

UPGRADING AND REPAIRING PCs,

16th Edition

Scott Mueller

que[®]

800 East 96th Street
Indianapolis, Indiana 46240

Contents at a Glance

Introduction	1
1 Development of the PC	9
2 PC Components, Features, and System Design	25
3 Microprocessor Types and Specifications	37
4 Motherboards and Buses	201
5 BIOS	397
6 Memory	457
7 The ATA/IDE Interface	531
8 The SCSI Interface	583
9 Magnetic Storage Principles	619
10 Hard Disk Storage	643
11 Floppy Disk Storage	685
12 High-Capacity Removable Storage	705
13 Optical Storage	737
14 Physical Drive Installation and Configuration	831
15 Video Hardware	867
16 Audio Hardware	941
17 I/O Interfaces from Serial and Parallel to IEEE 1394 and USB	981
18 Input Devices	1015
19 Internet Connectivity	1057
20 Local Area Networking	1101
21 Power Supply and Chassis/Case	1151
22 Building or Upgrading Systems	1209
23 Extreme Modifications: Overclocking, Cooling, and Chassis Upgrades	1253
24 PC Diagnostics, Testing, and Maintenance	1285
25 File Systems and Data Recovery	1353
Appendixes	
A Glossary	1419
B Key Vendor Contact Information	1479
C Troubleshooting Index	1483
List of Acronyms and Abbreviations	1503
Index	1509
On the DVD

Contents

Introduction 1

- New in the 16th Edition 1
- Book Objectives 2
- Is This Book for You? 3
- Chapter-by-Chapter Breakdown 3
- The 16th Edition DVD-ROM 6
 - Video 6
 - Searchable Databases 7
 - Technical Reference 7
- Upgrading and Repairing PCs Bookshelf 7
- Scott's Web Site—
upgradingandrepairingpcs.com 7
- A Personal Note 8

1 Development of the PC 9

- Computer History—Before Personal Computers 10
 - Timeline 10
 - Mechanical Calculators 14
 - The First Mechanical Computer 14
 - Electronic Computers 15
- Modern Computers 16
 - From Tubes to Transistors 16
 - Integrated Circuits 18
 - The First Microprocessor 18
- History of the PC 21
 - Birth of the Personal Computer 21
 - The IBM Personal Computer 22
 - The PC Industry More Than 20 Years Later 23

2 PC Components, Features, and System Design 25

- What Is a PC? 26
 - Who Controls PC Software? 26
 - Who Controls PC Hardware? 28
 - PC Design Guides 32
- System Types 33
- System Components 36

3 Microprocessor Types and Specifications 37

- Pre-PC Microprocessor History 38
- Microprocessors from 1971 to the Present 38
- Processor Specifications 41
 - Data I/O Bus 46
 - Address Bus 47

- Internal Registers (Internal Data Bus) 48
- Processor Modes 49
- Processor Speed Ratings 53
- Processor Speeds and Markings Versus Motherboard Speed 58
- Cyrix Processor Speeds 60
- AMD Processor Speeds 62
- Overclocking 65
- Cache Memory 67
 - How Cache Works 68
 - Level 2 Cache 70
- Processor Features 74
 - SMM (Power Management) 74
 - Superscalar Execution 74
 - MMX Technology 75
 - SSE, SSE2, and SSE3 76
 - 3DNow!, Enhanced 3DNow!, and Professional 3DNow! 77
 - Dynamic Execution 78
 - Dual Independent Bus Architecture 78
 - Hyper-Threading Technology 79
- Processor Manufacturing 80
 - Processor Re-marking 84
 - PGA Chip Packaging 85
 - Single Edge Contact and Single Edge Processor Packaging 86
- Processor Socket and Slot Types 88
 - Zero Insertion Force 90
 - Socket 1 90
 - Socket 2 91
 - Socket 3 92
 - Socket 4 92
 - Socket 5 93
 - Socket 6 93
 - Socket 7 (and Super7) 94
 - Socket 8 95
 - Socket 370 (PGA-370) 95
 - Socket 423 96
 - Socket 478 97
 - Socket A (Socket 462) 97
 - Socket 603 98
 - Socket 754 99
 - Socket 939 and 940 99
 - Socket T 99
 - Processor Slots 100

CPU Operating Voltages	102
Heat and Cooling Problems	104
Math Coprocessors (Floating-Point Units)	105
Processor Bugs	107
Processor Update Feature	107
Processor Codenames	108
Intel-Compatible Processors	
(AMD and Cyrix)	111
AMD Processors	111
Cyrix	111
P1 (086) First-Generation Processors	112
8088 and 8086 Processors	112
80186 and 80188 Processors	113
8087 Coprocessor	113
P2 (286) Second-Generation Processors	113
286 Processors	113
80287 Coprocessor	114
P3 (386) Third-Generation Processors	114
386 Processors	114
386DX Processors	116
386SX Processors	116
386SL Processors	116
80387 Coprocessor	116
P4 (486) Fourth-Generation Processors	117
486 Processors	117
486DX Processors	119
486SL	120
486SX	121
487SX	121
DX2/OverDrive and DX4 Processors	122
Pentium OverDrive for 486SX2 and DX2 Systems	123
AMD 486 (5x86)	124
Cyrix/TI 486	125
P5 (586) Fifth-Generation Processors	125
Pentium Processors	125
First-Generation Pentium Processor	128
Second-Generation Pentium Processor	129
Pentium-MMX Processors	131
Pentium Defects	132
Testing for the FPU Bug	133
Power Management Bugs	133
Pentium Processor Models and Steppings	133
AMD-K5	134
Intel P6 (686) Sixth-Generation Processors	135
Dynamic Execution	135
Dual Independent Bus	136
Other Sixth-Generation Improvements	136
Pentium Pro Processors	136
Pentium II Processors	140
Celeron	150
Pentium III	157
Pentium II/III Xeon	164
Other Sixth-Generation Processors	164
NexGen Nx586	164
AMD-K6 Series	165
AMD Athlon, Duron, and Athlon XP	168
AMD Duron	170
AMD Athlon XP	172
Athlon MP	174
Cyrix/IBM 6x86 (M1) and 6x86MX (MII)	175
VIA C3	176
Intel Pentium 4 (Seventh-Generation) Processors	176
Pentium 4 Extreme Edition	179
Memory Requirements	179
Power Supply Issues	179
Intel Processor Model Numbers	188
Beyond the Pentium 4	189
Eighth-Generation (64-Bit Register) Processors	189
Intel Itanium and Itanium 2	189
AMD Athlon 64 and 64 FX	192
AMD Opteron	196
Processor Upgrades	196
OverDrive Processors	197
Processor Benchmarks	197
Processor Troubleshooting Techniques	198
4 Motherboards and Buses 201	
Motherboard Form Factors	202
PC and XT	204
Full-Size AT	205
Baby-AT	206
LPX	207
ATX	210
microATX	217
FlexATX	219
ITX and Mini-ITX	221
BTX	224
NLX	227
WTX	232
Proprietary Designs	233
Backplane Systems	234
Motherboard Components	237
Processor Sockets/Slots	237
Chipsets	239
Chipset Evolution	239
Intel Chipsets	241
AMD Athlon/Duron Chipsets	243

Traditional North/South Bridge Architecture	243	Silicon Integrated Systems Chipsets for AMD Athlon/Duron Processors	303
Hub Architecture	245	ALiMagik1 for AMD Athlon/Duron Systems	309
High-Speed North-South Bridge Connections	246	NVIDIA nForce Chipsets for Athlon/Duron/Athlon XP	309
Intel's Early 386/486 Chipsets	248	ATI Radeon IGP Chipsets for Athlon/Duron/Athlon XP	312
Fifth-Generation (P5 Pentium Class) Chipsets	249	Intel Workstation Chipsets for Pentium 4 and Xeon	313
Intel 430LX (Mercury)	250	Intel 860	314
Intel 430NX (Neptune)	250	Intel E7205	314
Intel 430FX (Triton)	251	Intel E7505	315
Intel 430HX (Triton II)	252	Chipsets for Athlon 64	315
Intel 430VX (Triton III)	253	AMD 8000 (8151) Chipset	318
Intel 430TX	253	ALi Chipsets for Athlon 64	320
Third-Party (Non-Intel) P5 Pentium Class Chipsets	253	VIA Technologies Chipsets for Athlon 64	321
Sixth-Generation (P6 Pentium Pro/II/III Class) Chipsets	254	NVIDIA	323
Intel 450KX/GX (Orion Workstation/Server)	258	SiS	325
Intel 440FX (Natoma)	258	ATI	328
Intel 440LX	259	Super I/O Chips	328
Intel 440EX	259	Motherboard CMOS RAM Addresses	329
Intel 440BX	259	Motherboard Connectors	330
Intel 440ZX and 440ZX-66	261	System Bus Types, Functions, and Features	338
Intel 440GX	261	The Processor Bus (Front-Side Bus)	345
Intel 450NX	261	The Memory Bus	349
Intel 810, 810E, and 810E2	262	The Need for Expansion Slots	349
Intel 815 Family	265	Types of I/O Buses	350
Intel 820 and 820E	267	The ISA Bus	350
Intel 840	269	The Micro Channel Bus	354
Third-Party (Non-Intel) P6-Class Chipsets	271	The EISA Bus	354
Seventh-Generation (Pentium 4) Chipsets	274	Local Buses	356
Intel 850 Family	278	VESA Local Bus	358
Intel 845 Family	279	The PCI Bus	358
Intel 865 Family	281	PCI-Express	362
Intel 875P	282	Accelerated Graphics Port	364
Intel 915 Chipset Family	282	System Resources	367
Intel 925X Chipset	283	Interrupts	367
Third-Party Pentium 4 Chipsets	283	DMA Channels	374
SiS Chipsets for Pentium 4	283	I/O Port Addresses	376
ALi Corporation Chipsets for Pentium 4	287	Resolving Resource Conflicts	379
ATI Chipsets for Pentium 4	289	Resolving Conflicts Manually	381
VIA Chipsets for Pentium 4	291	Using a System-Configuration Template	381
Athlon/Duron/Athlon XP Chipsets	294	Heading Off Problems: Special Boards	386
AMD Chipsets for Athlon/Duron Processors	294	Plug-and-Play Systems	390
VIA Chipsets for Athlon, Duron, and Athlon XP	297	Motherboard Selection Criteria (Knowing What to Look For)	391
ProSavage KM133	300	Documentation	394
		Using Correct Speed-Rated Parts	395

5 BIOS 397

- BIOS Basics 398
- BIOS Hardware/Software 401
- Motherboard BIOS 402
 - ROM Hardware 403
 - ROM Shadowing 405
 - ROM Chip Types 405
 - ROM BIOS Manufacturers 410
- Upgrading the BIOS 415
 - Where to Get Your BIOS Update 417
 - Determining Your BIOS Version 417
 - Checking the BIOS Date 418
 - Backing Up Your BIOS's CMOS Settings 420
 - Motherboard CMOS RAM Addresses 425
 - Replacing a BIOS ROM 427
 - Year 2000 BIOS Issues 428
- Preboot Environment 428
- CMOS Setup Specifications 430
 - Running or Accessing the CMOS Setup Program 430
 - BIOS Setup Menus 430
 - Maintenance Menu 431
 - Main Menu 432
 - Advanced Menu 433
 - Security Menu 445
 - Power Menu 446
 - Boot Menu (Boot Sequence, Order) 447
 - Exit Menu 448
 - Additional BIOS Setup Features 449
- Plug and Play BIOS 450
 - PnP Device IDs 451
 - ACPI 451
 - Initializing a PnP Device 452
- BIOS Error Messages 453
 - General BIOS Boot Text Error Messages 454
 - ROM BIOS Messages Indicating Boot Failure (No Valid MBR Found) 454

6 Memory 457

- Memory Basics 458
 - ROM 460
 - DRAM 460
 - Cache Memory: SRAM 461
- RAM Types 464
 - Fast Page Mode DRAM 468
 - Extended Data Out RAM 468
 - SDRAM 469
 - DDR SDRAM 471
 - DDR2 SDRAM 472
 - RDRAM 473

- Memory Modules 476
 - SIMMs, DIMMs, and RIMMs 477
 - SIMM Pinouts 483
 - DIMM Pinouts 485
 - DDR DIMM Pinouts 487
 - DDR2 DIMM Pinouts 489
 - RIMM Pinouts 490
 - Physical RAM Capacity and Organization 493
 - Memory Banks 496
 - Memory Module Speed 497
 - Gold Versus Tin 497
 - Parity and ECC 500
- Installing RAM Upgrades 507
 - Upgrade Options and Strategies 507
 - Selecting and Installing Memory 508
- Troubleshooting Memory 513
 - Memory Defect Isolation Procedures 516
- The System Logical Memory Layout 517
 - Conventional (Base) Memory 520
 - Upper Memory Area 521
 - Extended Memory 526
 - Preventing ROM BIOS Memory Conflicts and Overlap 527
 - ROM Shadowing 528
 - Total Installed Memory Versus Total Usable Memory 528
 - Adapter Memory Configuration and Optimization 530

7 The ATA/IDE Interface 531

- An Overview of the IDE Interface 532
 - Precursors to IDE 532
 - IDE Origins 533
 - IDE Variations 533
 - Origins of ATA 534
- ATA Standards 536
 - ATA-1 (AT Attachment Interface for Disk Drives) 538
 - ATA-2 (AT Attachment Interface with Extensions-2) 538
 - ATA-3 (AT Attachment Interface-3) 539
 - ATA/ATAPI-4 (AT Attachment with Packet Interface Extension-4) 539
 - ATA/ATAPI-5 (AT Attachment with Packet Interface-5) 540
 - ATA/ATAPI-6 (AT Attachment with Packet Interface-6) 541
 - ATA/ATAPI-7 (AT Attachment with Packet Interface-7) 542
 - SATA/ATAPI-8 542
- Parallel ATA 543
 - Parallel ATA I/O Connector 543
 - Parallel ATA I/O Cable 546

Basic Hard Disk Drive Components	656
Hard Disk Platters (Disks)	657
Recording Media	658
Read/Write Heads	659
Head Actuator Mechanisms	661
Air Filters	668
Hard Disk Temperature Acclimation	669
Spindle Motors	669
Logic Boards	670
Cables and Connectors	671
Configuration Items	672
The Faceplate or Bezel	672
Hard Disk Features	673
Capacity	673
Performance	675
Reliability	681
Cost	683

11 Floppy Disk Storage 685

Floppy Storage Basics	686
Floppy Drive Interfaces	686
Drive Components	687
Read/Write Heads	688
The Head Actuator	689
The Spindle Motor	690
Circuit Boards	690
The Controller	691
The Faceplate	691
Connectors	692
The Floppy Disk Controller Cable	692
Disk Physical Specifications and Operation	695
How the Operating System Uses a Disk	696
Cylinders	697
Clusters or Allocation Units	697
Disk Change	698
Types of Floppy Disk Drives	699
1.44MB 3 1/2" Drives	699
Other Floppy Drive Types	700
Analyzing 3 1/2" Floppy Disk Construction	700
Floppy Disk Media Types and Specifications	701
Caring for and Handling Floppy Disks and Drives	702
Airport X-Ray Machines and Metal Detectors	703
Drive Installation Procedures	704
Troubleshooting Floppy Drives	704

12 High-Capacity Removable Storage 705

The Role of Removable Media Drives	706
Extra Storage	706
Backing Up Your Data	706
Comparing Disk, Tape, and Flash Memory Technologies	707
Magnetic Disk Media	707
Magnetic Tape Media	707
Flash Memory Media	708
Interfaces for Removable Media Drives	708
Overview of Removable Magnetic Storage Devices	709
Iomega Zip	710
SuperDisk LS-120 and LS-240	710
Hard-Disk-Size Removable-Media Drives	710
"Orphan" Removable-Media Drives	711
Magneto-Optical Drives	711
Magneto-Optical Technology	712
Comparing MO to "Pure" Magnetic Media	713
Key Factors in Selecting a Removable Drive	713
Flash Memory Devices	714
How Flash Memory Works	714
Types of Flash Memory Devices	714
Moving Data in Flash Memory Devices to Your Computer	719
Microdrive Technology	721
Tape Drives	722
Hard-Disk-Based Alternatives to Tape Backup	723
Disadvantages of Tape Backup Drives	723
Advantages to Tape Backup Drives	724
Common Tape Backup Standards	724
Comparing Tape Backup Technologies	730
Choosing a Tape Backup Drive	731
Tape Drive Installation	733
Tape Drive Backup Software	733
Tape Drive Troubleshooting	734
Tape Retensioning	736

13 Optical Storage 737

Optical Technology	738
CD-Based Optical Technology	738
CDs: A Brief History	739
CD-ROM Construction and Technology	740
Caring for Optical Media	751

- DVD 752
 - DVD History 753
 - DVD Construction and Technology 754
 - DVD Tracks and Sectors 755
 - Handling Errors 759
 - DVD Capacity (Sides and Layers) 760
 - Data Encoding on the Disc 763
 - Blu-ray Disc 763
 - HD-DVD 765
 - Optical Disc Formats 765
 - Compact Disc and Drive Formats 765
 - CD-ROM File Systems 775
 - DVD Formats and Standards 780
 - DVD Copy Protection 783
 - CD/DVD Read-Only Drives and Specifications 785
 - Performance Specifications 786
 - Interface 794
 - Loading Mechanism 796
 - Other Drive Features 798
 - Writable CDs 799
 - CD-R 800
 - CD-RW 804
 - MultiRead Specifications 806
 - How to Reliably Record CDs 808
 - Recording Software 811
 - Digital Audio Extraction 812
 - "For Music Use Only" CD-R/RW discs 814
 - CD Copy Protection 814
 - Recordable DVD Standards 815
 - DVD-RAM 817
 - DVD-R 818
 - DVD-RW 819
 - DVD+RW 819
 - Multiformat Rewritable Drives 821
 - CD/DVD Drive and Software Installation and Support 822
 - Booting from a Floppy Disk with CD/DVD Drive Support 822
 - Bootable CDs and DVDs—El Torito 824
 - Creating a Rescue CD 825
 - Making a Bootable CD/DVD for Emergencies 825
 - Troubleshooting Optical Drives 826
 - Updating the Firmware in a CD-RW or Rewritable DVD Drive 828
- 14 Physical Drive Installation and Configuration 831**
- Installing All Types of Drives 832
 - Hard Disk Installation Procedures 832
 - Drive Configuration 833
 - Host Adapter Configuration 833
 - Physical Installation 835
 - System Configuration 841
 - Formatting 842
 - Low-Level Formatting 842
 - Drive Partitioning 844
 - High-Level (Operating System) Formatting 853
 - FDISK and FORMAT Limitations 854
 - Replacing an Existing Drive 855
 - Drive Migration for MS-DOS Users 855
 - Drive Migration for Windows 9x/Me Users 855
 - Hard Disk Drive Troubleshooting and Repair 856
 - Testing a Drive 857
 - Installing an Optical Drive 858
 - Avoiding Conflict: Get Your Cards in Order 858
 - Drive Configuration 858
 - External (SCSI) Drive Hookup 860
 - Internal Drive Installation 861
 - Ribbon Cable and Card Edge Connector 862
 - SCSI Chains: Internal, External, or Both 863
 - Floppy Drive Installation Procedures 865
- 15 Video Hardware 867**
- Video Display Technologies 868
 - How CRT Display Technology Works 868
 - DVI—Digital Signals for CRT Monitors 871
 - LCD Panels 871
 - LCD and DLP Projectors 877
 - Plasma Displays 878
 - Video Adapter Types 879
 - Monitor Selection Criteria 880
 - The Right Size 880
 - Resolution 881
 - Dot Pitch (CRTs) 884
 - Image Brightness and Contrast (LCD Panels) 885
 - Interlaced Versus Noninterlaced 885
 - Energy and Safety 886
 - Frequencies 888
 - Controls 891
 - Testing a Display 892
 - Maintaining Your Monitor 893
 - Video Display Adapters 894
 - Obsolete Display Adapters 895
 - Current Display Adapters 895
 - Super VGA 896
 - VESA SVGA Standards 897
 - Integrated Video/Motherboard Chipsets 898
 - Video Adapter Components 900

16 Audio Hardware 941

Early PC Audio Adapters	942
Limitations of Sound Blaster Pro Compatibility	943
DirectX and Audio Adapters	943
PC Multimedia History	943
Audio Adapter Features	944
Basic Connectors	944
Connectors for Advanced Features	947
Volume Control	951
MIDI Support Features	952
Data Compression	952
Multipurpose Digital Signal Processors	953
Sound Drivers	953
Choosing the Best Audio Adapter for Your Needs	954
Gaming	955
DVD Movies on Your Desktop	955
Voice Dictation and Control	956
Sound Producers	956
Playing and Creating Digitized Sound Files	957
Audio Adapter Concepts and Terms	958
The Nature of Sound	958
Evaluating the Quality of Your Audio Adapter	958
Sampling	959

Who's Who in Audio	960
Chipset Makers Who Make Their Own Audio Adapters	960
Major Sound Chip Makers	962
Motherboard Chipsets with Integrated Audio	963
AOpen TubeSound	965
3D Audio	966
Positional Audio	967
3D Audio Processing	968
DirectX Support Issues	968
Installing the Sound Card	968
Connecting PC Speakers and Completing the Installation	970
Using Your Stereo Instead of Speakers	970
Troubleshooting Sound Card Problems	972
Hardware (Resource) Conflicts	972
Other Sound Card and Onboard Audio Problems	972
Speakers	976
Theater and Surround Sound Considerations	978
Microphones	979

17 I/O Interfaces from Serial and Parallel to IEEE 1394 and USB 981

Introduction to Input/Output Ports	982
USB and IEEE 1394 (i.LINK or FireWire)	982
Why Serial?	982
Universal Serial Bus	983
IEEE 1394	992
Comparing IEEE 1394 and USB	996
Standard Serial and Parallel Ports	997
Serial Ports	997
Typical Locations for Serial Ports	997
UARTs	1001
High-Speed Serial Port Cards	1003
Onboard Serial Ports	1003
Serial Port Configuration	1003
Testing Serial Ports	1004
Parallel Ports	1007
IEEE 1284 Parallel Port Standard	1007
Upgrading to EPP/ECP Parallel Ports	1010
Parallel Port Configuration	1011
Linking Systems with Serial or Parallel Ports	1011
Parallel-to-SCSI Converters	1013

To Emerson:

*“The real test for any choice is having to make the same choice again,
knowing full well what it might cost.” —The Oracle*

About the Author

Scott Mueller is president of Mueller Technical Research (MTR), an international research and corporate training firm. Since 1982, MTR has produced the industry's most in-depth, accurate, and effective seminars, books, articles, videos, and FAQs covering PC hardware and data recovery. MTR maintains a client list that includes Fortune 500 companies, the U.S. and foreign governments, major software and hardware corporations, as well as PC enthusiasts and entrepreneurs. His seminars have been presented to several thousands of PC support professionals throughout the world.

Scott personally teaches seminars nationwide covering all aspects of PC hardware (including troubleshooting, maintenance, repair, and upgrade), A+ Certification, and data recovery/forensics. He has a knack for making technical topics not only understandable, but entertaining as well; his classes are never boring! If you have 10 or more people to train, Scott can design and present a custom seminar for your organization.

Although he has taught classes virtually nonstop since 1982, Scott is best known as the author of the longest running, most popular, and most comprehensive PC hardware book in the world, *Upgrading and Repairing PCs*, which has not only been produced in more than 16 editions, but has also become the core of an entire series of books.

