldsymbol{x}$ with Bland's pivot rule. The root vertex is $\boldsymbol{x}^*$. We can easily find every vertex $\boldsymbol{x}'$ satisfying $\{\boldsymbol{x}', \boldsymbol{x}\} \in E(G_{\mathrm{rs}})$ by swapping a basic variable and a nonbasic variable from the basis corresponding to $\boldsymbol{x}'$. Of course, we can easily check if vertex $\boldsymbol{x}$ is the parent of vertex $\boldsymbol{x}'$ by running the simplex method by one step from $\boldsymbol{x}'$.

For enumerating (not necessarily maximal) cliques in a graph G, we also use (the directed graph) G_{rs} in the previous section. We define the parent of vertex v corresponding to clique C_v in G as the vertex u corresponding to clique C_u such that C_u is obtained from C_v by removing the vertex of the smallest index. The root is the empty set. Since a vertex w satisfying $(w, v) \in E(G_{\mathrm{rs}})$ corresponds to a clique obtained by adding a vertex to C_v, we can find it easily. Clearly we can check if v is the parent of u easily, too.

Note that the algorithms introduced in this section are for an easy explanation. One can develop faster algorithms for the problems.

Avoiding Long Delays

A naive implementation of the reverse search scheme sometimes causes a long delay between successive outputs of two objects. Consider the

case that the depth of T_{rs} is very deep and one has to return from a leaf to the root. In order to avoid this kind of long delays, a smart method is known [5, 7]. At the odd level of recursion, we output the objects before making the recursive calls, and at the even level of the recursion, we output after the termination of the recursive calls. In this way, at least one of three iterations outputs an object when the algorithm ascends or descends the search tree T_{rs}. The algorithm is shown below.

```
Procedure ENUMERATE_SUBTREE(v, parity)
  if parity = 0 then
    output v
  end if
  for all w satisfying (w, v) ∈ E(G_rs) do
    if v is the parent of w then
        ENUMERATE_SUBTREE(w,parity ⊕ 1)
    end if
  end for
  if parity = 1 then
    output v
  end if
end procedure
```

```
Procedure ENUMERATE
  find r
  ENUMERATE_SUBTREE(r, 0)
end procedure
```

Note

For the sake of easy understanding, we introduced G_{rs}. However, most of results using the reverse search type algorithms do not treat G_{rs}. It is easy to understand that we can develop reverse search algorithms only by good definitions of parent-child relations and fast algorithms to enumerate children of given objects. If one can develop a fast children enumeration algorithm which enumerates all the children of an object in time T and if the degrees of some vertices in G_{rs} are quite large compared with T, the resulting enumeration algorithm is faster than the naive implementation described in this entry. Such examples will appear in other entries in this book.

Keywords

Full partition function

Years and Authors of Summarized Original Work

2005; Miklós, Meyer, Nagy

Problem Definition

This problem is concerned with computing features of the Boltzmann distribution over RNA secondary structures in the context of the standard Gibbs free energy model used for RNA Secondary Structure Prediction by Minimum Free Energy (cf. corresponding entry). Thermodynam-

ics state that for a system with configuration space Ω and free energy given by $E: \Omega \mapsto \mathbf{R}$, the probability of the system being in state $\omega \in \Omega$ is proportional to $e^{-E(\omega)/RT}$ where R is the universal gas constant and T the absolute temperature of the system. The normalizing factor

$$Z = \sum_{\omega \in \Omega} e^{-E(\omega)/RT} \tag{1}$$

is called the *full partition function* of the system.

Over the past several decades, a model approximating the free energy of a structured RNA molecule by independent contributions of its secondary structure components has been developed and refined. The main purpose of this work has been to assess the stability of individual secondarystructures. However, it immediately translates into a distribution over all secondary structures. Early work focused on computing the pairing probability for all pairs of bases, i.e., the sum of the probabilities of all secondary structures containing that base pair. Recent work has extended methods to compute probabilities of base pairing probabilities for RNA heterodimers [2], i.e., interacting RNA molecules, and expectation, variance and higher moments of the Boltzmann distribution.

Notation

Let $s \in \{A, C, G, U\}^*$ denote the sequence of bases of an RNA molecule. Use $X \cdot Y$ where $X, Y \in \{A, C, G, U\}$ to denote a base pair between bases of type X and Y, and $i \cdot j$ where $1 \leq i < j \leq |s|$ to denote a base pair between bases $s[i]$ and $s[j]$.

Definition 1 (RNA Secondary Structure) A secondary structure for an RNA sequence s is a set of base pairs $S = \{i \cdot j \mid 1 \leq i < j \leq |s| \wedge i < j - 3\}$. For $i \cdot j, i' \cdot j' \in S$ with $i \cdot j \neq i' \cdot j'$

- $\{i, j\} \cap \{i', j'\} = \emptyset$ (each base pairs with at most one other base)
- $\{s[i], s[j]\} \in \{\{A, U\}, \{C, G\}, \{G, U\}\}$ (only Watson-Crick and G, U wobble base pairs)
- $i < i' < j \Rightarrow j' < j$ (base pairs are either nested or juxtaposed but not overlapping)

The second requirement, that only canonical base pairs are allowed, is standard but not consequential in solutions to the problem. The third requirement states that the structure does not contain pseudoknots. This restriction is crucial for the results listed in this entry.

Energy Model

The model of Gibbs free energy applied, usually referred to as the nearest-neighbor model, was originally proposed by Tinoco et al. [10, 11]. It approximates the free energy by postulating that the energy of the full three dimensional structure only depends on the secondary structure, and that this in turn can be broken into a sum of independent contributions from each loop in the secondary structure.

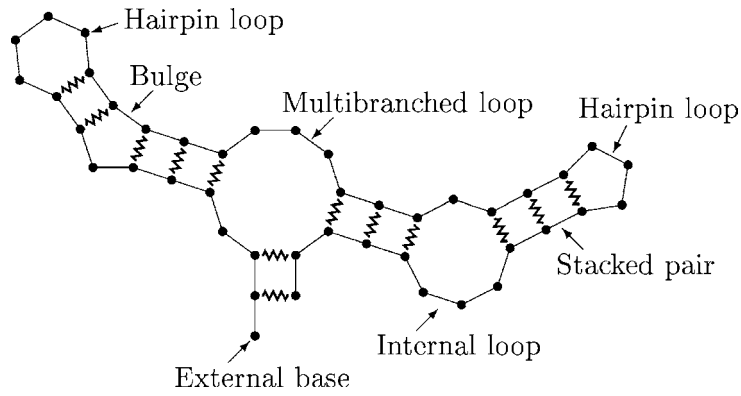
Definition 2 (Loops) For $i \cdot j \in S$, base k is *accessible* from $i \cdot j$ iff $i < k < j$ and $\neg \exists i' \cdot j' \in S: i < i' < k < j' < j$. The *loop closed by* $i \cdot j, \ell_{i \cdot j}$, consists of $i \cdot j$ and all the bases accessible from $i \cdot j$. If $i' \cdot j' \in S$ and i' and j' are accessible from $i \cdot j$, then $i' \cdot j'$ is an interior base pair in the loop closed by $i \cdot j$.

Loops are classified by the number of interior base pairs they contain:

- hairpin loops have no interior base pairs
- stacked pairs, bulges, and internal loops have one interior base pair that is separated from the closing base pair on neither side, on one side, or on both sides, respectively
- multibranched loops have two or more interior base pairs

Bases not accessible from any base pair are called external. This is illustrated in Fig. 1. The free energy of structure S is

$$\Delta G(S) = \sum_{i \cdot j \in S} \Delta G(\ell_{i \cdot j}) \tag{2}$$



RNA Secondary Structure Boltzmann Distribution, Fig. 1 A hypothetical RNA structure illustrating the different loop types. Bases are represented by *circles*, the RNA backbone by *straight lines*, and base pairs by *zigzagged lines*

where $\Delta G(\ell_{i\cdot j})$ is the free energy contribution from the loop closed by $i \cdot j$. The contribution of S to the full partition function is

$$e^{-\Delta G(S)/RT} = e^{-\sum_{i\cdot j \in S} \Delta G(\ell_{i\cdot j})/RT} = \prod_{\ell_{i\cdot j} \in S} e^{-\Delta G(\ell_{i\cdot j})/RT}. \quad (3)$$

Problem 1 (RNA Secondary Structure Distribution)
INPUT: RNA sequence s, absolute temperature T and specification of ΔG at T for all loops.
OUTPUT: $\sum_S e^{-\Delta G(S)/RT}$, where the sum is over all secondary structures for s.

Key Results

Solutions are based on recursions similar to those for RNA Secondary Structure Prediction by Minimum Free Energy, replacing sum and minimization with multiplication and sum (or more generally with a *merge function* and a *choice function* [8]). The key difference is that recursions are required to be non-redundant, i.e., any particular secondary structure only contributes through one path through the recursions.

Theorem 1 *Using the standard thermodynamic model for RNA secondary structures, the partition function can be computed in time $O(|s^3)$ and space $O(|s^2)$. Moreover, the computation can build data structures that allow $O(1)$ queries of the pairing probability of $i \cdot j$ for any $1 \le i < j \le |s|$ [5, 6, 7].*

Theorem 2 *Using the standard thermodynamic model for RNA secondary structures, the expectation and variance of free energy over the Boltzmann distribution can be computed in time $O(|s^3)$ and space $O(|s^2)$. More generally, the kth moment*

$$E_{\text{Boltzmann}}[\Delta G] = 1/Z \sum_S e^{-\Delta G(S)/RT} \Delta G^k(S), \quad (4)$$

where $Z = \sum_S e^{-\Delta G(S)/RT}$ is the full partition function and the sums are over all secondary structures for s, can be computed in time $O(k^2|s^3)$ and space $O(ks^2)$ [8].

In Theorem 2 the free energy does not hold a special place. The theorem holds for any function Φ defined by an independent contribution from each loop,

$$\Phi(S) = \sum_{i\cdot j \in S} \phi\left(\ell_{i\cdot j}\right), \quad (5)$$

provided each loop contribution can be handled with the same efficiency as the free energy contributions. Hence, moments over the Boltzmann distribution of e.g., number of base pairs, unpaired bases, or loops can also be efficiently computed by applying appropriately chosen indicator functions.

Applications

The original use of partition function computations was for discriminating between well defined and less well defined regions of a secondary structure. Minimum free energy predictions will always return a structure. Base pairing probabilities help identify regions where the prediction is uncertain, either due to the approximations of the model or that the real structure indeed does fluctuate between several low energy alternatives. Moments of Boltzmann distributions are used in identifying how biological RNA molecules deviates from random RNA sequences.

The data structures computed in Theorem 1 can also be used to efficiently sample secondary structures from the Boltzmann distribution. This has been used for probabilistic methods for secondary structure prediction, where the centroid of the most likely cluster of sampled structures is returned rather than the most likely, i.e., minimum free energy, structure [3]. This approach better accounts for the entropic effects of large neighborhoods of structurally and energetically very similar structures. As a simple illustration of this effect, consider twice flipping a coin with probability $p > 0.5$ for heads. The probability p^2 of heads in both flips is larger than the probability $p(1-p)$ of heads followed by tails or tails followed by heads (which again is larger than the probability $(1-p)^2$ of tails in both flips). However, if the order of the flips is ignored the probability of one heads and one tails is $2p(1-p)$. The probability of two heads remains p^2 which is smaller than $2p(1-p)$ when $p < \frac{2}{3}$. Similarly a large set of structures with fairly low free energy may be more likely, when viewed as a set, than a small set of structures with very low free energy.

Open Problems

As for RNA Secondary Structure Prediction by Minimum Free Energy, improvements in time and space complexity are always relevant. This may be more difficult for computing distributions, as the more efficient dynamic programming techniques of [9] cannot be applied. In the context of genome scans, the fact that the start and end positions of encoded RNA molecule is unknown has recently been considered [1].

Also the problem of including structures with pseudoknots, i.e., structures violating the last requirement in Definition 1, in the configuration space is an active area of research. It can be expected that all the methods of Theorems 3 through 6 in the entry on RNA Secondary Structure Prediction Including Pseudoknots can be modified to computation of distributions without affecting complexities. This may require some further bookkeeping to ensure non-redundancy of recursions, and only in [4] has this actively been considered.

Though the moments of functions that are defined as sums over independent loop contributions can be computed efficiently, it is unknown whether the same holds for functions with more complex definitions. One such function that has traditionally been used for statistics on RNA secondary structure [12] is the *order* of a secondary structure which refers to the nesting depth of multibranched loops.

2006; Ogurtsov, Shabalina, Kondrashov, Roytberg

Problem Definition

This problem is concerned with predicting the set of base pairs formed in the native structure of an RNA molecule. The main motivation stems from structure being crucial for function and the growing appreciation of the importance of RNA molecules in biological processes. Base pairing is the single most important factor determining structure formation. Knowledge of the secondary structure alone also provides information about stretches of unpaired bases that are likely candidates for active sites. Early work [7] focused on finding structures maximizing the number of base pairs. With the work of Zuker and Stiegler [17], focus shifted to energy minimization in a model approximating the Gibbs free energy of structures.

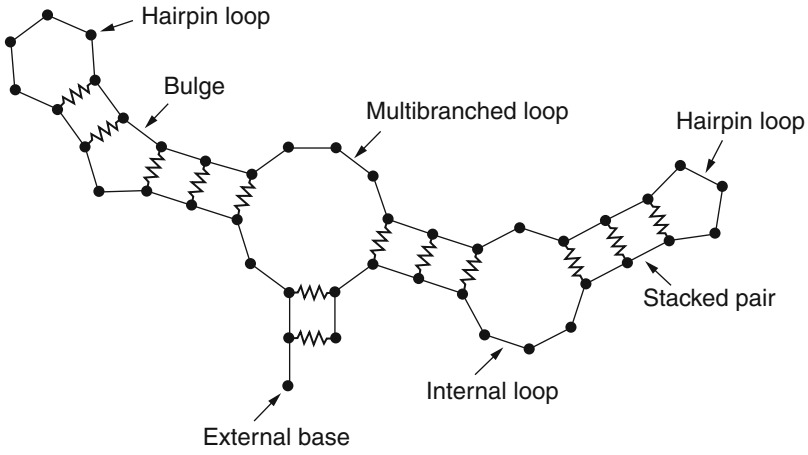
Notation

Let $s \in \{A, C, G, U\}^*$ denote the sequence of bases of an RNA molecule. Use $X \cdot Y$ where $X, Y \in \{A, C, G, U\}$ to denote a base pair between bases of type X and Y and $i \cdot j$ where $1 \leq i < j \leq |s|$ to denote a base pair between bases $s[i]$ and $s[j]$.

Definition 1 (RNA Secondary Structure) A secondary structure for an RNA sequence s is a set of base pairs $\mathcal{S} = \{i \cdot j \,|\, 1 \leq i < j \leq |s| \wedge i < j - 3\}$. For $i \cdot j, i' \cdot j' \in \mathcal{S}$ with $i \cdot j \neq i' \cdot j'$:

- $\{i, j\} \cap \{i', j'\} = \emptyset$ (each base pair with at most one other base)
- $\{s[i], s[j]\} \in \{\{A, U\}, \{C, G\}, \{G, U\}\}$ (only Watson-Crick and G, U wobble base pairs)
- $i < i' < j \Rightarrow j' < j$ (base pairs are either nested or juxtaposed but not overlapping)

The second requirement that only canonical base pairs are allowed is standard but not consequen-



RNA Secondary Structure Prediction by Minimum Free Energy, Fig. 1 A hypothetical RNA structure illustrating the different loop types. Bases are represented by *circles*, the RNA backbone by *straight lines*, and base pairs by *zigzagged lines*

tial in solutions to the problem. The third requirement states that the structure does not contain pseudoknots. This restriction is crucial for the results listed in this entry.

Energy Model

The model of Gibbs free energy applied, usually referred to as the nearest-neighbor model, was originally proposed by Tinoco et al. [10, 11]. It approximates the free energy by postulating that the energy of the full three-dimensional structure only depends on the secondary structure and that this in turn can be broken into a sum of independent contributions from each loop in the secondary structure.

Definition 2 (Loops) For $i \cdot j \in \mathcal{S}$, base k is *accessible* from $i \cdot j$ iff $i < k < j$ and $\neg\exists i' \cdot j' \in \mathcal{S} : i < i' < k < j' < j$. The *loop closed by* $i \cdot j, \ell_{i \cdot j}$, consists of $i \cdot j$ and all the bases accessible from $i \cdot j$. If $i' \cdot j' \in \mathcal{S}$ and i' and j' are accessible from $i \cdot j$, then $i' \cdot j'$ is an interior base pair in the loop closed by $i \cdot j$.

Loops are classified by the number of interior base pairs they contain:

- Hairpin loops have no interior base pairs.
- Stacked pairs, bulges, and internal loops have one interior base pair that is separated from the closing base pair on neither side, on one side, or on both sides, respectively.
- Multibranched loops have two or more interior base pairs.

Bases not accessible from any base pair are called external. This is illustrated in Fig. 1. The free energy of structure $\mathcal{S}$ is

$$\Delta G(\mathcal{S}) = \sum_{i \cdot j \in \mathcal{S}} \Delta G(\ell_{i \cdot j}), \qquad (1)$$

where $\Delta G(\ell_{i \cdot j})$ is the free energy contribution from the loop closed by $i \cdot j$.

Problem 1 (Minimum Free Energy Structure)

INPUT: RNA sequence s and specification of ΔG for all loops

$$\arg\min_{\mathcal{S}} \{\Delta G(\mathcal{S}) | \mathcal{S} \text{ secondary structure for } s\}.$$

OUTPUT: A secondary structure achieving the minimum of free energies, taken over all possible secondary structures

Key Results

Solutions are based on using dynamic programming to solve the general recursion

R

$$V[i,j] = \min_{k\geq 0; i<i_1<j_1<\cdots<i_k<j_k<j} \left\{ \Delta G(\ell_{i\cdot j; i_1\cdot j_1,\ldots,i_k\cdot j_k}) + \sum_{l=1}^{k} V[i_l, j_l] \right\}$$

$$W[i] = \min \left\{ W[i-1], \min_{0<k<i} \{W[k-1] + V[k,i]\} \right\},$$

where $\Delta G(\ell_{i\cdot j; i_1\cdot j_1,\ldots,i_k,j_k})$ is the free energy of the loop closed by $i \cdot j$ and interior base pairs $i_1 \cdot j_1, \ldots, i_k \cdot j_k$ and with initial condition $W[0] = 0$. In the following, it is assumed that all loop energies can be computed in time $O(1)$.

Theorem 1 *If the free energy of multibranched loops is a sum of:*

- *An affine function of the number of interior base pairs and unpaired bases*
- *Contributions for each base pair from stacking with either neighboring unpaired bases in the loop or with a neighboring base pair in the loop, whichever is more favorable*

a minimum free energy structure can be computed in time $O(|s|^4)$ and space $O(|s|^2)$ [17].

With these assumptions, the time required to handle the multibranched loop parts of the recursion reduces to $O(|s|^3)$. Hence, handling the $O(|s|^4)$ possible internal loops becomes the bottleneck.

Theorem 2 *If furthermore the free energy of internal loops is a sum of:*

- *A function of the total size of the loop, i.e., the number of unpaired bases in the loop*
- *A function of the asymmetry of the loop, i.e., the difference in number of unpaired bases on the two sides of the loop*
- *Contributions from the closing and interior base pairs stacking with the neighboring unpaired bases in the loop*

a minimum free energy structure can be computed in time $O(|s|^3)$ and space $O(|s|^2)$ [5].

Under these assumptions, the time required to handle internal loops reduces to $O(|s|^3)$. With further assumptions on the free energy contributions of internal loops, this can be reduced even further, again making the handling of multibranched loops the bottleneck of the computation.

Theorem 3 *If furthermore the size dependency is concave and the asymmetry dependency is constant for all but $O(1)$ values, a multibranched loop free minimum free energy structure can be computed in time $O(|s|^2 \log^2 |s|)$ and space $O(|s|^2)$ [8].*

The above assumptions are all based on the nature of current loop energies [6]. These energies have to a large part been developed without consideration of computational expediency and parameters determined experimentally, although understanding of the precise behavior of larger loops is limited. For multibranched loops, some theoretical considerations [4] would suggest that a logarithmic dependency would be more appropriate.

Theorem 4 *If the restriction on the dependency on number of interior base pairs and unpaired bases in Theorem 1 is weakened to any function that depends only on the number of interior base pairs, the number of unpaired bases, or the total number of bases in the loop, a minimum free energy structure can be computed in time $O(n^4)$ and space $O(n^3)$ [13].*

Theorem 5 *All the above theorems can be modified to compute a data structure that for any $1 \leq i < j \leq |s|$ allows us to compute the minimum free energy of any structure containing $i \cdot j$ in time $O(1)$ [15].*

Applications

Naturally, the key application of these algorithms is for predicting the secondary structure of

RNA molecules. This holds in particular for sequences with no homologues with common structure, e.g., functional analysis based on mutational effects and to some extent analysis of RNA aptamers. With access to structurally conserved homologues, prediction accuracy is significantly improved by incorporating comparative information [2].

Incorporating comparative information seems to be crucial when using secondary structure prediction as the basis of RNA gene finding. As it turns out, the minimum free energy of known RNA genes is not sufficiently different from the minimum free energy of comparable random sequences to reliably separate the two [9,14]. However, minimum free energy calculations are at the core of one successful comparative RNA gene finder [12].

Open Problems

Most current research is focused on refinement of the energy parametrization. The limiting factor of sequence lengths for which secondary structure prediction by the methods described here is still feasible is adequacy of the nearest-neighbor approximation rather than computation time and space. Still, improvements on time and space complexities are useful as biosequence analyses are invariably used in genome scans. In particular, improvements on Theorem 4, possibly for dependencies restricted to be logarithmic or concave, would allow for more advanced scoring of multibranched loops. A more esoteric open problem is to establish the complexity of computing the minimum free energy under the general formulation of (1), with no restrictions on loop energies except that they are computable in time polynomial in $|s|$.

Experimental Results

With the release of the most recent energy parameters [6], secondary structure prediction by finding a minimum free energy structure was found to recover approximately 73 % of the base pairs in a benchmark data set of RNA sequences with known secondary structure. Another independent assessment [1] put the recovery percentage somewhat lower at around 56 %. This discrepancy is discussed and explained in [1].

Data Sets

Families of homologous RNA sequences aligned and annotated with secondary structure are available from the Rfam database at www.sanger.ac.uk/Software/Rfam/. Three-dimensional structures are available from the Nucleic Acid Database at ndbserver.rutgers.edu/. An extensive list of this and other databases is available at www.imb-jena.de/RNA.html.

Problem Definition

This problem is concerned with predicting the set of base pairs formed in the native structure of an RNA molecule, including overlapping base pairs also known as pseudoknots. Standard approaches to RNA secondary structure prediction only allow sets of base pairs that are hierarchically nested. Though few known real structures require the removal of more than a small percentage of their base pairs to meet these criteria, a significant percentage of known real structures contain at least a few base pairs overlapping other base pairs. Pseudoknot substructures are known to be crucial for biological function in several contexts. One of the more complex known pseudoknot structures is illustrated in Fig. 1.

Notation

Let $s \in \{A, C, G, U\}^*$ denote the sequence of bases of an RNA molecule. Use $X \cdot Y$ where $X, Y \in \{A, C, G, U\}$ to denote a base pair between bases of type X and Y and $i \cdot j$ where $1 \leq i < j \leq |s|$ to denote a base pair between bases $s[i]$ and $s[j]$.

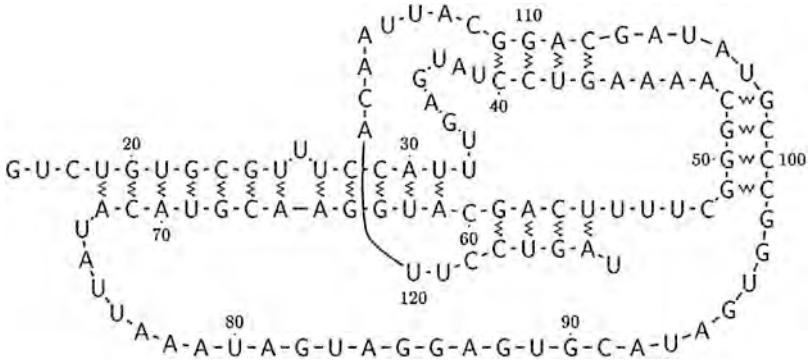
Definition 1 (RNA Secondary Structure) A secondary structure for an RNA sequence s is a set of base pairs $\mathcal{S} = \{i \cdot j | 1 \leq i \leq j \leq |s| \wedge i < j - 3\}$. For $i \cdot j, i' \cdot j' \in \mathcal{S}$ with $i \cdot j \neq i' \cdot j'$:

- $\{i, j\} \cap \{i', j'\} = \emptyset$ (each base pair with at most one other base)
- $\{s[i], s[j]\} \in \{\{A, U\}, \{C, G\}, \{G, U\}\}$ (only Watson-Crick and G, U wobble base pairs)

The second requirement that only canonical base pairs are allowed is standard but not consequential in solutions to the problem.

Scoring Schemes

Structures are usually assessed by extending the model of Gibbs free energy used for ▸ RNA Secondary Structure Prediction by Minimum Free Energy (cf. corresponding entry) with ad hoc



RNA Secondary Structure Prediction Including Pseudoknots, Fig. 1 Secondary structure of the *Escherichia coli* α operon mRNA from position 16 to position 127, cf. [5], Figure 1. The backbone of the RNA molecule is drawn as *straight lines*, while base pairings are shown with *zigzagged lines*

extrapolation of multibranched loop energies to pseudoknot substructures [11] or by summing independent contributions, e.g., obtained from base pair restricted minimum free energy structures from each base pair [13]. To investigate the complexity of pseudoknot prediction, the following three simple scoring schemes will also be considered:

Number of base pairs	$\#BP(\mathcal{S}) = \lvert\mathcal{S}\rvert$
Number of stacking base pairs	$\#SBP(\mathcal{S}) = \lvert\{i \cdot j \in \mathcal{S} \lvert i+1 \cdot j-1 \in \mathcal{S} \vee i-1 \cdot j+1 \in \mathcal{S}\}\rvert$
Number of base pair stackings	$\#BPS(\mathcal{S}) = \lvert\{i \cdot j \in \mathcal{S} \lvert i+1 \cdot j-1 \in \mathcal{S}\}\rvert$

These scoring schemes are inspired by the fact that stacked pairs are essentially the only loops having a stabilizing contribution in the Gibbs free energy model.

Problem 2 (Pseudoknot Prediction)

INPUT: RNA sequence s and an appropriately specified scoring scheme

OUTPUT: A secondary structure $\mathcal{S}$ for s that is optimal under the scoring scheme specified

Key Results

Theorem 1 *The complexities of pseudoknot prediction under the three simplified scoring schemes can be classified as follows, where* Σ *denotes the alphabet.*

Theorem 2 *If structures are restricted to be planar, i.e., the graph with the bases of the sequence as nodes and base pairs and backbone links of consecutive bases as edges is required to be planar, pseudoknot prediction under the #BPS scoring scheme is NP-hard for an alphabet of size 4. Conversely, a 1/2-approximation can be found in time* $O(|s|^3)$ *and space* $O(|s|^2)$ *by observing that an optimal pseudoknot free structure is a 1/2-approximation [6].*

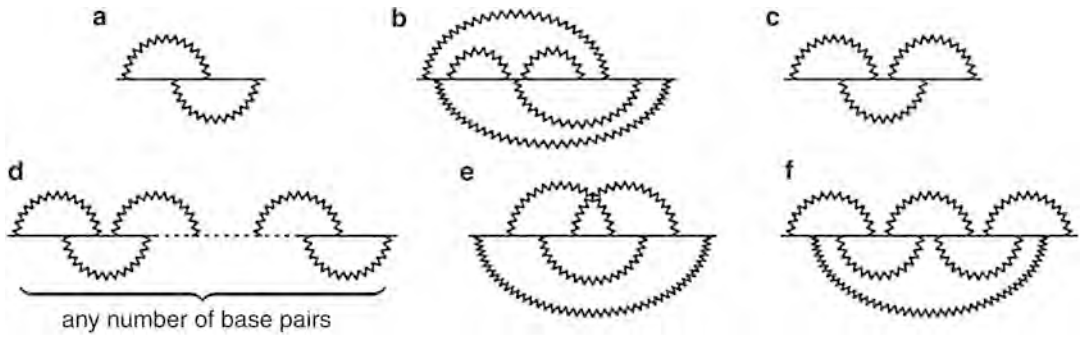
There are no steric reasons that RNA secondary structures should be planar, and the structure in Fig. 1 is actually nonplanar. Nevertheless, known real structures have relatively simple overlapping base pair patterns with very few nonplanar structures known. Hence, planarity has been used as a defining restriction on pseudoknotted structures [2, 15]. Similar reasoning has led to the development of several algorithms for finding an optimal structure from restricted classes of structures. These algorithms tend to use more realistic scoring schemes, e.g., extensions of the Gibbs free energy model, than the three simple scoring schemes considered above.

Theorem 3 *Pseudoknot prediction for a restricted class of structures including Fig. 2a–e, but not Fig. 2f, can be done in time* $O(|s|^6)$ *and space* $O(|s|^4)$ *[11].*

Theorem 4 *Pseudoknot prediction for a restricted class of planar structures including Fig. 2a–c, but not Fig. 2d–f, can be done in time* $O(|s|^5)$ *and space* $O(|s|^4)$ *[14].*

Theorem 5 *Pseudoknot prediction for a restricted class of planar structures including Fig. 2a, b, but not Fig. 2c–f, can be done in time* $O(|s|^5)$ *and space* $O(|s|^4)$ *or* $O(|s|^3)$ *[1, 4] (methods differ in generality of scoring schemes that can be used).*

	Fixed alphabet	Unbounded alphabet
#BP [13]	Time $O(\|s\|^3)$, space $O(\|s\|^2)$	Time $O(\|s\|^3)$, space $O(\|s\|^2)$
#SBP [7]	Time $O(\|s\|^{\|\Sigma\|^2+\|\Sigma\|^3})$, space $O(\|s\|^{\|\Sigma\|^2+\|\Sigma\|^3})$	NP hard
#BPS	NP hard for $\|\Sigma = 2\|$, PTAS [7] 1/3-approximation in time $O(\|s\|)$ [6]	NP hard [7], 1/3-approximation in time and space $O(\|s\|^2)$ [6]



RNA Secondary Structure Prediction Including Pseudoknots, Fig. 2 RNA secondary structures illustrating restrictions of pseudoknot prediction algorithms. Backbone is drawn as a *straight line*, while base pairings are shown with *zigzagged arcs*

Theorem 6 *Pseudoknot prediction for a restricted class of planar structures including Fig. 2a, but not Fig. 2b–f, can be done in time* $O(|s|^4)$ *and space* $O(|s|^2)$ *[1, 8].*

Theorem 7 *Recognition of structures belonging to the restricted classes of Theorems 3, 5, and 6 and enumeration of all irreducible cycles (i.e., loops) in such structures can be done in time* $O(|s|)$ *[3, 9].*

Applications

As for the prediction of RNA secondary structures without pseudoknots, the key application of these algorithms is for predicting the secondary structure of individual RNA molecules. Due to the steep complexities of the algorithms of Theorems 3–6, these are less well suited for genome scans than prediction without pseudoknots.

Enumerating all loops of a structure in linear time also allows scoring a structure in linear time, as long as the scoring scheme allows the score of a loop to be computed in time proportional to its size. This has practical applications in heuristic searches for good structures containing pseudoknots.

Open Problems

Efficient algorithms for prediction based on restricted classes of structures with pseudoknots that still contain a significant fraction of all known structures are an active area of research. Even using the more theoretical simple *#SBP* scoring scheme, developing, e.g., an $O(|s|^{|\Sigma|})$ algorithm for this problem would be of practical significance. From a theoretical point of view, the complexity of planar structures is the least well understood, with results for only the *#BPS* scoring scheme.

Classification of realistic energy models for RNA secondary structures with pseudoknots is much less developed than for RNA secondary structures without pseudoknots. Several recent papers have been addressing this gap [3, 9, 12].

Data Sets

PseudoBase at http://biology.leidenuniv.nl/~batenburg/PKB.html is a repository of representatives of most known RNA structures with pseudoknots.

URL to Code

The method of Theorem 3 is available at http://selab.janelia.org/software.html#pknots and of one of the methods of Theorem 5 at http://www.nupack.org, and an implementation applying a slight heuristic reduction of the class of structures considered by the method of Theorem 6 is available at http://bibiserv.techfak.uni-bielefeld.de/pknotsrg/ [10].

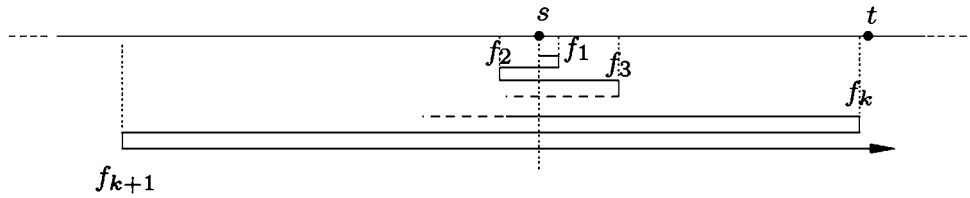
Problem Definition

Since ancient history mankind has been fascinated by the problem of orienting itself in unknown environments. Problems like *escaping*



Robotics, Fig. 1 Any reasonable strategy for searching for a point on a line can be expressed as a sequence $X = f_1, f_2, f_3, \ldots$ of the search depths of the strategy

from a labyrinth or *searching for target objects* have been considered and discussed intensively. Such problems can be easily modeled in a geometric setting.

For example, let us assume that an agent is searching for an unknown door along a wall. We assume that the door is detected, if the agent exactly hits the door. Geometrically one is searching for an unknown point along a line as depicted in Fig. 1. Although the location of the point is not known and is only detected by a visit, it should be found without too much detour. This classical problem in online navigation was discussed by [2] in the early 1990s.

Since the distance and the location of the goal is not known, obviously any reasonable (deterministic) strategy should move in the two directions alternatingly and with increasing depths, f_i, until the goal is detected.

A classical result of [13] shows that it is optimal to use a search strategy that doubles the search distance in every step, i.e., $f_i = 2^i$. It can be shown that the resulting path to an arbitrary target point t is never greater than 9 times the shortest path to the target t, regardless of the position of t. There is no deterministic strategy that attains a smaller factor; see also [2].

Navigation and Exploration

We categorize three fundamental tasks: navigation, exploration, and localization. Navigation (or search) means to find a way to a predescribed location in an unknown environment as shown above. Exploration means to draw a complete map of an unknown environment or to detect or visit *all* possible targets. Localization means to determine the currently unknown position on a known and given map. In many settings, the environment is modeled geometrically as a simple polygon with or without holes. To distinguish the underlying combinatorial problems from the geometric problems, an environment may also be modeled as a graph. For an overview of online searching and exploration problems, see [25] or the more recent survey of Gal [14].

Performance Measure, Competitive Analysis

A general concept for evaluating the efficiency of an online strategy is the so-called *competitive analysis*. Formally, for a class of problems Π and any instance $P \in \Pi$, the cost, $\mathrm{OnlAlg}(P)$, of the online algorithm is compared to the cost, $\mathrm{OfflOpt}(P)$, of the optimal offline algorithm. If there are constants C and A, so that

$$\mathrm{OnlAlg}(P) \leq C \times \mathrm{OfflOpt}(P) + A$$

holds for any $P \in \Pi$, the online algorithm is called C *competitive*. In the case of exploration and navigation, the robot should minimize its travel distance. Therefore, the *competitive ratio* C measures the length of the detour compared to the optimal shortest tour computed under full information. An overview of efficient computations of optimal offline solutions for shortest paths problems can be found in the survey of Mitchell [23]. Many online motion planning problems were classified by the competitive analysis; see the surveys [4, 10, 25].

A randomized online algorithm against an oblivious adversary uses randomization on a fixed predetermined input (which is unknown to the online algorithm). In this case, the competitive ratio is a random variable, and it is maximized over all possible inputs. For

example, an optimal randomized strategy for the introductory *point-on-a-line* problem given by Kao et al. [17] achieves an optimal competitive ratio of 4.5911 . . ..

Different Models

The robot can be equipped with a vision system or with a local touch sensor, only. The impact of a compass is of some interest. One can consider continuous geometric settings such as (a collection of) simple polygons or a concatenation of corridors. On the other hand, the geometric environment might be given by a discrete concatenation of single cells (i.e., a grid graph environment) or is modeled by a general graph. Furthermore, we can consider a single robot or a set of k agents which are working together and exchange information to some extent. Additionally the size of the memory of the agents can be limited. Tasks for a huge set of agents with very limited abilities are related to swarm behavior which is not the topic of this overview.

Key Results

Navigation

Blum et al. [6] studied the problem of a blind robot trying to reach a goal t from a start position s (*point-to-point navigation*) in a two-dimensional scene of n non-overlapping axis-parallel rectangles of width at least one. In the *wall problem*, t is an infinite vertical line. In the *room problem*, the obstacles are within a square room with entry door s and the target t lies on the outer boundary. $O(\sqrt{n})$ competitive online algorithms have been developed. A lower bound on the competitive ratio of $\Omega(\sqrt{n})$ for the wall problem was given by [24], and for the room problem optimal $\Theta(\log n)$ competitive algorithms have been presented by [3]. For randomized strategies and point-to-point navigation, there is an $\Omega(\log \log n)$ lower bound for the model of an oblivious adversary from [18], and [5] presented randomized $O(\log n)$ competitive algorithms for the same problem and also for the wall problem.

The introductory search problem for the line (or 2-rays) was extended to m concurrent rays where an optimal competitive ratio of $1 + 2m^m/(m-1)^{m-1}$ was shown; see [2,13]. An optimal strategy visits the m rays alternatingly with search depth $f_i = (m/(m-1))^i$. For p agents on m rays working in parallel and exchanging information, an optimal ratio of $1+2(m/p-1)(m/(m-p))^{m/p}$ can be achieved; see [21]. In a natural extension in dimension 2, the robot scans the area with a radar connected to the starting point. Gal [13] introduced this two-dimensional search problem and conjectures that a logarithmic spiral (i.e., the natural continuous extension of the doubling heuristic) gives an optimal strategy. The best logarithmic spiral attains a competitive ratio of 17.289 . . .; finally a proof for the optimality of spiral search is given in [20].

Exploration

Deng et al. [7] introduced the online gallery route problem. We consider a simple room modeled by a simple polygon and an agent equipped with a visibility system. The task of computing the shortest roundtrip so that the agent *sees* all points in the polygon is denoted as the shortest watchman route (SWR) problem. In the case of a rectilinear simple polygon and with L_1-metric, there is an optimal (i.e., 1-competitive) online algorithm which gives a $\sqrt{2}$-approximation of the SWR for the L_2-metric in the rectilinear problem.

For general simple polygons, the problem was first solved by Icking et al. [16] with a proven competitive ratio of 26.5, whereas the greatest known lower bound is given by 1.28; see [15].

For the exploration of a geometric environment with k rectilinear obstacles, there is an $\Omega(\sqrt{k})$ lower bound on the competitive ratio for deterministic and randomized strategies; see [1].

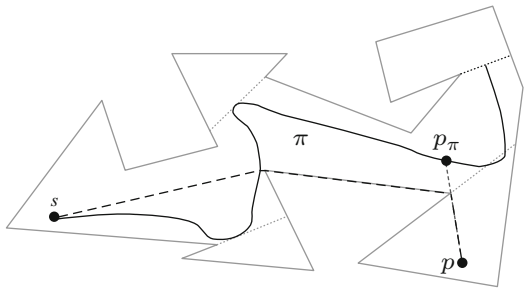
Online graph exploration by a set of k agents means that every vertex of an unknown graph has to be visited. In some configuration, additionally all edges have to be traversed. Assume that full communication among the agents is given. Finding the optimal makespan (finishing time)

algorithm for k agents is an NP-hard problem even for a given tree, and there is an $O(k/\log k)$ competitive algorithm for the online exploration (edges and vertices) version; see [12]. On the other hand, a special tree construction in [9] gives an $\Omega(\log k/\log\log k)$ lower bound on the competitive ratio. For cell environments (grid graph with or without holes), optimal competitive strategies exist.

Dependency Between Searching and Exploration

From the m-concurrent rays result above, one can easily deduce that there is no constant competitive online strategy for searching a point in simple polygons with n edges where n can grow. Nevertheless in a fixed polygon, any search strategy that sees all points defines a ratio for any point and has a worst case ratio; see Fig. 2. So there have to be some optimal *search path* for any fixed polygon. We want to find a general strategy that approximates the best search path for any polygon within a constant factor, i.e., within a constant *search ratio*.

The search ratio definition was first given by Koutsoupias et al. [19]; they studied graphs with unit edge length. The result of Koutsoupias et al. is restricted to the *offline* case where the graph is completely known a priori. Only the goal remains hidden. The above concept goes beyond competitive analysis, although the definitions of the search ratio and the competitive factor are quite similar. In the competitive framework, we compare the online path from the start to the goal to the shortest s–to–t path for any possible goal. For an approximation of the optimal search ratio, we compare the online path to the best possible offline path for any goal, which – in turn – may already have a very bad competitive ratio.



Robotics, Fig. 2 In a fixed polygon, a search path π *sees* all points and attains a ratio for any single point. At p_π the target point p is detected for the first time and defines a ratio

The key idea for solving this problem also indicates the general dependency between *searching* and *exploration*. We make use of efficient (probably constant competitive) exploration strategies for the given environments. If they can be restricted to a bounded distance in a somewhat greater environment, we successively increase the exploration depth by a *doubling* factor.

Fleischer et al. [11] showed that it is possible to approximate an optimal search path for searching a point in a simple polygon by a factor of roughly 4 if the goal has to be visited directly. If a vision system is used, a factor of roughly 8 can be guaranteed. The result even holds when the environment is not given in advance. And the result also holds even though the optimal search path in a given simple polygon is not known.

Applications

In practice a robot can efficiently arrive at a target point (given by coordinates) in an unknown environment with obstacles by Lumelsky's BUG strategy [22]. Many such BUG-variants were developed and successfully applied, for example, in some of the mars rover expeditions. If Lumelsky's BUG algorithm is assumed to navigate between convex obstacles, in the worst case it moves at most once around every significant obstacle, which is optimal in this case. Additionally a robot with a compass can sometimes find the goal exponentially faster than a robot without a compass.

Theoretical paradigms have practical relevance in robotics; see Dudek und Jenkin [8]. The doubling heuristic is widely accepted as an approximation scheme in practice. The general concept for the approximation of the optimal search path has some influence. If somebody is searching for a target in an unknown

environment, it seems to be unavoidably that the environment has to be explored efficiently with increasing depth.

The concept also shows that there is sometimes no significant difference between a known environment with unknown targets and a fully unknown environment. Roughly speaking, if somebody is searching for a goal in unknown position, it is not important whether the corresponding environment is fully known in advance or not known at all.

Open Problems

For many settings, the precise competitive complexity of an online motion planning problems is not known. Tight lower bounds are much harder to achieve. Some examples are given below. The lower bound construction for the navigation among obstacles usually make use of arbitrary *thin* obstacles. Is it possible to get rid of such a restriction?

- Exploration of a simple room with visibility: Upper bound 26.5 vs. lower bound 1.28
- Exploration of graphs by k agents: Upper bound $O(k/\log k)$ vs. lower bound $\Omega(\log k/\log\log k)$
- Optimality of spiral search? Upper bounds given by spiral search.
  - Searching for a line in the plane: Upper bound 13.81113 ... vs. lower bound $\sqrt{2}\cdot 9$
  - Searching for a ray in the plane: Upper bound 22.513 ... vs. lower bound 17.289 ...
- Navigation among k obstacles: Does the lower bound of $\Omega(\sqrt{k})$ hold for a fixed aspect ratio of the obstacles?
- Optimal search path: How to compute the optimal search path for a given polygon or graph?

Robust Bin Packing

Kim-Manuel Klein
University Kiel, Kiel, Germany

Keywords

Approximation; Bin packing; Competitive ratio; Migration factor; Online; Robust

Years and Authors of Summarized Original Work

2009; Epstein, Levin
2013; Jansen, Klein

Problem Definition

Consider the classical online bin packing problem, where items of sizes in $(0, 1]$ arrive over time. At the arrival of each item, it has to be assigned to a bin of capacity 1 such that the total size of all items in the bin does not exceed its capacity. The objective is to minimize the number of used bins.

Online bin packing was introduced by Ullman [10] and has seen enormous research since then (see the survey of Seiden [9] for an overview). The quality of an online algorithm is typically measured by the asymptotic performance guarantee of the algorithm divided by the optimal offline solution and is called the (asymptotic) *competitive ratio*. In the case of online bin packing, the best known algorithm has an asymptotic competitive ratio of 1.58889 (see [9]). On the other hand, it was shown that no algorithm can achieve a ratio better than 1.54037 (see [1]).

To obtain algorithms with improved competitive ratio for online bin packing, one can allow to rearrange already packed items as soon as a new item arrives. The notion of robustness allows to repack a set of already packed items with limited total size whenever a new item arrives. On the one hand, we want to guarantee that we use as few bins as possible, and on the other hand, when a new item arrives, we want to minimize the total size of repacked items.

A modern way to measure the repacking costs is the notion of the *migration factor*, developed by Sanders, Sivadasan, and Skutella [8]. It is defined by the total size of all moved items divided by the size of the arriving item. Following the notation of Sanders et al., an online algorithm with (asymptotic) approximation ratio $1 + \epsilon$ is called *robust* if its migration factor is of the size $f(\frac{1}{\epsilon})$, where f is an arbitrary function that only depends on $\frac{1}{\epsilon}$.

Key Results

In the case of robust bin packing, Epstein and Levin [3] proved that the asymptotic competitive

ratio of the robust bin packing problem can be arbitrarily close to the optimum. They developed an asymptotic PTAS for the problem using a migration factor of $2^{\mathcal{O}(\frac{1}{\epsilon^2}\log\frac{1}{\epsilon})}$. They also proved that there is no online algorithm for this problem which has a constant migration factor and that maintains an optimal solution. The asymptotic PTAS by Epstein and Levin was later improved by Jansen and Klein [7], who developed an asymptotic FPTAS for the problem with a migration factor of $\mathcal{O}(\frac{1}{\epsilon^4})$.

Techniques

Most robust algorithms rely on a sensitivity result for integer linear programs (ILPs) by Cook et al. [2]. It was first used by Sanders et al. [8] to develop a robust PTAS for the scheduling problem on identical machines with the objective value of minimizing the makespan. The theorem of Cook et al. roughly states that for every optimal integral solution y' of the ILP $\min\{cy \mid Ax \leq b'\}$, there exists an optimal integral solution y'' of the ILP $\min\{cy \mid Ax \leq b''\}$ with changed right-hand side b'' such that the distance between y' and y'' can be bounded by $\|y'' - y'\|_\infty \leq n\Delta\,(\|b'' - b'\|_\infty + 2)$, where n is the number of variables and Δ is the absolute value of the largest subdeterminant of A.

The major contribution by Epstein and Levin for the robust bin packing problem was to develop a dynamic rounding technique. Based on a classical rounding by Fernandez de La Vega and Lueker [5], the dynamic rounding techniques present a way on how item sizes can be rounded in a setting where new items arrive over time. This allows to formulate an ILP of fixed dimension. As a new item arrives online, the formulated ILP changes accordingly. The changed ILP has additional columns and the right-hand side of the ILP is increased. Using the theorem of Cooks et al. [2] allows then to find a solution for the changed ILP that is close to the existing solution. This way a new packing is constructed for the bin packing instance containing the newly arrived item.

Since the number of variables n and the largest subdeterminant Δ in the ILP formulation can only be bounded by an exponential term in $\frac{1}{\epsilon}$, the use of Cooks et al. theorem leads to an exponential migration factor. Jansen and Klein developed new LP and ILP techniques which are based on approximate solutions of the corresponding LP. Their central idea is to show that for any approximate solution x' with objective value $\|x'\|_1 \leq (1+\delta)\text{LIN}$, there is an approximate solution x'' with improved objective value $\|x'\|_1 \leq (1+\delta)\text{LIN} - 1$ such that $\|y'' - y'\|_1 = \mathcal{O}(\frac{1}{\delta})$. Based on this observation, they can avoid the use of Cooks et al. theorem to obtain an asymptotic PTAS for the bin packing problem with polynomial migration.

Open Problems

- There is the obvious open question on how much the migration factor of $\mathcal{O}(\frac{1}{\epsilon^4})$ from [7] can be improved and whether there are lower bounds for the migration factor. The existence of a robust algorithm with constant or sublinear migration is still open.
- Is there a robust approximation scheme for the case when items not only arrive but also depart? In the literature this problem is called fully dynamic bin packing and was considered by Ivković and Lloyd [6]. They developed an algorithm which achieves an asymptotic competitive ratio of $\frac{5}{4}$ using amortized $\mathcal{O}(\log n)$ shifting moves, where n is the number of packed items. A shifting move repacks one large item or a bundle of small items of bounded size.
- Epstein and Levin developed a robust asymptotic PTAS for the generalized bin packing problem, where d-dimensional cubes have to be packed into unit-sized cubes [4]. It would be interesting to find other robust approximation schemes for other packing problems like online strip packing or online bin packing with bins of different capacities.

Problem Definition

Algorithms in computational geometry are usually designed under the Real RAM model. In implementing these algorithms, however, fixed-precision arithmetic is used in place of exact arithmetic. This substitution introduces numerical errors in the computations that may lead to nonrobust behavior in the implementation, such as infinite loops or segmentation faults.

There are various approaches in the the literature addressing the problem of nonrobustness in geometric computations; see [9] for a survey. These approaches can be classified along two lines: the **arithmetic approach** and the **geometric approach**.

The arithmetic approach tries to address nonrobustness in geometric algorithms by handling the numerical errors arising because of fixed-precision arithmetic; this can be done, for instance, by using multi-precision arithmetic [6], or by using rational arithmetic whenever possible. In general, all the arithmetic operations, including exact comparison, can be performed on algebraic quantities. The drawback of such a general approach is its inefficiency.

The geometric approaches guarantee that certain geometric properties are maintained by the algorithm. For example, if the Voronoi diagram of a planar point set is being computed then it is desirable to ensure that the output is a planar graph as well. Other geometric approaches are finite resolution geometry [7], approximate predicates and fat geometry [8], consistency and topological approaches [4], and topology oriented approach [13]. The common drawback of these approaches is that they are problem or algorithm specific.

In the past decade, a general approach called the **Exact Geometric Computation** (EGC) [15] has become very successful in handling the issue of nonrobustness in geometric computations; strictly speaking, this approach is subsumed in the arithmetic approaches. To understand the EGC approach, it helps to understand the two parts common to all geometric computations: a *combinatorial structure* characterizing the discrete relations between geometric objects, e.g.,

whether a point is on a hyperplane or not; and a *numerical part* that consists of the numerical representation of the geometric objects, e.g., the coordinates of a point expressed as rational or floating-point numbers. Geometric algorithms characterize the combinatorial structure by numerically computing the discrete relations (that are embodied in geometric predicates) between geometric objects. Nonrobustness arises when numerical errors in the computations yield an incorrect characterization. The EGC approach ensures that all the geometric predicates are evaluated correctly thereby ensuring the correctness of the computed combinatorial structure and hence the robustness of the algorithm.

Notation

An **expression** E refers to a syntactic object constructed from a given set of operators over the reals $\mathbb{R}$. For example, the set of expressions on the set of operators $\{\mathbb{Z}, +, -, \times, \sqrt{}\}$ is the set of division-free radical expressions on the integers; more concretely, expressions can be viewed as directed acyclic graphs (DAG) where the internal nodes are operators with arity at least one, and the leaves are constants, i.e., operators with arity zero. The value of an expression is naturally defined using induction; note that the value may be undefined. Let E represent both the value of the expression and the expression itself.

Key Results

Following are the key results that have led to the feasibility and success of the EGC approach.

Constructive Zero Bounds

The possibility of EGC approach hinges on the computability of the sign of an expression. For determining the sign of algebraic expressions EGC libraries currently use a numerical approach based upon zero bounds. A **zero bound** $b > 0$ for an expression E is such that absolute value $|E|$ of E is greater than b if the value of E is valid and nonzero. To determine the sign of the expression E, compute an approximation $\tilde{E}$ to E such that $|\tilde{E} - E| < \frac{b}{2}$ if E is valid, otherwise $\tilde{E}$ is also invalid. Then sign of E is the same as the sign of $\tilde{E}$ if $|\tilde{E}| \geq \frac{b}{2}$, otherwise it is zero. A **constructive zero bound** is an effectively computable function B from the set of expressions to real numbers $\mathbb{R}$ such that $B(E)$ is a zero bound for any expression E. For examples of constructive zero bounds, see [2, 11].

Approximate Expression Evaluation

Another crucial feature in developing the EGC approach is developing algorithms for approximate expression evaluation, i.e., given an expression E and a relative or absolute precision p, compute an approximation to the value of the expression within precision p. The main computational paradigm for such algorithms is the **precision-driven approach** [15]. Intuitively, this is a downward-upward process on the input expression DAG; propagate precision values down to the leaves in the downward direction; at the leaves of the DAG, assume the ability to approximate the value associated with the leaf to any desired precision; finally, propagate the approximations in the upward direction towards the root. Ouchi [10] has given detailed algorithms for the propagation of "composite precision", a generalization of relative and absolute precision.

Numerical Filters

Implementing approximate expression evaluation requires multi-precision arithmetic. But efficiency can be gained by exploiting machine floating-point arithmetic, which is fast and optimized on current hardware. The basic idea is to to check the output of machine evaluation of predicates, and fallback on multi-precision methods if the check fails. These checks are called numerical filters; they certify certain properties of computed numerical values, such as their sign. There are two main classifications of numerical filters: *static filters* are those that can be mostly computed at compile time, but they yield overly pessimistic error bounds and thus are less effective; *dynamic filters* are implemented during run time and even though they have higher costs they are much more effective than static

filters, i.e., have better estimate on error bounds. See Fortune and van Wyk [5].

Applications

The EGC approach has led to the development of libraries, such as LEDA Real and CORE, that provide EGC number types, i.e., a class of expressions whose signs are guaranteed. CGAL, another major EGC Library that provides robust implementation of algorithms in computational geometry, offers various specialized EGC number types, but for general algebraic numbers it can also use LEDA Real or CORE.

Open Problems

1. An important challenge from the perspective of efficiency for EGC approach is high degree algebraic computation, such as those found in Computer Aided Design. These issues are beginning to be addressed, for instance [1].
2. The *fundamental problem of EGC* is the **zero problem**: given any set of real algebraic operators, decide whether any expression over this set is zero or not. The main focus here is on the decidability of the zero problem for non-algebraic expressions. The importance of this problem has been highlighted by Richardson [12]; recently some progress has been made for special non-algebraic problems [3].
3. When algorithms in EGC approach are embedded in larger application systems (such as mesh generation systems), the output of one algorithm needs to be cascaded as input to another; the output of such algorithms may be in high precision, so it is desirable to reduce the precision in the cascade. The geometric version of this problem is called the **geometric rounding problem**: given a consistent geometric object in high precision, "round" it to a consistent geometric object at a lower precision.
4. Recently a computational model for the EGC approach has been proposed [14]. The corresponding complexity model needs to be developed. Standard complexity analysis based on input size is inadequate for evaluating the complexity of real computation; the complexity should be expressed in terms of the output precision.

Problem Definition

In the classic online scheduling model, jobs arrive one after another. At the arrival of a new job, the scheduler must immediately and irrevocably assign it to a machine. In the *parallel machine* case, we have m identical machines to process the jobs. Each job j has a processing time p_j that is revealed at the moment of its appearance. The load of a machine is the sum of processing times of jobs assigned to it. The objective is to minimize the makespan, that is, the maximum machine load.

The fact that decisions are irrevocable imposes a hard constraint on the scheduler. However, many applications allow some amount of flexibility. *Robust scheduling* algorithms take this flexibility into account: whenever a job arrives, some reassignment of jobs can be performed. More precisely, given a parameter $\beta > 0$, the arrival of job j allows to migrate a set of jobs with a total processing time of at most $\beta \cdot p_j$. The factor β is called the *migration factor* of the algorithm and it is a measure of its robustness. In this context, the quality of solutions is assessed by competitive analysis: an algorithm is α-competitive if for any sequence of job arrivals the makespan of the algorithm is at most α times the (offline) optimum cost for the set of available jobs. An important goal in this area is to understand the trade-off between the migration and competitive factors.

Key Results

Greedy Approaches

In a setting where no migration is allowed, i.e., if $\beta = 0$, a competitive ratio of $2 - \frac{1}{m}$ is achievable by a greedy *list-scheduling* algorithm [7]. Although more sophisticated algorithms have smaller competitive ratios (see, e.g., [6]), no algorithm can achieve a performance guarantee smaller than $e/(e-1) \approx 1.58$ [1, 11], even if randomization is allowed.

Sanders et al. [10] give algorithms with improved competitive ratios for small values of β. A simplified version of their most basic algorithm is as follows. Let j be an arriving job and denote by OPT the minimum makespan of the instance including j. The algorithm works as follows.

1. If $p_j \leq \mathrm{OPT}/2$, assign job j to the machine with the smallest load.
2. Otherwise, consider a machine i in which all jobs are of size at most $\mathrm{OPT}/2$. Greedily remove jobs from i until their total processing

time is at least p_j. Add job j to i and greedily reassign each removed job to the least loaded machine.

The existence of the claimed machine in Step (2) follows since there can be at most m jobs of size larger than OPT/2 in the instance. The proof that the algorithm is 3/2-competitive is a simple exercise that follows since each greedily assigned job has size at most OPT/2. By construction the algorithm has migration factor 2. The fact that the algorithm needs the value OPT as input can be avoided by trying out a handful of different solutions.

With this simple approach the competitive guarantee is already below the lower bound of 1.58 for $\beta = 0$. Sanders et al. [10] shows that a refinement of this algorithm gives the same competitive guarantee and reduces β to 4/3. They also provide more sophisticated algorithms with smaller competitive factors, for example, a 4/3-competitive algorithm with migration factor 5/2.

Robust Approximation Schemes

The algorithms above show that already small migration factors can help to significantly improve the quality of solutions. However, they tell little about the trade-off between the competitive and migration ratios. Sanders et al. [10] study this trade-off by giving a *robust polynomial time approximation scheme* (robust PTAS), that is, a family of algorithms $\{A_\varepsilon\}_{\varepsilon>0}$ such that for any constant $\varepsilon > 0$ the algorithm A_ε is $(1+\varepsilon)$-competitive and uses a migration factor of $\beta(\varepsilon)$. We remark that β is a constant that depends only on ε and not on the specific input data.

The robust PTAS borrows ideas from the known PTAS for the offline problem [8]. At the arrival of a job j, the algorithm takes the given $(1+\varepsilon)$-approximate solution and updates it to a schedule with the same approximation guarantee. The algorithm behaves differently depending on the size of j. If p_j is in $O(\varepsilon\text{OPT})$, where OPT denotes the optimal makespan for the current instance including j, then we can safely assign this job to the least loaded machine and maintain the approximation guarantee. Otherwise, the processing times are rounded to simplify the instance and add symmetry to the solution. The corresponding offline minimum makespan problem for this instance can be posed as an integer program (IP) of the form $\min\{c^t x : A \cdot x = b, x \in \mathbb{N}^d\}$. A component x_C of x corresponds to the number of machines with a given *configuration* C, where each configuration is a compact description of a one machine schedule. Crucially, the number of different configurations, that is, the number of variables d in the IP, is a constant $2^{\text{poly}(1/\varepsilon)}$. Moreover, the complete instance is encoded in the right-hand side b. After a new job arrives, the corresponding IP can be updated by increasing one coordinate of b by one, obtaining a new vector b'. A sensitivity analysis result by Cook et al. [2] implies that for any optimal solution x of the IP, there exists an optimal solution x' with the right-hand side changed to b' such that $||x - x'||_1 \leq d^2 \cdot \Delta(A) \cdot (||b - b'||_\infty + 2)$. Here $\Delta(A)$ is the maximum $|\det(B)|$ over all square submatrices B of A, which in this case can be bounded by $2^{\text{poly}(1/\varepsilon)}$. Therefore, the number of machines that need to be modified in order to go from schedule x to x' is $||x - x'||_1 \leq 2^{\text{poly}(1/\varepsilon)}$. Since we are assuming that the new job has processing time in $\Omega(\varepsilon\text{OPT})$, and each machine has a load of $O(\text{OPT})$, we obtain an algorithm with migration factor $2^{\text{poly}(1/\varepsilon)}$.

Theorem 1 (Sanders et al. [10]) *The problem of minimum makespan on identical machines admits a robust PTAS with migration factor* $\beta = 2^{poly(1/\varepsilon)}$.

Applications

The basic technique for constructing a robust PTAS has been adapted to different related problem. Most results are based on the sensitivity analysis result mentioned above, but differ in other parts of the algorithm and analysis. In particular robust PTASs have been developed for bin packing [3] and cube packing [4]. Other objective functions for identical machine scheduling have also been considered, for example, minimizing the ℓ_p-norm of the vector of loads or maximizing

the minimum machine load. These problems do not admit robust PTASs; however, it is possible to design such algorithms for an amortized analogue of the migration factor [12]. Epstein and Levin [5] consider preemptive scheduling problems on parallel machines, obtaining a 1-competitive algorithm with migration factor $1 - 1/m$ for the minimum makespan and minimum ℓ_p-norm objectives. As opposed to the previous results, this algorithm does not rely on sensitivity analysis results for IPs.

The bin packing problem was considered by Jansen and Klein [9]. They improve the result in [3] to a robust PTAS with $\beta = \text{poly}(1/\varepsilon)$. To obtain this migration factor, they develop new sensitivity analysis results aimed specifically at approximation algorithms.

Open Problems

An interesting question is to determine the precise trade-off between the competitive and migration factors for the minimum makespan problem on identical machines. In particular, determine if the migration can be made to depend polynomially on $1/\varepsilon$ for a $(1 + \varepsilon)$-competitive algorithm. Another natural question is to extend these results to *related* machines. In this setting, each machine i runs at a speed s_i, and thus the time it takes to process job j on machine i is p_j/s_i.

Other natural objective functions on parallel machine scheduling are not fully understood. The machine covering version, where we seek to maximize the minimum machine load, does not admit a robust PTAS. More specifically, a competitive ratio smaller than $20/19$ is not possible with constant migration factor [12]. It is open if this competitive ratio is indeed achievable or if the lower bound can be improved. A similar situation holds for minimizing the ℓ_p-norm for any $p > 1$ [4].

Robustness in Self-Assembly

The abstract tile assembly model (aTAM), originally proposed by Winfree [1], provides a useful framework to study algorithmic tile self-assembly. As described in other sections, many theoretical studies have shown the efficiency and computational power of aTAM.

The aTAM, although widely accepted and experimentally verified, is an overly simplified combinatorial model in describing the self-assembly of DNA tiles. In reality, several effects are observed which lead to a loss of robustness compared to the aTAM. The assembly tends to be reversible, i.e., tiles can fall off from an existing assembly, even when the total binding strength exceeds the temperature threshold τ. Also, tiles sometimes attach with a weak strength but then quickly get incorporated and locked into a growing assembly, much like defects in a crystal. However, for sophisticated combinatorial assemblies like counters, which form the basis for controlling the size of a structure, a single error can lead to assemblies drastically larger or smaller (or different in other ways) than the intended structure. An error rate of 0.5–10 % is observed in previous experimental studies.

KTAM

A more sophisticated and accurate stochastic model called the kinetic tile assembly model (kTAM) was introduced by Winfree [1]. The kTAM calculates rates for various types of attachments and removals based on thermodynamic constants. It has the following assumptions:

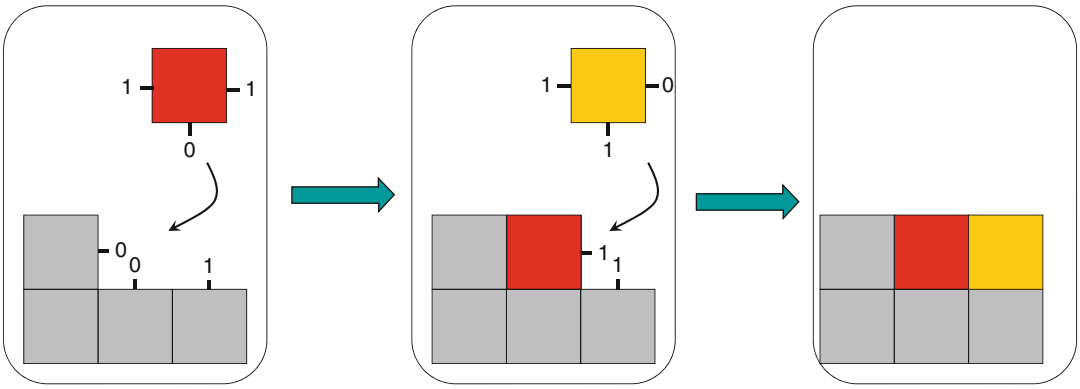
1. Tile concentrations are held constant throughout the self-assembly process.
2. Supertiles do not interact with each other. The only two reactions allowed are addition of a tile to a supertile and the dissociation of a tile from a supertile.
3. The forward rate constants for all tiles only depend on concentrations.
4. The reverse rate depends exponentially on the number of base-pair bonds which must be broken, and the mismatched sticky ends make no base-pair bonds.

There are two free parameters in this model, both of which are dimensionless free energies: $G_{mc} > 0$ measures the entropic cost of putting a tile at a binding site and depends on the tile concentration, and $G_{se} > 0$ measures the free energy cost of breaking a single strength-1 bond. Under this model, we can approximate the forward and reverse rates for each of the tile-supertile reactions in the process of self-assembly of DNA tiles as follows:

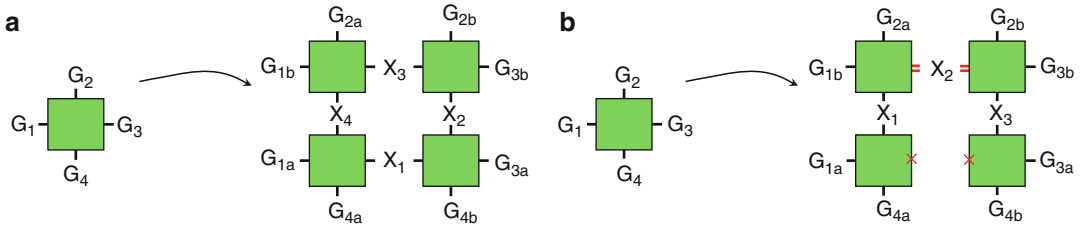
The rate of addition of a tile to a supertile, f, is $pe^{-G_{mc}}$. The rate of dissociation of a tile from a supertile, r_b, is $pe^{-bG_{se}}$, where b is the strength with which the tile is attached to the supertiles. The parameter p simply gives us the time scale for the self-assembly. Winfree showed that by setting appropriate tile concentrations and binding strengths such that $G_{mc} = 2G_{sc} - \epsilon$, the behavior predicted by kTAM approaches the behavior described by aTAM as $\epsilon \to 0$. However, the growth speed also goes to 0 (attachment and dissociation form an unbiased random walk) as $\epsilon \to 0$.

Problem Definition

Self-assembly processes in nature are often equipped with explicit mechanisms for both error prevention and error correction. For artificial self-assembly, these problems are even more important since we are interested in assembling large systems with great precision. Previously, a phenomenon called *insufficient attachments* has been identified to be a main source of error [3]. An insufficient attachment is the process in which a tile t first attach with total strength less than the temperature. However, before t falls off, adjacent tiles attach and secure t in place. An insufficient



Robustness in Self-Assembly, Fig. 1 An example of growth error caused by an insufficient attachment. The *red tile* first attaches with a weaker strength. Then the *yellow tile* attaches and secures the *red tile* in place



Robustness in Self-Assembly, Fig. 2 (**a**) An example of a 2×2 proofreading block. (**b**) An example of a 2×2 snaked proofreading block

attachment happening at a location at which another correct tile can attach via cooperative bindings is called a *growth error*. One example of growth error caused by insufficient attachment is illustrated in Fig. 1. An insufficient attachment happening at a location at which no tiles can attach according to aTAM is called a *facet error*. The rate at which any specific insufficient attachment happens is $e^{-2G_{mc}}/(e^{-G_{mc}} + e^{-G_{se}})$, which is roughly $e^{-G_{se}}$ times the rate of tile attachments when $G_{mc} \approx 2G_{sc}$. The main goal of this section is to introduce error-correction systems that deal with insufficient attachments.

Key Results

Proofreading Tilesets

The first error-correction scheme for the tile assembly model was the proofreading scheme proposed by Winfree and Bekbolatov [2]. The proofreading scheme turns any tile system with unidirectional growth into a new system that produces the same pattern (with scaling). The scheme replaces each tile type t by k^2 distinct tile types. These k^2 tile types are designed to form a $k \times k$ block. All internal glues have strength 1 and are unique to this block. The glues on the boundary of the block are duplicates of glues on the original tile t. A 2×2 block is illustrated in Fig. 2a. This construction enforces that whenever a growth error happens, at least k growth errors must happen locally in order for the assembly process to proceed. Thus when growth error happens, the erroneous tiles are more likely to detach than to stay and wait for another $k - 1$ growth errors to happen. Since the probability that a growth error happens at any given location is roughly $e^{-G_{se}}$, the probability that a growth error happens at any proofreading block and proceeds to produce the final incorrect assembly is $O(e^{-kG_{se}})$.

Snaked Proofreading Tilesets

The abovementioned proofreading system only handles growth errors but not facet errors, which

are a major source of error both in theoretical analysis and computer simulations [3]. Chen and Goel [3] proposed the snaked proofreading scheme which handles all errors caused by insufficient attachments. Similar to the proofreading scheme, the snaked proofreading scheme replaces each tile type by a block of $2k \times 2k$ tile types. The only difference is that some internal glues have strength 0 or 2 instead of 1. A 2×2 block is illustrated in Fig. 2b. Under correct growth, the snaked proofreading block checks its two input sides alternatively. Therefore, k insufficient attachments must happen before an erroneous block "thinks" it attaches correctly and propagate toward any single direction. As a result, the snaked proofreading scheme with block size $2k \times 2k$ ensures that without k insufficient attachments happening locally, all erroneous structures have $O(k^2)$ tiles and are expected to fall off in time polynomial in k. Assuming that the thermodynamic parameters G_{mc} and G_{se} can be set arbitrarily, the following theorem characterizes the performance of the snaked proofreading system.

Theorem 1 *With a $2k \times 2k$ snaked tile system, $k = O(\log n)$, an $n \times n$ square of blocks can be assembled in expected time $\tilde{O}(n)$ and with high probability, while remaining stable for $\tilde{\Omega}(n)$ time after being assembled.*

One main drawback for the proofreading and the snaked proofreading scheme is the resolution loss. Since each tile in the original system is replaced by a $k \times k$ block, the size of the original pattern is increased by a factor of k. Chen, Goel, and Luhrs [4] showed that if the third dimension can be used, two-dimensional tile systems can be proofread with no resolution loss. Their system replaces each tile by a column in the third dimension and thus maintains the original scale on the two-dimensional plane.

Problem Definition

One of the most often used techniques in modern computer networks is routing. *Routing* means selecting paths in a network along which to send data. Demands usually randomly appear on the nodes of a network, and routing algorithms should be able to send data to their destination. The transfer is done through intermediate nodes, using the connecting links, based on the topology of the network. The user waits for the network to guarantee that it has the required capacity during data transfer, meaning that the network behaves like its nodes would be connected directly by a physical line. Such service is usually called the *permanent virtual circuit (PVC)* service. To model real life situations, assume that demands arrive *on line*, given by source and destination points, and capacity (bandwidth) requirements.

Similar routing problems may occur in other environments, for example in parallel computation. In this case there are several processors connected together by wires. During an operation some data appear at given processors which should be sent to specific destinations. Thus, this also defines a routing problem. However, this paper mainly considers the network model, not the parallel computer one.

For any given situation there are several routing possibilities. A natural question is to ask which is the best possible algorithm. To find the best algorithm one must define an objective function, which expresses the effectiveness of the algorithm. For example, the aim may be to reduce the load of the network. Load can be measured in different ways, but to measure the utilization percent of the nodes or the links of the network is the most natural. In the online setting, it is interesting to compare the behavior of a routing algorithm designed for a specific instance to the best possible routing.

There are two fundamental approaches towards routing algorithms. The first approach is to route *adaptively*, i.e., depending on the actual loads of the nodes or the links. The second approach is to route *obviously*, without using any information about the current state of the network. Here the authors survey only results on oblivious routing algorithms.

Notations and Definitions

A mathematical model of the network routing problem is now presented.

Let $G(V, E, c)$ be a capacitated network, where V is the set of nodes and E is the set of edges with a capacity function $c : E \to R^+$. Let $|V| = n, |E| = m$. It can be assumed that G is directed, because if G is undirected then for each undirected edge $e = (u, v)$ two new nodes x, y and four new directed edges $e_1 = (u, x), e_2 = (v, x), e_3 = (y, u), e_4 = (y, u)$ with infinite capacity may be added to the graph. If e is considered as an undirected edge with the same capacity then a directed network equivalent to the original one is received.

Definition 1 A set of functions $f := \{f_{ij} | i, j \in V, f_{ij} : E(G) \to R^+\}$ is called a **multi–commodity flow** if

$$\sum_{e \in E_k^+} f_{ij}(e) = \sum_{e \in E_k^-} f_{ij}(e)$$

holds for all $k \neq i, k \neq j$, where $k \in V$ and E_k^+, E_k^- are the set of edges coming out from k and coming into k resp. Each function f_{ij} defines a **single–commodity flow** from i to j.

Definition 2 The **value** of a multi–commodity *flow* is an $n \times n$ matrix $T_f = (t_{ij}^f)$, where

$$t_{ij}^f = \sum_{e \in E_i^+} f_{ij}(e) - \sum_{e \in E_i^-} f_{ij}(e) \,,$$

$$\text{if } i \neq j \text{ and } v_{ii}^f = 0 \,, \text{ forall } i, j \in V \,.$$

Definition 3 Let D be a nonnegative $n \times n$ matrix where the diagonal entries are 0. D is called as **demand matrix**. The **flow** on an edge $e \in E$ routing the demand matrix D by routing r is defined by

$$\text{flow}(e, r, D) = \sum_{i,j \in V} d_{ij} r_{ij}(e) \,,$$

while the **edge congestion** is

$$\text{con}(e, r, D) = \frac{\text{flow}(e, r, D)}{c(e)} \,.$$

The **congestion** of demand D using routing r is

$$\text{con}(r, D) = \max_{e \in E} \text{con}(e, r, D) \,.$$

Definition 4 A multi–commodity flow r is called **routing** if $t_{ij}^r = 1$, and if $i \neq j$ for all $i, j \in V$.

Routing represents a way of sending information over a network. The real load of the edges can be represented by scaling the edge congestions with the demands.

Definition 5 The **oblivious performance ratio** P_r of routing r is

$$P_r = \sup_D \left\{ \frac{\text{con}(r, D)}{\text{opt}(D)} \right\}$$

where *opt*(*D*) is the optimal congestion which can be achieved on *D*. The **optimal oblivious routing ratio** for a network *G* is denoted by *opt*(*G*), where

$$\text{opt}(G) = \min_r P_r$$

Problem
Input: A capacitated network $G(V, E, c)$.
Output: An oblivious routing *r*, where P_r is minimal.

Key Results

Theorem 1 *There is a polynomial time algorithm that for any input network G (directed or undirected) finds the optimal oblivious routing ratio and the corresponding routing r.*

Theorem 2 *There is a directed graph G of n vertices such that opt(G) is at least* $\Omega(\sqrt{n})$.

Applications

Most importantly, with these results one can efficiently calculate the best routing strategy for a network topology with capacity constraints. This is a good tool for network planning. The effectiveness of a given topology can be tested without any knowledge of the the network traffic using this analysis.

Many researchers have investigated the variants of routing problems. For surveys on the most important models and results, see [10] and [11]. Oblivious routing algorithms were first analyzed by Valiant and Brebner [15]. Here, they considered the parallel computer model and investigated specific architectures, like hypercube, square grids, etc. Borodin and Hopcroft investigated general networks [6]. They showed that such simple deterministic strategies like oblivious routing can not be very efficient for online routing and proved a lower bound on the competitive ration of oblivious algorithms. This lower bound was later improved by Kaklamanis et al. [9], and they also gave an optimal oblivious deterministic algorithm for the hypercube.

In 2002, Räcke constructed a polylog competitive randomized algorithm for general undirected networks. More precisely, he proved that for any demand there is a routing such that the maximum edge congestion is at most polylog(n) times the optimal congestion for this demand [12]. The work of Azar et al. extends this result by giving a polynomial method for calculating the optimal oblivious routing for a network. They also prove that for directed networks no logarithmic oblivious performance ratio exists. Recently, Hajiaghayi et al. present an oblivious routing algorithm which is $O\left(\log^2 n\right)$-competitive with high probability in directed networks [8].

A special online model has been investigated in [5], where the authors define the so called "repeated game" setting, where the algorithm is allowed to chose a new routing in each day. This means that it is oblivious to the demands, that will occur the next day. They present an $1 + \varepsilon$-competitive algorithm for this model.

There are better algorithms for the adaptive case, for example in [2]. For the offline case Raghavan and Thomson gave an efficient algorithm in [13].

Open Problems

The authors investigated edge congestion in this paper, but in practice, node congestion may be interesting as well. Node congestion means the ratio of the total traffic traversing a node to its capacity. Some results can be found for this problem in [7] and in [3]. It is an open problem whether this method used for edge congestion analysis can be applied for such a model. Another interesting open question may be whether there is a more efficient algorithm to compute the optimal oblivious performance ratio of a network [1, 14].

Experimental Results

The authors applied their method on ISP network topologies and found that the calculated optimal oblivious ratios are surprisingly low, between 1.4 and 2. Other research dealing with this question found similar results [1, 14].

Problem Definition

Wireless networks are often modelled using geometric graphs. Using only local geometric information to compute a sequence of distributed forwarding decisions that send a message to its destination, routing algorithms can succeed on several common classes of geometric graphs. These graphs' geometric properties provide navigational cues that allow routing to succeed using only limited local information at each node.

Network Model

A common geometric graph model for wireless networks is to represent each node by a point in the Euclidean plane, $\mathcal{R}^2$, and to add an edge (u, v) for each pair of nodes that can communicate by direct wireless transmission. The absence of the edge (u, v) signifies that u cannot transmit directly to v, requiring a multi-hop transmission via a sequence of intermediate nodes that forms a route from u to v. The cost $c(e)$ of sending a message over an edge $e = (u, v)$ has been modeled in different ways; the most common measures include the *hop (link) metric* ($c(e) = 1$), the *Euclidean metric* ($c(e) = |e|$, where $|e| = \text{dist}(u, v)$ is the Euclidean length of the edge e), and the *energy metric* ($c(e) = |e|^\alpha$ for $\alpha \geq 2$).

In some models, transmission is assumed to be uniform in all directions and of equal range, say r, for all nodes. Under this assumption, the undirected edge (u, v) exists if and only if $\text{dist}(u, v) \leq r$. Thus, for each node v there is an edge from v to every node u that lies within a disk of radius r centered at v. This is the *unit disk graph* model for wireless networks. Common classes of geometric graphs that are used to model wireless networks include:

Unit Disk Graph. Vertices are points in $\mathcal{R}^2$ and each edge (u, v) exists if and only if $\text{dist}(u, v) \leq r$, for a given fixed $r > 0$.

Plane Graph. Vertices are points in $\mathcal{R}^2$ and no two edges cross.

Triangulation. Vertices are points in $\mathcal{R}^2$ and every interior face is a triangle.

Quasi-unit Disk Graph. Vertices are points in $\mathcal{R}^2$ and each edge (u, v) exists if $\text{dist}(u, v) \leq r_1$, may exist if $r_1 < \text{dist}(u, v) \leq r_2$, but does not exist if $\text{dist}(u, v) > r_2$, for given fixed $r_2 > r_1 > 0$.

Unit Ball Graph. Vertices are points in $\mathcal{R}^3$ and each edge (u, v) exists if and only if $\text{dist}(u, v) \leq r$, for a given fixed $r > 0$.

Gabriel Graph. Vertices are points in $\mathcal{R}^2$ and each edge (u, v) exists if and only if the disk with diameter (u, v) does not contain any other vertices.

Other classes of geometric graphs used to model wireless networks include relative neighborhood graphs, Delaunay triangulations, Yao graphs, convex subdivisions, monotone subdivisions, edge-augmented plane graphs, and physically based models such as SINR.

A geometric graph G is *civilized* with λ-*precision* if for every pair of nodes u and v in G, $\text{dist}(u, v) \geq \lambda$ for a given fixed $\lambda > 0$, where λ is independent of n, the number of nodes in G.

Communication Protocol

In several wireless network protocols, e.g., ad hoc or wireless sensor networks, there is no fixed infrastructure for routing nor any central servers. All nodes act as hosts as well as routers. Apart from a node's immediate neighborhood, the topology of the network is unknown, i.e., each node is aware of its own location (its (x, y) coordinates) as well as the coordinates of its neighbors. Nodes must discover and maintain routes in a distributed manner without knowledge of precomputed routing tables, any particular vertex labeling (other than spatial coordinates), nor the support of a central server. Additionally, some models incorporate constraints for limited memory and power. Depending on the particular model, a limited amount of information can be stored in message headers to assist with routing. When a node receives a message, it reads the header (possibly modifying the header information) before selecting one of its neighbors to which to forward the message. A *stateless* algorithm does not modify the header. Network nodes have no memory themselves; any dynamic state information is stored in the message header.

Furthermore, no precomputed information about the network is known to the nodes.

Geometric Routing

Given the coordinates of a target node t in a (wireless) geometric network G, a source node s in G is tasked with sending a message via a multi-hop route through G from s to t. Routing proceeds by computing a sequence of distributed forwarding decisions, where each node along the route selects one of its neighbors to which to forward the message. Geometric routing is uniform in that all nodes execute the same protocol. Each node makes a forwarding decision as a function of its coordinates, the coordinates of its neighbors, the coordinates of t, and any available state bits stored in the message header. The number of state bits available is critical to guaranteeing delivery in some classes of geometric graphs by enabling the route to avoid looping and reach t. A node may modify the state bits before forwarding the message. In some models, this state information corresponds to storing data about $O(1)$ nodes, e.g., storing the coordinates of $O(1)$ nodes.

The primary objective is to guarantee message delivery to the target node t. Secondary objectives include minimizing the total cost of communication (the sum of $c(e)$ for all edges e on the route) and minimizing the worst-case or average *dilation* (the ratio of the cost of the route followed relative to that of the route of lowest cost). These secondary objectives are motivated by the need for nodes to conserve power in many wireless networking settings.

Key Results

Local geometric routing assumes only limited control information stored in message headers and local information available at each node along the route. This locality provides network independence that results in natural scalability to larger networks and continued functionality after arbitrary changes to the network. A routing algorithm is said to *succeed* on a particular class of geometric graphs if it guarantees delivery from any source node s to any target node t on any graph in the class; otherwise, the algorithm *fails* on that class of graphs.

Below we summarize key local geometric routing algorithms and their properties.

Greedy Routing. Upon receiving a message, a node forwards it to its neighbor closest to the target node t. Greedy routing is stateless. This strategy succeeds on Delaunay triangulations, but fails on more general classes of geometric graphs such as non-Delaunay triangulations, convex subdivisions, plane graphs, and unit disk graphs.

Compass Routing [7]. Upon receiving a message, a node u forwards it to its neighbor v that minimizes the angle $\angle vut$ with the target node t. Compass routing is stateless. This strategy succeeds on regular triangulations but fails on more general classes of geometric graphs such as non-regular triangulations, convex subdivisions, plane graphs, and unit disk graphs.

Greedy-Compass Routing [2]. Upon receiving a message, a node u considers its two neighbors on either side of the line segment $\overline{ut}$ (node u's *compass neighbors*) and forwards the message to the one closest to t. Greedy-compass routing is stateless. This strategy succeeds on all triangulations but fails on more general classes of geometric graphs such as convex subdivisions, plane graphs, and unit disk graphs.

Bose et al. [2] show that no stateless algorithm can succeed on convex subdivisions (including plane graphs and unit disk graphs). Therefore, to succeed on classes of geometric graphs beyond triangulations, local routing algorithms require storing one or more state bits in the message header or predecessor information, i.e., the coordinates of the node that last forwarded the message.

One State Bit [4]. Upon receiving a message, a node u chooses between forwarding the message to its clockwise or counter-clockwise compass neighbor, depending on the value of a state bit. If the compass neighbor lies opposite the vertical line through t, the state bit is flipped. This

algorithm uses a single state bit. This strategy succeeds on all triangulations and convex subdivisions, but fails on more general classes of geometric graphs such as plane graphs and unit disk graphs.

Predecessor Awareness and Monotonicity [4]. Each node locally identifies its topmost left neighbor as its parent and its right neighbors as its children. With knowledge of the predecessor, the node forwards the message to its $(i+1)$st child after receiving it from its ith child and eventually back to its parent after receiving it from its last child. The resulting route contains a depth-first traversal of a spanning tree of the network. This algorithm is stateless, but each node requires knowledge of its predecessor, i.e., the coordinates of the node that last forwarded the message. This strategy succeeds on triangulations, convex subdivisions, monotone subdivisions, and edge-augmented graphs from these classes but fails on more general classes of geometric graphs such as non-monotone plane graphs and unit disk graphs.

Face Routing [1, 7]. The message is forwarded along the perimeters of faces in the sequence of faces that intersect the line segment from the source node s to the target node t. This strategy applies the *right-hand principle*, in which each face in the sequence is traversed in a counterclockwise direction, as if one were walking while sliding the right hand along the wall. To avoid cycling indefinitely, the algorithm must store the coordinates of $O(1)$ nodes that act as progress markers. Furthermore, each node requires knowledge of its predecessor. This strategy succeeds on plane graphs, including triangulations, convex subdivisions, and Gabriel graphs. The intersection of a unit disk graph with the Gabriel graph of a set of points is planar and remains connected if the original unit disk graph is connected. Furthermore, this subgraph can be computed locally; this property allows face routing to succeed on unit disk graphs [1], as well as quasi-unit disk graphs with bounded ratio $r_2/r_1 < \sqrt{2}$ and unit ball graphs contained within slabs of thickness less than $1/\sqrt{2}$ [6]. Although unit disk graphs are nonplanar in general, the nonplanarity is localized; face routing fails on more general classes of nonplanar geometric graphs such as quasi-unit disk graphs and unit ball graphs [6] and edge-augmented plane graphs. Face routing can have dilation $\Theta(n)$, where n is the number of network nodes.

Adaptive Face Routing (AFR) [8]. Adaptive face routing is a variant of face routing that achieves optimality on civilized unit disk graphs and civilized planar graphs with the Gabriel property. Like face routing, $O(1)$ state data are stored in the message header and each node requires knowledge of its predecessor. The algorithm attempts to estimate the length c of the shortest path from s and t by $\hat{c}$ (starting with $\hat{c} = 2|\overline{st}|$ and doubling it in every consecutive round). In each round, the face traversal is restricted to the region formed by the ellipse with the major axis $\hat{c}$ centered on $\overline{st}$. Each edge is traversed at most four times, and the dilation achieved is $\Theta(c)$.

Geometric Ad-hoc Routing (GOAFR$^+$) [9]. Combining methods from greedy routing, face routing, and adaptive face routing allows this hybrid algorithm to meet the bounds of adaptive routing on any unit disk graphs and planar graphs with the Gabriel property (not necessarily civilized). The algorithm first applies greedy routing and switches to face routing when the routed message enters a local minimum (a dead end), before again resuming greedy routing as early as possible by applying an *early fallback* technique.

General (Non-geometric) Networks

Is geometry necessary for local routing to succeed? Even with knowledge of the predecessor, stateless routing algorithms require knowledge of the induced subgraph of nodes up to distance $n/3$ away in the worst case [3]. That is, stateless routing using only *local* information is impossible. With $\Theta(\log n)$ state bits, local routing on arbitrary (not necessarily geometric) graphs is possible by deterministically recomputing a polynomial-length universal traversal sequence at each node along the route, where $\Theta(\log n)$ bits store an index into the sequence [5].

Open Problems

If a node's coordinates can be stored using $O(\log n)$ bits (e.g., if network nodes are positioned on a $n^c \times n^c$ grid), then face routing can be applied using $O(\log n)$ state bits. It remains open whether any local geometric routing algorithm can succeed on plane graphs using $o(\log n)$ state bits. Similarly, it would be interesting to characterize broad classes of geometric graphs on which local geometric routing is possible using $O(1)$ state bits. In addition to guaranteeing delivery, bounding dilation is of interest. For example, can $O(1)$ dilation be guaranteed on convex subdivisions using $O(1)$ state bits? Finally, the problem of traversing a graph (visiting all nodes) by a sequence of local forwarding decisions is interesting. Stateless algorithms are impossible for any non-Hamiltonian network. How many state bits are necessary for a local algorithm to traverse a triangulation?

Routing in Road Networks with Transit Nodes

Dominik Schultes
Institute for Computer Science, University of Karlsruhe, Karlsruhe, Germany

Keywords

Shortest paths

Years and Authors of Summarized Original Work

2007; Bast, Funke, Sanders, Schultes

Problem Definition

For a given directed graph $G = (V, E)$ with non-negative edge weights, the problem is to compute a shortest path in G from a source node s to a target node t for given s and t. Under the assumption that G does not change and that a lot

of source-target queries have to be answered, it pays to invest some time for a preprocessing step that allows for very fast queries. As output, either a full description of the shortest path or only its length $d(s, t)$ is expected – depending on the application.

Dijkstra's classical algorithm for this problem [4] iteratively visits all nodes in the order of their distance from the source until the target is reached. When dealing with very large graphs, this general algorithm gets too slow for many applications so that more specific techniques are needed that exploit special properties of the particular graph. One practically very relevant case is routing in road networks where junctions are represented by nodes and road segments by edges whose weight is determined by some weighting of, for example, expected travel time, distance, and fuel consumption. Road networks are typically sparse (i.e., $|E| = O(|V|)$), almost planar (i.e., there are only a few overpasses), and hierarchical (i.e., more or less 'important' roads can be distinguished). An overview on various speedup techniques for this specific problem is given in [7].