Scott has authored many books over the last 20+ years, including *Upgrading and Repairing PCs*, 1st through 16th and Academic editions; *Upgrading and Repairing Laptops*; *Upgrading and Repairing PCs: A+ Certification Study Guide*, 1st and 2nd editions; *Upgrading and Repairing PCs Technician's Portable Reference*, 1st and 2nd editions; *Upgrading and Repairing PCs Field Guide*; *Upgrading and Repairing PCs Quick Reference*; *Upgrading and Repairing PCs, Linux Edition*; *Killer PC Utilities*; *The IBM PS/2 Handbook*; and *Que's Guide to Data Recovery*.

Scott has produced several video training packages covering PC hardware, including a 6-hour, CD-based seminar titled *Upgrading and Repairing PCs Training Course: A Digital Seminar from Scott Mueller*. This course is ideal for those who cannot afford to bring Scott in-house.

Scott has also produced other videos over the years, including *Upgrading and Repairing PCs Video: 12th Edition*; *Your PC: The Inside Story*; as well as 2 hours of free video training that were included in each of the 10th, 12th, 13th, 14th, 15th, and 16th editions of *Upgrading and Repairing PCs*, as well as the new *Upgrading and Repairing Laptops* book. Scott has always included unique video segments with his books, rather than using the same clips every year. Many people have collected each of the older editions just to get the unique video training segments included with them.

Contact MTR directly if you have a unique book, article, or video project in mind, or if you want Scott to conduct a custom PC troubleshooting, repair, maintenance, upgrade, or data-recovery seminar tailored for your organization:

Mueller Technical Research
3700 Grayhawk Drive
Algonquin, IL 60102-6325
(847) 854-6794
(847) 854-6795 Fax
Internet: scottmueller@compuserve.com
Web: <http://www.upgradingandrepairingpcs.com>
<http://www.m-tr.com>

Scott's premiere work, *Upgrading and Repairing PCs*, has sold well over 2 million copies, making it by far the most popular and longest-running PC hardware book on the market today. Scott has been featured in *Forbes* magazine and has written several articles for *Maximum PC* magazine, several newsletters, and the *Upgrading and Repairing PCs* Web site.

Scott has recently completed two new works, *Upgrading and Repairing Laptops* and *Upgrading and Repairing PCs Video Training Course*.

If you have suggestions for the next version of this book, any comments about the book in general, or new book or article topics you would like to see covered, send them to Scott via email at scottmuellet@compuserve.com or visit www.upgradingandrepairingpcs.com and click the Ask Scott button.

When he is not working on PC-related books or on the road teaching seminars, Scott can usually be found in the garage working on several vehicular projects. He is currently working on a custom 1999 Harley-Davidson FLHRCI Road King Classic and a modified 1998 5.9L (360ci) Grand Cherokee—a hot rod 4×4.

Contributors and Technical Editors

Mark Edward Soper is president of Select Systems and Associates, Inc., a technical writing and training organization.

Mark has taught computer troubleshooting and other technical subjects to thousands of students from Maine to Hawaii since 1992. He is an A+ Certified hardware technician and a Microsoft Certified Professional. He has been writing technical documents since the mid-1980s and has contributed to several other Que books, including *Upgrading and Repairing PCs*, 11th, 12th, 13th, 14th, and 15th editions; *Upgrading and Repairing Networks, Second Edition*; and *Special Edition Using Microsoft Windows Millennium Edition*. Mark coauthored *Upgrading and Repairing PCs, Technician's Portable Reference*; *Upgrading and Repairing PCs Field Guide*; and *Upgrading and Repairing PCs: A+ Study Certification Guide, Second Edition*. He is the author of *The Complete Idiot's Guide to High-Speed Internet Connections*, *PC Help Desk in a Book*, and *Absolute Beginner's Guide to Cable Internet Connections* and is coauthor of *TechTV's Upgrading Your PC*.

Mark has been writing for major computer magazines since 1990, with more than 125 articles in publications such as *SmartComputing*, *PCNovice*, *PCNovice Guides*, and the *PCNovice Learning Series*. His early work was published in *WordPerfect Magazine*, *The WordPerfectionist*, and *PCToday*. Many of Mark's articles are available in back issues or electronically via the World Wide Web at www.smartcomputing.com. Select Systems maintains a subject index of all Mark's articles at <http://www.selectsystems.com>.

Mark welcomes comments at mesoper@selectsystems.com.

Mark Reddin is a Microsoft Certified Systems Engineer (MCSE) and A+ Certified PC technician. While a tyro, he enjoyed tinkering with computers during the time of the early Commodore and Atari systems (with all those wonderful games). Mark delved more seriously into computer technology during his undergraduate studies at Ball State University and has since been involved in the industry in various capacities. His experience with computers and networks has ranged from consulting to owning and operating a sales and repair shop. Additionally, he has been involved with numerous Que publications over the last few years, offering technical verification and development.

Acknowledgments

The new 16th edition continues the long tradition of making this the most accurate, in-depth, and up-to-date book of its kind on the market. This new edition is the product of a great deal of additional research and development over the previous editions. Several people have helped me with both the research and production of this book. I would like to thank the following people:

First, a very special thanks to my wife and partner, Lynn. Over the last few years, she has returned to school full-time, in addition to helping run our business. She recently graduated with full honors (congratulations!), receiving a degree in multimedia and Web design. She used her creative and technical skills to shoot and produce the video that is included with this book. I'm extremely proud of her for all I've seen her accomplish in the last few years. The dedication she has shown to her work has been inspiring.

Thanks to Lisa Carlson of Mueller Technical Research for helping with product research and office management. She has fantastic organizational skills that have been a tremendous help in managing all the information that comes into and goes out of this office.

I must give a special thanks to Rick Kughen at Que. Rick is the number one person responsible for taking what I submit and turning it into a finished book. His office is like a shrine to *Upgrading and Repairing PCs*, sporting a complete (and very rare) collection of every single edition since the first. His attention to detail is amazing, and he genuinely cares about both the book and my readers, often going far above and beyond the call of duty when it comes to customer service and support. Rick is always pushing to add extra value to the book and is constantly coming up with ways to improve the overall product.

Thanks also go to my new editor Todd Green. Although he is new to this book, he is a veteran in the publishing business and has been instrumental in helping to move this book through to completion.

I'd also like to thank Todd Brakke for doing the development editing for this edition. His excellent tips and suggestions really help to keep the material concise and up-to-date. I'd also like to thank the other editors, illustrators, designers, and technicians at Que who work so hard to complete the finished product and get this book out the door! They are a wonderful team that produces clearly the best computer books on the market. I am happy and proud to be closely associated with all the people at Que.

I would like to say thanks also to my publisher Greg Wiegand, who has stood behind all the *Upgrading and Repairing* book and video projects and is willing to take the risks in developing new versions like *Upgrading and Repairing Laptops*.

All the people at Que make me feel as if we are on the same team, and they are just as dedicated as I am to producing the best books possible.

I would also like to say thanks to Mark Soper, who has added expertise in areas that I might tend to neglect. Also thanks to Mark Reddin, who has become the primary technical editor for this book and who is not only extremely diligent in verifying details, but who also makes numerous suggestions about additional coverage, all of which are greatly appreciated. His input has been extremely important in helping me to ensure the highest level of technical accuracy and depth of coverage.

Special thanks go to Chris Beahan, who helped immensely in proofreading the text. Thanks also to all the other readers who emailed me with suggestions concerning this book; I welcome all your comments and even your criticisms. I take them seriously and apply them to the continuous improvement of this book. I especially enjoy answering the many questions you send me; your questions help me understand areas of the book that might need to be clarified and point out additional coverage that should be added. Interaction with my readers is the primary force that helps maintain this book as the most up-to-date and relevant work available *anywhere* on the subject of PC hardware.

Thanks to Tim Tavano, Carter Martin, Rob Luck, Andrew Puglise, and Zack Hall for helping out with the video shoot; we couldn't have done it without your assistance. Thanks to Doug Dodson and Bob Roark of PC Power and Cooling for supplying some very "cool" equipment for the video, as well. Finally, I would like to thank the thousands of people who have attended my seminars; you might not realize how much I learn from each of you and all your questions!

Many of my all-night writing raves are fueled by a variety of possibly less-than-nutritious (but very tasty and loaded with energy) food and beverage. In particular, this edition was fueled by many pounds of Starbucks coffee processed via a killer Capresso automatic coffee/espresso machine (utter nirvana for an addicted coffee drinker like me), cases of Coke Classic (no Pepsi allowed—gotta have the burn!), Red Bull and AMP energy drinks, Trolli Brite Crawler Eggs, and Pearson's Salted NutRolls. For special occasions when I really needed a boost, I enjoyed a couple of bottles of Skeleteens Brain Wash, the ultimate energy drink. Why, that covers the three major workaholic nerd/geek food groups right there: caffeine, sugar, and salt!

Tell Us What You Think!

As the reader of this book, *you* are our most important critic and commentator. We value your opinion and want to know what we're doing right, what we could do better, what areas you'd like to see us publish in, and any other words of wisdom you're willing to pass our way.

As an associate publisher for Que, I welcome your comments. You can email or write me directly to let me know what you did or didn't like about this book—as well as what we can do to make our books better.

Please note that I cannot help you with technical problems related to the topic of this book. We do have a User Services group, however, where I will forward specific technical questions related to the book.

When you write, please be sure to include this book's title and author as well as your name, email address, and phone number. I will carefully review your comments and share them with the author and editors who worked on the book.

Introduction

Welcome to *Upgrading and Repairing PCs, 16th Edition*. Since debuting as the first book of its kind on the market in 1988, no other book on PC hardware has matched the depth and quality of the information found in this tome. The 16th edition continues *Upgrading and Repairing PCs'* role as not only the best-selling book of its type, but also the most comprehensive and complete PC hardware reference available. This book examines PCs in depth, outlines the differences among them, and presents options for configuring each system.

More than just a minor revision, the 16th edition of *Upgrading and Repairing PCs* contains hundreds of pages of new, revised, and reworked content. The PC industry is moving faster than ever, and this book is the most accurate, complete, in-depth, and up-to-date book of its kind on the market today.

I wrote this book for people who want to upgrade, repair, maintain, and troubleshoot computers or for those enthusiasts who want to know more about PC hardware. This book covers the full gamut of PC-compatible systems from the oldest 8-bit machines to the latest in high-end 64-bit multigigahertz speed PC-based workstations. If you need to know about everything from the original PC to the latest in PC technology on the market today, this book and the accompanying information-packed disc is definitely for you.

This book covers state-of-the-art hardware and accessories that make the most modern personal computers easier, faster, and more productive to use. Inside these pages you will find in-depth coverage of every PC processor from the original 8088 to the latest Pentium 4 Prescott and Athlon 64/64 FX.

Upgrading and Repairing PCs also doesn't ignore the less glamorous PC components. Every part of your PC plays a critical role in its stability and performance. Over the course of this book's 1,500+ pages, you'll find out exactly why your motherboard's chipset might just be the most important part of your PC and what can go wrong when you settle for a run-of-the-mill power supply that can't get enough juice to that monster processor you just bought. You'll also find in-depth coverage of technologies such as new form factors (including BTX, DDR, and DDR2 SDRAM), graphics and audio cards, AGP, PCI and PCI Express, flat-panel displays, DVD+/-RW drives, Serial ATA, USB 2.0, FireWire, and high-capacity removable storage—it's all in here, right down to the guts-level analysis of your mouse and keyboard.

New in the 16th Edition

Many of you who are reading this have purchased one or more of the previous editions. Based on your letters, emails, and other correspondence, I know that, as much as you value each new edition, you want to know what new information I'm bringing you. So, here is a short list of the major improvements to this edition:

- In addition to the hundreds of pages of detail we have on every PC processor, including all those from Intel and AMD, this year we've added even more. Intel has moved to 90-nanometer chip production with the Prescott version of the Pentium 4, which has further unleashed the technology's extreme potential. AMD is making the first forays into 64-bit computing on the desktop with the Athlon 64 and 64 FX, using architectures previously limited only to servers. There are new sockets, new chipsets, and new motherboards designed to support these chips. You'll also find the straight dope on Intel's new processor numbering scheme.
- Intel's newer Pentium 4 processors have Hyper-threading (HT) technology, which makes a single processor function more like two processors running simultaneously. The new Prescott versions also have a deeper 31-stage pipeline. You'll find out whether your system has what it takes to support the HT technology processors and how the deeper pipeline affects performance and clock speeds. You'll also get information about higher bus speeds, new types of memory, and more.

- Newer chipsets use dual-channel DDR memory, which uses two banks simultaneously to match the speed of the processor bus, eliminating a bottleneck and optimizing performance. The latest type of memory is DDR2 memory, supported by the newest chipsets and boards. In Chapter 6, “Memory,” I not only expand my content on memory technologies, but also explain the benefits of the newer designs.
- An all-new chapter on system modifications, or *mods*, details the technology that controls the clock speed of your system and how it can be modified to make it faster by overclocking. Because more speed invariably means more heat, extreme cooling technologies are covered and the latest designs for cooling your PC are discussed. A simple modification is detailed that you can use to add the latest cooling technology to an existing system. Upgrading your chassis to include front-panel-mounted connectors for USB, FireWire, and other ports is detailed as well.
- Many changes are coming for PC chassis and motherboards, especially in the area of cooling. The ATX form factor has been the most popular form factor since 1996, but a new form factor called BTX is on the horizon. Chapter 4, “Motherboards and Buses,” has all the details on the new BTX form factor, including detailed information about the reasons behind the change and how the change will affect the chassis, processor cooling, and more. New bus slots called PCI Express are also making it onto the motherboard, and Chapter 4 includes detailed information about these new slots as well.
- Interested in turning your PC into a hot rod game machine? Read my coverage of audio, video, and Internet connectivity for the lowdown on supercharging your PC. Inside you’ll find new coverage of the latest video cards from NVIDIA (6800 series) and ATI (X800 series).
- As always, we have more new, high-quality technical illustrations. Every year we add, modify, and generally improve on the hundreds of figures in this book. These new and revised illustrations provide more technical detail, helping you understand difficult topics or showing you exactly how to complete a task.
- Just like last year, you’ll find a DVD-ROM or CD-ROM (depending on the version) plastered to the inside back cover of this book. On it you’ll find all the usual stand-bys, such as the Technical Reference and complete electronic versions of prior editions. Rather than recycle the same video clips from edition to edition as many of my competitors do, I’ve always included unique video clips for each new edition, and the 16th is no exception. I’ve included 2 hours of new video with this edition.

As with every edition, I’ve done as much research and homework as humanly possible to ensure that this volume is the most consistent and up-do-date text on PC hardware you’re going to find in a book.

Book Objectives

Upgrading and Repairing PCs focuses on several objectives. The primary objective is to help you learn how to maintain, upgrade, and repair your PC system. To that end, *Upgrading and Repairing PCs* helps you fully understand the family of computers that has grown from the original IBM PC, including all PC-compatible systems. This book discusses all areas of system improvement, such as motherboards, processors, memory, and even case and power-supply improvements. The book discusses proper system and component care, specifies the most failure-prone items in various PC systems, and tells you how to locate and identify a failing component. You’ll learn about powerful diagnostics hardware and software that enable a system to help you determine the cause of a problem and how to repair it.

PCs are moving forward rapidly in power and capabilities. Processor performance increases with every new chip design. *Upgrading and Repairing PCs* helps you gain an understanding of all the processors used in PC-compatible computer systems.

This book covers the important differences between major system architectures from the original Industry Standard Architecture (ISA) to the latest in AGP and PCI Express interface standards. *Upgrading and Repairing PCs* covers each of these system architectures and their adapter boards to help you make decisions about which type of system you want to buy in the future and to help you upgrade and troubleshoot such systems.

The amount of storage space available to modern PCs is increasing geometrically. *Upgrading and Repairing PCs* covers storage options ranging from larger, faster hard drives to state-of-the-art storage devices. In addition, it provides detailed information on upgrading and troubleshooting system RAM.

When you finish reading this book, you should have the knowledge to upgrade, troubleshoot, and repair almost any system and component.

Is This Book for You?

If you want to know more about PCs, then this book is most definitely for you!

Upgrading and Repairing PCs is designed for people who want a thorough understanding of PC hardware and how their PC systems work. Each section fully explains common and not-so-common problems, what causes problems, and how to handle problems when they arise. You will gain, for example, an understanding of disk configuration and interfacing that can improve your diagnostics and troubleshooting skills. You'll develop a feel for what goes on in a system so you can rely on your own judgment and observations and not some table of canned troubleshooting steps.

Upgrading and Repairing PCs is written for people who will select, install, configure, maintain, and repair systems they or their companies use. To accomplish these tasks, you need a level of knowledge much higher than that of an average system user. You must know exactly which tool to use for a task and how to use the tool correctly. This book can help you achieve this level of knowledge.

Scott has taught millions of people to upgrade and build PCs. Some of his students are computer experts, and some are computer novices. But they all have one thing in common: They believe Scott's book changed their lives. Scott can teach anyone.

Chapter-by-Chapter Breakdown

This book is organized into chapters that cover the components of a PC system. A few chapters serve to introduce or expand in an area not specifically component related, but most parts in the PC have a dedicated chapter or section, which will aid you in finding the information you want. Also note that the index has been improved greatly over previous editions, which will further aid in finding information in a book of this size.

Chapters 1 and 2 of this book serve primarily as an introduction. Chapter 1, "Development of the PC," begins with an introduction to the development of the original IBM PC and PC-compatibles. This chapter incorporates some of the historical events that led to the development of the microprocessor and the PC. Chapter 2, "PC Components, Features, and System Design," provides information about the various types of systems you encounter and what separates one type of system from another, including the types of system buses that differentiate systems. Chapter 2 also provides an overview of the types of PC systems that help build a foundation of knowledge essential for the remainder of the book, and it offers some insight as to how the PC market is driven and where components and technologies are sourced.

Chapter 3, "Microprocessor Types and Specifications," includes detailed coverage of Intel's Pentium 4 (Prescott, Northwood, and Willamette), Pentium III, Pentium II, Celeron, Xeon, and earlier central processing unit (CPU) chips. There's also new and extended coverage on AMD's line of high-performance Athlon 64/64 FX and Athlon XP processors as well as the Athlon, Duron, and K6 series. Because the processor is one of the most important parts of a PC, this book features more extensive

4 Introduction

and updated processor coverage than ever before. I dig deeply into the latest processor-upgrade socket and slot specifications, including coverage of Sockets 754, 939, and 940 for the Athlon 64/64 FX; Socket 423, Socket 478, and Socket T (LGA775) for the Pentium 4; Socket A (462) for AMD Athlon XP; and older sockets and slots such as Socket 7, Socket 370, Slot 1, and Slot A. Chapter 3 also tells you how to spot a re-marked processor. These are processors that have been modified by unscrupulous resellers to run faster than their rated speeds. These chips are then sold to the consumer as faster processors. I show you how to spot and avoid fakes.

Chapter 4, “Motherboards and Buses,” covers the motherboard, chipsets, motherboard components, and system buses in detail. This chapter contains discussions of motherboard form factors, including specifications on everything from Baby-AT to the various ATX and new BTX standards. A chipset can either make a good PC better or choke the life out of an otherwise high-speed CPU. I cover the latest chipsets for current processor families, including chipsets from Intel, AMD, VIA, NVIDIA, SiS, ALi, and more. This chapter also covers special bus architectures and devices, such as high-speed Peripheral Component Interconnect (PCI), including PCI Express, and Accelerated Graphics Port (AGP), including AGP 8x. Everything from the specifications of the latest chipsets to the proper spacing of holes on an ATX or BTX motherboard can be found here.

Chapter 5, “BIOS,” has a detailed discussion of the system BIOS, including types, features, and upgrades. This has grown from a section of a chapter to a complete chapter, with more information on this subject than ever before. Also included is updated coverage of the BIOS, with detailed information about BIOS setup utilities, Flash upgradable BIOSs, and Plug and Play BIOS.

See the exhaustive list of BIOS codes and error messages included on the accompanying disc. They're all printable, so be sure to print the codes for your BIOS in case you need them later.

Chapter 6, “Memory,” provides a detailed discussion of PC memory, including the latest in cache and main memory specifications. Next to the processor and motherboard, the system memory is one of the most important parts of a PC. It's also one of the most difficult things to understand because it is somewhat intangible and how it works is not always obvious. If you're confused about the difference between system memory and cache memory; L1 cache and L2 cache; external and integrated on-die L2 cache; SIMMs, DIMMs, and RIMMs; SDRAM versus DDR SDRAM versus RDRAM; 60-nanosecond EDO versus PC133 versus PC3200 and the new DDR2 memory, this is the chapter that can answer your questions. So, before you attempt to upgrade your PC with Fast Page mode EDO SIMMs—rather than with PC3200 DDR SDRAM DIMMs—be sure you read this chapter.

Chapter 7, “The ATA/IDE Interface,” provides a detailed discussion of ATA/IDE, including types and specifications. This covers the Ultra-ATA modes that allow 133MBps operation and why they won't increase your PC's performance much. There's also more new content on Serial ATA, the technology that is beginning to replace the parallel ATA we have been using for the last 16 years.

Chapter 8, “The SCSI Interface,” discusses SCSI, including the new Serial Attached SCSI (SAS) standard that is related to Serial ATA. This chapter covers the new low-voltage differential signaling used by some of the higher-speed devices on the market, as well as the latest information on cables, terminators, and SCSI configurations. This chapter also includes the latest on UltraSCSI.

Chapter 9, “Magnetic Storage Principles,” details the inner workings of magnetic storage devices such as disk and tape drives. Regardless of whether you understood electromagnetism in high school science, this chapter breaks down these difficult concepts and presents them in a way that will change the way you think about data and drives.

Chapter 10, “Hard Disk Storage,” breaks down how data is stored to your drives and how it is retrieved when you double-click a file.

Chapter 11, “Floppy Disk Storage,” takes an inside view of the venerable floppy disk drive. You learn how to properly connect these drives as well as how information is written to a floppy.

Chapter 12, “High-Capacity Removable Storage,” covers removable storage drives, such as SuperDisk (LS-120), Iomega Zip, Jaz, and Click! drives, as well as provides all-new coverage of magnetic tape drives.

Chapter 13, “Optical Storage,” covers optical drives and storage using CD and DVD technology, including CD recorders, rewritable CDs, and other optical technologies. This chapter includes detailed steps and advice for avoiding buffer underruns, creating bootable CDs, burning music CDs, and selecting the most reliable media. There’s even extensive coverage of DVD, with everything you need to know to understand the differences between DVD-R, DVD-RAM, DVD-RW, and DVD+RW. This chapter also tells you which of these the drive you buy needs to have support for.

Chapter 14, “Physical Drive Installation and Configuration,” covers how to install drives of all types in a PC system. You learn how to format and partition hard drives after they are installed.

Chapter 15, “Video Hardware,” covers everything there is to know about video cards and displays. Learn about how both CRT and flat-panel monitors work and which is best suited for you. If you’re a gamer or multimedia buff, you’ll want to read about choosing the right 3D graphics accelerator. The leading technologies are compared, and I help you choose the right card.

Chapter 16, “Audio Hardware,” covers sound and sound-related devices, including sound boards and speaker systems. Quality audio has become an increasingly important part of any good PC, and in this chapter I help you learn which features to look for in an audio card and which types of audio cards are suited to your needs. I even offer advice that can optimize your system’s audio performance for gaming, listening to CDs, and recording and playing MP3 music files.