Key Results

Transit-node routing [2, 3] is based on a simple observation intuitively used by humans: When you start from a source node s and drive to somewhere 'far away', you will leave your current location via one of only a few 'important' traffic junctions, called (forward) *access nodes* $\overrightarrow{A}(s)$. An analogous argument applies to the target t, i.e., the target is reached from one of only a few backward access nodes $\overleftarrow{A}(t)$. Moreover, the union of all forward and backward access nodes of all nodes, called *transit-node set* $\mathcal{T}$, is rather small. The two observations imply that for each node the distances to/from its forward/backward access nodes and for each transit-node pair (u, v), the distance between u and v can be stored. For given source and target nodes s and t, the length of the shortest path that passes at least one transit node is given by

$$d_{\mathcal{T}}(s,t) = \min\{d(s,u) + d(u,v) + d(v,t) \mid u \in \overrightarrow{A}(s), v \in \overleftarrow{A}(t)\}.$$

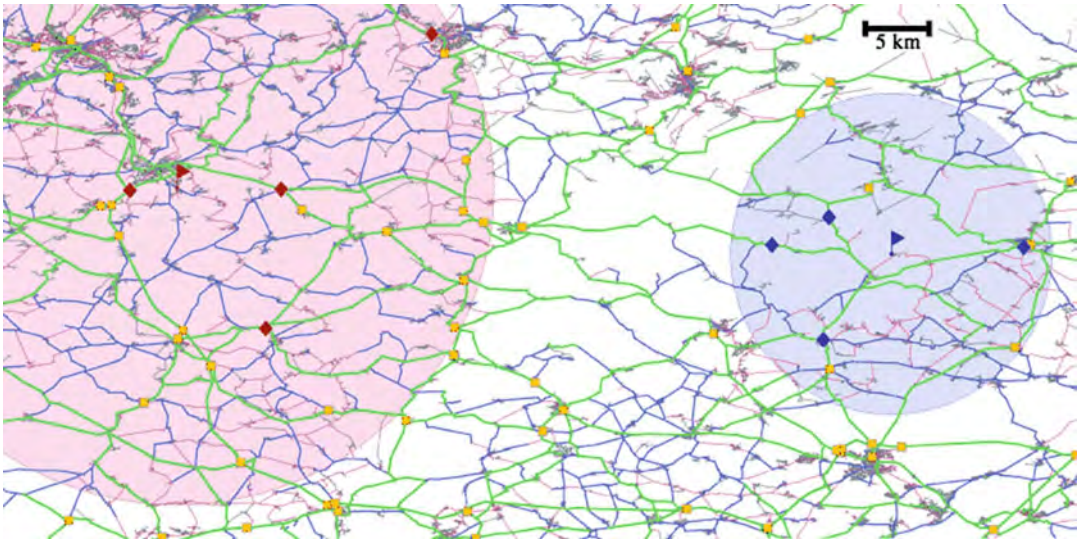
Note that all involved distances $d(s, u)$, $d(u, v)$, and $d(v, t)$ can be directly looked up in the precomputed data structures. As a final ingredient, a *locality filter* $L{:}V \times V \to \{\mathsf{true}, \mathsf{false}\}$ is needed that decides whether given nodes s and t are too close to travel via a transit node. L has to fulfill the property that $\neg L(s,t)$ implies that $d(s,t) = d_{\mathcal{T}}(s,t)$. Note that in general the converse need not hold since this might hinder an efficient realization of the locality filter. Thus, *false positives*, i.e., "$L(s,t) \wedge d(s,t) = d_{\mathcal{T}}(s,t)$", may occur.

The following algorithm can be used to compute $d(s, t)$:

> If $\neg L(s,t)$, then compute and return $d_{\mathcal{T}}(s,t)$; else, use any other routing algorithm.

Figure 1 gives an example. Knowing the length of the shortest path, a complete description of it can be efficiently derived using iterative table lookups and precomputed representations of paths between transit nodes. Provided that the above observations hold and that the percentage of false positives is low, the above algorithm is very efficient since a large fraction of all queries can be handled in line 1, $d_{\mathcal{T}}(s,t)$ can be computed using only a few table lookups, and source and target of the remaining queries in line 2 are quite close. Indeed, the remaining queries can be further accelerated by introducing a secondary layer of transit-node routing, based on a set of *secondary transit nodes* $\mathcal{T}_2 \supset \mathcal{T}$. Here, it is not necessary to compute and store a complete $\mathcal{T}_2 \times \mathcal{T}_2$ distance table, but it is sufficient to store only distances $\{d(u,v) \mid u, v \in \mathcal{T}_2 \wedge d(u,v) \neq d_{\mathcal{T}}(s,t)\}$, i.e., distances that cannot be obtained using the primary layer. Analogously, further layers can be added.

There are two different implementations: one is based on a simple geometric grid and one on *highway hierarchies*, the fastest previous approach [5, 6]. A highway hierarchy consists of a sequence of levels (Fig. 1), where level $i + 1$ is



Routing in Road Networks with Transit Nodes, Fig. 1 Finding the optimal travel time between two points (*flags*) somewhere between Saarbrücken and Karlsruhe amounts to retrieving the 2 × 4 *access nodes* (*diamonds*), performing 16 table lookups between all pairs of access nodes, and checking that the two disks defining the *locality filter* do not overlap. *Transit nodes* that do not belong to the access node sets of the selected source and target nodes are drawn as small squares. The figure draws the levels of the highway hierarchy using colors *gray*, *red*, *blue*, and *green* for levels 0–1, 2, 3, and 4, respectively

constructed from level i by bypassing low-degree nodes and removing edges that never appear far away from the source or target of a shortest path. Interestingly, these levels are geometrically decreasing in size and otherwise similar to each other. The highest level contains the most 'important' nodes and becomes the primary transit-node set. The nodes of lower levels are used to form the transit-node sets of subordinated layers.

Applications

Apart from the most obvious applications in car navigation systems and server-based route planning systems, transit-node routing can be applied to several other fields, for instance to massive traffic simulations and to various optimization problems in logistics.

Open Problems

It is an open question whether one can find better transit-node sets or a better locality filter so that the performance can be further improved. It is also not clear if transit-node routing can be successfully applied to other graph types than road networks. In this context, it would be desirable to derive some theoretical guarantees that apply to any graph that fulfills certain properties. For some practical applications, a *dynamic* version of transit-node routing would be required in order to deal with time-dependent networks or unexpected edge weight changes caused, for example, by traffic jams. The latter scenario can be handled by a related approach [8], which is, however, considerably slower than transit-node routing.

Experimental Results

Experiments were performed on road networks of Western Europe and the USA using a cost function that solely takes expected travel time into account. The results exhibit various trade-offs between average query time (5–63 μs for the USA), preprocessing time (59 min to 1,200 min), and storage overhead (21 bytes/node to 244 bytes/node). For the variant that uses three

Routing in Road Networks with Transit Nodes, Fig. 2 Query time distribution as a function of Dijkstra rank–the number of iterations Dijkstra's algorithm would need to solve this instance. The distributions are represented as box-and-whisker plots: each box spreads from the lower to the upper quartile and contains the median, the whiskers extended to the minimum and maximum value omitting, which are plotted individually

layers and is tuned for best query times, Tables 1 and 2 show statistics on the preprocessing and the query performance, respectively. The average query times of about 5 µs are six orders of magnitude faster than Dijkstra's algorithm. In addition, Fig. 2 gives for each rank r on the x-axis a distribution for 1,000 queries with random starting point s and the target node t for which Dijkstra's algorithm would need r iterations to find it. The three layers of transit-node routing with small transition zones in between can be recognized: for large ranks, it is sufficient to access only the

primary layer yielding query times of about 5 µs, for smaller ranks, additional layers have to be accessed resulting in median query times of up to 20 µs.

Data Sets

The European road network has been provided by the company PTV AG, the US network has been obtained from the TIGER/Line Files [9]. Both graphs have also been used in the 9th DIMACS Implementation Challenge on Shortest Paths [1].

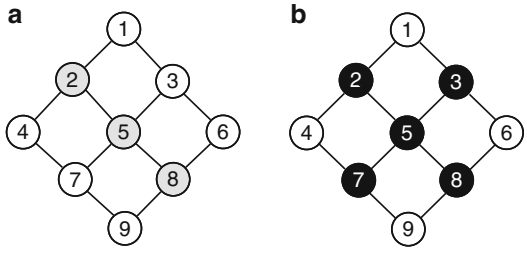
Problem Definition

Connected dominating set *CDS* is typically adapted in wireless multihop networks such as

wireless sensor, ad hoc networks. In order to achieve routing efficiency, a virtual backbone which is inspired by the backbone in wired networks is often used to improve routing because it can reduce the path search space and the routing table size [3]. According to [8, 10], there are many methods to construct a virtual backbone, and the competitive approach is connected dominating set(*CDS*). The detailed definition of *CDS* is as follows.

Given a connected graph $G(V, E)$ represents as a wireless sensor network, where V is the set of sensor nodes and E is the set of edges connecting sensor nodes in V. If there is a subset D($D \subseteq V$), each sensor node in V either belonging to D or adjacent to a sensor node in D, then we call D is a dominating set (*DS*). If the subgraph induced by *DS* is a connected graph, then we call *DS* is a connected dominating set(*CDS*).

Intuitively, if the size of *CDS* is smaller, the virtual backbone can play a greater role in routing. Many studies such as [1, 13, 14] and [9, 12] also aimed to construct a virtual backbone based on a *CDS* with minimum size which is called minimum connected dominating set (*MCDS*). A minimum CDS (MCDS) is a CDS that has the minimum number of nodes. For example, the gray nodes in Fig. 1a form an MCDS of the sample graph, while the black nodes in Fig. 1b make a CDS. However, these studies didn't ignore that if the size of the *CDS* is too small, some sensor nodes couldn't find a shortest routing path to their destination. Du et al. [10] analyzes how a virtual backbone based on *MCDS* makes some routing paths much longer than the shortest paths. Thus, there exists a disadvantage in *MCDS* which is the unavailability of shortest routing paths. If we only aim to construct a virtual backbone based on *MCDS*, we couldn't achieve a guaranteed routing constraint in data delivery. Routing constraint in *CDS* becomes much more important when constructing a virtual backbone.



Routing-Cost Constrained Connected Dominating Set, Fig. 1 (**a**) An example MCDS. (**b**) An example CDS

In this section, the problem of the routing constraint in connected dominating set (R-CDS) is given in formal by considering the wireless multihop network environment. The problem of R-CDS is defined as follows:

Given a graph $G = (V, E)$ where V represents a node set and E denotes an edge set, we would like to find a CDS D in polynomial time so that, for every pair of nodes u and v, there exists a path between u and v with intermediate nodes in D and path length at most $\alpha \cdot d(u, v)$, where α is a constant and $d(u, v)$ is the length of the shortest path between u and v. In addition, the size of the resulting CDS $|D|$ is bounded by $\beta \cdot opt_{MCDS}$, where β is a constant and opt_{MCDS} is the size of the MCDS.

The problem specified in wireless multihop networks has been considered under both general graph and unit disk graph(UDG) model and will be further discussed in the following section. With the UDG model, all nodes in the network have the same transmission range, and there does not exist any obstacle. As a result, as long as a receiving node is within the transmission range of a sending node, the receiving node will be able to receive the data successfully. With general graph model, the nodes in the network could have different transmission ranges, and obstacles might interfere with normal data communication. As a result, being in the transmission range of a sending node does not guarantee successful transmission.

Key Results

Many literatures also focus on the study of routing constraint in *CDS* which can be classified into two categories: the general graph and UDG.

In the general graph category, Ding et al. [2] studied a special connected dominating set (*CDS*) problem named minimum routing cost CDS

(*MOC-CDS*). They proved that constructing a minimum *MOC-CDS* in general graph is *NP*-hard and proposed a distributed heuristic algorithm (called as FlagContest) for constructing *MOC-CDS* with performance ratio $(1 - ln2) + 2ln\delta$. Du et al. [8] presented a constant-approximation scheme which produces a connected dominating set D, whose size |D| is within a factor α from that of the minimum connected dominating set, and each node pair exists in a routing path with all intermediate nodes in D and with length at most $5d(u, v)$, where $d(u, v)$ is the length of shortest path of this node pair. Ding et al. [3] developed an exact algorithm for minimum *CDS* with shortest path constraint called *SPCDS* and proved that finding such a minimum *SPCDS* can be achieved in polynomial time. Ding et al. [4] showed that under general graph model, α-*MOC-CDS* is NP-hard for any $\alpha \geq 1$. Ding et al. [5, 6] studied virtual backbone with guaranteed routing costs, named α minimum routing cost directional virtual backbone(α-*MOC-DVB*). They proved that the construction of a minimum α-*MOC-DVB* is an NP-hard problem in a general directed graph. Du et al. [10] proved that there is no polynomial-time constant approximation for α-*MOC-CDS* unless $P = NP$ when $\alpha \geq 2$.

In the UDG category, Wu et al. [15] studied the relationship between minimum connected dominating sets and maximal independent sets in unit disk graphs. Kim et al. [11] proposed a distributed algorithm under UDG model, *CDS-BD-D*, which constructs a *CDS* whose size and maximum path length are bounded. Du et al. [8] proposed two algorithms which are centralized algorithm and distributed algorithm to achieve constant-approximation performance ratio on MCDS and routing cost. Du et al. [7] studied a problem of minimizing the size of connected dominating set $|\ D\ |$ under constraint that for any two nodes u and v, $m_D(u, v) \leq \alpha m(u,\ v)$ where α is a constant, $m_D(u,\ v)$ is the number of intermediate nodes on a shortest path connecting u and v through D, and $m(u,\ v)$ is the number of intermediate nodes in a shortest path between u and v in a given unit disk graph.

In this chapter, we introduce that, under general graph model, there is no polynomial-time constant-approximation solution in terms of CDS size unless $P = NP$ shown in [10]. Under UDG model, we will present a polynomial-time constant-approximation algorithm GOC-MCDS-C which produces a CDS D with size $|D| \leq 176 \cdot opt_{MCDS} + 64$ and with a property that for any pair of nodes u and v, $d_D(u, v) \leq 7 \cdot d(u, v)$ in [10]. The distributed version of the algorithm, GOC-MCDS-D, is thoroughly analyzed.

Algorithm 1: Centralized algorithm GOC-MCDS-C

1: **Initially** Set $D \leftarrow \emptyset$.
2: **Step 1.** Construct a maximal independent set I.
3: **Step 2.** For every pair of nodes u, v in I with $d(u, v) \leq 3$, compute a shortest path $p(u, v)$ and put all intermediate nodes of $p(u, v)$ into C.
4: **Output** $D = C \cup I$.

Algorithm 2: Construct an MIS I (Stage 1)

1: **Initially** Every node is colored in white and is assigned with a positive integer ID; different nodes have different IDs.
2: **Step 1** Every white node sends its ID to its neighbors and then compares its ID with received IDs from neighbors. If its ID is smaller than every received ID from neighbors, then it turns the color from white to black.
3: **Step 2** Every black node sends message "black" to its neighbors. If a white node receives a message "black," then it turns its color from white to gray.
4: **Step 3** Go back to Step 1 until no white node exists.
5: **Output** All black nodes form a maximal independent set I

GOC-MCDS-C: The Centralized Algorithm

Under general graph model, the existing proof is that there is no polynomial-time constant approximation for the problem under investigation unless NP=P shown in [10]. However, under UDG model, polynomial-time constant-approximation algorithms do exist. Kim et al. [11] proposed a distributed algorithm, CDS-BD-D, that constructs a CDS whose size and maximum path length are bounded. In this section, we advance Kim et al.'s results by presenting the details of an innovative polynomial-time constant-approximation algorithm, GOC-MCDS-C. The proposed algorithm produces a

Algorithm 3: Connect the MIS I (Stage 2)

1: **Step 1** Every black node sends its ID to its neigh -bors.
2: **Step 2** Every node adds its own ID id_2 to each received ID id_1 and then sends those pairs of IDs (id_1, id_2) to all its neighbors.
3: **Step 3** Each node does the following: Suppose its ID is id^*:

1. For each pair of IDs id_1 and id_{1*} received in Step 1, if $id_1 < id_{1*}$, then send a message (id_{1*}, id^*, id_1) to the neighbor with ID id_1.
2. For each pair of messages (id_1, id_2) and (id_{1*}, id_{2*}) received at Step 2, if $id_1 < id_{1*}$, then send a message $(id_{1*}, id_{2*}, id^*, id_2, id_1)$ to the neighbor with ID id_2.
3. For each message (id_1, id_2) received at Step 2 and ID id_{1*} received at Step 1, if $id_1 < id_{1*}$, then send a message $(id_{1*}, id^*, id_2, id_1)$ to the neighbor with ID id_2; otherwise, send a message $(id_1, id_2, id^*, id_{1*})$ to the neighbor with ID id_{1*}.

4: **Step 4** When a node with ID id_2 received a message $(id_{1*}, id_{2*}, id^*, id_2, id_1)$ or $(id_{1*}, id^*, id_2, id_1)$, it sends this message to its neighbor with ID id_1.
5: **Step 5** Each black node with ID id_1 collects all messages in form (id_3, id_2, id_1) or (id_4, id_3, id_2, id_1) or $(id_5, id_4, id_3, id_2, id_1)$ received in Step 3 and Step 4. Suppose those messages form a set M. Then it performs the following computation:
while $M \neq \emptyset$ **do begin**
choose $(id_h, \ldots, id_2, id_1) \in M$;
send message $(id_h, \ldots, id_2, id_1)$ to node with ID id_2;
delete all messages starting with id_h from M;
end-while
6: **Step 6** When a node with ID id_i received a message $(\ldots, id_{i-1}, id_i, \ldots)$, it turns black. In addition, if id_i is not the leftmost id in the message, then it passes this message to node with ID id_{i-1}; if id_i is the leftmost id in the message, do nothing.
7: **Step 7** If no message is passed in Step 6, then stop. Otherwise, go back to Step 6.

CDS D with size $|D| \leq 176 \cdot opt_{MCDS} + 64$ and with a property that for any pair of nodes u and v, $d_D(u, v) \leq 7d(u, v)$[10]. Note that GOC-MCDS-C is a centralized algorithm. GOC-MCDS-C follows the steps of regular MCDS construction algorithms. Namely, there are two steps in total. During the first step, an MIS is constructed. In the second step, the nodes in the MIS are connected in order to form a CDS.

GOC-MCDS-D: The Distributed Algorithm

In this section, the distributed algorithm GOC-MCDS-D is described in details. The performance of GOC-MCDS-D is the same as that of GOC-MCDS-C shown in [10]. Similar to the centralized algorithm GOC-MCDS-C, GOC-MCDS-D consists of two stages. In the first stage, an MIS is constructed using Algorithm 2. In the second stage, the MIS is connected using Algorithm 3.

Open Problems

The coverage problems in wireless sensor networks which related to the routing-cost constrained in CDS are still an open problem.

R-Trees

Ke Yi
Hong Kong University of Science and Technology, Hong Kong, China

Keywords

External memory data structures; R-trees; Spatial databases

Years and Authors of Summarized Original Work

2004; Arge, de Berg, Haverkort, Yi

Problem Definition

Problem statement and the I/O model. Let S be a set of N axis-parallel hypercubes in $\mathbb{R}^d$. A very basic operation in a spatial database is to answer *window queries* on the set S. A window query Q is also an axis-parallel hypercube in $\mathbb{R}^d$ that asks us to return all hypercubes in S that intersect Q. Since the set S is typically huge in a large spatial database, the goal is to design a *disk-based* or *external memory* data structure (often called an *index* in the database literature) such that these window queries can be answered efficiently. In addition, given S, the data structure should be constructed efficiently and should be able to support insertions and deletions of objects.

When external memory data structures are concerned, the standard *external memory model* [2], a.k.a. the *I/O model*, is often used as the model of computation. In this model, the machine consists of an infinite-size external memory (disk) and a main memory of size M. A block of B consecutive elements can be transferred between main memory and disk in one *I/O operation* (or simply *I/O*). An external memory data structure is a structure that is stored on disk in blocks, but computation can only occur on elements in main memory, so any operation (e.g., query, update, and construction) on the data structure must be performed using a number I/Os, which is the measure for the complexity of the operation.

R-trees. The *R-tree*, first proposed by Guttman [9], is a multi-way tree $\mathcal{T}$, very similar to a *B-tree*, that is used to store the set S such that a window query can be answered efficiently. Each node of $\mathcal{T}$ fits in one disk block. The hypercubes of S are stored only in the leaves of $\mathcal{T}$. All leaves of $\mathcal{T}$ are on the same level, and each stores $\Theta(B)$ hypercubes from S; while

each internal node, except the root, has a fan-out of $\Theta(B)$. The root of $\mathcal{T}$ may have a fan-out as small as 2. For any node $u \in \mathcal{T}$, let $R(u)$ be the smallest axis-parallel hypercube, called the *minimal bounding box*, that encloses all the hypercubes stored below u. At each internal node $v \in \mathcal{T}$, whose children are denoted $v_1, \ldots, v_k$, the bounding box $R(v_i)$ is stored along with the pointer to v_i for $i = 1, \ldots, k$. Note that these bounding boxes may overlap. Please see Fig. 1 for an example of an R-tree in two dimensions.

For a window query Q, the query answering process starts from the root of $\mathcal{T}$ and visits all nodes u for which $R(u)$ intersects Q. When reaching a leaf v, it checks each hypercube stored at v to decide if it should be reported. The correctness of the algorithm is obvious, and the efficiency (the number of I/Os) is determined by the number of nodes visited.

Any R-tree occupies a linear number $O(N/B)$ disk blocks, but different R-trees might have different query, update, and construction costs. When analyzing the query complexity of window queries, the output size T is also used, in addition to N, M, and B.

Key Results

Although the structure of an R-tree is restricted, there is much freedom in grouping the hypercubes into leaves and grouping subtrees into bigger subtrees. Different grouping strategies result in different variants of R-trees. Most of the existing R-trees use various heuristics to group together hypercubes that are "close" spatially, so that a window query will not visit too many unnecessary nodes. Generally speaking, there are two ways to build an R-tree: repeated insertion and bulk loading. The former type of algorithms include the original R-tree [9], the R^+-tree [15], the R*-tree [6], etc. These algorithms use $O(\log_B N)$ I/Os to insert an object and hence $O(N \log_B N)$ I/Os to build the R-tree on S, which is not scalable for large N. When the set S is known in advance, it is much more efficient to bulk load the entire R-tree at once. Many bulk-loading algorithms have been proposed, e.g., [7, 8, 11, 13]. Most of these algorithms build the R-tree with $O\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ I/Os (the number of I/Os needed to sort N elements), and they typically result in better R-trees than those obtained by repeated insertion. During the past decades, there have been a large number of works devoted to R-trees from the database community, and the list here is by no means complete. The reader is referred to the book by Manolopoulos et al. [14] for an excellent survey on this subject in the database literature. However, no R-tree variant mentioned above has a guarantee on the query complexity; in fact, Arge et al. [3] constructed an example showing that some of the most popular R-trees may have to visit all the nodes without reporting a single result.

From the theoretical perspective, the following are the two main results concerning the worst-case query complexity of R-trees.

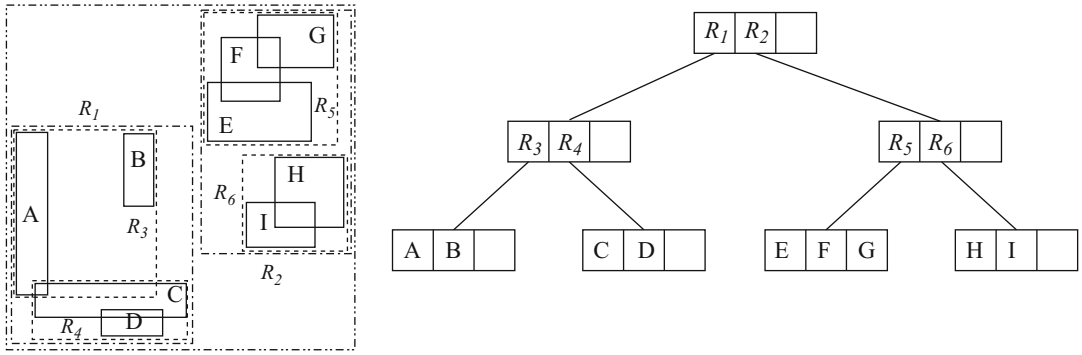
Theorem 1 ([1, 12]) *There is a set of N points in $\mathbb{R}^d$, such that for any R-tree $\mathcal{T}$ built on these points, there exists an empty window query for which the query algorithm has to visit $\Omega((N/B)^{1-1/d})$ nodes of $\mathcal{T}$.*

The *priority R-tree*, proposed by Arge et al. [3], matches the above lower bound.

Theorem 2 ([3]) *For any set S of N axis-parallel hypercubes in $\mathbb{R}^d$, the priority R-tree answers a window query with $O((N/B)^{1-1/d} + T/B)$ I/Os. It can be constructed with $O\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ I/Os.*

It is also reported that the priority R-tree performs well in practice, too [3]. However, it is not known how to update it efficiently while preserving the worst-case bound. The logarithmic method was used to support insertions and deletions [3], but the resulted structure is no longer an R-tree.

Note that the lower bound in Theorem 1 only holds for R-trees. If the data structure is not restricted to R-trees, better query bounds can be obtained for the window-query problem; see e.g., [4].



R-Trees, Fig. 1 An R-tree example in two dimensions

Applications

R-trees have been used widely in practice due to its simplicity and ability to store spatial objects of various shapes and to answer various queries. The areas of applications span from geographical information systems (GIS), computer-aided design, computer vision, and robotics. When the objects are not axis-parallel hypercubes, they are often approximated by their minimal bounding boxes, and the R-tree is then built on these bounding boxes. To answer a window query, first the R-tree is used to locate all the intersecting bounding boxes, followed by a filtering step that checks the objects exactly. The R-tree can also be used to support other kinds of queries, for example, aggregation queries, nearest neighbors, etc. In aggregation queries, each object o in S is associated with a weight $w(o) \in \mathbb{R}$, and the goal is to compute $\sum w(o)$ where the sum is taken over all objects that intersect the query range Q. The query algorithm is same as before, except that in addition it keeps running sum while traversing the R-tree and may skip an entire subtree rooted at some u if $R(u)$ is completely contained in Q. To find the nearest neighbor of a query point q, a priority queue is maintained, which stores all the nodes u that might contain an object that is closer to the current nearest neighbor found so far. The priority of u in the queue is the distance between q and $R(u)$. The search terminates when the current nearest neighbor is closer than the top element in the priority queue. However, no worst-case guarantees are known for R-trees answering these other types of queries, although they tend to perform well in practice.

Open Problems

Several interesting problems remain open with respect to R-trees. Some of them are listed here:

- Is it possible to design an R-tree with the optimal query bound $O((N/B)^{1-1/d} + T/B)$ that can also be efficiently updated? Or prove a lower bound on the update cost for such an R-tree.
- Is there an R-tree that supports aggregation queries for axis-parallel hypercubes in $O((N/B)^{1-1/d})$ I/Os? This would be optimal because the lower bound of Theorem 1 also holds for aggregation queries on R-trees. Note that, however, no sublinear worst-case bound exists for nearest-neighbor queries, since it is not difficult to design a worst-case example for which the distance between the query point q and any bounding box is smaller than the distance between q and its true nearest neighbor.
- When the window query Q shrinks to a point, that is, the query asks for all hypercubes in

S that contain the query point, the problem is often referred to as *stabbing queries* or *point enclosure queries*. The lower bound of Theorem 1 does not hold for this special case, while a lower bound of $\Omega(\log_2 N + T/B)$ was proven in [5], which holds in the strong *indexability* model. It is intriguing to find out the true complexity for stabbing queries using R-trees, which is between $\Omega(\log_2 N + T/B)$ and $O((N/B)^{1-1/d} + T/B)$.

Experimental Results

Nearly all studies on R-trees include experimental evaluations, mostly in two dimensions. Reportedly the Hilbert R-tree [10, 11] has been shown to have good query performance while being easy to construct. The R*-tree's insertion algorithm [6] has often been used for updating the R-tree. Please refer to the book by Manolopoulos et al. [14] for more discussions on the practical performance of R-trees.

Data Sets

Besides some synthetic data sets, the TIGER/Line data (http://www.census.gov/geo/www/tiger/) from the US Census Bureau has been frequently used as real-world data to test R-trees. The R-tree portal (http://www.rtreeportal.org/) also contains many interesting data sets.

URL to Code

Code for many R-tree variants is available at the R-tree portal (http://www.rtreeportal.org/). The code for the priority R-tree is available at (http://www.cs.duke.edu/~yike/prtree/).

Problem Definition

The aim is to design effective algorithms for controlling rumor propagation in social networks. Here, a rumor is viewed as an undesirable thing. Social networks are represented by undirected or directed graphs, depending on different contexts. In these graphs, nodes denote individuals and edges denote the influence between individuals.

A list of strategies has been proposed to limit the spread of a rumor in a network. We group some of the existing research works into two categories. The first one includes the works that launch the opposite cascade, protector, to spread in a network, such that the number of nodes that adopt the rumor at the end of both cascades diffusion is limited. The second contains the works that are concerned with the network structure, that is, they control the rumor propagation by blocking some edges or nodes or both of them together in a network.

In this work, we mainly introduce two specific works belonging to the two different categories. For each of them, we briefly introduce some related works.

Problem 1 [2]
Two cascades, rumor (bad campaign) and protector (limiting campaign), diffuse simultaneously in a network. Influence diffusion models are used to capture their propagation processes. The objective is to limit the rumor propagation through protector diffusion.

Given a directed graph $G = (V, E)$, original rumor sources $R \subseteq V$, an integer $k > 0$, and the time delay d (a nonnegative integer) for detecting rumor sources, the objective is to identify k nodes as initial protectors, such that the expected number of nodes adopting the rumor at the end of both rumor and protector propagation processes is minimized, or equivalently, the reduction in the expected number of nodes adopting the rumor is maximized.

Two Influence Diffusion Models

Two influence diffusion models are adopted in [2].

Multi-campaign Independent Cascade Model (MCICM) In this model, a network is viewed as a directed graph $G = (V, E)$. The initial set of rumor sources is denoted by R, and the initial set of protectors is denoted by P. Each node must be in one of the three statuses: infected (by the rumor), protected (by the protector), and inactive (neither infected nor protected). Each edge e_{uv} is associated with two values $0 \leq p_r(u, v) \leq 1$ and $0 \leq p_p(u, v) \leq 1$. Once a node becomes infected or protected, it remains so forever.

The diffusion process unfolds in discrete time steps. In any step $t \geq 1$, when a node u first becomes infected (protected), it has a single chance to activate each currently inactive neighbor v, and it succeeds with probability $p_r(u, v)$ $(p_p(u, v))$ provided no neighbor of v tries activating v at the

same step. In other words, at step $t+1$, node v will become infected (protected) with probability $p_r(u,v)$ ($p_p(u,v)$) provided no neighbor of v tries activating v at the same step. If there are two or more nodes trying to activate v at the same step, at most one of them can succeed. If infected node(s) and protected node(s) try to activate a node at the same step, protected nodes have priority over infected nodes. The process continues until no newly infected or protected node appears.

Campaign-Oblivious Independent Cascade (COICM) This model is similar to the MCICM model; the only difference is that instead of two probabilities are associated with each edge, only one probability $0 \leq p(u,v) \leq 1$ is associated with each edge e_{uv}. That is, each node has the same probability to forward the two kinds of information, indicating both rumor and protector cascades pass through the same edge with the same probability.

Problem 2 [8]

A single cascade, rumor, diffuses through networks. Influence diffusion models are used to capture rumor propagation process. The objective is to limit the propagation of rumors through blocking links in networks. The aim of [8] is to minimize contamination degree by appropriately removing a fixed number of links. Here, the contamination degree of a network is used to measure how badly the rumor will contaminate the network; see its definition later.

Given a directed graph $G=(V,E)$, a positive integer k where $k<|E|$, find a subset $B^* \subset E$ with $|B^*|=k$ such that $c(G(B^*)) \leq c(G(B))$ for any $B \subset E$ with $|B|=k$. Here $c(G)$ denotes the contamination degree. For any link $e \in E$, let $G(e)$ denote the graph $G(V, E \setminus e)$. And $G(e)$ is used as the graph constructed by blocking e in G. Similarly, for any $B \subset E$, let $G(B)$ denote graph $G(V, E \setminus B)$. Then $G(B)$ represents the graph constructed by blocking B in G.

Independent Cascade Model

In this model, a network is considered as a directed graph $G=(V,E)$. Each edge $e_{uv} \in E$ is assigned an influence probability $p(u,v)$, representing the possibility that node u influences node v successfully. For $e_{uv} \notin E$, let $p(u,v)=0$. Each node can only be in one of the following two statuses: inactive or infected. Once a node becomes infected, it stays infected forever.

The diffusion process unfolds in discrete time steps. Starting with an initial set of infected nodes A_0, at any step $t \geq 1$, when node u first becomes infected in step t, it has a single chance to activate any of its currently inactive neighbors. For neighbor node v, it succeeds with probability $p(u,v)$. If u succeeds in activating v, then v will become infected in step $t+1$, and if u fails in activating v, then v will stay inactive. If node u does not succeed in activating v, it will not have a second chance to do in all subsequent steps. The process continues until no more activations are possible. If multiple newly activated nodes are in-neighbors of the same inactive node, then their activation attempts are sequenced in an arbitrary order.

Key Results

For Problem 1

Given the set of rumor sources R, a set of initial protectors P, and rumor detection delay d, a set function $f_{Rd}(P)$ represents the number of nodes that are prevented by P with diffusion delay d from adopting R. In other words, function $f_{Rd}(P)$ denotes the nodes that will be infected by R if, instead of P, the empty set is selected as the set of protectors. Therefore, the problem is to select P such that the expectation of $f_{Rd}(P)$ is maximized.

The NP-hardness of this problem is proved. Then for the MCICM model, the high-effectiveness property where $p_p(u,v)=1$ for edge $e_{uv} \in E$ is adopted. Then the objective functions are proved to be submodular and monotone under both the MCICM model with the high-effectiveness property and the COICM model. Therefore, Algorithm 1 is applied to provide $(1-1/e)$-approximation solutions for the problem. However, the objective function is not

Algorithm 1: The greedy algorithm

Output: Set P
$P = \emptyset$
for *i = 1 to k* **do**
  for *each* $u \in V \setminus (R \cup P)$ **do**
    $N_u = 0$
    for *j = 1 to n* **do**
      $N_u += f_{Rd}(P \cup \{u\}) - f_{Rd}(P)$
    end
    $N_u = N_u / n$
  end
  $Loc = \arg\max_{u \in (V \setminus (R \cup P))} \{N_u\}$
  $P = P \cup Loc$
end
Output P

submodular under the MCICM model without the high-effectiveness property.

Variants of Problem 1

Several works in different contexts also consider using the diffusion of protectors to contain the spread of rumors. In comparison to Problem 1, they have adopted different influence diffusion models, as well as formulated different optimization problems.

Selection of Fixed Number of Protectors

The work of He et al. [5] studies rumors blocking maximization under an extension of the classical Linear Threshold (LT) model [6], in which they incorporate two cascades, rumor and protector. Each node in this model can be in one of the three states: infected, protected, and inactive. For each node, its currently infected neighbors and protected neighbors determine whether it will become infected, protected, or stay inactive, respectively. When a node is activated by its infected neighbors and protected neighbors at the same time, then infected neighbors have priority over protected neighbors. Each edge $e = (u, v)$ has two weights, w^r_{uv} (rumor propagation) and w^p_{uv} (protector propagation). Each node u picks two independent thresholds from $[0, 1]$; one is for rumor diffusion and the other is for protector diffusion.

Then they develop the objective function $S_R(X)$ for this problem, which represents the expected number of nodes that is saved (from being infected by rumors R) by X. This problem is shown to be NP-hard and the objective function is proved to be submodular and monotone, then the greedy algorithm with performance ratio $1 - \frac{1}{e}$ is applied. To efficiently compute the values of $S_R(X)$, the authors propose the CLDAG algorithm.

Instead of choosing initial protectors from nodes not in rumor sources, the authors in [10] select a fixed number of nodes from initial infected nodes (rumor sources) and the rest of the nodes in a network as initial protectors, such that the number of nodes protected during T time steps is maximized. They study this problem under the LT model and the IC model. Two approximation algorithms are proposed.

Protection of a Subset of Nodes

Instead of limiting rumor diffusion through launching a fixed number of protectors, the work of [12] exploits the problem which aims to select the smallest set of influential people as protectors, such that the diffusion process starting from these protectors limits the propagation of rumors R in a fraction $0 \leq \alpha \leq 1$ of the whole network in T time steps. They study four variants of this problem, which are the combinations of the two parameters: R (can be unknown or known) and T (can be constrained or unconstrained). These problems are studied under the extensions of the IC model and the LT model, in which two cascades, rumors and protectors, are considered. For each edge, both of them have the same influence probability (IC) or influence weight (LT). For each node, they have the same threshold (LT). The key point is that when the two cascades try to activate a node at the same time, protectors have priority over rumors.

The authors prove the NP-hardness of the four problems under the proposed models. For the variant that R is unknown and T is unconstrained, the Greedy Viral Stopper (GVS) algorithm is adopted to select the protectors, and the solution obtained is within a constant factor (in terms of the number of nodes in the network) ex-

tra from the optimal solution. The GVS algorithm can be used in the variants that R is known and T is either constrained or unconstrained. These variants are shown to be hard to approximate to a logarithmic factor in terms of the number of nodes in the network. To get a good solution within short time, the Community-Based Heuristic algorithm is proposed.

Noticing the community structure of social networks, the work of Fan et al. [3] contains rumor propagation by selecting a minimal set of initial protectors to protect a special kind of vertex set, which play the role as the "gates" of rumors' neighborhood communities. Two variants of the problem are studied under two different models, both variants are shown to be NP-hard, and approximation algorithms are developed to obtain good solutions.

Game Theory Aspect

The rumor blocking is also studied from the game theory aspect [13], where it uses graphs with nodes representing the tribal leaders and edges representing possible transmission of influence. Under this context, rumor blocking is viewed as a two-player game, in which one player, the rumor, will attempt to maximize the number of nodes accepting it while the second player, the protector, will attempt to minimize the rumor's influence. Both the rumor and the protector will choose their action sources (initial rumor sources and initial protector sources). In the zero-sum game context, the rumor's payoff is equal to the expected number of nodes infected, and the protector's payoff is the opposite of the rumor's payoff. The authors propose a double oracle algorithm for this game.

For Problem 2

Under the IC model, given an initial active set X, define the number of active nodes at the end of the influence diffusion process on G as $f(X;G)$. Let $\sigma(X;G)$ denote the expected value of $f(X;G)$. $\sigma(X;G)$ is called as the influence degree of node set X on graph G. Two notions of containment degrees are defined. One is called *Average Contamination Degree*, representing the average of influence degree of all the nodes in G, denoted as $c_0(G)$. Its definition is $c_0(G) = \frac{1}{|V|}\sum_{v\in V}\sigma(v;G)$. The other is called *Worst Contamination Degree*, representing the maximum of influence degree of all the nodes in G, denoted as $c_+(G)$. Its definition is: $c_+(G) = \max_{v\in V}\sigma(v;G)$. Approximation algorithms are proposed to find good solution for the problem.

Algorithm 2: The greedy algorithm - IC

Input: Graph $G_0 = (V_0, E_0)$, a positive integer $k < |E_0|$
Output: The set of links blocked
Initialize a subset $L \subseteq E_0$ as $L =$ Initialize a graph $G = (V, E)$ as $V = V_0$, $E = E_0$
while $|L| < k$ **do**
  select a link e^*, such that
  $e^* = \arg\min_{e\in E} c(G(e))$
  $L = L \cup \{e^*\}$
  $E = E \setminus \{e^*\}$
end
Output L

For a given graph $G = (V, E)$, exactly computing influence degree $c(G(e)); e \in E$ in Algorithm 2 is an open problem. Therefore, heuristic strategies are proposed to estimate $c(G(e)); e \in E$. These estimations are based on the *Bond Percolation Method* proposed by Kimura in [7], which we describe below.

Bond Percolation Method [7]

Assume there are propagation probabilities $\{p_e; e \in E\}$ on a graph $G = (V, E)$. In terms of information diffusion on a network, the *occupied* links represent the links that the information propagates, and the *unoccupied* links represent the links that the information does not propagates. The bond percolation process with occupation probabilities $\{p_e; e \in E\}$ on a graph $G = (V, E)$ is a stochastic process in which the probability of each link $e \in E$ becomes occupied is p_e.

Construct N graphs through the bond percolation process, that is, $\{G_n = (V, E_n); n = 1, \ldots, N\}$. For any $u \in V'$ on graph $G' = (V', E')$, let $F(u; G')$ represent the set of all the nodes that are *reachable* from u on G'. A node v is said to be reachable from u if there is a path from u to v through the links on G'. Define function $g(u; G, N) =$

$\frac{1}{N}\sum_{n=1}^{N}|F(u;G^n)|$. Then, $g(u;G,N)$ can be used to estimate $\sigma(u;G)$, where $u \in V$ and if N is sufficiently large. Decompose each G_n into the *strongly connected components (SCC)* as $V = \bigcup_{i=1}^{I_n} \mathrm{SCC}(u_i^n;G_n)$, where $u_i^n \in V$ and $\mathrm{SCC}(u_i^n;G_n)$ denotes the SCC of graph G_n that contains u_i^n. I_n is the number of the SCC of graph G_n, using the fact that $|F(u;G^n)| = |F(u_i^n;G_n)|$ for all $u \in V$ to calculate $\{|F(u;G^n)|;u \in V,n = 1,\ldots,N\}$, then compute $g(u;G,N)$, and finally $\sigma(u;G)$ can be calculated, where $u \in V$.

Estimation Method

We now describe how to estimate $c(G(e));e \in E$ in [8]. For a graph $G = (V,E)$, first, construct N sample graphs through the bond percolation process as $\{G_n = (V,E_n);n = 1,\ldots,N\}$. Next, for each $e \in E$, identify the subset of N, which is denoted as $S_N(e)$ and satisfies $S_N(e) = \{n \in \{1,\ldots,N\};e \notin E_n\}$. Now apply the bond percolation process on the graph $G(e) = (V,E \setminus \{e\})$ for $|S_N(e)|$ times, then $|S_N(e)|$ graphs are obtained by the occupied links, denote them as $\{G(e)^n;n = 1,\ldots,|S_N(e)|\}$. Given that N is large enough to ensure $|S_N(e)|$ sufficiently large, then the function $g(u;G(e),|S_N(e)|)$ equals to $\frac{1}{|S_N(e)|}\sum_{n=1}^{|S_N(e)|}|F(u;G(e)^n)|$, where $u \in V$, can be used to estimate $\sigma(u;G(e))$. Since each link of the graph G is independently declared occupied in the bond percolation process, then an alternative, $g'(u,e) = \frac{1}{|S_N(e)|}\sum_{n\in S_N(e)}|F(u;G^n)|$, is used to estimate $\sigma(u;G(e))$.

Variants of Problem 2

The authors in [9] adapt the method they used for the IC model to study Problem 2 under the LT model [6]. In [1], the authors incorporate the trust among users in the information propagation process, and they propose a measure to compute trust between a pair of users. Then a Weighted Trust Network (WTN) is built, and the objective of the problem is to find the Maximum Spanning Tree (MST) in the WTN and, finally, immunize all the edges in the MST of the WTN. Another method that controls rumor spread through blocking nodes and links simultaneously can be found in [4].

Nguyen et al. [11] study the rumor blocking problem under a dynamic social network structure. They propose to distribute patches to the most influential nodes in the social network, such that the number of nodes influenced by rumors is limited. In their work, they first take into account the network community structure and adaptively keeps it updated as the social network evolves, and then select most influential individuals from each communities to be patched.

The work of Zhu [14] focuses on the rumor blocking problem in cellular networks. First, a social relationship graph between mobile phones is obtained based on network traffic; the authors develop two graph-partitioning algorithms to partition the graph into many separate parts as possible and contain the rumor diffusion within each part. Then a minimum set of *key nodes*, which separate these different parts, is selected to be patched. The intuition is that the infected nodes in a part need to go through some of these key nodes to influence nodes in another part. Once these nodes are patched, it is impossible for the influence propagates among different parts.

Applications

Practical applications can be seen in controlling: propagation of computer viruses and worms propagates over computer networks, spread of malicious rumors through social networks, diffusion of infections or epidemics (such as swine flu) among groups of people, propagation of mobile worm in cellular networks, and so on.

Open Problems

There are many interesting directions that deserve further explorations. One direction is to improve existing influence diffusion models by considering continuous time influence diffusion, users' preferences to different kinds of information,

factors influencing users' threshold in adopting a kind of information, etc. Another direction is to design efficient strategies to control the spread of rumors when only partial of a network structure is observable. Another research issue is incorporating the detection of rumor sources into rumor blocking and continuous time delay of protectors.

Problem Definition

The problem concerns the design of efficient rate-based flow control algorithms for virtual-circuit communication networks where a connection is established by allocating a fixed path, called *session*, between the source and the destination. Rate-based flow-control algorithms repeatedly adjust the transmission rates of different sessions in an end-to-end manner with primary objectives to optimize the network utilization and achieve some kind of fairness in sharing bandwidth between different sessions.

A widely-accepted fairness criterion for flow-control is *max-min fairness* which requires that the rate of a session can be increased only if this increase does not cause a decrease to any other session with smaller or equal rate. Once max-min fairness has been achieved, no session rate can be increased any further without violating the above condition or exceeding the bandwidth *capacity* of some link. Call *max-min* rates the session rates when max-min fairness has been reached.

Rate-based flow control algorithms perform rate adjustments through a sequence of *operations* in a way that the capacities of network links are never exceeded. Some of these algorithms, called *conservative* [3, 6, 10, 11, 12], employ operations that gradually increase session rates until they converge to the max-min rates without ever performing any rate decreases. On the other hand, *optimistic* algorithms, introduced more recently by Afek, Mansour, and Ostfeld [1], allow for decreases, so that a session's rate may be intermediately be larger than its final max-min rate.

Optimistic algorithms [1, 7] employ a specific rate adjustment operation, called *update operation* (introduced in [1]). The goal of an `update` operation is to achieve fairness among a set of neighboring sessions and optimize the network utilization in a local basis. More specifically, an `update` operation calculates an increase for the rate of a particular session (the *updated* session) for each link the session traverses. The calculated increase on a particular link is the maximum possible that respects the max-min fairness condition between the sessions traversing the link; that

M.-Y. Kao (ed.), *Encyclopedia of Algorithms*,
DOI 10.1007/978-1-4939-2864-4

is, this increase should not cause a decrease to the rate of any other session traversing the link with smaller rate than the rate of the updated session after the increase. Once the maximum increase on each link has been calculated the minimum among them is applied to the session's rate (let e be the link for which the minimum increase has been calculated). This causes the decrease of the rates of those sessions traversing e which had larger rates than the increased rate of the updated session to the new rate. Moreover, the `update` operation guarantees that all the capacity of link e is allocated to the sessions traversing it (so the bandwidth of this link is fully utilized).

One important performance parameter of a rate-based flow control algorithm is its *locality* which is characterized by the amount of knowledge the algorithm requires to decide which session's rate to update next. *Oblivious* algorithms do not assume any knowledge of the network topology or the current session rates. *Partially oblivious* algorithms have access to session rates but they are unaware of the network topology, while *non-oblivious* algorithms require full knowledge of both the network topology and the session rates. Another crucial performance parameter of rate-based flow control algorithms is the *convergence complexity* measured as the maximum number of rate-adjustment operations performed in any execution until max-min fairness is achieved.

Key Results

Fatourou, Mavronicolas and Spirakis [7] have studied the convergence complexity of optimistic rate-based flow control algorithms under varying degrees of locality. More specifically, they have proved lower and upper bounds on the convergence complexity of oblivious, partially-oblivious and non-oblivious algorithms. These bounds are expressed in terms of n the number of sessions laid out on the network.

Theorem 1 (Lower Bound for Oblivious Algorithms, Fatourou, Mavronicolas and Spirakis [7]) *Any optimistic, oblivious, rate-based flow control algorithm requires $\Omega(n^2)$ update operations to compute the max-min rates.*

Fatourou, Mavronicolas and Spirakis [7] have presented algorithm `RoundRobin`, which applies `update` operations to sessions in a round robin order. Obviously, `RoundRobin` is oblivious. It has been proved [7] that the convergence complexity of `RoundRobin` is $O(n^2)$. This shows that the lower bound for oblivious algorithms is tight.

Theorem 2 (Upper Bound for Oblivious Algorithms, Fatourou, Mavronicolas and Spirakis [7]) `RoundRobin` *computes the max-min rates after performing $O(n^2)$ update operations.*

`RoundRobin` belongs to a class of oblivious algorithms, called `Epoch` [7]. Each algorithm of this class repeatedly chooses some permutation of all session indices and applies `update` operations on the sessions in the order determined by this permutation. This is performed n times. Clearly, `Epoch` is a class of oblivious algorithms. It has been proved [7] that each of the algorithms in this class has convergence complexity $O(n^2)$.

Another oblivious algorithm, called `Arbitrary`, has been presented in [1]. The algorithm works in a very simple way by choosing the next session to be updated in an arbitrary way, but it requires an exponential number of `update` operations to compute the max-min rates.

Fatourou, Mavronicolas and Spirakis [7] have proved that partially-oblivious algorithms do not achieve better convergence complexity than oblivious algorithms despite the knowledge they employ.

Theorem 3 (Lower Bound for Partially Oblivious Algorithms, Fatourou, Mavronicolas and Spirakis [7]) *Any optimistic, partially oblivious, rate-based flow control algorithm*

requires $\Omega(n^2)$ update operations to compute the max-min rates.

Afek, Mansour and Ostfeld [1] have presented a partially oblivious algorithm, called `GlobalMin`. The algorithm chooses as the session to update next the one with the minimum rate among all sessions. The convergence complexity of `GlobalMin` is $O(n^2)$ [1]. This shows that the lower bound for partially-oblivious algorithms is tight.

Theorem 4 (Upper Bound for Partially Oblivious algorithms, Afek, Mansour and Ostfeld [1]) `GlobalMin` *computes the max-min rates after performing $O(n^2)$ update operations.*

Another partially-oblivious algorithm, called `LocalMin`, is also presented in [1]. The algorithm chooses to schedule next a session which has a minimum rate among all the sessions that share a link with it. `LocalMin` has time complexity $O(n^2)$.

Fatourou, Mavronicolas and Spirakis [7] have presented a non-oblivious algorithm, called `Linear`, that exhibits linear convergence complexity. `Linear` follows the classical idea [3, 12] of selecting as the next updated session one of the sessions that traverse the most congested link in the network. To discover such a session, `Linear` requires knowledge of the network topology and the session rates.

Theorem 5 (Upper Bound for Non-Oblivious Algorithms, Fatourou, Mavronicolas and Spirakis [7]) *Linear computes the max-min rates after performing O(n) update operations.*

The convergence complexity of `Linear` is optimal, since n rate adjustments must be performed in any execution of an optimistic rate-based flow control algorithm (assuming that the initial session rates are zero). However, this comes at a remarkable cost in locality which makes `Linear` impractical.

Applications

Flow control is the dominant technique used in most communication networks for preventing data traffic congestion when the externally injected transmission load is larger than what can be handled even with optimal routing. Flow control is also used to ensure high network utilization and fairness among the different connections. Examples of networking technologies where flow control techniques have been extensively employed to achieve these goals are TCP streams [5] and ATM networks [4]. An overview of flow control in practice is provided in [3].

The idea of controlling the rate of a traffic source originates back to the data networking protocols of the ANSI Frame Relay Standard. Rate-based flow control is considered attractive due to its simplicity and its low hardware requirements. It has been chosen by the ATM Forum on Traffic Management as the best suited technique for the goals of ABR service [4].

A substantial amount of research work has been devoted in past to conservative flow control algorithms [3, 6, 10, 11, 12]. The optimistic framework has been introduced much later by Afek et al. [1] as a more suitable approach for real dynamic networks where decreases of session rates may be necessary (e.g., for accommodating the arrival of new sessions). The algorithms presented in [7] improve upon the original algorithms proposed in [1] in terms of either convergence complexity, or locality, or both. Moreover, they identify that certain classical scheduling techniques, such as round-robin [11], or adjusting the rates of sessions traversing one of the most congested links [3, 12] can be efficient under the optimistic framework. The first general lower bounds on the convergence complexity of rate-based flow control algorithms are also presented in [7].

The performance of optimistic algorithms has been theoretically analyzed in terms of an abstraction, namely the `update` operation, which has been designed to address most of the intricacies encountered by rate-based flow control algorithms. However, the `update` operation

masks low-level implementation details, while it may incur non-trivial, local computations on the switches of the network. Fatourou, Mavronicolas and Spirakis [9] have studied the impact on the efficiency of optimistic algorithms of local computations required at network switches in order to implement the `update` operation, and proposed a distributed scheme that implements a broad class of such algorithms. On a different avenue, Afek, Mansour and Ostfeld [2] have proposed a simple flow control scheme, called `Phantom`, which employs the idea of considering an imaginary session on each link [10, 12], and they have discussed how `Phantom` can be applied to ATM networks and networks of TCP routers.

A broad class of modern distributed applications (e.g., remote video, multimedia conferencing, data visualization, virtual reality, etc.) exhibit highly differing bandwidth requirements and need some kind of quality of service guarantees. To efficiently support a wide diversity of applications sharing available bandwidth, a lot of research work has been devoted on incorporating priority schemes on current networking technologies. Priorities offer a basis for modeling the diverse resource requirements of modern distributed applications, and they have been used to accommodate the needs of network management policies, traffic levels, or pricing. The first efforts for embedding priority issues into max-min fair, rate-based flow control were performed in [10, 12]. An extension of the classical theory of max-min fair, rate-based flow control to accommodate priorities of different sessions has been presented in [8]. (A number of other papers addressing similar generalizations of max-min fairness to account for priorities and utility have been presented after the original publication of [8].)

Many modern applications are not based solely on point-to-point communication but they rather require multipoint-to-multipoint transmissions. A max-min fair rate-based flow control algorithm for multicast networks is presented in [14]. Max-min fair allocation of bandwidth in wireless adhoc networks is studied in [15].

Open Problems

The research work on optimistic, rate-based flow control algorithms leaves open several interesting questions. The convergence complexity of the proposed optimistic algorithms has been analyzed only for a static set of sessions laid out on the network. It would be interesting to evaluate these algorithms under a dynamic network setting, and possibly extend the techniques they employ to efficiently accommodate arriving and departing sessions.

Although max-min fairness has emerged as the most frequently praised fairness criterion for flow control algorithms, achieving it might be expensive in highly dynamic situations. Afek et al. [1] have proposed a modified version of the `update` operation, called *approximate* `update`, which applies an increase to some session only if it is larger than some quantity $\delta > 0$. An *approximate* optimistic algorithm uses the approximate `update` operation and terminates if no session rate can be increased by more than δ. Obviously such an algorithm does not necessarily reach max-min fairness. It has been proved [1] that for some network topologies every approximate optimistic algorithm may converge to session rates that are away from their max-min counterparts by an exponential factor. The consideration of other versions of `update` operation or different termination conditions might lead to better max-min fairness approximations and deserves more study; different choices may also significantly impact the convergence complexity of approximate optimistic algorithms. It would be also interesting to derive trade-off results between the convergence complexity of such algorithms and the distance of the terminating rates they achieve to the max-min rates.

Fairness formulations that naturally approximate the max-min condition have been proposed by Kleinberg et al. [13] as suitable fairness criteria for certain routing and load balancing applications. Studying these formulations under the rate-based flow control setting is an interesting open problem.

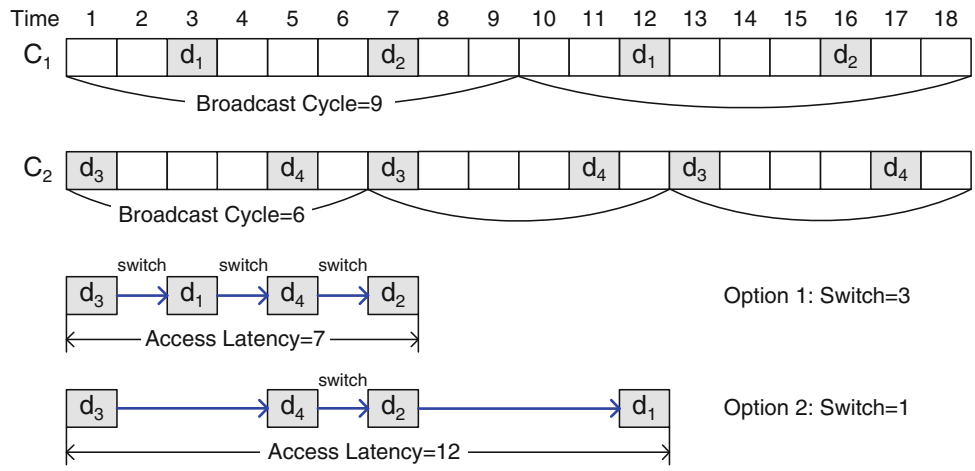
Problem Definition

Wireless data broadcasting means a set of data are repeatedly broadcast from a base station to a mass number of wireless and mobile clients. If a client wants a specific datum, it will access onto the broadcasting channel, get the location (appearance time) of the datum with the help indices, and wait until the datum has been broadcast. The scheduling problem in data broadcasting deals with the design of an efficient permutation strategy for a client to download a required subset of data from an multichannel broadcasting system, with both time and energy constraints. Here time constraint means the client wants the minimum downloading time from when it starts the query until the moment it has successfully download each piece of datum, while the energy constraint means the client wants the minimum switching numbers among channels to reduce extra battery consumption. Correspondingly, we can define the scheduling problem formally as follows:

A client wants to download a group of k data items $D = \{d_1, d_2, \ldots, d_k\}$, each with different sizes. Those data items are broadcasted on n different channels $C = \{c_1, c_2, \ldots, c_n\}$ repeatedly together with many other data items. Each channel may have different bandwidth and



Scheduling in Data Broadcasting, Fig. 1 Example of possible objective contradiction

broadcast cycle length. Let the time to download the smallest transmission packet be a unit time, and the length of d_i can be represented as l_i (also referring as downloading time).

Assume the client knows the locations (channel id and time offsets) of the required data set beforehand at the starting time $t = 0$ (with the help of indices, which is beyond the scope of our problem), and the target is how to download k known data from n channels efficiently with minimum downloading time (we also refer it as *access latency*) and minimum switching numbers.

Unfortunately, the two objectives in this problem are conflicting to each other. Figure 1 is an example to illustrate this phenomenon. In Fig. 1, there are two channels broadcasting 15 data items repeatedly. Suppose the gray data items {1,2,3,4} are of the request. The starting point of the client retrieving process is at $t = 0$. If we want to minimize the access latency, the request should be retrieved in the order of "$3 \rightarrow 1 \rightarrow 4 \rightarrow 2$" which takes only 7 time units but needs 3 switches (shown as Option 1 in Fig. 1). However, if we want to minimize the switches, the best retrieving order should be "$3 \rightarrow 4 \rightarrow 2 \rightarrow 1$" which needs only 1 switch but takes 12 time units (shown as Option 2 in Fig. 1). This example exhibits that access latency and number of switches cannot be minimized at the same time. They are contradictory factors.

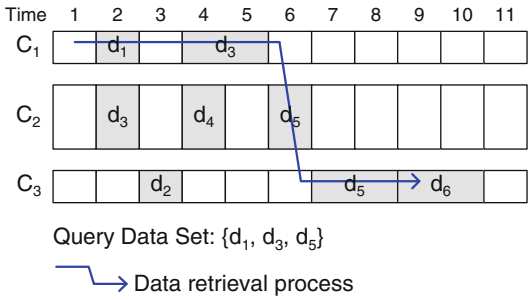
As a consequence, we want to fix one factor and minimize another objective, and thus have the following objective:

Objective

We hope to design a data downloading order for a client to download k data items from n broadcasting channels, such that the access latency t is minimized if we restrict the switch number among channels (denoted as h); otherwise, we will minimize the number of switches h once the access latency t is bounded.

Constraints

1. **Switch Constraint**: Note that if a client is downloading a data from channel c_i at time t_0, then it cannot switch to channel c_j, where $j \neq i$, to download another data at time $t_0 + 1$ due to connection protocols. Thus, we assume if a client wants to download data from another channel, it needs at least one time unit for channel switching. Figure 2 gives a typical process of data retrieval in multichannel broadcast environments. The query data set is $\{d_1, d_3, d_5\}$, and a user can download data object d_1 and d_3 from channel c_1 and then switch to channel c_3 at time $t = 6$ to download data object d_5 at time $t = 7$. However, after time $t = 5$, the user cannot switch from channel c_1 to c_2 to download data



Scheduling in Data Broadcasting, Fig. 2 Switch constraint

d_5 at time $t = 6$. From Fig. 2, we also get that the bandwidths of different channels are not necessarily the same. Actually, the bandwidth of channel c_2 is twice as that of c_1 or c_3, thus d_3 or d_5, which take two time slots on c_1 or c_3, can be broadcasted in one time unit by c_2.

2. **Objective Constraint**: We have to setup a reasonable threshold for latency constraint t and switch constraint h, such that we would achieve a feasible solution for the corresponding minimized switches and shortest access latency.

Problem 1 (Scheduling in Data Broadcasting)

INPUT: *The required data subset* $D = \{d_1, d_2, \ldots, d_k\}$ *broadcast on* n *different channels with their locations and downloading time* l_i, *a switch constraint* h *or latency constraint* t.

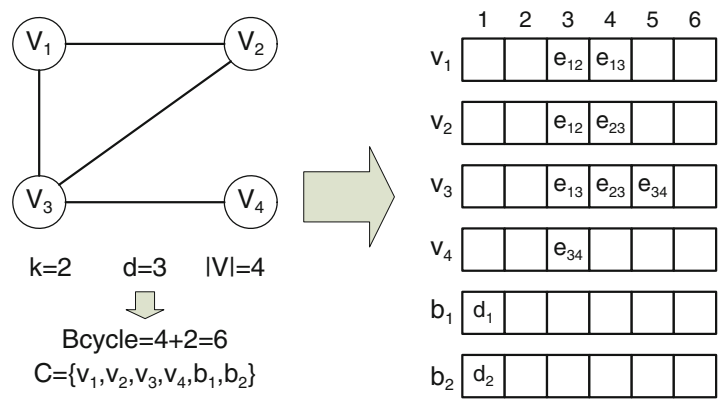
OUTPUT: *A permutation of* D *such that if starting from time slot zero, a client would achieve the shortest access latency (with switch threshold* h*) or the minimum switch numbers (with latency threshold* t*) if it follows this permutation to download each data item sequentially with switch constraint.*

Key Results

Scheduling is an important part in the wireless data broadcast system. Researchers tend to divide the scheduling problems into two subproblems. The first one is the data allocation problem in the server side, while the other one is the data retrieval problem in the client size.

With respect to server side scheduling, several works have been proposed to improve the system performance [1–5]. Acharya et al. [1] first dealt with the data allocation problem for single-channel environment. He proposed a scheduling algorithm considering data access frequencies and allowed frequent accessed data to be broadcasted more often. Most works concerned multi-channel environment. For data set with uniform length, Yee et al. [2] proposed an $O(t^2m)$ time-complexity dynamic programming algorithm to find the optimal schedule and also a near optimal greedy algorithm to reduce the time complexity. For nonuniform lengths case, Ardizzoni et al. [3] proved that this problem is strong NP-hard. Ardizzoni et al. [3], Anticaglia et al. [4], and Kenyon et al. [5] designed algorithms based on greedy and heuristic strategy.

Also most of the literature discussed the data allocation problem from server's point of view; several works [6–10] considered the data retrieval scheduling problem from the client's point of view. Shi et al. [6] defined the data retrieval problem in MIMO environment as parallel data retrieval scheduling with MIMO Antennae (PADRS-MIMO) and proposed two greedy heuristics to guarantee minimum switchings among channels or reduce the downloading time when the number of antennae in the mobile devices are limited. Lu et al. [7, 8] defined the largest number data retrieval (LNDR) and maximum cost data retrieval (MCDR) problems and considered the hopping cost. He also proved that when the hopping cost cannot be ignored, LNDR is NP-hard and designed a 1/2-approximation algorithm. Gao et al. [9, 10] designed a randomized algebraic algorithm that takes both energy cost and access time into consideration to schedule the data retrieval process in multichannel environments. The algorithm proposed can detect whether a given data retrieval problem has a solution with access time t and number of switchings h in $O\left(2^k(hnt)^{O(1)}\right)$ time, where n is the number of channels and k is the number of requested data items.



Scheduling in Data Broadcasting, Fig. 3 Example of VC reduction

Hardness Analysis

Define a tuple $s = \{i_s, j_s, t_s, t'_s\}$ to denote the datum d_{i_s}, which can be downloaded from channel c_{j_s} during the time span $[t_s, t'_s]$; then it is clear that a valid data retrieval schedule is a sequence of k intervals $s_1, s_2, \ldots, s_k$, each tuple corresponds to a distinct data item in D, and there are no conflicts between any two of the k tuples. To analyze the NP-hardness, we then define the decision problem of MCDR.

Definition 1 (Decision MCDR) Given a data set D, a channel set C, a time threshold t, and a switching threshold h, find a valid data retrieval schedule to download all the data in D from C before time t with at most h switchings.

Theorem 1 *MCDR problem is NP-hard.*

Proof We use $VC \leq_p MCDR$ to prove this theorem. Here VC is the decision problem of vertex cover, say, given a graph $G = (V, E)$, we want to find a minimum size vertex subset $VC \subseteq V$ such that for any edge $(v_i, v_j) \in E$, either $v_i \in VC$ or $v_j \in VC$. An instance of vector cover is: given a graph $G = (V, E)$ and integer k, does it have a vertex cover VC with size k? Then we construct an instance of MCDR from G and k as follows:

1. For each vertex $v_i \in V$, define a channel v_i. Define another k channels $b_1, \ldots, b_k$. Then the channel set is $C = \{v_1, \ldots, v_{|V|}, b_1, \ldots, b_k\}$. Totally $|V| + k$ channels. Let δ be the maximum vertex degree in G, and then each channel has broadcast cycle length $\delta + 3$.
2. For each edge $(v_i, v_j) \in E$, define a unit length data item e_{ij} in data set D_e and append it on channel c_i and c_j (the order can be arbitrary and starting from the third time unit).
3. For each channel b_i, define a unit length data item d_i in data set D_d and allocate it on the first time unit of channel b_i.
4. The data set $D = D_e \cup D_b$.

Figure 3 is an example to show how to construct the broadcast system. In this figure, $\delta = 3$, $k = 2$, $|V| = 4$; thus, the channel set should be $\{v_1, v_2, v_3, v_4, b_1, b_2\}$, each having broadcast length $\delta + 3 = 6$. Each e_{ij} represents an edge (v_i, v_j), and it is clear that if we download all data items from channel v_i, then it means we cover the edges connecting node v_i.

Next, we prove that G has a vertex cover with size k if and only if there is a valid data retrieval schedule S such that $t = k(\delta+3)$ and $h = 2k-1$.

$\Longrightarrow$: If G has a vertex cover VC with size k, then we can select the corresponding k channels in $\{v_i | v_i \in VC\}$ to receive all the data in k cycles. At the beginning of ith cycle (iteration), the client will visit b_i at $t = 1$, and hop to some $v_i \in VC$ channel, stay on this channel till the last time unit of the broadcast cycle, and then hop to b_{i+1}. There are k b_is, so each iteration client will download one of them. VC is a vertex cover, so following all

$v_i \in VC$ we must download every e_{ij}. The length of each broadcast cycle is $\delta + 3$, so the total access latency is $k(\delta + 3)$. In each broadcast cycle, the client will switch twice (except the last cycle), so $h = 2k - 1$.

$\Longleftarrow$: Assume MCDR has a valid schedule S with $t = k(\delta + 3)$ and $h = 2k - 1$. Let us consider D_b first. There are k b_i's located at the first time unit on k different channels. It means we have to switch at least $k - 1$ hops to download D_b, and then we only have another k hops for D_e, which means we can visit at most k channels in $\{v_i\}$. At the beginning of each broadcast cycle, we always stay at some channel b_i to download d_i, and then we switch to some v_i, and at the end of this cycle, we have to switch to channel b_{i+1} for d_{i+1}. This means we cannot switch to two vertex channels within one broadcast cycle, otherwise we cannot download $D = D_e \cup D_b$ in k iterations. Since S is valid, we visit k vertex channels and download all D_e data items, it means these k vertices form a vertex cover with size k.

This reduction can be done in polynomial time, and we can conclude that MCDR is NP-hard.

Randomized Algebraic Algorithm

To solve the above decision problem, we developed a randomized algebraic algorithm. It can detect if a given problem has a schedule to download all the requested data before time t and with at most h channel switchings in $O\left(2^k(nht)^{O(1)}\right)$ time, where n is the number of channels and k is the number of required data items. We also provide a fixed parameter tractable (FPT) algorithm with computational time $O\left(2^l(nht)^{O(1)}\right)$. It can determine whether there is a scheduling to download l data items from D in at most n time slots and at most h channel switches. Service provider can adjust n and h freely to fit their own requirement. We firstly give some preliminaries and then present our algorithms in detail.

Preliminaries

Here we introduce some notions about group algebra which are not often used in algorithm design.

Definition 2 Assume that $x_1, \ldots, x_k$ are variables in group algebra. Then,

1. A *monomial* has format $x_1^{a_1} x_2^{a_2} \ldots x_k^{a_k}$.
2. A *multilinear monomial* is a monomial such that each variable has degree exactly one. For example, $x_3x_5x_6$ is a multilinear monomial, but $x_3x_5^2x_6^3$ is not.
3. For a *polynomial* $p(x_1, \ldots, x_k)$, its *sum of product expansion* is $\sum_j p_j(x_1, \ldots, x_k)$, where each p_j is a monomial, which has a format $c_j x_1^{a_{j_1}} \ldots x_k^{a_{j_k}}$ with c_j respect to its coefficient.
4. $G_2 = (\{0, 1\}, +, \cdot)$ is a field with two elements $\{0, 1\}$ and two operations $+$ and $\cdot$. The addition operation is under the modular of 2 (mod 2).
5. Z_2^k is the group of binary k-vectors. Let w_0 denote the all-zero vector, which is the identity of Z_2^k, and then for every $v \in Z_2^k$, $v^2 = w_0$, $v \cdot w_0 = v$.

The operations between elements in the group algebra are standard.

Algorithm Description

The basic idea of our algebraic algorithm is that for each item $d_i \in D$, where D is the query data set, we create a variable x_i to represent it. Therefore, given $D = \{d_1, d_2, \ldots, d_k\}$, we construct a variable set $X = \{x_1, x_2, \ldots, x_k\}$. We then design a circuit $H_{t,h,n}$ such that a schedule without conflict will be generated by a multilinear monomial in the sum of product expansion of the circuit. The existence of schedules to download all the data items in D from the multiple channel set C is converted into the existence of multilinear monomials of $H_{t,h,n}$. Replace each variable by a specified binary vector which can remove all of the non-multilinear monomials by converting them to zero. Thus, the data retrieval problem is transformed into testing if a multivariate polynomial is zero. It is well known that randomized

algorithms can be used to check if a circuit is identical to zero in polynomial time. Thus, we have the following statements.

Lemma 1 *There is a polynomial time algorithm such that given a channel c_i, a time interval $[t_1, t_2]$, and an integer m, it constructs a circuit of polynomial $P_{i,t_1,t_2,m}$ such that for any subset $D' = \{d_{i_1}, \ldots, d_{i_m}\} \subseteq D$ which has a size of m and is downloadable in the time interval $[t_1, t_2]$ from channel c_i, the product expansion of $P_{i,t_1,t_2,m}$ contains a multilinear monomial $x_{i_1} x_{i_2} \ldots x_{i_m}$.*

Proof We can use a recursive way to compute the circuit $P_{i,t_1,t_2,m}$ in polynomial time.

1. $P_{i,t_1,t_2,0} = 0$.
2. $P_{i,t_1,t_2,1} = \sum_j x_j$, $x_j \subseteq X$, and the corresponding datad_j is entirely in the time interval $[t_1, t_2]$ of channel c_i.
3. $P_{i,t_1,t_2,l+1} = \sum_j x_j \cdot P_{i,t_1,t'_2,l} + P_{i,t_1,t'_2,l+1}$, d_j starts at time $t'_2 + 1$ and ends before time t_2 on channel c_i.

When computing $P_{i,t_1,t_2,l+1}$, x_j multiplies $P_{i,t_1,t'_2,l}$ is based on the case that d_j is downloadable from time $t'_2 + 1$ to t_2 in the final phase, and the other l data items are downloadable before time t'_2. The term $P_{i,t_1,t'_2,l+1}$ is the case that $l + 1$ items are downloaded before time t'_2. Note that the parameter m in $P_{i,t1,t2,m}$ controls the total number of data to be downloaded.

Definition 3 A subset data items $D' = \{d_{i_1}, \ldots, d_{i_m}\} \subseteq D$ is (i, t, h)-downloadable if we can download all data items in D' before time t, the total number of channel switches is at most h, and the last downloaded item is from channel c_i.

Lemma 2 *Given two integers t and h, there is a polynomial time algorithm to construct a circuit of polynomial $F_{i,t,h,m}$ such that for any (i, t, h)-downloadable subset $D' = \{d_{i_1}, \ldots, d_{i_m}\} \subseteq D$, the product expansion of $F_{i,t,h,m}$ contains a multilinear monomial $\left(x_{i_1}, \ldots, x_{i_m}\right) Y$, where Y is a multilinear monomial which does not include any variable in X.*

Proof We still use a recursive way to construct the circuit. Some additional variables are used as needed. Without loss of generality, we assume the data retrieval process start at time 0.

1. $F_{i,t,0,0} = 0$.
2. $F_{i,t,0,1} = P_{i,1,t,1} \cdot y_{i,t,0,1}$.
3. $F_{i,t,h'+1,m'+1} = y_{i,t,h'+1,m'+1,0} \left(\sum_{t'<t} F_{i,t',h'+1,m'} \cdot P_{i,t'+1,t,1}\right) + y_{i,t,h'+1,m'+1,1} \left(\sum_{j \neq i} \sum_{t'<t} F_{i,t'-1,h',m'} \cdot P_{i,t'+1,t,1}\right)$.

Then we can get Lemma 2 immediately.

The computation of $F_{i,t,h'+1,m'+1}$ is based on two cases, and we use two variables, $y_{i,t,h'+1,m'+1,0}$ and $y_{i,t,h'+1,m'+1,1}$, to mark them respectively. We now present an algorithm that involves one layer randomization to determine if there is a schedule to download all the data items in D before time t and with at most h channel switchings.

Theorem 2 *There is an $O\left(2^k (hnt)^{O(1)}\right)$ time randomized algorithm to determine if there is a scheduling to download $|D| = k$ data items before time t and the number of channel switches is at most h, where n is the total number of channels.*

Proof By Lemma 2, we can construct a circuit $H_{t,h,n} = \sum_{i=1}^{n} F_{i,t,h,k}$ in polynomial time. It is easy to see there is a scheduling for downloading the k data items before time t and with h channel switches, if and only if the sum product expansion of $H_{t,h,n}$ has a multilinear monomial $(x_1, \ldots, x_k)Y$.

We can replace each s_i by a vector $w_i = w_0^T + v_i^T$, where w_0 is the all-zero vector of dimension k and v_i is a binary vector of dimension k with its ith element being 1 and all other elements being 0. Assume $k = 3$, we define the following operations:

$$v_a \cdot v_b = \begin{pmatrix} a_1 \\ a_2 \\ a_3 \end{pmatrix} \cdot \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix} = \begin{pmatrix} (a_1 + b_1)(\text{mod}2) \\ (a_1 + b_2)(\text{mod}2) \\ (a_1 + b_3)(\text{mod}2) \end{pmatrix} \quad (1)$$

$$(v_a + v_b) \cdot v_c = v_a \cdot v_c + v_b \cdot v_c \quad (2)$$

By Eqs. 1 and 2, for any k-dimensional binary vector $w' = w_0 + v$, we have $w'^2 = w_0^2 + 2w_0 \cdot v + v^2 = w_0 + 2(w_0 \cdot v) + w_0 = 2(w_0 \cdot v) + 2w_0 = 0$, because of the coefficients are in the field of G_2. The replacement $x_i = w_i (i = 1, \ldots, m)$ makes all the non-multilinear monomials become zero. Meanwhile, all the multilinear monomials remain nonzero. Hence, it is clear that there is a scheduling to download all the data items in D before time t and with at most h channel switchings if and only if $H_{t,h,n|x_i=w_i(i=1,\ldots,k)}$ is a nonzero polynomial. The variables in Y makes it impossible to have cancelation when adding two identical multilinear monomials, which can be generated from different paths with variables in $\{x_1, \ldots, x_k\}$. It is well known that randomized algorithms can be used to check if a circuit is identical to zero in polynomial time [11, 12].

The algorithm generates less than 2^k terms during the computing process since there are at most 2^k distinct binary vectors. Therefore, the computational time is $O\left(2^k (nht)^{O(1)}\right)$.

Example Let $H_1 = x_1 x_2 y_1 + x_2^2 y_2$ and $H_2 = x_1^2 y_1 + x_2^2 y_2$. Consider the replacement $x_1 = w_1 = \binom{0}{0} + \binom{1}{0}$ and $x_2 = w_2 = \binom{0}{0} + \binom{0}{1}$. We have the following steps of operations.

$$\begin{aligned} &H_1|x_1 = w_1, x_2 = w_2 \\ &= \left(\binom{0}{0} + \binom{1}{0}\right)\left(\binom{0}{0} + \binom{0}{1}\right) y_1 \\ &\quad + \left(\binom{0}{0} + \binom{0}{1}\right)^2 y_2 \\ &= \left(\binom{0}{0} + \binom{0}{1} + \binom{1}{0} + \binom{1}{1}\right) y_1 \\ &\quad + \left(\binom{0}{0} + \binom{0}{1}\right) y_2 \\ &= \left(\binom{0}{0} + \binom{0}{1} + \binom{1}{0} + \binom{1}{1}\right) y_1 \\ &\quad + \left(2\binom{0}{0} + 2\binom{0}{1}\right) y_2 \\ &= \left(\binom{0}{0} + \binom{0}{1} + \binom{1}{0} + \binom{1}{1}\right) y_1 + (0+0) y_2 \\ &= \left(\binom{0}{0} + \binom{0}{1} + \binom{1}{0} + \binom{1}{1}\right) y_1 + 0 \\ &= \left(\binom{0}{0} + \binom{0}{1} + \binom{1}{0} + \binom{1}{1}\right) y_1 \\ &\neq 0 \end{aligned}$$

$$\begin{aligned} &H_2|x_1 = w_1, x_2 = w_2 \\ &= \left(\binom{0}{0} + \binom{1}{0}\right)^2 y_1 + \left(\binom{0}{0} + \binom{0}{1}\right)^2 y_2 \\ &= \left(\binom{0}{0} + \binom{1}{0} + \binom{1}{0} + \binom{0}{0}\right) y_1 \\ &\quad + \left(\binom{0}{0} + \binom{0}{1} + \binom{0}{1} + \binom{0}{0}\right) y_2 \\ &= \left(2\binom{0}{0} + 2\binom{1}{0}\right) y_1 + \left(2\binom{0}{0} + 2\binom{0}{1}\right) y_2 \\ &= (0+0) y_1 + (0+0) y_2 \\ &= 0 \end{aligned}$$

H_1 is a polynomial that contains a multilinear monomial. It becomes nonzero after replacement. H_2 is a polynomial that is without multilinear monomials. It becomes zero after the replacement. If we just down a subset of l data items in set D, we have the following theorem that involves two layers of randomization.

Theorem 3 *There is an $O\left(2^l (hnt)^{O(1)}\right)$ time randomized algorithm to determine if there is a scheduling to download l data items from D in at most t time units and at most h channel switches.*

Proof By Lemma 2, we can construct a polynomial $H_{t,h,l} = \sum_{i=1}^{l} F_{i,t,h,l}$ in polynomial time. Replace each x_i with a vector $w_i = w_0^T + v_i^T$, where w_0 is the all-zero vector of dimension l and v_i is a random distinct vector of dimension l. The replacement $x_i = w_i$ $(i = 1, \ldots, k)$ makes all monomials which has non-multilinear monomial at x part become zero.

Therefore, there is a scheduling to download l data items of D before time t and with the number of switches no more than h if and only if $H_{t,h,k|x_i=w_i(i=1,\ldots,k)}$ is not a zero polynomial in the field of G_2. Assume that the product expansion of $H_{t.h,l}$ has a multilinear monomial $(x_{i_1}, \ldots, x_{i_l})Y$, where Y is a multilinear monomial with variables not in $x_1, \ldots, x_k$. For a series of randomly assigned vectors with dimension l: $v_{j_1}, \ldots, v_{j_l}$, the probability that v_{j_i} is a linear combination of $v_{j_1}, \ldots, v_{j_{i-1}}$ is at most $\frac{2^{i-1}}{2^l} = \frac{1}{2^{l-i+1}}$. Therefore, with probability at most $\sum_{i=1}^{l} \frac{1}{2^{l-i+1}}$, v_{j_i} is a linear combination of $v_{j_1}, \ldots, v_{j_{i-1}}$ for some $i \leq l$. When $v_{j_i}, \ldots, v_{j_l}$ are linearly independent, the product of $v_{j_1}, \ldots, v_{j_l}$ is nonzero. Every multilinear monomial in the product expansion has different variables to form Y since it is determined by a unique path to generate the polynomial. Therefore, for those random vectors v_i, every multilinear monomial has a chance at least $1 - \frac{3}{4} = \frac{1}{4}$ to be nonzero. Therefore, if there is a solution, $H_{t,h,k|x_i=w_i(i,1,\ldots,l)}$ with random assignment Y is not zero in the field of G_2 with probability at least $\frac{1}{4}$.

After the replacements, it generates less than $2l$ terms since there are at most $2k$ different vectors for a group of Z_2^l. The coefficient of each vector is kept as a polynomial size circuit. Therefore, the computational time of our algorithm is $O\left(2^l (hnt)^{O(1)}\right)$, and if we run it 30 times, the error rate is $\left(\frac{3}{4}\right)^{30} < 0.0002$.

Applications

Scheduling problem is one of the most fundamental problems in combinatorial optimization, which could model various real-world practical applications. Especially, scheduling problem at client hand side would be very useful for data retrieval problem in wireless data broadcasting or data streaming environment to reduce energy consumption and improve query efficiency. Such problem would also be helpful for parallel query applications in distributed storage systems.

Open Problems

How to download data items efficiently in wireless data broadcast environment can usually be formulized as NP-hard problems with different constraints, and can be categorized into two kinds: single channel process and multiple channel process. The best known result for the former problem is constant-factor approximations, while currently there is no polynomial time approximation scheme (PTAS) for both of them. The results for this problem is also helpful for parallel data retrieval problem in distributed data storage system and cloud system.

Experimental Results

Many literature proposed experimental results for scheduling problem in data broadcasting. Shi et al. [6] simulated a base station with n broadcast channels and 10,000 items, each of size 1KB, and multiple clients with various requests of data. The access probability of the database follows Zipf distribution, n varies from 5 to 30, the number of antennae varies from 1 to 10, and the size of a request varies from 10 to 1,000. For each experiment, they generated 100 requests to get the average access latency and number of switchings during data retrieval. Lv et al. [7, 8] constructed two types of broadcast programs: special data broadcast without channel switching time (SDB) and general data broadcast with channel switching time (GDB). In both types of programs, they simulated a base station with n broadcast channels; the bandwidth of each channel is 1Mbit/sec. The database to be broadcasted has N data items, each of size 512 bytes. The time duration is denoted by t. The data items of query data set D

is generated with access probabilities following the Zipf distribution.

URLs to Code and Data Sets

Shi et al. [6] provided the program for users to test parameter setting for their own data sets and available channels (http://theory.utdallas.edu/dataengineering).

Problem Definition

The problem known as the reordering buffer problem or as the sorting buffer problem is concerned with sorting a sequence of colored

items according to their color using a limited size buffer. More precisely the items are to be processed and arrive one by one. Arriving items must first be placed into a buffer which can hold up to k items. Once the buffer is completely filled, an algorithm has to free space by selecting one of the items in the buffer for processing and removing that item from the buffer. After items stop arriving, the remaining items in the buffer may be processed in any order. Whenever an item is processed that has a different color than the item processed in the step before, this generates a cost of 1. The objective is to minimize the total cost.

Metric Space Generalization

This problem can be further generalized. Items, instead of having a color, correspond to points in a metric space. A single server must process all items. In order to process an item, the server has to move to the corresponding point in the metric space. At every point, the server has to chose one of the first k as of yet unprocessed items for processing and move the server accordingly. The goal is to minimize the total distance the server travels.

The uniform metric in which any two points either have distance 0 or distance 1 from one another corresponds to the original "color sorting" setting. Other metrics studied include line metrics and "star" metrics which are the distance metrics over weighted undirected trees of diameter 2.

Block Operation Setting

Another variant is the so-called block operation setting. Once again, the input consists of a sequence of colored items. The first k items are placed in a buffer. In each step, an algorithm selects one of the colors and processes all items of that color currently stored in the buffer, incurring a cost of 1. This is called a block operation. The processed items are removed from the buffer and replaced with the next items from the input sequence (if there are any). The goal is once again to minimize the total cost.

The difference between this block operation setting and the original setting is most pronounced for an input sequence consisting of ℓ items of a single color. While in the original setting such a sequence would not produce any cost, the cost in the block device setting would be ℓ/k since only k items can be processed per block operation.

Minor Variants Found in the Literature

In some cases, there are slight differences in which these problems are defined in the literature. Does a cost incur for the first ever processed item or, similarly, is the first position of the server in the metric space part of the input or does the algorithm get to chose that position (without incurring any cost)? Does an item first have to be placed in the buffer or can the algorithm process an arriving item directly, thereby bypassing the buffer? Do we need to remove the remaining items in the buffer once new items stopped arriving? It turns out however that these details are inconsequential for most of the results we are interested in.

Key Results

The main focus of study in the area of scheduling with a reordering buffer has been on online algorithms. In the online setting, the algorithm's decisions have to be based solely on the items that arrived in the past and must not depend on items arriving in the future. An online algorithm is called c-competitive if the cost of the algorithm is at most c times that of an optimal off-line solution.

The Online Problem

Deterministic Algorithms

Räcke, Sohler, and Westermann [29] first introduced the problem for the uniform metric

and gave a $O(\log^2 k)$-competitive online algorithm. After further improvements to $O(\log k)$ [18] and $O(\log k / \log\log k)$ [6] eventually, an $O(\sqrt{\log k})$-competitive online algorithms was designed [2]. This is almost optimal since a lower bound of $\Omega(\sqrt{\log k / \log\log k})$ is known [2]. Many of these upper bounds also generalize from the uniform metric to star metrics.

While the proof techniques for some of these results differ significantly, the basic idea behind all the algorithms is the same. As long as the buffer contains an item of the same color as the previously processed item, such an item is processed next. Otherwise, the algorithm has to pick a different color and performs a color switch which incurs a cost of 1. In order to decide which color to switch to, each color is assigned a "penalty" counter which is initially set to 0 and is reset to 0 whenever the color is selected for processing. If there is a color with penalty at least k, then an item with that color is selected next. Otherwise, an arbitrary color is selected and the penalty counters for each color are increased proportional to the number of items of that color that are stored in the buffer. For the $O(\sqrt{\log k})$-competitive algorithm, instead of picking an arbitrary color, a more sophisticated rule is used.

Randomized Algorithms

Randomized algorithms can achieve much smaller competitive ratios. The first randomized algorithm with a competitive ratio of $O(\log\log k)$ was given for the block operation model [3]. Shortly afterward, a randomized algorithm with the same competitive ratio was presented for the original model [8]. This is best possible since a matching lower bound is known [2]. These randomized algorithms are based on online primal-dual LP schemes [11].

Other Metric Spaces

Apart from the uniform metric, line metrics have received some attention. After a randomized $O(\log^2 n)$-competitive online algorithm for n equally spaced points on a line [27], an improved deterministic $O(\log n)$-competitive algorithm was given [24]. A deterministic $O(\log N \log\log N)$-competitive algorithm for a line metric with not necessarily equally spaced points was also given, but here N refers to the number of items in the input sequence [24]. An easy observation, however, shaves off the $\log\log N$ factor and improves the analysis to show $O(\log N)$ competitiveness (Cygan, Mucha, Private communication, 2011). There is still a significant gap between this upper bound and the best known lower bound of about 2.154 [24].

For general metric spaces, a randomized $O(\log^2 k \log n)$-competitive online algorithm is known, where n is the number of points in the metric space [19]. This result is based on a deterministic algorithm for trees that is turned into an algorithm for general metrics by using a metric embedding [23].

Stochastic Inputs

In a setting where the input is not adversarial constructed but where the colors of the items are drawn i.i.d. from an unknown distribution, a constant competitive ratio is achievable [22]. This result also holds when the colors of the items are fixed by an adversary but the order in which the items arrive is random. The proof is based on the fact that a constant competitive online algorithm is known for adversarial inputs, if the online algorithm can use a buffer that is four times as large as the one used by the optimal off-line algorithm. In the stochastic input setting, this difference in buffer size does not lead to significantly different cost, i.e., the cost of an optimal algorithm with buffer size k is only by a constant factor larger than the cost of an optimal algorithm with buffer size $4k$. This is not true for adversarial inputs [1].

The Off-Line Problem

The reordering buffer problem is NP-hard [5, 12] for the uniform metric, and the complexity for line metrics is unknown. Therefore, several papers focus on approximating the off-line scenario.

A constant factor approximation is known for the uniform metric [7]. For star metrics, the best known approximation factor of $O(\log\log k\gamma)$ is

achieved by a randomized algorithm, where γ denotes the ratio of the maximum to the minimum weight [25]. Both results are based on the intricate rounding of the solution to an LP relaxation of the corresponding problem.