Chapter 17, “I/O Interfaces from Serial and Parallel to IEEE 1394 and USB,” covers the standard serial and parallel ports still found in most systems, as well as newer technology such as USB and FireWire (IEEE 1394/i.LINK). I also cover the latest developments in USB 2.0, USB On-The-Go, and the new FireWire 800.

Chapter 18, “Input Devices,” covers keyboards, pointing devices, and game ports used to communicate with a PC. I also discuss wireless mice and keyboards.

Chapter 19, “Internet Connectivity,” compares high-speed connectivity methods that have come to the home desktop, including DSL, cable modems, and satellite.

Chapter 20, “Local Area Networking,” covers setting up an Ethernet network in your home or small office. I show you how to install NICs, make your own Ethernet cables, and set up Windows networking services.

Chapter 21, “Power Supply and Chassis/Case,” is a detailed investigation of the power supply, which still remains the primary cause of PC system problems and failures. When you buy a new PC, this undervalued component is the one most likely to be skimmed on, which helps explain why it’s the source of so many problems often attributed to Windows, memory, and several other components. You’ll also find detailed specifications on the power connectors found in systems from AT to ATX. They’re not all built equal, and making the wrong connections can be dangerous to you and your PC.

Chapter 22, “Building or Upgrading Systems,” is where I show you how to select the parts you’ll need for your upgrade or to build a PC from scratch. Then, I walk you step by step through the process. This chapter is loaded with professional photos that help you follow along.

Chapter 23, “Extreme Modifications: Overclocking, Cooling, and Chassis Upgrades,” covers the technology that controls the speed of your system and how to safely run the system faster than the basic specifications call for, or *overclock* it. A detailed examination of system cooling is also found here, from air cooling, to liquid cooling, and even refrigeration. The latest chassis upgrades to improve cooling are also discussed, and a simple modification is detailed that can dramatically improve the cooling in existing systems for less than \$10. Finally, many new motherboards have connections for front-panel I/O, and this chapter details options for adding front-panel I/O connections to existing systems.

Chapter 24, “PC Diagnostics, Testing, and Maintenance,” covers diagnostic and testing tools and procedures. This chapter also adds more information on general PC troubleshooting and problem determination. Here, I show you what the prepared PC technician has in his toolkit. I also show you a few tools you might have never seen or used before.

Chapter 25, “File Systems and Data Recovery,” covers file systems and data recovery procedures. If you’re a Windows XP user deciding whether to switch to NTFS, or if you’re not sure whether you should upgrade from FAT16 to FAT32, you should read this chapter. If you can’t access your drive because of a corrupted master boot record (MBR) or volume boot record (VBR), you’ll find information you can use to recover these sectors and regain access to your valuable data.

The 16th Edition DVD-ROM

The 16th edition of *Upgrading and Repairing PCs* includes a DVD-ROM or CD-ROM that contains as much valuable content as you’ll find in the pages of this book.

Video

Whether you purchased the DVD-ROM or CD-ROM edition of this book, you’re still going to have access to all-new professional-grade video (the DVD will play in your standalone DVD player, too). The CD-ROM version has just a tad less of it because of the reduced space. On the DVD you’ll find

- **Building a PC from Scratch.** This segment describes the task of building a PC from scratch in detail. It includes a discussion of all the components you need, the tools you need to build the system, and all the steps required to assemble a fully functional system. If you’ve never built your own PC before, this video will take you through all the steps and guide you through the entire process. Whether you are building an Intel or AMD processor-based system, you’ll find this very enlightening and informative. Even if you don’t want to build a complete system yourself, the installation procedures shown here can be applied to any system upgrade, such as upgrading motherboards, processors, memory, power supplies, drives, and more. This information is useful when troubleshooting a system as well, because in many cases you have to disassemble and reassemble all or part of the system to troubleshoot a problem.
- **OS and Driver Installation.** Part of building or upgrading a system includes partitioning and formatting the hard drive, as well as installing the operating system and drivers. Unfortunately, this is where many people have problems—for example, not knowing which drivers to install first or in which order they should be installed. In this segment, I detail all the steps needed to install Windows XP, the device drivers, and even the Windows updates on a new system. This can also be used when reloading an existing system or when upgrading the operating system from an older OS to the latest version of XP.

If you enjoy these video segments and want to see more, a full 6-hour video with many more segments like these is available in Scott’s *Upgrading and Repairing PCs Video Training Course*! The video training course packs in a total of 6 hours of live video training similar to Scott’s world-renowned 4-day seminars. For more information on the *Upgrading and Repairing PCs Video Training Course*, please visit www.upgradingandrepairingpcs.com. If you have any comments on these videos or are interested in an in-depth, hands-on seminar featuring all these topics and more, please contact Scott directly via scottmueller@compuserve.com.

Searchable Databases

On the accompanying disc you'll find detailed specifications for thousands of hard drives in this comprehensive Hard Drive Specifications Database.

Complementing that is a detailed list of technology vendors. The Vendor List is a searchable database of key industry contacts, searchable by name or keyword. This is crucial contact information that no hardware maven should be without!

Technical Reference

The Technical Reference is a PDF repository of material that has appeared in previous editions of *Upgrading and Repairing PCs* but has been moved to the disc to make room for coverage of new technologies. The disc, combined with the printed content of the book, makes *Upgrading and Repairing PCs* far more than 2,000 pages long!

Its contents include a detailed listing of BIOS codes and legacy coverage from earlier editions of the book. It's included on the disc in printable PDF format.

Upgrading and Repairing PCs Bookshelf

PDF versions of the 10th, 11th, 12th, 13th, 14th, and 15th editions of *Upgrading and Repairing PCs* are included on the DVD!

Scott's Web Site— *upgradingandrepairingpcs.com*

Don't miss my book Web site at www.upgradingandrepairingpcs.com! Here, you'll find a cache of helpful material to go along with the book you're holding. I've loaded this site with tons of material, from video clips to monthly book updates. I use this spot to keep you updated throughout the year on major changes in the PC hardware industry. Each month, I write new articles covering new technologies released after this book was printed. These articles are archived so you can refer to them anytime.

I also use this site to post your reader questions and my answers. The Frequently Asked Questions (FAQ) is a tremendous resource because you benefit from the hundreds of reader emails I answer each month. Log on and post a question. I endeavor to answer each and every email personally.

You'll also find exclusive video clips available nowhere else!

I also use this site to tell you about some of the other fantastic *Upgrading and Repairing PCs* products I work on, including

- *Upgrading and Repairing Laptops*
- *Upgrading and Repairing PCs, Video Training Course* from Que and Prentice Hall (see the advertisement in the back of this book for ordering details)
- *Upgrading and Repairing Networks*

Laptops have become the largest growing segment of PCs, and my new book *Upgrading and Repairing Laptops* covers these systems in great detail. If you want to know as much about laptop and notebook systems as you do about desktop PCs, you need *Upgrading and Repairing Laptops*. Be sure to check the upgradingandrepairingpcs.com Web site for more information on all my latest books, videos, articles, FAQs, and more!

A Personal Note

When asked which was his favorite Corvette, Dave McLellan, former manager of the Corvette platform at General Motors, always said, “Next year’s model.” Now with the new 16th edition, next year’s model has just become this year’s model, until next year that is....

I believe this book is absolutely the best book of its kind on the market, and that is due in large part to the extensive feedback I have received from both my seminar attendees and book readers. I am so grateful to everyone who has helped me with this book over the last 16 years as well as all the loyal readers who have been reading this book, many of you since the first edition was published. I have had personal contact with many thousands of you in the seminars I have been teaching since 1982, and I enjoy your comments and even your criticisms tremendously. Using this book in a teaching environment has been a major factor in its development. Some of you might be interested to know that I originally began writing this book in early 1985; back then it was self-published and used exclusively in my PC hardware seminars before being professionally published by Que in 1988. In one way or another, I have been writing and rewriting this book for more than 20 years! In the more than 16 years since it was professionally published, *Upgrading and Repairing PCs* has proven to be not only the first but also the most comprehensive and yet approachable and easy-to-understand book of its kind. With the new 16th edition, it is even better than ever. Your comments, suggestions, and support have helped this book to become the best PC hardware book on the market. I look forward to hearing your comments after you see this exciting new edition.

Scott

CHAPTER 1

Development of the PC

Computer History—Before Personal Computers

Many discoveries and inventions have directly and indirectly contributed to the development of the personal computer as we know it today. Examining a few important developmental landmarks can help bring the entire picture into focus.

The first computers of any kind were simple calculators. Even these evolved from mechanical devices to electronic digital devices.

Timeline

The following is a timeline of some significant events in computer history. It is not meant to be complete, just a representation of some of the major landmarks in computer development:

- | | | | |
|------|--|------|--|
| 1617 | John Napier creates “Napier’s Bones,” wooden or ivory rods used for calculating. | 1949 | Maurice Wilkes assembles the EDSAC, the first practical stored-program computer, at Cambridge University. |
| 1642 | Blaise Pascal introduces the Pascaline digital adding machine. | 1950 | Engineering Research Associates of Minneapolis builds the ERA 1101, one of the first commercially produced computers. |
| 1822 | Charles Babbage introduces the Difference Engine and later the Analytical Engine, a true general-purpose computing machine. | 1952 | The UNIVAC I delivered to the U.S. Census Bureau is the first commercial computer to attract widespread public attention. |
| 1906 | Lee De Forest patents the vacuum tube triode, used as an electronic switch in the first electronic computers. | 1953 | IBM ships its first electronic computer, the 701. |
| 1936 | Alan Turing publishes “On Computable Numbers,” a paper in which he conceives an imaginary computer called the Turing Machine, considered one of the foundations of modern computing. Turing later worked on breaking the German Enigma code. | 1954 | A silicon-based junction transistor, perfected by Gordon Teal of Texas Instruments, Inc., brings a tremendous reduction in costs. |
| 1937 | John V. Atanasoff begins work on the Atanasoff-Berry Computer (ABC), which would later be officially credited as the first electronic computer. | 1954 | The IBM 650 magnetic drum calculator establishes itself as the first mass-produced computer, with the company selling 450 in one year. |
| 1943 | Thomas (Tommy) Flowers develops the Colossus, a secret British code-breaking computer designed to decode secret messages encrypted by the German Enigma cipher machines. | 1955 | Bell Laboratories announces the first fully transistorized computer, TRADIC. |
| 1945 | John von Neumann writes “First Draft of a Report on the EDVAC,” in which he outlines the architecture of the modern stored-program computer. | 1956 | MIT researchers build the TX-0, the first general-purpose, programmable computer built with transistors. |
| 1946 | ENIAC is introduced, an electronic computing machine built by John Mauchly and J. Presper Eckert. | 1956 | The era of magnetic disk storage dawns with IBM’s shipment of a 305 RAMAC to Zellerbach Paper in San Francisco. |
| 1947 | On December 23, William Shockley, Walter Brattain, and John Bardeen successfully test the point-contact transistor, setting off the semiconductor revolution. | 1958 | Jack Kilby creates the first integrated circuit at Texas Instruments to prove that resistors and capacitors can exist on the same piece of semiconductor material. |
| | | 1959 | IBM’s 7000 series mainframes are the company’s first transistorized computers. |

- 1959 Robert Noyce's practical integrated circuit, invented at Fairchild Camera and Instrument Corp., allows printing of conducting channels directly on the silicon surface.
- 1960 Bell Labs designs its Dataphone, the first commercial modem, specifically for converting digital computer data to analog signals for transmission across its long-distance network.
- 1960 The precursor to the minicomputer, DEC's PDP-1, sells for \$120,000.
- 1961 According to *Datamation* magazine, IBM has an 81.2% share of the computer market in 1961, the year in which it introduces the 1400 series.
- 1964 CDC's 6600 supercomputer, designed by Seymour Cray, performs up to three million instructions per second—a processing speed three times faster than that of its closest competitor, the IBM Stretch.
- 1964 IBM announces System/360, a family of six mutually compatible computers and 40 peripherals that can work together.
- 1964 Online transaction processing makes its debut in IBM's SABRE reservation system, set up for American Airlines.
- 1965 Digital Equipment Corp. introduces the PDP-8, the first commercially successful minicomputer.
- 1966 Hewlett-Packard enters the general-purpose computer business with its HP-2115 for computation, offering a computational power formerly found only in much larger computers.
- 1969 The root of what is to become the Internet begins when the Department of Defense establishes four nodes on the ARPAnet: two at University of California campuses (one at Santa Barbara and one at Los Angeles) and one each at SRI International and the University of Utah.
- 1971 A team at IBM's San Jose Laboratories invents the 8" floppy disk.
- 1971 The first advertisement for a microprocessor, the Intel 4004, appears in *Electronic News*.
- 1971 The Kenbak-1, one of the first personal computers, advertises for \$750 in *Scientific American*.
- 1972 Hewlett-Packard announces the HP-35 as "a fast, extremely accurate electronic slide rule" with a solid-state memory similar to that of a computer.
- 1972 Intel's 8008 microprocessor makes its debut.
- 1972 Steve Wozniak builds his "blue box," a tone generator to make free phone calls.
- 1973 Robert Metcalfe devises the Ethernet method of network connection at the Xerox Palo Alto Research Center.
- 1973 The Micral is the earliest commercial, non-kit personal computer based on a microprocessor, the Intel 8008.
- 1973 The TV Typewriter, designed by Don Lancaster, provides the first display of alphanumeric information on an ordinary television set.
- 1974 Researchers at the Xerox Palo Alto Research Center design the Alto, the first workstation with a built-in mouse for input.
- 1974 Scelbi advertises its 8H computer, the first commercially advertised U.S. computer based on a microprocessor, Intel's 8008.
- 1975 Telenet, the first commercial packet-switching network and civilian equivalent of ARPAnet, is born.
- 1975 The January edition of *Popular Electronics* features the Altair 8800, which is based on Intel's 8080 microprocessor, on its cover.
- 1975 The visual display module (VDM) prototype, designed by Lee Felsenstein, marks the first implementation of a memory-mapped alphanumeric video display for personal computers.
- 1976 Steve Wozniak designs the Apple I, a single-board computer.
- 1976 The 5 1/4" flexible disk drive and disk are introduced by Shugart Associates.
- 1976 The Cray I makes its name as the first commercially successful vector processor.
- 1977 Tandy Radio Shack introduces the TRS-80.
- 1977 Apple Computer introduces the Apple II.
- 1977 Commodore introduces the PET (Personal Electronic Transactor).

- 1978 The VAX 11/780 from Digital Equipment Corp. features the capability to address up to 4.3GB of virtual memory, providing hundreds of times the capacity of most minicomputers.
- 1979 Motorola introduces the 68000 microprocessor.
- 1980 John Shoch, at the Xerox Palo Alto Research Center, invents the computer “worm,” a short program that searches a network for idle processors.
- 1980 Seagate Technology creates the first hard disk drive for microcomputers, the ST-506.
- 1980 The first optical data storage disk has 60 times the capacity of a 5 1/4" floppy disk.
- 1981 Xerox introduces the Star, the first personal computer with a graphical user interface (GUI).
- 1981 Adam Osborne completes the first portable computer, the Osborne I, which weighs 24 lbs. and costs \$1,795.
- 1981 IBM introduces its PC, igniting a fast growth of the personal computer market. The IBM PC is the grandfather of all modern PCs.
- 1981 Sony introduces and ships the first 3 1/2" floppy drives and disks.
- 1981 Philips and Sony introduce the CD-DA (compact disc digital audio) format.
- 1982 Sony is the first with a CD player on the market.
- 1983 Apple introduces its Lisa, which incorporates a GUI that’s very similar to the one first introduced on the Xerox Star.
- 1983 Compaq Computer Corp. introduces its first PC clone that uses the same software as the IBM PC.
- 1984 Apple Computer launches the Macintosh, the first successful mouse-driven computer with a GUI, with a single \$1.5 million commercial during the 1984 Super Bowl.
- 1984 IBM releases the PC-AT (PC Advanced Technology), three times faster than original PCs and based on the Intel 286 chip. The AT introduces the 16-bit ISA bus and is the computer on which all modern PCs are based.
- 1985 Philips introduces the first CD-ROM drive.
- 1986 Compaq announces the Deskpro 386, the first computer on the market to use what was then Intel’s new 386 chip.
- 1987 IBM introduces its PS/2 machines, which make the 3 1/2" floppy disk drive and VGA video standard for PCs. The PS/2 also introduces the MicroChannel Architecture (MCA) bus, the first plug-and-play bus for PCs.
- 1988 Apple cofounder Steve Jobs, who left Apple to form his own company, unveils the NeXT.
- 1988 Compaq and other PC-clone makers develop Enhanced Industry Standard Architecture (EISA), which unlike MicroChannel retains backward compatibility with the existing ISA bus.
- 1988 Robert Morris’s worm floods the ARPAnet. The 23-year-old Morris, the son of a computer security expert for the National Security Agency, sends a nondestructive worm through the Internet, causing problems for about 6,000 of the 60,000 hosts linked to the network.
- 1989 Intel releases the 486 (P4) microprocessor, which contains more than one million transistors. Intel also introduces 486 motherboard chipsets.
- 1990 The World Wide Web (WWW) is born when Tim Berners-Lee, a researcher at CERN—the high-energy physics laboratory in Geneva—develops Hypertext Markup Language (HTML).
- 1993 Intel releases the Pentium (P5) processor. Intel shifts from numbers to names for its chips after it learns it’s impossible to trademark a number. Intel also releases motherboard chipsets and, for the first time, complete motherboards as well.
- 1995 Intel releases the Pentium Pro processor, the first in the P6 processor family.
- 1995 Microsoft releases Windows 95, the first mainstream 32-bit operating system, in a huge rollout.
- 1997 Intel releases the Pentium II processor, essentially a Pentium Pro with MMX instructions added.

- 1997 AMD introduces the K6, which is compatible with the Intel P5 (Pentium).
- 1998 Microsoft releases Windows 98.
- 1998 Intel releases the Celeron, a low-cost version of the Pentium II processor. Initial versions have no cache, but within a few months Intel introduces versions with a smaller but faster L2 cache.
- 1999 Intel releases the Pentium III, essentially a Pentium II with SSE (Streaming SIMD Extensions) added.
- 1999 AMD introduces the Athlon.
- 1999 The IEEE officially approves the 5GHz band 802.11a 54Mbps and 2.4GHz band 802.11b 11Mbps wireless networking standards. The Wi-Fi Alliance is formed to certify 802.11b products, ensuring interoperability.
- 2000 The first 802.11b Wi-Fi-certified products are introduced, and wireless networking rapidly builds momentum.
- 2000 Microsoft releases Windows Me (Millennium Edition) and Windows 2000.
- 2000 Both Intel and AMD introduce processors running at 1GHz.
- 2000 AMD introduces the Duron, a low-cost Athlon with reduced L2 cache.
- 2000 Intel introduces the Pentium 4, the latest processor in the Intel Architecture 32-bit (IA-32) family.
- 2001 Intel releases the Itanium processor, its first 64-bit (IA-64) processor for PCs.
- 2001 The industry celebrates the 20th anniversary of the release of the original IBM PC.
- 2001 Intel introduces the first 2GHz processor, a version of the Pentium 4. It took the industry 28 1/2 years to go from 108KHz to 1GHz, but only 18 months to go from 1GHz to 2GHz.
- 2001 Microsoft releases Windows XP Home and Professional, for the first time merging the consumer (9x/Me) and business (NT/2000) operating system lines under the same code base (an extension of Windows 2000).
- 2001 Atheros introduces the first 802.11a 54Mbps high-speed wireless chips, allowing 802.11a products to finally reach the market.
- 2002 Intel releases the first 3GHz-class processor, a 3.06GHz version of the Pentium 4. This processor also introduces Intel's Hyper-Threading (HT) technology (which enables a single processor to work with two application threads at the same time) to desktop computing.
- 2003 Intel releases the Pentium M, a processor designed specifically for mobile systems, offering extremely low power consumption that results in dramatically increased battery life while still offering relatively high performance. The Pentium M becomes the cornerstone of Intel's Centrino brand.
- 2003 AMD releases the Athlon 64, the first 64-bit processor targeted at the mainstream consumer and business markets.
- 2003 The IEEE officially approves the 802.11g 54Mbps high-speed wireless networking standard, which uses the same 2.4GHz band as (and is backward-compatible with) 802.11b. 802.11g products reach the market quickly, some even before the official standard is approved.
- 2004 Intel introduces a version of the Pentium 4 codenamed Prescott, the first PC processor built on 90-nanometer technology.
- 2004 Intel introduces EM64T (Extended Memory 64 Technology), which is a 64-bit extension to Intel's IA-32 architecture. EM64T is software-compatible with and targeted at the same market as the AMD Athlon 64, and is not compatible with the 64-bit Itanium.

Mechanical Calculators

One of the earliest calculating devices on record is the abacus, which has been known and widely used for more than 2,000 years. The abacus is a simple wooden rack holding parallel rods on which beads are strung. When these beads are manipulated back and forth according to certain rules, several types of arithmetic operations can be performed.

Math with standard Arabic numbers found its way to Europe in the eighth and ninth centuries. In the early 1600s, a man named Charles Napier (the inventor of logarithms) developed a series of rods (later called Napier's Bones) that could be used to assist with numeric multiplication.

Blaise Pascal is usually credited with building the first digital calculating machine in 1642. It could perform the addition of numbers entered on dials and was intended to help his father, who was a tax collector. Then in 1671, Gottfried Wilhelm von Leibniz invented a calculator that was finally built in 1694. His calculating machine could not only add, but by successive adding and shifting, it could also multiply.

In 1820, Charles Xavier Thomas developed the first commercially successful mechanical calculator that could not only add but also subtract, multiply, and divide. After that, a succession of ever-improving mechanical calculators created by various other inventors followed.

The First Mechanical Computer

Charles Babbage, a mathematics professor in Cambridge, England, is considered by many to be the father of computers because of his two great inventions—each a different type of mechanical computing engine.

The Difference Engine, as he called it, was conceived in 1812 and solved polynomial equations by the method of differences. By 1822, he had built a small working model of his Difference Engine for demonstration purposes. With financial help from the British government, Babbage started construction of a full-scale model in 1823. It was intended to be steam-powered and fully automatic, and it would even print the resulting tables.

Babbage continued work on it for 10 years, but by 1833 he had lost interest because he now had an idea for an even better machine, something he described as a general-purpose, fully program-controlled, automatic mechanical digital computer. Babbage called his new machine an Analytical Engine. The plans for the Analytical Engine specified a parallel decimal computer operating on numbers (words) of 50 decimal digits and with a storage capacity (memory) of 1,000 such numbers. Built-in operations were to include everything that a modern general-purpose computer would need, even the all-important conditional function, which would allow instructions to be executed in an order depending on certain conditions, not just in numerical sequence. In modern computer languages, this conditional capability is manifested in the IF statement. The Analytical Engine was also intended to use punched cards, which would control or program the machine. The machine was to operate automatically by steam power and would require only one attendant.

The Analytical Engine is regarded as the first real predecessor to a modern computer because it had all the elements of what is considered a computer today. These included the following:

- *An input device.* Using an idea similar to the looms used in textile mills at the time, a form of punched cards supplied the input.
- *A control unit.* A barrel-shaped section with many slats and studs was used to control or program the processor.
- *A processor (or calculator).* A computing engine containing hundreds of axles and thousands of gears about 10 feet tall.
- *Storage.* A unit containing more axles and gears that could hold 1,000 50-digit numbers.
- *An output device.* Plates designed to fit in a printing press that were used to print the final results.

Alas, this potential first computer was never actually completed because of the problems in machining all the precision gears and mechanisms required. The tooling of the day was simply not good enough.