Bicriteria Approximations

For more general metric spaces, the best approximation ratios are achieved by bicriteria approximations, i.e., the approximation algorithm can make use of more buffer capacity than an optimal algorithm. For metric spaces given by the distance metric over a weighted undirected tree, a bicriteria approximation with approximation factor 9 to cost and $4 + 1/k$ to buffer size is known [10]. Using metric embeddings [23], this implies a randomized bicriteria approximation with approximation factor $O(\log n)$ to cost and $O(1)$ to buffer size, where n denotes the number of points in the metric space.

The Maximization Problem

In the maximization version of the problem, the goal is to maximize the total cost savings that result from reordering the input sequence. In terms of an optimal solution, the minimization and maximization scenario are identical. However, in terms of approximation, they behave quite differently in the sense that a c-approximate solution for the maximization problem usually has very different cost from a c-approximate solution for the minimization problem. For the uniform metric, the first result was an approximation algorithm with an approximation factor of 20 [28]. This was later improved to a factor of 9 [9].

Online Minimum Makespan Scheduling

Reordering buffers have also been studied in connection with other scheduling problems, in particular online minimum makespan scheduling. As in the classic problem without reordering, the input consists of a sequence of jobs with processing times, and a scheduling algorithm has to assign the jobs to m parallel machines, with the objective to minimize the makespan, which is the time it takes until all jobs are processed. However, it is not required that each arriving job has to be assigned immediately to one of the machines. A reordering buffer can be used to reorder the input sequence of jobs. At each point in time, the reordering buffer contains the first k jobs of the input sequence that have not been assigned so far. An online scheduling algorithm has to decide which job to assign to which machine next. Upon its decision, the corresponding job is removed from the buffer and assigned to the corresponding machine, and thereafter the next job in the input sequence takes its place.

Non-preemptive Scheduling

For non-preemptive scheduling, Englert, Özmen, and Westermann [20] give, for m identical machines, a tight bound on the competitive ratio. Depending on m, the achieved competitive ratio lies between 4/3 and 1.4659. This optimal ratio is achieved with a buffer of size of at most $\lceil 2.5 \cdot m \rceil + 2$. They show that larger buffer sizes do not result in an additional advantage and that a buffer of size $\Omega(m)$ is necessary to achieve this competitive ratio. This improves upon an optimal algorithm for two identical machines [26].

Further, they present several algorithms for different buffer sizes. In addition, for m uniformly related machines, they give a scheduling algorithm that achieves a competitive ratio of 2 with a reordering buffer of size m.

Subsequently to [20], a variety of related papers appeared (compare, e.g., [4, 14–16, 21]). For 2 uniformly related machines with speed ratio $s \geq 1$, it is shown that, for any $s > 1$, a buffer of size 3 is sufficient to achieve an optimal competitive ratio, and in the case $s \geq 2$, a buffer of size 2 already allows to achieve an optimal ratio [15].

Job Migrations

The results of [20] can be generalized to the problem of online minimum makespan scheduling with job migrations, i.e., where no reordering buffer is available, but a limited number of job reassignments may be performed. For m identical

machines, the same competitive ratio as in [20] can be achieved [4]. The algorithm uses, for $m \geq 11$, at most $7m$ migration operations and, for smaller m, $8m$ to $10m$ migration operations. A number of papers consider similar models (compare, e.g., [13, 17, 30, 31]).

Preemptive Scheduling

For preemptive scheduling on m identical machines, tight bounds on the competitive ratio can be achieved for any m. This bound is $4/3$ for even values of m and slightly lower for odd values of m [16]. A buffer of size $\Theta(m)$ is sufficient to achieve this bound, but a buffer of size $o(m)$ does not reduce the best overall competitive ratio $e/(e-1)$ that is known for the case without reordering [16].

Problem Definition

The classic secretary problem, a prime example of stopping theory, has been studied extensively in the computer science literature. Consider the scenario where an employer is interested in hiring one secretary out of a pool of candidates. The difficulty is that, although the employer does not know the utility of a candidate before she is interviewed, the irrevocable hiring decision for each candidate has to be made right after the interview and prior to interviewing the subsequent candidates. The goal is nonetheless to pick the best candidate or maximize the probability of achieving this.

Optimization Angle

The above scenario is hopeless from an algorithmic point of view since an adversarial input makes it impossible to hire the best candidate. We can take either of two paths to make the problem tractable: restrict the set of utilities or the arrival order of candidates. The former path yields, for instance, the stochastic variant of the problem. However, we follow the second idea here that leads to the classic secretary problem. The extra assumption, then, is that the candidates arrive in a random error; i.e., although each candidate may have an arbitrary adversarial utility, every permutation of the candidates is equally likely to be the arrival order.

A folklore solution to the problem, often attributed to [3], is to look into the first $\frac{1}{e}$ fraction of the candidates (called the "tuning set"), without giving them any offers, and then hire the first candidate with utility more than every one in the tuning set. It is not difficult to show that this approach hires the best candidate with probability

at least $\frac{1}{e}$. Indeed, it is known that this is the best possible performance.

There are two questions to be answered, once we extend the problem to multiple secretaries.

1. *What subsets of secretaries can be hired together?* The simplest answer is to allow at most k secretaries to be hired. Alternately, we can place (several) knapsack and/or matroid constraints on the feasible set. The former assigns a cost to each hire – say, the requested salary – that is to be paid out of a given budget. The latter permits only those combinations that form an independent set according to a given matroid. It is easy to see that both generalize the cardinality constraint.
2. *How do we compute the utility of a set?* The utility of a set can be defined as the sum of the utilities of individual secretaries in the set. More generally, a submodular or subadditive function may be employed to describe the utility of a set.

We then attempt to hire a feasible set of secretaries of maximum expected utility.

Mechanism Design Angle

Mechanism design literature has looked at this problem from a slightly different angle. In this setting, the players that arrive in a random order declare a *bid* – i.e., how much they value the item being sold – and then the seller decides who should get the item (or items) and how much they should be charged. Such decisions are to be taken irrevocably as in the optimization problem discussed above.

The players can play strategically, though, by declaring higher or lower bids in order to increase their chances of winning the item or to reduce the price they pay. In addition, they may declare their arrival/departure time untruthfully to achieve a better result. We want to design a "truthful" auction that precludes such undesirable outcomes. Although we allow the player to declare any nonnegative bid (if it is in her favor), we do not let them state an arrival time that is earlier than their actual one. (Presence intervals may be overlapping and/or nested.) We say that a mechanism is value-strategyproof if no player can benefit from declaring a bid different from her real value. Similarly the mechanism is called time-strategyproof if there is no benefit in stating the arrival/departure times untruthfully. We look for mechanisms that are both time- and value-strategyproof.

Key Results

Optimization

Kleinberg [6] studies the multiple-choice generalization where the goal is to hire k candidates, whose total utility (defined as the sum of the individual utilities) is maximized. He presents a tight performance guarantee of $1 + \Theta\left(\frac{1}{\sqrt{k}}\right)$ for the problem. In the case of $k = 1$, this is equivalent to the classic secretary problem. (The nontrivial direction follows from a construction where the utilities are hugely different.) Kleinberg's algorithm partitions the set of candidates into two (almost) equal pieces, recursively hires $\frac{k}{2}$ secretaries in the first, sets the threshold for the second piece by looking at the solution to the first piece, and picks as many as $\frac{k}{2}$ secretaries in the second piece who are better than threshold.

Babaioff et al. [1] look at the generalization where there is a restriction on the set of candidates that can be hired together; the restriction is in the form of a matroid. They present an $O(\log n)$ competitive ratio in this case along with improved bounds when the matroid has a special form. Their general matroid algorithm partitions the items into logarithmically many sets of almost equal utility and focuses (randomly) on one such set, which reduces the problem into that of maximizing the cardinality of the solution (solved via the greedy method).

The case of submodular utilities is discussed in Bateni et al. [2]: several matroid or knapsack constraints can be placed on the set of feasible candidates, and the total utility of a set is computed by a submodular function of the participating candidates. They provide constant competitive ratios as long as a fixed number of knapsack

constraints are present. When (a constant number of) matroid constraints are involved, too, their performance guarantees grow to $O(\log^2 k)$ where k is the rank of the matroid. They divide the input into different pieces where at most one secretary should be picked from each, not losing too much utility in the process. As a result, the submodular function collapses to an additive one within each piece (by taking the marginal values of secretaries with respect to the current solution). The classic algorithm is then used inside each piece. The main idea behind the matroid algorithm is that we only need to show that, whatever choices we have already committed to, there are enough options left that can appropriately augment the current solution. The argument goes by proving the existence of a magical solution with k' secretaries any of whose $\frac{k'}{2}$-size subsets has significant contribution (say, at least a $\frac{1}{\log k}$ fraction of the optimum) in the submodular function. Had we known k', a simple greedy algorithm would have sufficed to find a solution similar to the magical set. At the cost of another factor $O(\log k)$, we can guess k'.

Furthermore, Bateni et al. show that subadditive utility functions make the problem much more difficult. In particular, they provide matching $\Theta(\sqrt{k})$ competitive ratios.

Mechanism Design

The Dynkin's algorithm for the classic secretary problem can be readily turned into an auction: set the price after observing the tuning set, and then sell to anyone with a higher bid. This mechanism is not truthful, though, since high-bid players spanning across the time threshold have an incentive to declare later arrival time (i.e., after the threshold); this way, they will win the item but do not set the price.

Nevertheless, Hajiaghayi et al. [5] show how one can modify the mechanism slightly to make it truthful: after the threshold, consider the option of selling the item to the agent with the highest bid so far – if she is still present – and charge her the second-highest bid so far. Their method achieves constant competitiveness for both efficiency and revenue. Their $1/e$ competitiveness for efficiency is best possible since it generalizes the optimization problem; however, when comparing the revenue to that achieved by the Vickrey auction, their upper bound of $1/e^2$ for competitiveness fares against a lower bound of $1/e$. (It is possible, they show, to modify the mechanism slightly to trade efficiency loss for revenue gain; for instance, simultaneous 4 competitiveness for both objectives is possible.)

The general idea for the transformation is to define a "tuning period" where the price is set for everyone. Then, not only a simple auction-like mechanism is employed in the "hiring phase" to obtain a strategyproof mechanism, but also extra care should be given to the "transition phase" (from tuning to hiring) so as not to incentivize untruthful declaration of arrival time for those whose presence spans the transition. The same approach can be applied to the multiple-choice secretary problem to obtain constant-factor competitive mechanisms (for efficiency and revenue), but this bound is far from the one achieved in the optimization setting by Kleinberg [6].

Open Problems

Though there has been some improvements on the matroid case, we still do not know which cases are hard and admit no constant-factor competitive ratio. For submodular utilities (and simple cardinality constraints), in particular, there is a gap between $\left(1-\frac{1}{e}\right)/(e+1)$ algorithmic result [4] and the $1-\frac{1}{e}$ $\left(\text{or } 1-\frac{1}{\sqrt{k}}\right)$ target known for linear utilities.

Problem Definition

Temperature 1 (also called *noncooperative*) self-assembly is a model of the formation of structures by growing and branching tips. Despite its ubiquity in nature (in systems such as plants and mycelium or percolation processes) and apparent dynamic simplicity, it is one of the least understood models of self-assembly.

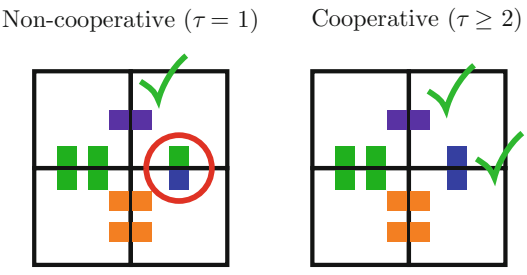
This model was introduced in a broader framework called the *abstract Tile Assembly Model* (aTAM) [10]. In the aTAM, we consider *tile assembly systems*, which are defined by a finite set T of square or cubic *tile types*, an initial *seed assembly* σ (one or more tiles stuck together), and an integer temperature $\tau = 1, 2, 3, \ldots$. All tiles, on each of their sides, have *glues* with an integer *color* and an integer *strength*.

The dynamics of tile self-assembly starts from the seed assembly and proceeds one tile at a time, asynchronously and nondeterministically. A tile can stick to an existing assembly if it can be placed so that the sum of the strengths on its sides matching the existing assembly is at least the temperature. In the case of temperature 1, this means that tiles can be placed as soon as one of their sides matches the existing assembly. At higher temperatures, we can require that newly placed tiles match *several* of their neighbors to attach.

Ultimately, after a countable (potentially infinite) number of steps, no tile can be added to the assembly, in which case we call it *terminal*. Like in Wang tilings, tiles cannot overlap, be rotated, or be flipped. However, tiles can have *mismatches* with their neighbors (Fig. 1).

Key Results

The first comparison between temperatures 1 and 2 was shown by Rothemund and Winfree [9], with the motivation of computing and efficiently



Self-Assembly at Temperature 1, Fig. 1 In the non-cooperative model, tiles can attach as soon as one side matches the neighborhood

building arbitrary shapes at the nanoscale. In this context, the generally accepted definition of "efficient" is *with significantly less tile types than the size of the output*.

Assembling Simple Shapes Efficiently

The first step toward these goals is the programming of simple shapes like squares or trees. At temperature ≥ 2, constructions with Turing machines can be used to show the following bound:

Theorem 1 (from [9]) *The smallest two-dimensional tileset T_n producing only squares of size $n \times n$ from a single-tile seed is of size $\theta\left(\frac{\log n}{\log \log n}\right)$.*

The smallest number of tile types that can assemble exactly a set of shapes is called the *tile complexity* of that set. In the noncooperative model, the following upper bound is known:

Theorem 2 (from [9]) *For all integer n, there is a tileset T_n, of size $2n - 1$, that produces only squares of size $n \times n$ from a single-tile seed.*

Whether this upper bound is optimal is still one of the major open problems of the model, and little progress has been made since its identification. The real motivation behind this question is whether we (or natural systems) can perform useful computations with this model.

Finding the smallest tileset for assembling an input shape can also be treated as an optimization problem: see Adleman et al. [1] for the case of tree shapes.

The Role of Geometry

A partial answer to this question was found by Cook, Fu, and Schweller [2], who tried to "fake" cooperation by blocking the growth of some parts of the assembly. They introduced two different ways to do this: removing the planarity constraint and allowing errors.

In both cases, "faking" cooperation means producing the same assemblies as a temperature 2 tile assembly systems up to rescaling by a constant factor.

Three-Dimensional Noncooperative Self-Assembly

In three dimensions, temperature 1 self-assembly is able to simulate Turing computations:

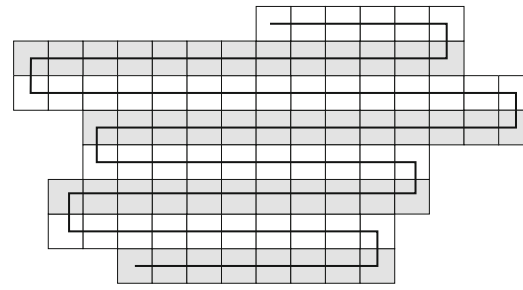
Theorem 3 (from [2]) *There is a three-dimensional tileset T such that for all Turing machine $\mathcal{M}$ and input $x \in \mathbb{N}$, there is a computable seed assembly $\sigma_{\mathcal{M},x}$ and a tile $t \in T$, such that all terminal assemblies of $(T, \sigma_{\mathcal{M},x}, 1)$ contain t if and only if $\mathcal{M}$ accepts input x.*

The construction simulates a Turing-universal cooperative tile assembly system called a *zigzag system*, in which rows grow on top of each other, alternatively to the left and to the right, using cooperation to copy and update the previous row (Fig. 2).

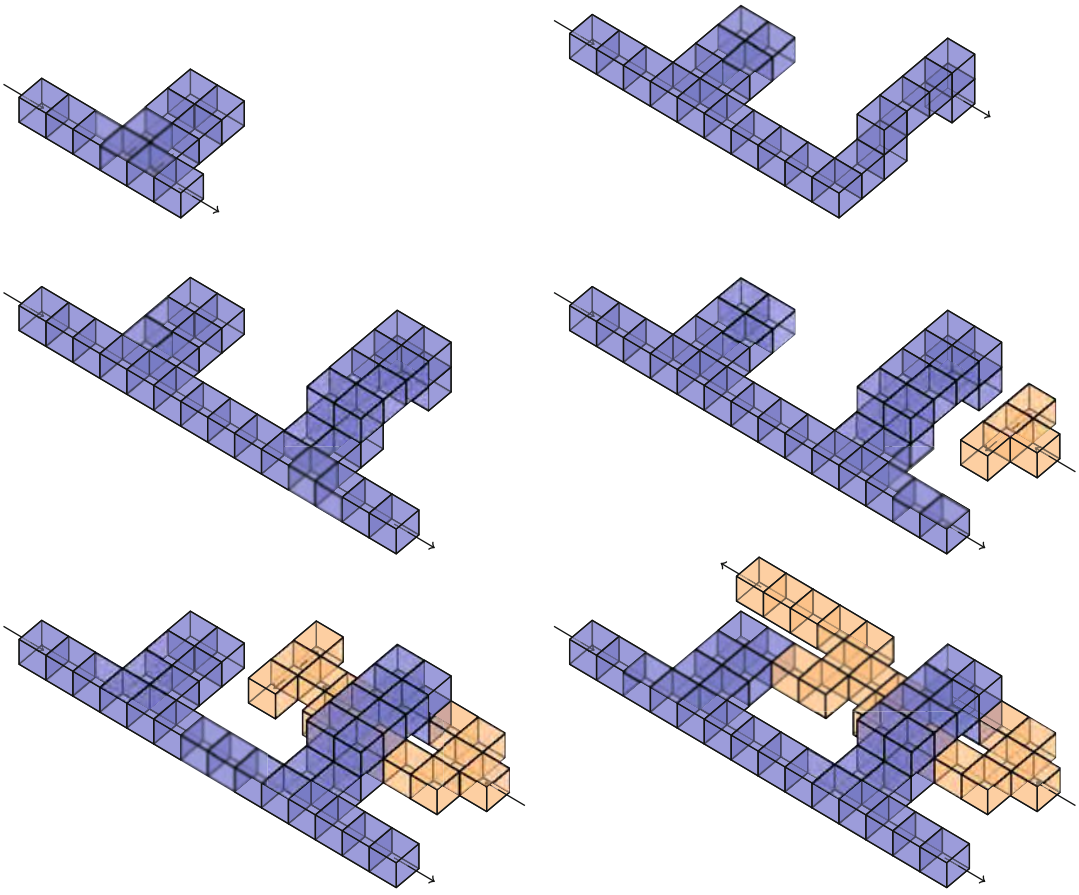
The idea is pictured on Fig. 3. A "main" path grows on each row, building "bridges" and "blockers" (in blue on Fig. 3) that encode bits. These bits can be read by the next row: before reading a bit, the main path (in orange on Fig. 3) of the row forks into two branches, respectively probing for a bridge (encoding a 1) and a blocker (encoding a 0). Exactly one branch passes through and can accumulate successive bits in its state, until a full tile has been read. Then, it rewrites bits encoding the next tile for the row above.

Allowing Erroneous Blocking

Adapting the mechanism used in the 3D construction to the planar case is widely conjectured impossible [9], because allowing the "wrong" branch to grow and collide against a previous



Self-Assembly at Temperature 1, Fig. 2 An example zigzag system (Figure from [2])



Self-Assembly at Temperature 1, Fig. 3 Bit selection in 3d

part of the assembly, in Fig. 3, *encloses* the other "correct" branch inside a finite portion of the plane.

However, it becomes possible if we consider a stochastic assembly schedule, where at each time step, exactly one tile attaches, and all tiles that can attach do so with equal probability. If we repeat the above construction k times consecutively, only one needs to succeed. We can therefore lower the probability of failure of each bit selection to 2^{-k}:

Theorem 4 (from [2]) *For all $\varepsilon > 0$ and all zigzag tile systems $\mathcal{T} = (T, s, 2)$, whose producible assemblies have size at most some constant r, there is a planar temperature 1 probabilistic tile assembly system $\mathcal{S}$ that simulates $\mathcal{T}$ without error with probability at least $1 - \varepsilon$.*

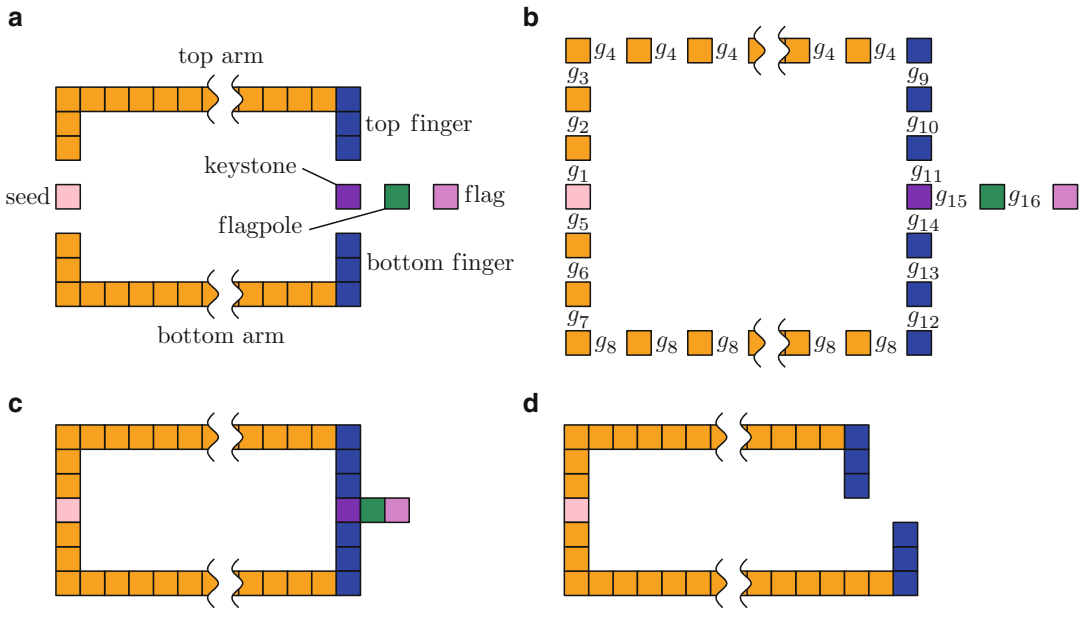
Of course, this construction means that the number of tile types and scaling factor will increase by a factor depending on ε and r.

Simulation up to Rescaling

One of the latest developments of tile assembly is the notion of *intrinsic universality* [3, 4, 11], a notion of simulation by rescaling only between tile assembly systems.

This idea is useful in particular to compare different models, because it provides qualitative properties to check, as opposed to quantitative properties such as tile complexity. The general argument is:

- At temperature 2 in two dimensions, there is a tileset known from [4] to be able to simu-



Self-Assembly at Temperature 1, Fig. 4 Tile assembly system $\mathcal{T}$ (Figure from [7])

late any other tile assembly system, modulo rescaling.

- However, there is a tile assembly system $\mathcal{T}$ that no tileset in model X (in our case, temperature 1) can simulate without errors.
- Therefore, model X is not as powerful as planar temperature 2.

This argument was used, for instance, to prove the first separation result between temperature 2 and the fully general model of temperature 1 [7]:

Theorem 5 (from [7]) *There is a planar (temperature 2) tile assembly system $\mathcal{T}$ (whose productions are pictured on Fig. 4) that no (two- or three- dimensional) tile assembly system $(A, \alpha, 1)$ can simulate up to rescaling.*

The proof uses a combinatorial argument (called the *window movie lemma*) to show that if there were a tile assembly system simulating all productions of $\mathcal{T}$, then it would also be able to produce other "illegal" assemblies (see Fig. 5) that do not represent any of $\mathcal{T}$'s producible assemblies.

Important Particular Cases

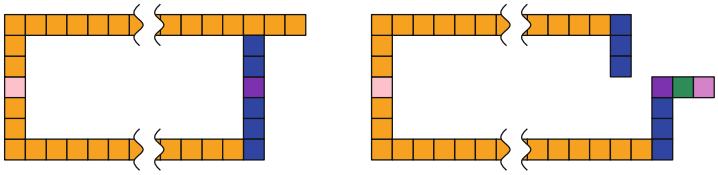
Noncooperative self-assembly, when restricted to dimension one, is similar to nondeterministic finite automata. It is therefore natural to look for a *pumping lemma*.

The first result in this direction was proven by Doty, Patitz, and Summers [5], who introduced the notion of *pumpable paths*: a path P is *pumpable* if it contains a subsegment $P_{i,i+1,\ldots,j}$ that can be repeated arbitrarily many (consecutive) times along $\overrightarrow{P_i P_j}$ while remaining self-avoiding.

Theorem 6 (from [5]) *Let $\mathcal{T}$ be a tile assembly system that assembles exactly one (potentially infinite) terminal assembly α. If any path in α, longer than a constant c, is pumpable, then there are finite families of vectors $\mathbf{b_1}, \ldots, \mathbf{b_n}$, $\mathbf{u_1}, \ldots, \mathbf{u_n}$, and $\mathbf{v_1}, \ldots, \mathbf{v_n} \in \mathbb{Z}^2$, such that:*

$$\mathrm{dom}(\alpha) = \bigcup_{1 \le i \le n} \{\mathbf{b_i} + j\,\mathbf{u_i} + k\,\mathbf{v_i} | j, k \in \mathbb{N}\}$$

In [5], examples were identified, of paths with segments that could be repeated, but only finitely many times due to collisions. The formalization of these examples was later done by Manuch,



Self-Assembly at Temperature 1, Fig. 5 Illegal productions, that a temperature 1 system that can simulate all productions of $\mathcal{T}$ must also be able to simulate (Figure modified from [7])

Stacho, and Stoll [6], proving lower bounds under the hypothesis that no mismatches can occur.

This approach was then extended by Reif and Song [8], to show that tile assembly systems without mismatches have a recursive set of productions. However, the decidability of the "no mismatches" hypothesis is still an open problem.

Applications

Given the successful experimental applications of tile self-assembly, particularly in the field of DNA nanotechnologies, it seems natural to try to implement them: indeed, intuition suggests that they would make no errors in cooperation tiles. However, no successful construction of noncooperative experiments has been reported; the reason might be that ensuring uniqueness of the seed is impossible, as any two tiles in solution together might bind, without any of them being bound to the seed.

Open Problems

Aside from understanding the exact geometric requirements for Turing universality, a number of open problems have been identified in this model:

1. From [9]: What is the tile complexity of squares of size $n \times n$ in the planar, temperature 1 model?

   A related problem, which has been in the folklore for some time, is the existence of a shape of tile complexity arbitrarily smaller than its Manhattan diameter.
2. From [5]: If $\mathcal{T}$ is a tile assembly system with exactly one terminal assembly, is there a constant c such that any path longer than c is pumpable?
3. From [7]: Is there a temperature 1 tile assembly system with a non-recursive set of productions?
4. From [7]: Is there a single tileset able to simulate any temperature 1 tile assembly system up to rescaling, using only noncooperative bindings?

Problem Definition

This problem is concerned with the self-assembly fractal patterns and structures. More specifically, it deals with discrete self-similar fractals and different notions of them self-assembling from tiles in the abstract Tile Assembly Model (aTAM) and derivative models. The self-assembly of fractals and fractal-like structures is particularly interesting due to their pervasiveness in nature, as well their complex aperiodic structures which result in them occupying less dimensional space than the space they are embedded within.

Using the terminology from [1], we define $\mathbb{N}_g$ as the subset $\{0, 1, \ldots, g-1\}$ of $\mathbb{N}$, and if $A, B \subseteq \mathbb{N}^2$ and $k \in \mathbb{N}$, then $A + kB = \{\mathbf{m} + k\mathbf{n} | \mathbf{m} \in A$ and $\mathbf{n} \in B\}$. We then define discrete self-similar fractals as follows.

We say that $\mathbf{X} \subset \mathbb{N}^2$ is a *discrete self-similar fractal* (or *dssf* for short) if there exist $1 < g \in \mathbb{N}$ and a set $\{(0,0)\} \subset G \subset \mathbb{N}_g^2$ with at least one point in every row and column, such that $\mathbf{X} = \bigcup_{i=1}^{\infty} X_i$, where X_i, the ith stage of $\mathbf{X}$, is defined by $X_1 = G$ and $X_{i+1} = X_i + g^i G$. We say that G is the generator of $\mathbf{X}$.

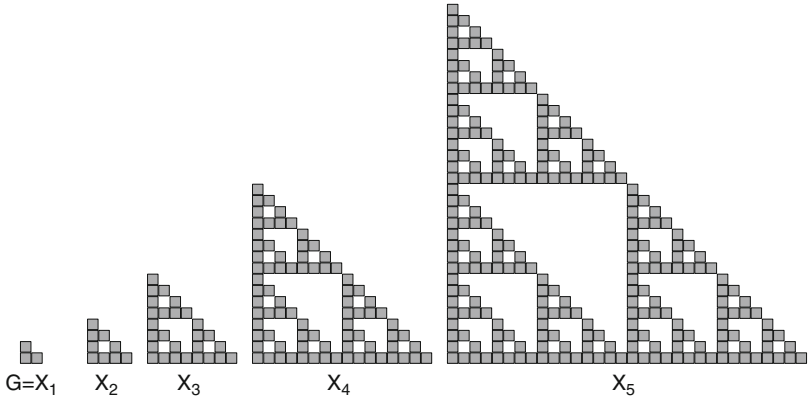
Figure 1 shows, as an example, the first 5 stages of the discrete self-similar fractal known as the Sierpinski triangle. In this example, $G = \{(0,0), (1,0), (0,1)\}$.

In general, we ask whether or not a given dssf $\mathbf{X}$ can self-assemble within a given model.

Variants

The general problem of determining whether or not a discrete self-similar fractal self-assembles within a given model has several variants, which determine the way in which the fractal shape is represented within a resulting assembly.

1. **Weak self-assembly.** If a dssf $\mathbf{X}$ weakly self-assembles using a tile set T, then there exists a subset of tile types $B \subseteq T$ such that, in



Self-Assembly of Fractals, Fig. 1 Example discrete self-similar fractal: the first 5 stages of the Sierpinski triangle

the terminal assembly α, for every point $\mathbf{p} \in \text{dom}\,\alpha$ such that $\mathbf{p} \in \mathbf{X}$, the tile type at location $\mathbf{p}$ in α is a type within B, and for every point $\mathbf{p} \in \text{dom}\,\alpha$ such that $\mathbf{p} \notin \mathbf{X}$, the tile type at location $\mathbf{p}$ in α is not within B. That is, the tile types in the subset B precisely "paint a picture" of $\mathbf{X}$, while tiles of types not in B may appear in locations outside of $\mathbf{X}$.

2. **Strict self-assembly.** If a dssf $\mathbf{X}$ strictly self-assembles, then it weakly self-assembles with $B = T$, i.e., the locations that exist in the domain of the terminal assembly are exactly those of $\mathbf{X}$.
3. **Approximate self-assembly.** A dssf $\mathbf{X}$, and thus a strictly self-assembled version of $\mathbf{X}$, has fractal dimension (i.e., zeta-dimension [3]) <2, and a weakly self-assembled version has dimension 2. Since it appears to be difficult if not impossible to strictly self-assemble many (or all) dssf's, it is interesting to consider if an approximation of a dssf $\mathbf{X}$ which retains the same fractal dimension as $\mathbf{X}$ can strictly self-assemble.

Key Results

Self-assembly of dssf's has been studied in all of the above variants and within the aTAM, 2HAM, and STAM [9]. As previously mentioned, the complexity of dssf's makes them interesting to study since they are infinite, aperiodic structures. This requires any system in which they self-assemble to rely on algorithmic self-assembly (rather than unique tile types hard coded to each position of the shape), and for this reason early experimental results even included the weak self-assembly of the initial few stages of the Sierpinski triangle [11] as a proof of concept that DNA-based tile implementations of the aTAM are capable of algorithmic self-assembly. Nonetheless, as infinite structures, dssf's are more often the focus of theoretical studies.

Weak Self-Assembly

As seen in [11], it is possible for a very simple tile set of only 7 tile types to weakly self-assemble the Sierpinski triangle. This tile set can essentially be thought of as computing the `xor` function on two inputs (i.e., $00 \to 0$, $01 \to 1$, $10 \to 1$, and $11 \to 0$), with the glues with which a tile initially binds to an assembly encoding the input bits and those to which tiles later attach encoding the output bits.

In [4] it was noted that another characterization of the Sierpinski triangle is as the nonzero residues modulo 2 of Pascal's triangle. They then provided a characterization of an infinite class of dssf's, known as *generalized Sierpinski carpets*, which can be defined as the residues, modulo a prime number, of the entries in a two-dimensional matrix generated by a simple recursive equation. (A well-known example among this class of

dssf's is the Sierpinski carpet.) They then proved that all generalized Sierpinski carpets weakly self-assemble in the aTAM.

Strict Self-Assembly

Although weak self-assembly of many dssf's can be achieved with very simple tile sets, it turns out that strict self-assembly is an entirely different, and much more difficult, problem. In fact, in [6] they proved that it is impossible for the Sierpinski triangle to strictly self-assemble in the aTAM. Furthermore, their proof showed that to be the case regardless of the temperature parameter. This result was extended in [10] to a proof that an infinite class of "pinch-point" dssf's, which includes the Sierpinski triangle, cannot strictly self-assemble in the aTAM at any temperature. Pinch-point fractals are those whose generators have exactly one point in their topmost row, the leftmost, and one in their eastmost column, the bottommost. Yet another extension was provided in [1], where the authors defined "tree" fractals, which again include the Sierpinski triangle, as those with generators which are trees and which have a single point in their topmost row and a single point in their rightmost column. They then proved that, regardless of the temperature or even of the scale factor, no tree fractal strictly self-assembles in the aTAM.

Additional results related to strict self-assembly of dssf's include the proof in [10] that in the aTAM at temperature 1 (i.e., systems with $\tau = 1$), it is impossible for any dssf to self-assemble within a locally deterministic system (see [12] for a definition of local determinism), and in [2] it was proven that the Sierpinski triangle also cannot self-assemble in the 2-Handed Assembly Model, at any temperature.

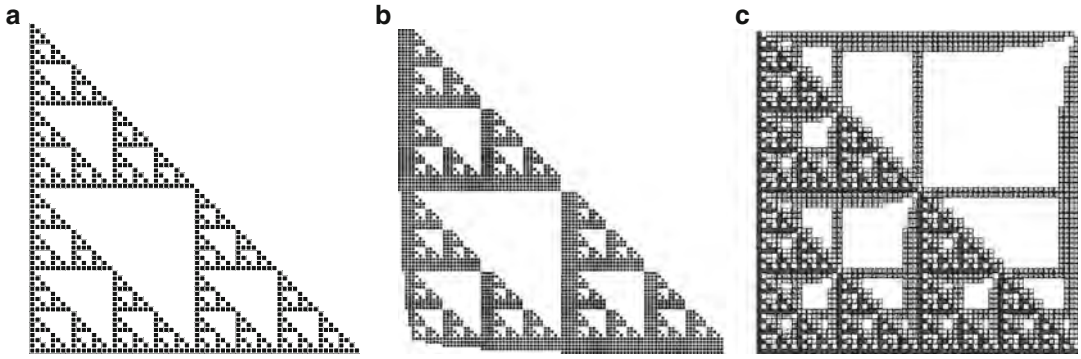
To date, the single positive result related to the strict self-assembly of a dssf is for an "active" model of self-assembly, where tiles are allowed to change the states of their glues during assembly, called the Signal-passing Tile Assembly Model (STAM). In [9] they gave a construction proving that the Sierpinski triangle can self-assemble within the STAM at temperature 1 and scale factor 2. By the result of [1], this is impossible in the aTAM and demonstrates the power of the active nature of the STAM, as that construction essentially builds stages of the Sierpinski triangle in a manner analogous to weak self-assembly, but then causes the unwanted interior portions to dissociate and then break apart.

Approximate Self-Assembly

It has been shown that an infinite subset of dssf's can weakly self-assemble in the aTAM, while another infinite subset cannot strictly self-assemble. Recall also that dssf's have fractal dimension <2, and since their strictly self-assembled versions retain their original fractal dimensions, so do they. However, their weakly self-assembled versions have dimension 2. Therefore, the question arises about whether or not some transformation of a dssf (especially, a dssf which cannot strictly self-assemble), which visually approximates the original dssf while retaining its fractal dimension, can strictly self-assemble in the aTAM.

This question was first answered positively in [6], where they defined a transformation for the Sierpinski triangle which they called "fibering," and they then gave a construction proving that the so-called fibered Sierpinski triangle does strictly self-assemble in the aTAM while maintaining the Sierpinski triangle's fractal dimension of ≈ 1.585. An example can be seen in Fig. 2b, showing how the fibering consists an additional row of tiles added to the south and west borders of each copy of each subsequent stage of the fractal. In [10] they extended the technique of fibering to include an infinite subclass of dssf's (which again includes the Sierpinski triangle) which they called "nice" dssf's. Nice dssf's are those whose generators are connected and contain all points on the west and south boundaries.

While the fibering technique creates visual approximations of fractals, it results in subsequent stages being further and further separated from each other. To counter this drawback, in [8] they introduced a technique for fibering the Sierpinski triangle "in place." An example can be seen in Fig. 2c, showing how this version of fibering only uses space on the interior of each stage of the fractal, thus allowing the stages to remain in the same positions relative to each other.



Self-Assembly of Fractals, Fig. 2 Various patterns corresponding to the Sierpinski triangle. (**a**) A portion of the discrete Sierpinski triangle. (**b**) A portion of the fibered Sierpinski triangle of [7] (Figure from [7]). (**c**) A portion of the in-place fibered Sierpinski triangle of [8] (Figure from [8])

Furthermore, this technique retains the same fractal dimension as the Sierpinski triangle, and they showed that it is impossible to use asymptotically less space than their construction while strictly self-assembling a shape which contains the Sierpinski triangle as a subset. In [5] this technique was extended to strictly self-assemble approximations for every generalized Sierpinski carpet.

Open Problems

1. Does there exist a discrete self-similar fractal which can strictly self-assemble in the aTAM, or conversely, can it be shown that none does?
2. What is the class of discrete self-similar fractals for which an approximation, such as fibering or in-place fibering, which maintains the original fractal dimension, strictly self-assembles in the aTAM?

Problem Definition

Abstract Tile Assembly Model

The abstract Tile Assembly Model (aTAM) [3] is a mathematical model of self-assembly in which system components are four-sided Wang tiles with glue types assigned to each tile edge. Any pair of glue types are assigned some nonnegative interaction strength denoting how strongly the pair of glues bind. An aTAM system is an ordered triplet (T, τ, σ) consisting of a set of tiles T, a positive integer threshold parameter τ called the system's *temperature*, and a special tile $\sigma \in T$ denoted as the *seed* tile. Assembly proceeds by attaching copies of tiles from T to a growing seed assembly whenever the placement of a tile on the 2D grid achieves a total strength of attachment from abutting edges, determined by the sum of pairwise glue interactions, that meets or exceeds the temperature parameter τ. The pairwise strength assignment between glues on tile edges is often restricted to be "linear" in that identical glue pairs may be assigned arbitrary positive values, while non-equal pairs are required to have interaction strengths of 0. We denote this restricted version of the model as the *standard* aTAM. When this restriction is not applied, i.e., any pair of glues may be assigned any positive integer strength, we call the model the *flexible glue* aTAM.

Given the aTAM's model of growth, we may consider the problem of designing an aTAM system which is guaranteed to grow into a target shape S, given by a set of 2D integer coordinates, and stop growing. Such systems are guaranteed to exist for any finite shape S, but solutions will typically vary in the number of tiles $|T|$ used. For a given shape S, an interesting problem is to design a system that assembles S while using the fewest, or close to the fewest, number of tiles $|T|$ possible. This fewest possible number of tiles required for the assembly of a given shape S is termed the *program-size* complexity of S.

Problem 1 Let $K_{SA}(n)$ and $K_{SA}^{\sim}(n)$ denote the program-size complexity of an $n \times n$ square for the standard aTAM and the flexible glue aTAM, respectively. What are $K_{SA}(n)$ and $K_{SA}^{\sim}(n)$?

Problem 2 Let $K_{SA}(n,k)$ and $K_{SA}^{\sim}(n,k)$ denote the program-size complexity of a $k \times n$ rectangle for the standard aTAM and the flexible glue aTAM, respectively. What are $K_{SA}(n,k)$ and $K_{SA}^{\sim}(n,k)$?

Problem 3 For an arbitrary given shape S, what is the program-size complexity of S? Let the *scale-free* program size of S be the smallest tile set system that uniquely builds some scaled-up version S. Let $K_{SA}(S)$ and $K_{SA}^{\sim}(S)$ denote the *scale-free* program size of S for the standard aTAM and the flexible glue aTAM, respectively. What are $K_{SA}(S)$ and $K_{SA}^{\sim}(S)$?

Key Results

The best known bounds for program-size complexity for squares, rectangles, and general scaled shapes are presented in this section.

$n \times n$ Squares

The efficient self-assembly of $n \times n$ squares has served as a benchmark for self-assembly algorithms within the aTAM and more general tile assembly models. Within the aTAM, the problem is well understood up to constant factors. The first result states a general upper bound for the program size of self-assembled squares for general n, which is matched by an information-theoretic lower bound that holds for almost all integers n. The precise bounds differ between the standard and flexible glue models but are tight in both cases. The lower bound of inequality (1) is proven in [3] and is based on the Kolmogorov complexity of the integer n. The lower bound of (2) is proven in [2] by the same approach. The upper bound of (1) is proven in [1] and offers an improvement over the initial upper bound of $O(\log n)$ from [3]. The $O(\log n)$ result of [3] is achieved by implementing a key primitive in tile self-assembly: a binary counter of $\log n$ tiles that grows to length n. The improvement of [1] is achieved by modifying the counter concept to work with an optimal, variable base. The upper bound of (2) is proven in [2] and is obtained by combining the aTAM counter primitives with a scheme for efficiently seeding the counter by extracting bits from the values of the flexible glue interactions.

Theorem 1 *There exist positive constants c_1 and c_2 such that for almost all integers $n \in \mathbb{N}$, the following inequalities hold. Moreover, the upper bounds hold for all $n \in \mathbb{N}$.*

$$c_1 \frac{\log n}{\log \log n} \leq K_{SA}(n) \leq c_2 \frac{\log n}{\log \log n}. \quad (1)$$

$$c_1 \sqrt{\log n} \leq K_{SA}^{\sim}(n) \leq c_2 \sqrt{\log n}. \quad (2)$$

While the above theorem presents a tight understanding of the program-size complexity for most self-assembled squares, the information-theoretic lower bound allows for special values of n to be assembled with a much smaller program size. The program size is in fact as small as one could reasonably hope for. In [3], a tile system is presented that simulates a Busy Beaver Turing Machine and assembles correspondingly large squares for each tile set size. This construction yields the following theorem implying that the largest self-assembled square for a given number of tiles grows faster than any computable function!

Theorem 2 *There exists a positive constant c such that for infinitely many n, $K_{SA}(n) \leq c f(n)$ for $f(n)$ any nondecreasing unbounded computable function.*

Thin Rectangles

The program size of self-assembled squares and other thick rectangles is dictated by information-theoretic bounds which stem from the aTAM's ability to simulate arbitrary Turing machines given enough geometric space to work within. When this space is cut down, such as in the case of building a thin $k \times n$ rectangle, the program size is limited by geometric factors. The following upper and lower bounds are shown in [2] and represent the best known bounds for *thin* $k \times n$ rectangles in which $k = O(\log / \log \log n)$. The lower bound is achieved by a pigeon-hole pumping argument on the types of tiles placed, along with their order of placement, along a

width k column of the target rectangle. The upper bound is based on the construction of a general-base, general-width counter, which generalizes the binary counter concept of [3].

Theorem 3 *There exist positive constants c_1 and c_2 such that for any $n, k \in \mathbb{N}$, the following inequalities hold.*

$$c_1 \frac{n^{1/k}}{k} \leq K^{\sim}_{SA}(n,k) \leq K_{SA}(n,k) \leq c_2(n^{1/k}+k).$$

Scaled Shapes

The program size of general shapes is difficult to analyze as it is highly dependent on geometric features of the target shape. However, if we consider the assembly of an arbitrarily scaled-up version of a target shape, these geometric difficulties can be eliminated and a very general result can be achieved. The next result from [4] shows that the scale-free program size of S is closely related to the Kolmogorov complexity of S. In particular, the scale-free program-size complexity of S is a log factor less than the Kolmogorov complexity of S for the standard model, and the scale-free program size complexity of S is the square root of the Kolmogorov complexity of S for the flexible glue model. The standard model result is shown in [4] and is achieved by encoding a compressed description of S in a small tile set which is extracted by a set of tiles simulating a Turing machine that extracts the pixels of S from this compressed representation. The need for the scale factor increase of S is to allow room for the Turing machine simulation. In fact, the required scale factor is the run time of the Turing machine that decompresses the optimal encoding of S. The flexible glue result is achieved by combining portions of the flexible glue construction for squares [2] with the construction of [4]. In the following theorem, $K(S)$ denotes the Kolmogorov complexity of S with respect to some fixed universal Turing machine.

Theorem 4 *For any shape S, there exist positive constants c_1 and c_2 such that*

$$c_1 \frac{K(S)}{\log K(S)} \leq K_{SA}(S) \leq c_2 \frac{K(S)}{\log K(S)}. \quad (3)$$

$$c_1 \sqrt{K(S)} \leq K^{\sim}_{SA}(S) \leq c_2 \sqrt{K(S)}. \quad (4)$$

Open Problems

A few important open problems in this area are as follows. In the case of squares, the program size is well understood as long as the temperature of the system is at least two. A long-standing open problem has been to determine the program-size complexity of $n \times n$ squares for temperature-1 self-assembly in which each positive glue force alone is sufficient to cause a tile attachment. To date, no known method is able to achieve $o(n)$ tile complexity at temperature-1 for an $n \times n$ square, but no proof exists that this cannot be done. With respect to thin $k \times n$ rectangles, the best upper and lower bound have a gap with respect to variable k. Does there exist a more efficient rectangle construction, or can a higher lower bound be derived? Finally, while the scale-free program-size complexity of general shapes is well understood, little is known about the (unscaled) program size of general shapes. What new tools and geometric classifications can be developed to analyze and bound this complexity for general shapes?

Problem Definition

Self-assembly is an asynchronous, decentralized process in which particles aggregate to form superstructures according to localized interactions. The most well-studied models of these particle systems, e.g., the abstract Tile Assembly Model of Winfree [11], utilize square-shaped particles arranged on a lattice by attaching edgewise. Particles attach to form larger *assemblies*, and a pair of assemblies or tiles can attach if they can translate to a nonoverlapping configuration with a set of k coincident edges, where $k \geq \tau$, a parameter of the system called the *temperature*.

In *seeded* assembly, individual particles attach to a growing *seed assembly*. This assembly may begin as a single-tile or a multi-tile assembly. In *unseeded* assembly (also called *hierarchical* [3], *two-handed* [2], or *polyomino* [7] assembly), there is no such restriction. The set of assemblies to which a single tile cannot attach (in seeded assembly) or that cannot attach to any other assembly (in unseeded assembly) are the *terminal assemblies* of the system.

Objectives In general, the goal is to design a system of minimal complexity that assembles into a unique terminal assembly with a desired shape or property. In models using square tiles, this is equivalent to designing a system using the fewest tile types. When tiles are allowed to be more general shapes, then the option of trading tile types for tile complexity becomes available. The motivation for this work is to understand how more complex tile shapes can be used to reduce the number of tile types in a system, and two benchmark problems regarding the computational power and efficiency of tile systems are considered in the context of systems of non-square tiles:

Problem 1 (Square Assembly)

INPUT*: A natural number n.*
OUTPUT*: A self-assembly system with a unique terminal assembly consisting of n^2 tiles in a $n \times n$ square shape.*

Problem 2 (Computational Power) *What systems of non-square tiles are capable of simulating computation, and to what extent?*

Key Results

In general, it is the case that allowing non-square tiles permits an asymptotic reduction in the number of tile types, and systems of very

few non-square tiles are capable of universal computation. At a high-level, such reductions are achieved by simulating many tiles via translations and rotations of a single tile type.

Models

Fu, Patitz, Schweller, and Sheline [6] introduce two models of general shaped types. The first, called the *geometric Tile Assembly Model (gTAM)*, is a model of seeded, translation-only assembly where tiles are polyomino-shaped – equivalent to prebuilt assemblies of square tiles. The second is an unseeded version they call the *Two-Handed Planar Geometric Tile Assembly Model (2GAM)*, which has the added restriction that assemblies can only attach if there exists a continuous motion bringing the two assemblies together during which they remain disjoint. This can be thought of as a restriction that the assemblies live in the plane and do not make use of the third dimension to maneuver into place.

Demaine et al. [4] introduce the *polygonal free-body Tile Assembly Model (pfbTAM)* in which tiles may have arbitrary simple polygonal shapes, attaching edgewise along equal-length edges. Systems without and without rotation are both permitted – we note that rotation is forbidden in the gTAM and 2GAM (as well as the aTAM).

Efficient Construction

Fu, Patitz, Schweller, and Sheline [6] prove that both the gTAM and 2GAM allow an asymptotic reduction in the number of tiles needed to assemble an $n \times n$ square of tiles. For the gTAM, they prove that such a square can be assembled using a temperature-1 system of $O(\sqrt{\log n})$ tile types, beating the optimal (temperature-2) system of $\Omega(\log n / \log \log n)$ square tiles by Adleman et al. [1]. This is a reduction in both the number of tile types (by a quadratic factor) and temperature. The temperature reduction is especially significant, as a lower bound of $\Omega(n)$ for temperature-1 aTAM systems is a widely believed conjecture [8–10].

For the 2GAM, they reduce the number of tile types even further, using a temperature-2 system $O(\log \log n)$ tile types to assemble an $n \times n$ square. However, this system comes with the caveat that system makes use of either a disconnected tile shape or a slightly three-dimensional shape.

Computational Power

Positive results on the computational power of general shaped tile systems fall into two categories: Turing universality and bounded-time computation. Fu, Patitz, Schweller, and Sheline [6] prove that any Turing machine computation can be carried out by a temperature-1 gTAM system. As with the temperature-1 construction of squares, this result is surprising due to the open conjecture regarding the computational power of square tile systems at temperature 1.

Demaine et al. [4] prove that any Turing machine computation can be carried out by a temperature-2 pfbTAM system (with rotation) consisting of a single tile. Their result actually proves that any aTAM system can be simulated by such a system, and thus Turing universality is achieved by simulating aTAM systems carrying out computation. Combined with the intrinsic universality result of Doty et al. [5], this result can be extended to prove that a *single* temperature-2 pfbTAM system (with rotation) consisting of a single tile can carry out any Turing machine computation, given an appropriate seed assembly consisting of copies of this tile.

Finally, Demaine et al. also prove that temperature-3 pfbTAM systems (*without* rotation) consisting of a single tile can carry out simulation of computationally universal cellular automata for a number of steps limited by the size of the seed assembly. Specifically, they prove that n steps can be carried out using a seed assembly of $O(n)$ tiles. A loose lower bound is also proved, namely, that more than three tiles are needed to carry out any computation.

Applications

The generic ability to reduce the number of tile types in a system by increasing the geometric complexity of these tiles extends many other

constructions in theoretical tile assembly. Additionally, there may be practical barriers to systems of many tile types, e.g., additional cost of manufacturing or longer assembly time due to heterogenous combinations of many particle types, that can be reduced or eliminated by replacing these systems with systems of fewer, more complex tile.

Open Problems

Obtaining an upper bound on the number of steps of a cellular automaton simulable by single-tile translation-only systems remains open. It is conjectured that a seed assembly of size n can only carry out $O(n^2)$ steps.

Problem Definition

In bin packing games with selfish items, n items are to be packed into (at most) n bins, where each item chooses a bin that it wishes to be packed

into. The cost of an item i of size $0 < s_i \leq 1$ is defined based on its size and the contents of its bin. Nash equilibria (NE) are defined as solutions where there is no item that can change its choice unilaterally and gain from this change. Bin packing games were inspired by the well-known bin packing problem [2]. In this problem, a set of items, each of size in $(0, 1]$, is given. The goal is to partition (or pack) the items into a minimum number of subsets that are called *bins*. Each bin has unit capacity, and the load of a bin is defined to be the total size of items packed into it (where the load cannot exceed 1). The problem is NP-hard in the strong sense, and thus theoretical research has focused on studying and developing approximation algorithms, which allow to design nearly optimal solutions, and on online algorithms, which receive the items one by one and must assign each item to a bin immediately and irrevocably (without any information on further items).

In a bin packing game, every item is operated by a selfish player. There are n bins, and the strategy of a player is the bin that it selects. If the resulting packing is valid (i.e., the load of no bin exceeds 1), then the set of items sharing a bin share its cost proportionally, i.e., let B be a bin (a subset of items). The cost of $i \in B$ is $s_i / \left(\sum_{j \in B} s_j \right)$. If the resulting packing is invalid, any item packed into an invalid bin has infinite cost. We are interested in pure Nash equilibria, and by the term NE, we refer to such an equilibrium. The problem was presented by Bilò [1].

There are several directions which can be explored. First, one would like to find out if any bin packing game has an NE. If this is the case, other kinds of equilibria might be of interest as well. For a class of games (such that each of them has an NE), a process of convergence is defined as follows. The process starts with an arbitrary configuration, and at each time, an item that can reduce its cost is selected and moved to another bin (where the cost of this item will be smaller than its cost before it is moved). Such a process can also be seen as local search. Items are moved one at a time; a single move (for one item) is called a step. Note that one item can participate in multiple steps. The questions which can be asked are whether the process converges for any initial packing (i.e., reaches a state that no further step can be applied) and how large can the number of steps be. As it turns out, any bin packing game has at least one NE, and the processes described here always converge [1, 8]. Since it is possible that the process converges in exponential time, it is of interest to develop a polynomial time algorithm that computes NE packings. Such an algorithm for this problem defined above was designed by Yu and Zhang [9]. Finally, once the existence of NE packing has been established, the primary goal becomes the study of the quality of worst-case equilibria. This concept is called *price of anarchy*. For a given game G (i.e., a set of items which is an input for bin packing), the price of anarchy of this game, denoted by $POA(G)$, is the ratio between the maximum number of nonempty bins in any NE packing and the minimum number of bins in any packing (the number of bins in an optimal packing, also called the social optimum, denoted by $OPT(G)$). The price of stability is similar, but best-case equilibria are studied, and as Bilò [1] proved that any game has a social optimum that is an NE, the price of stability is 1 for any game.

The price of anarchy (POA) of a class of games (here, the class of all bin packing games) is defined to be the supremum POA over all games in the class. However, as bin packing is typically studied with respect to the asymptotic approximation ratio, the POA for the bin packing class of games is defined, similarly to the asymptotic approximation ratio, as $\lim_{M \to \infty} \sup_{\{G : OPT(G) \geq M\}} POA(G)$.

Key Results

The POA was studied already in [1], where Bilò provided the first bounds on it, a lower bound of $\frac{8}{5}$ and an upper bound of $\frac{5}{3}$. The quality of NE solutions was further investigated in [4], where nearly tight bounds for the PoA were given, an

upper bound of 1.6428 and a lower bound of 1.6416 (see also [9]). The parametric POA, which is the POA for subclasses of games where the size of no item exceeds a given value, was considered as well [5].

NE packings are related to outputs of the algorithm First Fit (FF) for bin packing [7]. FF is in fact an online algorithm that packs each item, in turn, into a minimum index bin where it fits (using an empty bin if there is no other option). It is not difficult to see that every NE is an output of FF; sort the bins of the NE by non-increasing loads, and create a list of items according to the ordering of bins. FF will create exactly the bins of the original packing. Interestingly, the POA is significantly smaller than the asymptotic approximation ratio of FF (which is equal to 1.7 [7]). Note that the PoA is not equal to the approximation ratio of any natural algorithm for bin packing.

Some intuition regarding the difference between the asymptotic approximation ratio of First Fit and the POA of this class of games can be shown using a small example. Consider items of the following sizes (for a sufficiently small $\varepsilon > 0$): $\frac{1}{6} - 2\varepsilon$ (small items), $\frac{1}{3} + \varepsilon$ (medium items), and $\frac{1}{2} + \varepsilon$ (large items). The worst-case examples for FF are similar to this example, though the items of the first two types have a number of different sizes; small items can be slightly smaller or slightly larger than $\frac{1}{6}$, and medium items can be slightly smaller or slightly larger than $\frac{1}{3}$. Given the item types defined above, assume that there are $6N$ items of each type (for some positive integer N), when FF receives this input (sorted by non-decreasing size), it creates N bins with six small items packed into each bin, $3N$ bins with two medium items packed into each bin, and the remaining items are packed into dedicated bins. This packing is not an NE, as a medium item reduces its cost from $\frac{1}{2}$ to approximately $\frac{2}{5}$ if it joins a large item. Indeed, roughly speaking, if an NE packing consists of a large number of bins (compared to an optimal solution), a bin of this NE packing either has an item whose size exceeds $\frac{1}{2}$ or its load cannot be as small as approximately $\frac{2}{3}$. This allows a tighter analysis. Interestingly, in worst-case examples for the POA, medium items have sizes that are close to $\frac{1}{4}$ instead of $\frac{1}{3}$.

Related Results

Bin packing games, where the cost of an item is defined differently, were studied. One option is to assign equal costs to all players (which are packed together into a valid bin) [3, 6]. A generalized version where each item has a positive weight, and costs are based on cost sharing proportional to the weights of items that share a bin [3] was studied as well. The weights of items in the games described above (those of [1, 4]) are equal to their sizes. These are two classes of games, for which the POA turns out to be of interest. The POA for the class of games with equal weights is slightly (strictly) below 1.7, and in the case of general weights, the POA is equal to 1.7 [3]. Another topic of interest is the quality of other kinds of equilibria. Those are strong equilibria, which are solutions that are also resilient to deviations of subsets of items reducing their costs, and Pareto optimal equilibria, where the solution is required to be weakly (or strictly) Pareto optimal, that is, there is no alternative packing where all items reduce their costs (or a packing where no item increases its cost and at least one item reduces it) [3]. For these last kinds of equilibria, the POA is still above 1.6 (but at most 1.7).

Problem Definition

Consider having a set of resources E in a system. For each $e \in E$, let $d_e(\cdot)$ be the delay per user that requests its service, as a function of the total usage of this resource by all the users. Each such function is considered to be non−decreasing in the total usage of the corresponding resource. Each resource may be represented by a pair of points: an entry point to the resource and an exit point from it. So, each resource is represented by an arc from its entry point to its exit point and the model associates with this arc the cost (e.g., the delay as a function of the load of this resource) that each user has to pay if she is served by this resource. The entry/exit points of the resources need not be unique; they may coincide in order to express the possibility of offering joint service to users, that consists of a sequence of resources. Here, denote by V the set of all entry/exit points of the resources in the system. Any nonempty collection of resources corresponding to a directed path in $G \equiv (V, E)$ comprises an *action* in the system.

Let $N \equiv [n]$ be a set of users, each willing to adopt some action in the system. $\forall i \in N$, let w_i denote user i's *demand* (e.g., the flow rate from a source node to a destination node), while $\Pi_i \subseteq 2^E \setminus \emptyset$ is the collection of actions, any of which would satisfy user i (e.g., alternative routes from a source to a destination node, if G represents a communication network). The collection Π_i is called the *action set* of user i and each of its elements contains at least one resource. Any vector $\boldsymbol{r} = (r_1, \ldots, r_n) \in \Pi \equiv \times_{i=1}^{n} \Pi_i$ is a *pure strategies profile*, or a *configuration* of the users. Any vector of real functions $\boldsymbol{p} = (p_1, p_2, \ldots, p_n)$ s.t. $\forall i \in [n]$, $p_i : \Pi_i \to [0, 1]$ is a probability distribution over the set of allowable actions for user i (i.e., $\sum_{r_i \in \Pi_i} p_i(r_i) = 1$), and is called a *mixed strategies profile* for the n users.

A congestion model typically deals with users of identical demands, and thus, user cost function depending on the *number* of users adopting each action [1, 4, 6]. In this work the more general case is considered, where a *weighted congestion model* is the tuple $((w_i)_{i \in N}, (\Pi_i)_{i \in N}, (d_e)_{e \in E})$. That is, the users are allowed to have different demands for service from the whole system, and thus affect the resource delay functions in a different way, depending on their own weights.

A *weighted congestion game* associated with this model, is a game in strategic form with the set of users N and user demands $(w_i)_{i\in N}$, the action sets $(\Pi_i)_{i\in N}$ and cost functions $(\lambda^i_{r_i})_{i\in N, r_i\in\Pi_i}$ defined as follows: For any configuration $\boldsymbol{r}\in\Pi$ and $\forall e\in E$, let $\Lambda_e(\boldsymbol{r})=\{i\in N : e\in r_i\}$ be the set of users exploiting resource e according to $\boldsymbol{r}$ (called the *view* of resource e wrt configuration $\boldsymbol{r}$). The *cost* $\lambda^i(\boldsymbol{r})$ *of user* i *for adopting strategy* $r_i\in\Pi_i$ in a given configuration $\boldsymbol{r}$ is equal to the cumulative *delay* $\lambda_{r_i}(\boldsymbol{r})$ along this path:

$$\lambda^i(\boldsymbol{r})=\lambda_{r_i}(\boldsymbol{r})=\sum_{e\in r_i} d_e(\theta_e(\boldsymbol{r})) \qquad (1)$$

where, $\forall e\in E, \theta_e(\boldsymbol{r})\equiv\sum_{i\in\Lambda_e(\boldsymbol{r})} w_i$ is the load on resource e wrt the configuration $\boldsymbol{r}$.

On the other hand, for a mixed strategies profile $\boldsymbol{p}$, the *expected cost of user* i *for adopting strategy* $r_i\in\Pi_i$ is

$$\lambda^i_{r_i}(\boldsymbol{p})=\sum_{\boldsymbol{r^{-i}}\in\Pi^{-i}} P(\boldsymbol{p^{-i}},\boldsymbol{r^{-i}})\cdot \sum_{e\in r_i} d_e\left(\theta_e(\boldsymbol{r^{-i}}\oplus r_i)\right) \qquad (2)$$

where, $\boldsymbol{r^{-i}}$ is a configuration of all the users except for user i, $\boldsymbol{p^{-i}}$ is the mixed strategies profile of all users except for i, $\boldsymbol{r^{-i}}\oplus r_i$ is the new configuration with user i choosing strategy r_i, and $P(\boldsymbol{p^{-i}},\boldsymbol{r^{-i}})\equiv\prod_{j\in N\setminus\{i\}} p_j(r_j)$ is the occurrence probability of $\boldsymbol{r^{-i}}$.

Remark 1 Here notation is abused a little bit and the model considers the user costs $\lambda^i_{r_i}$ as functions whose exact definition depends on the other users' strategies: In the general case of a mixed strategies profile $\boldsymbol{p}$, (2) is valid and expresses the expected cost of user i wrt $\boldsymbol{p}$, conditioned on the event that i chooses path r_i. If the other users adopt a pure strategies profile $\boldsymbol{r^{-i}}$, we get the special form of (1) that expresses the exact cost of user i choosing action r_i.

A congestion game in which all users are indistinguishable (i.e., they have the same user cost functions) and have the same action set, is called *symmetric*. When each user's action set Π_i consists of sets of resources that comprise (simple) paths between a unique origin-destination pair of nodes (s_i,t_i) in a network $G=(V,E)$, the model refers to a *network congestion game*. If additionally all origin-destination pairs of the users coincide with a unique pair (s,t) one gets a *single commodity network congestion game* and then all users share exactly the same action set. Observe that a single-commodity network congestion game is not necessarily symmetric because the users may have different demands and thus their cost functions will also differ.

Selfish Behavior

Fix an arbitrary (mixed in general) strategies profile $\boldsymbol{p}$ for a congestion game $\left((w_i)_{i\in N},(\Pi_i)_{i\in N},(d_e)_{e\in E}\right)$. We say that $\boldsymbol{p}$ is a *Nash Equilibrium (NE)* if and only if $\forall i\in N, \forall r_i,\pi_i\in\Pi_i, p_i(r_i)>0\Rightarrow\lambda^i_{r_i}(\boldsymbol{p})\le\lambda^i_{\pi_i}(\boldsymbol{p})$. A configuration $\boldsymbol{r}\in\Pi$ is a *Pure Nash Equilibrium (PNE)* if and only if $(\forall i\in N,\forall\pi_i\in\Pi_i,\lambda_{r_i}(\boldsymbol{r})\le\lambda_{\pi_i}(\boldsymbol{r^{-i}}\oplus\pi_i)$ where, $\boldsymbol{r}^{-i}\oplus\pi_i$ is the same configuration with $\boldsymbol{r}$ except for user i that now chooses action π_i.

Key Results

In this section the article deals with the existence and tractability of PNE in weighted network congestion games. First, it is shown that it is not always the case that a PNE exists, even for a weighted single-commodity network congestion game with only linear and 2-wise linear (e.g., the maximum of two linear functions) resource delays. In contrast, it is well known [1, 6] that any unweighted (not necessarily single-commodity, or even network) congestion game has a PNE, for any kind of nondecreasing delays. It should be mentioned that the same result has been independently proved also by [3].

Lemma 1 *There exist instances of weighted single–commodity network congestion games with resource delays being either linear or 2–wise linear functions of the loads, for which there is no PNE.*

Theorem 2 *For any weighted multi–commodity network congestion game with linear resource delays, at least one PNE exists and can be computed in pseudo-polynomial time.*

Proof Fix an arbitrary network $G = (V, E)$ with linear resource/edge delays $d_e(x) = a_e x + b_e$, $e \in E$, $a_e, b_e \geq 0$. Let $\boldsymbol{r} \in \Pi$ be an arbitrary configuration for the corresponding weighted multi–commodity congestion game on G. For the configuration r consider the potential $\Phi(\boldsymbol{r}) = C(\boldsymbol{r}) + W(\boldsymbol{r})$, where

$$C(\boldsymbol{r}) = \sum_{e \in E} d_e(\theta_e(\boldsymbol{r}))\theta_e(\boldsymbol{r}) = \sum_{e \in E} [a_e \theta_e^2(\boldsymbol{r}) + b_e \theta_e(\boldsymbol{r})],$$

and

$$W(\boldsymbol{r}) = \sum_{i=1}^{n} \sum_{e \in r_i} d_e(w_i) w_i = \sum_{e \in E} \sum_{i \in \widetilde{e}(\boldsymbol{r})} d_e(w_i) w_i = \sum_{e \in E} \sum_{i \in \widetilde{e}(\boldsymbol{r})} (a_e w_i^2 + b_e w_i)$$

one concludes that

$$\Phi(\boldsymbol{r}') - \Phi(\boldsymbol{r}) = 2w_i [\lambda^i(\boldsymbol{r}') - \lambda^i(\boldsymbol{r})] ,$$

Note that the potential is a global system function whose changes are proportional to selfish cost improvements of any user. The global minima of the potential then correspond to configurations in which no user can improve her cost acting unilaterally. Therefore, any weighted multi–commodity network congestion game with linear resource delays admits a PNE. □

Applications

In [5] many experiments have been conducted for several classes of pragmatic networks. The experiments show even faster convergence to pure Nash Equilibria.

Open Problems

The Potential function reported here is polynomial on the loads of the users. It is open whether one can find a purely combinatorial potential, which will allow strong polynomial time for finding Pure Nash equilibria.

1974; Dijkstra

Problem Definition

An algorithm is self-stabilizing if it eventually manifests correct behavior regardless of initial state. The general problem is to devise self-stabilizing solutions for a specified task. The property of self-stabilization is now known to be feasible for a variety of tasks in distributed computing. Self-stabilization is important for distributed systems and network protocols subject to transient faults. Self-stabilizing systems automatically recover from faults that corrupt state.

The operational interpretation of self-stabilization is depicted in Fig. 1. Part (a) of the figure is an informal presentation of the behavior of a self-stabilizing system, with time on the x-axis and some informal measure of correctness on the y-axis. The curve illustrates a system trajectory, through a sequence of states, during execution. At the initial state, the system state is incorrect; later, the system enters a correct state, then returns to an incorrect state, and subsequently stabilizes to an indefinite period where all states are correct. This period of stability is disrupted by a transient fault that moves the system to an incorrect state, after which the scenario above repeats. Part (b) of the figure illustrates the scenario in terms of state predicates. The box represents the predicate *true*, which characterizes all possible states. Predicate $\mathcal{C}$ characterizes the correct states of the system, and $\mathcal{L} \subset \mathcal{C}$ depicts the closed *legitimacy* predicate. Reaching a state in $\mathcal{L}$ corresponds to entering a period of stability in part (a). Given an algorithm A with this type of behavior, it is said that A self-stabilizes to $\mathcal{L}$; when $\mathcal{L}$ is implicitly understood, the statement is simplified to: A is self-stabilizing.

Problem [3]. The first setting for self-stabilization posed by Dijkstra is a ring of n processes numbered 0 through $n-1$. Let the state of process i be denoted by $x[i]$. Communication is unidirectional in the ring using a *shared state* model. An atomic step of process i can be expressed by a guarded assignment of the form $g(x[i \ominus 1], x[i]) \rightarrow x[i] := f(x[i \ominus 1], x[i])$. Here, $\ominus$ is subtraction modulo n, so that $x[i \ominus 1]$ is the state of the previous process in the ring with respect to process i. The guard g is a boolean expression; if $g(x[i \ominus 1], x[i])$ is *true*, then process i is said to be *privileged* (or enabled). Thus in one atomic step, privileged process i reads the state of the previous process and computes a new state. Execution scheduling is controlled by a *central daemon*, which fairly chooses one among all enabled processes to take the next step. The problem is to devise g and f so that, regardless of initial states of $x[i]$, $0 \leq i < n$, eventually there is one privilege and every process enjoys a privilege infinitely often.

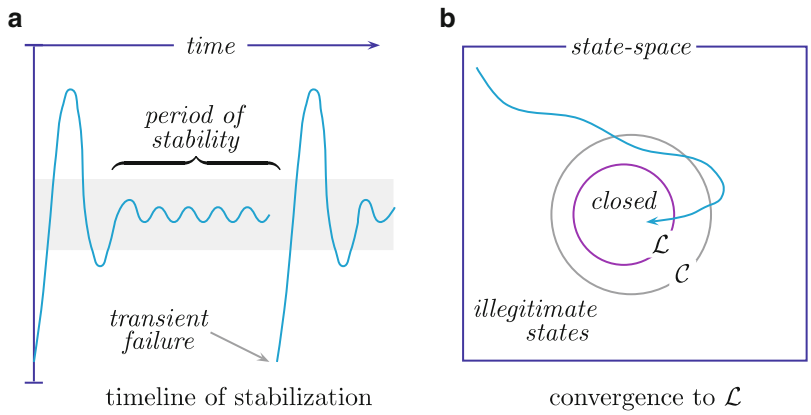
Complexity Metrics

The complexity of self-stabilization is evaluated by measuring the resource needed for convergence from an arbitrary initial state. Most prominent in the literature of self-stabilization are metrics for worst-case time of convergence and space required by an algorithm solving the given task. Additionally, for reactive self-stabilizing algorithms, metrics are evaluated for the stable behavior of the algorithm, that is, starting from a legitimate state, and compared to non-stabilizing algorithms, to measure costs of self-stabilization.

Key Results

Composition

Many self-stabilizing protocols have a layered construction. Let $\{ A_i \}_{i=0}^{m-1}$ be a set programs with the property that for every state variable x, if program A_i writes x, then no program A_j, for $j > i$, writes x. Programs in $\{ A_j \}_{j=i+1}^{m-1}$ may read variables written by A_i, that is, they use the output of A_i as input. Fair composition of programs B and C, written $B \,[]\, C$, assumes fair scheduling of steps of B and C. Let X_j be the set



Self-Stabilization, Fig. 1 Self-stabilization trajectories

of variables read by A_j and possibly written by $\{ A_i \}_{i=0}^{j-1}$.

Theorem 1 (Fair Composition [4]) *Suppose A_i is self-stabilizing to $\mathcal{L}_i$ under the assumption that all variables in X_i remain constant throughout any execution; then $A_0 [] A_1 [] \cdots [] A_{m-1}$ self-stabilizes to $\{ \mathcal{L}_i \}_{i=0}^{m-1}$.*

Fair composition with a layered set $\{ A_i \}_{i=0}^{m-1}$ corresponds to sequential composition of phases in a distributed algorithm. For instance, let B be a self-stabilizing algorithm for mutual exclusion in a network that assumes the existence of a rooted, spanning tree and let algorithm C be a self-stabilizing algorithm to construct a rooted spanning tree in a connected network; then $B [] C$ is a self-stabilizing mutual exclusion algorithm for a connected network.

Synchronization Tasks

One question related to the problem posed in section "Problem Definition" is whether or not there can be a *uniform* solution, where all processes have identical algorithms. Dijkstra's result for the unidirectional ring is a semi-uniform solution (all but one process have the same algorithm), using n states per process. The state of each process is a counter: process 0 increments the counter modulo k, where $k \geq n$ suffices for convergence; the other processes copy the counter of the preceding process in the ring. At a legitimate state, each time process 0 increments the counter, the resulting value is different from all other counters in the ring. This ring algorithm turns out to be self-stabilizing for the *distributed daemon* (any subset of privileged processes may execute in parallel) when $k > n$. Subsequent results have established that mutual exclusion on a unidirection ring is $\Theta(1)$ space per process with a non-uniform solution. Deterministic uniform solutions to this task are generally impossible, with the exceptional case where n is and prime. Randomized uniform solutions are known for arbitrary n, using $O(\lg \alpha)$ space where α is the smallest number that does not divide n. Some lower bounds on space for uniform solutions are derived in [7]. Time complexity of Dijkstra's algorithm is $O(n^2)$ rounds, and some randomized solutions have been shown to have expected $O(n^2)$ convergence time.

Dijkstra also presented a solution to mutual exclusion for a linear array of processes, using $O(1)$ space per process [3]. This result was later generalized to a rooted tree of processes, but with mutual exclusion relaxed to having one privilege along any path from root to leaf. Subsequent research built on this theme, showing how tasks for distributed wave computations have self-stabilizing solutions. Tasks of phase synchronization and clock synchronization have also been solved. See reference [9] for an example of self-stabilizing mutual exclusion in a multiprocessor shared memory model.

Graph Algorithms

Communication networks are commonly represented with graph models and the need for distributed graph algorithms that tolerate

transient faults motivates study of such tasks. Specific results in this area include self-stabilizing algorithms for spanning trees, center-finding, matching, planarity testing, coloring, finding independent sets, and so forth. Generally, all graph tasks can be solved by self-stabilizing algorithms: tasks that have network topology and possibly related factors, such as edge weights, for input, and define outputs to be a function of the inputs, can be solved by general methods for self-stabilization. These general methods require considerable space and time resource, and may also use stronger model assumptions than needed for specific tasks, for instance unique process identifiers and an assumed bound on network diameter. Therefore research continues on graph algorithms.

One discovery emerging from research on self-stabilizing graph algorithms is the difference between algorithms that terminate and those that continuously change state, even after outputs are stable. Consider the task of constructing a spanning tree rooted at process r. Some algorithms self-stabilize to the property that, for every $p \neq r$, the variable u_p refers to p's parent in the spanning tree and the state remains unchanged. Other algorithms are self-stabilizing protocols for token circulation with the side-effect that the circulation route of the token establishes a spanning tree. The former type of algorithm has $O(\lg n)$ space per process, whereas the latter has $O(\lg \delta)$ where δ is the degree (number of neighbors) of a process. This difference was formalized in the notion of *silent* algorithms, which eventually stop changing any communication value; it was shown in [5] for the link register model that silent algorithms for many graph tasks have $\Omega(\lg n)$ space.

Transformation

The simple presentation of [3] is enabled by the abstract computation model, which hides details of communication, program control, and atomicity. Self-stabilization becomes more complicated when considering conventional architectures that have messages, buffers, and program counters. A natural question is how to transform or refine self-stabilizing algorithms expressed in abstract models to concrete models closer to practice. As an example, consider the problem of transforming algorithms written for the central daemon to the distributed daemon model. This transformation can be reduced to finding a self-stabilizing token-passing algorithm for the distributed daemon model such that, eventually, no two neighboring processes concurrently have a token; multiple tokens can increase the efficiency of the transformation.

General Methods

The general problem of constructing a self-stabilizing algorithm for an input nonreactive task can be solved using standard tools of distributed computing: snapshot, broadcast, system reset, and synchronization tasks are building blocks so that the global state can be continuously validated (in some fortunate cases $\mathcal{L}$ can be locally checked and corrected). These building blocks have self-stabilizing solutions, enabling the general approach.

Fault Tolerance

The connection between self-stabilization and transient faults is implicit in the definition. Self-stabilization is also applicable in executions that asynchronously change inputs, silently crash and restart, and perturb communication [10]. One objection to the mechanism of self-stabilization, particularly when general methods are applied, is that a small transient fault can lead to a system-wide correction. This problem has been investigated, for example in [8], where it is shown how convergence can be optimized for a limited number of faults. Self-stabilization has also been combined with other types of failure tolerance, though this is not always possible: the task of counting the number of processes in a ring has no self-stabilizing solution in the shared state model if a process may crash [1], unless a failure detector is provided.

Applications

Many network protocols are self-stabilizing by the following simple strategy: periodically,

they discard current data and regenerate it from trusted information sources. This idea does not work in purely asynchronous systems; the availability of real-time clocks enables the simple strategy. Similarly, watchdogs with hardware clocks can provide an effective basis for self-stabilization [6].

Problem Definition

Semi-supervised learning [1, 4, 5, 8, 12] refers to the problem of using a large unlabeled data set U together with a given labeled data set L in order to generate prediction rules that are more accurate on new data than would have been achieved using just L alone. Semi-supervised learning is motivated by the fact that in many settings (e.g., document classification, image classification, speech recognition), unlabeled data is plentiful but labeled data is more limited or expensive, e.g., due to the need for human labelers. Therefore, one would like to make use of the unlabeled data if possible.

The general idea behind semi-supervised learning is that unlabeled data, while missing the labels, nonetheless often contains useful information. As an example, suppose one believes the correct decision boundary for some classification problem should be a linear separator that separates most of the data by a large margin. By observing enough unlabeled data to estimate the probability mass near to any given linear separator, one could in principle then discard separators in advance that slice through dense regions and instead focus attention on just

those that indeed separate most of the distribution by a large margin. This is the high-level idea behind semi-supervised SVMs. Alternatively, suppose data objects can be described by two different "kinds" of features, and one believes that each kind should be sufficient to produce an accurate classifier. Then one might want to train a *pair* of classifiers and use unlabeled data for which one classifier is confident but the other is not to bootstrap, labeling such examples with the confident classifier and then feeding them as training data to the less-confident classifier. This is the high-level idea behind Co-Training. Or, if one believes "similar examples should generally have the same label," one might construct a graph with an edge between examples that are sufficiently similar and aim for a classifier that is correct on the labeled data and has a small cut value on the unlabeled data; this is the high-level idea behind graph-based methods. (These will all be discussed in more detail later.) General surveys of semi-supervised learning appear in [5, 12].

A Formal Framework

We now present a formal model for analyzing semi-supervised learning due to Balcan and Blum [1]. This model was developed to provide a unified explanation for a wide range of semi-supervised learning algorithms including the semi-supervised SVMs, Co-Training, and graph-based methods mentioned above. Before describing it, however, we first describe the classic PAC and agnostic learning models for *supervised* learning that this model builds on.

In the PAC and agnostic learning models, data is assumed to be drawn iid from some fixed but initially unknown distribution D over an instance space $\mathcal{X}$ and labeled by some unknown target function $c^* : \mathcal{X} \to \{0, 1\}$. The *error* of some hypothesis function h is defined as $\text{err}(h) = \Pr_{x\sim D}[h(x) \neq c^*(x)]$. In the PAC model (also known as the *realizable case*), we assume that c^* is a member of some known class of functions $\mathcal{C}$, and we say that an algorithm PAC-learns $\mathcal{C}$ if for any given $\epsilon, \delta > 0$, with probability $\geq 1 - \delta$, it produces a hypothesis h such that $\text{err}(h) \leq \epsilon$. In the *agnostic case*, we do not assume that $c^* \in \mathcal{C}$ and instead aim to achieve error close to $\inf_{f\in\mathcal{C}}[\text{err}(f)]$.

The PAC and agnostic learning models in essence assume that one's prior beliefs about the target be described in terms of a class of functions $\mathcal{C}$. In order to capture the reasoning used in semi-supervised learning, however, we need to also describe beliefs about the *relation* between the target function and the data distribution. This is done in the model of Balcan and Blum [1] via a *notion of compatibility* χ between a hypothesis h and a distribution D. Formally, χ maps pairs (h, D) to $[0, 1]$ with $\chi(h, D) = 1$ meaning that h is highly compatible with D and $\chi(h, D) = 0$ meaning that h is very *in*compatible with D. The quantity $1 - \chi(h, D)$ is called the *unlabeled error rate* of h and denoted $\text{err}_{\text{unl}}(h)$. Note that for χ to be useful, it must be estimatable from a finite sample; to this end, χ is further required to be an expectation over individual examples. That is, overloading notation for convenience, we require $\chi(h, D) = \mathbf{E}_{x\sim D}[\chi(h, x)]$, where $\chi : \mathcal{C} \times \mathcal{X} \to [0, 1]$. As with the class $\mathcal{C}$, one can either assume that the target is fully compatible ($\text{err}_{\text{unl}}(c^*) = 0$) or instead aim to do well as a function of how compatible the target is. The case that we assume $c^* \in \mathcal{C}$ and $\text{err}_{\text{unl}}(c^*) = 0$ is termed the "doubly realizable case." The concept class $\mathcal{C}$ and compatibility notion χ are both viewed as *known*.

Examples

Suppose we believe the target should separate most data by a large margin γ. We can represent this belief by defining $\chi(h, x) = 0$ if x is within distance γ of the decision boundary of h and $\chi(h, x) = 1$ otherwise. In this case, $\text{err}_{\text{unl}}(h)$ will denote the probability mass of D within distance γ of h's decision boundary. Alternatively, if we do not wish to commit to a specific value of γ, we could define $\chi(h, x)$ to be a smooth function of the distance of x to the separator defined by h. As a very different example, in co-training (described in more detail below), we assume each example can be described using two "views" that each are sufficient for classification, that is, there exist c_1^*, c_2^* such that for each example $x = \langle x_1, x_2\rangle$, we have $c_1^*(x_1) = c_2^*(x_2)$. We can represent this belief by defining a hypothesis

$h = \langle h_1, h_2 \rangle$ to be compatible with an example $\langle x_1, x_2 \rangle$ if $h_1(x_1) = h_2(x_2)$ and incompatible otherwise; $\text{err}_{\text{unl}}(h)$ is then the probability mass of examples, under D, where the two halves of h disagree.

Intuition

In this framework, the way that unlabeled data helps in learning can be intuitively described as follows. Suppose one is given a concept class $\mathcal{C}$ (such as linear separators) and a compatibility notion χ (such as penalizing h for points within distance γ of the decision boundary). Suppose also that one believes $c^* \in \mathcal{C}$ (or at least is close) and that $\text{err}_{\text{unl}}(c^*) = 0$ (or at least is small). Then, unlabeled data can help by allowing one to estimate the *unlabeled error rate* of all $h \in \mathcal{C}$, thereby in principle reducing the search space from $\mathcal{C}$ (all linear separators) down to just the subset of $\mathcal{C}$ that is highly compatible with D. The key challenge is how this can be done efficiently (in theory, in practice, or both) for natural notions of compatibility, as well as identifying types of compatibility that data in important problems can be expected to satisfy.

Key Results

The following, from [1], illustrate formally how unlabeled data can help in this model. Fix some concept class $\mathcal{C}$ and compatibility notion χ. Given a labeled sample L, define $\widehat{\text{err}}(h)$ to be the fraction of mistakes of h on L. Given an unlabeled sample U, define $\chi(h, U) = \mathbf{E}_{x \sim U}[\chi(h, x)]$ and define $\widehat{\text{err}}_{\text{unl}}(h) = 1 - \chi(h, U)$. That is, $\widehat{\text{err}}(h)$ and $\widehat{\text{err}}_{\text{unl}}(h)$ are the empirical error rate and unlabeled error rate of h, respectively. Finally, given $\alpha > 0$, define $\mathcal{C}_{D,\chi}(\alpha)$ to be the set of functions $f \in \mathcal{C}$ such that $\text{err}_{\text{unl}}(f) \leq \alpha$.

Theorem 1 ([1]) *If $c^* \in \mathcal{C}$ then with probability at least $1 - \delta$, for a random labeled set L and unlabeled set U, the $h \in \mathcal{C}$ that optimizes $\widehat{\text{err}}_{\text{unl}}(h)$ subject to $\widehat{\text{err}}(h) = 0$ will have $\text{err}(h) \leq \epsilon$ for*

$$|U| \geq \frac{2}{\epsilon^2}\left[\ln|\mathcal{C}| + \ln\frac{4}{\delta}\right],$$

$$|L| \geq \frac{1}{\epsilon}\left[\ln|\mathcal{C}_{D,\chi}(\text{err}_{\text{unl}}(c^*) + 2\epsilon)| + \ln\frac{2}{\delta}\right].$$

Equivalently, for $|U|$ satisfying the above bound, for any $|L|$, with probability at least $1 - \delta$, the $h \in \mathcal{C}$ that optimizes $\widehat{\text{err}}_{\text{unl}}(h)$ subject to $\widehat{\text{err}}(h) = 0$ has

$$\text{err}(h) \leq \frac{1}{|L|}\left[\ln|\mathcal{C}_{D,\chi}(\text{err}_{\text{unl}}(c^*) + 2\epsilon)| + \ln\frac{2}{\delta}\right].$$

One can view Theorem 1 as bounding the number of labeled examples needed to learn well as a function of the "helpfulness" of the distribution D with respect to χ, for sufficiently large U. Namely, a helpful distribution is one in which $\mathcal{C}_{D,\chi}(\alpha)$ is small for α slightly larger than the compatibility of the true target function, so we do not need much labeled data to identify a good function among those in $\mathcal{C}_{D,\chi}(\alpha)$.

For infinite hypothesis classes, one needs to consider both the complexity of the class $\mathcal{C}$ and the complexity of the compatibility notion χ. Specifically, given $h \in \mathcal{C}$, define $\chi_h(x) = \chi(h, x)$ and let $\text{VCdim}(\chi(\mathcal{C}))$ denote the VC-dimension of the set $\{\chi_h | h \in \mathcal{C}\}$. A sample complexity bound from [1] based on ϵ-cover size is the following.

Theorem 2 ([1]) *Assume $c^* \in \mathcal{C}$ and let p be the size of the smallest set of functions H such that every function in $\mathcal{C}_{D,\chi}(\text{err}_{\text{unl}}(c^*) + \epsilon/3)$ is $\epsilon/6$-close to some function in H. Then $|U| = O\left(\frac{\max[\text{VCdim}(\mathcal{C}), \text{VCdim}(\chi(\mathcal{C}))]}{\epsilon^2}\ln\frac{1}{\epsilon} + \frac{1}{\epsilon^2}\ln\frac{2}{\delta}\right)$ and $|L| = O\left(\frac{1}{\epsilon}\ln\frac{p}{\delta}\right)$ is sufficient to identify a function $f \in \mathcal{C}$ of error at most ϵ with probability at least $1 - \delta$.*

Finally, for the general (agnostic) case that $c^* \notin \mathcal{C}$, we can define a regularizer based on empirical unlabeled error rates, and then get good bounds for optimizing a combination of the empirical labeled error and the regularization term. Specifically, for a hypothesis h, define $\hat{N}(h)$ to be the number of ways of partitioning the first $|L|$ points in U using $\{f \in \mathcal{C} : \widehat{\text{err}}_{\text{unl}}(f) \leq \widehat{\text{err}}_{\text{unl}}(h)\}$. Then we have

Theorem 3 ([1]) *With probability at least* $1-\delta$, *the hypothesis*

$$h = \arg\min_{h' \in \mathcal{C}} [\widehat{\text{err}}(h') + R(h')], \quad \textit{where}$$

$$R(h') = \sqrt{\frac{24 \ln(\hat{N}(h'))}{|L|}},$$

satisfies

$$\text{err}(h) \leq \min_{h' \in \mathcal{C}} \left[\text{err}(h') + R(h')\right] + 5\sqrt{\frac{\ln(8/\delta)}{|L|}}.$$

Co-Training

Co-Training is a semi-supervised learning method due to [4] for settings in which examples can be thought of as having two "views," that is, two distinct types of information. For example, in classifying webpages (e.g., into student home page, faculty member home page, course home page, etc.), one could use the words on the page itself, but one could also use information from links pointing *to* that page [4]. Or, in classifying visual images, one might have two cameras or even two different filters or preprocessing steps on images from the same camera [9]. Or, in understanding video, one can use visual images and spoken dialogue [7]. In such settings, one can think of an example x as a pair $x = \langle x_1, x_2 \rangle$. The idea of Co-Training is that if each view is in principle enough to achieve a good classification by itself, but each provides somewhat different information, then one can hope to improve performance using unlabeled data. Specifically, in Co-Training, one maintains two hypotheses, one for each view (e.g., a hypothesis that classifies webpages based on the text on the page itself and one that classifies webpages based on information from links pointing to the page). A hypothesis pair $h = \langle h_1, h_2 \rangle$ is compatible with an example $\langle x_1, x_2 \rangle$ if $h_1(x_1) = h_2(x_2)$ and is incompatible otherwise. So the unlabeled error rate of a hypothesis (pair) $h = \langle h_1, h_2 \rangle$ is the probability mass of examples $\langle x_1, x_2 \rangle$ on which the two parts of h disagree.

In practice, there are two primary ways that this notion of compatibility is used to learn from a small amount of labeled data and a large amount of unlabeled data. The first is *iterative co-training*, introduced in [4]. In iterative co-training, a small labeled sample L is used to produce predictors for each view that are confident in some part of their respective input spaces and not confident in other parts. Then, the algorithm searches through the (large) unlabeled set U to find examples $x = \langle x_1, x_2 \rangle$ for which one classifier is confident and the other is not. These examples are labeled by the confident classifier and handed to the less-confident classifier to improve its predictor. The other primary method is to optimize a global objective that combines accuracy over the labeled sample L with agreement over the unlabeled sample U. That is, one searches for the hypothesis pair h that minimizes $\widehat{\text{err}}(h) + \lambda \widehat{\text{err}}_{\text{unl}}(h)$ for some regularization parameter λ [6, 10]. This is generally a non-convex optimization problem, and so various heuristics are typically applied to perform the optimization.

Theoretically, the guarantees for Co-Training are strongest when the data satisfies independence given the label (with some probability p, a random positive example $\langle x_1, x_2 \rangle$ is drawn from $D_1^+ \times D_2^+$, and with probability $1-p$, a random negative example is drawn from $D_1^- \times D_2^-$) and in the realizable case (there exist targets $c_1^*, c_2^* \in \mathcal{C}$ such that all examples $\langle x_1, x_2 \rangle$ in the support of the distribution satisfy $c_1^*(x_1) = c_2^*(x_2)$). Specifically, two key results are

Theorem 4 ([4]) *Any class* $\mathcal{C}$ *that is efficiently PAC-learnable from random classification noise is efficiently learnable from unlabeled data alone in the realizable Co-Training setting, if data satisfies independence given the label and one is given an initial weakly useful predictor* $h_1(x_1)$.

Here, h is a *weakly useful predictor* of a function f if for some $\epsilon > 1/poly(n)$ we have both (a) $\Pr_{x \sim D}[h(x) = 1] \geq \epsilon$ and (b) $\Pr_{x \sim D}[f(x) = 1 | h(x) = 1] \geq \Pr_{x \sim D}[f(x) = 1] + \epsilon$. Theorem 4 implies that if one is able to use a small labeled sample to produce an initial hypothesis that gives a slight "edge" in predicting the target beyond just the overall class probabilities, then under independence given the label one can boost that to a high-accuracy predictor from just unlabeled data.

Furthermore, ignoring computation time, under independence given the label, any class of finite VC-dimension is learnable from a single labeled example. In the case of linear separators, this can be done computationally efficiently.

Theorem 5 ([1]) *Any class $\mathcal{C}$ of finite VC-dimension is learnable from polynomially many unlabeled examples and a single labeled example if D satisfies independence given the label. Furthermore, for linear separators this can be done in polynomial time.*

Semi-supervised SVMs

Semi-supervised SVMs (also called transductive SVMs) [8, 11] aim to find a linear separator that separates both the labeled sample L and the unlabeled sample U by the largest possible margin. That is, one wants to find a separator such that for γ as large as possible, all labeled examples are on the correct side of the separator by distance at least γ and all unlabeled examples are on *some* side of the separator by distance at least γ. In practice, one combines a large-margin objective with a hinge-loss penalty for labeled examples that fail to satisfy the condition, and a "hat-loss" penalty for unlabeled examples that fail to satisfy the condition. Formally, the goal is to minimize $c_1 w^T w + c_2 \sum_{(x_i,y_i)\in L} \alpha_i + c_3 \sum_{x_j \in U} \beta_j$ subject to $(w^T x_i) y_i \geq 1 - \alpha_i$ for all $(x_i, y_i) \in L$ and $(w^T x_j)\tilde{y}_j \geq 1 - \beta_j$ for all $x_j \in U$ (and $\alpha_i, \beta_j \geq 0$), where $y_i \in \{-1, 1\}$ is the (known) label of $x_i \in L$ and $\tilde{y}_j \in \{-1, 1\}$ is a variable representing the algorithm's guess of the label of $x_j \in U$. While the optimization problem is NP-hard, a number of heuristics have been developed. For example, Joachims [8] uses an iterative labeling heuristic to approximately optimize the objective. Semi-supervised SVMs have been shown to achieve high accuracy in a number of text classification domains where unlabeled data is plentiful [8].

Graph-Based Methods

Graph-based methods [3, 13] can be viewed as a (transductive) semi-supervised version of nearest-neighbor learning. In these methods, one creates a graph with a vertex for each example in $L \cup U$ and an edge between two examples x, x' if they are deemed to be sufficiently "similar" (or with edge weights based on *how* similar they are deemed to be). Similarity can be directly based on distance between the examples in the input space or given by some provided kernel function $k(x, x')$. Given the labels for the examples in L, one then finds a "most compatible" labeling for the examples in U, based on the belief that similar examples will typically have the same label. Specifically, in the mincut approach of [3], the labeling h produced is the cut of least total weight subject to agreeing with the known labels on examples in L or equivalently the cut that agrees with L minimizing $\sum_{e=(x,x')} w_e |h(x) - h(x')|$. In the algorithm of [13], in order to produce a smoother solution, the algorithm instead views the graph as an electrical network, finding the cut agreeing with L that minimizes $\sum_{e=(x,x')} w_e (h(x) - h(x'))^2$.

Open Problems

There are a number of open problems in developing computationally efficient semi-supervised learning algorithms. For example, can one extend the algorithm of Theorem 5 for Co-Training with linear separators to weaker conditions than independence given the label, while maintaining computational efficiency? (Note: A number of weaker conditions are known to produce good sample bounds if computational considerations are ignored [2].) More broadly, can one develop efficient algorithms for other classes or notions of compatibility that meet the cover-based sample complexity bounds of Theorem 2? Additional open problems are given in [1].

Separators in Graphs

Goran Konjevod
Department of Computer Science and Engineering, Arizona State University, Tempe, AZ, USA

Keywords

Balanced cuts

Years and Authors of Summarized Original Work

1998; Leighton, Rao
1999; Leighton, Rao

Problem Definition

The (balanced) separator problem asks for a cut of minimum (edge)-weight in a graph, such that the two shores of the cut have approximately equal (node)-weight.

Formally, given an undirected graph $G = (V, E)$, with a nonnegative edge-weight function $c : E \to \mathbb{R}_+$, a nonnegative node-weight function $\pi : V \to \mathbb{R}_+$, and a constant $b \leq 1/2$, a cut $(S : V \setminus S)$ is said to be *b-balanced*, or a *$(b, 1-b)$-separator*, if $b\pi(V) \leq \pi(S) \leq (1-b)\pi(V)$ (where $\pi(S)$ stands for $\sum_{v \in S} \pi(v)$).

Problem 1 (b-balanced separator)
INPUT: Edge- and node-weighted graph $G = (V, E, c, \pi)$, constant $b \leq 1/2$.
OUTPUT: A b-balanced cut $(S : V \setminus S)$. Goal: minimize the edge weight $c(\delta(S))$.

Closely related is the *product sparsest cut problem.*

Problem 2 ((Product) Sparsest cut)
INPUT: Edge- and node-weighted graph $G = (V, E, c, \pi)$.
OUTPUT: A cut $(S : V \setminus S)$ minimizing the ratio-cost $\frac{c}{c}(\delta(S)))/(\pi(S)\pi(V \setminus S))$.

Problem 2 is the most general version of sparsest cut solved by Leighton and Rao. Setting all

S

node weights are equal to 1 leads to the uniform version, Problem 3.

Problem 3 ((Uniform) Sparsest cut)
INPUT: Edge-weighted graph $G = (V, E, c)$.
OUTPUT: A cut $(S : V \setminus S)$ minimizing the ratio-cost $(c(\delta(S)))/(|S||V \setminus S|)$.

Sparsest cut arises as the (integral version of the) linear programming dual of *concurrent multicommodity flow* (Problem 4). An instance of a multicommodity flow problem is defined on an edge-weighted graph by specifying for each of k *commodities* a *source* $s_i \in V$, a *sink* $t_i \in V$, and a *demand* D_i. A feasible solution to the multicommodity flow problem defines for each commodity a flow function on E, thus routing a certain amount of flow from s_i to t_i. The edge weights represent capacities, and for each edge e, a capacity constraint is enforced: the sum of all commodities' flows through e is at most the capacity $c(e)$.

Problem 4 (Concurrent multicommodity flow)
INPUT: Edge-weighted graph $G = (V, E, c)$, commodities $(s_1, t_1, D_1), \ldots (s_k, t_k, D_k)$.
OUTPUT: A multicommodity flow that routes fD_i units of commodity i from s_i to t_i for each i simultaneously, without violating the capacity of any edge. Goal: maximize f.

Problem 4 can be solved in polynomial time by linear programming, and approximated arbitrarily well by several more efficient combinatorial algorithms (section "Implementation"). The maximum value f for which there exists a multicommodity flow is called the *max-flow* of the instance. The *min-cut* is the minimum ratio $(c(\delta(S)))/(D(S, V \setminus S))$, where $D(S, V \setminus S) = \sum_{i:|\{s_i,t_i\}\cap S|=1} D_i$. This dual interpretation motivates the most general version of the problem, the *nonuniform sparsest cut* (Problem 5).

Problem 5 ((Nonuniform) Sparsest cut)
INPUT: Edge-weighted graph $G = (V, E, c)$, commodities $(s_1, t_1, D_1), \ldots (s_k, t_k, D_k)$.
OUTPUT: A min-cut $(S : V \setminus S)$, that is, a cut of minimum ratio-cost $(c(\delta(S)))/(D(S, V \setminus S))$.

(Most literature focuses on either the uniform or the general nonuniform version, and both of these two versions are sometimes referred to as just the "sparsest cut" problem.)

Key Results

Even when all (edge- and node-) weights are equal to 1, finding a minimum-weight b-balanced cut is NP-hard (for $b = 1/2$, the problem becomes *graph bisection*). Leighton and Rao [23, 24] give a pseudo-approximation algorithm for the general problem.

Theorem 1 *There is a polynomial-time algorithm that, given a weighted graph $G = (V, E, c, \pi)$, $b \leq 1/2$ and $b' < \min\{b, 1/3\}$, finds a b'-balanced cut of weight $O((\log n)/(b - b'))$ times the weight of the minimum b-balanced cut.*

The algorithm solves the sparsest cut problem on the given graph, puts aside the smaller-weight shore of the cut, and recurses on the larger-weight shore until both shores of the sparsest cut found have weight at most $(1-b')\pi(G)$. Now the larger-weight shore of the last iteration's sparsest cut is returned as one shore of the balanced cut, and everything else as the other shore. Since the sparsest cut problem is itself NP-hard, Leighton and Rao first required an approximation algorithm for this problem.

Theorem 2 *There is a polynomial-time algorithm with approximation ratio $O(\log p)$ for product sparsest cut (Problem 2), where p denotes the number of nonzero-weight nodes in the graph.*

This algorithm follows immediately from Theorem 3.

Theorem 3 *There is a polynomial-time algorithm that finds a cut $(S : V \setminus S)$ with ratio-cost $(c(\delta(S)))/(\pi(S)\pi(V \setminus S)) \in O(f \log p)$, where*

f is the max-flow for the product multicommodity flow and p the number of nodes with nonzero weight.

The proof of Theorem 3 is based on solving a linear programming formulation of the multicommodity flow problem and using the solution to construct a sparse cut.

Related Results

Shahrokhi and Matula [27] gave a max-flow min-cut theorem for a special case of the multicommodity flow problem and used a similar LP-based approach to prove their result. An $O(\log n)$ upper bound for arbitrary demands was proved by Aumann and Rabani [6] and Linial et al. [26]. In both cases, the solution to the dual of the multicommodity flow linear program is interpreted as a finite metric and embedded into ℓ_1 with distortion $O(\log n)$, using an embedding due to Bourgain [10]. The resulting ℓ_1 metric is a convex combination of cut metrics, from which a cut can be extracted with sparsity ratio at least as good as that of the combination.

Arora et al. [5] gave an $O(\sqrt{\log n})$ pseudo-approximation algorithm for (uniform or product-weight) balanced separators, based on a semidefinite programming relaxation. For the nonuniform version, the best bound is $O(\sqrt{\log n}\log\log n)$ due to Arora et al. [4]. Khot and Vishnoi [18] showed that, for the nonuniform version of the problem, the semidefinite relaxation of [5] has an integrality gap of at least $(\log\log n)^{1/6-\delta}$ for any $\delta > 0$, and further, assuming their Unique Games Conjecture, that it is NP-hard to (pseudo)-approximate the balanced separator problem to within any constant factor. The SDP integrality gap was strengthened to $\Omega(\log\log n)$ by Krauthgamer and Rabani [20]. Devanur et al. [11] show an $\Omega(\log\log n)$ integrality gap for the SDP formulation even in the uniform case.

Implementation

The bottleneck in the balanced separator algorithm is solving the multicommodity flow linear program. There exists a substantial amount of work on fast approximate solutions to such linear programs [19, 22, 25]. In most of the following results, the algorithm produces a $(1+\epsilon)$-approximation, and its hidden constant depends on ϵ^{-2}. Garg and Könemann [15], Fleischer [14] and Karakostas [16] gave efficient approximation schemes for multicommodity flow and related problems, with running times $\tilde{O}((k+m)m)$ [15] and $\tilde{O}(m^2)$ [14, 16]. Benczúr and Karger [7] gave an $O(\log n)$ approximation to sparsest cut based on randomized minimum cut and running in time $\tilde{O}(n^2)$. The current fastest $O(\log n)$ sparsest cut (balanced separator) approximation is based on a primal-dual approach to semidefinite programming due to Arora and Kale [3], and runs in time $O(m+n^{3/2})(\tilde{O}(m+n^{3/2})$, respectively). The same paper gives an $O(\sqrt{\log n})$ approximation in time $O(n^2)(\tilde{O}(n^2)$, respectively), improving on a previous $\tilde{O}(n^2)$ algorithm of Arora et al. [2]. If an $O(\log^2 n)$ approximation is sufficient, then sparsest cut can be solved in time $\tilde{O}(n^{3/2})$, and balanced separator in time $\tilde{O}(m+n^{3/2})$ [17].

Applications

Many problems can be solved by using a balanced separator or sparsest cut algorithm as a subroutine. The approximation ratio of the resulting algorithm typically depends directly on the ratio of the underlying subroutine. In most cases, the graph is recursively split into pieces of balanced size. In addition to the $O(\log n)$ approximation factor required by the balanced separator algorithm, this leads to another $O(\log n)$ factor due to the recursion depth. Even et al. [12] improved many results based on balanced separators by using *spreading metrics*, reducing the approximation guarantee to $O(\log n\log\log n)$ from $O(\log^2 n)$.

Some applications are listed here; where no reference is given, and for further examples, see [24].

- Minimum cut linear arrangement and minimum feedback arc set. One single algorithm provides an $O(\log^2 n)$ approximation for both of these problems.

- Minimum chordal graph completion and elimination orderings [1]. Elimination orderings are useful for solving sparse symmetric linear systems. The $O(\log^2 n)$ approximation algorithm of [1] for chordal graph completion has been improved to $O(\log n \log\log n)$ by Even et al. [12].
- Balanced node cuts. The cost of a balanced cut may be measured in terms of the weight of nodes removed from the graph. The balanced separator algorithm can be easily extended to this node-weighted case.
- VLSI layout. Bhatt and Leighton [8] studied several optimization problems in VLSI layout. Recursive partitioning by a balanced separator algorithm leads to polylogarithmic approximation algorithms for crossing number, minimum layout area and other problems.
- Treewidth and pathwidth. Bodlaender et al. [9] showed how to approximate treewidth within $O(\log n)$ and pathwidth within $O(\log^2 n)$ by using balanced node separators.
- Bisection. Feige and Krauthgamer [13] gave an $O(\alpha \log n)$ approximation for the minimum bisection, using any α-approximation algorithm for sparsest cut.

Experimental Results

Lang and Rao [21] compared a variant of the sparsest cut algorithm from [24] to methods used in graph decomposition for VLSI design.

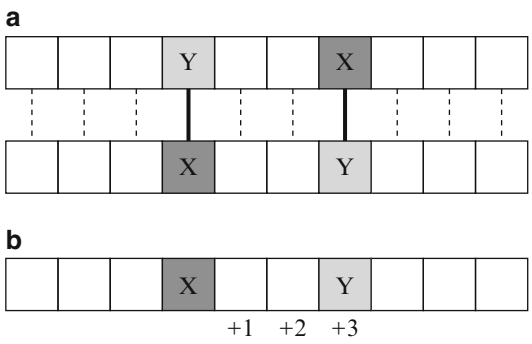
Problem Definition

The problem is to detect specific patterns in string and patterns in string pairs for discovery of sequence and spatial motifs in membrane proteins. A *spatial interaction* motif of residue pair X-Y is defined as a pattern in which a character or residue of type X is found interacting with a residue of type Y on two strings or sequences (Fig. 1a). We define a *sequence pair* XYk as a pattern in which a residue of type Y is found at the k-th position from a residue of type X along a single sequence (Fig. 1b). The propensity $P(X, Y)$ of residue pairing XY is $P(X, Y) = \frac{f_{\text{obs}}(X,Y)}{\mathbb{E}[f(X,Y)]}$, where $f_{\text{obs}}(X, Y)$ is the observed count of XY patterns and $\mathbb{E}[f(X, Y)]$ is the expected count of XY patterns according to some random null model. We define a *motif* as a residue pair with propensity >1.0 (or greater than some other predefined limit) and statistically significant.



Sequence and Spatial Motif Discovery in Short Sequence Fragments, Fig. 1 Examples of spatial and sequence patterns. (**a**) Two X-Y spatial patterns on interacting sequences. (**b**) An $XY3$ sequence pattern

The null model for calculating $\mathbb{E}[f(X,Y)]$ is critical for motif detection. For short sequence fragments, the null model for spatial motif detection cannot be the χ^2 distribution as was used in [13], since the assumption of Gaussian distribution is not valid for short sequences. The null model for sequence motif detection cannot be the binomial distribution as was used in [4, 10], since the assumption of drawing from a universal population with replacement is unrealistic for short sequence fragments. Instead, we use a combinatorial model called the *permutation model* more effective for discoveries of motifs [5–7]. This null model is similar for both pair types: the residues within each sequence are exhaustively and independently permuted *without replacement*, and each permutation occurs with equal probability. This model has been called the *internally random* model [6]. This permutation model is further extended to positional null model to correct position-specific bias in residue distributions [6].

Objective. Our task is to determine explicit formulas to calculate $\mathbb{E}[f(X,Y)]$ for each pair type under different conditions. Explicit probability distributions for $f(X,Y)$ can also be found for many special cases, which will allow for the calculation of statistical significance p-values. These formulas can also be used to study whole datasets of short sequences.

Key Results

Spatial Motifs by Permutation Model

Expectation for Interacting Residues of the Same Type

For cases in which X is the same as Y (i.e., X-X pairs), let x_1 be the number of residues of type X in the first sequence, x_2 the number of residues of type X in the second sequence, and l the common length of the sequence pair. The probability $\mathbb{P}_{XX}(i)$ of exactly $i = f(X,X)$ number of X-X contacts follows a hypergeometric distribution: $\mathbb{P}_{XX}(i) = \binom{x_1}{i}\binom{l-x_1}{x_2-i}/\binom{l}{x_2}$. Its expectation $\mathbb{E}[f(X,X)]$ is then:

$$\mathbb{E}[f(X,X)] = \frac{x_1 x_2}{l}.$$

Expectation for Interacting Residues of Different Types

When $X \neq Y$, the number of X-Y contacts in the permutation model for one sequence pair is the sum of two dependent hypergeometric variables, one variable for type X residues in the first sequence s_1 and type Y in the second sequence s_2, and another variable for type Y residues in s_1 and type X in s_2. The expected number of X-Y contacts $\mathbb{E}[f(X,Y)]$ is the sum of the two expected values $\mathbb{E}[f(X,Y|X \in s_1, Y \in s_2)] + \mathbb{E}[f(X,Y|Y \in s_1, X \in s_2)]$:

$$\mathbb{E}[f(X,Y)] = \frac{x_1 y_2}{l} + \frac{y_1 x_2}{l},$$

where x_1 and x_2 are the numbers of residues of type X in the first and second sequence, respectively, y_1 and y_2 are the numbers of residues of type Y in the first and second sequence, respectively, and l is the length of the sequence pair.

Significance of Spatial Motifs

To calculate the statistical significance in the form of p-value of interacting residues of the same type, two-tailed p-values can be calculated using the hypergeometric distribution for a dataset of sequence pairs.

For interacting residues of different types, the formula to determine the p-value for a specific

observed number of X-Y contacts is more complex because of the dependency. We define a 3-element multinomial function $M(a,b,c) \equiv \frac{a!}{b!c!(a-b-c)!}$, where $M(a,b,c) = 0$ if $a-b-c < 0$. This represents the number of distinct permutations, without replacement, in a multiset of size a containing three different types of elements, with number count b, c, and $a-b-c$ of each of the three element types.

The probability $\mathbb{P}(h,i,j,k)$ of inter-sequence matches, namely, the probability of h X-X contacts, i X-Y contacts, j Y-X contacts, and k Y-Y contacts occurring in a random permutation is (Fig. 2)

$$\mathbb{P}(h,i,j,k) = \frac{M(x_1,h,i)\cdot M(y_1,j,k)\cdot M(l-x_1-y_1, x_2-h-j, y_2-i-k)}{M(l,x_2,y_2)}.$$

The marginal probability $\mathbb{P}_{XY}(m)$ that there are a total of $i+j=m$ X-Y contacts is

$$\mathbb{P}_{XY}(m) = \sum_{h=0}^{x_1} \sum_{i=0}^{x_1-h} \sum_{k=0}^{y_1-(m-i)} \mathbb{P}(h,i,m-i,k).$$

There are x_1 possible values for h, one for each residue of type X on sequence 1; x_1-h possible values for i, once h has been determined; and $y_1-j = y_1-(m-i)$ possible values for k, once i has been determined. The i number of X-Y contacts plus the $m-i$ number of Y-X contacts will sum to the m number of contacts desired.

This closed-form formula allows calculation of p-values analytically. The running time is $O(l^4)$, due to the presence of 3 summations and $l!$ in the summand. For short sequences, the computing cost is not prohibitive.

Sequences of Different Lengths

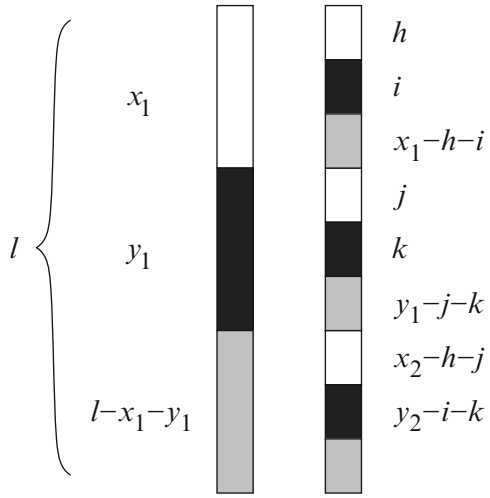
The requirement for interacting sequences to be of the same length may be relaxed by introducing a 21st "dummy" amino acid type. All unpaired residues in the longer member of a sequence pair will be paired to this extra amino acid type, and our standard method can be applied to determine the propensity of unpaired amino acids (i.e., residues paired with the "dummy" amino acid type).

Sequence Motifs by Permutation Model

The propensity $P(X,Y|k)$ for the XYk pattern of two ordered intrasequence residues of type X and type Y that are k positions away on the same sequence (Fig. 1b) is $P(X,Y|k) = \frac{f_{\text{obs}}(X,Y|k)}{\mathbb{E}[f(X,Y|k)]}$, where $f_{\text{obs}}(X,Y|k)$ is the observed count of XYk patterns, and $\mathbb{E}[f(X,Y|k)]$ is the expected count of XYk patterns.

Expectation of XYk and XXk Two-Residue Motifs

We can regard $f(X,Y|k)$ as the sum of identical Bernoulli variables $f_t(X,Y|k)$, each of which equals 1 if one of the x number of residues of type X occurs at position t in the sequence and one of the y number of residues of type Y occurs



Sequence and Spatial Motif Discovery in Short Sequence Fragments, Fig. 2 Division of residues in spatial motif analysis when $X \neq Y$. *White* = X, *black* = Y, *gray* = "neither" X or Y

at position $t + k$ or equals 0 otherwise. Since an XYk pattern cannot occur if $t > l - k$, we concern ourselves only with the first $l - k$ positions. We have: $\mathbb{E}[f_t(X, Y|k)] = \mathbb{P}[f_t(X, Y|k) = 1] = \frac{x}{l} \cdot \frac{y}{(l-1)}$ if $t \leq l-k$. There are $l-k$ such identical variables, and their expectations may be summed as

$$\mathbb{E}[f(X, Y|k)] = (l - k)\frac{xy}{l(l-1)}, \quad (1)$$

where l is the length of the sequence, x is the number of residues of type X, and y is the number of residues of type Y.

For XXk patterns, the expectation is calculated as

$$\mathbb{E}[f(X, X|k)] = (l - k)\frac{x(x-1)}{l(l-1)}, \quad (2)$$

as there will be $x - 1$ residues available to place the second X residue at position $t + k$ after the first X residue is placed at t. Although these Bernoulli random variables are dependent (i.e., the placement of one XYk pattern will affect the probability of another XYk pattern), their expectations may be summed, because expectation is a linear operator.

Significance of XYk and XXk Two-Residue Sequence Motifs

To calculate statistical significance p-values, several formulas have been derived to determine $\mathbb{P}_{XYk}(i)$, the probability of the occurrence of $i = f(X, Y|k)$ XYk patterns for different k values.

1. **Sequence motifs when $k = 1$.** We have

$$\mathbb{P}_{XY1}(i) = \frac{\binom{l-y}{x}\binom{x}{i}\binom{l-x}{y-i}}{\frac{l!}{x!y!(l-x-y)!}} = \frac{\binom{x}{i}\binom{l-x}{y-i}}{\binom{l}{y}}, \quad \text{and}$$

$$\mathbb{P}_{XX1}(i) = \frac{\binom{l-x+1}{x-i}\binom{x-1}{i}}{\binom{l}{x}},$$

with the convention that $\binom{n}{r} = 0$ if $n < r$.

2. **Sequence motifs with residues of different types and if $x \leq 2$ or $y \leq 2$.**
   - If either $x = 1$ or $y = 1$, we have

$$\mathbb{P}_{XYk}(1) = (l - k)\frac{xy}{l(l-1)}.$$

   For $i = 0$, we have simply $\mathbb{P}_{XYk}(0) = 1 - \mathbb{P}_{XYk}(1)$.
   - If $x = 2$ or $y = 2$, the probability of two XYk patterns is

$$\mathbb{P}_{XYk}(2) = \frac{\left[\binom{l-k}{2} - (l - 2k)\right]}{\frac{l(l-1)(l-2)(l-3)}{x(x-1)y(y-1)}}.$$

   We also have for the probabilities of exactly one XYk pattern or zero pattern:

$$\mathbb{P}_{XYk}(1) = \mathbb{E}[f(XYk)] - 2\mathbb{P}_{XYk}(2) \quad \text{and}$$

$$\mathbb{P}_{XYk}(0) = 1 - [\mathbb{P}_{XYk}(1) + \mathbb{P}_{XYk}(2)].$$

3. **Sequence motifs with residues of the same type if $x \leq 3$.**
   - If $x = 2$, the probability of one XXk pattern is

$$\mathbb{P}_{XXk}(1) = \mathbb{E}[f(XXk)] = (l-k)\frac{x(x-1)}{l(l-1)},$$

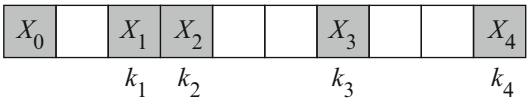
   The probability of no XXk pattern is

$$\mathbb{P}_{XXk}(0) = 1 - \mathbb{P}_{XXk}(1).$$

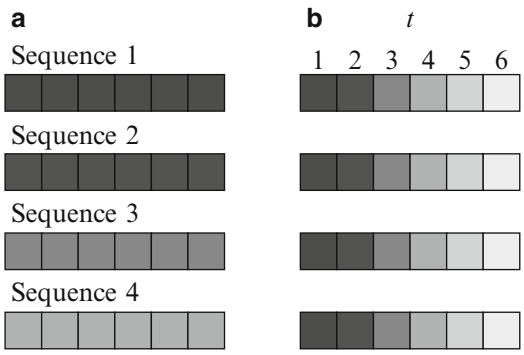
   - If $x = 3$, the probability of exactly two XXk patterns is

$$\mathbb{P}_{XXk}(2) = \frac{l - 2k}{\binom{l}{x}},$$

4. **Sequence motifs with $k > 1$, $x > 2$, and $y > 2$.** When $k > 1$, $x > 2$, and $y > 2$, the analytical formulas for $\mathbb{P}_{XYk}(i)$ become very complicated. However, when the sequences in the dataset used are short, it is possible to fully enumerate all permutations of a sequence and calculate $\mathbb{P}_{XYk}(i)$ and p-values exactly, as shown by Senes et al. [11]. Because x and y are usually small in short sequences, the computation time needed for motif analysis of short sequences is not prohibitive.



Sequence and Spatial Motif Discovery in Short Sequence Fragments, Fig. 3 Example of a multi-residue sequence pattern as described in the text. This pattern contains five specified residues in a span of ten residues. Here, X_0, X_1, X_2, X_3, and X_4 are specified amino acid types, and the corresponding k values are counted as the distance from the first position of the sequence (i.e., the position occupied by X_0). Thus, $k_1 = 2$, $k_2 = 3$, $k_3 = 6$, and $k_4 = 9$. All other residues (in *white*) are unspecified and may be any amino acid type. This pattern is written as $(X_0, X_1, X_2, X_3, X_4 \mid 2, 3, 6, 9)$



Sequence and Spatial Motif Discovery in Short Sequence Fragments, Fig. 4 Difference between (**a**) a *permutation* null model for sequence motif analysis and (**b**) a *position-dependent* null model. In both cases, only residues of the same shade are permuted with each other. In (**a**), residues are permuted only within each sequence individually, while in (**b**), residues are permuted across sequences but only within their specified position t

Propensity of Multi-residue Sequence Motifs

We now discuss the expected number $\mathbb{E}[f(X_0, X_1, X_2, \ldots, X_n | k_1, k_2, \ldots, k_n)]$ of a specific pattern containing $n+1$ residues placed in a contiguous subsequence of $k_n + 1$ residues ($k_n \geq n$). Here X_i is the residue type of the i-th fixed residue in the pattern and k_i is the position of this residue from the 0-th residue ($k_0 = 0$). Positions not specified by k_i can be any residue type. For example, the pattern $(A, L, Y | 2, 4)$ is written as AL2Y4 and represents AxLxY. A graphic example is shown in Fig. 3. Many examples of these multi-residue sequence motifs in proteins have been discovered, including the GxGxxG NADH binding motif [1] and the RSxSxP 14-3-3 binding motif [14].

The expected value can be calculated as:

$$\mathbb{E}[f(X_0, X_1, X_2, \ldots, X_n | k_1, k_2, \ldots, k_n)] = (l - k_n) \frac{\prod_{i=0}^{n} [x_i - \#(\mathbb{I}(X_i))]}{\frac{l!}{(l-n-1)!}}, \quad (3)$$

where x_i is the number of residues of type X_i, l is the length of the sequence, and $\#(\mathbb{I}(X_i))$ is the number of times residue type X_i appears in the "subpattern" $\{X_0, X_1, X_2, \ldots, X_{i-1}\}$.

Remark

The above discussions are for determining motifs in a single short sequence or sequence pair. This can be extended so analysis can be performed on a dataset of multiple short sequences to attain sufficient statistical significance. This has the advantage of capturing within-sequence relationships on a scale large enough to obtain reliable p-values. Details can be found in [6].

Spatial Motifs by Positional Null Model

When there are significant biases in residue preferences for certain positions in a sequence known a priori, e.g., the enrichment of aromatic residues at either end of a transmembrane α-helix or β-strand [12], these single-residue biases may confound two-residue propensities. The *positional null model* should be used for motif detection in such cases [6]. Instead of permuting residues across all positions within individual sequences, we permute residues across all sequences in a dataset within specific positions (Fig. 4).

Expectation and Significance of Interacting Residue Pairs

We allocate residues into regions, which do not overlap. Regions may have different lengths along the sequences. Interacting regions within a sequence pair are assumed to have equal length. If a residue in region r interacts with a residue in region s on a spatially adjacent sequence fragment, all residues in region r in the dataset

must only interact with residues in region s. For example, for interacting antiparallel β-strands, we divide each strand into three regions, the N-terminal, central core, and C-terminal regions, and all interacting strand pairs into two spatial pair types, N-terminal with C-terminal and core with core. We require that no core residue interact with an N-terminal or C-terminal residue.

The null model for position-dependent spatial motifs differs depending on whether paired residues are from the same region ($r = s$) or different regions ($r \neq s$), and whether the residue types in the pair are the same ($X = Y$) or different ($X \neq Y$).

1. **When $r = s$ and $X = Y$.** The expected value of X-X pairs in region r is

$$\mathbb{E}(X, X|rr) = \frac{\binom{x_r}{2}}{\binom{n_r}{2}} \cdot \frac{n_r}{2} = \frac{x_r(x_r - 1)}{2(n_r - 1)},$$

where n_r is the number of residues in region r. The probability $\mathbb{P}_{XX|rr}(i)$ of i X-X interacting pairs in region r in the dataset for p-values calculation calculated is

$$\mathbb{P}_{XX|rr}(i) = \frac{M(\frac{n_r}{2}, i, x_r - 2i) \cdot 2^{x_r - 2i}}{\binom{n_r}{x_r}},$$

where the 3-element multinomial function $M(a, b, c)$ is as defined before.

2. **When $r = s$ and $X \neq Y$.** The expected value when $X \neq Y$ is

$$\mathbb{E}(XY|rr) = \frac{x_r y_r}{\binom{n_r}{2}} \cdot \frac{n_r}{2} = \frac{x_r y_r}{n_r - 1}.$$

The probability $\mathbb{P}(i, j, k)$ of each combination of i, j, and k pairs of type X-Y, X-X, and Y-Y interactions, respectively, is

$$\mathbb{P}(i, j, k) = \frac{M(\frac{n_r}{2}, i, j, k, x_r - i - 2j, y_r - i - 2k) \cdot 2^{x_r + y_r - i - 2j - 2k}}{M(n_r, x_r, y_r)},$$

where the 6-variable multinomial function $M(a,b,c,d,e,f) \equiv \frac{a!}{b!c!d!e!f!(a-b-c-d-e-f)!}$. The probability $\mathbb{P}_{XY|rr}(i)$ of i X-Y pairs in the dataset is then

$$\mathbb{P}_{XY|rr}(i) = \sum_{j=0}^{\frac{x_r - i}{2}} \sum_{k=0}^{\frac{y_r - i}{2}} \mathbb{P}(i, j, k).$$

3. **When $r \neq s$.** We distinguish X_r, a residue of type X occurring in region r in one sequence, and X_s, a residue of type X occurring in region s in the other sequence. Thus, an X-Y pair, which we define as an $X_r - Y_s$ pair, is different from a Y-X pair, which is $Y_r - X_s$. Because there is a one-to-one correspondence between residues in region r and region s, $n_r = n_s$ is the total number of $r - s$ pairs.

In order for exactly i X-Y pairs to occur, i X_r residues must be drawn from a possible x_r residues of type X to match i Y_s residues drawn from a possible y_s residues of type Y. This can be modeled with a simple hypergeometric distribution. The expected value can be calculated as

$$\mathbb{E}(XY|rs) = \frac{x_r y_s}{n_r}.$$

The $\mathbb{P}_{XY|rs}(i)$ of i X-Y pairs is

$$\mathbb{P}_{XY|rs}(i) = \frac{\binom{x_r}{i}\binom{n_r - x_r}{y_s - i}}{\binom{n_r}{y_s}}.$$

Expectation and Significance of Sequence Motifs

We define the *positional residue frequency* x_t as the number of residues of type X occupying the t-th position of all sequences in the dataset. If sequences of different lengths are represented in the dataset, it is necessary to normalize t to be within an appropriate range $[1, l]$, to approximate

an average or predetermined sequence length of l:

$$t = \lceil \frac{l(t_{\text{obs}} - 0.5)}{l_{\text{obs}}} \rceil,$$

where $t_{\text{obs}} \in \{1, 2, 3, \cdots, l_{\text{obs}}\}$ is the actual position of the residue within its sequence, l_{obs} is the actual length of the sequence, $\lceil x \rceil$ represents the ceiling function, equal to the lowest integer greater than or equal to x, and the 0.5 factor is a correction for continuity to round to the next integer. This ensures that $1 \leq t \leq l$, no residues are removed from the model by truncation, and each position t will be represented by nearly the same number of residues.

For sequence motif, we use the model of permutation within each position in a sequence *with replacement* across all sequences. Although all other null models in this study rely on permutation without replacement, this model is based on datasets of multiple sequences instead of individual sequences, and the approximation of sampling without replacement will not be problematic once a sufficiently large sample of sequences is assembled.

1. XYk **motif at position** t**.** When $t \leq 1-k$, the probability of an XYk pattern at position t is

$$\mathbb{P}(X, Y|k, t) = \frac{x_t}{n_t} \cdot \frac{y_{t+k}}{n_{t+k}},$$

where x_t is the number of residues of type X in position t on all sequences, y_t is the number of residues of type Y in position t, and n_t is the number of all residues of all types in position t. This null model can be represented as a binomial distribution.

The expected frequency of XYk patterns at position t is

$$\mathbb{E}[f(X, Y|k, t)] = n_t \cdot \mathbb{P}(X, Y|k, t).$$

The probability of i XYk patterns at position t in the dataset is

$$\mathbb{P}_{XYk|t}(i) = \binom{n_t}{i} \mathbb{P}(X, Y|k, t)^i [1 - \mathbb{P}(X, Y|k, t)]^{n_t - i}.$$

Note that the probability that an XYk pattern appears at position t is 0 if $t > l - k$, as an XYk pattern would span across the end of a sequence of length l.

2. XYk **motif at any arbitrary position.** To calculate the dataset-wide probability of an XYk pattern at any arbitrary position of the sequence, we average $\mathbb{P}(X, Y|k, t)$ over all $l - k$ possible positions:

$$\mathbb{P}(X, Y|k) = \frac{1}{l-k} \sum_{t=1}^{l-k} \mathbb{P}(X, Y|k, t).$$

This can similarly be represented as a binomial distribution with probability distribution function: $\mathbb{P}_{XYk}(i) = \binom{n_k}{i} \mathbb{P}(X, Y|k)^i [1 - \mathbb{P}(X, Y|k)]^{n_k - i}$, where n_k is the number of all pairs of all residue types k residues apart in the dataset. The expected value is

$$\mathbb{E}[f(X, Y|k)] = n_k \cdot \mathbb{P}(X, Y|k).$$

Unlike the situation where only one position t is concerned, this distribution represents the sum of dependent Bernoulli variables. Methods of accounting for this dependence can be found in Robin et al. [10].

Applications

Several spatial and sequence motifs have been discovered using the approach discussed here [5–7]. The estimated propensities have also been used to develop empirical potential function for prediction of oligomerization stated [8], protein-protein interaction interfaces [3, 8], engineering of thermal resistance [2], and in predicting structures of β-barrel membrane proteins [9].

Open Problems

General analytical formulas for calculating probabilities of two-residue and multi-residue motifs under the permutation model are unknown.

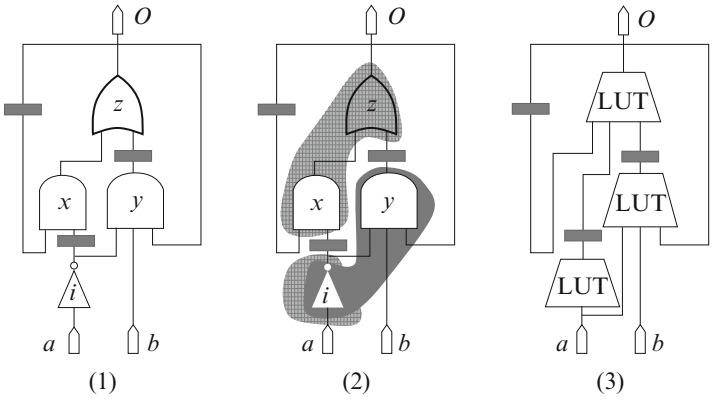
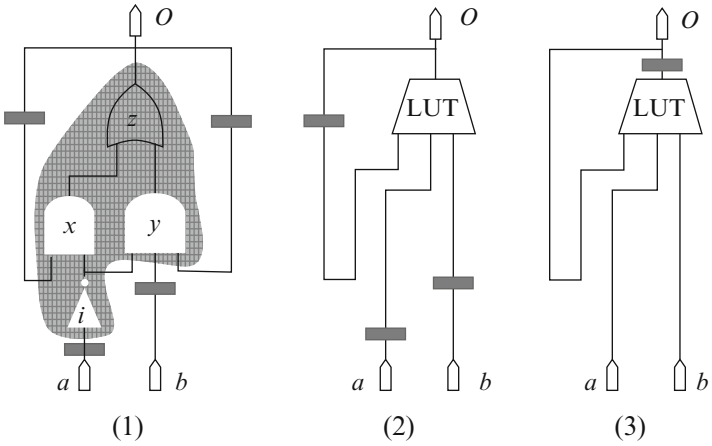
Problem Definition

One of the key steps in a VLSI design flow is technology mapping that converts a Boolean network of technology-independent logic gates and D-flipflops (FFs) into an equivalent one comprised of cells from a technology library [1, 4]. Technology mapping can be formulated as a covering problem where logic gates are covered by cells from the technology library. For ease of discussion, it is assumed that the cell library contains only one cell, a K-input lookup table (K-LUT) with one unit of delay. A K-LUT can implement any Boolean function with up to K inputs as is the case in field-programmable gate arrays (FPGAs) [1, 3].

Figure 1 shows an example of technology mapping. The original network in (1) with three FFs and four gates is covered by three 3-input cones as indicated in (2). The corresponding



Sequential Circuit Technology Mapping, Fig. 1 Technology mapping: (**1**) original network, (**2**) covering, (**3**) mapping solution



Sequential Circuit Technology Mapping, Fig. 2 Retiming and mapping: (**1**) retiming and covering, (**2**) mapping solution, (**3**) retimed solution

mapping solution using 3-LUTs is shown in (3). Note that gate i is covered by two cones so it will be replicated. The mapping solution has a *cycle time* (or *clock period*) of two units, which is the maximum number of LUTs on all paths without FFs.

Retiming relocates FFs in a network by moving FFs across logic nodes backward or forward [5]. Retiming does not alter the functionality of a network. Figure 2 (1) shows the network obtained from the one in Fig. 1 (1) by moving the FFs at the output of gates y and i to their inputs. It can now be covered with just one 3-input cone as indicated in (1). The corresponding mapping solution shown in (2) is better in both cycle time and area than the one in Fig. 1 (3) obtained without retiming.

A *K-bounded* network is one in which each gate has at most K inputs. The sequential circuit technology mapping problem can be defined as follows: *Given a K-bounded Boolean network N and a target cycle time ϕ, find a mapping solution with a cycle time of ϕ, assuming FFs can be relocated using retiming*.

Key Results

The first polynomial time algorithm for the problem was proposed in [9, 10]. An improved algorithm was proposed in [2] to reduce runtime. Both algorithms are based on min-cost flow computation.

In [8], an efficient algorithm was proposed to take advantage of the fact that K is a small integer usually between 3 and 6. The algorithm is based

Sequential Circuit Technology Mapping, Fig. 3 Cut enumeration procedure

foreach node v in N **do** C(v) $\Leftarrow \{\{v^0\}\}$

while (*new cuts discovered*) **do**

foreach node v in N **do** $C(v) \Leftarrow merge(C(u_1),....,C(u_t))$

on enumerating all K-input cones for each gate and will be described next.

Cut Enumeration

A Boolean network can be represented as an edge-weighted directed graph where the nodes denote logic gates and primary inputs/outputs. There is a directed edge (u, v) with weight d if u, after going through d FFs, drives v.

A *cone* for a node can be captured by a *cut* consisting of inputs to the cone. An element in a cut for v consists of the driving node u and the total weight d on the paths from u to v, denoted by u^d. If u can reach v on several paths with different FF counts, u will appear in the cut multiple times with different ds. For the cone for z in Fig. 2 (2), the corresponding cut is $\{z^1, a^1, b^1\}$. A cut of size K is called a K-cut.

Let (u_i, v), where $i = 1, \ldots, t$, be all input edges to v in N. Further assume the weight of (u_i, v) is d_i and $C(u_i)$ is a set of K-cuts for u_i. Let $merge(C(u_1), \ldots, C(u_t))$ denote the following set operation:

$$\{\{v^0\}\} \cup \{c_1^{d_1} \cup \cdots \cup c_t^{d_t} | c_1 \in (u_1), \ldots, c_t \in C(u_t), |c_1^{d_1} \cup \cdots \cup c_t^{d_t}| \leq K\}$$

where $c_i^{d_i} = \{u^{d+d_i} | u^d \in c_i\}$ for $i = 1, \ldots, t$. It is obvious that $merge(C(u_1), \ldots, C(u_t))$ is a set of K-cuts for v.

If the network N does not contain cycles, the K-cuts of all nodes can be determined using the merge operation in a topological order starting from the PIs. For general networks, Fig. 3 outlines the iterative cut computation procedure proposed in [8].

Figure 4 depicts the iterations in enumerating the 3-cuts for the network in Fig. 1 (1) where cuts are merged in the order i, x, y, z, and o. At the beginning, every node has a trivial cut formed by itself (Row 0). Row 1 shows the new cuts discovered in the first iteration. In second iteration, two more cuts are discovered (for x). After that, further merging does not yield any new cut and the procedure stops.

Lemma 1 *After at most Kn iterations, the cut enumeration procedure will find all the K-cuts for every node in N.*

Techniques have been proposed to speed up the procedure [8]. For practical networks, the cut enumeration procedure typically converges in just a few iterations.

Label Computation

After obtaining all K-cuts, the cuts are evaluated based on sequential arrival times (or l-values), which is an extension of traditional arrival times, to consider the effect of retiming [7, 9].

The labeling procedure tries to find a label for each node as outlined in Fig. 5, where w_v denotes the weight of the shortest paths from PIs to node v.

Figure 6 shows the iterations for label computation for the network in Fig. 1 (1), assuming that the target cycle time $\phi = 1$ and the nodes are evaluated in the order of i, x, y, z, and o. In the table, the current label as well as a corresponding cut for each node is listed. In this example, after the first iteration, none of the labels will change and the procedure stops.

It can be shown that the labeling procedure will stop after at most $n(n-1)$ iterations [10]. The following lemma relates labels to mapping:

Iter	*a*	*B*	*I*	*x*	*y*	*z*	*o*
0	$\{a^0\}$	$\{b^0\}$	$\{i^0\}$	$\{x^0\}$	$\{y^0\}$	$\{z^0\}$	$\{o^0\}$
1			$\{a^0\}$	$\{i^1,z^1\}$ $\{a^1,z^1\}$	$\{i^0,b^0,z^0\}$ $\{a^0,b^0,z^0\}$	$\{x^0,y^1\}$ $\{i^1,z^1,b^1\}$ $\{a^1,z^1,b^1\}$ $\{i^1,z^1,y^1\}$ $\{a^1,z^1,y^1\}$	$\{z^0\}$
2				$\{i^1,x^1,y^2\}$ $\{a^1,x^1,y^2\}$

1			$\{a^0\}$:1	$\{a^1,z^1\}$:0	$\{a^0,b^0,z^0\}$:1	$\{a^1,z^1,b^1\}$:0	$\{z^0\}$:0

Sequential Circuit Technology Mapping, Fig. 6 Label computation example

Lemma 2 *N has a mapping solution with cycle time* ϕ iff the labeling procedure returns "success."

Mapping Solution Generation

Once the labels for all nodes are computed successfully, a mapping solution can be constructed starting from primary outputs. At each node v, the procedure selects the cut that realizes the label of the node and then moves on to select a cut for u if u^d is in the cut selected for v. On the edge from u to v, d FFs are inserted. For the network in Fig. 1 (1), the mapping solution generated based on the labels found in Fig. 6 is exactly the one in Fig. 2 (2).

To obtain a mapping solution with the target cycle time ϕ, v will be retimed by a value of $\lceil l(v)/\phi \rceil - 1$. For the network in Fig. 1 (1), the final mapping solution after retiming is shown in Fig. 2 (3) which has a cycle time of 1.

Applications

The algorithm can be used to map a technology-independent Boolean network to a network consisting of cells from a target technology library. The concepts and framework are generally enough to be adapted to study other circuit optimizations such as sequential circuit clustering and sequential circuit restructuring [6].

Problem Definition

Short History

The k-set agreement problem is a paradigm of coordination problems. Defined in the setting of systems made up of processes prone to failures, it is a simple generalization of the consensus problem (that corresponds to the case $k = 1$). That problem was introduced in 1993 by Chaudhuri [2] to investigate how the number of choices (k) allowed for the processes is related to the maximum number of processes that can crash. (After it has crashed, a process executes no more steps: a crash is a premature halting.)

Definition

Let S be a system made up of n processes where up to t can crash and where each process has an input value (called a *proposed* value). The problem is defined by the three following properties (i.e., any algorithm that solves that problem has to satisfy these properties):

1. Termination. Every nonfaulty process decides a value.
2. Validity. A decided value is a proposed value.
3. Agreement. At most k different values are decided.

The Trivial Case

It is easy to see that this problem can be trivially solved if the upper bound on the number of process failures t is smaller than the allowed number of choices k, also called the *coordination degree*. (The trivial solution consists in having $t + 1$ predetermined processes that send their proposed values to all the processes, and a process deciding the first value it ever receives.) So, $k \leq$ t is implicitly assumed in the following.

Key Results

Key Results in Synchronous Systems

The Synchronous Model

In this computation model, each execution consists of a sequence of rounds. These are identified by the successive integers $1, 2$, etc. For the processes, the current round number appears as a global variable whose global progress entails their own local progress.

During a round, a process first broadcasts a message, then receives messages, and finally executes local computation. The fundamental synchrony property the a synchronous system provides the processes with is the following: a message sent during a round r is received by its destination process during the very same round r. If during a round, a process crashes while sending a message, an arbitrary subset (not known in advance) of the processes receive that message.

Main Results

The k-set agreement problem can always be solved in a synchronous system. The main result is for the minimal number of rounds (R_t) that are needed for the nonfaulty processes to decide in the worst-case scenario (this scenario is when exactly k processes crash in each round). It was shown in [3] that $R_t = \lfloor \frac{t}{k} \rfloor + 1$. A very simple algorithm that meets this lower bound is described in Fig. 1.

Although failures do occur, they are rare in practice. Let f denote the number of processes that crash in a given run, $0 \leq f \leq t$. We are interested in synchronous algorithms that terminate in at most R_t rounds when t processes crash in the current run, but that allow the nonfaulty processes to decide in far fewer rounds when there are few failures. Such algorithms are called *early-deciding* algorithms. It was shown in [4] that, in the presence of f process crashes, any early-deciding k-set agreement algorithm has runs in which no process decides before the round $R_f = \min(\lfloor \frac{f}{k} \rfloor + 2, \lfloor \frac{t}{k} \rfloor + 1)$. This lower bound shows an inherent tradeoff linking the coordination degree k, the maximum number of process failures t, the actual number of process failures f, and the best time complexity that can be achieved. Early-deciding k-set agreement algorithms for the synchronous model can be found in [4, 12].

Other Failure Models

In the send omission failure model, a process is faulty if it crashes or forgets to send messages. In the general omission failure model, a process is faulty if it crashes, forgets to send messages, or forgets to receive messages. (A send omission failure models the failure of an output buffer, while a receive omission failure models the failure of an input buffer.) These failure models were introduced in [11].

The notion of *strong* termination for set agreement problems was introduced in [13]. Intuitively, that property requires that as many processes as possible decide. Let a *good* process be a process that neither crashes nor commits receive omission failures. A set agreement algorithm is strongly terminating if it forces all the good processes to decide. (Only the processes that crash during the execution of the algorithm, or that do not receive enough messages, can be prevented from deciding.)

An early-deciding k-set agreement algorithm for the general omission failure model was described in [13]. That algorithm, which requires $t < n/2$, directs a good process to decide and stop in at most $R_f = \min(\lfloor \frac{f}{k} \rfloor + 2, \lfloor \frac{t}{k} \rfloor + 1)$ rounds. Moreover, a process that is not a good

Set Agreement, Fig. 1
A simple k-set agreement synchronous algorithm (code for p_i)

```
Function k-set_agreement (v_i)
(1) est_i ← v_i;
(2) when r = 1, 2, ..., ⌊t/k⌋ + 1 do % r: round number %
(3) begin_round
(4)       send (est_i) to all; % including p_i itself %
(5)       est_i ← min({est_j values received during
                                    the current round r});
(6) end_round;
(7) return (est_i)
```

process executes at most $R_f(not\ good)$) $\min(\lceil \frac{f}{k} \rceil + 2, \lfloor \frac{t}{k} \rfloor + 1)$ rounds.

As R_f is a lower bound for the number of rounds in the crash failure model, the previous algorithm shows that R_f is also a lower bound for the nonfaulty processes to decide in the more severe general omission failure model. Proving that $R_f(not\ good)$ is an upper bound for the number of rounds that a nongood process has to execute remains an open problem.

It was shown in [13] that, for a given coordination degree k, $t < \frac{k}{k+1}n$ is an upper bound on the number of process failures when one wants to solve the k-set agreement problem in a synchronous system prone to process general omission failures. A k-set agreement algorithm that meets this bound was described in [13]. That algorithm requires the processes execute $R = t + 2 - k$ rounds to decide. Proving (or disproving) that R is a lower bound when $t < \frac{k}{k+1}n$ is an open problem. Designing an early-deciding k-set agreement algorithm for $t < \frac{k}{k+1}n$ and $k > 1$ is another problem that remains open.

Key Results in Asynchronous Systems

Impossibility

A fundamental result of distributed computing is the impossibility to design a deterministic algorithm that solves the k-set agreement problem in asynchronous systems when $k \leq$ t [1, 7, 15]. Compared with the impossibility of solving asynchronous consensus despite one process crash, that impossibility is based on deep combinatorial arguments. This impossibility has opened new research directions for the connection between distributed computing and topology. This topology approach has allowed the discovery of links relating asynchronous k-set agreement with other distributed computing problems such as the *renaming* problem [5].

Circumventing the Impossibility

Several approaches have been investigated to circumvent the previous impossibility. These approaches are the same as those that have been used to circumvent the impossibility of asynchronous consensus despite process crashes.

One approach consists in replacing the "deterministic algorithm" by a "randomized algorithm." In that case, the termination property becomes "the probability for a correct process to decide tends to 1 when the number of rounds tends to $+\infty$." That approach was investigated in [9].

Another approach that has been proposed is based on failure detectors. Roughly speaking, a failure detector provides each process with a list of processes suspected to have crashed. As an example, the class of failure detectors denoted $\diamond\mathcal{S}_x$ includes all the failure detectors such that, after some finite (but unknown) time, (1) any list contains the crashed processes and (2) there is a set Q of x processes such that Q contains one correct process and that correct process is no longer suspected by the processes of Q (let us observe that correct processes can be suspected intermittently or even forever). Tight bounds for the k-set agreement problem in asynchronous systems equipped with such failure detectors, conjectured in [9], were proved in [6]. More precisely, such

a failure detector class allows the k-set agreement problem to be solved for $k \geq t - x + 2$ [9], and cannot solve it when $k < t - x + 2$ [6].

Another approach that has been investigated is the combination of failure detectors and conditions [8]. A condition is a set of input vectors, and each input vector has one entry per process. The entries of the input vector associated with a run contain the values proposed by the processes in that run. Basically, such an approach guarantees that the nonfaulty processes always decide when the actual input vector belongs to the condition the k-set algorithm has been instantiated with.

Applications

The set agreement problem was introduced to study how the number of failures and the synchronization degree are related in an asynchronous system; hence, it is mainly a theoretical problem. That problem is used as a canonical problem when one is interested in asynchronous computability in the presence of failures. Nevertheless, one can imagine practical problems the solutions of which are based on the set agreement problem (e.g., allocating a small shareable resources – such as broadcast frequencies – in a network).

Problem Definition

The SET COVER problem has as input a set R of m items, a set C of n subsets of R and a weight function $w\colon C \to \mathbb{Q}$. The task is to choose a subset $C' \subseteq C$ of minimum weight whose union contains all items of R.

The sets R and C can be represented by an $m \times n$ binary matrix A that consists of a row for every item in R and a column for every subset of R in C, where an entry $a_{i,j}$ is 1 iff the ith item in R is part of the jth subset in C. Therefore, the SET COVER problem can be formulated as follows.

> **Input**: An $m \times n$ binary matrix A and a weight function w on the columns of A.
> **Task:** Select some columns of A with minimum weight such that the submatrix A' of A that is induced by these columns has at least one 1 in every row.

While SET COVER is NP-hard in general [4], it can be solved in polynomial time on instances whose columns can be permuted in such a way that in every row the ones appear consecutively, that is, on instances that have the *consecutive ones property* (*C1P*). (The C1P can be defined symmetrically for columns; this article focuses on rows. SET COVER on instances with the C1P can be solved in polynomial time, e.g., with a linear programming approach, because the corresponding coefficient matrices are totally unimodular (see [9]).

Motivated by problems arising from railway optimization, Mecke and Wagner [7] consider the case of SET COVER instances that have "almost the C1P". Having almost the C1P means that the corresponding matrices are similar to matrices that have been generated by starting with a matrix that has the C1P and replacing randomly a certain percentage of the 1's by 0's [7]. For Ruf and Schöbel [8], in contrast, having almost the C1P means that the average number of blocks of consecutive 1's per row is much smaller than the number of columns of the matrix. This entry will also mention some of their results.

Notation

Given an instance (A, w) of SET COVER, let R denote the row set of A and C its column set. A column c_j *covers* a row r_i, denoted by $r_i \in c_j$, if $a_{i,j} = 1$.

A binary matrix has the *strong C1P* if (without any column permutation) the 1's appear consecutively in every row. A *block of consecutive 1's* is a maximal sequence of consecutive 1's in a row. It is possible to determine in linear time if a matrix has the C1P, and if so, to compute a column permutation that yields the strong C1P [2, 3, 6]. However, note that it is NP-hard to permute the columns of a binary matrix such that the number of blocks of consecutive 1's in the resulting matrix is minimized [1, 4, 5].

A *data reduction rule* transforms in polynomial time a given instance I of an optimization problem into an instance I' of the same problem such that $|I'| < |I|$ and the optimal solution for I' has the same value (e.g., weight) as the optimal solution for I. Given a set of data reduction rules, *to reduce* a problem instance means to repeatedly apply the rules until no rule is applicable; the resulting instance is called *reduced*.

Key Results

Data Reduction Rules

For SET COVER there exist well-known data reduction rules:

Row domination rule: If there are two rows $r_{i_1}, r_{i_2} \in R$ with $\forall c \in C: r_{i_1} \in c \text{implies} r_{i_2} \in c$, then r_{i_2} is *dominated* by r_{i_1}. Remove row r_{i_2} from A.

Column domination rule: If there are two columns $c_{j_1}, c_{j_2} \in C$ with $w(c_{j_1}) \geq w(c_{j_2})$ and $\forall r \in R: r \in c_{j_1}$ implies $r \in c_{j_2}$, then c_{j_1} is *dominated* by c_{j_2}. Remove c_{j_1} from A.

In addition to these two rules, a column $c_{j_1} \in C$ can also be dominated by a subset $C' \subseteq C$ of the columns instead of a single column: If there is a subset $C' \subseteq C$ with $w(c_{j_1}) \geq \sum_{c \in C'} w(c)$ and $\forall r \in R: r \in c_{j_1}$ implies $(\exists c \in C': r \in c)$, then remove c_{j_1} from A. Unfortunately, it is NP-hard to find a dominating subset C' for a given set c_{j_1}. Mecke and Wagner [7], therefore, present a restricted variant of this generalized column domination rule.

For every row $r \in R$, let $c_{\min}(r)$ be a column in C that covers r and has minimum weight under this property. For two columns $c_{j_1}, c_{j_2} \in C$, define $X(c_{j_1}, c_{j_2}) := \{c_{\min}(r) \mid r \in c_{j_1} \wedge r \notin c_{j_2}\}$. The new data reduction rule then reads as follows.

Advanced column domination rule: If there are two columns $c_{j_1}, c_{j_2} \in C$ and a row that is covered by both c_{j_1} and c_{j_2}, and if $w(c_{j_1}) \geq w(c_{j_2}) + \sum_{c \in X(c_{j_1}, c_{j_2})} w(c)$, then c_{j_1} is *dominated* by $\{c_{j_2}\} \cup X(c_{j_1}, c_{j_2})$. Remove c_{j_1} from A.

Theorem 1 ([7]) *A matrix A can be reduced in O(Nn) time with respect to the column domination rule, in O(Nm) time with respect to the row domination rule, and in O(Nmn) time with respect to all three data reduction rules described above, when N is the number of 1's in A.*

In the databases used by Ruf and Schöbel [8], matrices are represented by the column indices of the first and last 1's of its blocks of consecutive 1's. For such matrix representations, a fast data reduction rule is presented [8], which eliminates "unnecessary" columns and which, in the implementations, replaces the column domination rule. The new rule is faster than the column domination rule (a matrix can be reduced in $O(mn)$ time with respect to the new rule), but not as powerful: Reducing a matrix A with the new rule can result in a matrix that has more columns than the matrix resulting from reducing A with the column domination rule.

Algorithms

Mecke and Wagner [7] present an algorithm that solves SET COVER by enumerating all feasible solutions.

Given a row r_i of A, a *partial solution for the rows* $r_1, \ldots, r_i$ is a subset $C' \subseteq C$ of the columns of A such that for each row r_j with $j \in \{1, \ldots, i\}$ there is a column in C' that covers row r_j.

The main idea of the algorithm is to find an optimal solution by iterating over the rows of A and updating in every step a data structure S that keeps *all* partial solutions for the rows considered so far. More exactly, in every iteration step the algorithm considers the first row of A and updates the data structure S accordingly. Thereafter, the first row of A is deleted. The following code shows the algorithm.

```
1 Repeat m times: {
2   for every partial solution C' in S that does not
                                cover the first row of A: {
3     for every column c of A that covers the first row
                                of A: {
4       Add {c} ∪ C' to S; }
5 Delete C' from S; }
6 Delete the first row of A; }
```

This straightforward enumerative algorithm could create a set S of exponential size. Therefore, the data reduction rules presented above are used to delete after each iteration step partial solutions that are not needed any more. To this end, a matrix B is associated with the set S, where every row corresponds to a row of A and every column corresponds to a partial solution in S–an entry $b_{i,j}$ of B is 1 iff the jth partial solution of B contains a column of A that covers the row r_i. The algorithm uses the matrix $C := \left(\begin{array}{c|c} A & B \\ \hline 0 \ldots 0 & 1 \ldots 1 \end{array}\right)$, which is updated together with S in every iteration step. (The last row of C allows to distinguish the columns belonging to A from those belonging

to B.) Line 6 of the code shown above is replaced by the following two lines:

6 Delete the first row of the matrix C;
7 Reduce the matrix C and update S accordingly;}

At the end of the algorithm, S contains exactly one solution, and this solution is optimal. Moreover, if the SET COVER instance is nicely structured, the algorithm has polynomial running time:

Theorem 2 ([7]) *If A has the strong C1P, is reduced, and its rows are sorted in lexicographic order, then the algorithm has a running time of $O(M^{3n})$ where M is the maximum number of 1's per row and per column.*

Theorem 3 ([7]) *If the distance between the first and the last 1 in every column is at most k, then at any time throughout the algorithm the number of columns in the matrix B is $O(2^{kn})$, and the running time is $O(2^{2k}\, kmn^2)$.*

Ruf and Schöbel [8] present a branch and bound algorithm for SET COVER instances that have a small average number of blocks of consecutive 1's per row.

The algorithm considers in each step a row r_i of the current matrix (which has been reduced with data reduction rules before) and branches into bl_i cases, where bl_i is the number of blocks of consecutive 1's in r_i. In each case, one block of consecutive 1's in row r_i is selected, and the 1's of all other blocks in this row are replaced by 0's. Thereafter, a lower and an upper bound on the weight of the solution for each resulting instance is computed. If a lower bound differs by a factor of more than $1 + \epsilon$, for a given constant ε, from the best upper bound achieved so far, the corresponding instance is subjected to further branchings. Finally, the best upper bound that was found is returned.

In each branching step, the bl_i instances that are newly generated are "closer" to have the (strong) C1P than the instance from which they descend. If an instance has the C1P, the lower and upper bound can easily be computed by exactly solving the problem. Otherwise, standard heuristics are used.

Applications

SET COVER instances occur e.g., in railway optimization, where the task is to determine where new railway stations should be built. Each row then corresponds to an existing settlement, and each column corresponds to a location on the existing trackage where a railway station could be build. A column c covers a row r, if the settlement corresponding to r lies within a given radius around the location corresponding to c.

If the railway network consisted of one straight line rail track only, the corresponding SET COVER instance would have the C1P; instances arising from real world data are close to have the C1P [7, 8].

Experimental Results

Mecke and Wagner [7] make experiments on real-world instances as described in the Applications section and on instances that have been generated by starting with a matrix that has the C1P and replacing randomly a certain percentage of the 1's by 0's. The real-world data consists of a railway graph with 8,200 nodes and 8,700 edges, and 30,000 settlements. The generated instances consist of 50–50,000 rows with 10–200 1's per row. Up to 20 % of the 1's are replaced by 0's.

In the real-world instances, the data reduction rules decrease the number of 1's to between 1 % and 25 % of the original number of 1's without and to between 0.2 % and 2.5 % with the advanced column reduction rule. In the case of generated instances that have the C1P, the number of 1's is decreased to about 2 % without and to 0.5 % with the advanced column reduction rule. In instances with 20 % perturbation, the number of 1's is decreased to 67 % without and to 20 % with the advanced column reduction rule.

The enumerative algorithm has a running time that is almost linear for real-world instances and most generated instances. Only in the case of generated instances with 20 % perturbation, the running time is quadratic.

Ruf and Schöbel [8] consider three instance types: real-world instances, instances arising

from Steiner triple systems, and randomly generated instances. The latter have a size of 100×100 and contain either 1–5 blocks of consecutive 1's in each row, each one consisting of between one and nine 1's, or they are generated with a probability of 3 % or 5 % for any entry to be 1.

The data reduction rules used by Ruf and Schöbel turn out to be powerful for the real-world instances (reducing the matrix size from about $1{,}100 \times 3{,}100$ to 100×800 in average), whereas for all other instance types the sizes could not be reduced noticeably.

The branch and bound algorithm could solve almost all real-world instances up to optimality within a time of less than a second up to one hour. In all cases where an optimal solution has been found, the first generated subproblem had already provided a lower bound equal to the weight of the optimal solution.

Problem Definition

The study of the parameterized complexity of problems on directed graphs has been hitherto relatively unexplored. Usually the directed version of the problems require significantly different and more involved ideas than the ones for the undirected version. Furthermore, for directed graphs there are no known algorithmic meta-techniques: for example, there is no known algorithmic analogue of the Graph Minor Theory of Robertson and Seymour for directed graphs. As a result, the fixed-parameter tractability status of the directed versions of several fundamental problems such as Multiway Cut, Multicut, Feedback Vertex Set, etc., was open for a long time. The problem of Feedback Vertex Set best illustrates this gulf between undirected and directed graphs with respect to parameterized complexity. In this problem, we are given a graph and the question is whether there exists a set of size at most k whose deletion makes the graph acyclic. The undirected version was known to be FPT

since 1984 [10]. However, the directed version was a long-standing open problem until it was shown to be FPT in 2008 [1].

The framework of *shadowless solutions* aims to bridge this gap by providing an important first step in designing FPT algorithms for a general class of transversal problems on directed graphs. In undirected graphs, the framework of *shadowless solutions* was introduced in [9] and has since been used in [4, 6, 7]. It was adapted and generalized to directed graphs in [2, 3] for the following general class of problems:

Finding an $\mathcal{F}$-transversal for some T-connected $\mathcal{F}$
Input: A directed graph $G = (V, E)$, a positive integer k, a set $T \subseteq V$, and a set $\mathcal{F} = \{F_1, F_2, \ldots, F_q\}$ of subgraphs such that $\mathcal{F}$ is T-connected, i.e., $\forall\, i \in [q]$ each vertex of F_i can reach some vertex of T by a walk completely contained in $G[F_i]$ and is reachable from some vertex of T by a walk completely contained in $G[F_i]$.
Parameter: k
Question: Is there an $\mathcal{F}$-transversal $W \subseteq V$ with $|W| \leq k$, i.e., a set W such that $F_i \cap W \neq \emptyset$ for every $i \in [q]$?

The collection $\mathcal{F}$ is implicitly defined in a problem-specific way and need not be given explicitly in the input. In fact, it is possible that $\mathcal{F}$ is exponentially large. The *shadow* of a solution X is the set of vertices that are disconnected from T (in either direction) after the removal of X. More formally, the reverse shadow of X is given by $r_T(X) = \{v : X \text{is a } v \to T \text{ separator}\}$. Similarly, the forward shadow of X is given by $f_T(X) = \{v : X \text{is a } T \to v \text{ separator}\}$. The shadow of X is given by the union of its reverse and forward shadows, i.e., $\text{shadow}(X) = r(X) \cup f(X)$. A set X is said to be *shadowless* if its shadow is empty.

The aim is to ensure first that there is a solution whose shadow is empty, as finding such a shadowless solution can be a significantly easier task.

Key Results

For the $\mathcal{F}$-transversal problem defined above, [2] shows how to invoke the technique of *random sampling of important separators* and obtain a set Z which is disjoint from a minimum solution X and covers its shadow.

Theorem 1 (randomized covering of the shadow) *Let $T \subseteq V(G)$. There is an algorithm $\texttt{RandomSet}(G, T, k)$ that runs in $4^k \cdot n^{O(1)}$ time and returns a set $Z \subseteq V(G)$ such that for any set $\mathcal{F}$ of T-connected subgraphs, if there exists an $\mathcal{F}$-transversal of size $\leq k$, then the following holds with probability $2^{-2^{O(k)}}$: there is an $\mathcal{F}$-transversal X of size $\leq k$ such that*

1. *$X \cap Z = \emptyset$ and*
2. *Z covers the shadow of X, i.e., $r(X) \cup f(X) \subseteq Z$.*

The set $\mathcal{F}$ is *not* an input of the algorithm described by Theorem 1: the set Z constructed in the above theorem works for *every* T-connected set $\mathcal{F}$ of subgraphs. Therefore, issues related to the representation of $\mathcal{F}$ do not arise. Theorem 1 can be derandomized using the theory of splitters [11]:

Theorem 2 (deterministic covering of the shadow) *Let $T \subseteq V(G)$. We can construct a set $\{Z_1, Z_2, \ldots, Z_t\}$ with $t = 2^{2^{O(k)}} \cdot \log^2 n$ in time $2^{2^{O(k)}} \cdot n^{O(1)}$ such that for any set $\mathcal{F}$ of T-connected, if there exists an $\mathcal{F}$-transversal of size $\leq k$, then there is an $\mathcal{F}$-transversal X of size $\leq k$ such that for at least one $1 \leq i \leq t$ we have*

1. *$X \cap Z_i = \emptyset$ and*
2. *Z_i covers the shadow of X, i.e., $r(X) \cup f(X) \subseteq Z_i$.*

Consider one such set Z_i for some $1 \leq i \leq 2^{2^{O(k)}} \cdot \log^2 n$. Since this set Z_i is disjoint from a minimum solution X, it can be removed from the graph. However, we need to remember the

structure that the set Z_i imposed on the problem. This structure is problem specific, and the reduced (equivalent) instance is obtained on a supergraph of $G \setminus Z_i$ via the *torso operation*. It can be shown that the original instance G has a solution if and only if the reduced instance has a shadowless solution. Therefore, one can focus on the simpler task of finding a shadowless solution or more precisely, finding any solution under the guarantee that a shadowless solution exists.

Applications

The first FPT algorithms for the Directed Multiway Cut problem [3] and the Directed Subset Feedback Vertex Set problem [2] were obtained via the framework of shadowless solutions.

Directed Multiway Cut

In the Directed Multiway Cut problem, given a directed graph $G = (V, E)$, an integer k, and a set of terminals $T = \{t_1, t_2, \ldots, t_p\}$, the objective is to find whether there exists a set $X \subseteq V(G)$ of size at most k such that $G \setminus X$ has no $t_i \to t_j$ path for any $1 \leq i \neq j \leq p$. Let $\mathcal{F}$ be the set of all paths between pairs of (distinct) terminals. Then it is easy to show that $\mathcal{F}$ is T-connected, and the problem of finding an $\mathcal{F}$-transversal is exactly the same as the Directed Multiway Cut problem. It is shown in [3] that a shadowless solution of Directed Multiway Cut is also a solution of the underlying undirected instance of Multiway Cut, which is known to be FPT [8] parameterized by k. Combining with Theorem 2, this gives an FPT algorithm for the Directed Multiway Cut problem.

Directed Subset Feedback Vertex Set

In the Directed Subset Feedback Vertex Set problem, given a directed graph $G = (V, E)$, an integer k, and a set $S \subseteq V(G)$, the objective is to find whether there exists a set $X \subseteq V(G)$ of size at most k such that $G \setminus X$ has no S-cycles, i.e., cycles containing at least one vertex of S. The special case when $S = V(G)$ is the Directed Feedback Vertex Set problem. Let $\mathcal{F}$ be the set of all S-cycles and T be a solution of size $k + 1$ (which can be obtained via *iterative compression*). Then it is easy to show that $\mathcal{F}$ is T-connected, and the problem of finding an $\mathcal{F}$-transversal is exactly the same as the Directed Subset Feedback Vertex Set problem. It is shown in [2] that a shadowless solution of Directed Subset Feedback Vertex Set can be found in FPT time. Combining with Theorem 2, this gives an FPT algorithm for the Directed Subset Feedback Vertex Set problem. This generalizes the FPT algorithm for Directed Feedback Vertex Set [1].

Open Problems

The two main open problems which fit within the framework of "Finding an $\mathcal{F}$-transversal for some T-connected $\mathcal{F}$" are Directed Multicut and Directed Odd Cycle Transversal. Unfortunately, the structure of shadowless solutions is not yet understood well enough to be able to find them in FPT time.

Directed Multicut

In the Directed Multicut problem, given a directed graph $G = (V, E)$, an integer k, and a set of terminal pairs $T = \{(s_1, t_1), (s_2, t_2), \ldots, (s_p, t_p)\}$, the objective is to find whether there exists a set $X \subseteq V(G)$ of size at most k such that $G \setminus X$ has no $s_i \to t_i$ path for any $1 \leq i \leq p$. Let $\mathcal{F}$ be the union of set of all $s_i \to t_i$ paths for $1 \leq i \leq p$. Then it is easy to show that $\mathcal{F}$ is T-connected, and the problem of finding an $\mathcal{F}$-transversal is exactly the same as the Directed Multicut problem. It is known [9] that Directed Multicut parameterized by k is W[1]-hard. However, for the special case of $p = 2$ terminal pairs, the problem can be reduced to Directed Multiway Cut and is hence FPT parameterized by k [3]. The complexity for $p = 3$ parameterized by k is an important open problem. With respect to the bigger parameter $p + k$, the problem is known [5] to be FPT on directed acyclic graphs. However, this algorithm heavily uses the properties of a topological ordering, and the complexity parameterized by

$p + k$ on general graphs is another important open problem.

Directed Odd Cycle Transversal

In the Directed Odd Cycle Transversal problem, given a directed graph $G = (V, E)$ and an integer k, the objective is to find whether there exists a set $X \subseteq V(G)$ of size at most k such that $G \setminus X$ has no cycle of odd length. Let $\mathcal{F}$ be the set of all odd cycles in G and T be a solution of size $k + 1$ (which can be obtained via *iterative compression* [12]). Then it is easy to show that $\mathcal{F}$ is T-connected, and the problem of finding an $\mathcal{F}$-transversal is exactly the same as the Directed Odd Cycle Transversal problem. The complexity parameterized by k is open. Moreover, it is known that Directed Odd Cycle Transversal problem generalizes the Directed Feedback Vertex Set problem [1] and the Undirected Odd Cycle Transversal problem [12]. Hence, an FPT algorithm for Directed Odd Cycle Transversal would have to generalize the ideas used to obtain FPT algorithms for these two problems.

2003; Bansal, Pruhs

Problem Definition

The problem is concerned with scheduling dynamically arriving jobs in the scenario when the processing requirements of jobs are unknown to the scheduler. The lack of knowledge of how long a job will take to execute is a particularly attractive assumption in real systems where such

information might be difficult or impossible to obtain. The goal is to schedule jobs to provide good quality of service to the users. In particular the goal is to design algorithms that have good average performance and are also fair in the sense that no subset of users experiences substantially worse performance than others.

Notations

Let $\mathcal{J} = \{1, 2, \ldots, n\}$ denote the set of jobs in the input instance. Each job j is characterized by its release time r_j and its processing requirement p_j. In the online setting, job j is revealed to the scheduler only at time r_j. A further restriction is the *non-clairvoyant* setting, where only the existence of job j is revealed at r_j, in particular the scheduler does not know p_j until the job meets its processing requirement and leaves the system. Given a schedule, the completion time c_j of a job is the earliest time at which job j receives p_j amount of service. The flow time f_j of j is defined as $c_j - r_j$. The stretch of a job is defined as the ratio of its flow time divided by its size. Stretch is also referred to as normalized flow time or slowdown and is a natural measure of fairness as it measures the waiting time of a job per unit of service received. A schedule is said to be preemptive, if a job can be interrupted arbitrarily, and its execution can be resumed later from the point of interruption without any penalty. It is well known that preemption is necessary to obtain reasonable guarantees for flow time even in the offline setting [6].

Recall that the online shortest remaining processing time (SRPT) algorithm that at any time works on the job with the least remaining processing is optimum for minimizing average flow time. However, a common critique of SRPT is that it may lead to starvation of jobs, where some jobs may be delayed indefinitely. For example, consider the sequence where a job of size 3 arrives at time $t = 0$ and one job of size 1 arrives every unit of time starting $t = 1$ for a long time. Under SRPT, the size 3 job will be delayed until the size 1 jobs stop arriving. On the other hand, if the goal is to minimize the maximum flow time, then it is easily seen that first in first out (FIFO) is the optimum algorithm. However, FIFO can perform very poorly with respect to average flow time (e.g., many small jobs could be stuck behind a very large job that arrived just earlier). A natural way to balance both the average and worst case performance is to consider the ℓ_p norms of flow time and stretch, where the ℓ_p norm of the sequence $x_1, \ldots, x_n$ is defined as $\left(\sum_i x_i^p\right)^{1/p}$.

The shortest elapsed time first (SETF) is a non-clairvoyant algorithm that at any time works on the job that has received the least amount of service thus far. This is a natural way to favor short jobs given the lack of knowledge of job sizes. In fact, SETF is the continuous version of the multilevel feedback (MLF) algorithm. Unfortunately, SETF (or any other deterministic non-clairvoyant algorithm) performs poorly in the framework of competitive analysis, where an algorithm is called c-competitive if for every input instance, its performance is no worse than c times that of the optimum offline (clairvoyant) solution for that instance [7]. However, competitive analysis can be overly pessimistic in its guarantee. A way around this problem was proposed by Kalyanasundaram and Pruhs [5] who allowed the online scheduler a slightly faster processor to make up for its lack of knowledge of future arrivals and job sizes. Formally, an algorithm Alg is said to be s-speed, c-speed competitive where c is the worst case ratio over all instance I, of $\text{Alg}_s(I)/\text{Opt}_1(I)$, where Alg_s is the value of solution produced by Alg when given an s-speed processor, and Opt_1 is the optimum value using a speed 1 processor. Typically the most interesting results are those where c is small and $s = (1+\epsilon)$ for any arbitrary $\epsilon > 0$.

Key Results

In their seminal paper [5], Kalyanasundaram and Pruhs showed the following.

Theorem 1 ([5]) *SETF is a $(1+\epsilon)$-speed, $(1 + 1/\epsilon)$-competitive non-clairvoyant algorithm for minimizing the average flow time on a single machine with preemptions.*

For minimizing the average stretch, Muthukrishnan, Rajaraman, Shaheen, and Gehrke [6] considered the clairvoyant setting and showed that SRPT is 2-competitive for a single machine and 14-competitive for multiple machines. The non-clairvoyant setting was consider by Bansal, Dhamdhere, Konemann, and Sinha [7]. They showed that

Theorem 2 ([1]) *SETF is a* $(1+\epsilon)$*-speed,* $0(\log^2 P)$*-competitive for minimizing average stretch, where* P *is the ratio of the maximum to minimum job size. On the other hand, even with* $O(1)$*-speed, any non-clairvoyant algorithm is at least* $\Omega(\log P)$*-competitive. Interestingly, in terms of* n*, any non-clairvoyant algorithm must be* $\Omega(n)$*-competitive even with* $O(1)$*-speedup. Moreover, SETF is* $O(n)$*-competitive (even without extra speedup). For the special case when all jobs arrive at time 0, SETF is optimum up to constant factors. It is* $O(\log P)$*-competitive (without any extra speedup). Moreover, any non-clairvoyant must be* $\Omega(\log P)$*-competitive even with factor* $O(1)$*-speedup.*

The key idea of the above result was a connection between SETF and SRPT. First, at the expense of $(1+\epsilon)$-speedup, it can be seen that SETF is no worse than MLF where the thresholds are powers of $(1+\epsilon)$. Second, the behavior of MLF on an instance I can be related to the behavior of shortest job first (SJF) algorithm on another instance I' that is obtained from/by dividing each job into logarithmically many jobs with geometrically increasing sizes. Finally, the performance of SJF is related to SRPT using another $(1+\epsilon)$ factor speedup.

Bansal and Pruhs [2] considered the problem of minimizing the ℓ_p norms of flow time and stretch on a single machine. They showed the following.

Theorem 3 ([2]) *In the clairvoyant setting, SRPT and SJF are* $(1+\epsilon)$*-speed,* $O(1/\epsilon)$*-competitive for minimizing the* ℓ_p *norms of both flow time and stretch. On the other hand, for* $1 < p < \infty$*, no online algorithm (possibly clairvoyant) can be* $O(1)$*-competitive for minimizing* ℓ_p *norms of stretch or flow time without speedup. In particular, any randomized online algorithm is at least* $\Omega(n^{(p-1)/3p^2})$*-competitive for* ℓ_p *norms of stretch and is at least* $\Omega(n^{(p-1)/p(3p-1)})$*-competitive for* ℓ_p *norms of flow time.*

The above lower bounds are somewhat surprising, since SRPT and FIFO are optimum for the case $p = 1$ and $p = \infty$ for flow time.

Bansal and Pruhs [2] also consider the non-clairvoyant case.

Theorem 4 ([2]) *In the non-clairvoyant setting, SETF is* $(1+\epsilon)$*-speed,* $O(1/\epsilon^{2+2/p})$*-competitive for minimizing the* ℓ_p *norms of flow time. For minimizing* ℓ_p *norms of stretch, SETF is* $(1+\epsilon)$*-speed,* $O(1/\epsilon^{3+1/p} \cdot \log^{1+1/p} P)$*-competitive*

Finally, Bansal and Pruhs also consider round robin (RR) or processor sharing that at any time splits the processor equally among the unfinished jobs. RR is considered to be an ideal fair strategy since it treats all unfinished jobs equally. However, they show that

Theorem 5 *For any* $p \geq 1$*, there is an* $\epsilon > 0$ *such that even with a* $(1+\epsilon)$ *times faster processor, RR is not* $n^{o(1)}$*-competitive for minimizing the* ℓ_p *norms of flow time. In particular, for* $\epsilon < 1/2p$*, RR is* $(1+\epsilon)$*-speed,* $\Omega(n^{(1-2\epsilon p)/p})$*-competitive. For* ℓ_p *norms of stretch, RR is* $\Omega(n)$*-competitive as is in fact any randomized non-clairvoyant algorithm.*

The results above have been extended in a couple of directions. Bansal and Pruhs [3] extend these results to *weighted* ℓ_p norms of flow time and stretch. Chekuri, Khanna, Kumar, and Goel [4] have extended these results to the multiple machines case. Their algorithms are particularly elegant: Each job is assigned to some machine at random, and all jobs at a particular machine are processed using SRPT or SETF (as applicable).

Applications

SETF and its variants such as MLF are widely used in operating systems [9,10]. Note that SETF is not really practical since each job could be

preempted infinitely often. However, variants of SETF with fewer preemptions are quite popular.

Open Problems

It would be interesting to explore other notions of fairness in the dynamic scheduling setting. In particular, it would be interesting to consider algorithms that are both fair and have a good average performance.

An immediate open problem is whether the gap between $O(\log^2 P)$ and $\Omega(\log P)$ can be closed for minimizing the average stretch in the non-clairvoyant setting.

Shortest Paths Approaches for Timetable Information

Riko Jacob
Institute of Computer Science,
Technical University of Munich, Munich, Germany
IT University of Copenhagen, Copenhagen, Denmark

Keywords

Journey planner; Passenger information system; Timetable lookup; Trip planner

Years and Authors of Summarized Original Work

2004; Pyrga, Schulz, Wagner, Zaroliagis

Problem Definition

Consider the route-planning task for passengers of scheduled public transportation. Here, the running example is that of a train system, but the discussion applies equally to bus, light-rail and similar systems. More precisely, the task is to construct a timetable information system that, based upon the detailed schedules of all trains, provides passengers with good itineraries, including the transfer between different trains.

Solutions to this problem consist of a model of the situation (e.g., can queries specify a limit on the number of transfers?), an algorithmic approach, its mathematical analysis (does it always return the best solution? Is it guaranteed to work fast in all settings?), and an evaluation in the real world (Can travelers actually use the produced itineraries? Is an implementation fast enough on current computers and real data?).

Key Results

The problem is discussed in detail in a recent survey article [6].

Modeling

In a simplistic model, it is assumed that a transfer between trains does not take time. A more realistic model specifies a certain minimum transfer time per station. Furthermore, the objective of the optimization problem needs to be defined. Should the itinerary be as fast as possible, or as cheap as possible, or induce the least possible transfers? There are different ways to resolve this as surveyed in [6], all originating in multi-objective optimization, like resource constraints or Pareto-optimal solutions. From a practical point of view, the preferences of a traveler are usually difficult to model mathematically, and one might want to let the user choose the best option among a set of reasonable itineraries himself. For example, one can compute all itineraries that are not inferior to some other itinerary in all considered aspects. As it turns out, in real timetables the number of such itineraries is not too big, such that this approach is computationally feasible and useful for the traveler [5]. Additionally, the fare structure of most railways is fairly complicated [4], mainly because fares usually are not additive, i.e., are not the sum of fares of the parts of a trip.

Algorithmic Models

The current literature establishes two main ideas how to transform the situation into a shortest path problem on a graph. As an example, consider the simplistic modeling where transfer takes no time, and where queries specify starting time and station to ask for an itinerary that achieves the earliest arrival time at the destination.

In the time-expanded model [11], every arrival and departure event of the timetable is a vertex of the directed graph. The arcs of the graph represent consecutive events at one station, and direct train connections. The length of an arc is given by the time difference of its end vertices. Let s be the vertex at the source station whose time is directly after the starting time. Now, a shortest path from s to any vertex of the destination station is an optimal itinerary.

In the time-dependent model [3, 7, 9, 10], the vertices model stations, and the arcs stand for the existence of a direct (non-stop) train connection. Instead of edge length, the arcs are labeled with edge-traversal functions that give the arrival time at the end of the arc in dependence on the time a passenger starts at the beginning of the arc, reflecting the times when trains actually run. To solve this time-dependent shortest path problem, a modification of Dijkstra's algorithm can be used. Further exploiting the structure of this situation, the graph can be represented in a way that allows constant time evaluation of the link traversal functions [3]. To cope with more realistic transfer models, a more complicated graph can be used.

Additionally, many of the speed-up techniques for shortest path computations can be applied to the resulting graph queries.

Applications

The main application are timetable information systems for scheduled transit (buses, trains, etc.). This extends to route planning where trips in such systems are allowed, as for example in the setting of fine-grained traffic simulation to compute fastest itineraries [2].

Open Problems

Improve computation speed, in particular for fully integrated timetables and the multi-criteria case. Extend the problem to the dynamic case, where the current real situation is reflected, i.e., delayed or canceled trains, and otherwise temporarily changed timetables are reflected.

Experimental Results

In the cited literature, experimental results usually are part of the contribution [2, 4, 5, 6, 7, 8, 9, 10, 11]. The time-dependent approach can

be significantly faster than the time-expanded approach. In particular for the simplistic models speed-ups in the range 10–45 are observed [8, 10]. For more detailed models, the performance of the two approaches becomes comparable [6].

Shortest Paths in Planar Graphs with Negative Weight Edges

Jittat Fakcharoenphol[1] and Satish Rao[2]
[1]Department of Computer Engineering, Kasetsart University, Bangkok, Thailand
[2]Department of Computer Science, University of California, Berkeley, CA, USA

Keywords

Shortest paths in planar graphs with arbitrary arc weights; Shortest paths in planar graphs with general arc weights

Years and Authors of Summarized Original Work

2001; Fakcharoenphol, Rao

Problem Definition

This problem is to find shortest paths in planar graphs with general edge weights. It is known that shortest paths exist only in graphs that contain no negative weight cycles. Therefore, algorithms that work in this case must deal with the presence of negative cycles, i.e., they must be able to detect negative cycles.

In general graphs, the best known algorithm, the Bellman-Ford algorithm, runs in time $O(mn)$ on graphs with n nodes and m edges, while algorithms on graphs with no negative weight edges run much faster. For example, Dijkstra's algorithm implemented with the Fibonacchi heap runs in time $O(m + n \log n)$, and, in case of integer weights Thorup's algorithm runs in linear time. Goldberg [5] also presented an $O(m\sqrt{n} \log L)$-time algorithm where L denotes the absolute value of the most negative edge weights. Note that his algorithm is weakly polynomial.

Notations

Given a directed graph $G = (V, E)$ and a weight function w: $E \to \mathbb{R}$ on its directed edges, a *distance labeling* for a source node s is a function d: $V \to \mathbb{R}$ such that $d(v)$ is the minimum length over all s-to-v paths, where the *length of path P* is $\sum_{e \in P} w(e)$.