An interesting side note is that the punched card idea first proposed by Babbage finally came to fruition in 1890. That year a competition was held for a better method to tabulate the U.S. Census information, and Herman Hollerith, a Census Department employee, came up with the idea for punched cards. Without these cards, department employees had estimated the census data would take years to tabulate; with these cards they were able to finish in about six weeks. Hollerith went on to found the Tabulating Machine Company, which later became known as IBM.

IBM and other companies at the time developed a series of improved punch-card systems. These systems were constructed of electromechanical devices, such as relays and motors. Such systems included features to automatically feed in a specified number of cards from a “read-in” station; perform operations, such as addition, multiplication, and sorting; and feed out cards punched with results. These punched-card computing machines could process 50–250 cards per minute, with each card holding up to 80-digit numbers. The punched cards not only provided a means of input and output, but they also served as a form of memory storage. Punched-card machines did the bulk of the world’s computing for more than 50 years and gave many of the early computer companies their starts.

Electronic Computers

A physicist named John V. Atanasoff (with associate Clifford Berry) is credited with creating the first true digital electronic computer during 1937–1942, while working at Iowa State University. The Atanasoff-Berry Computer (called the ABC) was the first to use modern digital switching techniques and vacuum tubes as switches, and it introduced the concepts of binary arithmetic and logic circuits. This was made legally official on October 19, 1973, when following a lengthy court trial, U.S. Federal Judge Earl R. Larson voided the ENIAC patent of Eckert and Mauchly and named Atanasoff as the inventor of the first electronic digital computer.

Military needs during World War II caused a great thrust forward in the evolution of computers. In 1943, Tommy Flowers completed a secret British code-breaking computer called Colossus, which was used to decode German secret messages. Unfortunately, that work went largely uncredited because Colossus was kept secret until many years after the war.

Besides code-breaking, systems were needed to calculate weapons trajectory and other military functions. In 1946, John P. Eckert, John W. Mauchly, and their associates at the Moore School of Electrical Engineering at the University of Pennsylvania built the first large-scale electronic computer for the military. This machine became known as ENIAC, the Electrical Numerical Integrator and Calculator. It operated on 10-digit numbers and could multiply two such numbers at the rate of 300 products per second by finding the value of each product from a multiplication table stored in its memory. ENIAC was about 1,000 times faster than the previous generation of electromechanical relay computers.

ENIAC used approximately 18,000 vacuum tubes, occupied 1,800 square feet (167 square meters) of floor space, and consumed around 180,000 watts of electrical power. Punched cards served as the input and output; registers served as adders and also as quick-access read/write storage.

The executable instructions composing a given program were created via specified wiring and switches that controlled the flow of computations through the machine. As such, ENIAC had to be rewired and switched for each program to be run.

Although Eckert and Mauchly were originally given a patent for the electronic computer, it was later voided and the patent awarded to John Atanasoff for creating the Atanasoff-Berry Computer.

Earlier in 1945, the mathematician John von Neumann demonstrated that a computer could have a very simple, fixed physical structure and yet be capable of executing any kind of computation effectively by means of proper programmed control without the need for any changes in hardware.

In other words, you could change the program without rewiring the system. The *stored-program technique*, as von Neumann's ideas are known, became fundamental for future generations of high-speed digital computers and has become universally adopted.

The first generation of modern programmed electronic computers to take advantage of these improvements appeared in 1947. This group of machines included EDVAC and UNIVAC, the first commercially available computers. These computers included, for the first time, the use of true random access memory (RAM) for storing parts of the program and data that is needed quickly. Typically, they were programmed directly in machine language, although by the mid-1950s progress had been made in several aspects of advanced programming. The standout of the era is the UNIVAC (Universal Automatic Computer), which was the first true general-purpose computer designed for both alphabetical and numerical uses. This made the UNIVAC a standard for business, not just science and the military.

Modern Computers

From UNIVAC to the present, computer evolution has moved very rapidly. The first-generation computers were known for using vacuum tubes in their construction. The generation to follow would use the much smaller and more efficient transistor.

From Tubes to Transistors

Any modern digital computer is largely a collection of electronic switches. These switches are used to represent and control the routing of data elements called *binary digits* (or *bits*). Because of the on or off nature of the binary information and signal routing the computer uses, an efficient electronic switch was required. The first electronic computers used vacuum tubes as switches, and although the tubes worked, they had many problems.

The type of tube used in early computers was called a *triode* and was invented by Lee De Forest in 1906 (see Figure 1.1). It consists of a cathode and a plate, separated by a control grid, suspended in a glass vacuum tube. The cathode is heated by a red-hot electric filament, which causes it to emit electrons that are attracted to the plate. The control grid in the middle can control this flow of electrons. By making it negative, the electrons are repelled back to the cathode; by making it positive, they are attracted toward the plate. Thus, by controlling the grid current, you can control the on/off output of the plate.

Figure 1.1 Triode Vacuum Tube.

Unfortunately, the tube was inefficient as a switch. It consumed a great deal of electrical power and gave off enormous heat—a significant problem in the earlier systems. Primarily because of the heat they generated, tubes were notoriously unreliable—in larger systems, one failed every couple of hours or so.

The invention of the transistor, or semiconductor, was one of the most important developments leading to the personal computer revolution. The transistor was first invented in 1947 and announced in

1948 by Bell Laboratory engineers John Bardeen and Walter Brattain. Bell associate William Shockley invented the junction transistor a few months later, and all three jointly shared the Nobel Prize in Physics in 1956 for inventing the transistor. The transistor, which essentially functions as a solid-state electronic switch, replaced the less-suitable vacuum tube. Because the transistor was so much smaller and consumed significantly less power, a computer system built with transistors was also much smaller, faster, and more efficient than a computer system built with vacuum tubes.

Transistors are made primarily from the elements silicon and germanium, with certain impurities added. Depending on the impurities added—its electron content—the material becomes known as either N-Type (negative) or P-Type (positive). Both types are conductors, allowing electricity to flow in either direction. However, when the two types are joined, a barrier is formed where they meet that allows current to flow in only one direction when a voltage is present in the right polarity. This is why they are typically called *semiconductors*.

A transistor is made by placing two P-N junctions back to back. They are made by sandwiching a thin wafer of one type of semiconductor material between two wafers of the other type. If the wafer in between is made from P-type material, the transistor is designated an NPN. If the wafer in between is N-type, the transistor is designated PNP.

In an NPN transistor, the N-type semiconductor material on one side of the wafer is called the *emitter* (or *source*) and is normally connected to a negative current (see Figure 1.2). The P-type material in the center is called the *base*, and the N-type material on the other side of the base is called the *collector* (or *drain*).

Figure 1.2 NPN transistor.

An NPN transistor compares to a triode tube such that the emitter is equivalent to the cathode, the base is equivalent to the grid, and the collector is equivalent to the plate. By controlling the current at the base, you can control the flow of current between the emitter and collector.

Compared to the tube, the transistor is much more efficient as a switch and can be miniaturized to microscopic scale. In June 2001, Intel researchers unveiled the world's smallest and fastest silicon transistors, only 20 nanometers (billionths of a meter) in size. These are expected to appear in PC processors in the year 2007, which will have one billion transistors running at speeds of 20GHz! By comparison, in 2003 the AMD Athlon 64 had more than 105.9 million transistors, and the Pentium 4 Extreme Edition had more than 178 million transistors.

The conversion from tubes to transistors began the trend toward miniaturization that continues to this day. Today's small laptop (or palmtop) PC and even Tablet PC systems, which run on batteries, have more computing power than many earlier systems that filled rooms and consumed huge amounts of electrical power.

Although vacuum tubes have been replaced in virtually all consumer applications by transistors and integrated circuits, they remain popular for high-end audio applications because they produce a warmer and richer sound than transistors do. Because computers are increasingly used for audio processing and playback, Acer's Aopen division has released a motherboard (the AX4B-533 Tube) that uses a dual-triode tube along with a special noise-reduction design to produce excellent music playback.

Integrated Circuits

The third generation of modern computers is known for using integrated circuits instead of individual transistors. In 1959, engineers at Texas Instruments invented the *integrated circuit (IC)*, a semiconductor circuit that contains more than one transistor on the same base (or substrate material) and connects the transistors without wires. The first IC contained only six transistors. By comparison, the Intel Pentium Pro microprocessor used in many of today's high-end systems has more than 5.5 million transistors, and the integral cache built into some of these chips contains as many as an additional 32 million transistors! Today, many ICs have transistor counts in the multimillion range.

The First Microprocessor

Intel was founded on July 18, 1968, by Robert Noyce, Gordon Moore, and Andrew Grove. They had a specific goal: to make semiconductor memory practical and affordable. This was not a given at the time, considering that silicon chip-based memory was at least 100 times more expensive than the magnetic core memory commonly used in those days. At the time, semiconductor memory was going for about a dollar a bit, whereas core memory was about a penny a bit. Noyce said, "All we had to do was reduce the cost by a factor of a hundred; then we'd have the market; and that's basically what we did."

By 1970, Intel was known as a successful memory chip company, having introduced a 1Kb memory chip much larger than anything else available at the time. (1Kb equals 1,024 bits, and a byte equals 8 bits. This chip, therefore, stored only 128 bytes—not much by today's standards.) Known as the 1103 dynamic random access memory (DRAM), it became the world's largest-selling semiconductor device by the end of the following year. By this time, Intel had also grown from the core founders and a handful of others to more than 100 employees.

Because of Intel's success in memory chip manufacturing and design, Japanese manufacturer Basicom asked Intel to design a set of chips for a family of high-performance programmable calculators. At the time, all logic chips were custom designed for each application or product. Because most chips had to be custom designed specific to a particular application, no one chip could have any widespread usage.

Basicom's original design for its calculator called for at least 12 custom chips. Intel engineer Ted Hoff rejected the unwieldy proposal and instead designed a single-chip, general-purpose logic device that retrieved its application instructions from semiconductor memory. As the core of a four-chip set, a program could control this central processing unit and essentially tailor its function to the task at hand. The chip was generic in nature, meaning it could function in designs other than calculators. Previous designs were hard-wired for one purpose, with built-in instructions; this chip would read a variable set of instructions from memory, which would control the function of the chip. The idea was to design, on a single chip, almost an entire computing device that could perform various functions, depending on which instructions it was given.

There was one problem with the new chip: Basicom owned the rights to it. Hoff and others knew that the product had almost limitless application, bringing intelligence to a host of "dumb" machines. They urged Intel to repurchase the rights to the product. While Intel founders Gordon Moore and Robert Noyce championed the new chip, others within the company were concerned that the product would distract Intel from its main focus—making memory. They were finally convinced by the fact that every four-chip microcomputer set included two memory chips. As the director of marketing at the time recalled, "Originally, I think we saw it as a way to sell more memories, and we were willing to make the investment on that basis."

Intel offered to return Basicom's \$60,000 investment in exchange for the rights to the product. Struggling with financial troubles, the Japanese company agreed. Nobody else in the industry at the time, even at Intel, realized the significance of this deal. Of course, it paved the way for Intel's future in processors. The result was the 1971 introduction of the 4-bit Intel 4004 microcomputer set (the term *microprocessor* was not coined until later). Smaller than a thumbnail and packing 2,300 transistors with 10-micron (millionth of a meter) spacing, the \$200 chip delivered as much computing power as one of the first electronic computers, ENIAC. By comparison, ENIAC relied on 18,000

vacuum tubes packed into 3,000 cubic feet (85 cubic meters) when it was built in 1946. The 4004 ran at 108KHz (just over one tenth of 1MHz) and executed 60,000 operations in 1 second—primitive by today's standards, but a major breakthrough at the time.

Intel introduced the 8008 microcomputer in 1972, which processed 8 bits of information at a time, twice as much as the original chip. By 1981, Intel's microprocessor family had grown to include the 16-bit 8086 and the 8-bit 8088 processors. These two chips garnered an unprecedented 2,500 design wins in a single year. Among those designs was a product from IBM that was to become the first PC.

Note

The term *PC* defines a type of personal computer using Intel architecture processors and loosely based on the original IBM PC, XT, and AT designs. Other types of personal computers existed before the PC, but what we call PCs today have dominated the market since they were first introduced in 1981.

In 1982, Intel introduced the 286 chip. With 134,000 transistors, it provided about three times the performance of other 16-bit processors of the time. Featuring on-chip memory management, the 286 also offered software compatibility with its predecessors. This revolutionary chip was first used in IBM's benchmark PC-AT, the system upon which all modern PCs are based.

In 1985 came the Intel 386 processor. With a new 32-bit architecture and 275,000 transistors, the chip could perform more than five million instructions every second (MIPS). Compaq's DESKPRO 386 was the first PC based on the new microprocessor.

Next out of the gate was the Intel 486 processor in 1989. The 486 had 1.2 million transistors and the first built-in math coprocessor. It was some 50 times faster than the original 4004, equaling the performance of some mainframe computers.

Then, in 1993, Intel introduced the first P5 family (586) processor, called the Pentium, setting new performance standards with up to five times the performance of the Intel 486 processor. The Pentium processor used 3.1 million transistors to perform up to 90 MIPS—now up to about 1,500 times the speed of the original 4004.

Note

Intel's change from using numbers (386/486) to names (Pentium/Pentium Pro) for its processors was based on the fact that it could not secure a registered trademark on a number and therefore could not prevent its competitors from using those same numbers on clone chip designs.

The first processor in the P6 (686) family, called the Pentium Pro processor, was introduced in 1995. With 5.5 million transistors, it was the first to be packaged with a second die containing high-speed L2 memory cache to accelerate performance.

Intel revised the original P6 (686/Pentium Pro) and introduced the Pentium II processor in May 1997. Pentium II processors had 7.5 million transistors packed into a cartridge rather than a conventional chip, allowing them to attach the L2 cache chips directly on the module. The Pentium II family was augmented in April 1998, with both the low-cost Celeron processor for basic PCs and the high-end Pentium II Xeon processor for servers and workstations. Intel followed with the Pentium III in 1999, essentially a Pentium II with Streaming SIMD Extensions (SSE) added.

Around the time the Pentium was establishing its dominance, AMD acquired NexGen, who had been working on its Nx686 processor. AMD incorporated that design along with a Pentium interface into what would be called the AMD K6. The K6 was both hardware and software compatible with the Pentium, meaning it plugged into the same Socket 7 and could run the same programs. As Intel dropped its Pentium in favor of the Pentium II and III, AMD continued making faster versions of the K6 and made huge inroads in the low-end PC market.

During 1998, Intel became the first to integrate L2 cache directly on the processor die (running at the full speed of the processor core), dramatically increasing performance. This was first done on the second-generation Celeron processor (based on the Pentium II core), as well as the Pentium IIPE (performance-enhanced) chip used only in notebook systems. The first high-end desktop PC chip with on-die full-core speed L2 cache was the second-generation (Coppermine core) Pentium III introduced in late 1999. After this, all the major processor manufacturers also integrated the L2 cache on the processor die, a trend that continues today.

AMD introduced the Athlon in 1999 to compete with Intel head to head in the high-end desktop PC market. The Athlon became very successful, and it seemed for the first time that Intel had some real competition in the higher-end systems. In hindsight the success of the Athlon might be easy to see, but at the time they were introduced, their success was anything but assured. Unlike the previous K6 chips, which were both hardware- and software-compatible with Intel processors, the Athlon was only software-compatible and required a motherboard with an Athlon supporting chipset and processor socket.

The year 2000 saw both companies introduce more new chips to the market. AMD premiered both its Athlon Thunderbird and Duron processors. The Duron is essentially an Athlon with a smaller L2 cache designed for lower-cost systems, whereas the Thunderbird uses a more integrated on-die cache to ratchet up the Athlon's performance. The Duron is a lower-cost chip primarily targeted as competition for Intel's lower-cost Celeron processors.

Intel introduced the Pentium 4 in late 2000, the latest processor in the Intel Architecture 32-bit (IA-32) family. It also announced the Itanium processor (code named Merced), which is the first IA-64 (Intel Architecture-64 bit) processor. Itanium is Intel's first processor with 64-bit instructions and is opening a whole new category of operating systems and applications while still remaining backward compatible with 32-bit software.

2000 also saw another significant milestone written into the history books when both Intel and AMD crossed the 1GHz barrier, a speed that many thought could never be accomplished.

►► See "Intel Itanium and Itanium 2," p. 189.

In 2001, Intel introduced a Pentium 4 version running at 2GHz, the first PC processor to achieve that speed. AMD also introduced the Athlon XP, based on its newer Palomino core, as well as the Athlon MP, designed for multiprocessor server systems. During 2001, both AMD and Intel continued to increase the speed of their chips and enhance the existing Pentium III/Celeron, Pentium 4, and Athlon/Duron processors.

In 2002, Intel released a Pentium 4 version running at 3.06GHz, the first PC processor to achieve that speed. This and subsequent 3GHz+ processors feature Intel's hyper-threading (HT) technology, which turns the processor into a virtual dual-processor configuration. By running two application threads at the same time, HT-enabled processors can perform tasks at speeds 25%–40% faster than non-HT-enabled processors can. HT technology is also compatible with Windows XP Home Edition, which doesn't support dual-processor motherboards.

In 2003, AMD released its first 64-bit processor: the Athlon 64 (previously code named ClawHammer or K8). Unlike Intel's first 64-bit processors, the server-oriented Itanium and Itanium 2, which are optimized for a new 64-bit architecture and are relatively slow at running 32-bit x86 instructions used by conventional processors, the Athlon 64 is a 64-bit extension of the x86 family typified by the Athlon, Pentium 4, and earlier processors. Thus, the Athlon 64 runs 32-bit software as quickly as it runs 64-bit software. Intel followed with the Pentium 4 Extreme Edition, the first consumer-level processor that incorporated L3 cache. The whopping 2MB of cache added greatly to the transistor count as well as performance.

History of the PC

The fourth and current generation of the modern computer includes those that incorporate microprocessors in their designs. Of course, part of this fourth generation of computers is the personal computer, which itself was made possible by the advent of low-cost microprocessors and memory.

Birth of the Personal Computer

In 1973, some of the first microcomputer kits based on the 8008 chip were developed. These kits were little more than demonstration tools and didn't do much except blink lights. In April 1974, Intel introduced the 8080 microprocessor, which was 10 times faster than the earlier 8008 chip and addressed 64KB of memory. This was the breakthrough the personal computer industry had been waiting for.

A company called MITS introduced the Altair kit in a cover story in the January 1975 issue of *Popular Electronics*. The Altair kit, considered the first personal computer, included an 8080 processor, a power supply, a front panel with a large number of lights, and 256 bytes (not kilobytes) of memory. The kit sold for \$395 and had to be assembled. Assembly back then meant you got out your soldering iron to actually finish the circuit boards, not like today where you can assemble a system of premade components with nothing more than a screwdriver.

Note

Micro Instrumentation and Telemetry Systems was the original name of the company founded in 1969 by Ed Roberts and several associates to manufacture and sell instruments and transmitters for model rockets. Ed Roberts became the sole owner in the early 1970s, after which he designed the Altair. By January 1975, when the Altair was introduced, the company was called MITS, Inc., which then stood for nothing more than the name of the company. In 1977, Roberts sold MITS to Perlec, moved to Georgia, went to medical school, and is now a practicing physician!

The Altair included an open architecture system bus called the S-100 bus because it had 100 pins per slot. The open architecture meant that anybody could develop boards to fit in these slots and interface to the system. This prompted various add-ons and peripherals from numerous aftermarket companies. The new processor inspired software companies to write programs, including the CP/M (control program for microprocessors) operating system and the first version of the Microsoft BASIC (beginners all-purpose symbolic instruction code) programming language.

IBM introduced what can be called its first personal computer in 1975. The Model 5100 had 16KB of memory, a built-in 16-line-by-64-character display, a built-in BASIC language interpreter, and a built-in DC-300 cartridge tape drive for storage. The system's \$9,000 price placed it out of the mainstream personal computer marketplace, which was dominated by experimenters (affectionately referred to as *hackers*) who built low-cost kits (\$500 or so) as a hobby. Obviously, the IBM system was not in competition for this low-cost market and did not sell as well by comparison.

The Model 5100 was succeeded by the 5110 and 5120 before IBM introduced what we know as the IBM Personal Computer (Model 5150). Although the 5100 series preceded the IBM PC, the older systems and the 5150 IBM PC had nothing in common. The PC that IBM turned out was more closely related to the IBM System/23 DataMaster, an office computer system introduced in 1980. In fact, many of the engineers who developed the IBM PC had originally worked on the DataMaster.

In 1976, a new company called Apple Computer introduced the Apple I, which originally sold for \$666.66. The selling price was an arbitrary number selected by one of Apple's cofounders, Steve Jobs. This system consisted of a main circuit board screwed to a piece of plywood; a case and power supply were not included. Only a few of these computers were made, and they reportedly have sold to collectors for more than \$20,000. The Apple II, introduced in 1977, helped set the standard for nearly all the important microcomputers to follow, including the IBM PC.

The microcomputer world was dominated in 1980 by two types of computer systems. One type, the Apple II, claimed a large following of loyal users and a gigantic software base that was growing at a fantastic rate. The other type, CP/M systems, consisted not of a single system but of all the many systems that evolved from the original MITS Altair. These systems were compatible with one another and were distinguished by their use of the CP/M operating system and expansion slots, which followed the S-100 standard. All these systems were built by a variety of companies and sold under various names. For the most part, however, these systems used the same software and plug-in hardware. It is interesting to note that none of these systems was PC compatible or Macintosh compatible, the two primary standards in place today.

A new competitor looming on the horizon was able to see that to be successful, a personal computer needed to have an open architecture, slots for expansion, a modular design, and healthy support from both hardware and software companies other than the original manufacturer of the system. This competitor turned out to be IBM, which was quite surprising at the time because IBM was not known for systems with these open-architecture attributes! IBM, in essence, became more like the early Apple, and Apple itself became like everybody expected IBM to be. The open architecture of the forthcoming IBM PC and the closed architecture of the forthcoming Macintosh caused a complete turnaround in the industry.

The IBM Personal Computer

At the end of 1980, IBM decided to truly compete in the rapidly growing low-cost personal computer market. The company established the Entry Systems Division, located in Boca Raton, Florida, to develop the new system. The division was located intentionally far away from IBM's main headquarters in New York, or any other IBM facilities, so that this new division would be able to operate independently as a separate unit. This small group consisted of 12 engineers and designers under the direction of Don Estridge and was charged with developing IBM's first real PC. (IBM considered the previous 5100 system, developed in 1975, to be an intelligent programmable terminal rather than a genuine computer, even though it truly was a computer.) Nearly all these engineers had come to the new division from the System/23 DataMaster project, which was a small office computer system introduced in 1980 and was the direct predecessor of the IBM PC.

Much of the PC's design was influenced by the DataMaster design. In the DataMaster's single-piece design, the display and keyboard were integrated into the unit. Because these features were limiting, they became external units on the PC, although the PC keyboard layout and electrical designs were copied from the DataMaster.

Several other parts of the IBM PC system also were copied from the DataMaster, including the expansion bus (or input/output slots), which included not only the same physical 62-pin connector, but also almost identical pin specifications. This copying of the bus design was possible because the PC used the same interrupt controller as the DataMaster and a similar direct memory access (DMA) controller. Also, expansion cards already designed for the DataMaster could easily be redesigned to function in the PC.