Problem 1 (Single-Source-Shortest-Path)
INPUT: A directed graph $G = (V, E)$, weight function w: $E \to \mathbb{R}$, source node $s \in V$.
OUTPUT: If G does not contain negative length cycles, output a distance labeling d for source node s. Otherwise, report that the graph contains some negative length cycle.

The algorithm by Fakcharoenphol and Rao [4] deals with the case when G is planar. They gave an $O(n \log^3 n)$-time algorithm, improving on an $O(n^{3/2})$-time algorithm by Lipton, Rose, and Tarjan [9] and an $O(n^{4/3} \log nL)$-time algorithm by Henzinger, Klein, Rao, and Subramanian [6].

Their algorithm, as in all previous algorithms, uses a recursive decomposition and constructs a data structure called a dense distance graph, which shall be defined next.

A *decomposition* of a graph is a set of subsets $P_1, P_2, \ldots, P_k$ (not necessarily disjoint) such that the union of all the sets is V and for all $e = (u, v) \in E$, there is a unique P_i that contains e. A node v is a *border node* of a set P_i if $v \in P_i$ and there exists an edge $e = (v, x)$ where $x \notin P_i$. The subgraph induced on a subset P_i is referred to as a *piece* of the decomposition.

The algorithm works with a *recursive decomposition* where at each level, a piece with n nodes and r border nodes is divided into two subpieces such that each subpiece has no more than $2n/3$ nodes and at most $2r/3 + c\sqrt{n}$ border nodes, for some constant c. In this recursive context, a border node of a subpiece is defined to be any border node of the original piece or any new border node introduced by the decomposition of the current piece.

With this recursive decomposition, the *level of a decomposition* can be defined in the natural way, with the entire graph being the only piece in the level 0 decomposition, the pieces of the decomposition of the entire graph being the level 1 pieces in the decomposition, and so on.

For each piece of the decomposition, the all-pair shortest path distances between all its border nodes along paths that lie entirely inside the piece are recursively computed. These all-pair distances form the edge set of a non-planar graph representing shortest paths between border nodes. The dense distance graph of the planar graph is the union of these graphs over all the levels.

Using the dense distance graph, the shortest distance queries between pairs of nodes can be answered.

Problem 2 (Shortest-Path-Distance-Data-Structure)
INPUT: A directed graph $G = (V, E)$, weight function w: $E \to \mathbb{R}$, source node $s \in V$.
OUTPUT: If G does not contain negative length cycles, output a data structure that support distance queries between pairs of nodes. Otherwise, report that the graph contains some negative length cycle.

The algorithm of Fakcharoenphol and Rao relies heavily on planarity, i.e., it exploits properties regarding how shortest paths on each piece intersect. Therefore, unlike previous algorithms that require only that the graph can be recursively decomposed with small numbers of border nodes [10], their algorithm also requires that each piece has a nice embedding.

Given an embedding of the piece, a *hole* is a bounded face where all adjacent nodes are border nodes. Ideally, one would hope that there is a planar embedding of any piece in the recursive decomposition where all the border nodes are on a single face and are circularly ordered, i.e., there is no holes in each piece. Although this is not always true, the algorithm works with any decomposition with a constant number of holes in each piece. This decomposition can be found in $O(n \log n)$ time using the simple cycle separator algorithm by Miller [12].

Key Results

Theorem 1 *Given a recursive decomposition of a planar graph such that each piece of the decomposition contains at most a constant number of holes, there is an algorithm that constructs the dense distance graph is $O(n \log^3 n)$ time.*

Given the procedure that constructs the dense distance graph, the shortest paths from a source s can be computed by first adding s as a border node in every piece of the decomposition, computing the dense distance graph, and then extending the distances into all internal nodes on every piece. This can be done in time $O(n \log^3 n)$.

Theorem 2 *The single-source shortest path problem for an n-node planar graph with negative weight edges can be solved in time $O(n \log^3 n)$.*

The dense distance graph can be used to answer distance queries between pairs of nodes.

Theorem 3 *Given the dense distance graph, the shortest distance between any pair of nodes can be found in $O(\sqrt{n} \log^2 n)$ time.*

It can also be used as a dynamic data structure that answers shortest path queries and allows edge cost updates.

Theorem 4 *For planar graphs with only non-negative weight edges, there is a dynamic data structure that supports distance queries and update operations that change edge weights in amortized $O(n^{2/3} \log^{7/3} n)$ time per operation. For planar graph with negative weight edges, there is a dynamic data structures that supports the same set of operations in amortized $O(n^{4/5} \log^{13/5} n)$ time per operation.*

Note that the dynamic data structure does not support edge insertions and deletions, since these operations might destroy the recursive decomposition.

Applications

The shortest path problem has long been studied and continues to find applications in diverse areas. There are a many problems that reduce to the shortest path problem where negative weight edges are required, for example the minimum-mean length directed circuit. For planar graphs, the problem has wide application even when the underlying graph is a grid. For example, there are recent image segmentation approaches that use negative cycle detection [2, 3]. Some of other applications for planar graphs include separator algorithms [13] and multi-source multi-sink flow algorithms [11].

Open Problems

Klein [8] gives a technique that improves the running time of the construction of the dense distance graph to $O(n \log^2 n)$ when all edge weights are non-negative; this also reduces the amortized running time for the dynamic case down to $O(n^{2/3} \log^{5/3} n)$. Also, for planar graphs with no negative weight edges, Cabello [1] gives a faster algorithm for computing the shortest distances between k pairs of nodes. However, the problem

for improving the bound of $O(n \log^3 n)$ for finding shortest paths in planar graphs with general edge weights remains opened.

It is not known how to handle edge insertions and deletions in the dynamic data structure. A new data structure might be needed instead of the dense distance graph, because the dense distance graph is determined by the decomposition.

Problem Definition

A *point lattice* is the set of all integer linear combinations

$$\mathcal{L}(\mathbf{b}_1, \ldots, \mathbf{b}_n) = \left\{ \sum_{i=1}^{n} x_i \mathbf{b}_i : x_1, \ldots, x_n \in \mathbb{Z} \right\}$$

of n linearly independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n \in \mathbb{R}^m$ in m-dimensional Euclidean space. For computational purposes, the lattice vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ are often assumed to have integer (or rational)

entries, so that the lattice can be represented by an integer matrix $\mathbf{B} = [\mathbf{b}_1, \ldots, \mathbf{b}_n] \in \mathbb{Z}^{m \times n}$ (called *basis*) having the generating vectors as columns. Using matrix notation, lattice points in $\mathcal{L}(\mathbf{B})$ can be conveniently represented as $\mathbf{Bx}$ where $\mathbf{x}$ is an integer vector. The integers m and n are called the *dimension* and *rank* of the lattice respectively. Notice that any lattice admits multiple bases, but they all have the same rank and dimension.

The main computational problems on lattices are the *Shortest Vector Problem*, which asks to find the shortest nonzero vector in a given lattice, and the *Closest Vector Problem*, which asks to find the lattice point closest to a given target. Both problems can be defined with respect to any norm, but the Euclidean norm $\|\mathbf{v}\| = \sqrt{\sum_i v_i^2}$ is the most common. Other norms typically found in computer science applications are the ℓ_1 norm $\|\mathbf{v}\|_1 = \sum_i |v_i|$ and the *max* norm $\|\mathbf{v}\|_\infty = \max_i |v_i|$. This entry focuses on the Euclidean norm.

Since no efficient algorithm is known to solve SVP and CVP exactly in arbitrary high dimension, the problems are usually defined in their approximation version, where the approximation factor $\gamma \geq 1$ can be a function of the dimension or rank of the lattice.

Definition 1 (Shortest Vector Problem, SVP_γ) Given a lattice $\mathcal{L}(\mathbf{B})$, find a nonzero lattice vector $\mathbf{Bx}$ (where $\mathbf{x} \in \mathbb{Z}^n \setminus \{\mathbf{0}\}$) such that $\|\mathbf{Bx}\| \leq \gamma \cdot \|\mathbf{By}\|$ for any $\mathbf{y} \in \mathbb{Z}^n \setminus \{\mathbf{0}\}$.

Definition 2 (Closest Vector Problem, CVP_γ) Given a lattice $\mathcal{L}(\mathbf{B})$ and a target point $\mathbf{t}$, find a lattice vector $\mathbf{Bx}$ (where $\mathbf{x} \in \mathbb{Z}^n$) such that $\|\mathbf{Bx} - \mathbf{t}\| \leq \gamma \cdot \|\mathbf{By} - \mathbf{t}\|$ for any $\mathbf{y} \in \mathbb{Z}^n$.

Lattices have been investigated by mathematicians for centuries in the equivalent language of quadratic forms, and are the main object of study in the *geometry of numbers*, a field initiated by Minkowski as a bridge between geometry and number theory. For a mathematical introduction to lattices see [3]. The reader is referred to [6, 12] for an introduction to lattices with an emphasis on computational and algorithmic issues.

Key Results

The problem of finding an efficient (polynomial time) solution to SVP_γ for lattices in arbitrary dimension was first solved by the celebrated *lattice reduction* algorithm of Lenstra, Lenstra and Lovász [11], commonly known as the *LLL* algorithm.

Theorem 1 *There is a polynomial time algorithm to solve* SVP_γ *for* $\gamma = (2/\sqrt{3})^n$*, where* n *is the rank of the input lattice.*

The LLL algorithm achieves more than just finding a relatively short lattice vector: it finds a so-called *reduced basis* for the input lattice, i.e., an entire basis of relatively short lattice vectors. Shortly after the discovery of the LLL algorithm, Babai [2] showed that reduced bases can be used to efficiently solve CVP_γ as well within similar approximation factors.

Corollary 1 There is a polynomial time algorithm to solve CVP_γ for $\gamma = O(2/\sqrt{3})^n$, where n is the rank of the input lattice.

The reader is referred to the original papers [2, 11] and [12, chap. 2] for details. Introductory presentations of the LLL algorithm can also be found in many other texts, e.g., [5, chap. 16] and [15, chap. 27]. It is interesting to note that CVP is at least as hard as SVP (see [12, chap 2]) in the sense that any algorithm that solves CVP_γ can be efficiently adapted to solve SVP_γ within the same approximation factor.

Both SVP_γ and CVP_γ are known to be NP-hard in their exact ($\gamma = 1$) or even approximate versions for small values of γ, e.g., constant γ independent of the dimension. (See [13, chaps. 3 and 4] and [4, 10] for the most recent results.) So, no efficient algorithm is likely to exist to solve the problems exactly in arbitrary dimension. For any fixed dimension n, both SVP and CVP can be solved exactly in polynomial time using an algorithm of Kannan [9]. However, the dependency of the running time on the lattice dimension is $n^{O(n)}$. Using randomization, exact SVP can be

solved probabilistically in $2^{O(n)}$ time and space using the *sieving* algorithm of Ajtai, Kumar and Sivakumar [1].

As for approximate solutions, the LLL lattice reduction algorithm has been improved both in terms of running time and approximation guarantee. (See [14] and references therein.) Currently, the best (randomized) polynomial time approximation algorithm achieves approximation factor $\gamma = 2^{O(n \log\log n / \log n)}$.

Applications

Despite the large (exponential in n) approximation factor, the LLL algorithm has found numerous applications and lead to the solution of many algorithmic problems in computer science. The number and variety of applications is too large to give a comprehensive list. Some of the most representative applications in different areas of computer science are mentioned below.

The first motivating applications of lattice basis reduction were the solution of integer programs with a fixed number of variables and the factorization of polynomials with rationals coefficients. (See [11, 8], and [15, chap. 16].) Other classic applications are the solution of random instances of low-density subset-sum problems, breaking (truncated) linear congruential pseudorandom generators, simultaneous Diophantine approximation, and the disproof of Mertens' conjecture. (See [8] and [5, chap. 17].)

More recently, lattice basis reduction has been extensively used to solve many problems in cryptanalysis and coding theory, including breaking several variants of the RSA cryptosystem and the DSA digital signature algorithm, finding small solutions to modular equations, and list decoding of CRT (Chinese Reminder Theorem) codes. The reader is referred to [7, 13] for a survey of recent applications, mostly in the area of cryptanalysis.

One last class of applications of lattice problems is the design of cryptographic functions (e.g., collision resistant hash functions, public key encryption schemes, etc.) based on the apparent intractability of solving SVP_γ within small approximation factors. The reader is referred to [12, chap. 8] and [13] for a survey of such applications, and further pointers to relevant literature. One distinguishing feature of many such lattice based cryptographic functions is that they can be proved to be hard to break *on the average*, based on a *worst-case* intractability assumption about the underlying lattice problem.

Open Problems

The main open problems in the computational study of lattices is to determine the complexity of approximate SVP_γ and CVP_γ for approximation factors $\gamma = n^c$ polynomial in the rank of the lattice. Specifically,

- Are there polynomial time algorithm that solve SVP_γ or CVP_γ for polynomial factors $\gamma = n^c$? (Finding such algorithms even for very large exponent c would be a major breakthrough in computer science.)
- Is there an $\epsilon > 0$ such that approximating SVP_γ or CVP_γ to within $\gamma = n^\epsilon$ is NP-hard? (The strongest known inapproximability results [4] are for factors of the form $n^{O(1/\log\log n)}$ which grow faster than any poly-logarithmic function, but slower than any polynomial.)

There is theoretical evidence that for large polynomials factors $\gamma = n^c$, SVP_γ and CVP_γ are not NP-hard. Specifically, both problems belong to complexity class coAM for approximation factor $\gamma = O(\sqrt{n/\log n})$. (See [12, chap. 9].) So, the problems cannot be NP-hard within such factors unless the polynomial hierarchy PH collapses.

URL to Code

The LLL lattice reduction algorithm is implemented in most library and packages for computational algebra, e.g.,

- GAP (http://www.gap-system.org)
- LiDIA (http://www.cdc.informatik.tu-darmstadt.de/TI/LiDIA/)
- Magma (http://magma.maths.usyd.edu.au/magma/)
- Maple (http://www.maplesoft.com/)
- Mathematica (http://www.wolfram.com/products/mathematica/index.html)
- NTL (http://shoup.net/ntl/).

NTL also includes an implementation of Block Korkine-Zolotarev reduction that has been extensively used for cryptanalysis applications.

Similarity Between Compressed Strings, Table 1 Various scoring metrics

Metric	Match	Mismatch	Indel	Indel of k characters
Longest common subsequence	1	0	0	0
Levenshtein distance	0	1	1	k
Weighted edit distance	0	δ	μ	$k\mu$
Affine gap penalty	1	$-\delta$	$-\gamma-\mu$	$-\gamma-k\mu$

Problem Definition

The problem of computing similarity between two strings is concerned with comparing two strings using some scoring metric. There exist various scoring metrics and a popular one is the Levenshtein distance (or edit distance) metric. The standard solution for the Levenshtein distance metric was proposed by Wagner and Fischer [13], which is based on dynamic programming. Other widely used scoring metrics are the longest common subsequence metric, the weighted edit distance metric, and the affine gap penalty metric. The affine gap penalty metric is the most general, and it is a quite complicated metric to deal with. Table 1 shows the differences between the four metrics.

The problem considered in this entry is the similarity between two compressed strings. This problem is concerned with efficiently computing similarity without decompressing two strings. The compressions used for this problem in the literature are run-length encoding and Lempel-Ziv (LZ) compression [14].

Run-Length Encoding

A string S is run-length encoded if it is described as an ordered sequence of pairs (σ, i), often denoted "σ^i", each consisting of an alphabet symbol, σ, and an integer, i. Each pair corresponds to a *run* in S, consisting of i consecutive occurrences of σ. For example, the string *aaabbbbbaccccbb* can be encoded $a^3b^4a^1c^4b^2$ or, equivalently, $(a,3)(b,4)(a,1)(c,4)(b,2)$. Let A and B be two strings with lengths n and m, respectively. Let A' and B' be the run-length encoded strings of A and B, and n' and m' be the lengths of A' and B', respectively.

Problem 1
INPUT: Two run-length encoded strings A' and B', a scoring metric d.
OUTPUT: The similarity between A' and B' using d.

LZ Compression

Let X and Y be two strings with length $O(n)$. Let X' and Y' be the LZ compressed strings of X and Y, respectively. Then the lengths of X' and Y' are $O(hn/\log n)$, where $h \leq 1$ is the entropy of strings X and Y.

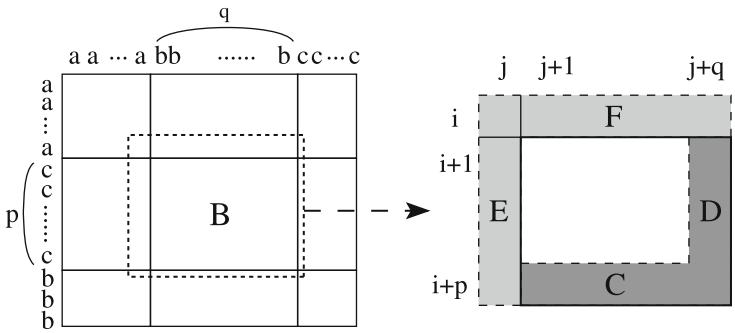
Problem 2
INPUT: Two LZ compressed strings X' and Y', a scoring metric d.
OUTPUT: The similarity between X' and Y' using d.

Block Computation

To compute similarity between compressed strings efficiently, one can use a block computation method. Dynamic programming tables are divided into submatrices, which are called "*blocks*". For run-length encoded strings, a block is a submatrix made up of two runs – one of A and one of B. For LZ compressed strings, a block is a submatrix made up of two phrases – one phrase from each string. See [5] for more details. Then, blocks are computed from left to right and from top to bottom. For each block, only the bottom row and the rightmost column are computed. Figure 1 shows an example of block computation.

Key Results

The problem of computing similarity of two run-length encoded strings, A' and B', has been



Similarity Between Compressed Strings, Fig. 1 Dynamic programming table for strings $a^r c^p b^t$ and $a^s b^q c^u$ is divided into 9 blocks. For one of the blocks, e.g., B, only the bottom row C and the rightmost column D are computed from E and F

studied for various scoring metrics. Bunke and Csirik [4] presented the first solution to Problem 1 using the longest common subsequence metric. The algorithm is based on block computation of the dynamic programming table.

Theorem 1 (Bunke and Csirik [4]) *A longest common subsequence of run-length encoded strings A' and B' can be computed in $O(nm' + n'm)$ time.*

For the Levenshtein distance metric, Arbell, Landau, and Mitchell [2] and Mäkinen, Navarro, and Ukkonen [10] presented $O(nm' + n'm)$ time algorithms, independently. These algorithms are extensions of the algorithm of Bunke and Csirik.

Theorem 2 (Arbell, Landau, and Mitchell [2], Mäkinen, Navarro, and Ukkonen [10]) *The Levenshtein distance between run-length encoded strings A' and B' can be computed in $O(nm' + n'm)$ time.*

For the weighted edit distance metric, Crochemore, Landau, and Ziv-Ukelson [6] and Mäkinen, Navarro, and Ukkonen [11] gave $O(nm' + n'm)$ time algorithms using techniques completely different from each other. The algorithm of Crochemore, Landau, and Ziv-Ukelson [6] is based on the technique which is used in the LZ compressed pattern matching algorithm [6], and the algorithm of Mäkinen, Navarro, and Ukkonen [11] is an extension of the algorithm for the Levenshtein distance metric.

Theorem 3 (Crochemore, Landau, and Ziv-Ukelson [6] Mäkinen, Navarro, and Ukkonen [11]) *The weighted edit distance between run-length encoded strings A' and B' can be computed in $O(nm' + n'm)$ time.*

For the affine gap penalty metric, Kim, Amir, Landau, and Park [8] gave an $O(nm' + n'm)$ time algorithm. To compute similarity in this metric efficiently, the problem is converted into a path problem on a directed acyclic graph and some properties of maximum paths in this graph are used. It is not necessary to build the graph explicitly since they came up with new recurrences using the properties of the graph.

Theorem 4 (Kim, Amir, Landau, and Park [8]) *The similarity between run-length encoded strings A' and B' in the affine gap penalty metric can be computed in $O(nm' + n'm)$ time.*

The above results show that comparison of run-length encoded strings using the longest common subsequence metric is successfully extended to more general scoring metrics.

For the longest common subsequence metric, there exist improved algorithms. Apostolico, Landau, and Skiena [1] gave an $O(n'm' \log(n'm'))$ time algorithm. This algorithm is based on tracing specific optimal paths.

Theorem 5 (Apostolico, Landau, and Skiena [1]) *A longest common subsequence of run-length encoded strings A' and B' can be computed in $O(n'm' \log(n' + m'))$ time.*

Mitchell [12] obtained an $O((d + n' + m') \log(d + n' + m'))$ time algorithm, where d is the number of matches of compressed characters. This algorithm is based on computing geometric

shortest paths using special convex distance functions.

Theorem 6 (Mitchell [12]) *A longest common subsequence of run-length encoded strings A' and B' can be computed in $O((d + n' + m')\log(d + n' + m'))$ time, where d is the number of matches of compressed characters.*

Mäkinen, Navarro, and Ukkonen [11] conjectured an $O(n'm')$ time algorithm on average under the assumption that the lengths of the runs are equally distributed in both strings.

Conjecture 1 (Mäkinen, Navarro, and Ukkonen [11]) A longest common subsequence of run-length encoded strings A' and B' can be computed in $O(n'm')$ time on average.

For Problem 2, Crochemore, Landau, and Ziv-Ukelson [6] presented a solution using the additive gap penalty metric. The additive gap penalty metric consists of 1 for match, $-\delta$ for mismatch, and $-\mu$ for indel, which is almost the same as the weighted edit distance metric.

Theorem 7 (Crochemore, Landau, and Ziv-Ukelson [6]) *The similarity between LZ compressed strings X' and Y' in the additive gap penalty metric can be computed in $O(hn^2/\log n)$ time, where $h \leq 1$ is the entropy of strings X and Y.*

Applications

Run-length encoding serves as a popular image compression technique, since many classes of images (e.g., binary images in facsimile transmission or for use in optical character recognition) typically contain large patches of identically-valued pixels. Approximate matching on images can be a useful tool to handle distortions. Even a one-dimensional compressed approximate matching algorithm would be useful to speed up two-dimensional approximate matching allowing mismatches and even rotations [3, 7, 9].

Open Problems

The worst-case complexity of the problem is not fully understood. For the longest common subsequence metric, there exist some results whose time complexities are better than $O(nm' + n'm)$ to compute the similarity of two run-length encoded strings [1, 11, 12]. It remains open to extend these results to the Levenshtein distance metric, the weighted edit distance metric and the affine gap penalty metric.

In addition, for the longest common subsequence metric, it is an open problem to prove Conjecture 1.

Problem Definition

A spanner is a *sparse* subgraph of a given undirected graph that preserves approximate distance between each pair of vertices. More precisely, a t-spanner of a graph $G = (V, E)$ is a subgraph (V, E_S), $E_S \subseteq E$ such that, for any pair of vertices, their distance in the subgraph is at most t times their distance in the original graph, where t is called the *stretch factor*. The spanners were defined formally by Peleg and Schäffer [15] though the associated notion was used implicitly by Awerbuch [3] in the context of network synchronizers.

Computing t-spanner of smallest size for a given graph is a well-motivated combinatorial problem with many applications. However, computing t-spanner of smallest size for a graph is NP-hard. In fact, for $t > 2$, it is NP-hard [11] even to approximate the smallest size of t-spanner of a graph with ratio $O(2^{(1-\mu)\ln n})$ for any $\mu > 0$. Having realized this fact, researchers have pursued another direction which is quite interesting and useful. Let S_G^t be the size of the sparsest t-spanner of a graph G, and let $\mathcal{S}_n^t$ be the maximum value of S_G^t over all possible graphs on n vertices. Does there exist a polynomial time algorithm which computes, for any weighted graph and parameter t, its t-spanner of size $O(\mathcal{S}_n^t)$? Such an algorithm would be the best one can hope for given the hardness of the original t-spanner problem. Naturally, the question arises as to how large can $\mathcal{S}_n^t$ be ? A 43-year-old girth lower bound conjecture by Erdös [13] implies that there are graphs on n vertices whose $2k-$ as well as $(2k-1)$-spanner will require $\Omega(n^{1+1/k})$ edges. This conjecture has been proved for $k = 1, 2, 3$, and 5. Note that a $(2k-1)$-spanner is also a $2k$-spanner, and the lower bound on the size is the same for both $2k$-spanner and $(2k-1)$-spanner. So the objective is to design an algorithm that, for any weighted graph on n vertices, computes a $(2k-1)$-spanner of $O(n^{1+1/k})$ size. Needless to say, one would like to design the fastest algorithm for this problem, and the most ambitious aim would be to achieve the linear time complexity.

Key Results

The key results of this entry are two very simple algorithms which compute a $(2k-1)$-spanner of a given weighted graph $G = (V, E)$. Let n and m

denote, respectively, the number of vertices and edges of G. The first algorithm, due to Althöfer et al. [2], is based on a greedy strategy and runs in $O(mn^{1+1/k})$ time. The second algorithm [6] is based on a very local approach and runs in an expected $O(m)$ time. To start with, consider the following simple observation. Suppose there is a subset $E_S \subset E$ that ensures the following proposition for every edge $(x, y) \in E \setminus E_S$.

> $\mathcal{P}_t(x, y)$: the vertices x and y are connected in the subgraph (V, E_S) by a path consisting of at most t edges, and the weight of each edge on this path is not more than that of the edge (x, y).

It follows easily that the subgraph (V, E_S) will be a t-spanner of G. The two algorithms for computing $(2k-1)$-spanner eventually compute such set E_S based on two completely different approaches.

Algorithm I

This algorithm selects edges for spanner in a greedy fashion and is similar to Kruskal's algorithm for computing a minimum spanning tree. The edges of the graph are processed in the increasing order of their weights. To begin with, the spanner $E_S = \emptyset$; and the algorithm adds edges to it gradually. The decision as to whether an edge, say (u, v), has to be added (or not) to E_S is made as follows:

> If the distance between u and v in the subgraph induced by the current spanner edges E_S is more than $t \cdot weight(u, v)$, then add the edge (u, v) to E_S; otherwise, discard the edge.

It follows that $\mathcal{P}_t(x, y)$ would hold for each edge of E missing in E_S, and so at the end, the subgraph (V, E_S) will be a t-spanner. A well-known result in elementary graph theory states that a graph with more than $n^{1+1/k}$ edges must have a cycle of length at most $2k$. It follows from the above algorithm that the length of any cycle in the subgraph (V, E_S) has to be at least $t + 1$. Hence, for $t = 2k - 1$, the number of edges in the subgraph (V, E_S) will be less than $n^{1+1/k}$. Thus, the algorithm I described above computes a $(2k-1)$-spanner of size $O(n^{1+1/k})$, which is indeed optimal based on the lower bound mentioned earlier.

A simple $O(mn^{1+1/k})$ implementation of algorithm I follows based on Dijkstra's algorithm. Cohen [10] and later Thorup and Zwick [19] designed algorithms for $(2k-1)$-spanner with an improved running time of $O(kmn^{1+1/k})$. These algorithms relied on several calls to Dijkstra's single-source Shortest path algorithm for distance computation and therefore were far from achieving linear time. On the other hand, since a spanner must approximate all-pairs distances in a graph, it appears difficult to compute a spanner by avoiding explicit distance information. Somewhat surprisingly, algorithm II, described in the following section, avoids any sort of distance computation and achieves expected linear time.

Algorithm II

This algorithm employs a novel clustering based on a very local approach and establishes the following result for the spanner problem:

> Given a weighted graph $G = (V, E)$ and an integer $k > 1$, a spanner of $(2k-1)$ stretch and $O(kn^{1+1/k})$ size can be computed in expected $O(km)$ time.

The algorithm executes in $O(k)$ rounds, and in each round it essentially explores adjacency list of each vertex to prune dispensable edges. As a testimony of its simplicity, we will present the entire algorithm for 3-spanner and its analysis in the following section. The algorithm can be easily adapted in other computational models (parallel, external memory, distributed) with nearly optimal performance (see [6] for more details).

Computing a 3-Spanner in Linear Time

To meet the size constraint of a 3-spanner, a vertex, on an average, contributes $\sqrt{n}$ edges to the spanner. So the vertices with degree $O(\sqrt{n})$ are easy to handle since all their edges can be selected in the spanner. For vertices with higher degree, a clustering (groupings) scheme is employed to tackle this problem which has its basis in *dominating sets*.

To begin with, there is a set of edges E' initialized to E and empty spanner E_S. The algorithm processes the edges E', moves some of them to the spanner E_S, and discards the remaining ones. It does so in the following two phases:

1. *Forming the clusters*
   A sample $\mathcal{R} \subset V$ is chosen by picking each vertex independently with probability $\frac{1}{\sqrt{n}}$. The clusters will be formed around these sampled vertices. Initially, the clusters are $\{\{u\}|u \in \mathcal{R}\}$. Each $u \in \mathcal{R}$ is called the *center* of its cluster. Each unsampled vertex $v \in V - \mathcal{R}$ is processed as follows:
   (a) If v is not adjacent to any sampled vertex, then every edge incident on v is moved to E_S.
   (b) If v is adjacent to one or more sampled vertices, let $\mathcal{N}(v, \mathcal{R})$ be the sampled neighbor that is nearest (Ties can be broken arbitrarily. However, it helps conceptually to assume that all weights are distinct) to v. The edge $(v, \mathcal{N}(v, \mathcal{R}))$ along with every edge that is incident on v with weight less than this edge is moved to E_S. The vertex v is added to the cluster centered at $\mathcal{N}(v, \mathcal{R})$.
   As a last step of the first phase, all those edges (u, v) from E' where u and v are not sampled and belong to the same cluster are discarded.
   Let V' be the set of vertices corresponding to the endpoints of the edges E' left after the first phase. It follows that each vertex from V' is either a sampled vertex or adjacent to some sampled vertex, and step 1(b) has partitioned V' into disjoint clusters each centered around some sampled vertex. Also note that, as a consequence of the last step, each edge of the set E' is an intercluster edge. The graph (V', E'), and the corresponding clustering of V', is passed onto the following (second) phase.
2. *Joining vertices with their neighboring clusters*
   Each vertex v of graph (V', E') is processed as follows. Let $E'(v, c)$ be the edges from the set E' incident on v from a cluster c. For each cluster c neighboring to v, the least-weight edge from $E'(v, c)$ is moved to E_S, and the remaining edges are discarded.

The number of edges added to the spanner E_S during the algorithm described above can be bounded as follows. Note that the sample set $\mathcal{R}$ is formed by picking each vertex randomly independently with probability $\frac{1}{\sqrt{n}}$. It thus follows from elementary probability that for each vertex $v \in V$, the expected number of incident edges with weight less than that of $(v, \mathcal{N}(v, \mathcal{R}))$ is at most $\sqrt{n}$. Thus, the expected number of edges contributed to the spanner by each vertex in the first phase of the algorithm is at most $\sqrt{n}$. The number of edges added to the spanner in the second phase is $O(n|\mathcal{R}|)$. Since the expected size of the sample $\mathcal{R}$ is $\sqrt{n}$, therefore, the expected number of edges added to the spanner in the second phase is at most $n^{3/2}$. Hence, the expected size of the spanner E_S at the end of the algorithm described above is at most $2n^{3/2}$. The algorithm is repeated if the size of the spanner exceeds $3n^{3/2}$. It follows using Markov's inequality that the expected number of such repetitions will be $O(1)$.

We now establish that E_S is a 3-spanner. Note that for every edge $(u, v) \notin E_S$, the vertices u, v belong to some cluster in the first phase. There are two cases now.

Case 1 : *(u and v belong to the same cluster)*

Let u and v belong to the cluster centered at $x \in \mathcal{R}$. It follows from the first phase of the algorithm that there is a 2-edge path $u - x - v$ in the spanner with each edge not heavier than the edge (u, v). (This provides a justification for discarding all intracluster edges at the end of the first phase.)

Case 2 : *(u and v belong to different clusters)*

Clearly, the edge (u, v) was removed from E' during phase 2, and suppose it was removed while processing the vertex u. Let v belong to the cluster centered at $x \in \mathcal{R}$.

In the beginning of the second phase, let $(u, v') \in E'$ be the least-weight edge among all the edges incident on u from the vertices of the cluster centered at x. So it

must be that $weight(u, v') \leq weight(u, v)$. The processing of vertex u during the second phase of our algorithm ensures that the edge (u, v') gets added to E_S. Hence, there is a path $\Pi_{uv} = u - v' - x - v$ between u and v in the spanner E_S, and its weight can be bounded as $weight(\Pi_{uv}) = weight(u, v') + weight(v', x) + weight(x, v)$. Since (v', x) and (v, x) were chosen in the first phase, it follows that $weight(v', x) \leq weight(u, v')$ and $weight(x, v) \leq weight(u, v)$. It follows that the spanner (V, E_S) has stretch 3. Moreover, both phases of the algorithm can be executed in $O(m)$ time using elementary data structures and bucket sorting.

The algorithm for computing a $(2k - 1)$-spanner executes k iterations where each iteration is similar to the first phase of the 3-spanner algorithm. For details and formal proofs, the reader may refer to [6].

Other Related Works

The notion of a spanner has been generalized in the past by many researchers.

Additive Spanners

A t-spanner as defined above approximates pairwise distances with multiplicative error and can be called a multiplicative spanner. In an analogous manner, one can define spanners that approximate pairwise distances with additive error. Such a spanner is called an additive spanner, and the corresponding error is called *surplus*. Aingworth et al. [1] presented the first additive spanner of size $O(n^{3/2} \log n)$ with surplus 2. Baswana et al. [7] presented a construction of $O(n^{4/3})$-size additive spanner with surplus 6. Recently, Chechik [9] presented a construction of $O(n^{7/5})$-size additive spanner with surplus 4. It is a major open problem if there exists any sparser additive spanner.

(α, β)-Spanner

Elkin and Peleg [12] introduced the notion of (α, β)-spanner for unweighted graphs, which can be viewed as a hybrid of multiplicative and additive spanners. An (α, β)-spanner is a subgraph such that the distance between any pair of vertices $u, v \in V$ in this subgraph is bounded by $\alpha\delta(u, v) + \beta$, where $\delta(u, v)$ is the distance between u and v in the original graph. Elkin and Peleg showed that an $(1 + \epsilon, \beta)$-spanner of size $O(\beta n^{1+\delta})$, for arbitrarily small $\epsilon, \delta > 0$, can be computed at the expense of sufficiently large surplus β. Recently, Thorup and Zwick [20] introduced a spanner where the additive error is sublinear in terms of the *distance* being approximated.

Other interesting variants of spanner include *distance preserver* proposed by Bollobás et al. [8] and *lightweight* spanner proposed by Awerbuch et al. [4]. A subgraph is said to be a d-preserver if it preserves exact distances for each pair of vertices which are separated by distance at least d. A lightweight spanner tries to minimize the number of edges as well as the total edge weight. A *lightness* parameter is defined for a subgraph as the ratio of total weight of all its edges and the weight of the minimum spanning tree of the graph. Awerbuch et al. [4] showed that for any weighted graph and integer $k > 1$, there exists a polynomially constructible $O(k)$-spanner with $O(k\rho n^{1+1/k})$ edges and $O(k\rho n^{1/k})$ lightness, where $\rho = \log(diameter)$.

In addition to the above work on the generalization of spanners, a lot of work has also been done on computing spanners for special classes of graphs, e.g., chordal graphs, unweighted graphs, and Euclidean graphs. For chordal graphs, Peleg and Schäffer [15] designed an algorithm that computes a 2-spanner of size $O(n^{3/2})$ and a 3-spanner of size $O(n \log n)$. For unweighted graphs, Halperin and Zwick [14] gave an $O(m)$ time algorithm for this problem. Salowe [18] presented an algorithm for computing a $(1 + \epsilon)$-spanner of a d-dimensional complete Euclidean graph in $O(n \log n + \frac{n}{\epsilon^d})$ time. However, none of the algorithms for these special classes of graphs seem to extend to general weighted undirected graphs.

Applications

Spanners are quite useful in various applications in the area of distributed systems and

communication networks. In these applications, spanners appear as the underlying graph structure. In order to build compact routing tables [17], many existing routing schemes use the edges of a sparse spanner for routing messages. In distributed systems, spanners play an important role in designing *synchronizers*. Awerbuch [3] and Peleg and Ullman [16] showed that the quality of a spanner (in terms of stretch factor and the number of spanner edges) is very closely related to the time and communication complexity of any synchronizer for the network. The spanners have also been used implicitly in a number of algorithms for computing all-pairs approximate shortest paths [5, 10, 19, 21]. For a number of other applications, please refer to the papers [2, 3, 15, 17].

Open Problems

The running time as well as the size of the $(2k-1)$-spanner computed by the algorithm described above are away from their respective worst-case lower bounds by a factor of k. For any constant value of k, both these parameters are optimal. However, for the extreme value of k, that is, for $k = \log n$, there is deviation by a factor of $\log n$. Is it possible to get rid of this multiplicative factor of k from the running time of the algorithm and/or the size of the $(2k-1)$-spanner computed? It seems that a more careful analysis coupled with advanced probabilistic tools might be useful in this direction.

Introduction

We have a two-sided market, one side is a set U of men, the other side is a set V of women. The first part of the input also contains the mutually acceptable man-woman pairs E. This makes up a bipartite graph $G(U \cup V, E)$. The second part of the input contains the preference lists of each person, that is a weak order (may contain ties) on his/her acceptable pairs.

A *matching* is a set of mutually disjoint acceptable man-woman pairs. Given a matching M, a man m and a woman w form a *blocking* pair, if they are an acceptable pair but are not partners in M, and they both prefer each other to their partner, or have no partner in M. That is either w is unmatched in M or w prefers m to her M-partner, *and* either m is unmatched in M or m prefers w to his M-partner. A matching M is *stable* if there are no blocking pairs.

We consider a two-sided market under incomplete preference lists with ties (SMTI), where the goal is to find a maximum size stable matching (MAX-SMTI).

Problem Definition

Problem 1 (MAX-SMTI)

INPUT: Set U of men, and set V of women and each person's preference list.
OUTPUT: A stable matching of maximum size.

Input format A list of an agent a consists of pairs (a_1, p_1), $(a_2, p_2), \ldots, (a_d, p_d)$, where a_i are the acceptable persons from the other gender and $1 \leq p_i \leq \max(|U|, |V|)$ are integers with ordering $p_1 \geq p_2 \geq \cdots \geq p_d$. Agent a strictly prefers a_i to a_j if $p_i > p_j$ and is indifferent between a_i and a_j if $p_i = p_j$. Moreover women needs a black-box procedure, which on input a_i outputs in constant time p_i (we assume that this procedure is also a part of the input). The size of the input is the number of agents plus the total length of the lists.

Definition of approximation ratios A goodness measure of an approximation algorithm A for a maximization problem is defined as follows: the *approximation ratio* of A is $\max\{\text{opt}(I)/A(I)\}$ over all instances I, where $\text{opt}(I)$ and $A(I)$ are the size of the optimal and the algorithm's solution on instance I, respectively.

Short history It was shown in [4] that finding the optimal solution is NP-hard; moreover, it is APX-hard [3]. The original Deferred Acceptance Algorithm of Gale and Shapley gives a 2-approximation; the first approximation algorithm with a strictly better ratio was presented in [5], where the approximation ratio was 15/8. This was improved in [6] to a 5/3-approximation and later in [9] to a 3/2-approximation; this latter algorithm had nonlinear running time. Recently in [10] and

in [7], linear time 3/2-approximation algorithms were given.

Key Results

A simple variation of the famous Deferred Acceptance Algorithm of Gale and Shapley is presented; which also runs in linear time and gives a 3/2-approximation for the problem MAX-SMTI. This algorithm is local; no central agent or knowledge about the global input is needed.

Algorithm

Preliminary Definitions and Concepts for the Algorithm

During the algorithm, the agents may have different statuses, and some Boolean properties described below, and also varying actual preferences.

A status of a man can be either a **lad** or a **bachelor** or an **old bachelor**. A man can be **active** or inactive. A man is active, if he is not an old bachelor and he is not **engaged** (i.e., he has actually no partner). A man can also be **uncertain**, described later. Initially every man is an active lad.

A status of a woman can be either **maiden** or **engaged**. An engaged woman is **flighty**, if her fiancé is *uncertain*. Initially every woman is maiden.

The actual preferences a man m is described as follows. If women w_1 and w_2 are indifferent on m's list, and w_1 is maiden but w_2 is engaged, then m **prefers maiden** w_1 to **engaged** w_2. An engaged lad is **uncertain** if his list contains a woman he prefers to his actual fiancée (this can happen, if there were two maidens with the same highest priority on m's list, and m became engaged to one of them).

The actual preferences a woman w is described as follows. If there are two men, m_1 and m_2 with the same priority in w's list, and m_1 is a lad, but m_2 is a bachelor, then w **prefers bachelor** m_2 to **lad** m_1. If w is flighty, then she prefers a man who is not uncertain, to a man who is uncertain (regardless of her original preferences).

The Algorithm

> While there exists an active man m, he proposes to his favorite woman w. If w accepts his proposal, they become engaged. If w rejects him, m deletes w from his list and remain active.
> When a woman w gets a new proposal from man m, she accepts this proposal if she (actually) prefers m to her current fiancé. Otherwise she rejects m.
> If w accepted m, then she rejects her previous fiancé, if there was one (breaks off her engagement), and becomes engaged to m.
> If m was engaged to a woman w and later w rejects him, then m becomes active again and deletes w from his list, except if m is uncertain, in this case m keeps w on the list.
> If the list of m becomes empty for the first time, he turns into a bachelor, his original list is recovered, and he reactivates himself. If the list of m becomes empty for the second time, he will turn into an old bachelor and will remain inactive forever.

After the algorithm finishes, the engaged pairs get married and form matching M.

Theorem 1 ([7]) *The algorithm always gives a stable matching M and it is $3/2$-approximating, i.e., the stable matching given has size at least $2/3$ of the maximum size stable matching.*

Running Time, Locality

This algorithm runs in linear time using the assumptions on the input format. Though it is clear that along every edge at most three proposals happen, the technical details must be worked out; see [7] for details.

Local algorithm Each agent (a man or woman) always makes a greedy decision based only on local information (his/her preference list, and provided by some communication with his/her acceptable partners). A local algorithm is linear if

every agent communicates with each acceptable partner only a constant time during the algorithm.

The algorithm presented is a linear time local algorithm (using the appropriate data structures); see [7] for details.

Problem Definition

Buffer management policies are online algorithms that control a limited buffer of packets with homogeneous or heterogeneous characteristics, deciding whether to accept new packets when they arrive, which packets to process and transmit, and possibly whether to push out packets already residing in the buffer. Although settings differ, the problem is always to achieve the best possible competitive ratio, i.e., find a policy with good worst-case guarantees in comparison with an optimal offline clairvoyant algorithm. The policies themselves are often simple, simplicity being an important advantage for implementation in switches; the hard problem is to find proofs of lower and especially upper bounds for their competitive

The work of Sergey Nikolenko was partially supported by the Government of the Russian Federation (grant 14.Z50.31.0030).

ratios. Thus, this problem is more theoretical in nature, although the resulting throughput guarantees are important tools in the design of network elements. Comprehensive surveys of this field have been given in the past by Goldwasser [9] and Epstein and van Stee [7].

General Model Description

We assume discrete slotted time. A packet is *fully processed* if the processing unit has scheduled the packet for processing for at least its required number of cycles. Each packet may have the following characteristics: (i) *required processing*, i.e., how many processing cycles the packet has to go through before it can be transmitted; (ii) *value*, i.e., how much the packet contributes to the objective function when it is transmitted; (iii) *output port*, i.e., where the packet is headed (in settings with multiple output ports, it is usually assumed that processing occurs independently at each port, so it becomes advantageous to have more busy output ports at a time); and (iv) *size*, i.e., how many slots (bytes) a packet occupies in the buffer. The objective of a buffer management policy is to maximize the total value of transmitted packets. Different settings may assume that some characteristics are uniform.

Competitive Analysis

Competitive analysis provides a uniform throughput guarantee for online algorithms across all traffic patterns. An online algorithm ALG is said to be α-*competitive* with respect to some objective function f (for some $\alpha \geq 1$ which is called the *competitive ratio*) if for any arrival sequence σ the objective function value on the result of ALG is at least $1/\alpha$ times the objective function value on the solution obtained by an offline clairvoyant algorithm, denoted OPT.

Problem 1 (Competitive Ratio) For a given switch architecture, packet characteristics, and an online algorithm ALG in a given setting, prove lower and upper bounds on its competitive ratio with respect to weighted throughput (total value of packets transmitted by an algorithm).

Key Results

Policies and lower and upper bounds on their competitive ratios are outlined according to problem settings; the latter differ in which packet characteristics they assume to be uniform and which are allowed to vary, and additional restrictions may be imposed on admission, processing and/or transmission order, and admissible packet characteristics.

Uniform Processing, Uniform Value, Shared Memory Switch

Since all packets are identical, the problem for a single queue with one output port is trivial. We consider an $M \times N$ shared memory switch that can hold B packets, with a separate processor on each output port. All packets require a single processing cycle and have equal value; the goal is to maximize the number of transmitted packets. Each packet is labeled with an output port where it has to be processed and transmitted.

Non-Push-Out Policies

Kesselman and Mansour [14] show an adversarial logarithmic lower bound: no non-push-out policy can achieve competitive ratio better than $d/2$ for $d = \log_d N$. On the positive side, they present the Harmonic policy that allocates approximately $1/i$ of the buffer to the ith largest queue and, for its variant, the Parametric Harmonic policy, show an upper bound of $c \log_c N + 1$.

Push-Out Policies

The best known policy is Longest Queue Drop (LQD): accept packets greedily if the buffer is not full; if it is, accept the new packet and then drop a packet from the longest queue (destined to the output port with the most packets assigned to it). Aiello et al. [1,10] show that the competitive ratio of LQD is between $\sqrt{2}$ and 2; they also provide nonconstant lower bounds for other popular policies and a general adversarial lower bound of $\frac{4}{3}$ on the competitive ratio of any online algorithm.

Uniform Processing, Uniform Value, Multiple Separated Queues

In an $N \times 1$ switch where each of N input queues has a separate independent buffer of size B, a policy must select which input queue to take a packet from and set admission policies for input queues. For uniform values, the problem was closed by Azar and Litichevskey [3] with a deterministic policy with competitive ratio converging to $\frac{e}{e-1} \approx 1.582$ for arbitrary B; a matching lower bound was shown by Azar and Richter [4].

Uniform Processing, Variable Values, Single Queue

Here, there is only one output port (a single queue), and each packet is fully processed in one cycle; however, packets have different values, making it desirable to drop packets with smaller value and process packets of larger value. It is easy to show that the Priority Queue (PQ) policy that sorts packets with respect to values and pushes out smaller values for larger ones is optimal. Research has concentrated on models with additional constraints: non-push-out policies that are not allowed to push admitted packets out and the FIFO model where packets have to be transmitted in order of arrival. Another important special case considers two possible values: 1 and $V > 1$.

Non-Push-Out Policies

Aiello et al. [2] consider five online policies for the two-valued case, considering the specific cases of $V = 1$, $V = 2$, and $V = \infty$. Andelman, Mansour, and Zhu provide a deterministic policy (Ratio Partition) that achieves optimal $\left(2 - \frac{1}{V}\right)$-competitiveness [26]. In the case of arbitrary values between 1 and $V > 1$, they show that the optimal competitive ratio is $\ln V$, proving tightly matching bounds of $1 + \ln V$ and $2 + \ln V + O(\ln^2 V/B)$ [2,26].

Push-Out Policies

In the FIFO model, there has been a line of adversarial lower bounds culminating in the lower bound of 1.419 shown by Kesselman, Mansour, and van Stee [18] that applies to all algorithms, with a stronger bound of 1.434 for $B = 2$ [2,26]. As for upper bounds, in this simple model the FIFO greedy push-out policy (accept every packet to end of queue, then push out the packet with smallest value if buffer has overflown) has been shown by Kesselman et al. to be 2-competitive [17]; in the two-valued case, they provide an adversarial lower bound of 1.282, and a long line of improvements for the upper bound has led to the optimal Account Strategy policy of Englert and Westermann [6]. They show an adversarial lower bound of $r = \frac{1}{2}(\sqrt{13} - 1) \approx 1.303$ for any $B \geq 2$ and $r_\infty = \sqrt{2} - \frac{1}{2}(\sqrt{5 + 4\sqrt{2}} - 3) \approx 1.282$ for $B \to \infty$ and show that Account Strategy achieves competitive ratio r for arbitrary B and r_∞ for $B \to \infty$. Thus, in the push-out two-valued case, the gap between lower and upper bounds has been closed completely.

Uniform Processing, Variable Values, Multiple Separated Queues

Kawahara et al. [11] consider an $N \times 1$ switch with N separated queues, each of which has a distinct buffer of size B and has a value α_j associated with it, $1 = \alpha_1 \leq \ldots \leq \alpha_N = \alpha$. A policy selects one of N queues, maximizing total transmitted value; [11] provides matching lower and upper bounds for the PQ policy as $1 + \frac{\sum_{j=1}^{n'} \alpha_j}{\sum_{j=1}^{n'+1} \alpha_j}$, where $n' = \arg\max_n \frac{\sum_{j=1}^{n} \alpha_j}{\sum_{j=1}^{n+1} \alpha_j}$, and an adversarial lower bound $1 + \frac{\alpha^3+\alpha^2+\alpha}{\alpha^4+4\alpha^3+3\alpha^2+4\alpha+1}$ for any online algorithm. Azar and Richter [4] show that any r-competitive policy for a FIFO queue with variable values yields a $2r$-competitive policy for multiple queues. Kobayashi et al. [21] show that an r-competitive policy for unit values and multiple queues yields a $\min\left\{Vr, \frac{Vr(2-r)+r^2-2r+2}{V(2-r)+r-1}\right\}$-competitive policy for the two-valued case.

Uniform Processing, Variable Values, Shared Memory Switch

Several output queues, each with a processor, share a buffer of size B, and each unit-sized packet is labeled with an output port

and an intrinsic value from 1 to V. Eugster, Kogan, Nikolenko, and Sirotkin [8] show a $(\sqrt[3]{V} - o(\sqrt[3]{V}))$ lower bound for the LQD (Longest Queue Drop) policy, an $\frac{1}{2}(\min\{V, B\} - 1)$ lower bound for the MVD (Minimal Value Drop) policy, and a $\frac{4}{3}$ lower bound for the MRD (Maximal Ratio Drop) policy.

Uniform Processing, CIOQ Switches

In CIOQ (Combined Input–Output Queued) switches, one maintains at each input a separate queue for each output (also called Virtual Output Queuing, VOQ). To get delay guarantees of an input queuing (IQ) switch closer to those of an output queuing switch (OQ), one usually assumes increased *speedup* S: the switching fabric runs S times faster than each of the input or the output ports. Hence, an OQ switch has a speedup of N (where N is the number of input/output ports), whereas an IQ switch has a speedup of 1; for $1 < S < N$, packets need to be buffered at the inputs before switching as well as at the outputs after switching. This architecture is called a CIOQ switch.

Uniform Values

Consider an $N \times N$ CIOQ switch with speedup S. Packets of equal size arrive at input ports, each labeled with the output port where it has to leave the switch. Each packet is placed in the input queue corresponding to its output port; when it crosses the switch fabric, it is placed in the output queue and resides there until it is sent on the output link. For unit-valued packets, Kesselman and Rosén [15] proposed a non-push-out policy which is 3-competitive for any S and 2-competitive for $S = 1$. Kesselman, Kogan, and Segal [13] show an upper bound of 4 on the competitiveness of a simple greedy policy.

Variable Values

For up to m packet values in $[1, V]$, Kesselman and Rosén [15] show two push-out policies to be $4S$- and $8\min\{m, 2\log V\}$-competitive. Azar and Richter [5] propose a push-out policy β-PG with parameter β; Kesselman et al. [20] show that the competitive ratio of β-PG is at most 7.5 for $\beta = 3$ and at most 7.47 for $\beta = 2.8$. Kesselman and Rosén [16] consider CIOQ switches with PQ buffers (transmit the highest value packet) and show that this policy is 6-competitive for any S.

Uniform Processing, Crossbar Switches

In the buffered crossbar switch architecture, a small buffer is placed on each crosspoint in addition to input and output queues, which greatly simplifies the scheduling process. For packets with unit length and value, Kesselman et al. [20] introduce a greedy switch policy with competitive ratio between $\frac{3}{2}$ and 4 and show a general lower bound of $\frac{3}{2}$ for unit-size buffers. For variable values and PQ buffers, they propose a push-out greedy switch policy with preemption factor β with competitive ratio between $(2\beta-1)/(\beta-1)$ (3.87 for $\beta = 1.53$) and $(\beta + 2)^2 + 2/(\beta - 1)$ (16.24 for $\beta = 1.53$). For variable values and FIFO buffers, they propose a β-push-out greedy switching policy with competitive ratio $6 + 4\beta + \beta^2 + 3/(\beta - 1)$ (19.95 for $\beta = 1.67$) [19].

Uniform Values, Variable Processing, Single Queue

In this setting, each packet contributes one unit to the objective function, but different packets have different processing requirements, i.e., they spend a different number of time slots at the processor. We denote maximal possible required processing by k.

Non-Push-Out Policies

For a single queue and packets with heterogeneous processing, non-push-out policies have not been considered in any detail. Kogan, López-Ortiz, Nikolenko, and Sirotkin [23] have shown that any greedy non-push-out policy is at least $\frac{1}{2}(k + 1)$-competitive. It remains an open problem to find non-push-out policies with sublinear competitive ratios or show that none exists.

Push-Out Policies

Keslassy et al. [12] showed that again, for a single queue, PQ (Priority Queue) that sorts packets with respect to required processing (smallest first) is optimal; research has concentrated on the FIFO case, where packets have to be transmitted in order of arrival. Kogan et al. [24] introduced

lazy policies that process packets down to a single cycle but then delay their transmission until the entire queue consists of such packets; then all packets are transmitted out in as many time slots as there are packets in the queue. In [24], LPO (Lazy Push-Out) was proven to be at most $(\max\{1, \ln k\} + 2 + o(1))$-competitive; [24] also provides a lower bound of $\lfloor \log_B k \rfloor + 1 - O(1/B)$ for both PO (push-out FIFO) and LPO; for large k this bound matches the upper bound up to a factor of $\log B$. Proving a matching upper bound for the PO policy remains an important open problem. In the two-valued case, when packets may have required processing only 1 or k, LPO has a lower bound of $2 - \frac{1}{k}$ and a matching upper bound of $2 + \frac{1}{B}$ [24]. Kogan, López-Ortiz, Nikolenko, and Sirotkin [23] introduce *semi-FIFO* policies, separating processing order from transmission order so that transmission can conform to FIFO constraints while processing order remains arbitrary. Lazy policies thus become a special case of semi-FIFO policies. The authors show a general upper bound of $\frac{1}{B} \log_{\frac{B}{B-1}} k + 3$ on the competitive ratio of any lazy policy and a matching lower bound of $\frac{1}{B} \log_{\frac{B}{B-1}} k + 1$ for several processing orders. In the two-valued case, when processing is only 1 or k, this upper bound improves to $2 + \frac{1}{B}$, so any lazy policy has constant competitiveness. LPQ (Lazy Priority Queue) also falls in the semi-FIFO class; its competitiveness is between $\left(2 - \frac{1}{B}\left\lceil \frac{B}{k} \right\rceil\right)$ and 2 even for arbitrary processing requirements. Kogan et al. [22] consider a generalization with packets of varying size, considering several natural policies and showing an upper bound of $4L$ for one of PO policies, where L is the maximal packet size.

Copying Cost

An important generalization of the heterogeneous processing model was introduced by Keslassy et al. [12]. They attach a penalty α called copying cost to admitting a packet in the queue; thus, the objective function is now $T - \alpha A$, where T is the number of transmitted packets and A is the number of accepted ones, and it becomes less advantageous to push packets out. To deal with copying cost, the authors propose to use β-push-out policies that push a packet out only if its required processing is at least $\beta > 1$ times less than the required processing of a packet which is being pushed out. Keslassy et al. [12] consider the PQ_β policy (Priority Queue with β-push-out) and show that it is at most $\frac{1}{1-\alpha \log_\beta k}\left(1 + \log_{\frac{\beta}{\beta-1}} \frac{k}{2} + 2\log_\beta k\right)(1-\alpha)$-competitive. Kogan, López-Ortiz, Nikolenko, and Sirotkin [23] show that for any processing order, a β-push-out lazy policy LA_β has competitive ratio at most $\left(3 + \frac{1}{B}\log_{\frac{\beta B}{\beta B - 1}} k\right)\frac{1-\alpha}{1-\alpha\log_\beta k}$. They show a lower bound $\frac{1-\alpha}{1-\alpha\log_\beta k}$ on the competitive ratio of any β-push-out policy, which matches the additional factor in the upper bound. In the two-valued case, the upper bound becomes $\left(2 + \frac{1}{B}\right)\frac{1-\alpha}{1-2\alpha}$, and the authors also show a matching lower bound of $\frac{(2B-2)(1-\alpha)}{(B-1)(1-2\alpha)+(1-\alpha)}$.

Uniform Values, Variable Processing, Multiple Separated Queues

Consider k separate queues of size B each; packets with required processing i fall into the ith queue, and the processor chooses which queue to process on a given time slot. Push-out is irrelevant since queues are independent and packets in a queue are identical. Kogan, López-Ortiz, Nikolenko, and Sirotkin [25] show linear lower bounds for several seemingly attractive policies: $\frac{1}{2}\min\{k, B\}$ for LQF (Longest Queue First), k for SQF (Shortest Queue First), $\frac{3k(k+2)}{4k+16}$ for PRR (Packet Round Robin), and an almost linear lower bound of $\frac{k}{H(k)}$, where $H(k) = \sum_{i=1}^{k} \frac{1}{i} \approx \ln k + \gamma$, for CRR (Cycle Round Robin). They introduce a policy called MQF (Minimal Queue First) that processes packets from a nonempty queue with minimal processing requirement. They show that MQF is at least $\left(1 + \frac{k-1}{2k}\right)$-competitive and prove a constant upper bound of 2. For the two-valued case with two queues, 1 and k, Kogan et al. [25] show exactly matching lower and upper bounds for MQF of $1 + \left(1 + \left\lfloor \frac{aB-1}{b} \right\rfloor\right) / \left(B + \left\lceil \frac{1}{a}\left(b\left\lfloor \frac{aB-1}{b} \right\rfloor + 1\right)\right\rceil\right)$.

Uniform Values, Variable Processing, Shared Memory Switch

In this setting, multiple queues with shared memory are implemented in the same way as for

uniform processing and heterogeneous values: there are N output ports, each output port manages a single output queue Q_i, and each output queue collects packets with the same processing requirement (so packets in a given queue are identical).

Non-Push-Out Policies

Eugster, Kogan, Nikolenko, and Sirotkin [8] consider non-push-out policies and show that NHST (Non-Push-Out Harmonic with Static Threshold: $|Q_i|$ is bounded by $\frac{B}{r_i Z}$) is $(kZ + o(kZ))$-competitive, NEST (Non-Push-Out with Equal Static Threshold: $|Q_i|$ is bounded by B/n) is $(N + o(N))$-competitive, NHDT (Non-Push-Out with Harmonic Dynamic Threshold: accept into Q_i if $\sum_{s=1}^{m} |Q_{j_s}| < \frac{B}{H_k}\left(1 + \frac{1}{2} + \ldots + \frac{1}{m}\right)$, where $j_1 \ldots j_m = i$ are queues for which $|Q_j| \geq |Q_i|$) is $(\frac{1}{2}\sqrt{k \ln k} - o(\sqrt{k \ln k}))$-competitive; finding better non-push-out policies is an open problem.

Push-Out Policies

The work [8] also shows lower bounds on the competitive ratio of well-known policies: $(\sqrt{k} - o(\sqrt{k}))$ for LQD (Longest Queue Drop), $(\ln k + \gamma)$ for BQD (Biggest Packet Drop), and $\left(\frac{4}{3} - \frac{6}{B}\right)$ for LWD (Largest Work Drop). The main result of [8] is that LWD is at most 2-competitive.

Open Problems

1. Close the gap between competitive ratios $\frac{4}{3}$ (lower bound for any policy) and 2 (upper bound for LQD) in the uniform processing, uniform value case.
2. Do there exist policies with constant competitive ratio in the uniform processing, variable values, shared memory multiple output queues setting?
3. Do there exist non-push-out policies with sublinear competitive ratio in the case of a single queue with packets with variable processing and uniform values?
4. Prove an upper bound on the competitiveness of PO (push-out) policy in the single-queue FIFO model with heterogeneous required processing and uniform values.
5. Do there exist non-push-out policies with logarithmic competitive ratio in the case of multiple output ports with shared memory that contain packets with variable processing and uniform values?
6. Design efficient policies for CIOQ and crossbar switches with packets with heterogeneous processing and uniform values; prove bounds on their competitive ratios.
7. Design efficient policies and prove bounds on their competitive ratios for the case of packets with both variable values and heterogeneous processing requirements in all of the above settings.

Problem Definition

A dynamic graph algorithm maintains a given property $\mathcal{P}$ on a graph subject to dynamic changes, such as edge insertions, edge deletions and edge weight updates. A dynamic graph algorithm should process queries on property $\mathcal{P}$ quickly, and perform update operations faster than recomputing from scratch, as carried out by the fastest static algorithm. An algorithm is *fully dynamic* if it can handle both edge insertions and edge deletions and *partially dynamic* if it can handle either edge insertions or edge deletions, but not both.

Given a graph with n vertices and m edges, the *transitive closure* (or *reachability*) problem

consists of building an $n \times n$ Boolean matrix M such that $M[x, y] = 1$ if and only if there is a directed path from vertex x to vertex y in the graph. The fully dynamic version of this problem can be defifined as follows:

Definition 1 (Fully dynamic reachability problem) The *fully dynamic reachability problem* consists of maintaining a directed graph under an intermixed sequence of the following operations:

- `insert`(u,v): insert edge (u,v) into the graph.
- `delete`(u,v): delete edge (u,v) from the graph.
- `reachable`(x,y): return *true* if there is a directed path from vertex x to vertex y, and *false* otherwise.

This entry addresses the *single-source* version of the fully-dynamic reachability problem, where one is only interested in queries with a fixed source vertex s. The problem is defined as follows:

Definition 2 (Single-source fully dynamic reachability problem) The *fully dynamic single-source reachability problem* consists of maintaining a directed graph under an intermixed sequence of the following operations:

- `insert`(u,v): insert edge (u,v) into the graph.
- `delete`(u,v): delete edge (u,v) from the graph.
- `reachable`(y): return *true* if there is a directed path from the source vertex s to vertex y, and *false* otherwise.

Approaches

A simple-minded solution to the problem of Definition would be to keep explicit reachability information from the source to all other vertices and update it by running any graph traversal algorithm from the source s after each insert or delete. This takes $O(m + n)$ time per operation, and then reachability queries can be answered in constant time.

Another simple-minded solution would be to answer queries by running a point-to-point reachability computation, without the need to keep explicit reachability information up to date after each insertion or deletion. This can be done in $O(m + n)$ time using any graph traversal algorithm. With this approach, queries are answered in $O(m + n)$ time and updates require constant time. Notice that the time required by the slowest operation is $O(m+n)$ for both approaches, which can be as high as $O(n^2)$ in the case of dense graphs.

The first improvement upon these two basic solutions is due to Demetrescu and Italiano, who showed how to support update operations in $O(n^{1.575})$ time and reachability queries in $O(1)$ time [1] in a directed acyclic graph. The result is based on a simple reduction of the single-source problem of Definition to the all-pairs problem of Definition. Using a result by Sankowski [2], the bounds above can be extended to the case of general directed graphs.

Key Results

This Section presents a simple reduction presented in [1] that allows it to keep explicit single-source reachability information up to date in subquadratic time per operation in a directed graph subject to an intermixed sequence of edge insertions and edge deletions. The bounds reported in this entry were originally presented for the case of directed acyclic graphs, but can be extended to general directed graphs using the following theorem from [2]:

Theorem 1 *Given a general directed graph with n vertices, there is a data structure for the fully dynamic reachability problem that supports each insertion/deletion in $O(n^{1.575})$ time and each reachability query in $O(n^{0.575})$ time. The algorithm is randomized with one-sided error.*

The idea described in [1] is to maintain reachability information from the source vertex s to all other vertices explicitly by keeping a Boolean array R of size n such that $R[y] = 1$ if and

only if there is a directed path from s to y. An instance D of the data structure for fully dynamic reachability of Theorem is also maintained. After each insertion or deletion, it is possible to update D in $O(n^{1.575})$ time and then rebuild R in $O(n \cdot n^{0.575}) = O(n^{1.575})$ time by letting $R[y] \leftarrow D.\texttt{reachable}(s,y)$ for each vertex y. This yields the following bounds for the single-source fully dynamic reachability problem:

Theorem 2 *Given a general directed graph with n vertices, there is a data structure for the single-source fully dynamic reachability problem that supports each insertion/deletion in $O(n^{1.575})$ time and each reachability query in $O(1)$ time.*

Applications

The graph reachability problem is particularly relevant to the field of databases for supporting transitivity queries on dynamic graphs of relations [3]. The problem also arises in many other areas such as compilers, interactive verification systems, garbage collection, and industrial robotics.

Open Problems

An important open problem is whether one can extend the result described in this entry to maintain fully dynamic single-source shortest paths in subquadratic time per operation.

Single-Source Shortest Paths

Seth Pettie
Electrical Engineering and Computer Science (EECS) Department, University of Michigan, Ann Arbor, MI, USA

Keywords

Shortest route; Quickest route

Years and Authors of Summarized Original Work

1999; Thorup

Problem Definition

The *single-source* shortest path problem (SSSP) is, given a graph $G = (V, E, l)$ and a *source* vertex $s \in V$, to find the shortest path from s to every $v \in V$. The difficulty of the problem depends on whether the graph is directed or undirected and the assumptions placed on the length function ℓ. In the most general situation, $l : E \to \mathbb{R}$ assigns arbitrary (positive and negative) real lengths. The algorithms of Bellman-Ford and Edmonds [1, 4] may be applied in this situation and have running times of roughly $O(mn)$, (Edmonds's algorithm works for undirected graphs and presumes that there are no negative length simple cycles.) where $m = |E|$ and $n = |V|$ are the number of edges and vertices. If ℓ assigns only *nonnegative* real edge lengths, then the

algorithms of Dijkstra and Pettie-Ramachandran [4,13] may be applied on directed and undirected graphs, respectively. These algorithms include a *sorting bottleneck* and, in the worst case, take $\Omega(m + n \log n)$ time. (The [13] algorithm actually runs in $O(m + n \log \log n)$ time if the ratio of any two edge lengths is polynomial in n).

A common assumption is that ℓ assigns *integer* edge lengths in the range $\{0, \ldots, 2^w - 1\}$ or $\{-2^{w-1}, \ldots, 2^{w-1} - 1\}$ and that the machine is a w-bit *word RAM*; that is, each edge length fits in one register. For general integer edge lengths, the best SSSP algorithms improve on Bellman-Ford and Edmonds by a factor of roughly $\sqrt{n}$ [6]. For nonnegative integer edge lengths, the best SSSP algorithms are faster than Dijkstra and Pettie-Ramachandran by up to a logarithmic factor. They are frequently based on integer priority queues [9].

Key Results

Thorup's primary result [16] is an optimal linear time SSSP algorithm for undirected graphs with integer edge lengths. This is the first and only linear time shortest path algorithm that does not make serious assumptions on the class of input graphs.

Theorem 1 *There is a SSSP algorithm for integer-weighted undirected graphs that runs in $O(m)$ time.*

Thorup avoids the sorting bottleneck inherent in Dijkstra's algorithm by precomputing (in linear time) a *component hierarchy*. The algorithm of [16] operates in a manner similar to Dijkstra's algorithm [4] but uses the component hierarchy to identify groups of vertices that can be visited in any order. In later work, Thorup [17] extended this approach to work when the edge lengths are floating-point numbers. (There is some flexibility in the definition of *shortest path* since floating-point addition is neither commutative nor associative).

Thorup's hierarchy-based approach has since been extended to directed and/or real-weighted graphs and to solve the *all pairs* shortest path (APSP) problem [11–13]. The generalizations to related SSSP problems are summarized below. See [11,12] for hierarchy-based APSP algorithms.

Theorem 2 (Hagerup [8], 2000) *A component hierarchy for a directed graph $G = (V, E, l)$, where $l : E \to \{0, \ldots, 2^w - 1\}$, can be constructed in $O(m \log w)$ time. Thereafter, SSSP from any source can be computed in $O(m + n \log \log n)$ time.*

Theorem 3 (Pettie and Ramachandran [13], 2005) *A component hierarchy for an undirected graph $G = (V, E, l)$, where $l : E \to \mathbb{R}^+$, can be constructed in $O(m\alpha(m, n) + \min\{n \log \log r, n \log n\})$ time, where r is the ratio of the maximum-to-minimum edge length. Thereafter, SSSP from any source can be computed in $O(m \log \alpha(m, n))$ time.*

The algorithms of Hagerup [8] and Pettie-Ramachandran [13] take the same basic approach as Thorup's algorithm: use some kind of component hierarchy to identify groups of vertices that can safely be visited in any order. However, the assumption of directed graphs [8] and real edge lengths [13] renders Thorup's hierarchy inapplicable or inefficient. Hagerup's component hierarchy is based on a directed analogue of the minimum spanning tree. The Pettie-Ramachandran algorithm enforces a certain degree of balance in its component hierarchy and, when computing SSSP, uses a specialized priority queue to take advantage of this balance.

Applications

Shortest path algorithms are frequently used as a subroutine in other optimization problems, such as flow and matching problems [1] and facility location [18]. A widely used commercial application of shortest path algorithms is finding efficient routes on road networks, e.g., as provided by Google Maps, MapQuest, or Yahoo Maps.

Open Problems

Thorup's SSSP algorithm [16] runs in linear time and is therefore optimal. The main open problem is to find a linear time SSSP algorithm that works on *real*-weighted *directed* graphs. For real-weighted undirected graphs, the best running time is given in Theorem 3. For integer-weighted directed graphs, the fastest algorithms are based on Dijkstra's algorithm (not Theorem 2) and run in $O(m\sqrt{\log\log n})$ time (randomized) and deterministically in $O(m + n\log\log n)$ time.

Problem 1 Is there an $O(m)$ time SSSP algorithm for integer-weighted directed graphs?

Problem 2 Is there an $O(m) + o(n\log n)$ time SSSP algorithm for real-weighted graphs, either directed or undirected?

The complexity of SSSP on graphs with positive and negative edge lengths is also open.

Experimental Results

Asano and Imai [2] and Pettie et al. [14] evaluated the performance of the hierarchy-based SSSP algorithms [13, 16]. There have been a number of studies of SSSP algorithms on integer-weighted directed graphs; see [7] for the latest and references to many others. The trend in recent years is to find practical preprocessing schemes that allow for very quick point-to-point shortest path queries. See [3, 10, 15] for recent work in this area.

Problem Definition

The ski rental problem was developed as a pedagogical tool for understanding the basic concepts in some early results in online algorithms. (In the interest of full disclosure, the earliest presentations of these results described the problem as the wedding-tuxedo-rental problem. Objections were presented that this was a gender-biased name for the problem, since while groomsmen can rent their wedding apparel, bridesmaids usually cannot. A further complication, owing to the difficulty of instantaneously producing fitted garments or ski equipment outlined below, suggests that some complications could have been avoided by focusing on the dilemma of choosing between daily lift passes or season passes, although this leads to the pricing complexities of purchasing season passes well in advance of the season, as opposed to the higher cost of purchasing them at the mountain during the ski season. A similar problem could be derived from the question as to whether to purchase the daily newspaper at a newsstand or to take a subscription, after adding the challenge that one's peers will treat one contemptuously if one has not read the news on days on which they have.) The ski rental problem considers the plight of one consumer who, in order to socialize with peers, is forced to engage in a variety of athletic activities, such as skiing, bicycling, windsurfing, rollerblading, sky diving, scuba-diving, tennis, soccer, and ultimate Frisbee, each of which has a set of associated apparatus, clothing, or protective gear.

In all of these, it is possible either to purchase the accoutrements needed or to rent them. For the purpose of this problem, it is assumed that one-time rental is less expensive than purchasing. It is also assumed that purchased items are durable, and suitable for reuse for future activities of the same type without further expense, until the items wear out (which occurs at the same rate for all users), are outgrown, become unfashionable, or are disposed of to make room for other purchased items. The social consumer must make the decision to rent or buy for each event, although it is assumed that the consumer is sufficiently parsimonious as to abjure rental if already in possession of serviceable purchased equipment. Whether purchases are as easy to arrange as rentals, or whether some advance planning is required (e.g., to mount bindings on a ski) is a further detail considered in this problem. It is assumed that the social consumer has no particular independent interest in these activities, and engages in these activities only to socialize with peers who choose to engage in these activities disregarding the consumer's desires.

These putative peers are more interested in demonstrating the superiority of their financial acumen to that of the social consumer in question than they are in any particular activity. To that end, the social consumer is taunted mercilessly based on the ratio of his/her total expenses on

rentals and purchases to theirs. Consequently, the peers endeavor to invite the social consumer to engage in events while they are costly to him/her, and once the activities are free to the social consumer, if continued activity would be costly to them, cease. But, to present an illusion of fairness, skis, both rented and purchased, have the same cost for the peers as they do for the social consumer in question. The ski rental problem takes a very restricted setting. It assumes that purchased ski equipment never needs replacement, and that there are no costs to a ski trip other than the skis (thus, no cost for the gasoline, for the lift and/or speeding tickets, for the hot chocolates during skiing, or for the après-ski liqueurs and meals). It is assumed that the social consumer experiences no physical disabilities preventing him/her from skiing and has no impending restrictions to his/her participation in ski trips (obviously, a near-term-fatal illness or an anticipated conviction leading to confinement for life in a penitentiary would eliminate any potential interest in purchasing alpine equipment – when the ratio of purchase to rental exceeds the maximum need for equipment, one should always rent). It is assumed that the social consumer's peers have disavowed any interest in activities other than skiing, and that the closet, basement, attic, garage, or storage locker included in the social consumer's rent or mortgage (or necessitated by other storage needs) has sufficient capacity to hold purchased ski equipment without entailing the disposal of any potentially useful items. Bringing these complexities into consideration brings one closer to the hardware-based problems which initially inspired this work.

The impact of invitations issued with sufficient time allowed for purchasing skis, as well as those without, will be considered.

Given all of that, what ratio of expenses can the social consumer hope to attain? What ratio can the social consumer not expect to beat? These are the basic questions of competitive analysis.

The impact of keeping secrets from one's peers is further considered. Rather than a fixed strategy for when to purchase skis, the social consumer may introduce an element of chance into the process. If the peers are able to observe his/her ski equipment and notice when it changes from rented skis to purchased skis, and change their schedule for alpine recreation in light of this observation, randomness provides no advantages. If, on the other hand, the social consumer announces to the peers, in advance of the first trip, how he/she will decide when the time is right for purchasing skis, including any use of probabilistic techniques, and they then decide on the schedule for ski trips for the coming winter, a deterministic decision procedure generally produces a larger competitive ratio than does a randomized procedure.

Key Results

Given an unbounded sequence of skiing trips, one should eventually purchase skis if the cost of renting skis, r, is positive. In particular, let the cost of purchasing skis be some number $p \geq r$. If one never intends to make a purchase, one's cost for the season will be rn, where n is the number of ski trips in which one participates. If n exceeds p/r, one's cost will exceed the price of purchasing skis; as n continues to increase, the ratio of one's costs to those of one's peers increases to nr/p, which grows unboundedly with n, since your peers, knowing that n exceeds p/r, will have purchased skis prior to the first trip.

On the other hand, if one rushes out to purchase skis upon being told that the ski season is approaching, one's peers will decide that this season looks inopportune, and that skiing is passé, leaving their costs at zero, and one's costs at p, leaving an infinite ratio between one's costs and theirs; if one chooses to defer the purchase until after one's first ski trip, this produces the less unfavorable ratio p/r or $1 + p/r$, depending on whether the invitation left one time to purchase skis before the first trip or not.

Suppose one chooses, instead, to defer one's purchase until after one has made k rentals, but before ski trip $k+1$. One's costs are then bounded by $kr + p$. After k ski trips, the cost to one's peers will be the lesser of kr and p (as one's peers will have decided whether to rent or buy for

the season upon knowing one's plans, which in this case amounts to knowing k), for a ratio equal to the larger of $1 + kr/p$ and $1 + p/kr$. Were they to choose to terminate the activity earlier (so $n < k$), the ratio would be only the greater of kr/p and 1, which is guaranteed to be less than the sum of the two – one's peers would be shirking their opportunity to make one's behavior look foolish were they to allow one to stop skiing prior to one's purchase of a pair of skis!

It is certain, since kr/p and p/kr are reciprocals, that one of them is at least equal to 1, ensuring that one will be compelled to spend at least twice as much as one's peers.

The analysis above applies to the case where ski trips are announced without enough warning to leave one time to buy skis. Purchases in that case are not instantaneous; in contrast, if one is able to purchase skis on demand, the cost to one's peers changes to the lesser of $(k+1)r$ and p. The overall results are not much different; the ratio choices become the larger of $1 + kr/p$ and $1 + (p - r)/((k + 1)r)$.

When probabilistic algorithms are considered with oblivious frenemies (those who know the way in which random choices will affect one's purchasing decisions, but who do not take time to notice that one's skis are no longer marked with the name and phone number of a rental agency), one can appear more thrifty.

A randomized algorithm can be viewed as a distribution over deterministic algorithms. No good algorithm can purchase skis prior to the first invitation, lest it exhibit infinite regrettability (some positive cost compared to zero). A good algorithm must purchase skis by the time one's peers will have; otherwise, one's cost ratio continues to increase with the number of ski trips. Moreover, the ratio should be the same after every ski trip; if not, then there is an earliest ratio not equal to the largest, and probabilities can be adjusted to change this earliest ratio to be closer to the largest while decreasing all larger ratios.

Consider, for example, the case of $p = 2r$, with purchases allowed at the time of an invitation. The best deterministic ratio in this case is 1.5. It is only necessary to choose a probability q, the probability of purchasing at the time of the first invitation. The cost after one trip is then $(1-q)r+2qr = r(1+q)$, for a ratio of $1+q$, and after two trips the cost is $q(2r) + (1 - q)(3r) = 3 - q)r$, producing a ratio of $(3 - q)/2$. Setting these to be equal yields $q = 1/3$, for a ratio of 4/3.

If insufficient time is allowed for purchases before skiing, the best deterministic ratio is 2. Purchasing after the first ski trip with probability q (and after the second with probability $1 - q$) leads to expected costs of $(1-q)r+3qr = r(1+2q)$ after the first trip, and $(1-q)(2+2)r+3qr = r(4 + q)$, leading to a ratio of $2 - q/2$. Setting $1 + 2q = 2 - q/2$ yields $q = 2/5$, for a ratio of 9/5.

More careful analysis, for which readers are referred to the references and the remainder of this volume, shows that the best achievable ratio approaches $\epsilon/(\epsilon - 1) \approx 1.58197$ as p/r increases, approaching the limit from below if sufficient warning time is offered, and from above otherwise.

Applications

The primary initial results were directed towards problems of computer architecture; in particular, design questions for capacity conflicts in caches, and shared memory design in the presence of a shared communication channel. The motivation for these analyses was to find designs which would perform reasonably well on as-yet-unknown workloads, including those to be designed by competitors who may have chosen alternative designs which favor certain cases. While it is probably unrealistic to assume that precisely the least-desirable workloads will occur in ordinary practice, it is not unreasonable to assume that extremal workloads favoring either end of a decision will occur.

History and Further Reading

This technique of finding algorithms with bounded worst-case performance ratios is common in analyzing approximation algorithms.

The initial proof techniques used for such analyses (the method of amortized analysis) were first presented by Sleator and Tarjan.

The reader is advised to consult the remainder of this volume for further extensions and applications of the principles of competitive online algorithms.

Slicing Floorplan Orientation

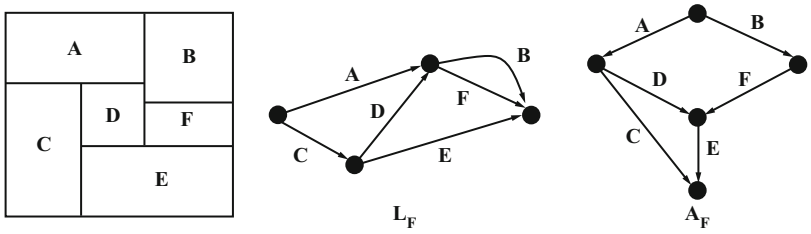
1983; Stockmeyer

Problem Definition

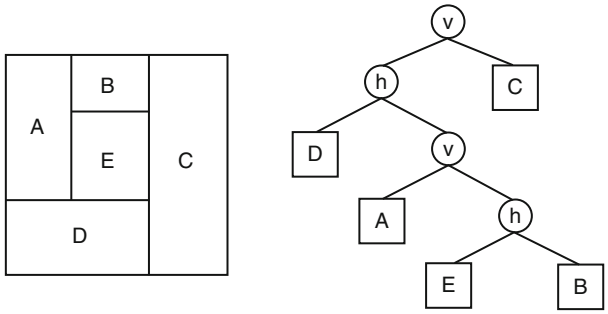
This problem is about finding the optimal orientations of the cells in a slicing floorplan to minimize the total area. In a floorplan, cells represent basic pieces of the circuit which are regarded as indivisible. After performing an initial placement, for example, by repeated application of a min-cut partitioning algorithm, the relative positions between the cells on a chip are fixed. Various optimizations can then be done on this initial layout to optimize different cost measures such as chip area, interconnect length, routability, etc. One such optimization, as mentioned in Lauther [3], Otten [4], and Zibert and Saal [13], is to determine the best orientation of each cell to minimize the total chip area. This work by Stockmeyer [8] gives a polynomial time algorithm to solve the problem optimally in a special type of floorplans called *slicing floorplans* and shows that this orientation optimization problem in general non-slicing floorplans is NP-complete.

Slicing Floorplan

A floorplan consists of an enclosing rectangle subdivided by horizontal and vertical line segments into a set of non-overlapping *basic rectangles*. Two different line segments can meet but not cross. A floorplan F is characterized by a pair of planar acyclic directed graphs A_F and L_F defined as follows. Each graph has one source and one sink. The graph A_F captures the "above" relationships and has a vertex for each horizontal line segment, including the top and the bottom of the enclosing rectangle. For each basic rectangle R, there is an edge e_r directed from segment σ to segment σ' if and only if σ (or part of σ) is the top of R and σ' (or part of σ') is the bottom of R. There is a one-to-one correspondence between the basic rectangles and the edges in A_F. The graph L_F is defined similarly for the



Slicing Floorplan Orientation, Fig. 1 A floorplan F and its A_F and L_F representing the above and left relationships



Slicing Floorplan Orientation, Fig. 2 A slicing floorplan F and its slicing tree representation

"left" relationships of the vertical segments. An example is shown in Fig. 1. Two floorplans F and G are equivalent if and only if $A_F = A_G$ and $L_F = L_G$. A floorplan F is slicing if and only if both its A_F and L_F are series parallel.

Slicing Tree

A slicing floorplan can also be described naturally by a rooted binary tree called *slicing tree*. In a slicing tree, each internal node is labeled by either an h or a v, indicating a horizontal or a vertical slice respectively. Each leaf corresponds to a basic rectangle. An example is shown in Fig. 2. There can be several slicing trees describing the same slicing floorplan, but this redundancy can be removed by requiring the label of an internal node to differ from that of its right child [12]. For the algorithm presented in this work, a tree of smallest depth should be chosen, and this depth minimization process can be done in $O(n \log n)$ time using the algorithm by Golumbic [2].

Orientation Optimization

In optimization of a floorplan layout, some freedom in moving the line segments and in choosing the dimensions of the rectangles are allowed. In the input, each basic rectangle R has two positive integers a_R and b_R, representing the dimensions of the cell that will be fit into R. Each cell has two possible orientations resulting in either the side of length a_R or b_R being horizontal. Given a floorplan F and an orientation p, each edge e in A_F and L_F is given a label $l(e)$ representing the height or the width of the cell corresponding to e depending on its orientation. Define an (F, ρ)-*placement* to be a labeling l of the vertices in A_F and L_F such that (i) the sources are labeled by zero and (ii) if e is an edge from vertex σ to $\sigma', l(\sigma') \geq l(\sigma) + l(e)$. Intuitively, if σ is a horizontal segment, $l(\sigma)$ is the distance of σ from the top of the enclosing rectangle, and the inequality constraint ensures that the basic rectangle corresponding to e is tall enough for the cell contained in it and similarly for the vertical segments. Now, $h_F(\rho)$ (resp. $w_F(\rho)$) is defined to be the minimum label of the sink in $A_F(\rho)$ (resp. $L_F(\rho)$) over all (F, ρ)-placements, where $A_F(\rho)$ (resp. $L_F(\rho)$) is obtained from A_F (resp. L_F) by labeling the edges and vertices as described above. Intuitively, $h_F(\rho)$ and $w_F(\rho)$ give the minimum height and width of a floorplan F given an orientation ρ of all the cells such that each cell fits well into its associated basic rectangle.

The orientation optimization problem can be defined formally as follows:

Problem 1 (Orientation Optimization Problem for Slicing Floorplan)
INPUT: A slicing floorplan F of n cells described by a slicing tree T, the widths and heights of the cells a_i and b_i for $i = 1...n$, and a cost function $\psi(h, w)$.
OUTPUT: An orientation ρ of all the cells that minimizes the objective function $\psi(h_F(\rho), w_F(\rho))$ over all orientations ρ.

For this problem, Lauther [3] has suggested a greedy heuristic. Zibert and Saal [13] use integer programming methods to do rotation optimization and several other optimization simultaneously for general floorplans. In the following sections, an efficient algorithm will be given to solve the problem optimally in $O(nd)$ time where n is the number of cells and d is the depth of the given slicing tree.

Key Results

In the following algorithm, $F(u)$ denotes the floorplan described by the subtree rooted at u in the given slicing tree T, and let $L(u)$ be the set of leaves in that subtree. For each node u of T, the algorithm constructs recursively a list of pairs:

$$\{(h_1, w_1), (h_2, w_2), \ldots, (h_m, w_m)\}$$

where (1) $m \leq |L(u)| + 1$, (2) $h_i > h_{i+1}$ and $w_i < w_{i+1}$ for $i = 1...m - 1$, (3) there is an orientation ρ of the cells in $L(u)$ such that $(h_i, w_i) = (h_F(u)(\rho), w_F(u)(\rho))$ for each $i = 1...m$, and (4) for each orientation ρ of the cells in $L(u)$, there is a pair (h_i, w_i) in the list such that $h_i \leq h_{F(u)}(\rho)$ and $w_i \leq w_{F(u)}(\rho)$.

$L(u)$ is thus a non-redundant list of all possible dimensions of the floorplan described by the subtree rooted at u. Since the cost function ψ is non-decreasing, it can be minimized over all orientations by finding the minimum $\psi(h_i, w_i)$ over all the pairs (h_i, w_i) in the list constructed at the root of T. At the beginning, a list is constructed at each leaf node of T representing the possible dimensions of the cell. If a leaf cell has dimensions a and b with $a > b$, the list is $\{(a, b), (b, a)\}$. If $a = b$, there will just be one pair (a, b) in the list. (If the cell has a fixed orientation, there will also be just one pair as defined by the fixed orientation.) Notice that the condition (1) above is satisfied in these leaf node lists. The algorithm then works its way up the tree and constructs the list at each node recursively. In general, assume that u is an internal node with children v and v' and u represents a vertical slice. Let $\{(h_1, w_1) \ldots (h_k, w_k)\}$ and $\{(h'_1, w'_1) \ldots (h'_m, w'_m)\}$ be the lists at v and v' respectively where $k \leq |L(v)| + 1$ and $m \leq |L(v')| + 1$. A pair (h_i, wi) from v can be put together by a vertical slice with a pair (h'_j, w'_j) from v' to give a pair:

$$\text{join}((h_i, w_i), (h'_j, w'_j)) = (\max(h_i, h'_j), w_i + w'_j)$$

in the list of u (see Fig. 3). The key fact is that most of the km pairs are sub-optimal and do not need to be considered. For example, if $h_i > h'_j$, there is no need to join (h_i, w_i) with (h'_z, w'_z) for any $z > j$ since

$$\max(h_i, h'_z) = \max(h_i, h'_j) = h_i,$$
$$w_i + w'_z > w_i + w'_j$$

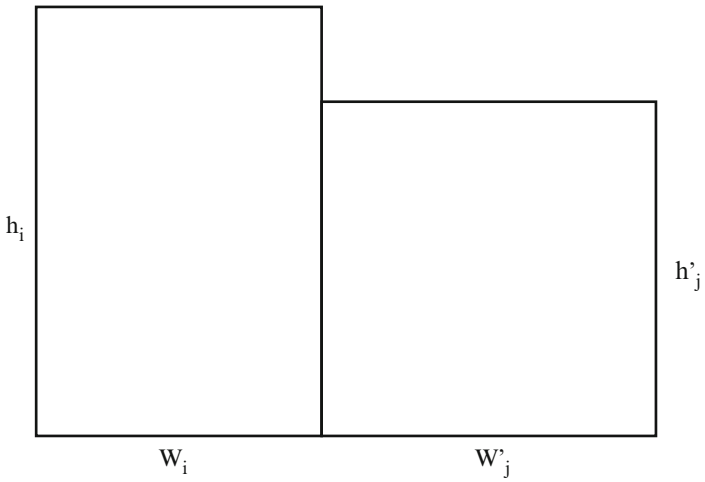
Similarly, if node u represents a horizontal slice, the join operation will be

$$\text{join}((h_i, w_i), (h'_j, w'_j)) = (h_i + h'_j, \max(w_i, w'_j))$$

The algorithm also keeps two pointers for each element in the lists in order to construct back the optimal orientation at the end. The algorithm is summarized by the following pseudocode:

Pseudocode *Stockmeyer()*

1. Initialize the list at each leaf node.
2. Traverse the tree in postorder. At each internal node u with children v and v', construct a list at node u as follows:
3. Let $\{(h_1, w_1) \ldots (h_k, w_k)\}$ and $\{(h'_1, w'_1) \ldots (h'_m, w'_m)\}$ be the lists at v and v' respectively.
4. Initialize i and j to one.



Slicing Floorplan Orientation, Fig. 3 An illustration of the merging step

5. If $i > k$ or $j > m$, the whole list at u is constructed.
6. Add join$((h_i, w_i), (h'_j, w'_j))$ to the list with pointers pointing to (h_i, w_i) and (h'_j, w'_j) in $L(v)$ and $L(v')$ respectively.
7. If $h_i > h'_j$, increment i by 1.
8. If $h_i > h'_j$, increment j by 1.
9. If $h_i > h'_j$, increment both i and j by 1.
10. Go to step 5
11. Compute $\psi(h_i, w_i)$ for each pair (h_i, w_i) in the list L_r at the root r of T.
12. Return the minimum $\psi(h_i, w_i)$ for all (h_i, w_i) in L_r and construct back the optimal orientation by following the pointers.

Correctness

The algorithm is correct since at each node u, a list is constructed that records all the possible non-redundant dimensions of the floorplan described by the subtree rooted at u. This can be proved easily by induction starting from the leaf nodes and working up the tree recursively. Since the cost function ψ is non-decreasing, it can be minimized over all orientations of the cells by finding the minimum $\psi(h_i, w_i)$ over all the pairs (h_i, w_i) in the list L_r constructed at the root r of T.

Runtime

At each internal node u with children v and v'. If the lengths of the lists at v and v' are k and m respectively, the time spent at u to combine the two lists is $O(k + m)$. Each possible dimension of a cell will thus invoke one unit of execution time at each node on its path up to the root in the postorder traversal. The total runtime is thus $O(d \times N)$ where N is the total number of realizations of all the n cells, which is equal to $2n$ in the orientation optimization problem. Therefore, the runtime of this algorithm is $O(nd)$.

Theorem 1 *Let $\psi(h, w)$ be non-decreasing in both arguments, i.e., if $h \leq h'$ and $w \leq w'$, $\psi(h, w) \leq \psi(h', w')$, and computable in constant time. For a slicing floorplan F described by a binary slicing tree T, the problem of minimizing $\psi(h_F(\rho), w_F(\rho))$ over all orientations ρ can be solved in time $O(nd)$ time, where n is the number of leaves of T (equivalently, the number of cells of F) and d is the depth of T.*

Applications

Floorplan design is an important step in the physical design of VLSI circuits. Stockmeyer's optimal orientation algorithm [8] has been generalized to solve the area minimization problem in slicing floorplans [7], in hierarchical non-slicing floorplans of order five [6,9], and in general floorplans [5]. The floorplan area minimization problem is similar except that each *soft cell* now has a number of possible realizations, instead of just two different orientations. The same technique

can be applied immediately to solve optimally the area minimization problem for slicing floorplans in $O(nd)$ time where n is the total number of realizations of all the cells in a given floorplan F and d is the depth of the slicing tree of F. Shi [7] has further improved this result to $O(n \log n)$ time. This is done by storing the list of non-redundant pairs at each node in a balanced binary search tree structure called *realization tree* and using a new merging algorithm to combine two such trees to create a new one. It is also proved in [7] that this $O(n \log n)$ time complexity is the lower bound for this area minimization problem in slicing floorplans.

For hierarchical non-slicing floorplans, Pan et al. [6] prove that the problem is NP-complete. Branch-and-bound algorithms are developed by Wang and Wong [9], and pseudopolynomial time algorithms are developed by Wang and Wong [10] and Pan et al. [6]. For general floorplans, Stockmeyer [8] has shown that the problem is strongly NP-complete. It is therefore unlikely to have any pseudopolynomial time algorithm. Wimer et al. [11] and Chong and Sahni [1] propose branch-and-bound algorithms. Pan et al. [5] develop algorithms for general floorplans that are approximately slicing.

Years and Authors of Summarized Original Work

2007; Braverman, Ostrovsky

Problem Definition

In the last decade, the theoretical study of the sliding window model was developed to advance applications with very large input and time-sensitive output. In some practical situations, input might be seen as an ordered sequence, and it is useful to restrict computations to recent portions of the input. Examples include the analysis of recent tweets and time series of the stock market.

To address the aforementioned practical situations, Datar et al. [20] introduced the sliding window model that assumes that the input is a stream (i.e., the ordered sequence) of data elements and divides the data elements into two categories: *active* elements and *expired* elements. Typically, a recent portion (i.e., a suffix) of the stream defines the window of active elements, and the reminder (i.e., a complimenting prefix) of the stream defines the set of expired elements. When a new data element arrives, the set of active elements expands to include the new element, but the set might also shrink by discarding some portion of oldest active elements. This process of additions and expirations reminds one of the movements of an interval (or a window) along a line and explains the name of the model. The number of active elements N is often called a *size of the sliding window*. There are two popular variants of the sliding window model. The variant of a *sequence-based* window fixes the number of active elements N, and every insertion (or arrival) of a new element corresponds to a deletion (or expiration) of the oldest active element (after the size of the stream becomes larger than N). For example, a sequence-based window on a stream of IP packets is a set of last N packets. The variant of a *timestamp-based* window associates each element with a nondecreasing timestamp, and the window contains all elements with timestamps larger than a certain value. Thus, there is no obvious dependence between the number of elements that arrive and expire. In the previous example, the timestamp-based window might be defined as a set of all packets that arrived within the last t seconds.

Formal Definition

We denote the stream D by a sequence of elements $\{p_i\}_{i=1}^{m}$ where $p_i \in [n]$. It is important to note that m is incremented for each new arrival. A *bucket* $B(x, y) = \{p_i, i \in [x, y]\}$ is the set of all stream elements between p_x and p_y, inclusively. A sequence-based window is defined $W = B(m - N + 1, m)$ where N is a predefined parameter. Consider a nondecreasing *timestamp* function $T : [m] \to R$ and let t be a parameter. Given T and t, a timestamp-based window is defined as $W = B(l(t), m)$ where $l(t) = \min\{i : T(i) \geq T(m) - t\}$. Consider function f that is defined on buckets. An algorithm maintains a $(1 \pm \epsilon)$-approximation of f on W if, at any moment, the algorithm outputs X s.t. $|f(W) - X| \leq \epsilon f(W)$. Similarly, a randomized algorithm maintains a $(1 \pm \epsilon, \delta)$-approximation if $P(|f(W) - X| > \epsilon f(W)) \leq \delta$. It is often the case that f can be computed precisely if the entire window is available, but sublinear-space approximations, i.e., computation when the size of the available memory is $o(N + n)$, might be challenging. For example, Datar et al. [20] show linear space is required to maintain a $(1 \pm \epsilon, \delta)$-approximation of a sum of active elements if $p_i \in \{1, 0, -1\}$. A typical question in the sliding window model is the following: given function f, what are the upper and lower bounds on the space complexity of maintaining $(1 \pm \epsilon, \delta)$-approximation of f.

History

In their pioneering papers, Datar et al. [20, 21] and Babcock et al. [3] gave the first formal definition of the sliding window model. The model arose in the context of relational databases as a special case of time-sensitive queries in temporal databases [3]. Below we give a short survey of a subset of known results. A survey of Datar and Motwani [1] provides additional details. Datar et al. [20] gave the first algorithms for estimating the count and sum of positive integers, average, L_p for $p \in [1, 2]$, and a wide class of *weakly additive functions*. Gibbons and Tirthapura [24] provided further improvements to count and sum and gave the first methods for distributed computations. Lee and Ting [29] provided an optimal solution for a relaxed version of the counting problem, where the correct answer is provided only if it is comparable with the window's size. Braverman and Ostrovsky [6, 7] extended the results in [20] to a wider class of *smooth functions*. Chi et al. [15] considered a problem of frequent itemsets. Arasu and Manku [2], Lee and Ting [30], and Golab et al. [26] considered the problem of finding frequent elements, frequency counts, and quantiles. Babcock, Datar, Motwani, and O'Callaghan [5] pro-

vided first algorithms for variance and k-medians problems. Feigenbaum, Kannan and Zhang [22] presented an efficient solution for the diameter of a data set in multidimensional space. Later, Chan and Sadjad [23] presented optimal solutions for this and other geometric problems. Babcock, Datar and Motwani [4] presented algorithms for uniform random sampling from sliding windows.

Recently, Crouch et al. [17] presented the first approximation algorithms for important graph problems such as combinatorial sparsifiers and spanners, graph matching, and minimum spanning tree. Among other results, the methods in [17] allow non-smooth statistics using a modified smooth histogram to be computed. McGregor provided a detailed survey of these and other graph algorithms [32]. Datar and Muthukrishnan [19] solved problems of rarity and similarity. Braverman et al. [11] gave improved algorithms for rarity, similarity, and L_2-heavy hitters. Cormode and Yi developed several first algorithms for sliding windows in distributed streams [16]. Babcock et al. [4] gave the first method of sampling an element with constant expected space complexity. Braverman et al. [9, 10] gave a solution with a space complexity that is a constant in the worst case. Tatbul and Zdonik [35] considered the problem of load shedding for aggregation queries. Golab and Özsu [25] gave the first algorithm for approximating multi-joins. Recently, Braverman et al. [13] extended the zero-one law for increasing frequency-based functions [8] to sliding windows.

Key Results

Smooth Histogram

Extending the results in [20], Braverman and Ostrovsky [6, 7] introduced a notion of a *smooth function* and presented techniques for approximating smooth functions over sliding windows. Denote by $B \subseteq_r A$ the event when bucket B is a suffix of A; i.e., if $A = \{p_{n_1}, \ldots, p_{n_2}\}$ (for some $n_1 < n_2$), then $B = \{p_{n_3}, \ldots, p_{n_2}\}$, where $n_1 \leq n_3 \leq n_2$. Denote by $A \cup C$ the union of adjacent buckets A and C.

Definition 1 Function f is (α, β)-*smooth* if it preserves the following properties:

1. $f(A) \geq 0$.
2. $f(A) \geq f(B)$ for $B \subseteq_r A$.
3. $f(A) \leq poly(|A|)$.
4. For any $0 < \epsilon < 1$, there exist $\alpha = \alpha(\epsilon, f)$ and $\beta = \beta(\epsilon, f)$ such that
   - $0 < \beta \leq \alpha < 1$.
   - If $B \subseteq_r A$ and $(1-\beta) f(A) \leq f(B)$, then $(1-\alpha) f(A \cup C) \leq f(B \cup C)$ for any adjacent C.

In other words, a nonnegative, nondecreasing, and polynomially bounded function f is (α, β)-smooth if the following is true. If $f(B)$ is a $(1 \pm \beta)$-approximation of $f(A)$, then $f(B \cup C)$ is $(1 \pm \alpha)$-approximation of $f(A \cup C)$ for any $B \subseteq_r A$ and C. The main technical result of [7] is a new data structure called "smooth histogram" that allows algorithms for insertion-only streams to be extended to sliding windows with space complexity increased by a polylogarithmic factor. If there exists an algorithm that computes f precisely using g space and h time per element, then a smooth histogram can be used to maintain a $(1 \pm \alpha)$-approximation of f over sliding windows, using $O\left(\frac{1}{\beta} \log n (g + \log n)\right)$ bits and $O\left(\frac{1}{\beta} h \log n\right)$ time. Further, $(1 \pm \rho)$-approximation of f on D results in $(1 \pm (\alpha + \rho))$-approximation of f over sliding windows. Examples of smooth functions include sum, count, min, diameter, weakly additive functions, L_p norms, frequency moments, length of longest subsequence, and geometric mean.

Let f be (α, β)-smooth for which there exists an algorithm Λ that calculates f on D using g space and h operation per element. To maintain f on sliding windows, we construct a data structure that we call *smooth histogram*. It consists of a set of indexes $x_1 < x_2 < \cdots < x_s = N$ and instances of Λ for each bucket $B(x_i, N)$. Informally, the smooth histogram ensures the following properties of the sequence. The first two elements of the sequence always

"sandwich" the window, i.e., $x_1 \leq N - n < x_2$. This requirement and the monotonicity of f give us useful bounds for the sliding window W: $f(x_2, N) \leq f(W) \leq f(x_1, N)$. Also, f should slowly but constantly decrease with i, i.e., $f(x_{i+2}, N) < (1 - \beta) f(x_i, N)$. This gradual decrease, together with the fact that f is polynomially bounded, ensures that the sequence is short, i.e., $s = O\left(\frac{1}{\beta} \log n\right)$. Finally, the values of f on successive buckets were close in the past, i.e., $f(x_{i+1}, N') \geq (1 - \beta) f(x_i, N')$ for some $N' \leq N$. This represents our key idea and exploits the properties of smoothness. Indeed, $f(x_2, N') \geq (1-\beta) f(x_1, N')$ for some $N' \leq N$; thus, by the (α, β)-smoothness of f, we have $f(x_2, N) \geq (1 - \alpha) f(x_1, N) \geq (1 - \alpha) f(W)$. We refer a reader to [7] for further technical details.

Applications

There are several applications of the theoretical methods for the sliding window model, for example, [15, 18, 31, 33, 36].

Open Problems

We list several interesting open problems. It would be important to understand the difference between the sliding window model and other streaming models such as the insertion-only model, the turnstile, and decay models. This is perhaps one of the most important unresolved open problems; see, e.g., Sohler [34]. In particular, it would be nice to understand the exact space complexity of the frequency moments that are well understood in the other streaming models [12, 27, 28]. Also, it would be interesting to extend the coreset methods [14] to sliding windows, obtain polylogarithmic solutions for clustering, and improve the first clustering algorithm in [5]. Also, it would be nice to further develop graph methods [17]. Improving the approximation ratio of the maximum matching and obtaining the $O(n^{1+1/t})$ space bound for $(2t - 1)$-spanners are important open problems.

Problem Definition

Given a smooth surface $S \subset \mathbb{R}^3$, we are required to compute a set of points $P \subset S$ and connect them with edges and triangles so that the resulted triangulation T is *geometrically* close and is *topologically* equivalent to S.

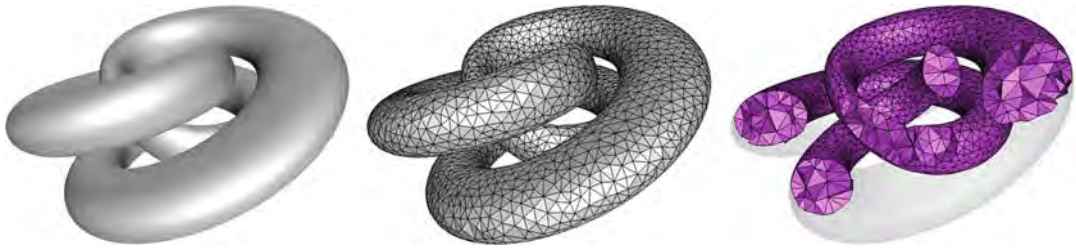
The output triangulation T is a simplicial 2-complex whose vertices are the points in P. Its underlying space, which is the pointwise union of the simplices (vertices, edges, triangles), is denoted with $|T|$. Geometric proximity is often characterized by Hausdorff distance between S and the underlying space $|T|$ of T. It is also desired that the triangle normals in T closely approximate the surface normals at its vertices. Topological equivalence is characterized by the existence of a *homeomorphism* between S and $|T|$. In some cases, the topological guarantee can be given in terms of *isotopy* which is stronger than homeomorphism. It is important to notice that, unlike polyhedral surfaces, a smooth surface cannot be represented *exactly* and hence needs to be approximated with a finite triangulation. This approximation requires that the mesh generation algorithms guarantee topological fidelity in addition to the geometric proximity.

In volume mesh generation, the space bounded by a smooth surface S is required to be tessellated with tetrahedra which form a simplicial 3-complex T. Similar to the surface case, it is required that the underlying space $|T|$ is geometrically close and topologically equivalent to the space bounded by S. It turns out that if the underlying space of the boundary 2-complex of T is geometrically close and has an isotopy to S, then so is $|T|$.

In both surface and volume meshes, it is desirable that the triangles and tetrahedra have good aspect ratio. This is often achieved by bounding the circumradius to shortest edge length ratios for triangles. Unfortunately, for tetrahedra, a bounded radius-edge ratio does not necessarily imply a bounded aspect ratio though most poor quality tetrahedra except slivers [4] are eliminated by bounded radius-edge ratio. Figure 1 shows an example of a surface and a volume mesh.

Key Results

Theoretically sound algorithms for surface meshing use the technique of Delaunay refinement originally proposed by Chew [8]. For a point set $P \subset \mathbb{R}^3$, let Vor P and Del P denote the Voronoi diagram and Delaunay triangulation of P, respectively. A typical Delaunay refinement algorithm iteratively samples the space to be meshed with a *locally furthest point* strategy that inserts points where a Voronoi face of appropriate dimension intersects the space. The decision of



Smooth Surface and Volume Meshing, Fig. 1 A knotted torus, its surface mesh, and its volume mesh

which points to be inserted is guided by certain desirable properties of the output such as topological equivalence, simplex radius-edge ratios, geometric proximity, and so on.

In both surface and volume meshing, the features of the surface S play an important role because regions of small features need to be sampled relatively densely to capture the geometry and topology of S. The definition of *local feature size* and ε-sample given by Amenta, Bern, and Eppstein [2] captures this idea.

Let S be a smooth, closed surface, that is, S is compact, C^2-smooth, and has no boundary. The *medial axis* $M(S)$ of S is defined as the closure of the set of points $x \in \mathbb{R}^3$ so that the distance $d(x, S)$ is realized by two or more points in S. The *local feature size* is defined as

$$f(x) = d(x, M).$$

A set of points $P \subset S$ is called an ε-sample of S if every point $x \in S$ has a sample point in P within $\varepsilon f(x)$ distance.

It turns out that if P is an ε-sample of S for a sufficiently small value of ε, a subcomplex of the Delaunay triangulation of this sample captures the topology of S. We define this subcomplex in generality and then specialize it to S.

Let V_ξ denote the dual Voronoi face of a Delaunay simplex ξ in Del P. The restricted Voronoi face of V_ξ with respect to $\mathbb{X} \subset \mathbb{R}^3$ is the intersection $V_\xi|_{\mathbb{X}} = V_\xi \cap \mathbb{X}$. The *restricted Voronoi diagram* and *restricted Delaunay triangulation* of P with respect to $\mathbb{X}$ are

$$\begin{aligned}\text{Vor } P|_{\mathbb{X}} &= \{V_\xi|_{\mathbb{X}} \mid V_\xi|_{\mathbb{X}} \neq \emptyset\} \text{ and Del } P|_{\mathbb{X}} \\ &= \{\xi \mid V_\xi|_{\mathbb{X}} \neq \emptyset\} \text{ respectively.}\end{aligned}$$

In words, Del $P|_{\mathbb{X}}$ consists of those Delaunay simplices in Del P whose dual Voronoi face intersects $\mathbb{X}$. We call these simplices *restricted*.

Now consider a sample P on the surface S. The restricted Delaunay triangulation of P with respect to S is Del $P|_S$. It is known that if P is an ε-sample of S for $\varepsilon \leq 0.09$, then Del $P|_S$ has its underlying space homeomorphic to S [1, 9]. To use this result one requires computing an ε-sample of S. A computation of local feature size or its approximation is necessary to determine if a sample is an ε-sample for a predetermined ε. Even if one is allowed to assume the availability of the local feature size at any given point, it is not immediately obvious how to place points on S so that they become ε-sample for a given $\varepsilon > 0$.

Surface Meshing

The following theorem about the fidelity of the restricted Delaunay triangulation of a dense sample on a smooth closed surface is the basis of provable surface meshing algorithms. It has been proved in various versions in [1, 5, 7, 9].

Theorem 1 *Let P be an ε-sample of a smooth, compact, boundary-less surface $S \subset \mathbb{R}^3$. The restricted Delaunay complex $T =$ Del $P|_S$ satisfies the following properties for $\varepsilon \leq 0.09$:*

1. *The underlying space $|T|$ is homeomorphic to S (actually, there is an ambient isotopy taking $|T|$ to S).*
2. *Every point in $|T|$ has a point $x \in S$ so that $d(p, x) \leq O(\varepsilon) f(x)$. Similarly, every point x in S has a point p in $|T|$ so that $d(p, x) \leq O(\varepsilon) f(x)$.*

3. *Each triangle $t \in T$ has a normal making an angle $O(\varepsilon)$ with the normal to the surface S at any of its vertices.*

Cheng, Dey, Edelsbrunner, and Sullivan [5] applied Chew's furthest point placement strategy [8] to maintain a dynamic surface mesh of a special type of surface called *skin surface* for which they computed the local feature size explicitly. The above theorem then allowed them to argue the geometric and topological fidelity of the output. Boissonnat and Oudot [3] used similar point placement strategy assuming that the local feature sizes are available, but they suggested how to initialize the meshing procedure for general surfaces. For a restricted triangle $t \in \text{Del}\, P|_S$, the dual Voronoi edge intersects S possibly at multiple points. Each ball centering such an intersection point and circumscribing vertices of t is called a *surface Delaunay ball* of t. Boissonnat and Oudot observed that if every surface Delaunay ball of each restricted triangle has small radius, say at most 0.05 times the local feature size at the center, then P a 0.09-sample of S. It follows that $\text{Del}\, P|_S$ at this point satisfies the properties stated in Theorem 1. The deduction of this conclusion also requires that every component of S has at least one Voronoi edge intersecting it which Boissonnat and Oudot ensure with *persistent triangles*.

When local feature sizes are not known, we cannot use the method of Boissonnat and Oudot [3]. Instead, we fall back upon a different strategy to drive the Delaunay refinement. A result of Edelsbrunner and Shah [10] says that if Voronoi faces intersect S in a closed topological ball of appropriate dimension, then the underlying space of the restricted Delaunay triangulation becomes homeomorphic to S. In fact, this is the basis of the proof of Theorem 1. Therefore, a Delaunay refinement driven by the violation of the topological ball conditions provides a viable strategy for meshing with topological guarantees. This strategy is followed by Cheng, Dey, Ramos, and Ray [6].

The algorithm of Cheng et al. avoids computing local feature sizes or their approximation; however, it needs to compute critical points of certain functions on the surface, which may not be easily computable. In a recent book on Delaunay mesh generation [7], Cheng, Dey, and Shewchuk have suggested a strategy that is more practical which leverages on both algorithms of Boissonnat and Oudot [3] and Cheng et al. [6]. It operates with an input parameter $\lambda > 0$. As long as the surface Delaunay balls of the restricted triangles are not all smaller than a ball of radius λ, the algorithm refines. It also refines if the restricted triangles around each vertex do not form a topological disk. The algorithm can be shown to terminate and has the following guarantees.

Theorem 2 ([7]) *There is a Delaunay refinement algorithm that runs with a parameter $\lambda > 0$ on an input smooth, compact, boundary-less surface S with the following guarantees:*

1. *The output mesh is a Delaunay subcomplex and is a 2-manifold for all values of λ.*
2. *If λ is sufficiently small, then the output mesh has similar guarantees with respect to the input surface S as in Theorem 1 (replace ε with λ).*

It should be noted that in any of the above algorithms, one may introduce the condition that the output triangles have radius-edge ratio of at most 1 without loosing any of the geometric or topological guarantees. Even a graded mesh can be guaranteed by supplying an appropriate grading function as input. For details see [7].

Volume Meshing

Let $\mathcal{O}$ denote the volume enclosed by a smooth surface S. Consider the surface mesh of S produced by one of the algorithms mentioned above. The volume enclosed by this surface mesh is already triangulated with Delaunay tetrahedra. We can further refine them for quality using the radius-edge ratio condition. The circumcenters of skinny tetrahedra can be added as long as they do not disturb the surface triangulation. One easy approach is to skip adding those circumcenters who encroach the surface Delaunay balls meaning that they lie inside these balls. This ensures that all

surface triangles remain intact. The trade-off of this easy fix is that the tetrahedra near the boundary may not have bounded radius-edge ratios. To ensure the quality for all tetrahedra, additional effort is required to maintain the surface. Oudot, Rineau, and Yvinec [11] proposed an algorithm for guaranteed quality volume meshing.

The algorithm first runs the algorithm of [3] to obtain a surface triangulation with a vertex set P on the surface. It uses two parameters ε and ρ where ε controls the level of refinement and ρ controls the aspect ratios of the tetrahedra and triangles. It ensures that all restricted triangles on the surface have vertices from S. It refines surface triangles as in surface meshing algorithm. Then, it refines the tetrahedra. Refinement of surface triangles is given priority over the tetrahedra. Oudot et al. [11] prove that their algorithm terminates and has the following geometric and topological guarantees.

Theorem 3 ([11]) *Given a volume $\mathcal{O}$ bounded by a smooth surface S, for $\varepsilon \leq 0.05$ and $\rho > 1$, there is an algorithm that produces $T = \text{Del}\, P|_{\mathcal{O}}$ where each tetrahedron in T has radius-edge ratio at most ρ and $|T|$ is homeomorphic (isotopic) to $\mathcal{O}$ and the boundary of T is $\text{Del}\, P|_S$. Furthermore, the isotopy moves a point $x \in S$ by at most $O(\varepsilon^2) f(x)$ distance.*

An improved version of the algorithm and its analysis in presented in the book [7].

2004; Beier, Vöcking

Problem Definition

Smoothed analysis has originally been introduced by Spielman and Teng [22] in 2001 to explain why the simplex method is usually fast in practice despite its exponential worst-case running time. Since then it has been applied to a wide range of algorithms and optimization problem. In smoothed analysis, inputs are generated in two steps: first, an adversary chooses an arbitrary instance, and then this instance is slightly perturbed at random. The smoothed performance of an algorithm is defined to be the worst expected performance the adversary can achieve. This model can be viewed as a less pessimistic worst-case analysis, in which the randomness rules out pathological worst-case instances that are rarely observed in practice but dominate the worst-case analysis. If the smoothed running time of an algorithm is low (i.e., the algorithm is efficient in expectation on any perturbed instance) and inputs are subject to a small amount of random noise, then it is unlikely to encounter an instance on which the algorithm performs poorly. In practice, random noise can stem, for example, from measurement errors, numerical imprecision, or rounding errors. It can also model arbitrary influences, which we cannot quantify exactly, but for which there is also no reason to believe that they are adversarial. After its invention smoothed analysis has been applied in a variety of different contexts, e.g., linear programming [8, 19, 21, 23], multi-objective optimization [5, 10, 17, 18], online and approximation algorithms [4, 7, 20], searching and sorting [3, 12, 15, 16], game theory [9, 11], and local search [1, 2, 13, 14].

Key Results

Simplex Method

Spielman and Teng [22] considered linear programs of the form

$$\begin{aligned} &\text{maximize} \quad c^T x \\ &\text{subject to} \quad (\overline{A} + G)x \leq (\overline{b} + h), \end{aligned}$$

where $\overline{A} \in \mathbb{R}^{n \times d}$ and $\overline{b} \in \mathbb{R}^n$ are chosen arbitrarily by an adversary and the entries of the matrix $G \in \mathbb{R}^{n \times d}$ and the vector $h \in \mathbb{R}^n$ are independent Gaussian random variables that represent the perturbation. These Gaussian random variables have mean 0 and standard deviation $\sigma \cdot (\max_i \|(\overline{b}_i, \overline{a}_i)\|)$, where the vector $(\overline{b}_i, \overline{a}_i) \in \mathbb{R}^{d+1}$ consists of the i-th component of $\overline{b}$ and the i-th row of $\overline{A}$ and $\|\cdot\|$ denotes the Euclidean norm. Without loss of generality, we can scale the linear program specified by the adversary and assume that $\max_i \|(\overline{b}_i, \overline{a}_i)\| = 1$. Then the perturbation consists of adding an independent Gaussian random variable with standard deviation σ to each entry of $\overline{A}$ and $\overline{b}$. The smaller σ is chosen, the more concentrated are the random variables, and hence, the better worst-case instances can be approximated by the adversary. Intuitively, σ can be seen as a measure specifying how close the analysis is to a worst-case analysis.

Spielman and Teng analyzed the smoothed running time of the simplex algorithm using the *shadow vertex pivot rule*. This pivot rule has a simple and intuitive geometric description which makes probabilistic analyses feasible. Let x_0 denote the given initial vertex of the polytope $\mathcal{P}$ of feasible solutions. Since x_0 is a vertex of the polytope, there exists an objective function $u^T x$ which is maximized by x_0 subject to the constraint $x \in \mathcal{P}$. In the first step, the shadow vertex pivot rule computes an objective function $u^T x$ with this property. If x_0 is not an optimal solution of the linear program, then the vectors c and u are linearly independent and span a plane. The shadow vertex method projects the polytope $\mathcal{P}$ onto this plane. The *shadow*, that is, the projection of $\mathcal{P}$ onto this plane is a possibly open polygon. One can show that both x_0 and the optimal solution x^* are projected onto vertices of the polygon and that each path between the projections of x_0 and x^* in the polygon corresponds to a path between x_0 and x^* in the polytope. Hence, one only needs to follow the edges of the polygon starting from the projection of x_0 to (the projection of) x^*.

The number of steps performed by the simplex method with shadow vertex pivot rule is upper bounded by the number of vertices of the two-dimensional projection of the polytope. Hence, bounding the expected number of vertices on the

polygon is the crucial step for bounding the expected running time of the simplex method with shadow vertex pivot rule. Spielman and Teng first consider the case that the polytope $\mathcal{P}$ is projected onto a fixed plane specified by two fixed vectors c and u. They show that the expected number of vertices of the polygon is polynomially bounded in d, n, and $1/\sigma$. Though this result is the main ingredient of the analysis, alone it does not yield a polynomial bound on the smoothed running time of the simplex method. We have, for example, not yet described how the initial solution x_0 is found. It is also problematic that the vector u is not independent of the constraints because it is determined by x_0 which in turn is determined by a subset of the constraints. Spielman and Teng showed in a very involved analysis the following theorem.

Theorem 1 *The smoothed running time of the shadow vertex simplex method is bounded polynomially in d, n, and $1/\sigma$.*

Later, this analysis was substantially improved and simplified by Vershynin [23], who proved that the smoothed running time is even polynomially bounded in d, $\log n$, and $1/\sigma$.

Binary Optimization Problems

Beier and Vöcking [6] studied the question which *linear binary optimization problems* have *polynomial smoothed complexity*. Intuitively these are the problems that can be solved efficiently on perturbed inputs. An instance I of such an optimization problem Π consists of a set of feasible solutions $\mathcal{S} \subseteq \{0,1\}^n$ and a linear objective function $f : \{0,1\}^n \to \mathbb{R}$ of the form maximize (or minimize) $f(x) = c^T x$ for some $c \in \mathbb{R}^n$. Many well-known optimization problems can be formulated this way, e.g., the problem of finding a *Minimum Spanning Tree*, the *Knapsack Problem*, and the *Traveling Salesman Problem*.

It is assumed that an adversary is allowed to choose the coefficients of the objective function from the interval $[-1, 1]$. In the second step, these coefficients are perturbed by adding independent Gaussian random variables with mean 0 and standard deviation σ to them. Naturally one might define that a problem Π has *polynomial smoothed complexity* if there exists an algorithm A for Π whose expected running time $\mathbf{E}[T_A(I)]$ is bounded polynomially in the input size $|I|$ and $1/\sigma$. This definition, however, is not sufficiently robust as it depends on the machine model. An algorithm with expected polynomial running time on one machine model might have expected exponential running time on another machine model even if the former can be simulated by the latter in polynomial time. In contrast, the definition from [6] yields a notion of polynomial smoothed complexity that does not vary among classes of machines admitting polynomial time simulations among each other. It states that a problem Π has polynomial smoothed complexity if there exists an algorithm A for Π and some $\alpha > 0$ such that $\mathbf{E}[T_A(I)^\alpha]$ is bounded polynomially in the input size $|I|$ and $1/\sigma$.

Beier and Vöcking proved the following theorem that characterizes the class of linear binary optimization problems with polynomial smoothed complexity.

Theorem 2 *A linear binary optimization problem Π has polynomial smoothed complexity if and only if there exists a randomized algorithm for solving Π whose expected worst-case running time is pseudo-polynomial with respect to the coefficients in the objective function.*

For example, the knapsack problem, which can be solved by dynamic programming in pseudo-polynomial time, has polynomial smoothed complexity even if the weights are fixed and only the profits are randomly perturbed. Moreover, the traveling salesman problem does not have polynomial smoothed complexity when only the distances are randomly perturbed, unless P = NP, since a simple reduction from Hamiltonian cycle shows that it is strongly NP-hard.

Open Problems

An interesting open question is whether or not other pivot rules for the simplex method also have polynomial smoothed running time. It would also be interesting to see whether the insights gained from smoothed analysis can be used to improve existing algorithms.

Snapshots in Shared Memory

Eric Ruppert
Department of Computer Science and Engineering, York University, Toronto, ON, Canada

Keywords

Atomic scan

Years and Authors of Summarized Original Work

1993; Afek, Attiya, Dolev, Gafni, Merritt, Shavit

Problem Definition

Implementing a snapshot object is an abstraction of the problem of obtaining a consistent view of several shared variables while other processes are concurrently updating those variables.

In an asynchronous shared-memory distributed system, a collection of n processes communicate by accessing shared data structures, called *objects*. The system provides basic types of shared objects; other needed types must be built from them. One approach uses locks to guarantee exclusive access to the basic objects, but this approach is not fault-tolerant, risks deadlock or livelock, and causes delays when a process holding a lock runs slowly. Lock-free algorithms avoid these problems but introduce new challenges. For example, if a process reads two shared objects, the values it reads may not be consistent if the objects were updated between the two reads.

A *snapshot object* stores a vector of m values, each from some domain D. It provides two operations: scan and update(i, v), where $1 \leq i \leq m$ and $v \in D$. If the operations are invoked sequentially, an update(i, v) operation changes the value of the ith component of the stored vector to v, and a scan operation returns the stored vector.

Correctness when snapshot operations by different processes overlap in time is described by the *linearizability* condition, which says operations should appear to occur instantaneously. More formally, for every execution, one can choose an instant of time for each operation (called its *linearization point*) between the invocation and the completion of the operation. (An incomplete operation may either be assigned no linearization point or given a linearization point at any time after its invocation.) The responses returned by all completed operations in the execution must return the same result as they would if all operations were executed sequentially in the order of their linearization points.

An implementation must also satisfy a progress property. *Wait-freedom* requires that each process completes each scan or update in a finite number of its own steps. The weaker *non-blocking* progress condition says the system cannot run forever without some operation completing.

This article describes implementations of snapshots from more basic types, which are also linearizable, without locks. Two types of snapshots have been studied. In a *single-writer* snapshot, each component is owned by a process, and only that process may update it. (Thus, for single-writer snapshots, $m = n$.) In a *multi-writer* snapshot, any process may update any component. There also exist algorithms for *single-scanner* snapshots, where only one process may scan at a time [10, 13, 14, 16]. Snapshots were introduced by Afek et al. [1], Anderson [2] and Aspnes and Herlihy [4].

Space complexity is measured by the number of basic objects used and their size (in bits). Time complexity is measured by the maximum number of steps a process must do to finish a scan or update, where a step is an access to a basic shared object. (Local computation and local memory accesses are usually not counted.) Complexity bounds will be stated in terms of $n, m, d = \log |D|$ and k, the number of operations invoked in an execution. Ordinarily, there is no bound on k.

Most of the algorithms below use read-write registers, the most elementary shared object type. A *single-writer* register may only be written by one process. A *multi-writer* register may be written by any process. Some algorithms using stronger types of basic objects are discussed in section "Wait-Free Implementations from Small, Stronger Objects".

Key Results

A Simple Non-blocking Implementation from Small Registers

Suppose each component of a single-writer snapshot object is represented by a single-writer register. Process i does an update(i, v) by writing v and a sequence number into register i, and incrementing its sequence number. Performing a scan operation is more difficult than merely reading each of the m registers, since some registers

might change while these reads are done. To scan, a process repeatedly reads all the registers. A sequence of reads of all the registers is called a *collect*. If two collects return the same vector, the scan returns that vector (with the sequence numbers stripped away). The sequence numbers ensure that, if the same value is read in a register twice, the register had that value during the entire interval between the two reads. The scan can be assigned a linearization point between the two identical collects, and updates are linearized at the write. This algorithm is non-blocking, since a scan continues running only if at least one update operation is completed during each collect. A similar algorithm, with process identifiers appended to the sequence numbers, implements a non-blocking multi-writer snapshot from m multi-writer registers.

Wait-Free Implementations from Large Registers

Afek et al. [1] described how to modify the non-blocking single-writer snapshot algorithm to make it wait-free using scans embedded within the updates. An update(i, v) first does a scan and then writes a triple containing the scan's result, v and a sequence number into register i. While a process P is repeatedly performing collects to do a scan, either two collects return the same vector (which P can return) or P will eventually have seen three different triples in the register of some other process. In the latter case, the third triple that P saw must contain a vector that is the result of a scan that started after P's scan, so P's scan outputs that vector. Updates and scans that terminate after seeing two identical collects are assigned linearization points as before. If one scan obtains its output from an embedded scan, the two scans are given the same linearization point. This is a wait-free single-writer snapshot implementation from n single-writer registers of $(n+1)d + \log k$ bits each. Operations complete within $O(n^2)$ steps. Afek et al. [1] also describe how to replace the unbounded sequence numbers with handshaking bits. This requires $n\Theta(nd)$-bit registers and n^2 1-bit registers. Operations still complete in $O(n^2)$ steps.

The same idea can be used to build multi-writer snapshots from multi-writer registers. Using unbounded sequence numbers yields a wait-free algorithm that uses m registers storing $\Theta(nd + \log k)$ bits each, in which each operation completes within $O(mn)$ steps. (This algorithm is given explicitly in [9].) No algorithm can use fewer than m registers if $n \geq m$ [9]. If handshaking bits are used instead, the multi-writer snapshot algorithm uses n^2 1-bit registers, $m(d + \log n)$-bit registers and n (md)-bit registers, and each operation uses $O(nm + n^2)$ steps [1].

Guerraoui and Ruppert [12] gave a similar wait-free multi-writer snapshot implementation that is anonymous, i.e., it does not use process identifiers and all processes are programmed identically.

Anderson [3] gave an implementation of a multi-writer snapshot from a single-writer snapshot. Each process stores its latest update to each component of the multi-writer snapshot in the single-writer snapshot, with associated timestamp information computed by scanning the single-writer snapshot. A scan is done using just one scan of the single-writer snapshot. An update requires scanning and updating the single-writer snapshot twice. The implementation involves some blow-up in the size of the components, i.e., to implement a multi-writer snapshot with domain D requires a single-writer snapshot with a much larger domain D'. If the goal is to implement multi-writer snapshots from single-writer registers (rather than multi-writer registers), Anderson's construction gives a more efficient solution than that of Afek et al.

Attiya, Herlihy and Rachman [7] defined the *lattice agreement* object, which is very closely linked to the problem of implementing a single-writer snapshot when there is a known upper bound on k. Then, they showed how to construct a single-writer snapshot (with no bound on k) from an infinite sequence of lattice agreement objects. Each snapshot operation accesses the lattice agreement object twice and does $O(n)$ additional steps. Their implementations of lattice agreement are discussed in section "Wait-Free Implementations from Small, Stronger Objects".

Attiya and Rachman [8] used a similar approach to give a single-writer snapshot implementation from large single-writer registers using $O(n \log n)$ steps per operation. Each update has an associated sequence number. A scanner traverses a binary tree of height $\log k$ from root to leaf (here, a bound on k is required). Each node has an array of n single-writer registers. A process arriving at a node writes its current vector into a single-writer register associated with the node and then gets a new vector by combining information read from all n registers. It proceeds to the left or right child depending on the sum of the sequence numbers in this vector. Thus, all scanners can be linearized in the order of the leaves they reach. Updates are performed by doing a similar traversal of the tree. The bound on k can be removed as in [7]. Attiya and Rachman also give a more direct implementation that achieves this by recycling the snapshot object that assumes a bound on k. Their algorithm has also been adapted to solve condition-based consensus [15].

Attiya, Fouren and Gafni [6] described how to adapt the algorithm of Attiya and Rachman [8] so that the number of steps required to perform an operation depends on the number of processes that actually access the object, rather than the number of processes in the system.

Attiya and Fouren [5] solve lattice agreement in $O(n)$ steps. (Here, instead of using the terminology of lattice agreement, the algorithm is described in terms of implementing a snapshot in which each process does at most one snapshot operation.) The algorithm uses, as a data structure, a two-dimensional array of $O(n^2)$ *reflectors*. A reflector is an object that can be used by two processes to exchange information. Each reflector is built from two large single-writer registers. Each process chooses a path through the array of reflectors, so that at most two processes visit each reflector. Each reflector in column i is used by process i to exchange information with one process $j < i$. If process i reaches the reflector first, process j learns about i's update (if any). If process j reaches it first, then process i learns all the information that j has already gathered. (If both reach it at about the same time, both processes learn the information described above.) As the processes move from column $i-1$ to column i, a process that enters column i at some row r will have gathered all the information that has been gathered by any process that enters column i below row r (and possibly more). This invariant is maintained by ensuring that if process i passes information to any process $j < i$ in row r of column i, it also passes that information to all processes that entered column i above row r. Furthermore, process i exits column i at a row that matches the amount of information it learns while traveling through the column. When processes have reached the rightmost column of the array, the ones in higher rows know strictly more than the ones in lower rows. Thus, the linearization order of their scans is the order in which they exit the rightmost column, from bottom to top. The techniques of Attiya, Herlihy and Rachman [7, 8], mentioned above, can be used to remove the restriction that each process performs at most one operation. The number of steps per operation is still $O(n)$.

Wait-Free Implementations from Small, Stronger Objects

All of the wait-free implementations described above use registers that can store $\Omega(m)$ bits each, and are therefore not practical when m is large. Some implementations from smaller objects equipped with stronger synchronization operations, rather than just reads and writes, are described in this section. An object is considered to be small if it can store $O(d + \log n + \log k)$ bits. This means that it can store a constant number of component values, process identifiers and sequence numbers.

Attiya, Herlihy and Rachman [7] gave an elegant divide-and-conquer recursive solution to the lattice agreement problem. The division of processes into groups for the recursion can be done dynamically using test&set objects. This provides a snapshot algorithm that runs in $O(n)$ time per operation, and uses $O(kn^2 \log n)$ small single-writer registers and $O(kn \log^2 n)$ test&set objects. (This requires modifying their implementation to replace those registers that are large, which are written only once, by many small

registers.) Using randomization, each test&set object can be replaced by single-writer registers to give a snapshot implementation from registers only with $O(n)$ expected steps per operation.

Jayanti [13] gave a multi-writer snapshot implementation from $O(mn^2)$ small compare & swap objects where updates take $O(1)$ steps and scans take $O(m)$ steps. He began with a very simple single-scanner, single-writer snapshot implementation from registers that uses a secondary array to store a copy of recent updates. A scan clears that array, collects the main array, and then collects the secondary array to find any overlooked updates. Several additional mechanisms are introduced for the general, multi-writer, multi-scanner snapshot. In particular, compare & swap operations are used instead of writes to coordinate writers updating the same component and multiple scanners coordinate with one another to simulate a single scanner. Jayanti's algorithm builds on an earlier paper by Riany, Shavit and Touitou [16], which gave an implementation that achieved similar complexity, but only for a single-writer snapshot.

Applications

Applications of snapshots include distributed databases, storing checkpoints or backups for error recovery, garbage collection, deadlock detection, debugging distributed programmes and obtaining a consistent view of the values reported by several sensors. Snapshots have been used as building blocks for distributed solutions to randomized consensus and approximate agreement. They are also helpful as a primitive for building other data structures. For example, consider implementing a counter that stores an integer and provides increment, decrement and read operations. Each process can store the number of increments it has performed minus the number of its decrements in its own component of a single-writer snapshot object, and the counter may be read by summing the values from a scan. See [10] for references on many of the applications mentioned here.

Open Problems

Some complexity lower bounds are known for implementations from registers [9], but there remain gaps between the best known algorithms and the best lower bounds. In particular, it is not known whether there is an efficient wait-free implementation of snapshots from small registers.

Experimental Results

Riany, Shavit and Touitou gave performance evaluation results for several implementations [16].

Keywords

Genome rearrangements

Problem Definition

One of the most promising ways to determine evolutionary distance between two organisms is to compare the order of appearance of identical (e.g., orthologous) genes in their genomes. The resulting genome rearrangement problem calls for finding a shortest sequence of rearrangement operations that sorts one genome into the other. In this work [8], Hartman and Sharan provide a 1.5-approximation algorithm for the problem of sorting by transpositions, transreversals, and revrevs, improving on a previous 1.75 ratio for this problem. Their algorithm is also faster than current approaches and requires $O(n^{3/2}\sqrt{\log n})$ time for n genes.

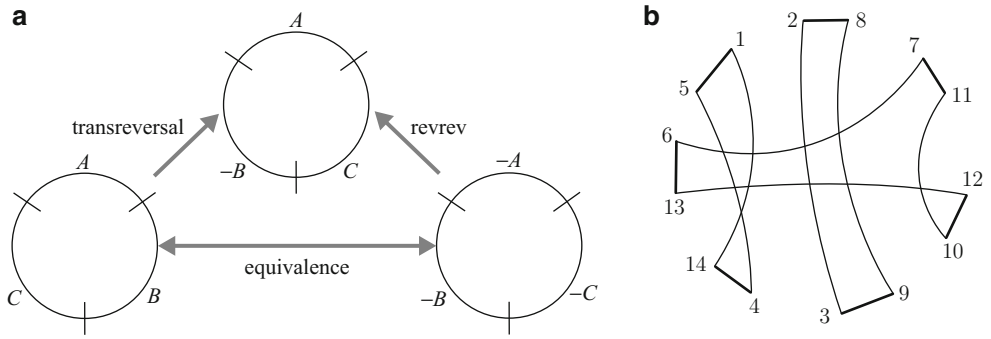
Notations and Definition

A *signed permutation* $\pi = [\pi_1, \pi_2, \ldots, \pi_n]$ on $n(\pi) \equiv n$ elements is a permutation in which each element is labeled by a sign of plus or minus. A *segment* of π is a sequence of consecutive elements $\pi_i, \pi_{i+1}, \ldots, \pi_k$, where $1 \leq i \leq k \leq n$. A *reversal* ρ is an operation that reverses the order of the elements in a segment and also flips their signs. Two segments $\pi_i, \pi_{i+1}, \ldots, \pi_k$ and $\pi_j, \pi_{j+1}, \ldots, \pi_l$ are said to be *contiguous* if $j = k+1$ or $i = l+1$. A *transposition* τ is an operation that exchanges two contiguous (disjoint) segments. A *transreversal* $\tau\rho_{A,B}$ (respectively, $w\tau\rho_{B,A}$) is a transposition that exchanges two segments A and B and also reverses A (respectively, B). A *revrev* operation $\rho\rho$ reverses each of the two contiguous segments (without transposing them). The problem of finding a shortest sequence of transposition, transreversal, and revrev operations that transforms a permutation into the identity permutation is called *sorting by transpositions, transreversals, and revrevs*. The *distance* of a permutation π, denoted by $d(\pi)$, is the length of the shortest sorting sequence.

Key Results

Linear vs. Circular Permutations

An operation is said to *operate* on the affected segments as well as on the elements in those segments. Two operations μ and μ' are *equivalent* if they have the same rearrangement result, i.e., $\mu \cdot \pi = \mu' \cdot \pi$ for all π. In this work [8], Hartman and Sharan showed that for an element x of a circular permutation π, if μ is an operation that operates on x, then there exists an equivalent operation μ' that does not operate on x. Based on this property, they further proved that the problem of sorting by transpositions, transreversals, and revrevs is



Sorting by Transpositions and Reversals (Approximate Ratio 1.5), Fig. 1 (**a**) The equivalence of transreversal and revrev on circular permutations. (**b**) The breakpoint graph $G(\pi)$ of the permutation $\pi = [1, -4, 6, -5, 2, -7, -3]$, for which $f(\pi) = [1, 2, 8, 7, 11, 12, 10, 9, 3, 4, 14, 13, 6, 5]$. It is convenient to draw $G(\pi)$ on a circle such that *black edges* (i.e., *thick lines*) are on the circumference and *gray edges* (i.e., *thin lines*) are chords

equivalent for linear and circular permutations. Moreover, they observed that revrevs and transreversals are equivalent operations for circular permutations (as illustrated in Fig. 1a), implying that the problem of sorting a linear/circular permutation by transpositions, transreversals, and revrevs can be reduced to that of sorting a circular permutation by transpositions and transreversals only.

The Breakpoint Graph

Given a signed permutation π on {1,2,...,n} of n elements, it is transformed into an unsigned permutation $f(\pi) = \pi' = [\pi'_1, \pi'_2, \ldots, \pi'_{2n}]$ on {1,2,...,2 n} of $2n$ elements by replacing each positive element i with two elements $2i - 1, 2i$ (in this order) and each negative element $-i$ with $2i, 2i - 1$. The extended $f(\pi)$ is considered here as a circular permutation by identifying $2n + 1$ and 1 in both indices and elements. To ensure that every operation on $f(\pi)$ can be mimicked by an operation on π, only operations that cut before odd position are allowed for $f(\pi)$. The *breakpoint graph* $(G\pi)$ is an edge-colored graph on $2n$ vertices $\{1, 2, \ldots, 2n\}$, in which for every $1 \le i \le n, \pi'_{2i}$ is joined to π'_{2i+1} by a black edge and $2i$ is joined to $2i + 1$ by a gray edge (e.g., see Fig. 1b). Since the degree of each vertex in $G(\pi)$ is exactly 2, $G(\pi)$ uniquely decomposes into cycles. A *k-cycle* (i.e., a cycle of *lengthk*) is a cycle with k black edges, and it is *odd* if k is odd. The number of odd cycles in $G(\pi)$ is denoted by $c_{\text{odd}}(\pi)$. It is not hard to verify that $G(\pi)$ consists of n 1-cycles, and hence, $c_{\text{odd}}(\pi) = n$, if π is an identity permutation $[1, 2, \ldots, n]$. Gu et al. [5] have shown that $c_{\text{odd}}(\mu \cdot \pi) \le c_{\text{odd}}(\pi) + 2$ for all linear permutations π and operations μ. In this work [8], Hartman and Sharan further noted that the above result holds also for circular permutations and proved that the lower bound of $d(\pi)$ is $(n(\pi) - c_{\text{odd}}(\pi))/2$.

Transformation into 3-Permutations

A permutation is called *simple* if its breakpoint graph contains only k-cycle, where $k \le 3$. A simple permutation is also called a *3-permutation* if it contains no 2-cycles. A transformation from π to $\hat{\pi}$ is said to be *safe* if $n(\pi) - c_{\text{odd}}(\pi) = n(\hat{\pi}) - c_{\text{odd}}(\hat{\pi})$. It has been shown that every permutation π can be transformed into a simple one π' by safe transformations and, moreover, every sorting of π' mimics a sorting of π with the same number of operations [6, 11]. Here, Hartman and Sharan [8] further showed that every simple permutation π' can be transformed into a 3-permutation $\hat{\pi}$ by safe paddings (of transforming those 2-cycles into 1-twisted 3-cycles) and, moreover, every sorting of $\hat{\pi}$ mimics a sorting of π' with the same number of operations. Hence, based on these two properties, an arbitrary permutation π can be transformed into a 3-permutation $\hat{\pi}$ such that every sorting of $\hat{\pi}$ mimics a sorting of π with the

same number of operations, suggesting that one can restrict attention to circular 3-permutations only.

Cycle Types

An operation that cuts some black edges is said to *act* on these edges. An operation is further called a *k-operation* if it increases the number of odd cycles by k. A (0, 2,2)-*sequence* is a sequence of three operations, of which the first is a 0-operation and the next two are 2-operations. An odd cycle is called *oriented* if there is a 2-operation that acts on three of its black edges; otherwise, it is *unoriented*. A *configuration* of cycles is a subgraph of the breakpoint graph that contains one ore more cycles. As shown in Fig. 2a–d, there are four possible configurations of single 3-cycles. A black edge is called *twisted* if its two adjacent gray edges cross each other in the circular breakpoint graph. A cycle is k-twisted if k of its black edges is twisted. For example, the 3-cycles in Fig. 2a–d are 0-, 1-, 2-, and 3-twisted, respectively. Hartman and Sharan observed that a 3-cycle is oriented if and only if it is 2- or 3-twisted.

Cycle Configurations

Two pairs of black edges are called *intersecting* if they alternate in the order of their occurrence along the circle. A pair of black edges *intersects* with cycle C, if it intersects with a pair of black edges that belong to C. Cycles C and *Dintersect* if there is a pair of black edges in C that intersects with D (see Fig. 2e). Two intersecting cycles are called *interleaving* if their black edges alternate in their order of occurrence along the circle (see Fig. 2f). Clearly, the relation between two cycles is one of (1) nonintersecting, (2) intersecting but non-interleaving, and (3) interleaving. A pair of black edges is *coupled* if they are connected by a gray edge and when reading the edges along the cycle, they are read in the same direction. For example, all pairs of black edges in Fig. 2a are coupled. Gu et al. [5] have shown that given a pair of coupled black edges (b_1, b_2), there exists a cycle C that intersects with (b_1, b_2). A *1-twisted pair* is a pair of 1-twisted cycles, whose twists are consecutive on the circle in a configuration that consists of these two cycles only. A 1-twisted cycle is called *closed* in a configuration if its two coupled edges intersect with some other cycle in the configuration. A configuration is *closed* if at least one of its 1-twisted cycles is closed; otherwise, it is called *open*.

The Algorithm

The basic ideas of the Hartman and Sharan's 1.5-approximation algorithm [8] for the problem of sorting by transpositions, transreversals, and revrevs are as follows. Hartman and Sharan reduced the problem to that of sorting a circular 3-permutation by transpositions and transreversals only and then focused on transforming the 3-cycles into 1-cycles in the breakpoint graph of this 3-permutation. By definition, an oriented (i.e., 2- or 3-twisted) 3-cycle admits a 2-operation and, therefore, they continued to consider unoriented (i.e., 0- or 1-twisted) 3-cycles only. Since configurations involving only 0-twisted 3-cycles were handled with (0,2,2)-sequences in [7], Hartman and Sharan restricted their attention to those configurations that consist of 0- and 1-twisted 3-cycles. They showed that these configurations are all closed and that it can be sorted by a (0,2,2)-sequence of operations for each of the following five possible closed configurations: (1) a closed configuration with two unoriented, interleaving 3-cycles that do not form a 1-twisted pair; (2) a closed configuration with two intersecting, 0-twisted 3-cycles; (3) a closed configuration with two intersecting, 1-twisted 3-cycles; (4) a closed

configuration with a 0-twisted 3-cycles that intersects with the coupled edges of a 1-twisted 3-cycle; and (5) a closed configuration that contains $k \geq 2$ mutually interleaving 1-twisted 3-cycles such that all their twists are consecutive on the circle and k is maximal with this property. As a result, the sequence of operations used by Hartman and Sharan in their algorithm contains only 2-operations and (0,2,2)-sequences. Since every sequence of three operations increases the number of odd cycles by at least 4 out of 6 possible in 3 steps, the ratio of their approximation algorithm is 1.5. Furthermore, Hartman and Sharan showed that their algorithm can be implemented in $O(n^{3/2}\sqrt{\log n})$ time using the data structure of Kaplan and Verbin [10], where n is the number of elements in the permutation.

Theorem 1 *The problem of sorting linear permutations by transpositions, transreversals, and revrevs is linearly equivalent to the problem of sorting circular permutations by transpositions, transreversals, and revrevs.*

Theorem 2 *There is a 1.5-approximation algorithm for sorting by transpositions, transreversals, and revrevs, which runs in $O(n^{3/2}\sqrt{\log n})$ time.*

Applications

When trying to determine evolutionary distance between two organisms using genomic data, biologists may wish to reconstruct the sequence of evolutionary events that have occurred to transform one genome into the other. One of the most promising ways to do this phylogenetic study is to compare the order of appearance of identical (e.g., orthologous) genes in two different genomes [9, 12]. This comparison of computing global rearrangement events (such as reversals, transpositions, and transreversals of genome segments) may provide more accurate and robust clues to the evolutionary process than the analysis of local point mutations (i.e., substitutions, insertions, and deletions of nucleotides/amino acids). Usually, the two genomes being compared are represented by signed permutations, with each element standing for a gene and its sign representing the (transcriptional) direction of the corresponding gene on a chromosome. Then the goal of the resulting genome rearrangement problem is to find a shortest sequence of rearrangement operations that transforms (or, equivalently, *sorts*) one permutation into the other. Previous work focused on the problem of sorting a permutation by reversals. This problem has been shown by Capara [2] to be NP-hard, if the considered permutation is unsigned. However, for signed permutations, this problem becomes tractable and Hannenhalli and Pevzer [6] gave the first polynomial-time algorithm for it. On the other hand, there has been less progress on the problem of sorting by transpositions. Thus far, the complexity of this problem is still open, although several 1.5-approximation algorithms [1, 3, 7] have been proposed for it. Recently, the approximation ratio of sorting by transpositions was further improved to 1.375 by Elias and Hartman [4]. Gu et al. [5] and Lin and Xue [11] gave quadratic-time 2-approximation algorithms for sorting signed, linear permutations by transpositions and transreversals. In [11], Lin and Xue considered the problem of sorting signed, linear permutations by transpositions, transreversals, and revrevs and proposed a quadratic-time 1.75-approximation algorithm for it. In this work [8], Hartman and Sharan further showed that this problem is equivalent for linear and circular permutations and can be reduced to that of sorting signed, circular permutations by transpositions and transreversals only. In addition, they provided a 1.5-approximation algorithm that can be implemented in $O(n^{3/2}\sqrt{\log n})$ time.

Sorting Signed Permutations by Reversal (Reversal Distance)

David A. Bader
College of Computing, Georgia Institute of Technology, Atlanta, GA, USA

Keywords

Inversion distance; Reversal distance; Sorting by reversals

Years and Authors of Summarized Original Work

2001; Bader, Moret, Yan

Problem Definition

This entry describes algorithms for finding the minimum number of steps needed to sort a signed permutation (also known as inversion distance, reversal distance). This is a real-world problem and, for example, is used in computational biology.

Inversion distance is a difficult computational problem that has been studied intensively in recent years [1, 4, 6–10]. Finding the inversion distance between unsigned permutations is NP-hard [7], but with signed ones, it can be done in linear time [1].

Key Results

Bader et al. [1] present the first worst-case linear-time algorithm for computing the reversal distance that is simple and practical and runs faster than previous methods. Their key innovation is a new technique to compute connected components of the overlap graph using only a stack, which results in the simple linear-time algorithm for computing the inversion distance between two signed permutations. Bader et al. provide ample experimental evidence that their linear-time algorithm is efficient in practice as well as in theory: they coded it as well as the algorithm of Berman and Hannenhalli, using the best principles of algorithm engineering to ensure that both implementations would be as efficient as possible and compared their running times on a large range of instances generated through simulated evolution.

Bafna and Pevzner introduced the cycle graph of a permutation [3], thereby providing the basic data structure for inversion distance computations. Hannenhalli and Pevzner then developed the basic theory for expressing the inversion distance in easily computable terms

(number of breakpoints minus number of cycles plus number of hurdles plus a correction factor for a fortress [3, 15]-hurdles and fortresses are easily detectable from a connected component analysis). They also gave the first polynomial-time algorithm for sorting signed permutations by reversals [9]; they also proposed a $O(n^4)$ implementation of their algorithm which runs in quadratic time when restricted to distance computation. Their algorithm requires the computation of the connected components of the overlap graph, which is the bottleneck for the distance computation. Berman and Hannenhalli later exploited some combinatorial properties of the cycle graph to give a $O(n\alpha(n))$ algorithm to compute the connected components, leading to a $O(n^2\alpha(n))$ implementation of the sorting algorithm [6], where α is the inverse Ackerman function. (The later Kaplan-Shamir-Tarjan (KST) algorithm [10] reduces the time needed to compute the shortest sequence of inversions, but uses the same algorithm for computing the length of that sequence.)

No algorithm that actually builds the overlap graph can run in linear time, since that graph can be of quadratic size. Thus, Bader's key innovation is to construct an *overlap forest* such that two vertices belong to the same tree in the forest exactly when they belong to the same connected component in the overlap graph. An overlap forest (the composition of its trees is unique, but their structure is arbitrary) has exactly one tree per connected component of the overlap graph and is thus of linear size. The linear-time step for computing the connected components scans the permutation twice. The first scan sets up a trivial forest in which each node is its own tree, labeled with the beginning of its cycle. The second scan carries out an iterative refinement of this first forest, by adding edges and so merging trees in the forest; unlike a Union-Find, however, this algorithm does not attempt to maintain the trees within certain shape parameters. This step is the key to Bader's linear-time algorithm for computing the reversal distance between signed permutations.

Applications

Some organisms have a single chromosome or contain single-chromosome organelles (such as mitochondria or chloroplasts), the evolution of which is largely independent of the evolution of the nuclear genome. Given a particular strand from a single chromosome, whether linear or circular, we can infer the ordering and directionality of the genes, thus representing each chromosome by an ordering of oriented genes. In many cases, the evolutionary process that operates on such single-chromosome organisms consists mostly of inversions of portions of the chromosome; this finding has led many biologists to reconstruct phylogenies based on gene orders, using as a measure of evolutionary distance between two genomes the inversion distance, i.e., the smallest number of inversions needed to transform one signed permutation into the other [11, 12, 14].

The linear-time algorithm is in wide use (as it has been cited nearly 200 times within the first several years of its publication). Examples include the handling multichromosomal genome rearrangements [16], genome comparison [5], parsing RNA secondary structure [13], and phylogenetic study of the HIV-1 virus [2].

Open Problems

Efficient algorithms for computing minimum distances with weighted inversions, transpositions, and inverted transpositions are open.

Experimental Results

Bader et al. give experimental results in [1].

URL to Code

An implementation of the linear-time algorithm is available as *C* code from www.cc.gatech.edu/~bader. Two other dominated implementations are available that are designed to compute the shortest sequence of inversions as well as its length:

one, due to Hannenhalli that implements his first algorithm [9], which runs in quadratic time when computing distances, while the other, a Java applet written by Mantin (http://www.math.tau.ac.il/~rshamir/GR/), that implements the KST algorithm [10], but uses an explicit representation of the overlap graph and thus also takes quadratic time. The implementation due to Hannenhalli is very slow and implements the original method of Hannenhalli and Pevzner and not the faster one of Berman and Hannenhalli. The KST applet is very slow as well since it explicitly constructs the overlap graph.

Problem Definition

A *signed permutation* π of size n is a permutation over $\{-n, \ldots, -1, 1 \ldots n\}$, where $\pi_{-i} = -\pi_i$ for all i. We note $\pi = (\pi_1, \ldots, \pi_n)$.

The *reversal* $\rho = \rho_{i,j} (1 \leq i \leq j \leq n)$ is an operation that reverses the order and flips the signs of the elements $\pi_i, \ldots, \pi_j$ in a permutation π:

$$\pi \cdot \rho = (\pi_1, \ldots, \pi_{i-1}, -\pi_j, \ldots, -\pi_i \pi_{j+1}, \ldots, \pi_n).$$

If $\rho_1, \ldots, \rho_k$ is a sequence of reversals, it is said to *sort* a permutation π if $\pi \cdots \rho_1 \cdots \rho_k = Id$, where $Id = (1, 2, \ldots, n)$ is the identity permutation. The length of a shortest sequence of reversals sorting π is called the *reversal distance* of π and is denoted by $d(\pi)$.

If the computation of $d(\pi)$ is solved in linear time [3] (see the entry ▸ Sorting Signed Permutations by Reversal (Reversal Distance)), the computation of a sequence $\rho^1, \ldots, \rho^k$ of size $k = d(\pi)$ that sorts π is more complicated, and no linear time algorithm is known so far. The best complexity is currently achieved by the subquadratic solution of Tannier and Sagot [17], which has later been improved by Tannier, Bergeron and Sagot [18], and Han [9].

Key Results

The $O(n^4)$ Self-Reduction

Recall there is a linear algorithm to compute the reversal distance thanks to the formula $d(\pi) = n + 1 - c(\pi) + t(\pi) + h(\pi) + f(\pi)$, where $c(\pi)$ is the number of cycles in the breakpoint graph and $h(\pi) + f(\pi)$ is computed from the unoriented components of the permutation (see the entry ▸ Sorting Signed Permutations by Reversal (Reversal Distance)). Once this is known, the self-reduction technique trivially computes a sequence of size $d(\pi)$: try every possible reversal ρ at one step, until you find one such that $d(\pi \cdot \rho) = d(\pi) - 1$. Such a reversal is called a *sorting reversal*. This necessitates $O(n)$ computations for every possible reversal. There are at most $n(n+1)/2 = O(n^2)$ reversals to try, so iterating this to find a sequence yields an $O(n^4)$ algorithm.

The first polynomial algorithm by Hannenhalli and Pevzner [10] was not achieving a better complexity, and the algorithmic study of finding the shortest sequences of reversals began its history.

The Quadratic Roof

All the published solutions for the computations of a sorting sequence are divided into two, following the division of the distance formula into its parameters: a first part computes a sequence of reversals so that the resulting permutation has no unoriented component, and a second part sorts all oriented components.

The first part was given its best solution by Kaplan, Shamir, and Tarjan [12], whose algorithm runs in linear time when coupled with the linear distance computation [3], and it is based on Hannenhalli and Pevzner's [10] early results.

The second part is the bottleneck of the whole procedure. At this point, if there is no unoriented component, the distance is $d(\pi) = n + 1 - c(\pi)$, so a sorting reversal is one that increases $c(\pi)$ and does not create unoriented components.

A reversal that increases $c(\pi)$ is called *oriented*. Finding an oriented reversal is an easy part: any two consecutive numbers that have different signs in the permutation define one. This can easily be done in linear time or sublinear with ad hoc data structures to maintain the permutation during the scenario. The hard part is to make sure it does not create unoriented components.

The quadratic solutions (see, e.g., the one of Kaplan, Shamir, and Tarjan [12]) are based on the linear recognition of sorting reversals. No better algorithm is known so far to recognize sorting reversals, and it seemed that a lower bound had been reached, as witnessed by a survey

of Ozery-Flato and Shamir [15] in which they wrote that "a central question in the study of genome rearrangements is whether one can obtain a subquadratic algorithm for sorting by reversals." This was obtained by Tannier and Sagot [17], who proved that the recognition of sorting reversal at each step is not necessary, but only the recognition of oriented reversals.

A Promising New but Still Quadratic Method

The algorithm is based on the following theorem, taken from [18]. A sequence of oriented reversals $\rho_1, \ldots, \rho_k$ is said to be *maximal* if there is no oriented reversal in $\pi \cdot \rho_1 \ldots \rho_k$. In particular a sorting sequence is maximal, but the converse is not true.

Theorem 1 *If S is a maximal but not a sorting sequence of oriented reversals for a permutation, then there exists a nonempty sequence S' of oriented reversals such that S may be split into two parts $S = S_1, S_2$, and S_1, S', S_2 is a sequence of oriented reversal.*

This allows to construct sequences of oriented reversals instead of sorting reversals, increase their size by adding reversals inside the sequence instead of at the end, and obtain a sorting sequence.

This algorithm, with a classical data structure to represent permutations (e.g., as an array), has still an $O(n^2)$ complexity, because at each step it has to test the presence of an oriented reversal and apply it to the permutation.

Composing with Data Structures

The slight modification of a data structure invented by Kaplan and Verbin [11] allows to pick and apply an oriented reversal in $O(\sqrt{n \log n})$, and using this, Tannier and Sagot's algorithm achieves $O(n^{3/2}\sqrt{\log n})$ time complexity.

Han [9] announced another data structure that allows to pick and apply an oriented reversal in $O(\sqrt{n})$ time, and integrating this to the algorithm can plausibly decrease the complexity of the overall method to $O(n^{3/2})$. Swenson et al. [16] gave an $O(n \log n)$ solution for picking oriented reversals, but their attempts of integrating it to the overall procedure seems to fail on worst cases.

Extensions

Once sorting by reversals has reached its best solutions, there are natural extensions guided by the main motivation for the problem in computational biology: sample among optimal solutions, and handle several permutations and more operations than just the reversal.

Counting optimal solutions is conjectured to be #P-complete [14], but sampling almost uniformly from the solution space is still open, and has been given a heuristic solution [14], including suboptimal solutions in the sample.

Algorithms to enumerate all sorting reversals at one step have also been worked out [4], which provides a way for enumeration. A structure of the solution space was proposed, but with a possibly exponential number of objects to enumerate [5].

The median problem consists in handling more than one permutation and is a particular case of the so-called small parsimony problem, which consists in reconstructing ancestral states in a phylogenetic context. Additional operations can be transpositions, duplications, or many others. Many generalizations and variants have been listed in a book on Combinatorics of Genome Rearrangements [8]. Almost all are NP-hard.

Applications

The motivation as well as the main application of this problem is in computational biology. Signed permutations are an adequate object to model the relative position and orientation of homologous segments of DNA in two species.

Reversal scenarios were used to test some evolutionary properties, like the propension of rearrangement to cut around the replication origin [1] or the fragility of certain genomic regions [2]. But evolutionary hypotheses can hardly be

tested from a single optimal solution; this would necessitate a better view of the solution space.

The gain of complexity for sorting by reversals inspired many other algorithmic works, and several problems in genome rearrangement found a better solution thanks to the subquadratic gain described here. But the computational difficulties of the problem (parameters $h(\pi)$ and $f(\pi)$, additional complexity for generating a scenario compared to the distance calculation, NP-completeness of every generalization with more operations, more permutations, more realistic models) lead most computational biologists to progressively abandon the reversal model for simpler ones (DCJ [19], SCJ [7]).

Sometimes heroic gains in complexity are worth for computer science but seem just like going a bit further in a dead end for applications. Research consists in breaking walls without always knowing if behind there is a space for a community to work in or another thicker wall.

Open Problems

Still there are a couple of questions that remain unsolved before closing (or reopening?) this entry:

- I conjecture that the "real" complexity of giving a reversal scenario is $O(n \log n)$. It is more or less what Swenson et al. [16] also claim, but without giving a full proof.
- Counting and sampling, even approximately, are open. I learned this interesting conjecture from Istvan Miklos: is it possible to walk in the entire space of sequences of sorting reversals by small transformations of scenarios, consisting at each step to change at most 4 reversals? This would be a first step to design an almost uniform sampler.

Experimental Results

To my knowledge the data structure that allows the subquadratic complexity described in this entry has never been implemented. The size of the data, as well as the limited possibilities of applications of handling only two genomes and a single optimal solution, makes the subquadratic version, while a good piece of algorithmics, not really worth for applications.

URL to Code

- There are a few old programs still able to give a sorting sequence of reversals: in San Diego http://grimm.ucsd.edu/GRIMM/, New Mexico www.cs.unm.edu/~moret/GRAPPA/, or Tel Aviv www.math.tau.ac.il/~rshamir/GR/ and more recent ones in Lyon http://doua.prabi.fr/software/luna or Bielefeld http://bibiserv.techfak.uni-bielefeld.de/dcj/welcome.html.
- The standard software for Bayesian sampling in the space of sorting sequences (including nonoptimal ones) is Badger http://bibiserv.techfak.uni-bielefeld.de/dcj/welcome.html, and there is also one biased to optimal solutions called DCJ2HP http://www.renyi.hu/~miklosi/DCJ2HP/ that uses a parallel tempering between DCJ solutions (easier to sample) and reversals solutions.

Problem Definition

Let $G = (V, E)$ be an undirected graph, with nonnegative weights on the edges $w : E \to \mathbb{R}_+$. Let d_G be the shortest-path metric on G, with respect to the weights. For a spanning (subgraph) tree T of G, define the stretch of an edge $\{u, v\} \in E$ in T as $\text{stretch}_T(u, v) = \frac{d_T(u,v)}{d_G(u,v)}$ and the average stretch as

$$\text{avg} - \text{stretch}_T(G) = \frac{1}{|E|} \sum_{e \in E} \text{stretch}_T(e) .$$

We shall consider the problem of finding a tree T whose average stretch is small. We also study the problem of finding a distribution over spanning trees, such that for all $e \in E$, $\mathbb{E}_T[\text{stretch}_T(e)]$ is small.

Key Results

Low-stretch spanning trees were first studied by [3], who showed that any graph on n vertices has a spanning tree with average stretch $2^{O(\sqrt{\log n \log\log n})}$ and showed a family of graphs

that requires $\Omega(\log n)$ average stretch. Their result was substantially improved by [7], who showed an upper bound of $O(\log^2 n \log\log n)$, and later [1] improved this to a near optimal $\tilde{O}(\log n)$.

The main result discussed here is from [2]:

Theorem 1 *For any graph G with n vertices and m edges, there is a deterministic algorithm that constructs a spanning tree T, such that* $\text{avg} - \text{stretch}_T(G) \leq O(\log n \log\log n)$. *The running time of the algorithm is* $O(m \log n \log\log n)$.

We also show an efficient algorithm to sample from a distribution over spanning trees, such that the expected stretch of any edge is bounded by $O(\log n \log\log n \log\log\log n)$.

Applications

An important problem in algorithm design is obtaining fast algorithms for solving linear systems. For many applications, the matrix is sparse, and while little is known for general sparse matrices, the case of symmetric diagonally dominant (SDD) matrices has received a lot of attention recently. In a seminal sequence of results, Spielman and Teng [12] showed a near-linear time solver for this important case. This solver has proven a powerful algorithmic tool and is used to calculate eigenvalues, obtain spectral graph sparsifiers [11], and approximate maximum flow [6] and many other applications. A basic step in solving these systems $Ax = b$ is combinatorial preconditioning. If one uses the Laplacian matrix corresponding to a spanning tree (and a few extra edges) of the graph whose Laplacian matrix is A, then the condition number depends on the total stretch of the tree. This will improve the run-time of iterative methods, such as conjugate gradient or Chebyshev iterations. See [9, 10] for the latest progress on this direction. In this work we show that one can construct such a spanning tree with both run-time and total stretch bounded by $O(m \log n \log\log n)$.

Probabilistic embedding into trees, introduced by [4], has been a successful paradigm in algorithm design. Many hard optimization problems on graphs can be reduced, via embedding, to a similar problem on a tree, which is often considerably easier. This framework can be applied to approximation algorithms, online algorithms, network design, and other settings. Some of the notable examples are metrical task system, buy-at-bulk network design, the k-server problem, group Steiner tree, etc. An asymptotical optimal result of expected $O(\log n)$ distortion for probabilistic embedding into trees was given by [8]. The trees in the support of the FRT distribution are not subgraphs of the input graph and may contain Steiner nodes and new edges. While this is fine for most applications, there are some that must have trees which are subgraphs, such as minimum cost communication spanning tree: Given a weighted graph $G = (V, E)$ and a requirement matrix $R = (r_{uv})$, the objective is to find a spanning tree T that minimizes $\sum_{u,v \in V} r_{uv} \cdot d_T(u, v)$. Our result implies a $\tilde{O}(\log n)$ approximation.

Petal Decomposition

A basic tool that is often used in constructing tree metrics and spanning trees with low stretch is *sparse graph decomposition*. The idea is to partition the graph into small diameter pieces, such that few edges are cut. Each cluster of the decomposition is partitioned recursively, which yields a hierarchical decomposition. Creating a tree recursively on each cluster of the decomposition, and connecting these in a tree structure, will yield a spanning tree of the graph. The edges cut by the decomposition are potentially stretched by a factor proportional to the diameter of the created tree. The construction has to balance between these two goals: cut a small number of edges and maintain small diameter in the created tree.

One of the main difficulties in such a spanning tree construction is that the radius (The radius of a graph is the maximal distance from a designated center.) may increase by a small factor at every application of the decomposition, which

translates to increased stretch. If we drop the requirement that the tree is a *spanning tree* of the graph and just require a tree metric, then this difficulty does not appear, and indeed, optimal $\Theta(\log n)$ bound is known on the average stretch [5,8]. Our *petal decomposition* allows essentially optimal control on the radius increase of the spanning tree; it increases by at most a factor of 4 over all the recursion levels.

Highways

One of the components in the decomposition scheme is highways. Each cluster $X \subseteq V$ in our decomposition scheme has a designated center $x_0 \in X$ and a "target" $t \in X$. It is guaranteed that the shortest path from x_0 to t will be fully contained in the *final* spanning tree T. This path is called the petal's highway. Intuitively, the highway will provide short paths from the center x_0 to many of the points in the cluster.

Cones and Petals

A cone is a generalization of a ball; the notion of cones was introduced in [7] and was used also in [1] for low-stretch spanning trees. Informally, a cone $C(t,r)$ of radius r centered at t (with respect to the cluster center x_0) contains all the points $z \in X$ such that $d(z,t) + d(t,x_0) \leq d(z,x_0) + r$ (here d is the shortest-path metric on X). In other words, the cone contains all the points for which the path to x_0 through t is not much longer than the direct shortest path to x_0. The parameter r is a bound on the radius increase in the current decomposition.

One way to define a petal is as a *union of cones*. The petal $P(t,r)$ around a target t with radius r is defined as $\bigcup_{0 \leq k \leq r} C(p_k, k/2)$, where p_k is the point of distance $r-k$ from t on the shortest path from t to x_0. The center of the petal is defined as $x = p_0$, and the path from x to t is the petal's highway. The `petal-decomposition` algorithm iteratively picks an arbitrary target of distance at least $3\Delta/4$ (where Δ is the radius of X) away from x_0, generates a petal for it, and removes the petal from the graph. When there are no longer such points, the remaining points will form the central cluster (the stigma). The first petal requires extra care in its target choice, as it may contain the designated target of the cluster, which implies we cannot allow the shortest path to this target to be cut by this or subsequent petals. The radii of the petals are chosen by a region-growing argument that cuts few edges, where the length of the possible range for the radius is $\approx\Delta$. This is in contrast with the previous work, where in order to give an appropriate bound on the radius increase, the range was much smaller than Δ, which immediately translates to a loss in the stretch. The precise method for choosing r is essentially given in [7], and we also give a randomized version similar in spirit to the one in [1].

Fast Petal Construction

The alternative way to define petals and cones is as balls in an appropriately defined *directed* graph created from G. This suggests that we can use a variant of Dijkstra to compute a petal in nearly linear time in the sum of degrees of its vertices. Let $\tilde{G} = (V, A, \bar{w})$ be the weighted directed graph induced by adding the two directed edges $(u,v), (v,u) \in A$ for each $\{u,v\} \in E$ and setting $\bar{w}(u,v) = d(u,v) - (d(v,x_0) - d(u,x_0))$. The cone $C(t,r)$ is simply the ball around t of radius r in $\tilde{G}$. The petal $P(t,r)$ is the ball around t of radius $r/2$ in $\tilde{G}$ with one change: the weight of each edge on the path from t to $x = p_0$ is changed to be $1/2$ of its original weight (i.e., $1/2$ of its weight in G).

Ideas in the Analysis

Informally, the crucial property of a petal and its highway is the following: Assume $z \in P(t,r)$, and $P_{x_0 z}$ is the shortest path from the original center x_0 to z. By forming the petal, we remove all edges between $P(t,r)$ and $X \setminus P(t,r)$ except for the edge from the petal center x toward x_0. Hence, any path from x_0 to z must go through the petal center x. If the new shortest path $P'_{x_0 z}$ (after forming the petal) is (additively) $k/2$ longer than the length of $P_{x_0 z}$, then $z \in C(p_k, k/2)$ and so $P'_{x_0 z}$ will contain part of the new petal's highway of length at least k. Such a property could allow the following wishful thinking: Suppose that in each iteration we increase the distance of a point to the center by at most α but also mark a new

portion of the path of length 2α as edges that are guaranteed to appear in the final tree (part of a highway). In such a case, it is easy to see that the final path will have stretch at most 2: If the original distance was b, once the total increase is b, we have marked $2b$ – all of the path – as a highway that will appear in the tree. Unfortunately, the path from x to z in the final tree may not use the prescribed highway of the parent cluster so the above "wishful thinking" argument does not work.

The key algorithmic idea to alleviate this problem is to decrease the weight of an edge by half when it becomes part of a highway (we ensure that this happens at most once for every edge). This reweighting signals later iterations to use the prescribed highway, as this must remain the shortest path. We maintain the invariant that in every cluster, the highway edges are the only cluster edges which have been reweighted. Now, in every petal (except for maybe the first), we create a *new* petal highway when we form $P(t, r)$. For any $z \in P(t, r)$, *the length of the path from* x_0 *to* z *does not increase at all* (after reweighting the highway): For some $k \leq r$, it increased by at most $k/2$, but a highway length of at least k was reduced by $1/2$.

We have to take care of radius increase generated by the very first petal as well, where it could be that no new highway is created (this petal's highway may be a part of the highway of the original cluster). In this case, we use the fact that the path from x_0 to x_1 (the center of the first petal) must also be on the highway of the original cluster and that its length is at least $\Delta/2$. This implies that even though we may have increased the radius, at least half of the path is guaranteed not to increase ever again. We use a subtle inductive argument to make this intuition precise, and in fact we lose a factor of 2 for each of these cases, so the maximal increase is by a factor of 4.

Sparse Fourier Transform

Eric Price
Department of Computer Science, The University of Texas, Austin, TX, USA

Keywords

Compressed sensing; Sparse recovery

Years and Authors of Summarized Original Work

2012; Hassanieh, Indyk, Katabi, Price

Problem Definition

Suppose that we have access to a vector $x \in \mathbb{C}^n$. How much time does it take to compute its Fourier transform $\hat{x}$? One can do this with the Fast Fourier Transform (FFT) in $O(n \log n)$ time. But can we do better?

We do not know the answer in general, but some classes of algorithms cannot do better [1, 20] and certainly one cannot do better than $O(n)$ time for arbitrary signals x. But the Fourier transform is ubiquitous in signal processing, appearing in compression of audio, images, and video, in manipulation of audio, and in recovery of radio or MRI signals, so we would really like to do better. If we cannot improve on the FFT in general, then perhaps we can for the signals commonly seen in these applications. To do this, we need some notion for how the signals we typically see are "easier" than arbitrary ones.

One such notion is *sparsity*. The main reason to use the Fourier transform in compression is because it concentrates the energy of the signal into a few large (or "heavy") coordinates and many small ones; signals with such concentrated coordinates are called *sparse*. One can then throw out the small coordinates and only store the heavy ones; this is the main principle behind lossy compression such as MP3 or JPEG. In fact, in all the applications discussed in the previous paragraph, the signals typically have an approximately sparse Fourier transform. This brings us to the problem described in this entry: can we speed up the Fourier transform for signals when the result is approximately sparse?

Moreover, as with lossy compression, we often only care about the heavy coordinates and are willing to tolerate an error proportional to the energy in the small coordinates. This relaxation will allow us to compute the sparse Fourier transform in *sublinear* time.

Formal Definition

The discrete Fourier transform $\hat{x} \in \mathbb{C}^n$ of a vector $x \in \mathbb{C}^n$ is given by

$$\hat{x}_j = \sum_{i=1}^{n} \omega^{ij} \text{ for } \omega = e^{2\pi \mathbf{i}/n}$$

We say that $\hat{x}$ is *exactly* k-sparse if it has at most k nonzero coordinates, i.e., $|\text{supp}(x)| \leq k$. We say that $\hat{x}$ is *approximately* k-sparse if most of the energy is contained in the heaviest k coordinates, in particular

$$\text{Err}_k(x) := \min_{k\text{-sparse } \hat{y}} \|\hat{x} - \hat{y}\|_2$$

is small relative to $\|\hat{x}\|_2$. A sparse Fourier transform algorithm can access $x \in \mathbb{C}^n$ in arbitrary positions and outputs a vector $\hat{x}'$ such that

$$\|\hat{x} - \hat{x}'\|_2 \leq C \,\text{Err}_k(x) + \delta \|\hat{x}\|_2 \qquad (1)$$

for some approximation factor $C > 1$ and $\delta \ll 1$. An algorithm for the exactly sparse case would do this for $C = \infty$, while robust algorithms can achieve $C = O(1)$ or even $C = 1 + \varepsilon$. The algorithms we will discuss will feature a logarithmic dependence on $1/\delta$, so one typically sets $\delta = 1/\text{poly}(n)$, and for typical signals, the right-hand side of (1) will be dominated by the $C \,\text{Err}_k(x)$ term; we will assume this for the rest of the entry.

We would like to optimize both the sample complexity – the number of positions of x that are accessed by the algorithm – and the

running time. Optimizing sample complexity is important for applications such as spectrum sensing or MRIs, which do not have the input x in memory but must sample it at some expense.

We also allow the algorithm to be randomized and to fail with some small probability p. For simplicity we set p to a small constant; for any algorithm one can amplify this probability with a $O(\log \frac{1}{p})$ overhead in sample complexity and time. It is an open question whether the algorithms that achieve the best known time and sample complexities can be modified to avoid this overhead.

Related Work

The modern research on sparse Fourier transforms is closely related to work on sparse recovery from general linear measurements. In this problem, one would like to (approximately) recover an (approximately) sparse vector x from linear measurements Ax for some "measurement" matrix A with fewer rows than columns. The sparse Fourier transform is precisely this where A is a subset of rows of the inverse Fourier matrix.

Broadly speaking, there are two conceptual classes of algorithms and results for the general linear measurement setting. The first class, often called *compressed sensing* and first studied in [2, 3, 7], generally (1) involves independent random linear measurements,;(2) shows with high probability, the measurement matrix gives good recovery *for all* vectors x; (3) optimizes the sample complexity but not the running time, which is superlinear or polynomial in n; and (4) give algorithms that work for general classes of measurements and work for both random Gaussian and random Fourier matrices at the same time. These papers often refer to properties like the restricted isometry property that measurement matrices may have and use either convex optimization (e.g., L1 minimization or the LASSO) or iterative greedy methods (e.g., IHT or CoSaMP) to perform the recovery.

The second class, more often called *sparse recovery*, is largely an outgrowth of the streaming algorithms literature [4, 5]. These results generally (1) involve more structured linear measurements that use randomness and also have dependencies among the samples; (2) show *for each* vector x that, with high probability, the measurement matrix gives good recovery; (3) optimize both the sample complexity and the running time, so both may be sublinear in n; and (4) give algorithms that are closely connected to the measurement matrix and would not work for matrices with different structure. These papers often construct the matrix to emulate hash tables and use medians to perform robust recovery.

These statements are generalizations, and not every algorithm matches the trend in all four ways, but they hold more often than not. Our algorithm falls in the second class, which for Fourier measurements can achieve both better sample complexity and better running time than algorithms in the first class.

There's a much older collection of algorithms that can do sparse Fourier transforms in the exact setting when $|\text{supp}(\hat{x})| \leq k$. These include Prony's method from 1795, the matrix pencil method, and Berlekamp-Massey syndrome decoding. These can achieve the optimal sample complexity of $2k$ and recovery time poly(k) (down to $O(k^2 + k \log^c \log n)$ [8]). Additionally, they use a deterministic set of samples and work for all vectors x. However, it is not known how to make the techniques in these algorithms robust to approximately sparse signals, so they do not apply to the signals appearing in typical applications.

Noise-tolerant sparse Fourier transforms were first studied over the Boolean cube, also known as the Hadamard transform. In this setting, Goldreich and Levin [12, 18] showed how to get $O(k \log(n/k))$ samples and $O(k \log^c n)$ time, which is essentially optimal. Mansour [19] extended this to the $\mathbb{C}^n$ setting that we consider in this entry but with more than k^2 sample complexity. Over the next couple decades, a number of subsequent works, including [9, 10, 13, 14, 16], have improved our understanding of the $\mathbb{C}^n$ setting.

Key Results

At present, the two best sparse Fourier transform algorithms are [13], which is fastest at $O(k \log(n/k) \log n)$ time and sample complexity, and [14], which has nearly optimal $O(k \log n)$ sample complexity at the cost of $\tilde{O}(n)$ running time. These works build on [9, 10, 17].

We know that the optimal *nonadaptive* sample complexity – that is, among algorithms that choose the sample set Ω independently of the vector x – is $\Omega(k \log(n/k))$ [6], which matches [14] for $k < n^{0.99}$. One could imagine constructing an algorithm that uses adaptive samples, where one uses the first few samples to decide where to look in future samples. In the general sparse recovery setting, this adaptivity can lead to significant improvements [15], but we know that $\Omega(k \log(n/k)/\log\log n)$ Fourier samples remain necessary in the adaptive setting [13].

Algorithm Overview

At a high level, sparse recovery algorithms are built in three stages: one-sparse recovery, where we solve the problem for $k = 1$; partial k-sparse recovery, where we find and estimate *most* (say, 90 %) of the heavy coordinates or of the energy; and full k-sparse recovery, where we get a good approximation to the entire signal and achieve (1). Each stage uses the previous as (nearly) a black box. This architecture generally holds for the class of "sparse recovery" algorithms; in the sparse Fourier transform setting, the pieces change, but the architecture does not. We will go through each in turn.

One-Sparse Recovery

Let us consider the one-sparse setting for $C = O(1)$. We have access to $x_j = v\omega^{i^* j} + g_j$ for some "signal" $(v, i^*) \in \mathbb{C} \times [n]$ and "noise" $g \in \mathbb{C}^n$ with $\|g\|_2 \le c|v|\sqrt{n}$ for a sufficiently small constant c. To satisfy (1), we would like to find i^* exactly and find v to within $O(\|g\|/\sqrt{n})$.

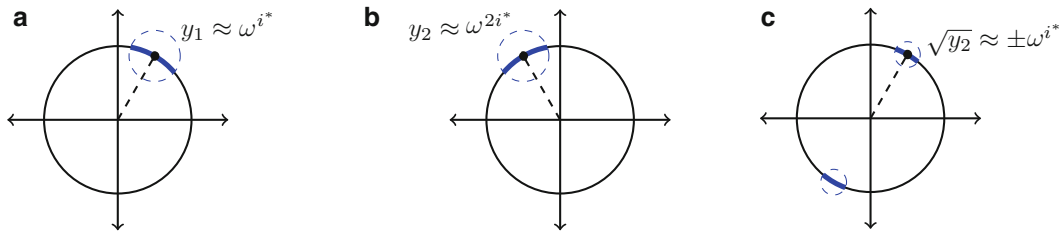
The tricky bit is to find i^*; once we know i^*, then $x_j \omega^{-i^* j}$ is a good estimator of v. In particular, for a random $j \in [n]$, we have $\mathbb{E}_j |x_j \omega^{-i^* j} - v|^2 = \|g\|^2/n$, so taking the median of several such estimates will have $O(\|g\|/\sqrt{n})$ error with large probability. So that just leaves us to find i^*.