The DataMaster used an Intel 8085 CPU, which had a 64KB address limit and an 8-bit internal and external data bus. This arrangement prompted the PC design team to use the Intel 8088 CPU, which offered a much larger (1MB) memory address limit and an internal 16-bit data bus, but only an 8-bit external data bus. The 8-bit external data bus and similar instruction set enabled the 8088 to be easily interfaced into the earlier DataMaster designs.

IBM brought its system from idea to delivery of functioning systems in one year by using existing designs and purchasing as many components as possible from outside vendors. The Entry Systems Division was granted autonomy from IBM's other divisions and could tap resources outside the company, rather than go through the bureaucratic procedures that required exclusive use of IBM resources. IBM contracted out the PC's languages and operating system to a small company named Microsoft. That decision was the major factor in establishing Microsoft as the dominant force in PC software today.

Note

It is interesting to note that IBM had originally contacted Digital Research (the company that created CP/M, then the most popular personal computer operating system) to have it develop an operating system for the new IBM PC. However, Digital was leery of working with IBM and especially balked at the nondisclosure agreement IBM wanted Digital to sign. Microsoft jumped on the opportunity left open by Digital Research and, consequently, has become one of the largest software companies in the world. IBM's use of outside vendors in developing the PC was an open invitation for the aftermarket to jump in and support the system—and it did.

On August 12, 1981, a new standard was established in the microcomputer industry with the debut of the IBM PC. Since then, hundreds of millions of PC-compatible systems have been sold, as the original PC has grown into an enormous family of computers and peripherals. More software has been written for this computer family than for any other system on the market.

The PC Industry More Than 20 Years Later

In the more than 20 years since the original IBM PC was introduced, many changes have occurred. The IBM-compatible computer, for example, advanced from a 4.77MHz 8088-based system to 3GHz or faster Pentium 4–based systems—about 20,000 times faster than the original IBM PC (in actual processing speed, not just clock speed). The original PC had only one or two single-sided floppy drives that stored 160KB each using DOS 1.0, whereas modern systems easily can have 200GB (200 billion bytes) or more of hard disk storage.

A rule of thumb in the computer industry (called Moore's Law, originally set forth by Intel cofounder Gordon Moore) is that available processor performance and disk-storage capacity doubles every one and a half to two years, give or take.

Since the beginning of the PC industry, this pattern has held steady and, if anything, seems to be accelerating.

Moore's Law

In 1965, Gordon Moore was preparing a speech about the growth trends in computer memory and made an interesting observation. When he began to graph the data, he realized a striking trend existed. Each new chip contained roughly twice as much capacity as its predecessor, and each chip was released within 18–24 months of the previous chip. If this trend continued, he reasoned, computing power would rise exponentially over relatively brief periods of time.

Moore's observation, now known as Moore's Law, described a trend that has continued to this day and is still remarkably accurate. It was found to not only describe memory chips, but also accurately describe the growth of processor power and disk drive storage capacity. It has become the basis for many industry performance forecasts. As an example, in 30 years the number of transistors on a processor chip increased more than 18,000 times, from 2,300 transistors on the 4004 processor in 1971 to more than 140 million transistors on the Pentium III Xeon processor in May 2000. By 2007, Intel expects to release processors with one billion transistors running at 20GHz speeds.

In addition to performance and storage capacity, another major change since the original IBM PC was introduced is that IBM is not the only manufacturer of PC-compatible systems. IBM originated the PC-compatible standard, of course, but today it no longer sets the standards for the system it originated. More often than not, new standards in the PC industry are developed by companies and organizations other than IBM.

Today, it is Intel, Microsoft, and to an extent AMD who are primarily responsible for developing and extending the PC hardware and software standards. Some have even taken to calling PCs "Wintel" systems, owing to the dominance of the first two companies. Although AMD originally produced

Intel processors under license and later produced low-cost, pin-compatible counterparts to Intel's 486 and Pentium processors (AMD 486, K5/K6), starting with the Athlon, AMD has created completely unique processors that have been worthy rivals to Intel's Pentium II, III, and 4 models.

In more recent years, Intel, Microsoft, and AMD have carried the evolution of the PC forward. The introduction of hardware standards such as the Peripheral Component Interconnect (PCI) bus, Accelerated Graphics Port (AGP) bus, ATX and NLX motherboard form factors, processor socket and slot interfaces, and numerous others show that Intel is really pushing PC hardware design these days. Intel is also responsible for the motherboard chipsets used to support these features, enabling its newest processors to be immediately available in systems. AMD also makes chipsets for its own processors, but AMD chipsets have acted primarily as reference designs for other vendors to improve upon. Consequently, AMD-based systems often offer much more aggressive customization features than Intel-based systems at a lower cost. In a similar fashion, Microsoft is pushing the software side of things with the continual evolution of the Windows operating system as well as applications such as the Office suite. Both Intel and Microsoft continue to capitalize on the widespread popularity of the Internet, multimedia, and other types of rich media. Such uses as interactive gaming, DVD editing, broadband Internet access, and photo-quality printing are giving more and more people important reasons to use a PC. Even though recent sales have leveled off from the explosive growth of the mid-to-late 1990s, the reality is that most people who want to use a PC for a business or recreational task have one. Today, literally hundreds of system manufacturers follow the collective PC standard and produce computers that are fully PC compatible. In addition, thousands of peripheral manufacturers produce components that expand and enhance PC-compatible systems.

PC-compatible systems have thrived not only because compatible hardware can be assembled easily, but also because the primary operating system was available not from IBM but from a third party (Microsoft). The core of the system software is the basic input/output system (BIOS), and this was also available from third-party companies, such as AMI, Phoenix, and others. This situation enabled other manufacturers to license the operating system and BIOS software and sell their own compatible systems. The fact that DOS borrowed the functionality and user interface from both CP/M and Unix probably had a lot to do with the amount of software that became available. Later, with the success of Windows, even more reasons would exist for software developers to write programs for PC-compatible systems.

One reason Apple Macintosh systems never enjoyed the extreme success of PC systems is that Apple controls all the primary systems software (BIOS and OS) and, with one short-lived exception, has refused to license it to other companies for use in compatible systems.

After years of declining market share, Apple seemed to recognize that refusing to license its operating system was a flawed stance and in the mid-1990s licensed its software to third-party manufacturers such as Power Computing. After a short time, though, Apple canceled its licensing agreements with other manufacturers. Because Apple remains essentially a closed system, other companies cannot develop compatible machines, meaning Apple-compatible systems are available from only one source: Apple. Although the development of low-cost models such as the iMac and Apple's continued popularity with educators and artists have helped Apple maintain and modestly increase its market share, Apple will never effectively compete with the PC-compatible juggernaut because of its closed-system approach. It is fortunate for the computing public as a whole that IBM created a more open and extendible standard, which today finds systems being offered by hundreds of companies in thousands of configurations. This type of competition among manufacturers and vendors of PC-compatible systems is the reason such systems offer so much performance and so many capabilities for the money.

The PC continues to thrive and prosper, and new technology continues to be integrated into these systems, enabling them to grow with the times. These systems offer a high value for the money and have plenty of software available to run on them. It's a safe bet that PC-compatible systems will dominate the personal computer marketplace for the next 20 years.

CHAPTER 2

PC Components, Features, and System Design

What Is a PC?

I normally ask the question, “What exactly is a PC?” when I begin one of my PC hardware seminars. Of course, most people immediately answer that PC stands for *personal computer*, which in fact it does. They might then continue by defining a personal computer as any small computer system purchased and used by an individual. Unfortunately, that definition is not nearly precise or accurate enough for our purposes. I agree that a PC is a personal computer, but not all personal computers are PCs. For example, an Apple Macintosh system is clearly a personal computer, but nobody I know would call a Mac a PC, least of all Mac users! For the true definition of what a PC is, you must look deeper.

Calling something a PC implies that it is something much more specific than just any personal computer. One thing it implies is a family relation to the original IBM PC from 1981. In fact, I’ll go so far as to say that IBM literally *invented* the type of computer we call a PC today; that is, IBM designed and created the very first one, and IBM originally defined and set all the standards that made the PC distinctive from other personal computers. Note that it is very clear in my mind—as well as in the historical record—that IBM did *not* invent the personal computer. (Most recognize the historical origins of the personal computer in the MITS Altair, introduced in 1975.) So, IBM did not invent the personal computer, but it did invent what today we call the PC. Some people might take this definition a step further and define a PC as any personal computer that is “IBM compatible.” In fact, many years back, PCs were called either IBM compatibles or IBM clones, in essence paying homage to the origins of the PC at IBM.

The reality today is that although IBM clearly designed and created the first PC in 1981 and controlled the development and evolution of the PC standard for several years thereafter, IBM is no longer in control of the PC standard; that is, it does not dictate what makes up a PC today. IBM lost control of the PC standard in 1987 when it introduced its PS/2 line of systems. Up until then, other companies that were producing PCs literally copied IBM’s systems right down to the chips; connectors; and even the shapes (form factors) of the boards, cases, and power supplies. After 1987, IBM abandoned many of the standards it created in the first place. That’s why for many years now I have refrained from using the designation “IBM compatible” when referring to PCs.

If a PC is no longer an IBM-compatible system, what is it? The real question seems to be, “Who is in control of the PC standard today?” That question is best broken down into two parts. First, who is in control of PC software? Second, who is in control of PC hardware?

Who Controls PC Software?

Most of the people in my seminars don’t even hesitate for a split second when I ask this question; they immediately respond, “Microsoft!” I don’t think there is any argument with that answer. Microsoft clearly controls the operating systems used on PCs, which have migrated from the original MS-DOS to Windows 3.1/95/98/Me, Windows NT/2000, and now Windows XP.

Microsoft has effectively used its control of the PC operating system as leverage to also control other types of PC software, such as utilities and applications. For example, many utility programs originally offered by independent companies, such as disk caching, disk compression, file defragmentation, file structure repair, and even simple applications such as calculator and notepad programs, are now bundled in (included with) Windows. Microsoft has even bundled more comprehensive applications such as Web browsers, ensuring an automatic installed base for these applications—much to the dismay of companies who produce competing versions. Microsoft has also leveraged its control of the operating system to integrate its own networking software and applications suites more seamlessly into the operating system than others. That’s why it now dominates most of the PC software universe, from operating systems to networking software to utilities, from word processors to database programs to spreadsheets.

In the early days of the PC, when IBM was clearly in control of the PC hardware standard, it hired Microsoft to provide most of the core software for the PC. IBM developed the hardware, wrote the basic input/output system (BIOS), and then hired Microsoft to develop the disk operating system

(DOS), as well as several other programs and utilities for the PC. In what was later viewed as perhaps the most costly business mistake in history, IBM failed to secure exclusive rights to the DOS it had contracted from Microsoft, either by purchasing it outright or by an exclusive license agreement. Instead, IBM licensed it nonexclusively, which subsequently allowed Microsoft to sell the same MS-DOS code it developed for IBM to any other company that was interested. Early PC cloners such as Compaq eagerly licensed this same operating system code, and suddenly consumers could purchase the same basic MS-DOS operating system with several different company names on the box. In retrospect, that single contractual error made Microsoft into the dominant software company it is today and subsequently caused IBM to lose control of the very PC standard it had created.

As a writer myself (of words, not software), I can appreciate what an incredible oversight this was. Imagine that a book publisher comes up with a great idea for a very popular book and then contracts with and subsequently pays an author to write it. Then, by virtue of a poorly written contract, the author discovers that he can legally sell the very same book (perhaps with a different title) to all the competitors of the original publisher. Of course, no publisher I know would allow this to happen; yet that is exactly what IBM allowed Microsoft to do back in 1981. By virtue of its deal with Microsoft, IBM had essentially lost control of the software it commissioned for its new PC from day one.

It is interesting to note that in the PC business, software enjoys copyright protection, whereas hardware can be protected only by patents, which are difficult, time-consuming, and expensive to get and which also expire after 17 years. To patent something requires that it be a unique and substantially new design. This made it impossible to patent most aspects of the IBM PC because it was designed using previously existing parts that anybody could purchase off the shelf! In fact, most of the important parts for the original PC came from Intel, such as the 8088 processor, 8284 clock generator, 8253/54 timer, 8259 interrupt controller, 8237 DMA (direct memory access) controller, 8255 peripheral interface, and 8288 bus controller. These chips made up the heart and soul of the original PC motherboard.

Because the design of the original PC was not wholly patentable, anybody could duplicate the hardware of the IBM PC. All she had to do was purchase the same chips from the same manufacturers and suppliers IBM used and design a new motherboard with a similar circuit. Seemingly as if to aid in this, IBM even published complete schematic diagrams of its motherboards and all its adapter cards in very detailed and easily available technical reference manuals. I have several of these early IBM manuals and still refer to them from time to time for specific component-level PC design information. In fact, I still recommend these original manuals to anybody who wants to delve deeply into PC hardware design.

The difficult part of copying the IBM PC was the software, which is protected by copyright law. Phoenix Software (today known as Phoenix Technologies) was among the first to develop a legal way around this problem, which enabled it to functionally duplicate (but not exactly copy) software such as the BIOS. The *BIOS* is defined as the core set of control software that drives the hardware devices in the system directly. These types of programs are normally called *device drivers*, so in essence, the BIOS is a collection of all the core device drivers used to operate and control the system hardware. The *operating system* (such as DOS or Windows) uses the drivers in the BIOS to control and communicate with the various hardware and peripherals in the system.

►► See Chapter 5, "BIOS," p. 397.

Phoenix's method for legally duplicating the IBM PC BIOS was an ingenious form of reverse-engineering. It hired two teams of software engineers, the second of which had to be specially screened to consist only of people who had never before seen or studied the IBM BIOS code. The first team did study the IBM BIOS and wrote as complete a description of what it did as possible. The second team read the description written by the first team and set out to write from scratch a new BIOS that did everything the first team described. The end result was a new BIOS written from scratch with code that, although not identical to IBM's, had exactly the same functionality.

Phoenix called this a "clean room" approach to reverse-engineering software, and it can escape any legal attack. Because IBM's original PC BIOS consisted of only 8KB of code and had limited functionality,

duplicating it through the clean room approach was not very difficult nor time-consuming. As the IBM BIOS evolved, Phoenix—as well as the other BIOS companies—found that keeping up with any changes IBM made was relatively easy. Discounting the power on self test (POST) or BIOS Setup program (used for configuring the system) portion of the BIOS, most motherboard BIOSs, even today, have only about 32KB–128KB of active code. Today, Phoenix and American Megatrends (AMI) are the leading developers of BIOS software for PC system and motherboard manufacturers. A third major producer of BIOS software, Award Software, is owned by Phoenix Technologies, which continues to sell Award BIOS–based products.

After the hardware and BIOS of the IBM PC were duplicated, all that was necessary to produce a fully IBM-compatible system was DOS. Reverse-engineering DOS, even with the clean room approach, would have been a daunting task because DOS is much larger than the BIOS and consists of many more programs and functions. Also, the operating system has evolved and changed more often than the BIOS, which by comparison has remained relatively constant. This means that the only way to get DOS on an IBM compatible was to license it. This is where Microsoft came in. Because IBM (who hired Microsoft to write DOS in the first place) did not ensure that Microsoft signed an exclusive license agreement, Microsoft was free to sell the same DOS it designed for IBM to anybody else who wanted it. With a licensed copy of MS-DOS, the last piece was in place and the floodgates were open for IBM-compatible systems to be produced whether IBM liked it or not.

In retrospect, this is exactly why there are no clones or compatibles of the Apple Macintosh system. It is not that Mac systems can't be duplicated; in fact, Mac hardware is fairly simple and easy to produce using off-the-shelf parts. The real problem is that Apple owns the Mac OS as well as the BIOS, and because Apple has seen fit not to license them, no other company can sell an Apple-compatible system. Also, note that the Mac BIOS and OS are very tightly integrated; the Mac BIOS is very large and complex, and it is essentially a part of the OS, unlike the much simpler and more easily duplicated BIOS found on PCs. The greater complexity and integration has allowed both the Mac BIOS and OS to escape any clean-room duplication efforts. This means that without Apple's blessing (in the form of licensing), no Mac clones are likely ever to exist.

It might be interesting to note that during 1996–1997, an effort was made by the more liberated thinkers at Apple to license its BIOS/OS combination, and several Mac-compatible machines were developed, produced, and sold. Companies such as Sony, Power Computing, Radius, and even Motorola invested millions of dollars in developing these systems, but shortly after these first Mac clones were sold, Apple rudely canceled all licensing! This was apparently the result of an edict from Steve Jobs, who had been hired back to run the company and who was one of the original architects of the closed-box, proprietary-design Macintosh system in the first place. By canceling these licenses, Apple has virtually guaranteed that its systems will never be a mainstream success. Along with its smaller market share come much higher system costs, fewer available software applications, and fewer hardware upgrades as compared to PCs. The proprietary design also means that major repair or upgrade components, such as motherboards, power supplies, and cases, are available only from Apple at very high prices and upgrades of these components are usually not cost effective.

I often think that if Apple had a different view and had licensed its OS and BIOS early on, this book might be called *Upgrading and Repairing Macs* instead!

Who Controls PC Hardware?

Although it is clear that Microsoft has always controlled PC software by virtue of its control over the PC operating system, what about the hardware? It is easy to see that IBM controlled the PC hardware standard up through 1987. After all, IBM invented the core PC motherboard design; the original expansion bus slot architecture (8/16-bit ISA bus); serial and parallel port implementations; video card design through VGA and XGA standards; floppy and hard disk interface and controller implementations; power supply designs; keyboard interfaces and designs; mouse interface; and even the physical shapes (form factors) of everything from the motherboard to the expansion cards, power supplies, and system chassis. All these pre-1987 IBM PC, XT, and AT system design features are still influencing modern systems today.

But to me the real question is which company has been responsible for creating and inventing newer and more recent PC hardware designs, interfaces, and standards? When I ask people that question, I normally see some hesitation in their responses—some people say Microsoft (but it controls the software, not the hardware), and some say Compaq or Dell, or they name a few other big-name system manufacturers. Only a few surmise the correct answer—Intel.

I can see why many people don't immediately realize this; I mean, how many people actually own an Intel-brand PC? No, not just one that says "Intel inside" on it (which refers only to the system having an Intel processor), but a system that was designed and built by, or even purchased through, Intel. Believe it or not, I think that many—if not most—people today do have Intel PCs!

Certainly this does not mean that consumers have purchased their systems from Intel because Intel does not sell complete PCs to end users. You can't currently order a system from Intel, nor can you purchase an Intel-brand system from somebody else. What I am talking about is the motherboard. In my opinion, the single most important part in a PC system is the motherboard, and I'd say that whoever made your motherboard would be considered the manufacturer of your system. Even back when IBM was the major supplier of PCs, it primarily made the motherboard and contracted out the other components of the system (power supply, disk drives, and so on) to others.

▶▶ See "Motherboards and Buses," p. 201.

Many of the top-selling system manufacturers do design and make their own motherboards. According to *Computer Reseller News* magazine, the top desktop systems manufacturers for the last several years have consistently been names such as HP, Compaq (now owned by HP), and IBM. These companies, for the most part, do design and manufacture their own motherboards, as well as many other system components. In some cases, they even design their own chips and chipset components for their own boards. Although sales are high for these individual companies, a larger overall segment of the market is what those in the industry call the *white-box* systems.

White-box is the term used by the industry to refer to what would otherwise be called *generic* PCs—that is, PCs assembled from a collection of industry-standard, commercially available components. The white-box designation comes from the fact that historically most of the chassis used by this type of system have been white (or ivory or beige).

The great thing about white-box systems is that they use industry-standard components that are interchangeable. This interchangeability is the key to future upgrades and repairs because it ensures that a plethora of replacement parts will be available to choose from and will interchange. For many years, I have recommended avoiding proprietary systems and recommended more industry-standard white-box systems instead.

Companies selling white-box systems do not really manufacture the systems; they assemble them. That is, they purchase commercially available motherboards, cases, power supplies, disk drives, peripherals, and so on, and assemble and market everything together as complete systems. Dell, Gateway, and Micron (now MPC) are some of the larger white-box system assemblers today, but hundreds more could be listed. In overall total volume, this ends up being the largest segment of the PC marketplace today. What is interesting about white-box systems is that, with very few exceptions, you and I can purchase the same motherboards and other components any of the white-box manufacturers can (although we would probably pay more than they do because of the volume discounts they receive). We can assemble a virtually identical white-box system from scratch ourselves, but that is a story for Chapter 22, "Building or Upgrading Systems."

Note that some of these white-box companies have incredible sales—for example, Dell has taken the top PC sales spot from Compaq (now HP), who had held it for many years. Gateway and the other white-box system builders are not far behind.

The point of all this is, of course, that if Dell, Gateway, MPC, and others do not manufacture their own motherboards, who does? You guessed it—Intel. Not only do those specific companies mainly use Intel motherboards, if you check around, you'll find today that many of the systems in the white-box market

come with Intel motherboards. The only place Intel doesn't have a presence is the AMD-based systems designed to support Athlon-branded processors.

Although this is an extreme case, one review of 10 systems in *Computer Shopper* magazine listed 8 out of the 10 systems evaluated as having Intel motherboards. In fact, those 8 used the exact same Intel motherboard. Therefore, those systems differed only in the cosmetics of the exterior case assemblies and by which peripheral components, such as video card, disk drives, keyboard, and so on, were selected. The funny thing was that many of the peripheral items were identical among the systems as well. Before you compare preassembled systems from different manufacturers, be sure to get a listing of which parts they are using; you might be surprised to see how similar the systems on the market at any given time can be.

Although Intel still dominates motherboard sales, that dominance has faltered somewhat from a few years back. Because of Intel's focus on Rambus memory during the early Pentium 4 days, many of the lower-cost system builders switched to alternative products. Also, most of Intel's boards are designed to make overclocking either impossible or extremely difficult, so "hotrod" system builders typically choose non-Intel boards.

AMD, on the other hand, manufactures processors and chipsets but not complete motherboards. For that, AMD relies on a number of other motherboard manufacturers to make boards designed to accept AMD processors. These boards use either the AMD chipsets or other chipsets made by third-party companies specifically to support AMD processors. The same motherboard companies making boards for AMD processor-based systems also make motherboards for Intel processor-based systems, in essence competing directly with Intel's own motherboards.

▶▶ See "Chipsets," p. 239.

How did Intel come to dominate the interior of our PCs? Intel has been the dominant PC processor supplier since IBM chose the Intel 8088 CPU in the original IBM PC in 1981. By controlling the processor, Intel naturally controlled the chips necessary to integrate its processors into system designs. This naturally led Intel into the chipset business. It started its chipset business in 1989 with the 82350 Extended Industry Standard Architecture (EISA) chipset, and by 1993 it had become—along with the debut of the Pentium processor—the largest-volume major motherboard chipset supplier. Now I imagine Intel sitting there, thinking that it makes the processor and all the other chips necessary to produce a motherboard, so why not just eliminate the middleman and make the entire motherboard, too? The answer to this, and a real turning point in the industry, came about in 1994 when Intel became the largest-volume motherboard manufacturer in the world. And Intel has remained solidly on top ever since. It doesn't just lead in this category by any small margin; in fact, during 1997, Intel made more motherboards than the next eight largest motherboard manufacturers combined, with sales of more than 30 million boards, worth more than \$3.6 billion! Note that this figure does not include processors or chipsets—only the boards themselves. These boards end up in the various system assembler brand PCs you and I buy, meaning that most of us are now essentially purchasing Intel-manufactured systems, no matter who actually wielded the screwdriver.

Intel controls the PC hardware standard because it controls the PC motherboard. It not only makes the vast majority of motherboards being used in systems today, but it also supplies the vast majority of processors and motherboard chipsets to other motherboard manufacturers.