As a first step, consider for a fixed $a \in [n]$ looking at the random variable

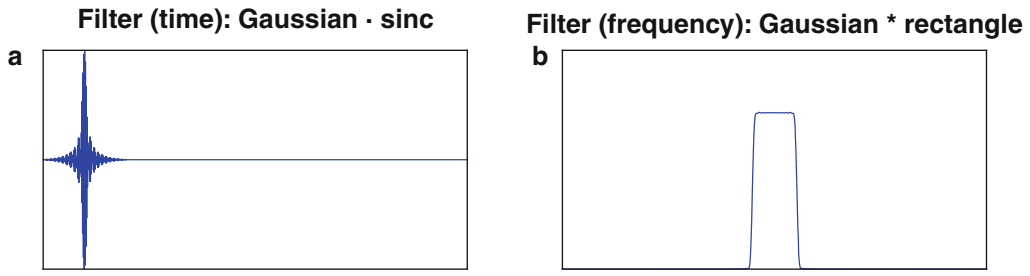
$$y_a := x_{a+j}/x_j \approx \omega^{i^* a}$$

as a distribution over random $j \in [n]$, where addition of indices is taken modulo n. This allows us to remove the influence of v and focus on i^*. We can show that $y_a - \omega^{i^* a} < O(c)$ with large (say, 3/4) probability. Suppose this were instead true with probability 1.

By knowing $\omega^{i^* a}$ to within $O(c)$, we know $i^* a \bmod n$ to with $\pm O(cn)$. For small enough c, this is within $\pm n/4$. Then we could look at y_1 to learn i^* to within $\pm n/4$, y_2 to refine the estimate to $\pm n/8$, and y_4 to refine to $\pm n/16$, until we identify i^* using $\log n$ different y_a. This is illustrated in Fig. 1.



Sparse Fourier Transform, Fig. 1 The first two steps of estimating i^* using y_1 and y_2. Using y_1 we can identify i^* to an $O(cn)$ size region. With y_2 we learn $2i^* \bmod n$ to within $O(cn)$, which tells us that i^* is within one of two antipodal regions of half the size. Based on y_1, we can throw out the spurious region and narrow our estimate of i^* (**a**) Error in y_1. (**b**) Error in y_2. (**c**) Set of ω^{i^*} consistent with y_2



Sparse Fourier Transform, Fig. 2 Filters used in [13]. (**a**) In time domain: $O(k \log n)$ sparse. (**b**) In frequency domain: width $O(n/k)$ rectangle

In reality y_a has a small constant chance of failure at each stage. One could fix this by taking $O(\log \log n)$ different samples of y_a at each stage and using the median, which would give an algorithm with $O(\log n \log \log n)$ sample complexity and time. An alternative, as used in [13], is to learn i^* in chunks of $O(\log \log n)$ bits at a time, which gets the optimal $O(\log n)$ sample complexity using $O(\log^{1.1} n)$ running time.

Partial *k*-Sparse Recovery

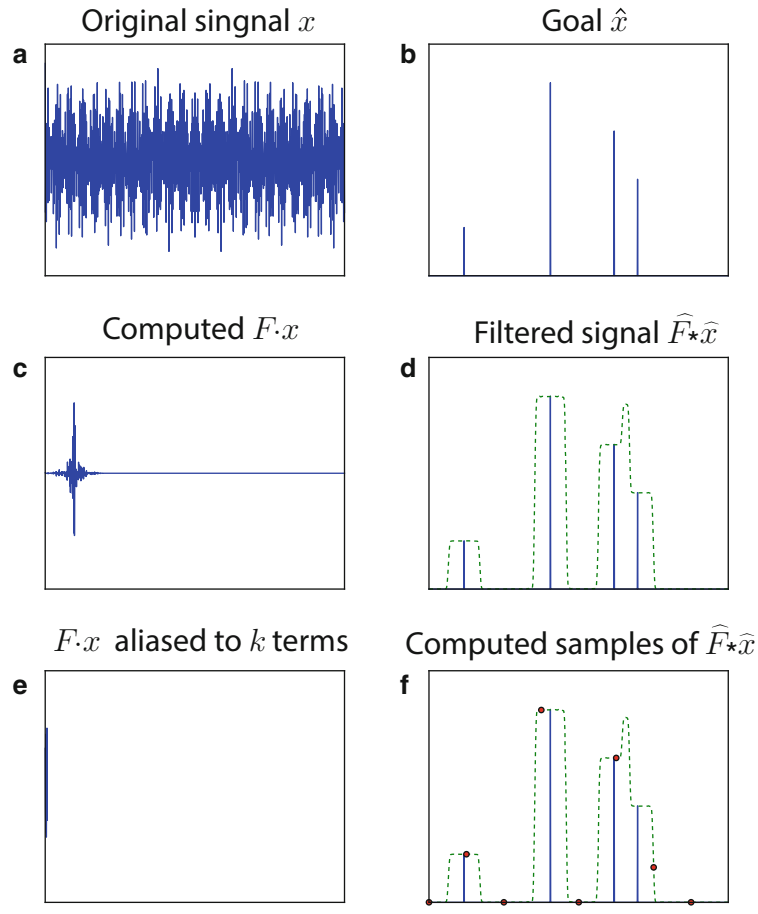
The goal of partial k-sparse recovery is to find *most* of the heavy coordinates of $\hat{x}$. The general idea is to "hash" the coordinates randomly into $B = O(k)$ bins in a way that lets us take measurements of the signal restricted to frequencies within each bin. By taking the measurements corresponding to the one-sparse recovery algorithm, we recover frequencies that are alone in their bin. This will happen with a large constant (say, 90 %) probability for each heavy frequency, so we recover *most* of the heavy frequencies well.

To see how this is done, we start with a deterministic way of hashing the frequencies into bins and then show how to randomize it. Hashing is based on filters that are sparse in both time and frequency domain. The filter F is designed to be as close as possible to a rectangular filter in frequency domain while still being sparse in frequency domain. Figure 2 demonstrates the filter used in [13], where F is a sinc function times a (truncated) Gaussian with support size $O(k \log n)$. In frequency domain, $\hat{F}$ approximates a rectangle of width $O(n/k)$, matching it up to a small transition region between the passband and the stopband and with $1/n^c$ error inside the passband and stopband.

Using these filters, Fig. 3 demonstrates a method for learning information about the signal. Given the signal x, we compute the $O(k \log n)$-size vector $F \cdot x$. We then "alias" it down to $B = O(k)$ elements – adding up terms $1, B+1, 2B+1, \ldots$ – and take the B-dimensional DFT. This lets us compute the red points in Fig. 3f in $O(k \log n + B \log B) = O(k \log n)$ time. The red points are B evenly spaced samples of $\hat{x} * \hat{F}$.

We can think of the ith red point in a different way. The ith red point is the sum of all the entries of $\hat{x} \cdot \text{shift}(\hat{F}, in/B)$, where $\text{shift}(\hat{F}, in/B)$ denotes shifting $\hat{F}$ to the right by in/B. This equals the zeroth time domain coefficient of the vector with Fourier coefficients given by $\hat{x} \cdot \text{shift}(\hat{F}, in/B)$. And if our algorithm looks not at $y_j = F_j x_j$ but $y_j^{(a)} = F_j x_{j+a}$ when computing the red points, then the ith red point will equal the ath time domain coefficient of the vector with Fourier coefficients given by $\hat{x} \cdot \text{shift}(\hat{F}, in/B)$. This lets us sample from the time domain representation of the vectors with Fourier coefficients given by $\hat{x} \cdot \text{shift}(\hat{F}, in/B)$ for $i \in [B]$. It takes $O(k \log n)$ time to get these samples, for $O(\log n)$ overhead (in time and samples) per "effective" sample.

Now, we simply choose our samples a from the distribution requested by the one-sparse recovery algorithm. In every bucket for which $\hat{x} \cdot \text{shift}(\hat{F}, in/B)$ is one-sparse, this procedure will let us recover the heavy frequency. Because the different shifts of $\hat{F}$ give B different buckets,



Sparse Fourier Transform, Fig. 3 The algorithm for hashing used in [13]. For simplicity, the illustrations do not include noise. (**a**) The signal in time domain. (**b**) Corresponds to this signal in frequency domain. (**c**) We observe $\boldsymbol{F} \cdot \boldsymbol{x}$ for a sparse $\boldsymbol{F}$. (**d**) Which has the dashed $\boldsymbol{n}$-dimensional DFT. (**e**) We alias from $\boldsymbol{O(k \log n)}$ terms to $\boldsymbol{O(k)}$. (**f**) And compute the $\boldsymbol{O(k)}$-dimensional DFT (*dots*)

if the frequencies were randomly distributed, this technique would get us partial sparse recovery. The one-sparse recovery algorithm only takes $O(\log(n/k))$ samples because each frequency is known to lie within an $n/B = O(n/k)$ size region; hence the overall method takes $O(k \log n \log(n/k))$ time and samples.

We would like the algorithm to work for arbitrary input signals, so we need a way of randomizing the frequencies. To do this, we further refine the algorithm to choose a random $\sigma, b \in [n]$ with σ relatively prime to n. Then we have the algorithm look at $y_j^{(a)} = F_j x_{\sigma(j+a)} \omega^{-\sigma j b}$. The effect of σ, b is to apply an hash function $j \to \sigma^{-1} j + b$ in frequency domain; this is approximately pairwise independent, so the frequencies become effectively randomly distributed. Each frequency then has a good chance of landing alone in its bucket, so we can recover most frequencies in $O(k \log(n/k) \log n)$ time and samples.

Full *k*-Sparse Recovery

Once we have partial k-sparse recovery, one can naively achieve full k-sparse recovery by repeating the algorithm $O(\log k)$ times. Since each heavy frequency is recovered with 90 % probability in each stage, the median of all the estimations will recover all the heavy frequencies – and in fact achieve (1) – with high probability. This method is simple but loses a $\log k$ factor in running time and sample complexity, which more intricate techniques can avoid.

One such technique, used in [13] and based off [11], is to use smaller and smaller k in successive iterations. Once we have performed partial sparse recovery on $\hat{x}$ to get $\hat{x}^{(1)}$ that contains

90 % of the heavy hitters, we can then perform sparse recovery on the residual $\hat{x} - \hat{x}^{(1)}$. The residual is then roughly $k/10$-sparse, so we run a partial $k/10$-sparse recovery algorithm in the second stage that is much faster than in the first stage. Similar geometric decay happens in later stages, so the total time spent will be dominated by the first stage. This gives $O(k \log(n/k) \log n)$ time and sample complexity for the problem.

Sparse Graph Spanners

Michael Elkin
Department of Computer Science, Ben-Gurion University, Beer-Sheva, Israel

Keywords

$(1+\epsilon, \beta)$-spanners; Almost additive spanners

Years and Authors of Summarized Original Work

2004; Elkin, Peleg

Problem Definition

For a pair of numbers α, β, $\alpha \geq 1$, $\beta \geq 0$, a subgraph $G' = (V, H)$ of an unweighted undirected graph $G = (V, E)$, $H \subseteq E$, is an (α, β)-spanner of G if for every pair of vertices $u, w \in V$, $\text{dist}_{G'}(u, w) \leq \alpha \cdot \text{dist}_G(u, w) + \beta$, where $\text{dist}_G(u, w)$ stands for the distance between u and w in G. It is desirable to show that for every n-vertex graph there exists a sparse (α, β)-spanner with as small values of α and β as possible. The problem is to determine asymptotic tradeoffs between α and β on one hand, and the sparsity of the spanner on the other.

Key Results

The main result of Elkin and Peleg [8] establishes the existence and efficient constructibility of

$(1+\epsilon,\beta)$-spanners of size $O(\beta n^{1+1/\kappa})$ for every n-vertex graph G, where $\beta=\beta(\epsilon,\kappa)$ is constant whenever κ and ϵ are. The specific dependence of β on κ and ϵ is $\beta(\kappa,\epsilon)=\kappa^{\log\log\kappa-\log\epsilon}$.

An important ingredient of the construction of [8] is a partition of the graph G into regions of small diameter in such a way that the supergraph induced by these regions is sparse. The study of such partitions was initiated by Awerbuch [3], that used them for network synchronization. Peleg and Schäffer [10] were the first to employ such partitions for constructing spanners. Specifically, they constructed $(O(\kappa),1)$-spanners with $O(n^{1+1/\kappa})$ edges. Althofer et al. [2] provided an alternative proof of the result of Peleg and Schäffer that uses an elegant greedy argument. This argument also enabled Althofer et al. to extend the result to weighted graphs, to improve the constant hidden by the O-notation in the result of Peleg and Schäffer, and to obtain related results for planar graphs.

Applications

Efficient algorithms for computing sparse $(1+\epsilon,\beta)$-spanners were devised in [7] and [13]. The algorithm of [7] was used in [7, 9, 12] for computing almost shortest paths in centralized, distributed, streaming, and dynamic centralized models of computations. The basic approach used in these results is to construct a sparse spanner, and then to compute exact shortest paths on the constructed spanner. The sparsity of the latter guarantees that the computation of shortest paths in the spanner is far more efficient than in the original graph.

Open Problems

The main open question is whether it is possible to achieve similar results with $\epsilon=0$. More formally, the question is: Is it true that for any $\kappa\geq 1$ and any n-vertex graph G there exists $(1,\beta(\kappa))$-spanner of G with $O(n^{1+1/\kappa})$ edges? This question was answered in affirmitive for κ equal to 2, 5/2, and 3 [1, 4-6, 8]. Some lower bounds were recently proved by Woodruff [14].

A less challenging problem is to improve the dependence of β on ϵ and κ. Some progress in this direction was achieved by Thorup and Zwick [13], and very recently by Pettie [11].

Sparsest Cut

Shuchi Chawla
Department of Computer Science, University of Wisconsin–Madison, Madison, WI, USA

Keywords

Minimum ratio cut

Years and Authors of Summarized Original Work

2004; Arora, Rao, Vazirani

Problem Definition

In the Sparsest Cut problem, informally, the goal is to partition a given graph into two or more large pieces while removing as few edges as possible. Graph partitioning problems such as this one occupy a central place in the theory of network flow, geometric embeddings, and Markov chains, and form a crucial component of divide-and-conquer approaches in applications such as packet routing, VLSI layout, and clustering.

Formally, given a graph $G = (V, E)$, the *sparsity* or *edge expansion* of a non-empty set $S \subset V$, $|S| \leq \frac{1}{2}|V|$, is defined as follows:

$$\alpha(S) = \frac{|E(S, V \setminus S)|}{|S|} .$$

The sparsity of the graph, $\alpha(G)$, is then defined as follows:

$$\alpha(G) = \min_{S \subset V, |S| \leq \frac{1}{2}|V|} \alpha(S) .$$

The goal in the Sparsest Cut problem is to find a subset $S \subset V$ with the minimum sparsity, and to determine the sparsity of the graph.

The first approximation algorithm for the Sparsest Cut problem was developed by Leighton and Rao in 1988 [13]. Employing a linear programming relaxation of the problem, they obtained an $O(\log n)$ approximation, where n is the size of the input graph. Subsequently Arora, Rao and Vazirani [4] obtained an improvement over Leighton and Rao's algorithm using a semi-definite programming relaxation, approximating the problem to within an $O(\sqrt{\log n})$ factor.

In addition to the Sparsest Cut problem, Arora et al. also consider the closely related Balanced Separator problem. A partition $(S, V \setminus S)$ of the graph G is called a c-balanced separator for $0 < c \leq \frac{1}{2}$, if both S and $V \setminus S$ have at least $c|V|$ vertices. The goal in the Balanced Separator problem is to find a c-balanced partition with the minimum sparsity. This sparsity is denoted $\alpha_c(G)$.

Key Results

Arora et al. provide an $O(\sqrt{\log n})$ *pseudo-approximation* to the balanced-separator problem using semi-definite programming. In particular, given a constant $c \in (0, \frac{1}{2}]$, they produce a separator with balance c' that is slightly worse than c (that is, $c' < c$), but sparsity within an $O(\sqrt{\log n})$ factor of the sparsity of the optimal c-balanced separator.

Theorem 1 *Given a graph $G = (V, E)$, let $\alpha_c(G)$ be the minimum edge expansion of a c-balanced separator in this graph. Then for every fixed constant $a < 1$, there exists a polynomial-time algorithm for finding a c'-balanced separator in G, with $c' \geq ac$, that has edge expansion at most $O(\sqrt{\log n}\alpha_c(G))$.*

Extending this theorem to include unbalanced partitions, Arora et al. obtain the following:

Theorem 2 *Let $G = (V, E)$ be a graph with sparsity $\alpha(G)$. Then there exists a polynomial-time*

algorithm for finding a partition $(S, V \setminus S)$, *with* $S \subset V$, $S \neq \emptyset$, *having sparsity at most* $O(\sqrt{\log n}\alpha(G))$.

An important contribution of Arora et al. is a new geometric characterization of vectors in n-dimensional space endowed with the squared-Euclidean metric. This result is of independent significance and has lead to or inspired improved approximation factors for several other partitioning problems (see, for example, [1, 5, 6, 7, 11]).

Informally, the result says that if a set of points in n-dimensional space is randomly projected on to a line, a good separator on the line is, with high probability, a good separator (in terms of squared-Euclidean distance) in the original high-dimensional space. Separation on the line is related to separation in the original space via the following definition of stretch.

Definition 1 (Def. 4 in [4]) Let $\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_n$ be a set of n points in $\mathcal{R}^n$, equipped with the squared-Euclidean metric $\mathrm{d}(x, y) = \|x - y\|_2^2$. The set of points is said to be (t, γ, β) *-stretched at scale* ℓ, if for at least a γ fraction of all the n-dimensional unit vectors u, there is a partial matching $M_u = \{(x_i, y_i)\}_i$ among these points, with $|M_u| \geq \beta n$, such that for all $(x, y) \in M_u$, $\mathrm{d}(x, y) \leq \ell^2$ and $\langle u, \vec{x} - \vec{y} \rangle \geq t\ell/\sqrt{n}$. Here $\langle \cdot, \cdot \rangle$ denotes the dot product of two vectors.

Theorem 3 *For any* $\gamma, \beta > 0$, *there is a constant* $C = C(\gamma, \beta)$ *such that if* $t > C \log^{1/3} n$, *then no set of n points in* $\mathcal{R}^n$ *can be* (t, γ, β)*-stretched for any scale* ℓ.

In addition to the SDP-rounding algorithm, Arora et al. provide an alternate algorithm for finding approximate sparsest cuts, using the notion of expander flows. This result leads to fast (quadratic time) implementations of their approximation algorithm [3].

Applications

One of the main applications of balanced separators is in improving the performance of divide and conquer algorithms for a variety of optimization problems.

One example is the Minimum Cut Linear Arrangement problem. In this problem, the goal is to order the vertices of a given n vertex graph G from 1 through n in such a way that the capacity of the largest of the cuts $(\{1, 2, \cdots, i\}, \{i + 1, \cdots, n\})$, $i \in [1, n]$, is minimized. Given a ρ-approximation to the balanced separator problem, the following divide and conquer algorithm gives an $O(\rho \log n)$-approximation to the Minimum Cut Linear Arrangement problem: find a balanced separator in the graph, then recursively order the two parts, and concatenate the orderings. The approximation follows by noting that if the graph has a balanced separator with expansion $\alpha_c(G)$, only $O(\rho n \alpha_n(G))$ edges are cut at every level, and given that a balanced separator is found at every step, the number of levels of recursion is at most $O(\log n)$.

Similar approaches can be used for problems such as VLSI layout and Gaussian elimination. (See the survey by Shmoys [14] for more details on these topics.)

The Sparsest Cut problem is also closely related to the problem of embedding squared-Euclidean metrics into the Manhattan (ℓ_1) metric with low distortion. In particular, the integrality gap of Arora et al.'s semi-definite programming relaxation for Sparsest Cut (generalized to include weights on vertices and capacities on edges) is exactly equal to the worst-case distortion for embedding a squared-Euclidean metric into the Manhattan metric. Using the technology introduced by Arora et al., improved embeddings from the squared-Euclidean metric into the Manhattan metric have been obtained [5, 7].

Open Problems

Hardness of approximation results for the Sparsest Cut problem are fairly weak. Recently Chuzhoy and Khanna [9] showed that this problem is APX-hard, that is, there exists a constant $\epsilon > 0$, such that a $(1 + \epsilon)$-approximation

algorithm for Sparsest Cut would imply P = NP. It is conjectured that the weighted version of the problem is NP-hard to approximate better than $O((\log \log n)^c)$ for some constant c, but this is only known to hold true assuming a version of the so-called Unique Games conjecture [8, 12]. On the other hand, the semi-definite programming relaxation of Arora et al. is known to have an integrality gap of $\Omega(\log \log n)$ even in the unweighted case [10]. Proving an unconditional super-constant hardness result for weighted or unweighted Sparsest Cut, or obtaining $o(\sqrt{\log n})$-approximations for these problems remain open.

The directed version of the Sparset Cut problem has also been studied, and is known to be hard to approximate within a $2^{\Omega(\log^{1-\epsilon} n)}$ factor [9]. On the other hand, the best approximation known for this problem only achieves a polynomial factor of approximation–a factor of $O(n^{11/23} \log^{O(1)} n)$ due to Aggarwal, Alon and Charikar [2].

Frequency scaling; Speed scaling; Voltage scaling

Years and Authors of Summarized Original Work

1995; Yao, Demers, Shenker

Problem Definition

Speed scaling is a power management technique in modern processor that allows the processor to run at different speeds. There is a power function $P(s)$ that specifies the power, which is energy used per unit of time, as a function of the speed. In CMOS-based processors, the cube-root rule states that $P(s) \approx s^3$. This is usually generalized to assume that $P(s) = s^\alpha$ form some constant α. The goals of power management are to reduce temperature and/or to save energy. Energy is power integrated over time. Theoretical investigations to date have assumed that there is a fixed ambient temperature and that the processor cools according to Newton's law, that is, the rate of cooling is proportional to the temperature difference between the processor and the environment.

In the resulting scheduling problems, the scheduler must not only have a job-selection policy to determine the job to run at each time, but also a speed scaling policy to determine the speed at which to run that job. The resulting problems are generally dual objective optimization problems. One objective is some quality of service measure for the schedule, and the other objective is temperature or energy.

We will consider problems where jobs arrive at the processor over time. Each job i has a release time r_i when it arrives at the processor, and a work requirement w_i. A job i run at speed s takes w_i/s units of time to complete.

Key Results

Yao et al. [5] initiated the theoretical algorithmic investigation of speed scaling problems. Yao et al. [5] assumed that each job i had a deadline d_i, and that the quality of service measure was deadline feasibility (each job completes by its deadline). Yao et al. [5] gives a greedy algorithm YDS to find the minimum energy feasible schedule. The job selection policy for YDS is to run the job with the earliest deadline. To understand the speed scaling policy for YDS, define the intensity of a time interval to be the work that must be completed in this time interval divided by the length of the time interval. YDS then finds the maximum intensity interval, runs the jobs that must be run in this interval at constant speed, eliminates these jobs and this time interval from the instance, and proceeds recursively. Yao et al. [5] gives two online algorithms: OA and AVR. In OA the speed scaling policy is the speed that YDS would run at, given the current state and given that no more jobs will be released in the future. In AVR, the rate at which each job is completed is constant between the time that a job is released and the deadline for that job. Yao et al. [5] showed that AVR is $2^{\alpha-1}\alpha^\alpha$-competitive with respect to energy.

The results in [5] were extended in [2]. Bansal et al. [2] showed that OA is α^α-competitive with respect to energy. Bansal et al. [2] proposed another online algorithm, BKP. BKP runs at the speed of the maximum intensity interval containing the current time, taking into account only the work that has been released by the current time. They show that the competitiveness of BKP with respect to energy is at most $2(\alpha/(\alpha-1))^\alpha \mathrm{e}^\alpha$. They also show that BKP is e-competitive with respect to the maximum speed.

Bansal et al. [2] initiated the theoretical algorithmic investigation of speed scaling to manage temperature. Bansal et al. [2] showed that the deadline feasible schedule that minimizes maximum temperature can in principle be computed in polynomial time. Bansal et al. [2] showed that the competitiveness of BKP with respect to maximum temperature is at most $2^{\alpha+1}\mathrm{e}^\alpha(6(\alpha/(\alpha-1))^\alpha + 1)$.

Pruhs et al. [4] initiated the theoretical algorithmic investigation into speed scaling when the quality-of-service objective is average/total flow time. The flow time of a job is the delay from when a job is released until it is completed. Pruhs et al. [4] give a rather complicated polynomial-time algorithm to find the optimal flow time schedule for unit work jobs, given

a bound on the energy available. It is easy to see that no $O(1)$-competitive algorithm exists for this problem.

Albers and Fujiwara [1] introduce the objective of minimizing a linear combination of energy used and total flow time. This has a natural interpretation if one imagines the user specifying how much energy he is willing to use to increase the flow time of a job by a unit amount. Albers and Fujiwara [1] give an $O(1)$-competitive online algorithm for the case of unit work jobs. Bansal et al. [3] improves upon this result and gives a 4-competitive online algorithm. The speed scaling policies of the online algorithms in [1] and [3] essentially run as power equal to the number of unfinished jobs (in each case modified in a particular way to facilitate analysis of the algorithm). Bansal et al. [3] extend these results to apply to jobs with arbitrary work, and even arbitrary weight. The speed scaling policy is essentially to run at power equal to the weight of the unfinished work. The expression for the resulting competitive ratio is a bit complicated but is approximately 8 when the cube-root rule holds.

The analysis of the online algorithms in [2] and [3] heavily relied on amortized local competitiveness. An online algorithm is locally competitive for a particular objective if for all times the rate of increase of that objective for the online algorithm, plus the rate of change of some potential function, is at most the competitive ratio times the rate of increase of the objective in any other schedule.

Applications

None

Open Problems

The outstanding open problem is probably to determine if there is an efficient algorithm to compute the optimal flow time schedule given a fixed energy bound.

Problem Definition

The sphere packing problem seeks to pack spheres into a given geometric domain. The problem is an instance of geometric packing. Geometric packing is a venerable topic in mathematics. Various versions of geometric packing problems have been studied, depending on the shapes of packing domains, the types of packing objects, the position restrictions on the objects, the optimization criteria, the

dimensions, etc. It also arises in numerous applied areas. The sphere packing problem under consideration here finds applications in radiation cancer treatment using Gamma Knife systems. Unfortunately, even very restricted versions of geometric packing problems (e.g., regular-shaped objects and domains in lower dimensional spaces) have been proved to be NP-hard. For example, for *congruent packing* (i.e., packing copies of the same object), it is known that the 2-D cases of packing fixed-sized congruent squares or disks in a simple polygon are NP-hard [7]. Baur and Fekete [2] considered a closely related *dispersion problem* of packing k congruent disks in a polygon of n vertices such that the radius of the disks is maximized; they proved that the dispersion problem cannot be approximated arbitrarily well in polynomial time unless P = NP, and gave a $\frac{2}{3}$-approximation algorithm for the L_∞ disk case with a time bound of $O(n^{38})$.

Chen et al. [4] proposed a practically efficient heuristic scheme, called *pack-and-shake*, for the **congruent sphere packing** problem, based on computational geometry techniques. The problem is defined as follows.

The Congruent Sphere Packing Problem

Given a d-D polyhedral region $R(d = 2, 3)$ of n vertices and a value $r > 0$, find a packing SP of R using spheres of radius r, such that (i) each sphere is contained in R, (ii) no two distinct spheres intersect each other in their interior, and (iii) the ratio (called the packing density) of the covered volume in R by SP over the total volume of R is maximized.

In the above problem, one can view the spheres as "solid" objects. The region R is also called the *domain* or *container*. Without loss of generality, let $r = 1$.

Much work on congruent sphere packing studied the case of packing spheres into an unbounded domain or even the whole space [5]. There are also results on packing congruent spheres into a bounded region. Hochbaum and Maass [8] presented a unified and powerful *shifting technique* for designing pseudo-polynomial time approximation schemes for packing congruent squares into a rectilinear polygon. But, the high time complexities associated with the resulting algorithms restrict their applicability in practice. Another approach is to formulate a packing problem as a non-linear optimization problem, and resort to an available optimization software to generate packings; however, this approach works well only for small problem sizes and regular-shaped domains.

To reduce the running time yet achieve a dense packing, a common idea is to consider objects that form a certain lattice or double-lattice. A number of results were given on lattice packing of congruent objects in the whole (especially high dimensional) space [5]. For a bounded rectangular 2-D domain, Milenkovic [10] adopted a method that first finds the densest translational lattice packing for a set of polygonal objects in the whole plane, and then uses some heuristics to extract the actual bounded packing.

Key Results

The *pack-and-shake* scheme of Chen et al. [4] for packing congruent spheres in an irregular-shaped 2-D or 3-D bounded domain R consists of three phases. In the first phase, the d-D domain R is partitioned into a set of convex subregions (called *cells*). The resulting set of cells defines a dual graph G_D, such that each vertex v of G_D corresponds to a cell $C(v)$ and an edge connects two vertices if and only if their corresponding cells share a $(d-1)$-D face. In the second phase, the algorithm repeats the following *trimming and packing* process until $G_D = \emptyset$: Remove the lowest degree vertex v from G_D and pack the cell $C(v)$. In the third phase, a *shake* procedure is applied to globally adjust the packing to obtain a denser one.

The objective of the trimming and packing procedure is that after each cell is packed, the remaining "packable" subdomain R' of R is always kept as a connected region. The rationale for maintaining the connectivity of R' is as follows. To pack spheres in a bounded domain R, two

typical approaches have been used: (a) packing spheres layer by layer going from the boundary of R towards its interior [9], and (b) packing spheres starting from the "center" of R, such as its medial axis, towards its boundary [3, 13, 14]. Due to the shape irregularity of R, both approaches may fragment the remaining "packable" subdomain R' into more and more disconnected regions; however, at the end of packing each such region, a small "unpackable" area may eventually remain that allows no further packing. It could fit more spheres if the "packable" subdomain R' is lumped together instead of being divided into fragments, which is what the trimming and packing procedure aims to achieve.

Due to the packing of its adjacent cells that have been done by the trimming and packing procedure, the boundary of a cell $C(v)$ that is to be packed may consist of both line segments and arcs (from packed spheres). Hence, a key problem is to pack spheres in a cell bounded by curves of low degrees. Chen et al.'s algorithms [4] for packing each cell are based on certain lattice structures and allow the cell to both translate and rotate. Their algorithms have fairly low time bounds. In certain cases, they even run in nearly linear time.

An interesting feature of the cell packings generated by the trimming and packing procedure is that the resulted spheres cluster together in the middle of the cells of the domain R, leaving some small unpackable areas scattered along the boundary of R. The "shake" procedure in [4] thus seeks to collect these small areas together by "pushing" the spheres towards the boundary of R, in the hope of obtaining some "packable" region in the middle of R.

The approach in [4] is to first obtain a densest lattice unit sphere packing $LSP(C)$ for each cell C of R, and then use a "shake" procedure to globally adjust the resulting packing of R to generate a denser packing SP in R. Suppose the plane P is already packed by infinitely many unit spheres whose center points form a lattice (e.g., the hexagonal lattice). To obtain a densest packing $LSP(C)$ for a cell C from the lattice packing of the plane P, a position and orientation of C on P need to be computed such that C contains the maximum number of spheres from the lattice packing of P. There are two types of algorithms in [4] for computing an optimal placement of C on P: translational algorithms that allow C to be translated only, and translational/rotational algorithms that allow C to be both translated and rotated.

Let $n = |C|$, the number of bounding curves of C, and m be the number of spheres along the boundary of C in a sought optimal packing of C.

Theorem 1 *Given a polygonal region C bounded by n algebraic curves of constant degrees, a densest lattice unit sphere packing of C based only on translational motion can be computed in $O(N \log N + K)$ time, where $N = f(n, m)$ is a function of n and m, and K is the number of intersections between N planar algebraic curves of constant degrees that are derived from the packing instance.*

Note: In the worst case, $N = f(n, m) = n \times m$. But in practice, N may be much smaller. The N planar algebraic curves in Theorem 1 form a structure called *arrangement*. Since all these curves are of a constant degree, any two such curves can intersect each other at most a constant number of times. In the worst case, the number K of intersections between the N algebraic curves, which is also the *size* of the arrangement, is $O(N^2)$. The arrangement of these curves can be computed by the algorithms [1, 6] in $O(N \log N + K)$ time.

Theorem 2 *Given a polygonal region C bounded by n algebraic curves of constant degrees, a densest lattice unit sphere packing of C based on both translational and rotational motions can be computed in $O(T(n) + (N + K') \log N)$ time, where $N = f(n, m)$ is a function of n and m, K' is the size of the arrangement of N*

pseudo-plane surfaces in 3-D that are derived from the packing instance, and T(n) is the time for solving $O(n^2)$ quadratic optimization problem instances associated with the packing instance.

In Theorem 2, $K' = O(N^3)$ in the worst case. In practice, K' can be much smaller.

The results on 2-D sphere packing in [4] can be extended to d-D for any constant integer $d \geq 3$, so long as a good d-D lattice packing of the d-D space is available.

Applications

Recent interest in the considered congruent sphere packing problem was motivated by medical applications in Gamma Knife radiosurgery [4, 11, 12]. Radiosurgery is a minimally invasive surgical procedure that uses radiation to destroy tumors inside human body while sparing the normal tissues. The Gamma Knife is a radiosurgical system that consists of 201 Cobalt-60 sources [3, 14]; the gamma-rays from these sources are all focused on a common center point, thus creating a spherical volume of radiation field. The Gamma Knife treatment normally applies high radiation dose. In this setting, overlapping spheres may result in overdose regions (called *hot spots*) in the target treatment domain, while a low packing density may cause underdose regions (called *cold spots*) and a non-uniform dose distribution. Hence, one may view the spheres used in Gamma Knife packing as "solid" spheres. Therefore, a key geometric problem in Gamma Knife treatment planning is to fit multiple spheres into a 3-D irregular-shaped tumor [3, 13, 14]. The total treatment time crucially depends on the number of spheres used. Subject to a given packing density, the minimum number of spheres used in the packing (i.e., treatment) is desired. The Gamma Knife currently produces spheres of four different radii (4, 8, 14, and 18 mm), and hence the Gamma Knife sphere packing is in general not congruent. In practice, a commonly used approach is to pack larger spheres first, and then fit smaller spheres into the remaining subdomains, in the hope of reducing the total number of spheres involved and thus shortening the treatment time. Therefore, congruent sphere packing can be used as a key subroutine for such a common approach.

Open Problems

An open problem is to analyze the quality bounds of the resulting packing for the algorithms in [4]; such packing quality bounds are currently not yet known. Another open problem is to reduce the running time of the packing algorithms in [4], since these algorithms, especially for sphere packing problems in higher dimensions, are still very time-consuming. In general, it is highly desirable to develop efficient sphere packing algorithms in d-D ($d \geq 2$) with guaranteed good packing quality.

Experimental Results

Some experimental results of the 2-D pack-and-shake sphere packing algorithms were given in [4]. The planar hexagonal lattice was used for the lattice packing. On packings whose sizes are in the hundreds, the C++ programs of the algorithms in [4] based only on translational motion run very fast (a few minutes), while those of the algorithms based on both translation and rotation take much longer time (hours), reflecting their respective theoretical time bounds, as expected. On the other hand, the packing quality of the translation-and-rotation based algorithms is a little better than the translation based algorithms. The packing densities of all the algorithms in the experiments are well above 70 % and some are even close to or above 80 %. Comparing with the nonconvex programming methods, the packing algorithms in [4] seemed to run faster based on the experiments.

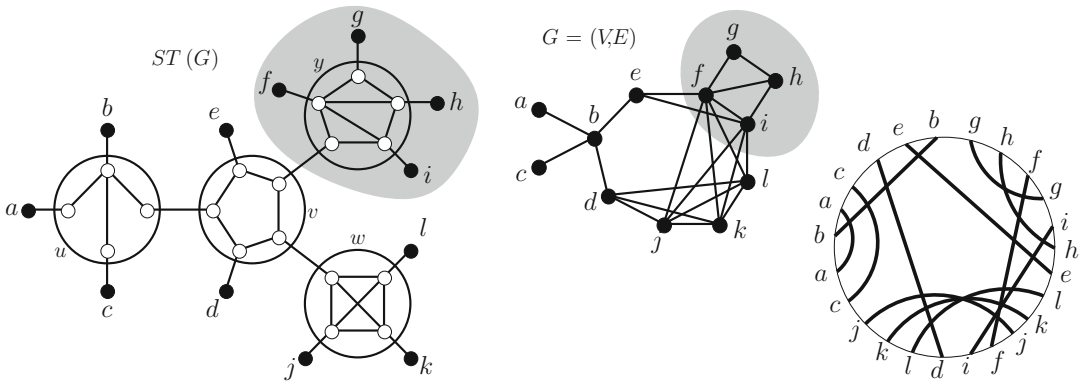
Problem Definition

Introduced by Cunningham and Edmonds [11], the *split decomposition*, also known as the *join (or 1-join) decomposition*, ranges among the classical graph decomposition schemes. Given a graph $G = (V, E)$, a bipartition (A, B) of the vertex set V (with $|A| \geq 2$ and $|B| \geq 2$) is a *split* if there are subsets $A' \subseteq A$ and $B' \subseteq B$, called *frontiers*, such that there is an edge between a vertex $u \in A$ and $v \in B$ if and only if $u \in A'$ and $v \in B'$ (see Fig. 1). A graph is *prime* if it does not contain any split. Observe that an induced cycle of length at least 5 is a prime graph. A graph is *degenerate* if every bipartition (A, B) with $|A| \geq 2$ and $|B| \geq 2$ is a split. It can be shown that a degenerate graphs are either *cliques* or *stars*. The split decomposition consists in recursively decompose a graph into a set of disjoint graphs $\{G_1, \ldots G_k\}$, called *split components*, each of which is either prime or degenerate. There are two cases:

1. If G is prime or degenerate, then return the set $\{G\}$;



Split Decomposition via Graph-Labelled Trees, Fig. 1 A circle graph G with a chord diagram on the *right* and its split decomposition tree $ST(G)$ on the *left*. The nodes v and y are prime nodes, whereas u is a star node and w a clique node. The bipartition $(\{f, g, h, i\}, V \setminus \{f, g, h, i\})$ forms a split of G and corresponds to a tree edge of $ST(G)$. The frontiers are $\{f, i\}$ on one side and $\{e, j, k, l\}$ on the other. Observe that $(\{k, l\}, V \setminus \{k, l\})$ is also a split but which is not represented by the tree edge between nodes Y and Z in $ST(G)$. Because G is not a prime graph, it can be represented with several chord diagram. For example, exchanging the chord of y with the chord of z yields an alternative chord diagram

2. If G is neither prime nor degenerate, it contains a split (A, B), with frontiers A' and B'. The split components of G is then the union of the split components of the graphs $G[A] + (a, A')$ and $G[B] + (b, B')$, where a and b are new vertices, called *markers*.

Observe that the split decomposition process naturally defines a decomposition tree whose nodes represent the split components. This decomposition tree can be represented by a *graph-labeled tree* (GLT) (see [16,18]) defined as a pair $(T, \mathcal{F})$, where T is a tree and $\mathcal{F}$ a set of graphs, such that each node u of T is *labeled* by the graph $G(u) \in \mathcal{F}$, and there exists a bijection ρ_u between the edges of T incident to u and the vertices of $G(u)$, called *marker vertices*. We say that two leaves ℓ_a and ℓ_b of T are *accessible* if for every pair of consecutive tree edges uv and vw on the path from ℓ_a and ℓ_b in T, $\rho_v(uv)$ and $\rho_v(vw)$ are adjacent in $G(v)$. From a GLT $(T, \mathcal{F})$, we define an *accessibility graph* $\mathcal{G}(T, \mathcal{F})$ whose vertex set is the leaf set of T and two vertices a and b are adjacent if the corresponding leaves ℓ_a and ℓ_b are accessible. It is easy to observe that every tree edge e of a GLT $(T, \mathcal{F})$ defines a split (A, B) of $\mathcal{G}(T, \mathcal{F})$ where A and B respectively contain the vertices corresponding to the leaves of the two connected components of $T-e$. Cunningham and Edmonds [11] formalized the family of splits as an example of *partite family of bipartitions* thereby implying that every graph admits a canonical split decomposition tree (see Fig. 1). In terms of GLTs, this translates as follows:

Theorem 1 ([11, 16, 18]) *Let G be a connected graph. There exists a unique GLT $(T, \mathcal{F})$ whose labels are either prime or degenerate, having a minimal number of nodes and such that $G = \mathcal{G}(T, \mathcal{F})$. This GLT is called the* split tree *of G and denoted $ST(G)$.*

The problem we are interested in is to efficiently compute the split tree $ST(G)$ of a graph $G = (V, E)$. The first polynomial-time algorithm was and runs in time $O(nm)$, where $n = |V|$ and $m = |E|$. Ma and Spinrad [23] later developed an $O(n^2)$ algorithm. Finally Dahlhaus [12] designed the first linear-time algorithm which was recently revisited by Charbit et al. [5].

Key Results

As mentioned above, the split tree of a graph can be computed in linear time. The algorithm we

describe here is nearly optimal, that is, runs in time $O(n+m)\cdot\alpha(n+m)$, where α is the inverse Ackermann function. The fact that this algorithm incrementally builds the split tree is responsible of the small additional complexity cost. More precisely, updating the tree structure of the GLT representing the split tree relies on the union-find data structure [15]. But having an incremental split decomposition algorithm allows an extension of the algorithm, within the same time complexity, to the circle graph recognition [17], a problem for which computing the split decomposition is a corner step. But so far, a subquadratic time complexity cannot be reached using the previous linear (or quadratic) split decomposition algorithms.

Theorem 2 ([18]) *The split tree $ST(G)$ of a graph $G = (V, E)$, with $|V| = n$ and $|E| = m$, can be built incrementally according to an LBFS ordering in time $O(n + m) \cdot \alpha(n + m)$, where α is the inverse Ackermann function.*

It is important to observe that to reach the expected complexity, the algorithm inserts the vertices according to a *LexBFS ordering* [25]. These orderings, resulting from a *lexicographic breadth-first search*, appear in a number of recognition algorithms, such as *chordal graphs* [25], *comparability graphs* [20], *interval graphs* [22], and *cographs* [3]. The idea is that structural properties can be shown on the last vertex visited by a LexBFS. For example, in chordal graphs the last vertex is simplicial; in comparability graphs it is a source of some transitive orientation. LexBFS, introduced in [25], works as follows: it numbers the vertices decreasingly from $n = |V|$ down to 1; initially every vertex receives an empty label; then iteratively, an arbitrary unnumbered vertex x with lexicographically largest label is selected and numbered i, and i is appended to the label of every unnumbered neighbor of x. On the graph of Fig. 1, $\sigma = b, a, e, d, c, f, i, j, k, l, h, g$ is a LexBFS ordering.

Applications

Many graph classes can be characterized by means of the split decomposition. Below, we review the most important of these classes. Finally, we discuss the links between split decomposition and other decomposition approaches.

Graph Classes

Distance Hereditary Graphs

The family of graphs for which the split tree does not contain any prime node is called *totally decomposable* (or *totally separable*). This terminology follows from the observation that for every subgraph of size at least 4, every nontrivial bipartition of the vertex set forms a split. A graph G is *distance hereditary* [1] if for every induced connected subgraph H of G and every pair of vertices x and y of H, the distance between x and y is the same in H and G. It turns out that a graph G is totally decomposable if and only if it is *distance hereditary* [1]. In other words, a graph G is distance hereditary if and only if every node of $ST(G)$ is either a star or a clique node. The first linear-time recognition algorithm of distance hereditary graphs, due to [21], relies on a breadth-first search characterization (see also [13]). More recently, a linear-time algorithm has been designed to update the split tree of a distance hereditary graph under vertex and edge insertion, leading to an alternative (vertex incremental) linear-time recognition algorithm for distance hereditary graphs.

Theorem 3 ([16]) *Let $ST(G)$ be the split tree of a distance hereditary graph $G = (V, E)$, $S \subseteq V$ be a subset of vertices of G and $e = (x, y) \notin E$ be a non-edge of G. Then:*

- *In $O(1)$-time, we can compute $ST(G + e)$ where $G+e = (V, E\cup\{e\})$ if $G+e$ is distance hereditary;*
- *In $O(|S|)$-time, we can compute $ST(G + (x, S)$ where $G + (x, S) = (V \cup \{x\}, E \cup \{(x, y) \mid y \in S\}$ if $G + (x, S)$ is distance hereditary.*

Subclasses of Totally Decomposable Graphs

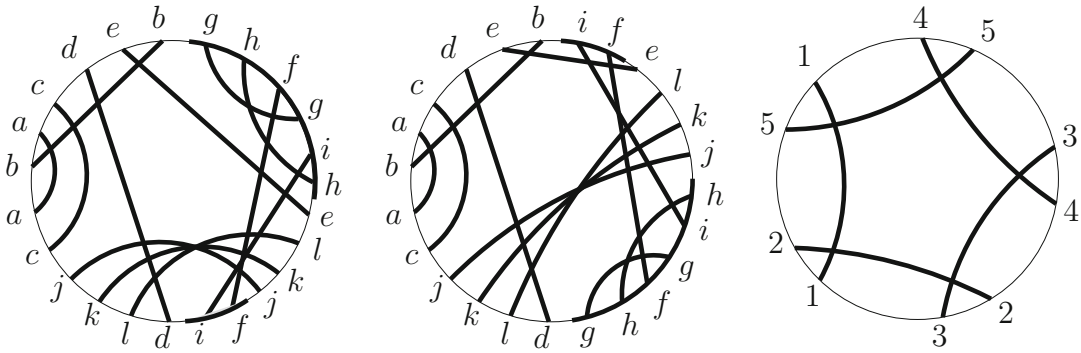
A GLT is called *clique-star tree* if its nodes are labeled either with cliques or stars. As a consequence of the discussion of the previous paragraph, distance hereditary graphs are the graphs corresponding the clique-star trees. Imposing any constraint on a clique-star tree thereby immediately defines a subclass of distance hereditary graphs. It turns out that many important graph subclasses of distance hereditary graphs can be characterized with the split decomposition.

The *cographs*, also known as *complement-reducible graphs* [8] or P_4*-free graphs*, are probably the most studied subclass of distance hereditary graphs. Cographs are also known as the class of graphs totally decomposable with respect to the modular decomposition [19], and their combinatorial structure is captured by the so-called cotree. As noticed in [16], it is easy to observe that a graph G is a cograph if and only if its split tree $ST(G)$ is a clique-star tree that can be rooted either at a node or at a tree edge such that every star node is "oriented" toward that root (that is the marker vertex corresponding the center of every star node is oriented toward the root).

The class of *ptolemaic graphs* or *3-leaf power* are also interesting. The class of ptolemaic graphs is defined as the intersection of distance hereditary graphs and chordal graphs. Chordal graphs are the graphs without induced chordless cycles of length four or more. It follows that a graph G is ptolemaic if and only if $ST(G)$ is a clique-star tree such that for every pair of star nodes u and v, not both extremities of the path from u to v in $ST(G)$ are attached to the center marker vertex of u and v (otherwise this would generate a chordless 4-cycle). As a subclass of chordal graph, 3-leaf powers inherit the restrictions of ptolemaic graphs on the split tree with the additive constraint that no clique node lies on the path between two star nodes (see [16] for details).

Circle Graphs

The split decomposition plays an important role in the context of *circle graphs* defined as intersection graphs of a set of chords in a circle. The main reason is that a graph G is a circle graph if and only if every split component of G is a circle graph. In other words, as clique and stars are circle graphs, G is a circle graph if and only if the prime nodes of $ST(G)$ are labeled with circle graphs. Observe that this characterization shows that distance hereditary graphs form a subclass of circle graphs. By the way the first quadratic time circle graph recognition algorithm was obtained by computing the split decomposition of the input graph and reducing the problem to the recognition of prime circle graphs [23, 26]. The key property is that a prime circle graph has a unique (up to mirror) *chord diagram* [2, 14] (see Fig. 2).



Split Decomposition via Graph-Labelled Trees, Fig. 2 On the *left*, two distinct chord diagrams of the graph G depicted in Fig. 1 results from symmetric insertion of the chords representing the vertices $\{f, g, h, i\}$ (remind that $(\{f, g, h, i\}, V \setminus \{f, g, h, i\})$ form a split). On the *right*, the chord diagram on $\{1, 2, 3, 4, 5\}$ is the unique (up to rotation and mirror) chord diagram of the 5-cycle, which is a prime graph

The linear-time split decomposition algorithm [12], proposed in the mid-1990s, did not lead to a linear-time circle graph recognition algorithm. For almost two decades, the quadratic time complexity [27] remained the best known complexity. The quadratic barrier has been broken using the almost linear-time split decomposition algorithm of [17]. The key ingredient was to insert the vertices according to a LexBFS ordering. Indeed, in the unique chord diagram of a prime circle graph G, the neighborhood of the last vertex x of a LexBFS ordering satisfies a sort of consecutiveness property. More precisely, the chord diagram of G contains a set of consecutive chord extremities starting and ending with the extremities of x's chord and containing one and only one chord extremity per neighbor of x and no chord extremity of non-neighbors of x. This property is used to incrementally build the split tree of a circle graph using chord diagrams to represent prime nodes. It is worth to observe that the split tree of a circle graph G together with the chord diagrams of each of its prime nodes provides a canonical (linear space) representation of the set of (exponentially many) chord diagrams of G.

Theorem 4 ([17]) *Let $G = (V, E)$ be a graph such that $|V| = n$ and $|E| = m$. There exists a $O(n + m) \cdot \alpha(n + m)$-time algorithm, where α is the inverse Ackermann function, deciding whether G is a circle graph. Moreover, if G is a circle graph, the algorithm outputs a split-tree representation G from which any chord diagram of G can be extracted in linear time.*

Perfect Graphs

The recent proof [6] of the famous conjecture of Berge on perfect graphs states that a graph is *perfect* if and only if it does not contain an odd cycle of length at least 5 nor its complement as induced subgraph. It is easy to observe that a graph is perfect if and only if its prime components are perfect graphs. The split decomposition does not formally appear in the structural decomposition theorem of perfect graphs [6, 28] as it is subsumed by the so-called balanced skew partition. In the context of perfect graphs, *parity graphs* [4] form a nice example of class of graphs simply characterized through their split decomposition. A graph is a parity graph if for every pair x, y of vertices, the length of every chordless path between x and y is of the same parity. This constraint can be translated into a condition on odd cycles or into a condition on their split tree. Indeed it can be proved that a graph is a parity graph if and only if its prime nodes are labeled with bipartite graphs [7].

Related Graph Decompositions

Modular Decomposition

The split decomposition is often introduced as a generalization of the *modular decomposition* (also known as homogeneous decomposition) [19]. A *module* in a graph $G = (V, E)$ is a subset M of vertices such that every vertex not in M is either fully adjacent or fully nonadjacent to the vertices of M. Clearly, if M is a module of size at least 2, then $(M, V \setminus M)$ defines a split. Indeed the split decomposition is sometimes used to further decompose graphs that are primes with respect to the modular decomposition.

Width Parameters

Rank-width [24] and *clique-width* [10] are two important width parameters both sharing some connections with the split decomposition. As the rank-width of a graph is small if its clique-width is small and vice versa, we only briefly describe the former parameter. A rank-decomposition of a graph G is defined as a ternary tree whose leaves are in one-to-one correspondence with the vertices of G. It follows that every internal tree edge defines a bipartition, say (A, B) of the vertices of G. The rank-width of a bipartition (A, B) is defined as the rank of the incidence matrix between A and B, and the width of a rank-decomposition is the maximum width over its bipartitions. The rank-width of a graph G is then the minimum width over its rank-decompositions. Observe that the every split is a rank-width 1 bipartition. It follows that the rank-width of a graph is the maximum rank-width of its prime components. As a consequence rank-width one graphs are exactly distance hereditary graphs. To conclude, let us

mention that computing the split decomposition of a graph is a key step in the polynomial-time recognition algorithm of clique-width three graphs [9].

Squares and Repetitions, Fig. 1 The structure of $RUNS(x)$ where $x = \texttt{baababaababbabaababaab} = \texttt{b}z^2(z^R)^2\texttt{b}$, for $z = \texttt{aabab}$. The operation $\cdot^R$ is reversing the string

Problem Definition

Periodicities and repetitions in strings have been extensively studied and are important both in theory and practice (combinatorics of words, pattern-matching, computational biology). The words of the type ww and www, where w is a nonempty primitive (not of the form u^k for an integer $k > 1$) word, are called squares and cubes, respectively. They are well-investigated objects in combinatorics on words [16] and in string-matching with small memory [5].

A string w is said to be periodic iff $period(w) \leq |w|/2$, where $period(w)$ is the smallest positive integer p for which $w[i] = w[i + p]$ whenever both sides of the equality are defined. In particular each square and cube is periodic.

A repetition in a string $x = x_1 x_2 \ldots x_n$ is an interval $[i \,..\, j] \subseteq [1 \,..\, n]$ for which the associated factor $x[i \,..\, j]$ is periodic. It is an occurrence of a periodic word $x[i \,..\, j]$, also called a positioned repetition. A word can be associated with several repetitions, see Fig. 1.

Initially people investigated mostly positioned squares, but their number is $\Omega(n \log n)$ [2], hence algorithms computing all of them cannot run in linear time, due to the potential size of the output. The optimal algorithms reporting all positioned squares or just a single square were designed in [1, 2, 3, 19]. Unlike this, it is known that only $O(n)$ (un-positioned) squares can appear in a string of length n [8].

The concept of maximal repetitions, called runs (equivalent terminology) in [14], has been introduced to represent all repetitions in a succinct manner. The crucial property of runs is that there are only $O(n)$ runs in a word of length n [15, 21].

A *run* in a string x is an interval $[i \,..\, j]$ such that both the associated string $x[i \,..\, j]$ has period $p \leq (j - i + 1)/2$, and the periodicity cannot be extended to the right nor to the left: $x[i - 1] \neq x[x + p - 1]$ and $x[j - p + 1] \neq x[j + 1]$ when the elements are defined. The set of runs of x is denoted by $RUNS(x)$. An example is displayed in Fig. 1.

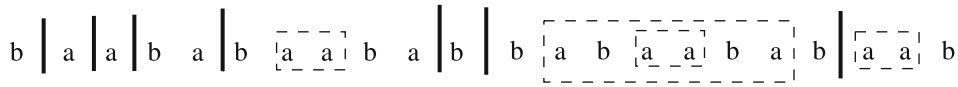
Key Results

The main results concern fast algorithms for computing positioned squares and runs, as well as combinatorial estimation on the number of corresponding objects.

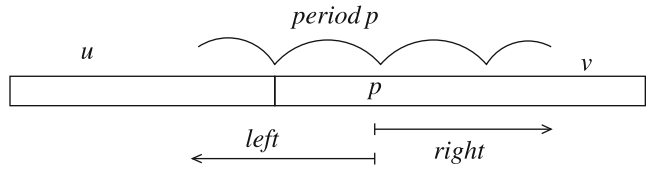
Theorem 1 (Crochemore [1], Apostolico-Preparata [2], Main-Lorentz [19]) *There exists an $O(n \log n)$ worst-case time algorithm for computing all the occurrences of squares in a string of length n.*

Techniques used to design the algorithms are based on partitioning, suffix trees, and naming segments. A similar result has been obtained by Franek, Smyth, and Tang using suffix arrays [11]. The key component in the next algorithm is the function described in the following lemma.

Lemma 2 (Main-Lorentz [19]) *Given two square-free strings u and v, reporting if uv contains a square centered in u can be done in worst-case time $O(|u|)$.*



Squares and Repetitions, Fig. 2 The f-factorization of the example string $x = \texttt{baababaababbabaababaab}$ and the set of its internal runs; all other runs overlap factorization points



Squares and Repetitions, Fig. 3 If an overlapping run with period p starts in u, ends in v, and its part in v is of size at least p then it is easily detectable by computing continuations of the periodicity p in two directions: left and right

Using suffix trees or suffix automata together with the function derived from the lemma, the following fact has been shown.

Theorem 3 (Crochemore [3], Main-Lorentz [19]) *Testing the square-freeness of a string of length n can be done in worst-case time $O(n \log a)$, where a is the size of the alphabet of the string.*

As a consequence of the algorithms and of the estimation on the number of squares, the most important result related to repetitions can be formulated as follows.

Theorem 4 (Kolpakov-Kucherov [15], Rytter [21], Crochemore-Ilie [4])

(1) *All runs in a string can be computed in linear time (on a fixed-size alphabet).*
(2) *The number of all runs is linear in the length of the string.*

The point (2) is very intricate, it is of purely combinatorial nature and has nothing to do with the algorithm. We sketch shortly the basic components in the constructive proof of the point (1). The main idea is to use, as for the previous theorem, the f-factorization (see [3]): a string x is decomposed into factors $u_1, u_2, \ldots, u_k$, where u_i is the longest segment which appears before (possibly with overlap) or is a single letter if the segment is empty.

The runs which fit in a single factor are called internal runs, other runs are called here overlapping runs. There are three crucial facts:

- all overlapping runs can be computed in linear time,
- each internal run is a copy of an earlier overlapping run,
- the f-factorization can be computed in linear time (on a fixed-size alphabet) if we have the suffix tree or suffix automaton of the string. Figure 2 shows f-factorization and internal runs of an example string.

It follows easily from the definition of the f-factorization that if a run overlaps two (consecutive) factors u_{k-1} and u_k then its size is at most twice the total size of these two s factors.

Figure 3 shows the basic idea for computing runs that overlap $u\,v$ in time $O(|u| + |v|)$. Using similar tables as in the Morris–Pratt algorithm (border and prefix tables), see [6], we can test the continuation of a period p from position p in v to the left and to the right. The corresponding tables can be constructed in linear time in a preprocessing phase. After computing all overlapping runs the internal runs can be copied from their earlier occurrences by processing the string from left to right.

Another interesting result concerning periodicities is the following lemma and its fairly immediate corollary.

Lemma 5 (Three Prefix Squares, Crochemore-Rytter [5]) *If u, v, and w are three primitive words satisfying: $|u| < |v| < |w|$, uu is a prefix of vv, and vv is a prefix of ww, then $|u| + |v| \leq |w|$*

Corollary 1 *Any nonempty string x possesses less than $\log_\Phi |y|$ prefixes that are squares.*

In the configuration of the lemma, a second consequence is that uu is a prefix of w. Therefore, a position in a string x cannot be the largest position of more than two squares, which yields the next corollary. A simple direct proof of it is by Ilie [13], see also [17].

Corollary 2 (Fraenkel and Simpson [8]) *Any string x contains at most $2|x|$ (different) squares, that is: card$\{u \mid u$ primitive and u^2 factor of $y\} \leq 2|x|$.*

The structure of all squares and of un-positioned runs has been also computed within the same time complexities as above in [18] and [12].

Applications

Detecting repetitions in strings is an important element of several questions: pattern matching, text compression, and computational biology to quote a few. Pattern-matching algorithms have to cope with repetitions to be efficient as these are likely to slow down the process; the large family of dictionary-based text compression methods use a weaker notion of repeats (like the software gzip); repetitions in genomes, called satellites, are intensively studied because, for example, some over-repeated short segments are related to genetic diseases; some satellites are also used in forensic crime investigations.

Open Problems

The most intriguing question remains the asymptotically tight bound for the maximum number $\rho(n)$ of runs in a string of size n. The first proof (by painful induction) was quite difficult and has not produced any *concrete* constant coefficient in the $O(n)$ notation. This subject has been studied in [9, 10, 22, 23]. The best-known lower bound of approximately $0.927\,n$ is from [10]. The exact number of runs has been considered for special strings: *Fibonacci words* and (more generally) *Sturmian words* [7, 14, 20]. It is proved in a structural and intricate manner in the full version of [21] that $\rho(n) \leq 3.44\,n$, by introducing a *sparse-neighbors technique*. The neighbors are runs for which both the distance between their starting positions is small and the difference between their periods is also proportionally small (according to some fixed coefficient of proportionality). The occurrences of neighbors satisfy certain *sparsity* properties which imply the linear upper bound. Several variations for the definitions of neighbors and sparsity are possible. Considering runs having close centers the bound has been lowered to $1.6\,n$ in [4].

As a conclusion, we believe that the following fact is valid.

Conjecture: A string of length n contains less than n runs, i.e., $|\mathrm{RUNS}|(n) < n$.

Cross-References

Elements of the present entry are of main importance for run-length compression as well as for ▸ Multidimensional Compressed Pattern Matching. They are also related to the ▸ Approximate Tandem Repeats entries because "tandem repeat" is a synonym of repetition and "power."

Stable Marriage

Robert W. Irving
School of Computing Science, University of Glasgow, Glasgow, UK

Keywords

Stable matching

Years and Authors of Summarized Original Work

1962; Gale, Shapley

Problem Definition

The objective in *stable matching problems* is to match together pairs of elements of a set of participants, taking into account the preferences of those involved and focusing on a stability requirement. The stability property ensures that no pair of participants would both prefer to be matched together rather than to accept their allocation in the matching. Such problems have widespread application, for example, in the allocation of medical students to hospital posts, students to schools or colleges, etc.

An instance of the classical *stable marriage problem* (SM), introduced by Gale and Shapley [2], involves a set of $2n$ participants comprising n men $\{m_1, \ldots, m_n\}$ and n women $\{w_1, \ldots, w_n\}$. Associated with each participant is a *preference list*, which is a total order over the participants of the opposite sex. A man m_i *prefers* woman w_j to woman w_k if w_j precedes w_k on the preference list of m_i and similarly for the women.

A *matching* M is a bijection between the sets of men and women, in other words a set of man-woman pairs so that each man and each woman belongs to exactly one pair of M. For a man m_i, $M(m_i)$ denotes the *partner* of m_i in M, i.e., the unique woman w_j such that (m_i, w_j) is in M. Similarly, $M(w_j)$ denotes the partner of woman w_j in M. A matching M is *stable* if there is no *blocking pair*, namely, a pair (m_i, w_j) such that m_i prefers w_j to $M(m_i)$ and w_j prefers m_i to $M(w_j)$.

Relaxing the requirements that the numbers of men and women are equal and that each participant should rank *all* of the members of the opposite sex gives the *stable marriage problem with incomplete lists* (SMI). So an instance of SMI comprises a set of n_1 men $\{m_1, \ldots, m_{n1}\}$ and a set of n_2 women $\{w_1, \ldots, w_{n2}\}$, and each participant's preference list is a total order over a *subset* of the participants of the opposite sex. The implication is that if woman w_j does not appear on the list of man m_i, then she is not an acceptable partner for m_i and vice versa. A man-woman pair is *acceptable* if each member of the pair is on the preference list of the other, and a matching M is now a set of acceptable pairs such that each man and each woman is in *at most* one pair of M. In this context, a blocking pair for matching M is an acceptable pair (m_i, w_j) such that m_i either is unmatched in M or prefers w_j to $M(m_i)$ and, likewise, w_j either is unmatched or prefers m_i to $M(w_j)$. A matching is stable if it has no blocking pair. So in an instance of SMI, a stable matching need not match all of the participants.

Gale and Shapley also introduced a many-one version of stable marriage, which they called the *college admissions problem*, but which is now more usually referred to as the ▸ Hospitals/Residents Problem (HR) because of its well-known applications in the medical employment field. This problem is covered in detail in Entry 150 of this volume.

A comprehensive treatment of many aspects of the stable marriage problem, as of 1989, appears in the monograph of Gusfield and Irving [5]. A more recent detailed exposition is given by Manlove [14].

Key Results

Theorem 1 *For every instance of SM or SMI, there is at least one stable matching.*

Theorem 1 was proved constructively by Gale and Shapley [2] as a consequence of the algorithm that they gave to find a stable matching.

Theorem 2 *1. For a given instance of SM involving n men and n women, there is a $O(n^2)$ time algorithm that finds a stable matching.*
2. For a given instance of SMI in which the combined length of all the preference lists is a, there is a $O(a)$ time algorithm that finds a stable matching.

The algorithm for SMI is a simple extension of that for SM. Each can be formulated in a variety of ways, but is most usually expressed in terms of a sequence of "proposals" from the members of one sex to the members of the other. A pseudocode version of the SMI algorithm appears in Fig. 1, in which the traditional approach of allowing men to make proposals is adopted.

The complexity bound of Theorem 2(1) first appeared in Knuth's monograph on stable marriage [12]. The fact that this algorithm is asymptotically optimal was subsequently established by Ng and Hirschberg [17] via an adversary argument. On the other hand, Wilson [21] proved that the average running time, taken over all possible instances of SM, is $O(n \log n)$.

The algorithm of Fig. 1, in its various guises, has come to be known as the Gale-Shapley algorithm. The variant of the algorithm given here is called *man oriented*, because men have the advantage of proposing. Reversing the roles of men and women gives the *woman-oriented* variant. The "advantage" of proposing is remarkable, as spelled out in the next theorem.

Theorem 3 *The man-oriented version of the Gale-Shapley algorithm for SM or SMI yields the man-optimal stable matching in which each man has the best partner that he can have in any stable matching, but in which each woman has her worst possible partner. The woman-oriented version yields the woman-optimal stable matching, which has analogous properties favoring the women.*

```
M = ∅;
assign each person to be free;      /* i. e., not a member of a pair in M */
while (some man m is free and has not proposed to every woman on his list)
    m proposes to w, the first woman on his list to whom he has not proposed;
    if (w is free)
        add (m, w) to M;            /* w accepts m */
    else if (w prefers m to her current partner m′)
        remove (m′, w) from M;      /* w rejects m′, setting m′ free */
        add (m, w) to M;            /* w accepts m */
    else
        M remains unchanged;        /* w rejects m */
return M;
```

Stable Marriage, Fig. 1 The Gale-Shapley algorithm

The optimality property of Theorem 3 was established by Gale and Shapley [2], and the corresponding "pessimality" property was first observed by McVitie and Wilson [16].

As observed earlier, a stable matching for an instance of SMI need not match all of the participants. But the following striking result was established by Gale and Sotomayor [3] and Roth [19] (in the context of the more general HR problem).

Theorem 4 *In an instance of SMI, all stable matchings have the same size and match exactly the same subsets of the men and women.*

For a given instance of SM or SMI, there may be many different stable matchings. Indeed Knuth [12] showed that the maximum possible number of stable matchings grows exponentially with the number of participants. He also pointed out that the set of stable matchings forms a distributive lattice under a natural dominance relation, a result attributed to Conway. This powerful algebraic structure that underlies the set of stable matchings can be exploited algorithmically in a number of ways. For example, Gusfield [4] showed how all k stable matchings for an instance of SM can be generated in $O(n^2 + kn)$ time (▸ Optimal Stable Marriage).

Extensions of these problems that are important in practice, so-called SMT and SMTI (extensions of SM and SMI, respectively), allow the presence of *ties* in the preference lists. In this context, three different notions of stability have been defined [7] – *weak*, *strong*, and *super-stability*, depending on whether the definition of a blocking pair requires that both members should improve, or at least one member improves and the other is no worse off, or merely that neither member is worse off. The following theorem summarizes the basic algorithmic results for these three varieties of stable matchings.

Theorem 5 *For a given instance of SMT or SMTI:*

1. *A weakly stable matching is guaranteed to exist and can be found in $O(n^2)$ or $O(a)$ time, respectively.*
2. *A super-stable matching may or may not exist; if one does exist, it can be found in $O(n^2)$ or $O(a)$ time, respectively.*
3. *A strongly stable matching may or may not exist; if one does exist, it can be found in $O(n^3)$ or $O(na)$ time, respectively.*

Theorem 5 parts (1) and (2) are due to Irving [7] (for SMT) and Manlove [13] (for SMTI). Part (3) is due to Kavitha et al. [11], who improved earlier algorithms of Irving and Manlove.

It turns out that, in contrast to the situation described by Theorem 4, weakly stable matchings in SMTI can have different sizes. The natural problem of finding a maximum cardinality

weakly stable matching, even under severe restrictions on the ties, is NP-hard [15]. ▸ Stable Marriage with Ties and Incomplete Lists explores this problem further.

Interesting special cases of SM and its variants arise when the preference lists on one or both sides are derived from a "master" list that ranks participants (e.g.,, according to some objective criterion). Such problems are explored by Irving et al. [10].

The stable marriage problem is an example of a *bipartite* matching problem. The extension in which the bipartite requirement is dropped is the so-called *stable roommates* (SR) problem.

Gale and Shapley had observed that, unlike the case of SM, an instance of SR may or may not admit a stable matching, and Knuth [12] posed the problem of finding an efficient algorithm for SR or proving it NP-complete. Irving [6] established the following theorem via a nontrivial extension of the Gale-Shapley algorithm.

Theorem 6 *For a given instance of SR, there exists a $O(n^2)$ time algorithm to determine whether a stable matching exists and if so to find such a matching.*

Variants of SR may be defined, as for SM, in which preference lists may be incomplete and/or contain ties – these are denoted by SRI, SRT, and SRTI – and in the presence of ties, the three flavors of stability, weak, strong, and super, are again relevant.

Theorem 7 *For a given instance of SRT or SRTI:*

1. *A weakly stable matching may or may not exist, and it is an NP-complete problem to determine whether such a matching exists.*
2. *A super-stable matching may or may not exist; if one does exist, it can be found in $O(n^2)$ or $O(a)$ time, respectively.*
3. *A strongly stable matching may or may not exist; if one does exist, it can be found in $O(n^4)$ or $O(a^2)$ time, respectively.*

Theorem 7 part (1) is due to Ronn [18], part (2) is due to Irving and Manlove [9], and part (3) is due to Scott [20].

Applications

Undoubtedly the best known and most important applications of stable matching algorithms are in centralized matching schemes in the medical and educational domains. ▸ Hospitals/Residents Problem includes a summary of some of these applications.

Open Problems

The parallel complexity of stable marriage remains open. The best known parallel algorithm for SMI is due to Feder et al. [1] and has $O(\sqrt{a}\log^3 a)$ running time using a polynomially bounded number of processors. It is not known whether the problem is in NC, but nor is there a proof of P-completeness.

One of the open problems posed by Knuth in his early monograph on stable marriage [12] was that of determining the maximum possible number x_n of stable matchings for any SM instance involving n men and n women. This problem remains open, although Knuth himself showed that x_n grows exponentially with n. Irving and Leather [8] conjecture that, when n is a power of 2, this function satisfies the recurrence

$$x_n = 3x_{n/2}^2 - 2x_{x/4}^4.$$

Many open problems remain in the setting of weak stability, such as finding a good approximation algorithm for a maximum cardinality weakly stable matching – see ▸ Stable Marriage with Ties and Incomplete Lists – and enumerating all weakly stable matchings efficiently.

Problem Definition

In the stable marriage problem first defined by Gale and Shapley [7], there is one set each of men and women having the same size, and each person has a strict preference order on persons of the opposite gender. The problem is to find a matching such that there is no pair of a man and a woman who prefer each other to their partners in the matching. Such a matching is called a *stable marriage* (or *stable matching*). Gale and Shapley showed the existence of a stable marriage and gave an algorithm for finding one. Fleiner [4] extended the stable marriage problem to the framework of matroids, and Eguchi, Fujishige, and Tamura [3] extended this formulation to a more general one in terms of discrete convex analysis, which was developed by Murota [8, 9]. Their formulation is described as follows.

Let M and W be sets of men and women who attend a dance party at which each person dances a waltz T times and the number of times that

he/she can dance with the same person of the opposite gender is unlimited. The problem is to find an "agreeable" allocation of dance partners, in which each person is assigned at most T persons of the opposite gender with possible repetition. Let $E = M \times W$, i.e., the set of all man-woman pairs. Also define $E_{(i)} = \{i\} \times W$ for all $i \in M$ and $E_{(j)} = M \times \{j\}$ for all $j \in W$. Denoting by $x(i, j)$ the number of dances between man i and woman j, an allocation of dance partners can be described by a vector $x = (x(i, j) : i \in M, j \in W) \in \mathbf{Z}^E$, where $\mathbf{Z}$ denotes the set of all integers. For each $y \in \mathbf{Z}^E$ and $k \in M \cup W$, denote by $y_{(k)}$ the restriction of y on $E_{(k)}$. For example, for an allocation $x \in \mathbf{Z}^E$, $x_{(k)}$ represents the allocation of person k with respect to x. Each person k describes his/her preferences on allocations by using a value function $f_k : \mathbf{Z}^{E_{(k)}} \to \mathbf{R} \cup (-\infty)$, where $\mathbf{R}$ denotes the set of all reals and $f_k(y) = -\infty$ means that allocation $y \in \mathbf{Z}^{E_{(k)}}$ is unacceptable for k. Note that the valuation of each person on allocations is determined only by his/her allocations. Let dom $f_k = \{y | f_k(y) \in \mathbf{R}\}$. Assume that each value function f_k satisfies the following assumption:

(A) dom f_k is bounded and hereditary and has $\mathbf{0}$ as the minimum point, where $\mathbf{0}$ is the vector of all zeros and heredity means that for any $y, y' \in \mathbf{Z}^{E_{(k)}}$, $\mathbf{0} \le y' \le y \in$ dom f_k implies $y' \in$ dom f_k.

For example, the following value functions with $M = \{1\}$ and $W = \{2, 3\}$

$$f_1(x(1,2), x(1,3)) =$$
$$\begin{cases} 10(x(1,2) + x(1,3)) - x(1,2)^2 - x(1,3)^2 & \text{if } x(1,2), x(1,3) \ge 0 \\ & \text{and } x(1,2) + x(1,3) \le 3 \\ -\infty & \text{otherwise,} \end{cases}$$

$$f_j(x(1,j)) = \begin{cases} x(1,j) & \text{if } x(1,j) \in \{0,1,2,3\} (j = 2,3) \\ -\infty & \text{otherwise} \end{cases}$$

represent the case where (1) everyone wants to dance as many times, up to three, as possible and (2) man 1 wants to divide his dances between women 2 and 3 as equally as possible. Allocations $(x(1,2), x(1,3)) = (1,2)$ and (2,1) are stable in the sense below.

A vector $x \in \mathbf{Z}^E$ is called a *feasible allocation* if $x_{(k)} \in$ dom f_k for all $k \in M \cup W$. An allocation x is said to satisfy *incentive constraints* if each person has no incentive to unilaterally decrease the current units of x, that is, if it satisfies

$$f_k(x_{(k)}) = \max\{f_k(y) | y \le x_{(k)}\} \ (\forall k \in M \cup W). \quad (1)$$

An allocation x is called *unstable* if it does not satisfy incentive constraints or there exist $i \in M$, $j \in W$, $y' \in \mathbf{Z}^{E_{(i)}}$ and $y'' \in \mathbf{Z}^{E_{(j)}}$ such that

$$f_i(x_{(i)}) < f_i(y'), \quad (2)$$

$$y'(i, j') \le x(i, j') \quad (\forall j' \in W \backslash \{j\}), \quad (3)$$

$$f_j(x_{(j)}) < f_j(y''), \quad (4)$$

$$y''(i', j) \le x(i', j) \quad (\forall i' \in M \backslash \{i\}), \quad (5)$$

$$y'(i, j) = y''(i, j). \quad (6)$$

Conditions (2) and (3) say that man i can strictly increase his valuation by changing the current number of dances with j without increasing the numbers of dances with other women, and (4) and (5) describe a similar situation for women. Condition (6) requires that i and j agree on the number of dances between them. An allocation x is called *stable* if it is not unstable.

Problem 1 Given disjoint sets M and W and value functions $f_k : \mathbf{Z}^{E_{(k)}} \to \mathbf{R} \cup \{-\infty\}$ for $k \in M \cup W$ satisfying assumption (A), find a stable allocation x.

S

Remark 1 A time schedule for a given feasible allocation can be given by a famous result on graph coloring, namely, "any bipartite graph can be edge-colorable with the maximum degree colors."

Key Results

The work of Eguchi, Fujishige, and Tamura [3] gave a solution to Problem 1 in the case where each value function f_k is $\mathrm{M}^\natural$-concave.

Discrete Convex Analysis: $\mathrm{M}^\natural$-Concave Functions

Let V be a finite set. For each $S \subseteq V$, e_S denotes the characteristic vector of S defined by $e_S(v) = 1$ if $v \in S$ and $e_S(v) = 0$ otherwise. Also define e_0 as the zero vector in $\mathbf{Z}^V$. For a vector $x \in \mathbf{Z}^V$, its positive support $\mathrm{supp}^+(x)$ and negative support $\mathrm{supp}^-(x)$ are defined by $\mathrm{supp}^+(x) = \{u \in V | x(u) > 0\}$ and $\mathrm{supp}^-(x) = \{u \in V | x(u) < 0\}$. A function $f : \mathbf{Z}^V \to \mathbf{R} \cup \{-\infty\}$ is called *$M^\natural$-concave* if it satisfies the following condition $\forall\, x, y \in \mathrm{dom}\, f$, $\forall\, u \in \mathrm{supp}^+(x-y)$, $\exists v \in \mathrm{supp}^-(x-y) \cup \{0\}$:

$$f(x) + f(y) \leq f(x - e_u + e_v) + f(y + e_u - e_v).$$

The above condition says that the sum of the function values at two points does not decrease as the points symmetrically move one or two steps closer to each other on the set of integral lattice points of $\mathbf{Z}^V$. This is a discrete analogue of the fact that for an ordinary concave function, the sum of the function values at two points does not decrease as the points symmetrically move closer to each other on the straight line segment between the two points.

Example 1 A nonempty family $\mathcal{T}$ of subsets of V is called a *laminar family* if $X \cap Y = \emptyset$, $X \subseteq Y$ or $Y \subseteq X$ holds for every $X, Y \in \mathcal{T}$. For a laminar family $\mathcal{T}$ and a family of univariate concave functions $f_Y : \mathbf{R} \to \mathbf{R} \cup \{-\infty\}$ indexed by $Y \in \mathcal{T}$, the function $f : \mathbf{Z}^V \to \mathbf{R} \cup \{-\infty\}$ defined by

$$f(x) = \sum_{Y \in \mathcal{T}} f_Y \left(\sum_{v \in Y} x(v) \right) \quad (\forall\, x \in \mathbf{Z}^V)$$

is $\mathrm{M}^\natural$-concave. The stable marriage problem can be formulated as Problem 1 by using value functions of this type.

Example 2 For the independence family $\mathcal{I} \subseteq 2^V$ of a matroid on V and $w \in \mathbf{R}^V$, the function $f : \mathbf{Z}^V \to \mathbf{R} \cup \{-\infty\}$ defined by

$$f(x) = \begin{cases} \sum_{u \in X} w(u) & \text{if } x = e_X \text{ for some } X \in \mathcal{I} \\ -\infty & \text{otherwise} \end{cases} \quad (\forall\, x \in \mathbf{Z}^V)$$

is $\mathrm{M}^\natural$-concave. Fleiner [4] showed that there always exists a stable allocation for value functions of this type.

Theorem 1 ([6]) *Assume that the value functions $f_k (k \in M \cup W)$ are $\mathrm{M}^\natural$-concave satisfying (A). Then, a feasible allocation x is stable if and only if there exist $Z_M = (z_{(i)} | i \in M) \in (\mathbf{Z} \cup \{+\infty\})^E$ and $z_W = (z_{(j)} | j \in W) \in (\mathbf{Z} \cup \{+\infty\})^E$ such that*

$$x_{(i)} \in \arg\max\{f_i(y) | y \leq z_{(i)}\} \quad (\forall\, i \in M), \tag{7}$$

$$x_{(j)} \in \arg\max\{f_j(y) | y \leq z_{(j)}\} \quad (\forall\, j \in W), \tag{8}$$

$$z_M(e) = +\infty \text{ or } z_W(e) = +\infty \quad (\forall\, e \in E), \tag{9}$$

where $\arg\max\{f_i(y) | y \leq z_{(i)}\}$ denotes the set of all maximizers of f_i under the constraints $y \leq z_{(i)}$.

Theorem 2 ([3]) *Assume that the value functions $f_k (k \in M \cup W)$ are $\mathrm{M}^\natural$-concave satisfying (A). Then, there always exists a stable allocation.*

Eguchi, Fujishige, and Tamura [3] proved Theorem 2 by showing that the following algorithm finds a feasible allocation x, and z_M, z_W satisfying (7), (8), and (9).

Here, $z_W \vee x_M$ is defined by $(z_W \vee x_M)(e) = \max\{z_W(e), x_M(e)\}$ for all $e \in E$.

Algorithm EXTENDED-GS

Input: $M^\natural$-concave functions f_M, f_W with $f_M(x) = \sum_{i \in M} f_i(x_{(i)})$ and $f_W(x) = \sum_{j \in W} f_j(x_{(j)})$;
Output: (x, z_M, z_W) satisfying (7), (8), and (9);
$z_M := (+\infty, \cdots, +\infty)$, $z_W := x_W := \mathbf{0}$;
repeat{
let x_M be any element in
$\arg\max\{f_M(y) | x_W \le y \le z_M\}$;
let x_W be any element in
$\arg\max\{f_W(y) | y \le x_M\}$;
for each $e \in E$ with $x_M(e) > x_W(e)$ {
$z_M(e) := x_W(e)$;
$z_W(e) := +\infty$;
};
} **until** $x_M = x_W$;
return $(x_M, z_M, z_W \vee x_M)$.

Applications

Abraham, Irving, and Manlove [1] dealt with a student-project allocation problem which is a concrete example of models in [4] and [3] and discussed the structure of stable allocations.

Fleiner [5] generalized the stable marriage problem and its extension in [4] to a wide framework and showed the existence of a stable allocation by using a fixed point theorem.

Fujishige and Tamura [6] proposed a common generalization of the stable marriage problem and the assignment game defined by Shapley and Shubik [10] by utilizing $M^\natural$-concave functions and gave a constructive proof of the existence of a stable allocation.

Open Problems

Algorithm EXTENDED-GS solves the maximization problem of an $M^\natural$-concave function in each iteration. A maximization problem of an $M^\natural$-concave function f on E can be solved in polynomial time in $|E|$ and $\log L$, where $L = \max\{||x - y||_\infty | x, y \in \text{dom } f\}$, provided that the function value $f(x)$ can be calculated in constant time for each x [11, 12]. Eguchi, Fujishige, and Tamura [3] showed that EXTENDED-GS terminates after at most L iterations, where L is defined by $\{||x||_\infty | x \in \text{dom } f_M\}$ in this case, and there exist a series of instances in which EXTENDED-GS requires numbers of iterations proportional to L. On the other hand, Baïou and Balinski [2] gave a polynomial time algorithm in $|E|$ for the special case where f_M and f_W are linear on rectangular domains. Whether a stable allocation for the general case can be found in polynomial time in $|E|$ and $\log L$ or not is open.

Problem Definition

Over the last 50 years, the stable marriage problem has been extensively studied for many problem settings (see, e.g., [11]), and one of the most intensively studied problem settings is MAX SMTI (MAXimum Stable Marriage with Ties and Incomplete lists). An input for the stable marriage problem consists of n men, n women, and each person's preference list for the people of the opposite sex. In MAX SMTI, the preference list of each person can be incomplete, which means that each person is allowed to exclude unacceptable people from the preference list, and the preference list of each person is allowed to include *ties* to show indifference between two or more people.

The objective of MAX SMTI is to find the largest matching that satisfies a stability condition. Before describing the stability condition, we review some notation. A matching M is defined as a set of pairs of man m and woman w such that m and w are acceptable to each other. The *size* of a matching M is defined as the number of pairs in M. We say that a person p is *single* if p is not matched in M. When man m and woman w are matched in M, we write $M(m) = w$ and $M(w) = m$. We say that matching M is *stable* if it does not contain any pair of man and woman, each of whom prefers the other to the partner in M (if any). More precisely, a matching M is stable if there is no pair of man m' and woman w' that satisfy all three conditions (i)–(iii): (i) m' and w' are acceptable to each other but not matched in M, (ii) m' is single in M or m' strictly prefers w' to $M(m')$, and (iii) w' is single in M or w' strictly prefers m' to $M(w')$. MAX SMTI asks us to find a stable matching of the largest size, and this problem is known to be NP-hard [12]. Therefore, the approximability of this problem has been intensively studied.

In this entry, we show recent results for two major variants of MAX SMTI. One of the variants is MAX SMOTI (MAXimum Stable Marriage with One-Sided Ties and Incomplete lists), in which only women are allowed to include ties in their preference lists and the preference lists of men are strictly ordered. The other variant is MAX SSMTI (Special SMTI), which is an even more restricted variant of MAX SMOTI where the ties are only allowed at the ends of the women's preference lists. Note that these two variants are still known to be NP-hard [12].

Problem 1 (MAX SMOTI)
INPUT: n men, n women, and each person's preference list, where only women have ties
OUTPUT: A stable matching of maximum size

Problem 2 (MAX SSMTI)
INPUT: n men, n women, and each person's preference list, where ties are at the ends of the women's preference lists
OUTPUT: A stable matching of maximum size

Stable Marriage with One-Sided Ties, Table 1 Examples of instances for MAX SMOTI and MAX SSMTI

MAX SMOTI		MAX SSMTI	
$m_1 : w_2\ w_1$	$w_1 : m_1\ m_2$	$m_1 : w_1\ w_3$	$w_1 : (m_1\ m_2\ m_3)$

$m_3 : w_3\ w_2$	$w_3 : m_2\ m_3$	$m_3 : w_3\ w_1$	$w_3 : m_2\ (m_1\ m_3)$

Examples

Table 1 shows examples of instances for MAX SMOTI and MAX SSMTI. The instance for MAX SMOTI contains a set of men $\{m_1, m_2, m_3\}$ and a set of women $\{w_1, w_2, w_3\}$. The preference list of each person is described in decreasing order of preference, and tied people are enclosed in a pair of parenthesis. For example, woman w_2 is indifferent between m_1 and m_2 but prefers m_1 or m_2 over m_3. A matching $M = \{(m_2, w_1), (m_3, w_2)\}$ is not stable for this MAX SMOTI instance, because m_2 strictly prefers w_2 to w_1 $(= M(m_2))$ and w_2 strictly prefers m_2 to m_3 $(= M(w_2))$. An example of a stable matching for this instance is $M' = \{(m_1, w_2), (m_2, w_3)\}$, and we can find another larger stable matching $M^* = \{(m_1, w_1), (m_2, w_2), (m_3, w_3)\}$ of size 3.

Key Results

Here we review past research on MAX SMOTI and MAX SSMTI. We start by describing a simple proposal-based algorithm (often referred to as the Gale-Shapley algorithm or the deferred acceptance algorithm), which is guaranteed to find a *stable* matching. In this algorithm, all of the men and women are initially set to be single. We pick an arbitrary man m who is single, and let man m propose to woman w at the top of his preference list. When man m proposes to w, he deletes woman w from his preference list. Woman w always accepts any proposal if she is single, which makes a matching pair of m and w. We repeat this proposal procedure to find more and more matching pairs. When a woman w, who is already matched to a man m, receives another proposal from man m', woman w chooses the more highly ranked man based on her preference list. (That is, the matching partner of w is unchanged if w prefers m to m', and the matching partner of w is changed from m to m' and m becomes unmatched if w prefers m' to m.) If m and m' are tied in w's preference list, then w chooses an arbitrary man. The proposal procedure continues until we cannot find any man who can propose. (That is, this algorithm terminates when all of the men become matched or the preference lists of all single men become empty.) Any matching obtained by this algorithm can be proven to be stable. The size of the obtained stable matching depends mostly on the decisions by women when a woman receives two proposals from men who are tied in her preference list. In the worst case, the size of an obtained matching can be half of the optimum matching, and hence, the approximation ratio of this algorithm is 2. It was an open problem whether or not there exists an approximation algorithm whose approximation ratio is strictly better than 2. Iwama, Miyazaki, and Yamauchi [8] provided an affirmative answer for this open problem with a 1.875-approximation algorithm.

After this breakthrough, Király [10] developed a new simple 1.5-approximation algorithm for MAX SMOTI (which also applies to MAX SSMTI) by improving the decision strategy of the proposal-based algorithm when women receive multiple proposals from tied men. His algorithm proceeds in the same way as the proposal-based algorithm until one of the men's preference lists become empty. When the preference list of a man becomes empty, he enters into his second round. Specifically, he recovers his original preference list so that he can propose to the women in his original preference list again, but his status is changed to "promoted." A promoted man is not allowed to recover his original preference list when his preference list becomes empty the second time, and hence, no man can enter a

third round in Kiráry's algorithm. The decision strategy of the women is changed so that a woman is forced to choose a promoted man (if one exists) when she receives two proposals from men who are tied in her preference list. This improvement of the decision strategy is the key to achieve the 1.5-approximation.

Iwama, Miyazaki, and Yanagisawa [9] further improved the approximation ratio to 25/17 (< 1.4706) for MAX SMOTI with a new algorithm GSA-LP, which uses a more complex proposal sequence of the men and a more sophisticated decision strategy for the women. In GSA-LP, we compute an optimum solution for a linear programming relaxation of a natural integer programming formulation of the problem in advance and use it for the decision strategy of the women. In addition, the proposal sequence is changed so that a man can propose to a woman many times, and a man is allowed to recover his original preference list at most twice (in other words, a man is allowed to go into a third round). These changes yield an improved approximation ratio for MAX SMOTI. Very recently, GSA-LP was shown to achieve a 1.25-approximation for MAX SSMTI [5].

For MAX SMOTI, there are successive improvements over GSA-LP. Huang and Kavitha [4] developed another new algorithm that achieves a 22/15 (<1.4667)-approximation by using a maximum matching algorithm. Radnai [14] showed 41/28 (<1.4643)-approximation by using a more detailed analysis of this new algorithm and also showed that a lower bound of the approximation ratio of this algorithm is at least 13/9 (>1.4444). Dean and Jalasutram improved the analysis of GSA-LP and showed that the approximation ratio of GSA-LP is at most 19/13 (<1.4616) if we increase the number of rounds from three to four [1]. We also note that if the lengths of ties are restricted to two, then the approximation ratio of this restricted MAX SMOTI variant can be further improved. A randomized algorithm [2] achieves 10/7 (<1.4286)-approximation and Huang and Kavitha devised another deterministic algorithm [4] with the same approximation ratio.