Intel also has had a hand in setting several recent PC hardware standards, such as the following:

- PCI (Peripheral Component Interconnect) local bus interface
- PCI Express (originally known as 3GIO), the interface elected by the PCI Special Interest Group (PCI SIG) to replace PCI as a high-performance bus for future PCs
- Accelerated Graphics Port (AGP) interface for high-performance video cards
- ATX motherboard form factor (and variations such as MicroATX and FlexATX), which, beginning in 1996–1997, replaced the (somewhat long-in-the-tooth) IBM-designed Baby-AT form factor that had been used since the early 1980s

- NLX motherboard form factor to replace the proprietary and limited LPX design used by many lower-cost systems, which finally brought motherboard upgradability to those systems
- Desktop Management Interface (DMI) for monitoring system hardware functions
- Dynamic Power Management Architecture (DPMA) and Advanced Power Management (APM) standards for managing power use in the PC

Intel dominates not only the PC, but the entire semiconductor industry. According to the sales figures compiled by iSuppli.com, Intel has more than two and a half times the sales of the next closest semiconductor company (Samsung) and about nine times the sales of competitor AMD (see Table 2.1).

Table 2.1 Top 30 Semiconductor Companies Ranked by 2002 Semiconductor Sales

Supplier	2002 Rank	2002 Sales	2001 Rank	2001 Sales	2000 Rank	2000 Sales
Intel	1	\$23.47	1	\$23.54	1	\$30.21
Samsung	2	\$9.18	4	\$6.14	4	\$8.94
STMicro	3	\$6.31	3	\$6.36	6	\$7.89
TI	4	\$6.20	5	\$6.05	3	\$9.20
Toshiba	5	\$6.19	2	\$6.54	2	\$10.43
Infineon	6	\$5.36	8	\$4.56	8	\$6.74
NEC	7	\$5.26	6	\$5.30	5	\$8.20
Motorola	8	\$4.73	7	\$4.83	7	\$7.71
Philips	9	\$4.36	9	\$4.41	9	\$6.27
Hitachi	10	\$4.05	10	\$4.24	12	\$5.69
Mitsubishi	11	\$3.62	11	\$3.87	11	\$5.79

*Dollars in millions

As you can see by these figures, it is no wonder that a popular industry news Web site called The Register (<http://www.theregister.co.uk>) uses the term “Chipzilla” when referring to the industry giant.

Whoever controls the operating system controls the software for the PC, and whoever controls the processor—and therefore the motherboard—controls the hardware. Because Microsoft and Intel together seem to control software and hardware in the PC today, it is no surprise the modern PC is often called a “Wintel” system.

PC Design Guides

Even though Intel controls PC hardware, Microsoft recognizes its power over the PC from the operating system perspective and has been collaborating with Intel. Together, they have released a series of documents called the “PC *xx* Design Guides” (where *xx* designates the year) as a set of standard specifications to guide both hardware and software developers who are creating products that work with Windows. The requirements in these guides are part of Microsoft’s “Designed for Windows” logo requirement. In other words, if you produce either a hardware or software product and you want the official “Designed for Windows” logo to be on your box, your product must meet the PC *xx* minimum requirements.

Following are the documents that have been produced in this series:

- “Hardware Design Guide for Microsoft Windows 95”
- “Hardware Design Guide Supplement for PC 95”
- “PC 97 Hardware Design Guide”
- “PC 98 System Design Guide”
- “PC 99 System Design Guide”
- “PC 2000 System Design Guide”
- “PC 2001 System Design Guide”

These documents are available for download from the PC Design Guides Web site (<http://www.pcdesguide.org>), as well as the Microsoft Web site (<http://www.microsoft.com/whdc/hwdev/platform/pcdesign/desguide/pcguides.msp>).

These system-design guides present information for engineers who design and build personal computers, expansion cards, and peripheral devices that are to be used with Windows 9x/Me, NT/2000, and XP operating systems. The requirements and recommendations in these guides form the basis for the requirements of the “Designed for Windows” logo program for hardware Microsoft sponsors.

These guides include requirements for basic (desktop and mobile) systems, workstations, and even entertainment PCs. They also address Plug and Play device configuration and power management in PC systems; requirements for universal serial bus (USB) and IEEE-1394; and new devices supported under Windows, including new graphics and video device capabilities, DVD, scanners and digital cameras, and other devices.

Note

These guides do not mean anything directly for the end user; instead, they are meant to be guides for PC manufacturers to design and build their systems. As such, they are guides or recommendations, and they do not have to be followed to the letter. In some ways, they are a market-control tool for Intel and Microsoft to further wield their influence over PC hardware and software. In reality, the market often dictates that some of these recommendations are disregarded, which is one reason they continue to evolve with new versions year after year.

The PC 2001 System Design Guide is the most recent comprehensive design guide produced by Microsoft and Intel. These companies now produce individual whitepapers and other resources for this purpose. For updated system design information, see the following Web sites:

- The Microsoft Windows Platform Design – Overview site at <http://www.microsoft.com/whdc/hwdev/platform/default.msp>
- The Intel developer Web site at <http://developer.intel.com>

System Types

PCs can be broken down into many categories. I like to break them down in two ways—by the type of software they can run and by the motherboard host bus, or processor bus design and width. Because this book concentrates mainly on hardware, let's look at that first.

When a processor reads data, the data moves into the processor via the processor's external data bus connection. The processor's data bus is directly connected to the processor host bus on the motherboard. The processor data bus or host bus is also sometimes referred to as the *local bus* because it is local to the processor that is connected directly to it. Any other devices connected to the host bus essentially appear as if they are directly connected to the processor as well. If the processor has a 32-bit data bus, the motherboard must be wired to have a 32-bit processor host bus. This means the system can move 32 bits of data into or out of the processor in a single cycle.

▶▶ See "Data I/O Bus," p. 46.

Different processors have different data bus widths, and the motherboards designed to accept them require a processor host bus with a matching width. Table 2.2 lists all the Intel and major Intel-compatible processors, their data bus widths, and their internal register sizes.

Table 2.2 Intel and Intel-Compatible Processors and Their Data Bus/Register Widths

Processor	Data Bus Width	Register Size
8088	8-bit	16-bit
8086	16-bit	16-bit
286	16-bit	16-bit
386SX	16-bit	32-bit
386DX	32-bit	32-bit
486/AMD-5x86	32-bit	32-bit
Pentium/AMD-K6	64-bit	32-bit
Pentium Pro/Celeron/II/III	64-bit	32-bit
AMD Duron/Athlon/Athlon XP	64-bit	32-bit
Pentium 4	64-bit	32-bit
Itanium	64-bit	64-bit
AMD Athlon 64	64-bit	64-bit

A common misconception arises in discussions of processor widths. Although the Pentium and newer processors all have 64-bit data bus widths, their internal registers are only 32 bits wide, and they process 32-bit commands and instructions. The Intel Itanium and AMD Athlon 64 are the first Intel-compatible processors to have 64-bit internal registers. Thus, from a software point of view, all chips from the 386 to the Athlon/Duron and Celeron/Pentium 4 have 32-bit registers and execute 32-bit instructions. From the electronic or physical perspective, these 32-bit, software-capable processors have been available in physical forms with 16-bit (386SX), 32-bit (386DX and 486), and 64-bit

(Pentium and beyond) data bus widths. The data bus width is the major factor in motherboard and memory system design because it dictates how many bits move in and out of the chip in one cycle.

- ▶▶ See "Internal Registers (Internal Data Bus)," p. 48.

The Itanium processor has a new Intel architecture 64-bit (IA-64) instruction set, but it can also process the same 32-bit instructions as processors ranging from the 386 through the Pentium 4. The Athlon 64 has a new x86-compatible 64-bit architecture but is designed to use 32-bit instructions written for normal Intel or compatible x86 processors as efficiently as a normal Athlon XP or comparable processor would.

- ▶▶ See "Processor Specifications," p. 41.

Referring to Table 2.2, you can see that all Pentium and newer systems have a 64-bit processor bus. Pentium processors, whether they are the original Pentium, Pentium MMX, Pentium Pro, or even the Pentium II/III or 4, all have 64-bit data buses, as do comparable processors from AMD (K6 family, Athlon, Duron, Athlon XP, and Athlon 64).

As you can see from Table 2.2, systems can be broken down into the following hardware categories:

- 8-bit
- 16-bit
- 32-bit
- 64-bit

What is interesting is that besides the bus width, the 16- through 64-bit systems are remarkably similar in basic design and architecture. The older 8-bit systems are very different, however. This gives us two basic system types, or classes, of hardware:

- 8-bit (PC/XT-class) systems
- 16/32/64-bit (AT-class) systems

In this verbiage, PC stands for personal computer; XT stands for an extended PC; and AT stands for an advanced-technology PC. The terms *PC*, *XT*, and *AT*, as they are used here, are taken from the original IBM systems of those names. The XT was a PC system that included a hard disk for storage in addition to the floppy drives found in the basic PC system. These systems had an 8-bit 8088 processor and an 8-bit Industry Standard Architecture (ISA) bus for system expansion. The *bus* is the name given to expansion slots in which additional plug-in circuit boards can be installed. The 8-bit designation comes from the fact that the ISA bus found in the PC/XT class systems can send and receive only 8 bits of data in a single cycle. The data in an 8-bit bus is sent along eight wires simultaneously, in parallel.

- ▶▶ See "The ISA Bus," p. 350.

16-bit and greater systems are said to be AT-class, which indicates that they follow certain standards and that they follow the basic design first set forth in the original IBM AT system. AT is the designation IBM applied to systems that first included more advanced 16-bit (and later, 32- and 64-bit) processors and expansion slots. AT-class systems must have a processor that is compatible with Intel 286 or higher processors (including the 386, 486, Pentium, Pentium Pro, Pentium II, Pentium III, Pentium 4, and Pentium M processors), and they must have a 16-bit or greater system bus. The system bus architecture is central to the AT system design, along with the basic memory architecture, interrupt request (IRQ), direct memory access (DMA), and I/O port address design. All AT-class systems are similar in the way these resources are allocated and how they function.

The first AT-class systems had a 16-bit version of the ISA bus, which is an extension of the original 8-bit ISA bus found in the PC/XT-class systems. Eventually, several expansion slot or bus designs were developed for AT-class systems, including the following:

- 16-bit ISA/AT bus
- 16-bit PC Card (PCMCIA) bus
- 16/32-bit Extended ISA (EISA) bus

- 16/32-bit PS/2 Micro Channel Architecture (MCA) bus
- 32-bit VESA Local (VL) bus
- 32/64-bit Peripheral Component Interconnect (PCI) bus
- 32-bit CardBus (PCMCIA) bus
- PCI Express bus
- ExpressCard bus
- 32-bit Accelerated Graphics Port (AGP) bus

A system with any of these types of expansion slots is by definition an AT-class system, regardless of the actual Intel or Intel-compatible processor that is used. AT-type systems with 386 or higher processors have special capabilities not found in the first generation of 286-based ATs. These distinct capabilities are in the areas of memory addressing, memory management, and possible 32- or 64-bit wide access to data. Most systems with 386DX or higher chips also have 32-bit bus architectures to take full advantage of the 32-bit data transfer capabilities of the processor.

Until recently, PC systems continued to incorporate a 16-bit ISA slot for backward-compatibility and lower-function adapters. However, in virtually all motherboards today, ISA slots have been completely replaced by PCI slots along with an AGP slot (a specialized expansion slot design) available in most systems (except for a few entry-level models with integrated video) for high-performance graphics. In addition, most portable systems use PC Card (PCMCIA) and CardBus slots in the portable unit and PCI slots in optional docking stations.

Chapter 4, “Motherboards and Buses,” contains in-depth information on these and other PC system buses, including technical information such as pinouts, performance specifications, and bus operation and theory.

Table 2.3 summarizes the primary differences between the older 8-bit (PC/XT) systems and modern AT systems. This information distinguishes between these systems and includes all IBM and compatible models.

Table 2.3 Differences Between PC/XT and AT Systems

System Attributes	(8-Bit) PC/XT Type	(16/32/64-Bit) AT Type
Supported processors	All x86 or x88	286 or higher
Processor modes	Real	Real/Protected/Virtual Real
Software supported	16-bit only	16- or 32-bit
Bus slot width	8-bit	16/32/64-bit
Slot type	ISA only	ISA, EISA, MCA, PC Card, CardBus, ExpressCard, VL-Bus, PCI, PCI Express, and AGP
Hardware interrupts	8 (6 usable)	16 (11 usable)
DMA channels	4 (3 usable)	8 (7 usable)
Maximum RAM	1MB	16MB/4GB or more
Floppy controller speed	250Kbps	250/300/500/1,000 Kbps
Standard boot drive	360KB or 720KB	1.2MB/1.44MB/2.88MB
Keyboard interface	Unidirectional	Bidirectional
CMOS memory/clock	None standard	MC146818-compatible
Serial-port UART	8250B	16450/16550A or greater

The easiest way to identify a PC/XT (8-bit) system is by the 8-bit ISA expansion slots. No matter which processor or other features the system has, if all the slots are 8-bit ISA, the system is a PC/XT. AT (16-bit plus) systems can be similarly identified—they have 16-bit or greater slots of any type. These can be ISA, EISA, MCA, PC Card (formerly PCMCIA), CardBus, VL-Bus, or PCI. Any system using the new high-speed

serial buses such as PCI Express or ExpressCard also qualifies as an AT-class system. Using this information, you can properly categorize virtually any system as a PC/XT type or an AT type. No PC/XT type (8-bit) systems have been manufactured for many years. Unless you are in a computer museum, virtually every system you encounter today is based on the AT-type design.

System Components

A modern PC is both simple and complicated. It is simple in the sense that over the years, many of the components used to construct a system have become integrated with other components into fewer and fewer actual parts. It is complicated in the sense that each part in a modern system performs many more functions than did the same types of parts in older systems.

This section briefly examines all the components and peripherals in a modern PC system. Each item is discussed further in later chapters.

The components and peripherals necessary to assemble a basic modern PC system are listed in Table 2.4.

Table 2.4 Basic PC Components

Component	Description
Motherboard	The motherboard is the core of the system. It really is the PC; everything else is connected to it, and it controls everything in the system. Motherboards are covered in detail in Chapter 4.
Processor	The processor is often thought of as the “engine” of the computer. It’s also called the CPU (central processing unit). Processors are covered in detail in Chapter 3, “Microprocessor Types and Specifications.”
Memory (RAM)	The system memory is often called RAM (for random access memory). This is the primary memory, which holds all the programs and data the processor is using at a given time. Memory is discussed in Chapter 6, “Memory.”
Case/chassis	The case is the frame or chassis that houses the motherboard, power supply, disk drives, adapter cards, and any other physical components in the system. The case is covered in detail in Chapter 21, “Power Supply and Chassis/Case.”
Power supply	The power supply feeds electrical power to every single part in the PC. The power supply is covered in detail in Chapter 21.
Floppy drive	The floppy drive is a simple, inexpensive, low-capacity, removable-media, magnetic-storage device. Many recent systems use other types of removable magnetic or USB-based flash memory devices instead of floppy drives for removable storage. Floppy drives are covered in detail in Chapter 11, “Floppy Disk Storage,” and other removable-media drives are covered in Chapter 12, “High-Capacity Removable Storage.”
Hard drive	The hard disk is the primary archival storage memory for the system. Hard disk drives are also discussed in Chapter 10, “Hard Disk Storage.”
CD or DVD drive	CD (compact disc) and DVD (digital versatile disc) drives are relatively high-capacity, removable media, optical drives; many recent systems include a rewriteable CD (CD-RW) along with or combined with a DVD-ROM drive. These drives are covered in detail in Chapter 13, “Optical Storage.”
Keyboard	The keyboard is the primary device on a PC that is used by a human to communicate with and control a system. Keyboards are covered in Chapter 18, “Input Devices.”
Mouse	Although many types of pointing devices are on the market today, the first and most popular device for this purpose is the mouse. The mouse and other pointing devices are discussed in Chapter 18.
Video card*	The video card controls the information you see on the monitor. Video cards are covered in detail in Chapter 15, “Video Hardware.”
Monitor	Monitors are covered in Chapter 15.
Sound card*	It enables the PC to generate complex sounds. Sound cards and speakers are discussed in detail in Chapter 16, “Audio Hardware.”
Modem*	Most prebuilt PCs ship with a modem (generally an internal modem). Modems and other Internet-connectivity devices and methods are covered in Chapter 19, “Internet Connectivity.”

*Components marked with an * may be integrated into the motherboard on many recent systems, particularly entry-level systems.*

CHAPTER 3

Microprocessor Types and Specifications

Pre-PC Microprocessor History

The brain or engine of the PC is the *processor* (sometimes called *microprocessor*), or *central processing unit (CPU)*. The CPU performs the system's calculating and processing. The processor is often the most expensive single component in the system (although graphics card pricing now surpasses it in some cases); in higher-end systems it can cost up to four or more times more than the motherboard it plugs into. Intel is generally credited with creating the first microprocessor in 1971 with the introduction of a chip called the 4004. Today Intel still has control over the processor market, at least for PC systems. This means that all PC-compatible systems use either Intel processors or Intel-compatible processors from a handful of competitors (such as AMD or VIA/Cyrix).

Intel's dominance in the processor market hadn't always been assured. Although Intel is generally credited with inventing the processor and introducing the first one on the market, by the late 1970s the two most popular processors for personal computers were *not* from Intel (although one was a clone of an Intel processor). Personal computers of that time primarily used the Z-80 by Zilog and the 6502 by MOS Technologies. The Z-80 was noted for being an improved and less expensive clone of the Intel 8080 processor, similar to the way companies such as AMD, VIA/Cyrix, IDT, and Rise Technologies have cloned Intel's Pentium processors. In the Z-80 case, though, the clone had become far more popular than the original. Some might argue that AMD has achieved that type of status over the past year, but even though they have made significant gains, Intel still controls the PC processor market.

Back then I had a system containing both of those processors, consisting of a 1MHz (yes, that's *1*, as in one megahertz!) 6502-based Apple II system with a Microsoft Softcard (Z-80 card) plugged into one of the slots. The Softcard contained a 2MHz Z-80 processor. This enabled me to run software for both processors on the one system. The Z-80 was used in systems of the late 1970s and early 1980s that ran the CP/M operating system, whereas the 6502 was best known for its use in the early Apple I and II computers (before the Mac).

The fate of both Intel and Microsoft was dramatically changed in 1981 when IBM introduced the IBM PC, which was based on a 4.77MHz Intel 8088 processor running the Microsoft Disk Operating System (MS-DOS) 1.0. Since that fateful decision was made to use an Intel processor in the first PC, subsequent PC-compatible systems have used a series of Intel or Intel-compatible processors, with each new one capable of running the software of the processor before it—from the 8088 to the current Pentium 4/III/Celeron and Athlon/Athlon XP. The following sections cover the various types of processor chips that have been used in personal computers since the first PC was introduced almost two decades ago. These sections provide a great deal of technical detail about these chips and explain why one type of CPU chip can do more work than another in a given period of time.

Microprocessors from 1971 to the Present

It is interesting to note that the microprocessor had existed for only 10 years prior to the creation of the PC! Intel invented the microprocessor in 1971; the PC was created by IBM in 1981. Now more than 20 years later, we are still using systems based more or less on the design of that first PC. The processors powering our PCs today are still backward compatible in many ways with the 8088 that IBM selected for the first PC in 1981.

November 15, 2001 marked the 30th anniversary of the microprocessor, and in those 30 years processor speed has increased more than 18,500 times (from 0.108MHz to 2GHz). The story of the development of the first microprocessor, the Intel 4004, can be read in Chapter 1, "Development of the PC." The 4004 was introduced on November 15, 1971 and originally ran at a clock speed of 108KHz (108,000 cycles per second, or just over one-tenth a megahertz). The 4004 contained 2,300 transistors and was built on a 10-micron process. This means that each line, trace, or transistor could be spaced

about 10 microns (millionths of a meter) apart. Data was transferred 4 bits at a time, and the maximum addressable memory was only 640 bytes. The 4004 was designed for use in a calculator but proved to be useful for many other functions because of its inherent programmability. For example, the 4004 was used in traffic light controllers, blood analyzers, and even in the NASA Pioneer 10 deep space probe!

In April 1972, Intel released the 8008 processor, which originally ran at a clock speed of 200KHz (0.2MHz). The 8008 processor contained 3,500 transistors and was built on the same 10-micron process as the previous processor. The big change in the 8008 was that it had an 8-bit data bus, which meant it could move data 8 bits at a time—twice as much as the previous chip. It could also address more memory, up to 16KB. This chip was primarily used in dumb terminals and general-purpose calculators.

The next chip in the lineup was the 8080, introduced in April 1974, running at a clock rate of 2MHz. Due mostly to the faster clock rate, the 8080 processor had 10 times the performance of the 8008. The 8080 chip contained 6,000 transistors and was built on a 6-micron process. Similar to the previous chip, the 8080 had an 8-bit data bus, so it could transfer 8 bits of data at a time. The 8080 could address up to 64KB of memory, significantly more than the previous chip.

It was the 8080 that helped start the PC revolution because this was the processor chip used in what is generally regarded as the first personal computer, the Altair 8800. The CP/M operating system was written for the 8080 chip, and Microsoft was founded and delivered its first product: Microsoft BASIC for the Altair. These initial tools provided the foundation for a revolution in software because thousands of programs were written to run on this platform.

In fact, the 8080 became so popular that it was cloned. A company called Zilog formed in late 1975, joined by several ex-Intel 8080 engineers. In July 1976, it released the Z-80 processor, which was a vastly improved version of the 8080. It was not pin compatible but instead combined functions such as the memory interface and RAM refresh circuitry, which enabled cheaper and simpler systems to be designed. The Z-80 also incorporated a superset of 8080 instructions, meaning it could run all 8080 programs. It also included new instructions and new internal registers, so software designed for the Z-80 would not necessarily run on the older 8080. The Z-80 ran initially at 2.5MHz (later versions ran up to 10MHz) and contained 8,500 transistors. The Z-80 could access 64KB of memory.

RadioShack selected the Z-80 for the TRS-80 Model 1, its first PC. The chip also was the first to be used by many pioneering systems, including the Osborne and Kaypro machines. Other companies followed, and soon the Z-80 was the standard processor for systems running the CP/M operating system and the popular software of the day.

Intel released the 8085, its follow-up to the 8080, in March 1976. Even though it predated the Z-80 by several months, it never achieved the popularity of the Z-80 in personal computer systems. It was popular as an embedded controller, finding use in scales and other computerized equipment. The 8085 ran at 5MHz and contained 6,500 transistors. It was built on a 3-micron process and incorporated an 8-bit data bus.

Along different architectural lines, MOS Technologies introduced the 6502 in 1976. This chip was designed by several ex-Motorola engineers who had worked on Motorola's first processor, the 6800. The 6502 was an 8-bit processor like the 8080, but it sold for around \$25, whereas the 8080 cost about \$300 when it was introduced. The price appealed to Steve Wozniak, who placed the chip in his Apple I and Apple II designs. The chip was also used in systems by Commodore and other system manufacturers. The 6502 and its successors were also used in game consoles, including the original Nintendo Entertainment System (NES) among others. Motorola went on to create the 68000 series, which became the basis for the Apple Macintosh line of computers. Today those systems use the PowerPC chip, also by Motorola and a successor to the 68000 series.

All these previous chips set the stage for the first PC processors. Intel introduced the 8086 in June 1978. The 8086 chip brought with it the original x86 instruction set that is still present in current x86-compatible chips such as the Pentium 4 and AMD Athlon. A dramatic improvement over the previous chips, the 8086 was a full 16-bit design with 16-bit internal registers and a 16-bit data bus. This meant that it could work on 16-bit numbers and data internally and also transfer 16 bits at a time in and out of the chip. The 8086 contained 29,000 transistors and initially ran at up to 5MHz. The chip also used 20-bit addressing, so it could directly address up to 1MB of memory. Although not directly backward compatible with the 8080, the 8086 instructions and language were very similar and enabled older programs to quickly be ported over to run. This later proved important to help jump-start the PC software revolution with recycled CP/M (8080) software.

Although the 8086 was a great chip, it was expensive at the time and more importantly required expensive 16-bit board designs and infrastructure to support it. To help bring costs down, in 1979 Intel released what some called a *crippled* version of the 8086 called the 8088. The 8088 processor used the same internal core as the 8086, had the same 16-bit registers, and could address the same 1MB of memory, but the external data bus was reduced to 8 bits. This enabled support chips from the older 8-bit 8085 to be used, and far less expensive boards and systems could be made. These reasons are why IBM chose the 8088 instead of the 8086 for the first PC.

This decision would affect history in several ways. The 8088 was fully software compatible with the 8086, so it could run 16-bit software. Also, because the instruction set was very similar to the previous 8085 and 8080, programs written for those older chips could be quickly and easily modified to run. This enabled a large library of programs to be quickly released for the IBM PC, thus helping it become a success. The overwhelming blockbuster success of the IBM PC left in its wake the legacy of requiring backward compatibility with it. To maintain the momentum, Intel has pretty much been forced to maintain backward compatibility with the 8088/8086 in most of the processors it has released since then.

To date, backward compatibility has been maintained, but innovating and adding new features has still been possible. One major change in processors was the move from the 16-bit internal architecture of the 286 and earlier processors to the 32-bit internal architecture of the 386 and later chips, which Intel calls IA-32 (Intel Architecture, 32-bit). Intel's 32-bit architecture dates to 1985, and it took a full 10 years for both a partial 32-bit mainstream OS (Windows 95) as well as a full 32-bit OS requiring 32-bit drivers (Windows NT) to surface, and another 6 years for the mainstream to shift to a fully 32-bit environment for the OS and drivers (Windows XP). That's a total of 16 years from the release of 32-bit computing hardware to the full adoption of 32-bit computing in the mainstream with supporting software. I'm sure you can appreciate that 16 years is a lifetime in technology.

Now we are poised for another major architectural jump, as Intel and AMD have introduced 64-bit extensions to the standard 32-bit Intel architecture. Intel had introduced the IA-64 (Intel Architecture, 64-bit) in the form of the Itanium and Itanium 2 processors several years earlier, but this standard was something completely new and not an extension of the existing 32-bit technology. IA-64 was first announced in 1994 as a CPU development project with Intel and HP (codenamed Merced), and the first technical details were made available in October 1997. The result was the IA-64 architecture and Itanium chip, which was officially released in 2001.

Unfortunately, the IA-64 architecture is not an extension of IA-32 but is instead a whole new and completely different architecture. This is fine for non-PC environments such as servers (for which IA-64 was designed), but the PC market has always hinged on backward compatibility. Even though emulating IA-32 within IA-64 is possible, such emulation and support is slow.

AMD seized this opportunity to develop 64-bit extensions to IA-32, which it calls AMD64 and which is also called x86-64. Intel has now introduced its own set of 64-bit extensions, which it calls EM64T or IA-32e mode. As it turns out, the Intel extensions are almost identical to the AMD extensions, meaning they should be software compatible. It seems for the first time that Intel has actually followed AMD in the development of PC architecture.

Of course, what we need to make all this work is a 64-bit operating system and, more importantly, 64-bit drivers for all of our hardware to work under that OS. It will be important to keep all the memory size, software, and driver issues in mind when considering the transition from 32-bit to 64-bit technology. It might not take 16 years for 64-bit computing to become mainstream, but it won't happen overnight either.

PCs have certainly come a long way. The original 8088 processor used in the first PC contained 29,000 transistors and ran at 4.77MHz. The AMD Athlon 64 and Athlon 64 FX include 106 million transistors, the Pentium 4 580 (Prescott core) runs at 4GHz and has 125 million transistors, and the Extreme Edition Pentium 4 versions have even more due to their integrated L3 cache. Transistor count and cache sizes are expected to rise even more in the future.

Although it is technically not a PC processor, Intel's Itanium 2 (Madison core) gives a glimpse at where things are going for the processor in the PC on your desk. The Itanium 2 incorporates up to 6MB of integrated L3 cache and has an incredible 410 million transistors on a 374 sq.mm (over 19.3mm square) die using 0.13-micron technology. This establishes new records for transistor count as well as the amount of on-die cache. Future processor models with one billion transistors or more are in development. Intel has also released processors running at speeds up to and beyond 4GHz, and AMD is not very far behind. And the progress doesn't stop there because, according to Moore's Law, processing speed and transistor counts are doubling every 1.5–2 years.

Processor Specifications

Many confusing specifications often are quoted in discussions of processors. The following sections discuss some of these specifications, including the data bus, address bus, and speed. The next section includes a table that lists the specifications of virtually all PC processors.

Processors can be identified by two main parameters: how wide they are and how fast they are. The speed of a processor is a fairly simple concept. Speed is counted in megahertz (MHz) and gigahertz (GHz), which means millions and billions, respectively, of cycles per second—and faster is better! The width of a processor is a little more complicated to discuss because three main specifications in a processor are expressed in width. They are

- Data (I/O) bus
- Address bus
- Internal registers

Note that the processor data bus is also called the front side bus (FSB), processor side bus (PSB), or just CPU bus. All these terms refer to the bus that is between the CPU and the main chipset component (North Bridge or Memory Controller Hub). Intel uses the FSB or PSB terminology, whereas AMD uses only FSB. Personally I usually just like to say "CPU bus" in conversation or when speaking during my training seminars because that is the least confusing of the terms while also being completely accurate.

The number of bits a processor is designated can be confusing. All modern processors have 64-bit data buses; however, that does not mean they are classified as 64-bit processors. Processors such as the Pentium 4 and Athlon XP are 32-bit processors because their internal registers are 32 bits wide, although their data I/O buses are 64 bits wide and their address buses are 36 bits wide (both wider than their predecessors, the Pentium and K6 processors). The Itanium series and the AMD Opteron and Athlon 64 are 64-bit processors because their internal registers are 64 bits wide.

First, I'll present some tables describing the differences in specifications between all the PC processors; then the following sections will explain the width and other specifications in more detail. Refer to these tables as you read about the various processor specifications, and the information in the tables will become clearer.

Tables 3.1–3.4 list the Intel processors, AMD processors, and alternative processors from other manufacturers.

Table 3.1 Intel Processor Specifications

Processor	Process (Micron)	Clock Multiplier	Voltage	Internal Register Size	Data Bus Width	Max. Memory	L1 Cache
8088	3.0	1x	5V	16-bit	8-bit	1MB	—

1. L2 cache runs at full-core speed but is contained in a separate chip die.

2. The Itanium also includes an additional 2MB (150M transistors) or 4MB (300M transistors) of integrated on-cartridge L3 cache running at full-core speed.

Data I/O Bus

Perhaps the most important features of a processor are the speed and width of its external data bus. This defines the rate at which data can be moved into or out of the processor.

The processor bus discussed most often is the external data bus—the bundle of wires (or pins) used to send and receive data. The more signals that can be sent at the same time, the more data can be transmitted in a specified interval and, therefore, the faster (and wider) the bus. A wider data bus is like having a highway with more lanes, which enables greater throughput.

Data in a computer is sent as digital information consisting of a time interval in which a single wire carries 3.3V or 5V to signal a 1 data bit or 0V to signal a 0 data bit. The more wires you have, the more individual bits you can send in the same time interval. All modern processors from the original Pentium through the latest Pentium 4, Athlon XP, Athlon 64, and even the Itanium and Itanium 2 have a 64-bit (8-byte) wide data bus. Therefore, they can transfer 64 bits of data at a time to and from the motherboard chipset or system memory.

A good way to understand this flow of information is to consider a highway and the traffic it carries. If a highway has only one lane for each direction of travel, only one car at a time can move in a certain direction. If you want to increase traffic flow, you can add another lane so that twice as many cars pass in a specified time. You can think of an 8-bit chip as being a single-lane highway because 1 byte flows through at a time. (1 byte equals 8 individual bits.) The 16-bit chip, with 2 bytes flowing at a time, resembles a two-lane highway. You might have four lanes in each direction to move a large number of automobiles; this structure corresponds to a 32-bit data bus, which has the capability to move 4 bytes of information at a time. Taking this further, a 64-bit data bus is like having an 8-lane highway moving data in and out of the chip.

Another ramification of the data bus in a chip is that the width of the data bus also defines the size of a bank of memory. So, a processor with a 32-bit data bus (such as the 486) reads and writes memory 32 bits at a time, whereas processors with a 64-bit data bus (most current processors) read and write memory 64 bits at a time.

In 486 class systems, because standard 72-pin single inline memory modules (SIMMs) are only 32 bits wide, they must be installed one at a time in most 486 class systems. When used in 64-bit Pentium class systems,

L2 Cache	L3 Cache	L2/L3 Cache Speed	Multimedia Instructions	No. of Transistors	Date Introduced

3. Samuel 2 core (improved version of Cyrix III core).

5. Ezra-T core.

4. Ezra core.

6. Nehemiah core.

they must be installed two at a time. The current module standard, dual inline memory modules (DIMMs), are 64 bits wide. So, they are normally installed one at a time, unless the system is designed or configured for dual-channel memory. Dual-channel memory reads and writes two banks simultaneously, which means two DIMMs must be installed at a time. To improve memory performance, most future chipsets will support and eventually require that DIMM memory modules be installed in identical pairs.

The Rambus inline memory modules (RIMMs) used in some Pentium III and 4 systems are somewhat of an anomaly because they play by a different set of rules. They are typically only 16 or 32 bits wide. Depending on the module type and chipset, they are either used individually or in pairs.

▶▶ See "Memory Banks," p. 496.

Address Bus

The address bus is the set of wires that carries the addressing information used to describe the memory location to which the data is being sent or from which the data is being retrieved. As with the data bus, each wire in an address bus carries a single bit of information. This single bit is a single digit in the address. The more wires (digits) used in calculating these addresses, the greater the total number of address locations. The size (or width) of the address bus indicates the maximum amount of RAM a chip can address.

The highway analogy in the "Data I/O Bus" section can be used to show how the address bus fits in. If the data bus is the highway and the size of the data bus is equivalent to the number of lanes, the address bus relates to the house number or street address. The size of the address bus is equivalent to the number of digits in the house address number. For example, if you live on a street in which the address is limited to a two-digit (base 10) number, no more than 100 distinct addresses (00–99) can exist for that street (10^2). Add another digit, and the number of available addresses increases to 1,000 (000–999), or 10^3 .

Computers use the binary (base 2) numbering system, so a two-digit number provides only four unique addresses (00, 01, 10, and 11), calculated as 2^2 . A three-digit number provides only eight addresses (000–111), which is 2^3 . For example, the 8086 and 8088 processors use a 20-bit address bus that calculates as a maximum of 2^{20} or 1,048,576 bytes (1MB) of address locations. Table 3.5 describes the memory-addressing capabilities of processors.

Table 3.5 Processor Physical Memory-Addressing Capabilities

Processor Family	Address Bus	Bytes	Kilobytes (KB)	Megabytes (MB)	Gigabytes (GB)	Terabytes (TB)

Note: The terms kilobytes (KB), megabytes (MB), and terabytes (TB) are used here and throughout this chapter by convention; however, technically they should in the future be represented as kibibytes (KiB), gibibytes (GiB), and tebibytes (TiB). See www.iec.ch/zone/si/si_bytes.htm for more information.

The data bus and address bus are independent, and chip designers can use whatever size they want for each. Usually, however, chips with larger data buses have larger address buses. The sizes of the buses can provide important information about a chip's relative power, measured in two important ways. The size of the data bus is an indication of the chip's information-moving capability, and the size of the address bus tells you how much memory the chip can handle.

Internal Registers (Internal Data Bus)

The size of the internal registers indicates how much information the processor can operate on at one time and how it moves data around internally within the chip. This is sometimes also referred to as the *internal data bus*. A *register* is a holding cell within the processor; for example, the processor can add numbers in two different registers, storing the result in a third register. The register size determines the size of data on which the processor can operate. The register size also describes the type of software or commands and instructions a chip can run. That is, processors with 32-bit internal registers can run 32-bit instructions that are processing 32-bit chunks of data, but processors with 16-bit registers can't. Most advanced processors today—chips from the 386 to the Pentium 4—use 32-bit internal registers and can therefore run the same 32-bit operating systems and software. The Itanium and Athlon 64 processors have 64-bit internal registers, which require new operating systems and software to fully be utilized.

Some very old processors have an internal data bus (made up of data paths and storage units called registers) that is larger than the external data bus. The 8088 and 386SX are examples of this structure. Each chip has an internal data bus twice the width of the external bus. These designs, which sometimes are called *hybrid designs*, usually are low-cost versions of a “pure” chip. The 386SX, for example, can pass data around internally with a full 32-bit register size; for communications with the outside world, however, the chip is restricted to a 16-bit-wide data path. This design enabled a systems designer to build a lower-cost motherboard with a 16-bit bus design and still maintain software and instruction set compatibility with the full 32-bit 386. However, both the 8088 and the 386SX had lower performance than the 8086 and 386DX processors at the same speeds.

Internal registers often are larger than the data bus, which means the chip requires two cycles to fill a register before the register can be operated on. For example, both the 386SX and 386DX have internal 32-bit registers, but the 386SX must “inhale” twice (figuratively) to fill them, whereas the 386DX can do the job in one “breath.” The same thing would happen when the data is passed from the registers back out to the system bus.

The Pentium is an example of this type of design. All Pentiums have a 64-bit data bus and 32-bit registers—a structure that might seem to be a problem until you understand that the Pentium has two internal 32-bit pipelines for processing information. In many ways, the Pentium is like two 32-bit chips in one. The 64-bit data bus provides for very efficient filling of these multiple registers. Multiple pipelines are called *superscalar* architecture, which was introduced with the Pentium processor.

▶▶ See “Pentium Processors,” p. 125.

More advanced sixth- and seventh-generation processors from Intel and AMD have as many as six internal pipelines for executing instructions. Although some of these internal pipes are dedicated to special functions, these processors can execute multiple operations in one clock cycle.

Processor Modes

All Intel and Intel-compatible 32-bit processors (from the 386 on up) can run in several modes. Processor modes refer to the various operating environments and affect the instructions and capabilities of the chip. The processor mode controls how the processor sees and manages the system memory and the tasks that use it.

The three main modes of operation with several submodes are as follows:

- Real mode (16-bit software)
- IA-32 mode:
 - Protected mode (32-bit software)
 - Virtual real mode (16-bit programs within a 32-bit environment)
- IA-32e 64-bit extension mode (also called AMD64, x86-64, or EM64T):
 - 64-bit mode (64-bit software)
 - Compatibility mode (32-bit software)

Table 3.6 summarizes the processor modes.

Table 3.6 Processor Modes

Mode	Submode	OS Required	Software	Memory Address Size	Default Operand Size	Register Width
Real	—	16-bit	16-bit	24-bit	16-bit	16-bit
IA-32	Protected	32-bit	32-bit	32-bit	32-bit	32/16-bit
	Virtual real	32-bit	16-bit	24-bit	16-bit	16-bit
IA-32e	64-bit	64-bit	64-bit	64-bit	32-bit	64-bit
	Compatibility	64-bit	32-bit	32-bit	32-bit	32/16-bit

Real Mode

Real mode is sometimes called 8086 mode because it is based on the 8086 and 8088 processors. The original IBM PC included an 8088 processor that could execute 16-bit instructions using 16-bit internal registers and could address only 1MB of memory using 20 address lines. All original PC software

was created to work with this chip and was designed around the 16-bit instruction set and 1MB memory model. For example, DOS and all DOS software, Windows 1.x through 3.x, and all Windows 1.x through 3.x applications are written using 16-bit instructions. These 16-bit operating systems and applications are designed to run on an original 8088 processor.

◀◀ See “Internal Registers (Internal Data Bus),” p. 48.

◀◀ See “Address Bus,” p. 47.

Later processors such as the 286 could also run the same 16-bit instructions as the original 8088, but much faster. In other words, the 286 was fully compatible with the original 8088 and could run all 16-bit software just the same as an 8088, but, of course, that software would run faster. The 16-bit instruction mode of the 8088 and 286 processors has become known as *real mode*. All software running in real mode must use only 16-bit instructions and live within the 20-bit (1MB) memory architecture it supports. Software of this type is usually single-tasking—only one program can run at a time. No built-in protection exists to keep one program from overwriting another program or even the operating system in memory, so if more than one program is running, one of them could bring the entire system to a crashing halt.

IA-32 Mode (32-Bit)

Then came the 386, which was the PC industry's first 32-bit processor. This chip could run an entirely new 32-bit instruction set. To take full advantage of the 32-bit instruction set, a 32-bit operating system and a 32-bit application were required. This new 32-bit mode was referred to as *protected mode*, which alludes to the fact that software programs running in that mode are protected from overwriting one another in memory. Such protection helps make the system much more crash-proof because an errant program can't very easily damage other programs or the operating system. In addition, a crashed program can be terminated while the rest of the system continues to run unaffected.

Knowing that new operating systems and applications—which take advantage of the 32-bit protected mode—would take some time to develop, Intel wisely built a backward compatible real mode into the 386. That enabled it to run unmodified 16-bit operating systems and applications. It ran them quite well—much more quickly than any previous chip. For most people, that was enough. They did not necessarily want any new 32-bit software; they just wanted their existing 16-bit software to run more quickly. Unfortunately, that meant the chip was never running in the 32-bit protected mode, and all the features of that capability were being ignored.

When a high-powered processor such as a Pentium 4 is running DOS (real mode), it acts like a “Turbo 8088.” Turbo 8088 means the processor has the advantage of speed in running any 16-bit programs; it otherwise can use only the 16-bit instructions and access memory within the same 1MB memory map of the original 8088. Therefore, if you have a 256MB Pentium 4 or Athlon system running Windows 3.x or DOS, you are effectively using only the first megabyte of memory, leaving the other 255MB largely unused!

New operating systems and applications that ran in the 32-bit protected mode of the modern processors were needed. Being stubborn, we resisted all the initial attempts at getting switched over to a 32-bit environment. It seems that as a user community, we are very resistant to change and would be content with our older software running faster rather than adopting new software with new features. I'll be the first one to admit that I was one of those stubborn users myself!

Because of this resistance, true 32-bit operating systems such as Unix or variants (such as Linux), OS/2, and even Windows NT/2000 or XP have taken a long time in getting a mainstream share in the PC marketplace. Windows XP is the first full 32-bit OS that has become a true mainstream product, and that is primarily because Microsoft has coerced us in that direction with Windows 95, 98, and Me (which are mixed 16-/32-bit systems). Windows 3.x was the last full 16-bit operating system. In fact, it was not really considered a complete operating system because it ran on top of DOS.

The Itanium processor family and the AMD Opteron add 64-bit native capability to the table for servers, whereas the AMD Athlon 64 provides this capability for desktop computers. Both processors run all the existing 32-bit software, but to fully take advantage of the processor, a 64-bit OS and applications are required. Microsoft has released 64-bit versions of Windows XP, and several companies have released 64-bit applications for networking and workstation use.

Note

The Intel Itanium family and the AMD Athlon 64/Opteron use different 64-bit architectures. Thus, 64-bit software written for one will not work on the other without being recompiled by the software vendor. This means that software written specifically for the Intel 64-bit architecture will not run on the AMD 64-bit processors and vice versa.

IA-32 Virtual Real Mode

The key to the backward compatibility of the Windows 32-bit environment is the third mode in the processor: virtual real mode. *Virtual real* is essentially a virtual real mode 16-bit environment that runs inside 32-bit protected mode. When you run a DOS prompt window inside Windows, you have created a virtual real mode session. Because protected mode enables true multitasking, you can actually have several real mode sessions running, each with its own software running on a virtual PC. These can all run simultaneously, even while other 32-bit applications are running.

Note that any program running in a virtual real mode window can access up to only 1MB of memory, which that program will believe is the first and only megabyte of memory in the system. In other words, if you run a DOS application in a virtual real window, it will have a 640KB limitation on memory usage. That is because there is only 1MB of total RAM in a 16-bit environment and the upper 384KB is reserved for system use. The virtual real window fully emulates an 8088 environment, so that aside from speed, the software runs as if it were on an original real mode-only PC. Each virtual machine gets its own 1MB address space, an image of the real hardware BIOS routines, and emulation of all other registers and features found in real mode.

Virtual real mode is used when you use a DOS window to run a DOS or Windows 3.x 16-bit program. When you start a DOS application, Windows creates a virtual DOS machine under which it can run.

One interesting thing to note is that all Intel and Intel-compatible (such as AMD and Cyrix) processors power up in real mode. If you load a 32-bit operating system, it automatically switches the processor into 32-bit mode and takes control from there.

It's also important to note that some 16-bit (DOS and Windows 3.x) applications misbehave in a 32-bit environment, which means they do things that even virtual real mode does not support. Diagnostics software is a perfect example of this. Such software does not run properly in a real-mode (virtual real) window under Windows. In that case, you can still run your Pentium 4 in the original no-frills real mode by either booting to a DOS floppy or, in the case of Windows 9x (excluding Me), interrupting the boot process and commanding the system to boot plain DOS. This is accomplished on Windows 9x systems by pressing the F8 key when you see the prompt `Starting Windows...` on the screen or immediately after the beep when the power on self test (POST) is completed. In the latter case, it helps to press the F8 key multiple times because getting the timing just right is difficult and Windows 9x looks for the key only during a short two-second time window.

If successful, you will then see the Startup menu. You can select one of the command-prompt choices that tell the system to boot plain 16-bit real mode DOS. The choice of Safe Mode Command Prompt is best if you are going to run true hardware diagnostics, which do not normally run in protected mode and should be run with a minimum of drivers and other software loaded.

Even though Windows Me is based on Windows 98, Microsoft removed the DOS Startup menu option in an attempt to further wean us from any 16-bit operation. Windows NT, 2000, and XP also lack the capability to start up DOS in this manner. For these operating systems, you need a startup disk (CD or floppy),

which you can use to boot the system in real mode. Generally, you would do this to perform certain maintenance procedures, such as running hardware diagnostics or doing direct disk sector editing.

Although real mode is used by 16-bit DOS and “standard” DOS applications, special programs are available that “extend” DOS and allow access to extended memory (over 1MB). These are sometimes called *DOS extenders* and usually are included as part of any DOS or Windows 3.x software that uses them. The protocol that describes how to make DOS work in protected mode is called DOS protected mode interface (DPMI).

DPMI was used by Windows 3.x to access extended memory for use with Windows 3.x applications. It allowed these programs to use more memory even though they were still 16-bit programs. DOS extenders are especially popular in DOS games because they enable them to access much more of the system memory than the standard 1MB most real mode programs can address. These DOS extenders work by switching the processor in and out of real mode. In the case of those that run under Windows, they use the DPMI interface built into Windows, enabling them to share a portion of the system’s extended memory.