For the negative side, both MAX SMOTI and MAX SSMTI are NP-hard to approximate within any constant factor better than 21/19 (>1.1052) and hard to approximate within any constant factor better than 5/4 (= 1.25) under the unique games conjecture [3, 15]. These lower bounds hold even if we restrict the lengths of the ties to two. Note that the approximation ratio of the GSA-LP algorithm for MAX SSMTI is 1.25, which matches the lower bound under the unique games conjecture.

Applications

MAX SSMTI was introduced by Irving and Manlove [6] based on an actual application of the Scottish Foundation Allocation Scheme, which allocates residents (medical students) to hospitals. In this scheme, each resident submits a strictly ordered preference list, while each hospital submits a preference list that may contain one tie of arbitrary length at the end of the list. The objective of this allocation scheme is to maximize the number of allocated residents, and it is easy to reformulate this many-to-one allocation scheme as a one-to-one matching problem (MAX SSMTI) using a cloning technique [11].

Open Problems

An obvious future goal is to narrow the gap between the upper and lower bounds of the approximability of MAX SMOTI. Assuming the unique games conjecture is true, we now know that the best possible approximation ratio is between 1.4616 and 1.25. Even if we restrict the lengths of ties to two, all we can do now is reduce the upper bound slightly down to 1.4286. Thus, there is still much room for improvement.

As for MAX SSMTI, the 1.25-approximation of the GSA-LP algorithm is the best possible if the unique games conjecture is true. A future project could investigate if we can construct a faster approximation algorithm, because the

GSA-LP algorithm uses a linear programming relaxation technique, which takes superlinear time in the worst case.

Experimental Results

Irving and Manlove [7] reported on experimental evaluations of some heuristic algorithms including the Király's algorithm on real-world and random instances for MAX SMOTI. Subsequently, Podhradský [13] conducted experimental evaluations on random instances for MAX SMOTI and MAX SSMTI using some other heuristic algorithms including GSA-LP.

Problem Definition

In the original setting of the stable marriage problem introduced by Gale and Shapley [2], each preference list has to include all members of the other party, and furthermore, each preference list must be totally ordered (see entry ▸ Stable Marriage also).

One natural extension of the problem is then to allow persons to include ties in preference lists. In this extension, there are three variants of the stability definition, super-stability, strong stability, and weak stability (see below for definitions). In the first two stability definitions, there are instances that admit no stable matching, but there is a polynomial-time algorithm in each case that determines if a given instance admits a stable matching and finds one if one exists [9]. On the other hand, in the case of weak stability, there always exists a stable matching, and one can be found in polynomial time.

Another possible extension is to allow persons to declare unacceptable partners, so that preference lists may be incomplete. In this case, every instance admits at least one stable matching, but a stable matching may not be a perfect matching. However, if there are two or more stable matchings for one instance, then all of them have the same size [3].

The problem treated in this entry allows both extensions simultaneously, which is denoted as SMTI (stable marriage with ties and incomplete lists).

Notations

An instance I of SMTI comprises n men, n women, and each person's preference list that may be incomplete and may include ties. If a man m includes a woman w in his list, w is *acceptable* to m. $w_i \succ_m w_j$ means that m strictly prefers w_i to w_j in I. $w_i =_m w_j$ means that w_i and w_j are tied in m's list (including the case $w_i = w_j$). The statement $w_i \succeq_m w_j$ is true if and only if $w_i \succ_m w_j$ or $w_i =_m w_j$. Similar notations are used for women's preference lists. A matching M is a set of pairs (m, w) such that m is acceptable to w, and vice versa, and each person appears at most once in M. If a man m is matched with a woman w in M, it is written as $M(m) = w$ and $M(w) = m$.

A man m and a woman w are said to form a *blocking pair for weak stability* for M if they are not matched together in M, but by matching them, both become better off, namely, (i) $M(m) \neq w$ but m and w are acceptable to each other, (ii) $w \succ_m M(m)$ or m is single in M, and (iii) $m \succ_w M(w)$ or w is single in M.

Two persons x and y are said to form a *blocking pair for strong stability* for M if they are not matched together in M, but by matching them, one becomes better off, and the other does not become worse off, namely, (i) $M(x) \neq y$ but x and y are acceptable to each other, (ii) $y \succ_x M(x)$ or x is single in M, and (iii) $x \succeq_y M(y)$ or y is single in M.

A man m and a woman w are said to form a *blocking pair for super-stability* for M if they are not matched together in M, but by matching them, neither becomes worse off, namely, (i) $M(m) \neq w$ but m and w are acceptable to each other, (ii) $w \succeq_m M(m)$ or m is single in M, and (iii) $m \succeq_w M(w)$ or w is single in M.

A matching M is called *weakly stable* (*strongly stable* and *super-stable*, respectively) if there is no blocking pair for weak (strong and super, respectively) stability for M.

Problem 1 (SMTI)

INPUT: n men, n women, and each person's preference list
OUTPUT: A stable matching

Problem 2 (MAX SMTI)

INPUT: n men, n women, and each person's preference list
OUTPUT: A stable matching of maximum size

The following problem is a restriction of MAX SMTI in terms of the length of preference lists:

Problem 3 ((p,q)-MAX SMTI)

INPUT: n men, n women, and each person's preference list, where each man's preference list includes at most p women and each woman's preference list includes at most q men
OUTPUT: A stable matching of maximum size

Definition of the Approximation Ratio

A goodness measure of an approximation algorithm T for a maximization problem is defined as follows: the *approximation ratio* of T is $\max\{opt(x)/T(x)\}$ over all instances x of size N, where $opt(x)$ and $T(x)$ are the sizes of the optimal and the algorithm's solutions, respectively.

Key Results

SMTI and MAX SMTI in Super-Stability and Strong Stability

Theorem 1 ([20]) *There is an $O(n^2)$-time algorithm that determines if a given SMTI instance admits a super-stable matching and finds one if one exists.*

Theorem 2 ([17]) *There is an $O(n^3)$-time algorithm that determines if a given SMTI instance admits a strongly stable matching and finds one if one exists.*

It is shown that all stable matchings for a fixed instance are of the same size [20]. Therefore, the above theorems imply that MAX SMTI can also be solved in the same time complexity.

SMTI and MAX SMTI in Weak Stability

In the case of weak stability, every instance admits at least one stable matching, but one instance can have stable matchings of different sizes. If the size is not important, a stable matching can be found in polynomial time by breaking ties arbitrarily and applying the Gale-Shapley algorithm.

Theorem 3 *There is an $O(n^2)$-time algorithm that finds a weakly stable matching for a given SMTI instance.*

However, if larger stable matchings are required, the problem becomes hard.

Theorem 4 ([5, 13, 21, 24]) *MAX SMTI is NP-hard and cannot be approximated within $33/29 - \epsilon$ for any positive constant ϵ unless P=NP. ($33/29 > 1.137$)*

The following approximation ratio is achieved by a local search type algorithm.

Theorem 5 ([14]) *There is a polynomial-time approximation algorithm for MAX SMTI whose approximation ratio is at most 15/8 (=1.875).*

There are a couple of approximation algorithms for restricted inputs.

Theorem 6 ([6]) *There is a polynomial-time randomized approximation algorithm for MAX SMTI whose expected approximation ratio is at most $10/7(\simeq 1.429)$ if, in a given instance, ties appear in one side only and the length of each tie is two.*

Theorem 7 ([6]) *There is a polynomial-time randomized approximation algorithm for MAX SMTI whose expected approximation ratio is at most $7/4(= 1.75)$ if, in a given instance, the length of each tie is two.*

Theorem 8 ([7]) *There is a polynomial-time approximation algorithm for MAX SMTI whose approximation ratio is at most $2/(1 + L^{-2})$ if, in a given instance, ties appear in one side only and the length of each tie is at most L.*

Theorem 9 ([7]) *There is a polynomial-time approximation algorithm for MAX SMTI whose approximation ratio is at most $13/7(\simeq 1.858)$ if, in a given instance, the length of each tie is two.*

(p, q)-MAX SMTI in Weak Stability

Irving et al. [12] show the boundary between P and NP-hardness in terms of the length of preference lists.

Theorem 10 ([12]) *$(2,\infty)$-MAX SMTI is solvable in time $O(n^{\frac{3}{2}} \log n)$.*

Theorem 11 ([12]) *$(3,3)$-MAX SMTI is NP-hard.*

Theorem 12 ([12]) *$(3,4)$-MAX SMTI is NP-hard and cannot be approximated within some constant $\delta(> 1)$ unless P=NP.*

Applications

One of the most famous applications of the stable marriage problem is a centralized assignment system between medical students (residents) and

hospitals. This is an extension of the stable marriage problem to a many-one variant: Each hospital declares the number of residents it can accept, which may be more than one, while each resident has to be assigned to at most one hospital. Actually, there are several applications in the world, known as NRMP in the USA [4], CaRMS in Canada [1], SFAS (previously known as SPA) in Scotland [10, 11], and JRMP in Japan [16]. One of the optimization criteria is clearly the number of matched residents. In a real-world application such as the above hospitals-residents matching, hospitals and residents tend to submit short preference lists that may include ties, in which case, the problem can be naturally considered as MAX SMTI.

Open Problems

An apparent open problem is to narrow the gap of approximability and inapproximability of MAX SMTI in weak stability.

Since the publication of the key result of this chapter (Theorem 5), there have been a lot of improvement. Király [18] presented a linear time 5/3-approximation algorithm (see ▸ Simpler Approximation for Stable Marriage). McDermid [22] then presented a 1.5-approximation algorithm (see ▸ Simpler Approximation for Stable Marriage), and Király [19] and Paluch [23] presented simpler algorithms with the same approximation ratio, which is the current best upper bound. The lower bound was improved by Yanagisawa [24], who showed that MAX SMTI is inapproximable to within a ratio smaller than $33/29(>1.137)$ unless P = NP. He also showed that MAX SMTI is inapproximable within a ratio smaller than $4/3(>1.333)$ under the Unique Games Conjecture (UGC).

As for the special case where ties can appear in one side only (see ▸ Stable Marriage with One-Sided Ties), Király [18] presented a 1.5-approximation algorithm. It was then improved to $25/17(<1.471)$ [15] and to $22/15(<1.467)$ [8], which is the current best upper bound. The current best lower bounds are $21/19(\simeq 1.105)$ under P$\neq$NP and 1.25 under UGC [7].

P. J. Šafárik University, Košice, Slovakia

Keywords

Coalition formation; Hedonic games; Stability

Years and Authors of Summarized Original Work

2002; Cechlárová, Hajduková
2004; Ballester

Problem Definition

Let N be a finite set of players; a nonempty subset of N is called a coalition. Each player $i \in N$ has a preference relation $\succeq_i$ (complete, reflexive, and transitive) over all the coalitions that contain i. Notation $S \succeq_i T$ means that player i *weakly prefers* coalition S to coalition T; if $S \succeq_i T$ and not $T \succeq_i S$, then player i *strictly prefers* S to T, denoted by $S \succ_i T$. If $S \succeq_i T$ and $T \succeq_i S$, then player i *is indifferent between* coalitions S and T (there is a *tie* in his preference list). Player i has strict preferences if her preference list contains no ties. There are several possible ways of representing preferences, but it is usually supposed that preference relations can be evaluated in polynomial time.

An instance I of the stable partition problem (or coalition formation game, or hedonic game) is given by the set of players and their preferences.

A partition Π is a collection of disjoint coalitions whose union equals N. It is supposed that each participant's appreciation of a coalition structure only depends on the coalition $\Pi(i)$ she is a member and not on the composition of other coalitions. Of interest are partitions that fulfill some kind of stability requirements.

We say that a coalition $S \subseteq N$ *strongly blocks* a partition Π, if each player $i \in S$ strictly prefers S to $\Pi(i)$, and a coalition $S \subseteq N$ *weakly blocks* a partition Π, if each player $i \in S$ weakly prefers S to $\Pi(i)$ and there exists at least one player $j \in S$ who strictly prefers S to $\Pi(j)$. Partition Π is:

- *Individually stable* if each player i weakly prefers $\Pi(i)$ to $\{i\}$;
- *Nash stable (NS)* if each player i weakly prefers $\Pi(i)$ to $X \cup \{i\}$ for each $X \in \Pi \cup \emptyset$;

- *Individually stable (IS)* if whenever a player i strictly prefers $X \cup \{i\}$ to $\Pi(i)$ for some $X \in \Pi$, then $X \succ_j X \cup \{i\}$ for at least one player $j \in X$;
- *Contractually individually stable (CIS)* if whenever a player i strictly prefers $X \cup \{i\}$ to $\Pi(i)$ for some $X \in \Pi$, then $X \succ_j X \cup \{i\}$ for at least one player $j \in X$ or $\Pi(i) \succ_j \Pi(i) \backslash \{i\}$ for at least one player $i \in \Pi(i)$;
- *Core stable* if it admits no blocking coalition;
- *Strictly core stable* if it admits no weakly blocking coalition;

Most of these definitions were introduced in [3] and [4] where also some sufficient conditions for the existence of stable partitions were formulated. An overview of the implications between these definitions can be found in [1]. The following problems have been studied algorithmically for various stability notions $\mathbb{S}$:

- $\mathbb{S}$-STABILITY-VERIFICATION: Given I and a partition Π, is Π a $\mathbb{S}$-stable partition?
- $\mathbb{S}$-STABILITY-EXISTENCE: Given I, does a $\mathbb{S}$-stable partition exist?
- $\mathbb{S}$-STABILITY-CONSTRUCTION: Given I, construct a $\mathbb{S}$-stable partition.
- $\mathbb{S}$-STABILITY-STRUCTURE: Describe the structure of $\mathbb{S}$-stable partitions for a given I.

The computational complexity of these problems depends on the specification of the preference relation in the input.

An Important special case of the stable partition problem arises when each coalition can contain at most two players. This is known under the name the *Stable Matching Problem* and is treated in detail in [14]; see also references in the entry Stable Marriage.

Key Results

Trivial Encoding

In the *trivial encoding*, each player lists all her individually rational coalitions (i.e., those that player i weakly prefers to coalition $\{i\}$).

Theorem 1 *Under the trivial encoding, the* STABILITY-VERIFICATION *problem is polynomially solvable for any stability definition.* STABILITY-EXISTENCE *is NP-complete for IR, NS, core, and strict core [2].* CORE-STABILITY-EXISTENCE *is NP-complete [2], even in the case when each player i has her preference list of the form $C_1(i) \succ_i C_2(i) \succ_i \{i\}$ and all acceptable coalitions have size three [11].*

As the trivial encoding may be of exponential size in the number of players, more succinct preference representations have been studied.

Anonymous Preferences

Players have anonymous preferences if all coalitions of the same size are tied, i.e., players do not care about the actual content of the coalitions, only about their sizes.

Theorem 2 *Under anonymous preferences, the* CORE-STABILITY-VERIFICATION *problem is polynomially solvable and* CORE-STABILITY-EXISTENCE *is NP-complete [2].*

Additive Preferences

In an additive hedonic game, each player i has a real-valued function $v_i : N \to \mathbb{R}$ and $S \succ_i T$ if and only if $\sum_{j \in S} v_i(j) > \sum_{j \in T} v_i(j)$.

Theorem 3 *In additive hedonic games,* STABILITY-VERIFICATION *is co-NP-complete in the strong sense for core and strict core [1, 17].* CORE-STABILITY-EXISTENCE *and* STRICT-CORE-STABILITY-EXISTENCE *are strongly NP-hard [18] even in the symmetric case [1].* INDIVIDUAL-STABILITY-EXISTENCE *and* NASH-STABILITY-EXISTENCE *are strongly NP-complete [1, 18]. Moreover,* CORE-STABILITY-EXISTENCE *is $\sum_2^p$-complete [19].*

Special cases of additive preferences arise if $v_i(j) \in \{-1, |N|\}$ for each $i, j \in N$ (friend-oriented case) or $v_i(j) \in \{1, -|N|\}$ for each $i, j \in N$ (enemy-oriented case). Under friend-oriented as well as under enemy-oriented preferences, a core-stable partition always exists [12], however, the following assertion holds.

Theorem 4 ([12]) *Under enemy-oriented preferences,* CORE-STABILITY-VERIFICATION *and* CORE-STABILITY-CONSTRUCTION *are strongly NP-complete and NP-hard, respectively.*

Preferences Derived from the Best and/or Worst Player

Suppose that each player i linearly orders only individual players or, more precisely, a subset of them – these are *acceptable* for i.

Preferences over players are extended to preferences over coalitions on the basis of the best or the worst player in the coalition as follows:

B-preferences – a player orders coalitions first on the basis of the most preferred member of the coalition, and if those are equal or tied, the coalition with smaller cardinality is preferred;

W-preferences – a player orders coalitions on the basis of the least preferred member of the coalition;

BW-preferences – a player orders coalitions first on the basis of the best member of the coalition, and if those are equal or tied, the coalition with a more preferred worst member is preferred.

In this case, preferences are considered *strict*, if the preferences over individuals are strict, and they are called *dichotomous* if all acceptable participants are tied in each preference list.

Theorem 5 *Under B-preferences,* STABILITY-VERIFICATION *is polynomial for core and strict core. A strict core and a core stable partition always exist if preferences over players are strict [9]. However, if preferences over players contain ties,* STABILITY-EXISTENCE *for core and strict core is NP-complete [6]. In the dichotomous case, a core stable partition can be constructed in polynomial time, but* STRICT-CORE-STABILITY-EXISTENCE *is NP-complete [5].*

Let us remark here that in the case of strict preferences, a strict core stable partition can be found by the famous Top Trading Cycles algorithm [9, 20].

The stable partition problem under W-preferences was studied in [7] and many features similar to the Stable Roommates Problem [14] were described. First, if a blocking coalition exists, then there is a blocking coalition of size at most 2. Hence, CORE-STABILITY-VERIFICATION is polynomial. CORE-STABILITY-EXISTENCE and CORE-STABILITY-CONSTRUCTION are polynomial in the strict preferences case, which can be shown using an extension of Irving's Stable Roommates Algorithm (discussed in detail in [14]). This algorithm can also be used to derive some results for CORE-STABILITY-STRUCTURE. In the case of ties, CORE-STABILITY-EXISTENCE is NP-complete.

Under BW preferences, in the strict preferences case, a core partition always exists and one can be obtained by the Top Trading Cycles algorithm, but STRICT-CORE-STABILITY-EXISTENCE is NP-hard. If preferences contain ties, CORE-STABILITY-EXISTENCE is NP-hard too [8]. CORE-STABILITY-VERIFICATION remains open.

Applications

Stable partitions arise in various economic and game theoretical models. They appear in the study of countries formation [10] and in multi-agent coordination scenarios and social networking services [13]. Stability is also desired in barter exchange economies with discrete commodities [20, 21], including exchange of kidneys for transplantations [5, 16]. Notice that in case when the cooperation of players consists in the exchange of some items within one partition set, the exchange cycle has also to be specified.

Open Problems

Due to the great number of variants, a lot of open problems exists. In almost all cases, STABILITY-STRUCTURE is not satisfactorily solved. For instances with no stable partition, one may seek one that minimizes the number of players who have an incentive to deviate. Parallel algorithms were also not studied.

Experimental Results

Stochastic local search algorithms for CORE-STABILITY-VERIFICATION in the additive preferences case were reported in [15].

Problem Definition

Stackelberg games [15] may model the interplay among an authority and rational individuals that selfishly demand resources on a large-scale

network. In such a game, the authority *(Leader)* of the network is modeled by a distinguished player. The selfish users *(Followers)* are modeled by the remaining players.

It is well known that selfish behavior may yield a *Nash Equilibrium* with cost arbitrarily higher than the optimum one, yielding unbounded *Coordination Ratio* or *Price of Anarchy (PoA)* [7, 13]. Leader plays his strategy first assigning a portion of the total demand to some resources of the network. Followers observe and react selfishly assigning their demand to the most appealing resources. Leader aims to drive the system to an a posteriori Nash equilibrium with cost close to the overall optimum one [4, 6, 8, 10]. Leader may also be eager for his own rather than system's performance [2, 3].

A Stackelberg game can be seen as a special, and easy [6] to implement, case of *Mechanism Design*. It avoids the complexities of either computing taxes or assigning prices, or even designing the network at hand [9]. However, a central authority capable to control the overall demand on the resources of a network may be unrealistic in networks which evolute and operate under the effect of many and diversing economic entities. A realistic way [4] to act centrally even in large nets could be via *Virtual Private Networks (VPNs)* [1]. Another flexible way is to combine such strategies with *Tolls* [5, 14].

A dictator controlling the entire demand optimally on the resources surely yields PoA = 1. On the other hand, rational users do prefer a liberal world to live. Thus, it is important to compute the optimal Leader strategy which controls the *minimum* of the resources *(Price of Optimum)* and yields PoA $=$ 1. What is the complexity of computing the Price of Optimum? This is not trivial to answer, since the Price of Optimum depends crucially on computing an optimal Leader strategy. In particular, [6] proved that computing the optimal Leader strategy is hard.

The central result of this lemma is Theorem 5. It says that on nonatomic flows and arbitrary $s-t$ networks and latencies, computing the minimum portion of flow and Leader's optimal strategy sufficient to induce PoA $=$ 1 is easy [10].

Problem $(G(V,E),s,t \in V,r)$ INPUT: Graph $G, \forall e \in E$ latency ℓ_e, flow r, a source-destination pair (s,t) of vertices in V.
OUTPUT: (i) The minimum portion α_G of the total flow r sufficient for an optimal Stackelberg strategy to induce the optimum on G. (ii) The optimal Stackelberg strategy.

Models and Notations

Consider a graph $G(V,E)$ with parallel edges allowed. A number of rational and selfish users wish to route from a given source s to a destination node t an amount of flow r. Alternatively, consider a partition of users in k commodities, where user(s) in commodity i wish to route flow r_i through a source-destination pair (s_i,t_i), for each $i = 1,\ldots,k$. Each edge $e \in E$ is associated to a latency function $\ell_e()$, positive, differentiable, and strictly increasing on the flow traversing it.

Nonatomic Flows

There are infinitely many users, each routing his/her infinitesimally small amount of the total flow r_i from a given source s_i to a destination vertex t_i in graph $G(V,E)$. A flow f is an assignment of jobs f_e on each edge $e \in E$. The cost of the injected flow f_e (satisfying the standard constraints of the corresponding network-flow problem) that traverses edge $e \in E$ equals; $c_e(f_e) = f_e \times \ell_e(f_e)$. It is assumed that on each edge e the cost is convex with respect to the injected flow f_e. The overall system's cost is the sum $\sum_{e\in E} f_e \times \ell_e(f_e)$ of all edge costs in G. Let $f_{\mathcal{P}}$ the amount of flow traversing the $s_i - t_i$ path $\mathcal{P}$. The latency $\ell_{\mathcal{P}}(f)$ of $s_i - t_i$ path $\mathcal{P}$ is the sum $\sum_{e\in\mathcal{P}} \ell_e(f_e)$ of latencies per edge $e \in \mathcal{P}$. The cost $C_{\mathcal{P}}(f)$ of $s_i - t_i$ path $\mathcal{P}$ equals the flow $f_{\mathcal{P}}$ traversing it multiplied by path latency $\ell_{\mathcal{P}}(f)$. That is, $C_{\mathcal{P}}(f) = f_{\mathcal{P}} \times \sum_{e\in\mathcal{P}} \ell_e(f_e)$. In a Nash equilibrium, all $s_i - t_i$ paths traversed by nonatomic users in part i have a common latency, which is at most the latency of any untraversed

$s_i - t_i$ path. More formally, for any part i and any pair $\mathcal{P}_1$, $\mathcal{P}_2$ of $s_i - t_i$ paths, if $f_{\mathcal{P}_1} > 0$ then $\ell_{\mathcal{P}_1}(f) \leq \ell_{\mathcal{P}_2}(f)$. By the convexity of edge costs, the Nash equilibrium is unique and computable in polynomial time given a floating-point precision. Also computable is the unique *Optimum* assignment O of flow, assigning flow o_e on each $e \in E$ and minimizing the overall cost $\sum_{e \in E} o_e \ell_e(o_e)$. However, not all optimally traversed $s_i - t_i$ paths experience the same latency. In particular, users traversing paths with high latency have incentive to reroute toward more speedy paths. Therefore, the optimal assignment is unstable on selfish behavior.

A Leader dictates a *weak* Stackelberg strategy if on each commodity $i = 1, \ldots, k$ controls a fixed α portion of flow $r_i, \alpha \in [0, 1]$. A *strong* Stackelberg strategy is more flexible, since Leader may control $\alpha_i r_i$ flow in commodity i such that $\sum_{i=1}^{k} \alpha_i = \alpha$. Let a Leader dictating flow s_e on edge $e \in E$. The a posteriori latency $\tilde{\ell}_e(n_e)$ of edge e, with respect to the induced flow n_e by the selfish users, equals $\tilde{\ell}_e(n_e) = \ell_e(n_e + s_e)$. In the a posteriori Nash equilibrium, all $s_i - t_i$ paths traversed by the free selfish users in commodity i have a common latency, which is at most the latency of any selfishly untraversed path, and its cost is $\sum_{e \in E} (n_e + s_e) \times \tilde{\ell}_e(n_e)$.

Atomic Splittable Flows

There is a finite number of atomic users $1, \ldots, k$. Each user i is responsible for routing a non-negligible flow-amount r_i from a given source s_i to a destination vertex t_i in graph G. In turn, each flow-amount r_i consists of infinitesimally small jobs.

Let flow f assigning jobs f_e on each edge $e \in E$. Each edge flow f_e is the sum of partial flows $f_e^1, \ldots, f_e^k$ injected by the corresponding users $1, \ldots, k$. That is, $f_e = f_e^1 + \cdots + f_e^k$. As in the model above, the latency on a given $s_i - t_i$ path $\mathcal{P}$ is the sum $\sum_{e \in \mathcal{P}} \ell_e(f_e)$ of latencies per edge $e \in \mathcal{P}$. Let $f_{\mathcal{P}}^i$ be the flow that user i ships through an $s_i - t_i$ path $\mathcal{P}$. The cost of user i on a given $s_i - t_i$ path $\mathcal{P}$ is analogous to her path flow $f_{\mathcal{P}}^i$ routed via $\mathcal{P}$ times the total path latency $\sum_{e \in \mathcal{P}} \ell_e(f_e)$. That is, the path cost equals $f_{\mathcal{P}}^i \times \sum_{e \in \mathcal{P}} \ell_e(f_e)$. The overall cost $C_i(f)$ of user i is the sum of the corresponding path costs of all $s_i - t_i$ paths.

In a Nash equilibrium no user i can improve his cost $C_i(f)$ by rerouting, given that any user $j \neq i$ keeps his routing fixed. Since each atomic user minimizes its cost, if the game consists of only one user, then the cost of the Nash equilibrium coincides to the optimal one.

In a Stackelberg game, a distinguished atomic Leader player controls flow r_0 and plays first assigning flow s_e on edge $e \in E$. The a posteriori latency $\tilde{\ell}_e(x)$ of edge e on induced flow x equals $\tilde{\ell}_e(x) = \ell_e(x + s_e)$. Intuitively, after Leader's move, the induced selfish play of the k atomic users is equivalent to atomic splittable flows on a graph where each initial edge latency ℓ_e has been mapped to $\tilde{\ell}_e$. In game parlance, each atomic user $i \in \{1, \ldots, k\}$, having *fixed* Leader's strategy, computes his *best reply* against all other atomic users $\{1, \ldots, k\} \backslash \{i\}$. If n_e is the induced Nash flow on edge e, this yields total cost $\sum_{e \in E} (n_e + s_e) \times \tilde{\ell}_e(n_e)$.

Atomic Unsplittable Flows

The users are finite $1, \ldots, k$ and user i is allowed to send his non-negligible job r_i only on a *single* path. Despite this restriction, all definitions given in atomic splittable model remain the same.

Key Results

Let us see first the case of atomic splittable flows, on parallel M/M/1 links with different speeds connecting a given source-destination pair of vertices.

Theorem 1 (Korilis, Lazar, Orda [6]) *The Leader can enforce in polynomial time the network optimum if his/her controls flow* r_0 *exceeding a critical value* $\underline{r}^0$.

In the sequel, we focus on nonatomic flows on $s-t$ graphs with parallel links. In [6] primarily were studied cases that Leader's flow cannot induce network's optimum and was shown that an optimal Stackelberg strategy is easy to compute. In this vain, if $s-t$ parallel link instances are restricted to ones with linear latencies of equal slope, then an optimal strategy is easy [4].

Theorem 2 (Kaporis, Spirakis [4]) *The optimal Leader strategy can be computed in polynomial time on any instance (G, r, α) where G is an $s-t$ graph with parallel links and linear latencies of equal slope.*

Another positive result is that the optimal strategy can be approximated within $(1+\epsilon)$ in polynomial time, given that link latencies are polynomials with nonnegative coefficients.

Theorem 3 (Kumar, Marathe [8]) *There is a fully polynomial approximate Stackelberg scheme that runs in poly $\left(m, \frac{1}{\epsilon}\right)$ time and outputs a strategy with cost $(1+\epsilon)$ within the optimum strategy.*

For parallel link $s-t$ graphs with arbitrary latencies more can be achieved: in polynomial time a "threshold" value α_G is computed, sufficient for the Leader's portion to induce the optimum. The complexity of computing optimal strategies changes in a dramatic way around the critical value α_G from "hard" to "easy" (G, r, α) Stackelberg scheduling instances. Call α_G as the *Price of Optimum* for graph G.

Theorem 4 (Kaporis, Spirakis [4]) *On an input $s-t$ parallel link graph G with arbitrary strictly increasing latencies, the minimum portion α_G sufficient for a Leader to induce the optimum, as well as his/her optimal strategy, can be computed in polynomial time.*

As a conclusion, the Price of Optimum α_G essentially captures the hardness of instances (G, r, α). Since, for Stackelberg scheduling instances $(G, r, \alpha \geq \alpha_G)$, the optimal Leader strategy yields PoA $= 1$ and it is computed as hard as in P, while for $(G, r, \alpha < \alpha_G)$ the optimal strategy yields PoA < 1 and it is as easy as *NP* [10].

The results above are limited to parallel links connecting a given $s-t$ pair of vertices. Is it possible to efficiently compute the Price of Optimum for nonatomic flows on arbitrary graphs? This is not trivial to settle. Not only because it relies on computing an optimal Stackelberg strategy, which is hard to tackle [10], but also because Proposition B.3.1 in [11] ruled out previously known performance guarantees for Stackelberg strategies on general nets.

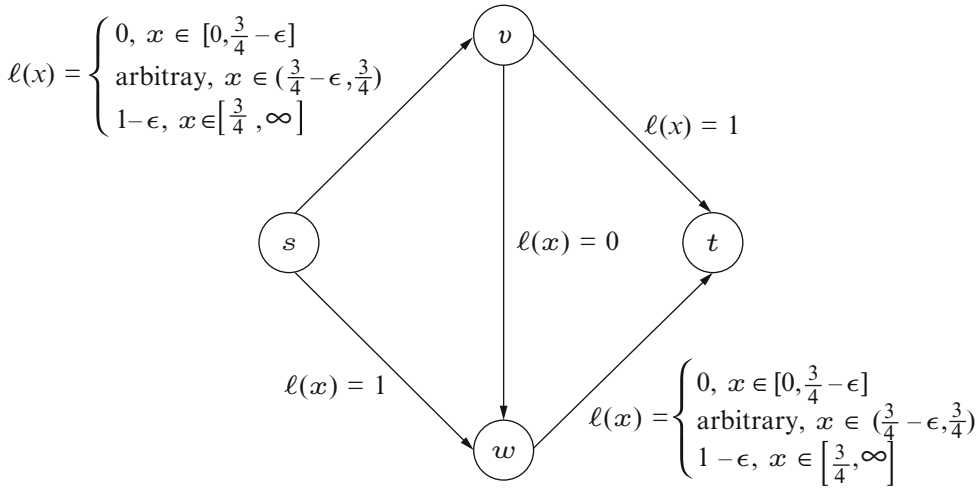
The central result of this lemma is presented below and completely resolves this question (extending Theorem 4).

Theorem 5 (Kaporis, Spirakis [4]) *On arbitrary $s-t$ graphs G with arbitrary latencies, the minimum portion α_G sufficient for a Leader to induce the optimum, as well as her optimal strategy, can be computed in polynomial time.*

Example

Consider the optimum assignment O of flow r that wishes to travel from source vertex s to sink t. O assigns flow o_e incurring latency $\ell_e(o_e)$ per edge $e \in G$. Let $\mathcal{P}_{s\to t}$ the set of all $s-t$ paths. The *shortest paths* in $\mathcal{P}_{s\to t}$ with respect to costs $\ell_e(o_e)$ per edge $e \in G$ can be computed in polynomial time. That is, the paths that given flow assignment O achieve path latency: $\min_{P\in\mathcal{P}_{s\to t}} \left(\sum_{e\in P} \ell_e(o_e)\right)$, i.e., minimize their path latency. It is crucial to observe that if we want the *induced* Nash assignment by the Stackelberg strategy to attain the optimum cost, then these shortest paths are *the only choice* for selfish users that are eager to travel from s to t. Furthermore, the uniqueness of the optimum assignment O determines the minimum part of flow which can be selfishly scheduled on these shortest paths. Observe that any flow assigned by O on a non-shortest $s-t$ path has incentive to opt for a shortest one. Then a Stackelberg strategy *must* freeze the flow on all non-shortest $s-t$ paths.

In particular, the idea sketched above achieves coordination ratio 1 on the graph in Fig. 1. On this graph Roughgarden proved that $\frac{1}{\alpha}\times$ (optimum



Stackelberg Games: The Price of Optimum, Fig. 1 A bad example for Stackelberg routing

cost) guarantee is *not* possible for general (s,t)-networks, Appendix B.3 in [11]. The optimal edge flows are ($r = 1$):

$$o_{s\to v} = \tfrac{3}{4} - \epsilon, o_{s\to w} = \tfrac{1}{4} + \epsilon, o_{v\to w} = \tfrac{1}{2} - 2\epsilon,$$
$$o_{v\to t} = \tfrac{1}{4} + \epsilon, o_{w\to t} = \tfrac{3}{4} - \epsilon$$

The shortest path $P_0 \in \mathcal{P}$ with respect to the optimum O is $P_0 = s \to v \to w \to t$ (see [11] pp. 143, 5th-3th lines before the end) and its flow is $f_{P_0} = \frac{1}{2} - 2\epsilon$. The non-shortest paths are $P_1 = s \to v \to t$ and $P_2 = s \to w \to t$ with corresponding optimal flows: $f_{P_1} = \frac{1}{4} + \epsilon$ and $f_{P_2} = \frac{1}{4} + \epsilon$. Thus, the Price of Optimum is

$$f_{P_1} + f_{P_2} = \frac{1}{2} + 2\epsilon = r - f_{P_0}$$

Applications

Stackelberg strategies are widely applicable in networking [6], see also Section 6.7 in [12].

Open Problems

It is important to extend the above results on atomic unsplittable flows.

2013; Winslow

Problem Definition

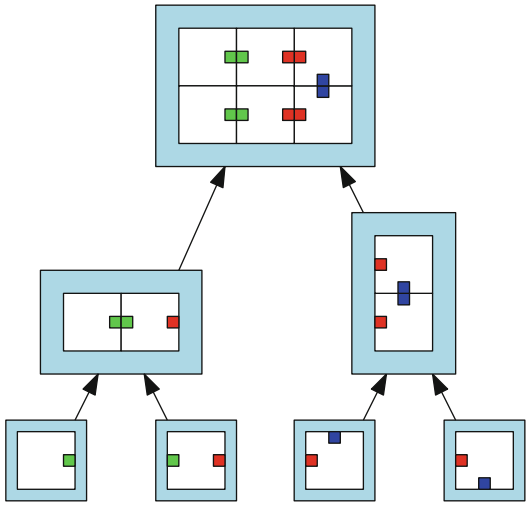
Algorithmic self-assembly is concerned with hands-off assembly of complex structures by mixing collections of simple particles that aggregate according to local rules. Staged self-assembly utilizes sequences of mixings to reduce the number of particle types used. The standard model of staged self-assembly builds on the abstract Tile Assembly Model (aTAM) of Winfree [7], where each particle is a non-rotatable unit square *tile* with a labeled *glue* on each side. Tiles attach to other tiles edgewise via glues of the same label, forming polyomino-shaped aggregates called *assemblies*.

In the simplest model, a pair of assemblies (of which single tiles are a special case) can attach via a single matching glue. In a more general model, a pair of assemblies can attach if they share a total of $\tau \in \mathbb{N}$ glues. The parameter τ is called the *temperature* of the system.

The self-assembly process is carried out by combining an infinite number of copies of a collection of *reagent assemblies* in a *bin*, where they attach in every possible way. The subset of the resulting assemblies that cannot attach to any other assemblies define the *product assemblies* of the mixing, i.e., the set of assemblies that remain once the assembly process is complete. A system consisting of a single bin with single-tile reagent assemblies is a *hierarchical* [2], *two-handed* [1], or *polyomino* [5] self-assembly system.

In a *staged self-assembly system* [3], the products of one bin can be used as the reagents of other bin (see Fig. 1). The directed acyclic graph describing the relationship mixings is called the *mix graph* of the system. An initial set of mixings each have a single tile as the only product assembly and no reagent assemblies.

Objectives In general, the goal is to design a system with a mixing containing a single product assembly of a desired polyomino shape while minimizing the size of some aspect of the system. Several aspects are considered, including the number of distinct tiles (*tile complexity*), number of edges of the mix graph (*mix graph complexity*),



Staged Assembly, Fig. 1 A staged self-assembly system. Each bin (*blue box*) contains the product assemblies of the bin. The reagent assemblies of a bin are the products of other bins (*incoming arrows*)

width of the mix graph (*bin complexity*), height of the mix graph (*stage complexity*), and temperature of the system. The computational complexity of finding an optimal system for an input shape under some measure of system complexity is also considered. In some cases, the desired polyomino shape also has each cell labeled, and the goal is to construct a given labeled shape using labeled tiles.

Problem 1 (Smallest Staged Self-Assembly System)

INPUT*: A labeled polyomino P.*
OUTPUT*: A staged self-assembly system containing a bin with a single product assembly with labeled shape P that is minimum in some measure.*

Key Results

We describe the results by increasing generality of the shapes assembled.

Lines

In the most constrained case, the input polyomino is an unlabeled $1 \times n$ polyomino (a *line*). Lines can be assembled by $\tau = 1$ systems using $O(1)$ tile types, $O(1)$ bins, and $O(\log n)$ stages and mix graph edges. The idea is to repeatedly double the length of a line assembly as proved by Demaine et al. [3].

Demaine, Eisenstat, Ishaque, and Winslow [4] prove that the case of labeled lines is roughly equivalent to the problem of finding the smallest context-free grammar that is a single string consisting of the labels of the line read from left to right. In particular, any context-free grammar $\mathcal{G}$ with $|\mathcal{G}|$ rules and deriving a single string σ can be converted into a $\tau = 1$ staged self-assembly system $\mathcal{S}$ assembling a line with left-to-right label string σ, where the number of edges in the mix graph of $\mathcal{S}$ is $O(|\mathcal{G}|)$. The complexity of the smallest staged self-assembly system where the input polyomino is a labeled line and the system has an upper limit on the number of glue types appearing on the tiles was proven to be NP-hard [4].

Squares

Demaine et al. [3] prove that unlabeled $n \times n$ squares are possible with a $\tau = 1$ staged systems containing $O(1)$ tile types and bins, $O(\log n)$ stages, and thus a mix graph with $O(\log n)$ stages. The system uses an idea similar to that for assembling lines but in two steps: first assemble $n \times 1$ columns and then combine them to form $n \times 2$, then $n \times 4$, etc., rectangles. This construction uses a *jigsaw* technique to ensure attaching rectangles cannot assemble askew.

Demaine et al. also prove that unlabeled $n \times n$ squares can be assembled using $\tau = 2$ staged systems using $O(1)$ tile types, $O(\sqrt{\log n})$ bins, and $O(\log \log n)$ stages. The approach is to *simulate* known $\tau = 2$ single-bin systems that efficiently assemble squares by constructing *macrotiles*: large assemblies that simulate the behavior of distinct tile types by encoding glue types in geometry on their surfaces. Such macrotiles allow staged systems to trade off tile types for stages by replacing many distinct tile types with an initial sequence of stages that assemble macrotile versions of the tiles.

General Shapes

For general shapes, several different results highlight the trade-offs in complexity enabled by staged assembly. Demaine et al. [3] prove that any unlabeled shape can be assembled by a $\tau = 1$ staged system using $O(1)$ tile types, $O(\log n)$ bins, and a number of stages proportional to the diameter of the dual grid graph of the shape. If the shape is monotone, then a similar system with $O(n)$ bins and $O(\log n)$ stages (increased bins but decreased stages) exists.

If the system is permitted to assemble a scaled version of the input shape, then the system of Soloveichik and Winfree [6] can be simulated with macrotiles, resulting in a $\tau = 2$ staged system with $O(1)$ tile types, $O(K/\log K)$ bins, and $O(\log \log K)$ stages, where K is the Kolmogorov complexity of the shape. For labeled shapes, Winslow [8] proves that any polyomino context-free grammar $\mathcal{G}$ (a generalization of context-free grammars to two dimensions) with $|\mathcal{G}|$ rules deriving a single labeled polyomino P can be converted into a staged system $\mathcal{S}$ assembling a scaled version of P consisting of labeled macrotiles where the number of edges in the mix graph of $\mathcal{S}$ is $O(|\mathcal{G}|)$.

Applications

The theory of algorithmic self-assembly is rooted in the design of nanoscale particle systems, particularly DNA-based systems. For staged self-assembly in particular, the capability of assembling complex shapes using only $O(1)$ tile types is highly desirable in practice, as engineering many tile types with desired glues is often far more challenging than carrying out a sequence of mixings.

Open Problems

The complexity of the smallest staged self-assembly problem where the number of glue types used is unconstrained remains open, both for the case of lines and general shapes. For lines, the problem is known to be in NP and when the number of glues is constrained is NP-complete (both proved in [4]). For general shapes, the problem is only known to be in PSPACE (proved in [9]) and NP-hard when the number of glues is constrained, following from the special case of lines. The complexity of verifying that a staged assembly system produces a given shape also remains open and is only known to lie in PSPACE.

Keywords

Multiple HMM; Statistical alignment; Stochastic modeling of insertions and deletions; Time-continuous Markov models

Years and Authors of Summarized Original Work

2003; Hein, Jensen, Pedersen

Problem Definition

The three main types of mutations modifying biological sequences are insertions, deletions, and substitutions. The simplest model involving these three types of mutations is the so-called Thorne-Kishino-Felsenstein model [16]. In this model, the characters of a sequence evolve independently. Each character in the sequence can be substituted with another character according to a prescribed reversible time-continuous Markov model on the possible characters. Insertion-deletions are modeled as a birth-death process. Insertions can happen at the beginning of the sequence, at the end of the sequence, and between any two characters. It is possible to insert a character into the empty sequence. The time span between two insertions is exponentially distributed with parameter λ, and this parameter does not depend on the context of the position. The newborn character is drawn from the equilibrium distribution of the substitution process. Each character is deleted after an exponentially distributed waiting time with parameter μ, and its two positions where insertions can happen are joined.

The multiple statistical alignment problem is to calculate the likelihood of a set of sequences, namely, what is the probability of observing a set of sequences, given all the necessary parameters that describe the evolution of sequences. Hein, Jensen, and Pedersen were the first who gave an algorithm to calculate this probability [5]. Their algorithm has $O(5^n L^n)$ running time, where n is the number of sequences, and L is the geometric mean of the sequences. The running time has been improved to $O(2^n L^n)$ by Lunter et al. [9].

Notations

Substitutions

A time-continuous Markov model for a substitution process on an alphabet Σ is given by a $k \times k$ rate matrix Q, with constraints

$$q_{i,j} \geq 0 \qquad \forall i \neq æ \tag{1}$$

$$\sum_i q_{i,j} = 0 \qquad \forall i \tag{2}$$

where k is the size of the alphabet. The probability that a character a_i will be character a_j after time t can be calculated with the exponentiation of the rate matrix:

$$P_t(a_j|a_i) = p_{i,j} \qquad \text{where} \tag{3}$$

$$P = e^{Qt} \tag{4}$$

The exponentiated matrix can be easily calculated if the rate matrix is diagonalized, namely, if $Q = W\Lambda W^{-1}$, where Λ is a diagonal matrix, then

$$e^{Qt} = We^{\Lambda t}W^{-1} \tag{5}$$

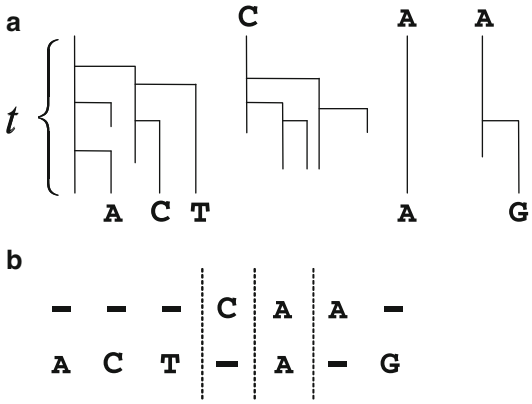
$e^{\Lambda t}$ can be easily calculated, since it is a diagonal matrix containing $e^{\lambda_i t}$ in the ith position of the diagonal.

Insertions and Deletions

A Galton-Watson tree is a rooted, edge-weighted binary tree that describes a birth-death process for a time span t. The process starts at the root of the tree, and a split represents a birth. Edge weights represent times, and leaves having a distance from the root smaller than t represent death events. Leaves being t time fare from the root are the individuals that live at time point t.

Insertion-deletion events transforming one sequence into another can be described with Galton-Watson forests: births represent insertions, and deaths represent deletions. Each character of the ancestral sequence has a tree, and there is an additional tree at the beginning of the sequence associated to an imaginary character. This imaginary character cannot die. Roots of the trees are the characters of the ancestral sequence, and each character of the descendant sequence is a leaf of one of the trees, being t time fare from the root. There might be additional leaves that are not associated with characters of the descendant sequences; these are the died out lineages. The forest is aligned such that edges do not cross each other while the characters of the two sequences keep their original order. Each Galton-Watson forest indicates an alignment of the two sequences; see Fig. 1. Given a birth and death process, the probability density of a Galton-Watson tree can be calculated easily. Assuming independence, the probability of a Galton-Watson forest is the product of the probabilities of its trees. The probability of an alignment is the integral of the probabilities of the forests that represent it. Due to independence, it is enough to tell the probability of alignment patterns that might arise as an image of a Galton-Watson tree (see Fig. 1b); the probability of an alignment is the product of the probabilities of its patterns.

In the Thorne-Kishino-Felsenstein model (TKF91 model) [16], both the birth and the death processes are Poisson processes with parameters λ and μ, respectively. The probability of the possible patterns can be found on Fig. 2.



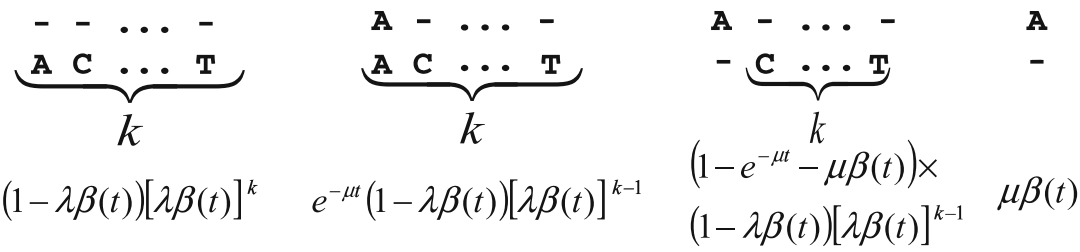
Statistical Multiple Alignment, Fig. 1 (**a**) A Galton-Watson forest representing insertion-deletion events. The first tree starts with an immortal element that is responsible to the insertions at the beginning of the sequence. (**b**) The alignment indicated by the Galton-Watson forest above. Each tree makes a pattern of the alignment; patterns are separated with *dashed lines*

Evolutionary Trees

An evolutionary tree is a leaf-labeled, edge-weighted, rooted binary tree. Labels are the species related by the evolutionary tree, and weights are evolutionary distances. It might happen that the evolutionary changes had different speed at different lineages, and hence the tree is not necessary ultrametric, namely, the root not necessary has the same distance to all leaves. The nodes of an evolutionary tree can be partially ordered such that two nodes are comparable if there is a path from the root to any of the leaves containing the two nodes in question, and in this case the smaller node is the one that is closer to the root on the path. Each node v of an evolutionary tree indicates a subtree that contains v and all the nodes that are greater than v. Hereafter we consider only these subtrees.

Given a set S of l-long sequences over alphabet Σ, a substitution model M on Σ and an evolutionary tree T are labeled by the sequences. The likelihood of the tree is the probability of observing the sequences at the leaves of the tree, given that the substitution process starts at the root of the tree with the equilibrium distribution. This likelihood is denoted by $P(S|T, M)$. The substitution likelihood problem is to calculate the likelihood of the tree.

Let Σ be a finite alphabet and let $S_1 = s_{1,1}s_{1,2}\ldots s_{1,L_1}$, $S_2 = s_{2,1}s_{2,2}\ldots s_{2,L_2}$, $\ldots$ $S_n = s_{n,1}s_{n,2}\ldots s_{n,L_n}$ be sequences over this alphabet. Let a TKF91 model $TKF91$ be given with its parameters: substitution model M, insertion rate λ, and deletion rate μ. Let T be an evolutionary tree labeled by S_1, S_2, $\ldots$ S_n. The multiple statistical alignment problem is to calculate the likelihood of the tree, $P(S_1, S_2, \ldots S_n|T, TKF91)$, given that



Statistical Multiple Alignment, Fig. 2 The probabilities of alignment patterns. From *left* to *right*: k insertions at the beginning of the alignment, a match followed by $k-1$ insertions, a deletion followed by k insertions, and a deletion not followed by insertions. $\beta = \frac{1-e^{(\lambda-\mu)t}}{\mu-\lambda e^{(\lambda-\mu)t}}$

the TKF91 process starts at the root with the equilibrium distribution.

Multiple Hidden Markov Models

It will turn out that the TKF91 model can be transformed to a multiple Hidden Markov Model; therefore we formally define it here. A multiple Hidden Markov Model (multiple HMM) is a directed graph with distinguished start and end states, (the in degree of the start and the out degree of the end state are both 0), together with the following described transition and emission distributions. Each vertex has a transition distribution over its out edges. The vertexes can be divided into two classes, the emitting and silent states. Each emitting state emits one-one random character to a prescribed set of sequences; it is possible that a state emits only one character to one sequence. For each state, an emission distribution over the alphabet and the set of sequences gives the probabilities which characters will be emitted to which sequences. The Markov process is a random walk from the start to the end, following the transition distribution on the out edges. When the walk is in an emitting state, characters are emitted according to the emission distribution of the state. The process is hidden since the observer sees only the emitted sequences, and the observer does not observe which character is emitted by which state, even the observer does not see which characters are co-emitted. The multiple HMM problem is to calculate the emission probability of a set of sequences for a multiple HMM. This probability can be calculated with the forward algorithm that has $O(V^2L^n)$ running time, where V is the number of emitting states in the multiple HMM, L is the geometric mean of the sequences, and n is the number of sequences [3].

Key Results

Substitutions have been modeled with time-continuous Markov models since the late 1960s [8], and an efficient algorithm for likelihood calculations was published in 1980 [4]. The running time of this efficient algorithm grows linearly both with the number of sequences and with the length of the sequences being analyzed, and it grows squarely with the size of the alphabet. The algorithm belongs to the class of dynamic programming algorithms. For each character, subtree, and position x, the algorithm calculates what would be the likelihood of the characters in position x in the sequences belonging to the subtree if the substitution process started in the root of the subtree with the given character. These probabilities are called conditional likelihoods. It is easy to show that

$$L_p(\alpha, x) = \left(\sum_{\alpha_1} P_{t_1}(\alpha_1|\alpha) L_{d_1}(\alpha_1, x)\right) \left(\sum_{\alpha_2} P_{t_2}(\alpha_2|\alpha) L_{d_2}(\alpha_2, x)\right) \quad (6)$$

where d_1 and d_2 are the descendant nodes of the parent node p and t_1 and t_2 are the length of the edges connecting p with d_1 and d_2, respectively. The likelihood of the tree can be calculated from the conditional likelihoods of the tree. Recall that

$P(S|T, M)$ is the likelihood of observing a set of sequences S on the leaves of an evolutionary tree T under the substitution model M:

$$P(S|T, M) = \prod_x \sum_\alpha L_{root}(\alpha, x)\pi_\alpha \quad (7)$$

Thorne, Kishino, and Felsenstein gave an $O(nm)$ running time algorithm for calculating the likelihood of an n-long and an m-long sequence under their model [16]. It was not clear for long time how to extend this algorithm to more than two sequences. In 2001, several researchers [7,12] realized that the TKF91 model for two sequences is equivalent with a pair Hidden Markov Model (pair HMM) in the sense that the transition and emission probabilities of the pair HMM can be parameterized with λ, μ and the transition and equilibrium probabilities of the substitution model; moreover there is a bijection between the paths emitting the two sequences and alignments such that the probability of a path in the pair HMM equals to the probability of the corresponding alignment of the two sequences. Hence the likelihood of two sequences can be calculated with the forward algorithm of the pair HMM.

After this discovery, it was relatively easy to develop an algorithm for multiple statistical alignment [5]. The key observation is that a multiple HMM can be created as a composition of pair HMMs along the evolutionary tree. This technique was already known in the speech recognition literature [14], and was also rediscovered by Ian Holmes [6], who named this technique as transducer composition. The number of states in the so-created multiple HMM is $O(5^{\frac{n}{2}})$, where n is the number of leaves of the tree. The emission probabilities are the substitution likelihoods on the tree, which can be efficiently calculated as shown above. The running time of the forward algorithm is $5^n L^n$, where L is the geometric mean of the sequence lengths.

Lunter et al. [9] introduced an algorithm that does not need a multiple HMM description of the TKF91 model to calculate the likelihood of a tree. Using a logical sieve algorithm, they were able to reduce the running time to $O(2^n L^n)$. They called their algorithm the "one-state recursion" since their dynamic programming algorithm does not need different state of a multiple HMM to calculate the likelihood correctly.

Applications

Since the running time of the best known algorithm for multiple statistical alignment grows exponentially with the number of sequences, on its own it is not useful in practice. However, Lunter et al. also showed that there is a one-state recursion to calculate the likelihood of the tree given an alignment [10]. The running time of this algorithm grows only linearly with both the alignment length and the number of sequences. Since the number of states in a multiple HMM that can emit the same multiple alignment column might grow exponentially, this version of the one-state recursion is a significant improvement. The one-state recursion for multiple alignments is used in a Bayesian Markov chain Monte Carlo where the state space is the Descartes product of the possible multiple alignments and evolutionary trees. The one-state recursion provides an efficient likelihood calculation for a point in the state space [11].

Csűrös and Miklós introduced a model for gene content evolution that is equivalent with the multiple statistical alignment problem for alphabet size 1 [2]. They gave a polynomial running time algorithm that calculates the likelihood of the tree. The running time is $O(n + hL^2)$, where n is the number of sequences, h is the height of the evolutionary tree, and L is the sum of the sequence lengths.

Thorne, Kishino, and Felsenstein also introduced a fragment model, also called the TKF92 model, in which multiple insertions and deletions are allowed [17]. The birth process is still a Poisson process, but instead of single characters, fragments of characters are inserted with a geometrically distributed length. The fragments are unbreakable, and the death process is going on the fragments. The TKF92 model for a pair of sequences also can be described into a pair HMM and the TKF92 model on a tree can be

transformed to a multiple HMM. Such multiple HMM is used in the StatAlign software package [13]. The software package has been extended to predict the common structure of sequences (e.g., slowly quickly evolving regions, RNA secondary structures) by combining this multiple HMM with other stochastic models describing the structure of sequences [1, 15].

Open Problems

It is conjectured that the multiple statistical alignment problem cannot be solved in polynomial time for any nontrivial alphabet size. One also can ask what the most likely multiple alignment is or, equivalently, what the most probable path in the multiple HMM is that emits the given sequences. For a set of sequences, a TKF91 model, and an evolutionary tree, the decision problem "Is there a multiple alignment that is more probable than p" is conjectured to be NP-complete.

It is conjectured that there is no one-state recursion for the TKF92 model.

Statistical Query Learning

Vitaly Feldman
IBM Research – Almaden, San Jose, CA, USA

Keywords

Classification noise; Noise-tolerant learning; PAC learning; SQ dimension; Statistical query

Years and Authors of Summarized Original Work

1998; Kearns

Problem Definition

The problem deals with learning to classify from random labeled examples in Valiant's PAC model [30]. In the *random classification noise* model of Angluin and Laird [1], the label of each example given to the learning algorithm is flipped randomly and independently with some fixed probability η called the *noise rate*. Robustness to such benign form of noise is an important goal in the design of learning algorithms. Kearns defined a powerful and convenient framework for constructing noise-tolerant algorithms based on *statistical queries*. Statistical query (SQ) learning is a natural restriction of PAC learning that models algorithms that use statistical properties of a data set, rather than individual examples. Kearns demonstrated that any learning algorithm that is based on statistical queries can be automatically converted to a learning algorithm in the presence of random classification noise of arbitrary rate smaller than the information-theoretic barrier of $1/2$. This result was used to give the first noise-tolerant algorithm for a number of important learning problems. In fact, virtually all known noise-tolerant PAC algorithms were either obtained from SQ algorithms or can be easily cast into the SQ model.

In subsequent work, the model of Kearns has been extended to other settings and found a number of additional applications in machine learning and theoretical computer science.

Definitions and Notation

Let $\mathcal{C}$ be a class of $\{-1, +1\}$-valued functions (also called *concepts*) over an input space X. In the basic PAC model, a learning algorithm is given examples of an unknown function f from $\mathcal{C}$ on points randomly chosen from some unknown distribution $\mathcal{D}$ over X and should produce a hypothesis h that approximates f. More formally, an *example oracle* $\mathrm{EX}(f, \mathcal{D})$ is an oracle that upon being invoked returns an example $\langle x, f(x)\rangle$, where x is chosen randomly with respect to $\mathcal{D}$, independently of any previous examples. A learning algorithm for $\mathcal{C}$ is an algorithm that for every $\epsilon > 0$, $\delta > 0$, $f \in \mathcal{C}$, and distribution $\mathcal{D}$ over X, given ϵ, δ, and access to $\mathrm{EX}(f, \mathcal{D})$ outputs, with probability at least $1 - \delta$, a hypothesis h that ϵ-approximates f with respect to $\mathcal{D}$ (i.e., $\mathbf{Pr}_{\mathcal{D}}[f(x) \neq h(x)] \leq \epsilon$). Efficient learning algorithms are algorithms that run in time polynomial in $1/\epsilon$, $1/\delta$ and the size of the learning problem s. The size of a learning problem is determined by the description length of f under some fixed representation scheme for functions in $\mathcal{C}$ and the description length of an element in X (often proportional to the dimension n of the input space).

A number of variants of this basic framework are commonly considered. The basic PAC model is also referred to as *distribution-independent* learning to distinguish it from *distribution-specific* PAC learning in which the learning algorithm is required to learn with respect to a single distribution $\mathcal{D}$ known in advance. A *weak* learning algorithm is a learning algorithm that can produce a hypothesis whose error on the target concept is noticeably less than $1/2$ (and not necessarily any $\epsilon > 0$). More precisely, a weak learning algorithm produces a hypothesis h such that $\mathbf{Pr}_{\mathcal{D}}[f(x) \neq h(x)] \leq 1/2 - 1/p(s)$ for some fixed polynomial p. The basic PAC model is often referred to as *strong* learning in this context.

In the random classification noise model $\mathrm{EX}(f, \mathcal{D})$ is replaced by a faulty oracle $\mathrm{EX}^{\eta}(f, \mathcal{D})$, where η is the noise rate. When queried, this oracle returns a noisy example $\langle x, b\rangle$ where $b = f(x)$ with probability $1 - \eta$ and $\neg f(x)$ with probability η independently of previous examples. When η approaches $1/2$ the label of the corrupted example approaches the result of a random coin flip, and therefore, the running time of learning algorithms in this model is allowed to depend on $\frac{1}{1-2\eta}$ (the dependence must be polynomial for the algorithm to be considered efficient). For simplicity, one usually assumes that η is known to the learning algorithm. This assumption can be removed using a simple technique due to Laird [26].

To formalize the idea of learning from statistical properties of a large number of examples, Kearns introduced a new oracle $\mathrm{STAT}(f, \mathcal{D})$ that replaces $\mathrm{EX}(f, \mathcal{D})$. The oracle $\mathrm{STAT}(f, \mathcal{D})$ takes

as input a *statistical query* (SQ) of the form (χ, τ), where χ is a $\{-1, +1\}$-valued function on labeled examples and $\tau \in [0, 1]$ is the *tolerance* parameter. Given such a query, the oracle responds with an estimate v of $\mathbf{Pr}_{\mathcal{D}}[\chi(x, f(x)) = 1]$ that is accurate to within an additive $\pm\tau$.

Note that the oracle does not guarantee anything else on the value v beyond $|v - \mathbf{Pr}_{\mathcal{D}}[\chi(x, f(x)) = 1]| \leq \tau$ and an SQ learning algorithm needs to work with any possible implementation of the oracle. Yang proposed a stronger, *honest* version of the oracle which to a call with function χ returns the value of $\chi(x, f(x))$, where x is chosen randomly and independently according to $\mathcal{D}$ [32]. This version was shown to be equivalent to the original model up to polynomial factors [17].

Chernoff bounds easily imply that $\mathrm{STAT}(f, \mathcal{D})$ can, with high probability, be simulated using $\mathrm{EX}(f, \mathcal{D})$ by estimating $\mathbf{Pr}_{\mathcal{D}}[\chi(x, f(x)) = 1]$ on $O(\tau^{-2})$ examples. Therefore, the SQ model is a restriction of the PAC model. Efficient SQ algorithms allow only efficiently evaluatable χ's and impose an inverse polynomial lower bound on the tolerance parameter over all oracle calls. Kearns also observes that in order to simulate all the statistical queries used by an algorithm, one does not necessarily need new examples for each estimation. Instead, assuming that the set of possible queries of the algorithm has Vapnik-Chervonenkis dimension d, all its statistical queries can be simulated using $\tilde{O}(d\,\tau^{-2}(1-2\eta)^{-2}\log(1/\delta))$ examples [24].

Key Results

Statistical Queries and Noise-Tolerance

The main result given by Kearns is a way to simulate statistical queries using noisy examples.

Lemma 1 ([24]) *Let (χ, τ) be a statistical query such that χ can be evaluated on any input in time T and let $\mathrm{EX}^{\eta}(f, \mathcal{D})$ be a noisy oracle. The value $\mathbf{Pr}_{\mathcal{D}}[\chi(x, f(x)) = 1]$ can, with probability at least $1-\delta$, be estimated within τ using $O(\tau^{-2}(1-2\eta)^{-2}\log(1/\delta))$ examples from $\mathrm{EX}^{\eta}(f, \mathcal{D})$ and time $O(\tau^{-2}(1-2\eta)^{-2}\log(1/\delta)\cdot T)$.*

This simulation is based on estimating several probabilities using examples from the noisy oracle and then offsetting the effect of noise. The lemma implies that any efficient SQ algorithm for a concept class $\mathcal{C}$ can be converted to an efficient learning algorithm for $\mathcal{C}$ tolerating random classification noise of any rate $\eta < 1/2$.

Theorem 1 ([24]) *Let $\mathcal{C}$ be a concept class efficiently* PAC *learnable from statistical queries. Then $\mathcal{C}$ is efficiently* PAC *learnable in the presence of random classification noise of rate η for any $\eta < 1/2$.*

Balcan and Feldman describe more general conditions on noise under which a specific SQ algorithm can be simulated in the presence of noise [3].

Statistical Query Algorithms

Kearns showed that, despite the major restriction on the way an SQ algorithm accesses the examples, many PAC learning algorithms known at the time can be modified to use statistical queries instead of random examples [24]. Examples of learning algorithms for which he described an SQ analogue and thereby obtained a noise-tolerant learning algorithm include:

- Learning decision trees of constant rank.
- *Attribute-efficient* algorithms for learning conjunctions.
- Learning axis-aligned rectangles over $\mathbb{R}^n$.
- Learning AC^0 (constant-depth unbounded fan-in) Boolean circuits over $\{0,1\}^n$ with respect to the uniform distribution in quasipolynomial time.

Subsequent works have provided numerous additional examples of algorithms used in theory and practice of machine learning that can either be implemented using statistical queries or can be replaced by an alternative SQ-based algorithm of similar complexity. For example, the Perceptron algorithm and learning of linear threshold functions [6, 12], boosting [2], attribute-efficient learning via the Winnow algorithm (cf. [16]), k-means clustering [5] and convex optimization-

based methods [20]. We note that many learning algorithms rely only on evaluations of functions on random examples and therefore can be seen as using access to the honest statistical query oracle. In such cases the SQ implementation follows immediately from the equivalence of the Kearns' SQ oracle and the honest one [17].

The only known example of a technique for which there is no SQ analogue is Gaussian elimination for solving linear equations over a finite field. This technique can be used to learn parity functions that are not learnable using SQs (as we discuss below). As a result, with the exception of the parity learning problem, known bounds on the complexity of learning from random examples are, up to polynomial factors, the same as known bound for learning with statistical queries.

Statistical Query Dimension

The restricted way in which SQ algorithms use examples makes it simpler to understand the limitations of efficient learning in this model. A long-standing open problem in learning theory is learning of the concept class of all parity functions over $\{0,1\}^n$ with noise (a parity function is a XOR of some subset of n Boolean inputs). Kearns has demonstrated that parities cannot be efficiently learned using statistical queries even under the uniform distribution over $\{0,1\}^n$ [24]. This hardness result is unconditional in the sense that it does not rely on any unproven complexity assumptions.

The technique of Kearns was generalized by Blum et al. who proved that efficient SQ learnability of a concept class $\mathcal{C}$ is characterized by a relatively simple combinatorial parameter of $\mathcal{C}$ called the *statistical query dimension* [7]. The quantity they defined, measures the maximum number of "nearly uncorrelated" functions in a concept class. (The definition and the results were simplified and strengthened in subsequent works [17, 29] and we use the improved statements here.) More formally,

Definition 1 For a concept class $\mathcal{C}$ and distribution $\mathcal{D}$, the *statistical query dimension* of $\mathcal{C}$ with respect to $\mathcal{D}$, denoted SQ-DIM$(\mathcal{C},\mathcal{D})$, is the largest number d such that $\mathcal{C}$ contains d functions $f_1, f_2, \ldots, f_d$ such that for all $i \neq j$, $|\mathbf{E}_{\mathcal{D}}[f_i f_j]| \leq \frac{1}{d}$.

Blum et al. relate the SQ dimension to learning in the SQ model as follows.

Theorem 2 ([7, 17]) *Let $\mathcal{C}$ be a concept class and $\mathcal{D}$ be a distribution such that* SQ-DIM$(\mathcal{C},\mathcal{D}) = d$.

- *If all queries are made with tolerance of at least $1/d^{1/3}$, then at least $d^{1/3}-2$ queries are required to learn $\mathcal{C}$ with error $1/2 - 1/(2d^3)$ in the SQ model.*
- *There exists an algorithm for learning $\mathcal{C}$ with respect to $\mathcal{D}$ that makes d fixed queries, each of tolerance $1/(4d)$, and finds a hypothesis with error at most $1/2 - 1/(2d)$.*

Thus SQ-DIM characterizes weak SQ learnability relative to a fixed distribution $\mathcal{D}$ up to a polynomial factor. Parity functions are uncorrelated with respect to the uniform distribution and therefore, any concept class that contains a superpolynomial number of parity functions cannot be learned by statistical queries with respect to the uniform distribution. This, for example, includes such important concept classes as *k-juntas* over $\{0,1\}^n$ (or functions that depend on at most k input variables) for $k = \omega(1)$ and *decision trees* of superconstant size.

Simon showed that (strong) PAC learning relative to a fixed distribution $\mathcal{D}$ using SQs can also be characterized by a more general and involved dimension [28]. Simpler and tighter characterizations of distribution-specific PAC learning using SQs have been demonstrated by Feldman [15] and Szörényi [29]. Feldman also extended the characterization to the agnostic learning model.

Despite characterizing the number of queries of certain tolerance, the SQ-DIM and its generalizations capture surprisingly well the computational complexity of SQ learning of most concept classes. One reason for this is that if a concept class has polynomial SQ-DIM then it can be learned by a polynomial-time algorithm with advice also referred to as a "non-uniform"

algorithm (cf. [18]). However it was shown by Feldman and Kanade that for strong PAC learning there exist artificial problems whose computational complexity is larger than their statistical query complexity [18].

Applications of these characterizations to proving lower bounds on SQ algorithms can be found in [11, 15, 19, 25]. Relationships of SQ-DIM to other notions of complexity of concept classes were investigated in [22, 27].

Applications

The ideas behind the use of statistical queries to produce noise-tolerant algorithms were adapted to learning using *membership queries* (or ability to ask for the value of the unknown function at any point) and used to give a noise-tolerant algorithm for learning DNF with respect to the uniform distribution [9, 21]. The SQ model of learning was generalized to active learning (or learning where labels are requested only for some of the points) and used to obtain new efficient noise-tolerant active learning algorithms [3].

The restricted way in which an SQ algorithm uses data implies it can be used to obtain learning algorithms with additional useful properties. Blum et al. [5] show that an SQ algorithm can be used to obtain a *differentially-private* [13] algorithm for the problem. In fact, SQ algorithms are equivalent to *local* (or *randomized-response*) differentially-private algorithms [23]. Chu et al. [10] show that SQ algorithms can be automatically parallelized on multicore architectures and give many examples of popular machine learning algorithms that can be sped up using this approach.

The SQ learning model has also been instrumental in understanding Valiant's model of evolution as learning [31]. Feldman showed that the model is equivalent to learning with a restricted form of SQs referred to as correlational SQs [14]. A correlational SQ is a query of the form $\chi(x, \ell) = g(x) \cdot \ell$ for some $g : X \to [-1, 1]$. Such queries were first studied by Ben-David et al. [4] (remarkably, before the introduction of the SQ model itself) and distribution-specific learning with such queries is equivalent to learning with (unrestricted) SQs.

Statistical query-based access can naturally be defined for any problem where the input is a set of i.i.d. samples from a distribution. Feldman et al. show that lower bounds based on SQ-DIM can be extended to this more general setting and give examples of applications [17, 20].

Open Problems

The main questions related to learning with random classification noise are still open. Is every concept class efficiently learnable in the PAC model also learnable in the presence of random classification noise? Is every concept class efficiently learnable in the presence of random classification noise of arbitrarily high rate (less than $1/2$) also efficiently learnable using statistical queries? A partial answer to this question was provided by Blum et al. who show that Gaussian elimination can be used in low dimension to obtain a class learnable with random classification noise of constant rate $\eta < 1/2$ but not learnable using SQs [8]. For both questions a central issue seems to be obtaining a better understanding of the complexity of learning parities with noise.

The complexity of learning from statistical queries remains an active area of research with many open problems. For example, there is currently an exponential gap between known lower and upper bounds on the complexity of distribution-independent SQ learning of polynomial-size DNF formulae and AC^0 circuits (cf. [27]). Several additional open problems on complexity of SQ learning can be found in [16, 19, 22].

Problem Definition

The timing behavior of integrated systems is strongly affected by the characteristics of transistors and wires in the system. Variations in the manufacturing process can cause drifts in these characteristics from one manufactured part to another. The traditional approach to addressing these variations was to choose a worst-case value for each process parameter, but this has become unsustainable in the face of current-day variations. Statistical timing analysis provides a computationally efficient way to translate the probability density function of the underlying process parameter spread to the distribution of circuit timing.

A key underlying structure for timing analysis is a graph $G(V, E)$ of a combinational circuit, where the vertex set V corresponds to the gates, primary inputs, and primary outputs of the circuit, and each connection between these gates corresponds to an edge in E. The delay of each gate corresponds to a probability distribution that is a function of the distributions of the underlying (possibly correlated) process parameters, and the task of combinational statistical timing analysis is to obtain the distribution of the maximum (or minimum) delay of the circuit, over all primary outputs. The extension of this problem to general edge-triggered sequential circuits is straightforward. Such circuits can be decomposed into independent combinational blocks, and the maximum (or minimum) operator acts on the delay distribution at all primary outputs of all combinational blocks of the sequential circuit.

Key Results

The framework that is used for statistical timing analysis is based on graph-based topological traversals that maintain a closed-form structure for the delay from the primary inputs of the circuit to the output of each vertex (referred to as the *arrival time*). The computation under this paradigm scales linearly with $|E|$. While it is certainly possible to perform statistical timing analysis through Monte Carlo simulations based on samples of the process parameter space, such an approach is uncompetitive compared to graph traversal algorithms. The traversal approach consists of three key steps [1, 2]:

- Translating the underlying process parameter variations to an orthogonal set of random variables
- Representing gate delay variations in terms of this orthogonal set
- Performing a topological traversal of G and computing the arrival time at each node and maximum delay of the circuit

Orthogonalizing Process Parameter Distributions

A common assumption is that the underlying process parameters, such as the transistor width W and effective length L_{eff} of devices, gate oxide thickness (T_{ox}), and device threshold voltage (V_{t}) due to random dopant fluctuations, show a Gaussian distribution. Each individual device is separately represented by such a parameter. The distributions of T_{ox} and V_{t} are largely uncorrelated across devices. In contrast, the dimension-based parameters, W and L_{eff}, show strong spatial correlations, whereby the distributions of nearby devices are strongly correlated, and this correlation falls off as a function of distance.

The existence of correlations can significantly complicate the task of statistical timing analysis, since all pairwise combinations of random variables must be considered during the optimization, potentially leading to quadratic complexity in $|V|$. To overcome this, an initial principal component analysis (PCA) [7] step is carried out that orthogonalizes the underlying Gaussians, enabling linear-time analysis. PCA is a one-time operation for a given process (which is used for numerous designs). Therefore, although its worst-case com-

plexity is cubic in $|V|$, the expense is practically manageable as it is amortized over numerous designs. Furthermore, sparsity properties of the correlation matrix realistically imply that in practice, the cost of PCA scales considerably slower than this cubic rate.

For cases where the underlying process parameters may be a mix of Gaussians or non-Gaussians, it is possible to orthogonalize the Gaussian parameters using PCA and non-Gaussian parameters using independent component analysis (ICA) [4]. The approach in [8] extends the graph-based approach presented here and shows how statistical timing analysis can be performed for case where some or all process parameters are non-Gaussian.

Gate Delay Distribution

To build a model for the gate delay that captures the underlying variations in process parameters, we observe that the delay function $d = f(\mathbf{P})$, where $\mathbf{P}$ is a set of process parameters, can be approximated d linearly using a first-order Taylor expansion:

$$d = d_0 + \sum_{\forall \text{ parameters } p_i} \left[\frac{\partial f}{\partial p_i}\right]_0 \Delta p_i \quad (1)$$

where d_0 is the nominal value of d, calculated at the nominal values of parameters in the set $\mathbf{P}$; $\left[\frac{\partial f}{\partial p_i}\right]_0$ is computed at the nominal values of p_i; $\Delta p_i = p_i - \mu_{p_i}$ is a normally distributed random variable; and $\Delta p_i \sim N(0, \sigma_{p_i})$. The delay function here can be arbitrarily complex.

If all parameters in $\mathbf{P}$ can be modeled by Gaussian distributions, this approximation implies that d is a linear combination of Gaussians, which is therefore Gaussian. Its mean μ_d and variance σ_d^2 are

$$\mu_d = d_0 \quad (2)$$

$$\sigma_d^2 = \sum_{\forall i} \left[\frac{\partial f}{\partial p_i}\right]_0^2 \sigma_{p_i}^2 + 2 \sum_{\forall i \neq j} \left[\frac{\partial f}{\partial p_i}\right]_0 \left[\frac{\partial f}{\partial p_j}\right]_0 \text{cov}\left(p_i, p_j\right) \quad (3)$$

where $\text{cov}\left(p_i, p_j\right)$ is the covariance of p_i and p_j.

This approximation is valid when Δp_i has relatively small variations, in which domain the first-order Taylor expansion is adequate and the approximation is acceptable with little loss of accuracy. This is generally true of the impact of within-die variations on delay, where the process parameter variations are relatively small in comparison with the nominal values, and the function changes by a small amount under this perturbation. Hence, the delays, as functions of the process parameters, can be approximated as normal distributions when the parameter variations are assumed to be normal. Higher-order expansions based on quadratics have also be explored to cover cases where the variations are larger [6, 11].

Circuit Delay Distribution

A PCA-based approach maintains the invariant that the output arrival time at each gate is a Gaussian variable represented as

$$a_i(p_1, \ldots, p_n) = a_i^0 + \sum_{i=1}^{n} k_i p_i' + k_{n+1} p_{n+1}' \quad (4)$$

Here, the primed variables correspond to the principal components of the unprimed variables and maintain the form of the arrival time after each sum and max operation. Gate delays, as represented in Eq. 1, can be translated into a similar representation based on principal components as a one-time step during gate library characterization. Under orthogonalization, many operations become much simpler since the covariance terms disappear: for example, Eq. 3 can

be evaluated in linear time instead of quadratic time.

The task of statistical timing analysis is to translate these gate delay distributions to circuit delay probabilities while performing a topological traversal. The operations performed at each node encountered during this traversal in STA are of two types [5]:

- A gate (vertex) is being processed in STA when the arrival times of all inputs are known, at which time the candidate delay values at the output are computed using the "sum" operation that adds the delay at each input with the input-to-output pin delay.
- Once these candidate delays have been found, the "max" operation is applied to determine the maximum arrival time at the output.

Since the gate delays are Gaussian, the "sum" operation is merely an addition of Gaussians, which is well known to be a Gaussian. The computation of the max function, however, poses greater problems. The set of candidate delays are all Gaussian, so that this function must find the maximum of Gaussians. Such a maximum may be reasonably approximated using a Gaussian [3]. A detailed description of how the invariant representation is maintained under the max operation is presented in [1, 2].

The cost of this method corresponds to running a bounded number of deterministic STAs, and it is demonstrated to be accurate, given the statistics of **P**.

Applications

Statistical timing analysis has been extensively used in industry [10] and has seeded a large amount of academic research. Integrated circuit manufacturing foundries have promoted the use of statistical timing analysis by providing PCA-like information with their process parameter models, thus enabling design flows that are statistically based.

The ideas of statistical analysis have also motivated simpler and more approximate methods, used in industry today, based on on-chip variation (OCV) derating factors. In its most elementary form, OCV adds margins to each timing path to account for possible variation. More involved versions of OCV, such as advanced OCV (AOCV), capture the essence of spatial correlation by using derating factors that depend on factors such as spatial distance and logical depth of a path [9].

Experimental Results

Statistical timing analysis based on orthogonalization brings down the computational cost from quadratic to linear in the number of variables and can be applied to large circuit instances. The method is capable of considering both spatial correlations and structural correlations, i.e., correlations between paths that share gates, since such correlations are embedded into the invariant representation. This makes the approach accurate and computationally practical, as described in [1, 2, 10] and the large body of follow-on work.

Steiner Forest

Guido Schäfer
Institute for Mathematics and Computer Science, Technical University of Berlin, Berlin, Germany

Keywords

Requirement join; *R*-join

Years and Authors of Summarized Original Work

1995; Agrawal, Klein, Ravi

Problem Definition

The *Steiner forest problem* is a fundamental problem in network design. Informally, the goal is to establish connections between pairs of vertices in a given network at minimum cost. The problem generalizes the well-known *Steiner tree problem*. As an example, assume that a telecommunication company receives communication requests from their customers. Each customer asks for a connection between two vertices in a given network. The company's goal is to build a minimum cost network infrastructure such that all communication requests are satisfied.

Formal Definition and Notation

More formally, an instance $I = (G, c, R)$ of the Steiner forest problem is given by an undirected graph $G = (V, E)$ with vertex set V and edge set E, a non-negative cost function $c: E \to \mathbb{Q}^+$, and a set of vertex pairs $R = \{(s_1, t_1), \ldots, (s_k, t_k)\} \subseteq V \times V$. The pairs in R are called *terminal pairs*. A feasible solution is a subset $F \subseteq E$ of the edges of G such that for every terminal pair $(s_i, t_i) \in R$ there is a path between s_i and t_i in the subgraph $G[F]$ induced by F. Let the cost $c(F)$ of F be defined as the total cost of all edges in F, i.e., $c(F) = \sum_{e \in F} c(e)$. The goal is to find a feasible solution F of minimum cost $c(F)$. It is easy to see that there exists an optimum solution which is a forest.

The Steiner forest problem may alternatively be defined by a set of *terminal groups* $R = \{g_1, \ldots, g_k\}$ with $g_i \subseteq V$ instead of terminal pairs. The objective is to compute a minimum cost subgraph such that all terminals belonging to the same group are connected. This definition is equivalent to the one given above.

Related Problems

A special case of the Steiner forest problem is the *Steiner tree problem* (see also the entry ▸ Steiner Trees). Here, all terminal pairs share a common root vertex $r \in V$, i.e., $r \in \{s_i, t_i\}$ for all terminal pairs $(s_i, t_i) \in R$. In other words, the problem consists of a set of terminal vertices $R \subseteq V$ and a root vertex $r \in V$ and the goal is to connect the

terminals in R to r in the cheapest possible way. A minimum cost solution is a tree.

The *generalized Steiner network problem* (see the entry ▸ Generalized Steiner Network), also known as the *survivable network design problem*, is a generalization of the Steiner forest problem. Here, a *connectivity requirement* function $r: V \times V \to \mathbb{N}$ specifies the number of edge disjoint paths that need to be established between every pair of vertices. That is, the goal is to find a minimum cost multi-subset H of the edges of G (H may contain the same edge several times) such that for every pair of vertices $(x, y) \in V$ there are $r(x, y)$ edge disjoint paths from x to y in $G[H]$. The goal is to find a set H of minimum cost. Clearly, if $r(x, y) \in \{0, 1\}$ for all $(x, y) \in V \times V$, this problem reduces to the Steiner forest problem.

Key Results

Agrawal, Klein and Ravi [1, 2] give an approximation algorithm for the Steiner forest problem that achieves an approximation ratio of 2. More precisely, the authors prove the following theorem.

Theorem 1 *There exists an approximation algorithm that for every instance $I = (G, c, R)$ of the Steiner forest problem, computes a feasible forest F such that*

$$c(F) \leq \left(2 - \frac{1}{k}\right) \cdot \mathsf{OPT}(I),$$

where k is the number of terminal pairs in R and $\mathsf{OPT}(I)$ is the cost of an optimal Steiner forest for I.

Related Work

The Steiner tree problem is NP-hard [10] and APX-complete [4, 8]. The current best lower bound on the achievable approximation ratio for the Steiner tree problem is 1.0074 [21]. Goemans and Williamson [11] generalized the results obtained by Agrawal, Klein and Ravi to a larger class of connectivity problems, which they term *constrained forest problems*. For the Steiner forest problem, their algorithm achieves the same approximation ratio of $(2 - 1/k)$. The algorithms of Agrawal, Klein and Ravi [2] and Goemans and Williamson [11] are both based on the classical *undirected cut formulation* for the Steiner forest problem [3]. The integrality gap of this relaxation is known to be $(2 - 1/k)$ and the results in [2, 11] are therefore tight. Jain [15] presents a 2-approximation algorithm for the generalized Steiner network problem.

Primal-Dual Algorithm

The main ideas of the algorithm by Agrawal, Klein and Ravi [2] are sketched below; subsequently, AKR is used to refer to this algorithm. The description given here differs from the one in [2]; the interested reader is referred to [2] for more details.

The algorithm is based on the following integer programming formulation for the Steiner forest problem. Let $I = (G, c, R)$ be an instance of the Steiner forest problem. Associate an indicator variable $x_e \in \{0, 1\}$ with every edge $e \in E$. The value of x_e is 1 if e is part of the forest F and 0 otherwise. A subset $S \subseteq V$ of the vertices is called a *Steiner cut* if there exists at least one terminal pair $(s_i, t_i) \in R$ such that $|\{s_i, t_i\} \cap S| = 1$; S is said to *separate* terminal pair (s_i, t_i). Let $\mathcal{S}$ be the set of all Steiner cuts. For a subset $S \subseteq V$, define $\delta(S)$ as the the set of all edges in E that have exactly one endpoint in S. Given a Steiner cut $S \in \mathcal{S}$, any feasible solution F of I must contain at least one edge that *crosses* the cut S, i.e., $\sum_{e \in \delta(S)} x_e \geq 1$. This gives rise to the following *undirected cut formulation*:

$$\text{minimize} \quad \sum_{e \in E} c(e) x_e \qquad \text{(IP)}$$

$$\text{subject to} \quad \sum_{e \in \delta(S)} x_e \geq 1 \quad \forall S \in \mathcal{S} \qquad (1)$$

$$x_e \in \{0, 1\} \quad \forall e \in E. \qquad (2)$$

The dual of the linear programming relaxation of (IP) has a variable y_S for every Steiner cut $S \in \mathcal{S}$. There is a constraint for every edge $e \in E$ that requires that the total dual assigned to sets $S \in \mathcal{S}$ that contain exactly one endpoint of e is at most the cost $c(e)$ of the edge:

$$\text{maximize} \quad \sum_{S \in \mathcal{S}} y_S \qquad \text{(D)}$$

$$\text{subject to} \quad \sum_{S \in \mathcal{S}: e \in \delta(S)} y_S \leq c(e) \quad \forall e \in E \quad (3)$$

$$y_S \geq 0 \quad \forall S \in \mathcal{S}. \quad (4)$$

Algorithm AKR is based on the *primal-dual schema* (see, e.g., [22]). That is, the algorithm constructs both a feasible primal solution for (IP) and a feasible dual solution for (D). The algorithm starts with an infeasible primal solution and reduces its degree of infeasibility as it progresses. At the same time, it creates a feasible dual packing of subsets of large total value by raising dual variables of Steiner cuts.

One can think of an execution of AKR as a process over time. Let x^τ and y^τ, respectively, be the primal incidence vector and feasible dual solution at time τ. Initially, let $x_e^0 = 0$ for all $e \in E$ and $y_S^0 = 0$ for all $S \in \mathcal{S}$. Let F^τ denote the forest corresponding to the set of edges with $x_e^\tau = 1$. A tree T in F^τ is called *active* at time τ if it contains a terminal that is separated from its mate; otherwise it is *inactive*. Intuitively, AKR grows trees in F^τ that are active. At the same time, the algorithm raises dual values of Steiner cuts that correspond to active trees. If two active trees collide, they are merged. The process terminates if all trees are inactive and thus there are no unconnected terminal pairs. The interplay of the primal (growing trees) and the dual process (raising duals) is somewhat subtle and outlined next.

An edge $e \in E$ is *tight* if the corresponding constraint (3) holds with equality; a path is tight if all its edges are tight. Let H^τ be the subgraph of G that is induced by the tight edges for dual y^τ. The connected components of H^τ induce a partition $\mathcal{C}^\tau$ on the vertex set V. Let $\mathcal{S}^\tau$ be the set of all Steiner cuts contained in $\mathcal{C}^\tau$, i.e., $\mathcal{S}^\tau = \mathcal{C}^\tau \cap \mathcal{S}$. AKR raises the dual values y_S for all sets $S \in \mathcal{S}^\tau$ uniformly at all times $\tau \geq 0$. Note that y^τ is dual feasible. The algorithm maintains the invariant that F^τ is a subgraph of H^τ at all times. Consider the event that a path P between two trees T_1 and T_2 of F^τ becomes tight. The missing edges of P are then added to F^τ and the process continues. Eventually, all trees in F^τ are inactive and the process halts.

Applications

The computation of (approximate) solutions for the Steiner forest problem has various applications both in theory and practice; only a few recent developments are mentioned here.

Algorithms for more complex network design problems often rely on good approximation algorithms for the Steiner forest problem. For example, the recent approximation algorithms [6, 9, 12] for the *multi-commodity rent-or-buy problem* (MRoB) are based on the random sampling framework by Gupta et al. [12, 13]. The framework uses a Steiner forest approximation algorithm that satisfies a certain *strictness* property as a subroutine. Fleischer et al. [9] show that AKR meets this strictness requirement, which leads to the current best 5-approximation algorithm for MRoB. The strictness property also plays a crucial role in the boosted sampling framework by Gupta et al. [14] for two-stage stochastic optimization problems with recourse.

Online versions of Steiner tree and forest problems have been studied by by Awerbuch et al. [5] and Berman and Coulston [7]. In the area of algorithmic game theory, the development of *group-strategyproof cost sharing mechanisms* for network design problems such as the Steiner tree problem has recently received a lot of attention; see e.g., [16, 17, 19, 20]. An adaptation of AKR yields such a cost sharing mechanism for the Steiner forest problem [18].

Definition

Given a set of points, called *terminals*, in a metric space, the problem is to find the shortest tree interconnecting all terminals. There are three important metric spaces for Steiner trees, the Euclidean plane, the rectilinear plane, and the edge-weighted network. The Steiner tree problems in those metric spaces are called the *Euclidean Steiner tree (EST)*, the *rectilinear Steiner tree (RST)*, and the *network Steiner tree (NST)*, respectively. EST and RST have been found to have polynomial-time approximation schemes (PTAS) by using adaptive partition. However, for NST, there exists a positive number r such that computing r-approximation is NP-hard. So far, the best performance ratio of polynomial-time approximation for NST is achieved by k-restricted Steiner trees. However, in practice, the iterated 1-Steiner tree is used very often. Actually, the iterated 1-Steiner was proposed as a candidate of good approximation for Steiner minimum trees a long time ago. It has a very good record in computer experiments, but no correct analysis was given showing the iterated 1-Steiner tree having a performance ratio better than that of the minimum spanning tree until the recent work by Du et al. [9]. There is minimal difference in construction of the 3-restricted Steiner tree and the iterated 1-Steiner tree, which makes a big difference in analysis of those two types of trees. Why does the difficulty of analysis make so much difference? This will be explained in this article.