Another exception in real mode is that the first 64KB of extended memory is actually accessible to the PC in real mode, despite the fact that it’s not supposed to be possible. This is the result of a bug in the original IBM AT with respect to the 21st memory address line, known as A20 (A0 is the first address line). By manipulating the A20 line, real-mode software can gain access to the first 64KB of extended memory—the first 64KB of memory past the first megabyte. This area of memory is called the *high memory area (HMA)*.

IA-32e 64-Bit Extension Mode (AMD64, x86-64, EM64T)

64-bit extension mode is an enhancement to the IA-32 architecture originally designed by AMD and later adopted by Intel. Processors with 64-bit extension technology can run in real (8086) mode, IA-32 mode, or IA-32e mode. IA-32 mode enables the processor to run in protected mode and virtual real mode. IA-32e mode allows the processor to run in 64-bit mode and compatibility mode, which means you can run both 64-bit and 32-bit applications simultaneously. IA-32e mode includes two submodes:

- *64-bit mode*. Enables a 64-bit operating system to run 64-bit applications
- *Compatibility mode*. Enables a 64-bit operating system to run most existing 32-bit software

IA-32e 64-bit mode is enabled by loading a 64-bit operating system and is used by 64-bit applications. In the 64-bit submode, the following new features are available:

- 64-bit linear memory addressing
- Physical memory support beyond 4GB (limited by the specific processor)
- Eight new general-purpose registers (GPRs)
- Eight new registers for streaming SIMD extensions (MMX, SSE, SSE2, and SSE3)
- 64-bit-wide GPRs and instruction pointers

IA-32e compatibility mode enables 32-bit and 16-bit applications to run under a 64-bit operating system. Unfortunately, legacy 16-bit programs that run in virtual real mode (that is, DOS programs) are not supported and will not run, which is likely to be the biggest problem for many users. Similar to 64-bit mode, compatibility mode is enabled by the operating system on an individual code basis, which means 64-bit applications running in 64-bit mode can operate simultaneously with 32-bit applications running in compatibility mode.

What we need to make all this work is a 64-bit operating system and, more importantly, 64-bit drivers for all our hardware to work under that OS. A 64-bit OS already exists in two versions:

- Windows XP 64-bit Edition for Itanium
- Windows XP 64-bit Edition for 64-bit Extended Systems

Of those, the first is for IA-64 processors, such as Itanium and Itanium 2, and has been available in a released production version since 2001. The latter is for IA-32 processors with 64-bit extensions, such as the Athlon 64, Opteron, and future Xeon and Pentium processors supporting 64-bit extensions, and was released in a production version in the last half of 2004.

The differences between Windows XP 32-bit and 64-bit versions are shown in Table 3.7.

Table 3.7 Windows XP 32-Bit Versus 64-Bit

Address Space	Windows XP 32-Bit	Windows XP 64-Bit
Physical memory	4GB	32TB
Virtual memory	4GB	16TB
Paging file	16TB	512TB
Paged pool	470MB	128GB
Non-paged pool	256MB	128GB
System cache	1GB	1TB

The major difference between 32-bit and 64-bit Windows XP is memory support, specifically breaking the 4GB barrier found in 32-bit Windows systems. Windows XP 32-bit supports up to 4GB of physical or virtual memory, with up to 2GB of dedicated memory per process. Windows XP 64-bit Edition supports up to 32GB of physical memory and up to 16TB of virtual memory. Support for more memory means applications can preload more data into either physical or virtual memory, which the processor can access much more quickly. If you need more than 4GB of RAM, 64-bit systems and 64-bit Windows are required.

Windows XP 64-bit runs 32-bit Windows applications with no problems, but it does not run DOS applications or other programs that run in virtual real mode. Also, drivers are another big problem. 32-bit processes cannot load 64-bit dynamic link libraries (DLLs), and 64-bit processes cannot load 32-bit DLLs. This essentially means that, for all the devices you have connected to your system, you need both 32-bit and 64-bit drivers for them to work. Acquiring 64-bit drivers for older devices or devices that are no longer supported can be difficult or impossible. Even for new devices, it can be a couple of years before manufacturers provide 64-bit drivers as a standard feature.

You should keep all the memory size, software, and driver issues in mind when considering the transition from 32-bit to 64-bit technology. The transition from 32-bit hardware to mainstream 32-bit computing took 16 years. As I've already stated, it might not take 16 years for 64-bit computing to become mainstream, but it will most likely take at least a few years.

Processor Speed Ratings

A common misunderstanding about processors is their different speed ratings. This section covers processor speed in general and then provides more specific information about Intel, AMD, and VIA/Cyrix processors.

A computer system's clock speed is measured as a frequency, usually expressed as a number of cycles per second. A crystal oscillator controls clock speeds using a sliver of quartz sometimes contained in what looks like a small tin container. Newer systems include the oscillator circuitry in the motherboard chipset, so it might not be a visible separate component on newer boards. As voltage is applied to the quartz, it begins to vibrate (oscillate) at a harmonic rate dictated by the shape and size of the crystal (sliver). The oscillations emanate from the crystal in the form of a current that alternates at the harmonic rate of the crystal. This alternating current is the clock signal that forms the time base on which the computer operates. A typical computer system runs millions of these cycles per second, so speed is measured in megahertz. (One hertz is equal to one cycle per second.) An alternating current signal is like a sine wave, with the time between the peaks of each wave defining the frequency (see Figure 3.1).

Figure 3.1 Alternating current signal showing clock cycle timing.

Note

The hertz was named for the German physicist Heinrich Rudolf Hertz. In 1885, Hertz confirmed the electromagnetic theory, which states that light is a form of electromagnetic radiation and is propagated as waves.

A single cycle is the smallest element of time for the processor. Every action requires at least one cycle and usually multiple cycles. To transfer data to and from memory, for example, a modern processor such as the Pentium 4 needs a minimum of three cycles to set up the first memory transfer and then only a single cycle per transfer for the next three to six consecutive transfers. The extra cycles on the first transfer typically are called *wait states*. A wait state is a clock tick in which nothing happens. This ensures that the processor isn't getting ahead of the rest of the computer.

►► See "SIMMs, DIMMs, and RIMMs," p. 477.

The time required to execute instructions also varies:

- **8086 and 8088.** The original 8086 and 8088 processors take an average of 12 cycles to execute a single instruction.
- **286 and 386.** The 286 and 386 processors improve this rate to about 4.5 cycles per instruction.
- **486.** The 486 and most other fourth-generation Intel-compatible processors, such as the AMD 5x86, drop the rate further, to about 2 cycles per instruction.
- **Pentium, K6 series.** The Pentium architecture and other fifth-generation Intel-compatible processors, such as those from AMD and Cyrix, include twin instruction pipelines and other improvements that provide for operation at one or two instructions per cycle.
- **Pentium Pro, Pentium II/III/4/Celeron, and Athlon/Athlon XP/Duron.** These P6 and P7 (sixth- and seventh-generation) processors can execute as many as three or more instructions per cycle.

Different instruction execution times (in cycles) make comparing systems based purely on clock speed or number of cycles per second difficult. How can two processors that run at the same clock rate perform differently with one running "faster" than the other? The answer is simple: efficiency.

The main reason the 486 was considered fast relative to a 386 is that it executes twice as many instructions in the same number of cycles. The same thing is true for a Pentium; it executes about twice as many instructions in a given number of cycles as a 486. Therefore, given the same clock speed, a Pentium is twice as fast as a 486, and consequently a 133MHz 486 class processor (such as the AMD 5x86-133) is not even as fast as a 75MHz Pentium! That is because Pentium megahertz are "worth" about double what 486 megahertz are worth in terms of instructions completed per cycle.

The Pentium II and III are about 50% faster than an equivalent Pentium at a given clock speed because they can execute about that many more instructions in the same number of cycles.

Unfortunately, after the Pentium III, it becomes much more difficult to compare processors on clock speed alone. This is because the different internal architectures make some processors more efficient than others, but these same efficiency differences result in circuitry that is capable of running at different maximum speeds. The less efficient the circuit, the higher the clock speed it can attain, and vice versa.

Comparing relative processor performance, you can see that a 1GHz Pentium III is about equal to a (theoretical) 1.5GHz Pentium, which is about equal to a 3GHz 486, which is about equal to a 6GHz 386 or 286, which is about equal to a 12GHz 8088. The original PC's 8088 ran at only 4.77MHz; today, we have systems that are comparatively at least 2,500 times faster! As you can see, you must be careful in comparing systems based on pure MHz alone because many other factors affect system performance.

Evaluating CPU performance can be tricky. CPUs with different internal architectures do things differently and can be relatively faster at certain things and slower at others. To fairly compare various CPUs at different clock speeds, Intel has devised a specific series of benchmarks called the *iCOMP* (*Intel Comparative Microprocessor Performance*) index that can be run against processors to produce a relative gauge of performance. The iCOMP index benchmark has been updated twice and released in original iCOMP, iCOMP 2.0, and now iCOMP 3.0 versions.

Table 3.8 shows the relative power, or iCOMP 2.0 index, for several processors.

Note

Note that this reflects the most recent iCOMP index. Intel uses other benchmarks for the Pentium 4.

Table 3.8 Intel iCOMP 2.0 Index Ratings

Processor	iCOMP 2.0 Index	Processor	iCOMP 2.0 Index
Pentium 75	67	Pentium Pro 200	220
Pentium 100	90	Celeron 300	226
Pentium 120	100	Pentium II 233	267
Pentium 133	111	Celeron 300A	296
Pentium 150	114	Pentium II 266	303
Pentium 166	127	Celeron 333	318
Pentium 200	142	Pentium II 300	332
Pentium-MMX 166	160	Pentium II OverDrive 300	351
Pentium Pro 150	168	Pentium II 333	366
Pentium-MMX 200	182	Pentium II 350	386
Pentium Pro 180	197	Pentium II OverDrive 333	387
Pentium-MMX 233	203	Pentium II 400	440
Celeron 266	213	Pentium II 450	483

The iCOMP 2.0 index is derived from several independent benchmarks and is a stable indication of relative processor performance. The benchmarks balance integer with floating-point and multimedia performance.

When Intel developed the Pentium III, it discontinued the iCOMP 2.0 index and released the iCOMP 3.0 index. iCOMP 3.0 is an updated benchmark that incorporates an increasing use of 3D, multimedia, and Internet technology and software, as well as the increasing use of rich data streams and

computer-intensive applications, including 3D, multimedia, and Internet technology. iCOMP 3.0 combines six benchmarks: WinTune 98 Advanced CPU Integer test, CPUmark 99, 3D WinBench 99-3D Lighting and Transformation Test, MultimediaMark 99, Jmark 2.0 Processor Test, and WinBench 99-FPU WinMark. These newer benchmarks take advantage of the SSE (Streaming SIMD Extensions), additional graphics and sound instructions built into the PIII. Without taking advantage of these new instructions, the PIII would benchmark at about the same speed as a PII at the same clock rate.

Table 3.9 shows the iCOMP Index 3.0 ratings for Pentium II and III processors.

Table 3.9 Intel iCOMP 3.0 Ratings

Processor	iCOMP 3.0 Index	Processor	iCOMP 3.0 Index
Pentium II 350	1000	Pentium III 650	2270
Pentium II 450	1240	Pentium III 700	2420
Pentium III 450	1500	Pentium III 750	2540
Pentium III 500	1650	Pentium III 800	2690
Pentium III 550	1780	Pentium III 866	2890
Pentium III 600	1930	Pentium III 1000	3280
Pentium III 600E	2110		

Intel and AMD currently rate their latest processors using the commercially available BAPCo SYSmark 2002 and 2004 benchmark suites. The ratings for the various processors under the 2002 and 2004 benchmark suites are shown in Tables 3.10 and 3.11.

Table 3.10 SYSmark 2002 Scores for Various Processors

CPU	Clock	SYSmark 2002 Rating	CPU	Clock	SYSmark 2002 Rating
Pentium 4 Extreme Edition	3.2GHz	362	AMD Athlon XP	1.72GHz	195
Pentium 4	3.2GHz	344	Pentium 4	1.9GHz	192
Pentium 4	3.0GHz	328	Pentium 4	1.8GHz	187
Pentium 4	3.06GHz	324	Pentium 4	1.7GHz	178
Pentium 4	2.8GHz	312	Pentium 4	1.6GHz	171
Pentium 4	2.6GHz	295	AMD Athlon XP	1.67GHz	171
Pentium 4	2.67GHz	285	Pentium 4	1.5GHz	162
Pentium 4	2.53GHz	273	AMD Athlon XP	1.53GHz	149

SYSmark 2002 and 2004 are commercially available application-based benchmarks that reflect the normal usage of business users employing modern Internet content creation and Microsoft Office applications. However, it is important to note that the scores listed here are produced by complete systems and are affected by things such as the specific version of the processor, the motherboard and chipset used, the amount and type of memory installed, the speed of the hard disk, and other factors. For complete disclosure of the other factors resulting in the given scores, see the BAPCo Web site.

SYSmark 2002 incorporates the following applications, which it uses for testing:

- *Internet Content Creation.* Includes Adobe Photoshop 6.01, Premiere 6.0, Microsoft Windows Media Encoder 7.1, Macromedia Dreamweaver 4, and Flash 5
- *Office Productivity.* Includes Microsoft Word 2002, Excel 2002, PowerPoint 2002, Outlook 2002, Access 2002, Netscape Communicator 6.0, Dragon NaturallySpeaking Preferred v.5, WinZip 8.0, and McAfee VirusScan 5.13

SYSmark 2004 incorporates the following applications, which it uses for testing:

- *Internet Content Creation.* Includes Adobe After Effects 5.5, Adobe Photoshop 7.01, Adobe Premiere 6.5, Discreet 3ds max 5.1, Macromedia Dreamweaver MX, Macromedia Flash MX, Microsoft Windows Media Encoder 9 Series, Network Associates McAfee VirusScan 7.0, and WinZip Computing WinZip 8.1
- *Office Productivity.* Includes Adobe Acrobat 5.0.5, Microsoft Access 2002, Microsoft Excel 2002, Microsoft Internet Explorer 6, Microsoft Outlook 2002, Microsoft PowerPoint 2002, Microsoft Word 2002, Network Associates McAfee VirusScan 7.0, ScanSoft Dragon Naturally Speaking 6 Preferred, and WinZip Computing WinZip 8.1

SYSmark runs various scripts to do actual work using these applications and is used by many companies for testing and comparing PC systems and components. It is a much more modern and real-world benchmark than the iCOMP benchmark Intel previously used, and because it is available to anybody, the results can be independently verified. SYSmark 2002 and 2004 can be purchased from BAPCo at www.bapco.com.

Processor Speeds and Markings Versus Motherboard Speed

Another confusing factor when comparing processor performance is that virtually all modern processors since the 486DX2 run at some multiple of the motherboard speed. For example, a Pentium 4 2.53GHz chip runs at a multiple of 19/4 (4.75x) times the motherboard speed of 533MHz, whereas an AMD Athlon XP 2800+ using the latest Barton core (2.083GHz) runs at 75/12 (6.25x) times the motherboard speed of 333MHz. Up until early 1998, most motherboards ran at 66MHz or less. Starting in April 1998, Intel released both processors and motherboard chipsets designed to run at 100MHz.

By late 1999, chipsets and motherboards running at 133MHz became available to support the newer Pentium III processors. At that time, AMD Athlon motherboards and chipsets were introduced running a 100MHz clock but using a double transfer technique for an effective 200MHz data rate between the Athlon processor and the main chipset North Bridge chip.

In 2000 and 2001, processor bus speeds advanced further to 266MHz for the AMD Athlon and Intel Itanium and 400MHz to 533MHz for the Pentium 4. In 2002, the AMD Athlon XP processors began to support a processor bus speed of 333MHz. In 2003, Intel introduced the first Pentium 4 processors that supported a processor bus speed of 800MHz. Typically, the speed of the CPU bus is selected to match whatever memory types Intel and AMD want to support. Most of the modern CPU bus speeds are based on the speeds of the CPU as well as the available SDRAM, DDR SDRAM, and RDRAM memory. Note that the processor bus speed of Pentium 4 processors is not directly equivalent to a particular memory speed.

Note

See Chapter 4, "Motherboards and Buses," for more information on chipsets and bus speeds.

You can set the motherboard speed and multiplier setting via jumpers or another configuration mechanism (such as BIOS setup) on the motherboard. Modern systems use a variable-frequency synthesizer circuit usually found in the main motherboard chipset to control the motherboard and CPU speed. Most Pentium motherboards have three or four speed settings. The processors used today are available in a variety of versions that run at different frequencies based on a given motherboard speed. For example, most of the Pentium chips run at a speed that is some multiple of the true motherboard speed. For example, Pentium-class processors and motherboards run at the speeds shown in Table 3.12.

Note

For information on specific AMD, Cyrix, or VIA processors, see their respective sections later in this chapter.

Table 3.12 Intel Processor and Motherboard Speeds

CPU Type	CPU Speed (MHz)	CPU Clock Multiplier	Motherboard Speed (MHz)
Pentium	75	1.5x	50
Pentium	60	1x	60
Pentium	90	1.5x	60
Pentium	120	2x	60
Pentium	150	2.5x	60

Pentium 4	3400	4.25x	800
Itanium	733	2.75x	266
Itanium	800	3x	266
Itanium 2	1000	2.5x	400

If all other variables are equal—including the type of processor, the number of wait states (empty cycles) added to different types of memory accesses, and the width of the data bus—you can compare two systems by their respective clock rates. However, the construction and design of the memory controller (contained in the motherboard chipset) as well as the type and amount of memory installed can have an enormous effect on a system's final execution speed.

In building a processor, a manufacturer tests it at various speeds, temperatures, and pressures. After the processor is tested, it receives a stamp indicating the maximum safe speed at which the unit will operate under the wide variation of temperatures and pressures encountered in normal operation. These ratings are clearly marked on the processor package.

Cyrix Processor Speeds

Cyrix/IBM/VIA 6x86 processors—which were designed to compete with the Intel Pentium, early Pentium II, and AMD K5 and K6 series of processors—used a PR (performance rating) scale that was not equal to the true clock speed in megahertz. For example, the Cyrix 6x86MX/MII-PR366 actually runs at only 250MHz (2.5×100MHz). This is a little misleading—you must set up the motherboard as if a

250MHz processor were being installed, instead of the 366MHz you might suspect. Unfortunately, this led people to believe these systems were faster than they really were.

Table 3.13 shows the relationship between the Cyrix 6x86, 6x86MX, and M-II P-Ratings versus the actual chip speeds in MHz.

Table 3.13 Cyrix P-Ratings Versus Actual Chip Speeds in MHz

CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)
6x86	PR90	80	2x	40
6x86	PR120	100	2x	50
6x86	PR133	110	2x	55
6x86	PR150	120	2x	60
6x86	PR166	133	2x	66
6x86	PR200	150	2x	75
6x86MX	PR133	100	2x	50
6x86MX	PR133	110	2x	55
6x86MX	PR150	120	2x	60
6x86MX	PR150	125	2.5x	50
6x86MX	PR166	133	2x	66
6x86MX	PR166	137.5	2.5x	55
6x86MX	PR166	150	3x	50
6x86MX	PR166	150	2.5x	60
6x86MX	PR200	150	2x	75
6x86MX	PR200	165	3x	55
6x86MX	PR200	166	2.5x	66
6x86MX	PR200	180	3x	60
6x86MX	PR233	166	2x	83
6x86MX	PR233	187.5	2.5x	75
6x86MX	PR233	200	3x	66
6x86MX	PR266	207.5	2.5x	83
6x86MX	PR266	225	3x	75
6x86MX	PR266	233	3.5x	66
M-II	PR300	225	3x	75
M-II	PR300	233	3.5x	66
M-II	PR333	250	3x	83
M-II	PR366	250	2.5x	100
M-II	PR400	285	3x	95
M-II	PR433	300	3x	100
Cyrix III	PR433	350	3.5x	100
Cyrix III	PR466	366	3x	122
Cyrix III	PR500	400	3x	133
Cyrix III	PR533	433	3.5x	124
Cyrix III	PR533	450	4.5x	100

Note that a given P-Rating can mean several different actual CPU speeds—for example, a Cyrix 6x86MX-PR200 might actually be running at 150MHz, 165MHz, 166MHz, or 180MHz, but *not* at 200MHz.

This P-Rating was supposed to indicate speed in relation to an Intel Pentium processor, but the processor being compared to in this case is the original non-MMX, small L1 cache version running on

an older motherboard platform with an older chipset and slower technology memory. The P-Rating did not compare well against the Celeron, Pentium II, or Pentium III processors. In other words, the MII-PR366 really ran at only 250MHz and compared well against Intel processors running at closer to that speed, making the ratings somewhat misleading.

AMD Processor Speeds

AMD's Athlon XP processors are excellent performers and have several notable features, but they unfortunately bring with them a resurrection of the infamous Cyrix/AMD performance rating. This is a simulated MHz number that does not indicate the actual speed of the chip but instead indicates an estimate of the relative MHz of a first-generation Intel Pentium 4 that would be approximately equal in performance. If this sounds confusing, that's because it is!

Table 3.14 shows the P-Rating and actual speeds of the AMD K5, K6, Athlon, Athlon XP, and Duron processors.

Table 3.14 AMD P-Ratings Versus Actual Chip Speeds in MHz

CPU Type	P-Rating	Actual CPU Speed (MHz)	Clock Multiplier	Motherboard Speed (MHz)
K5	75	75	1.5x	50
K5	90	90	1.5x	60
K5	100	100	1.5x	66
K5	120	90	1.5x	60
K5	133	100	1.5x	66
K5	166	116	1.75x	66
K6	166	166	2.5x	66
K6	200	200	3x	66
K6	233	233	3.5x	66
K6	266	266	4x	66
K6	300	300	4.5x	66

Athlon XP	1600+	1400	5.25x	266
Athlon XP	1700+	1466	5.5x	266
Athlon XP	1800+	1533	5.75x	266
Athlon XP	1900+	1600	6x	266
Athlon XP	2000+	1666	6.25x	266
Athlon XP	2100+	1733	6.5x	266
Athlon XP	2200+	1800	6.75x	266
Athlon XP	2400+	2000	7.5x	266
Athlon XP	2500+*	1833	5.5x	333
Athlon XP	2600+	2083	6.25x	333
Athlon XP	2600+	2133	8x	266
Athlon XP	2700+	2167	6.5x	333
Athlon XP	2800+*	2083	6.25x	333
Athlon XP	2800+	2250	6.75x	333
Athlon XP	3000+*	2167	6.5x	333
Athlon XP	3200+*	2333	7x	333

Note that the 200MHz and 266MHz bus speeds in the Athlon/Duron use 100MHz and 133MHz clock signals and two transfers per cycle for double the effective rate. Some motherboards refer to the CPU bus speed by the half-speed 100MHz or 133MHz clock and therefore use twice the clock multiplier settings shown here.

*These processors use the Barton core, which uses a larger 512KB cache instead of other Athlon XP models' 256KB cache to improve performance.

AMD's performance tests show that the 1.8GHz Athlon runs at the same "performance level" as a theoretical 2.2GHz Pentium 4, so it calls the chip an Athlon XP 2200+, assigning the 2200+ number as a designation of performance relative to Pentium 4MHz. This type of marketing, where a chip is assigned a number indicating a relative—rather than a true—speed rating, has been tried before with limited success. In some cases it left a bad impression with customers who felt that they were deceived when they found out the true MHz rating of the chips and systems they had purchased.

I liken the performance numbers AMD is using to the wind chill factor often used by weather reporters in the winter. There is of course the *real* temperature, and then there is the so-called wind chill factor, which is an estimated rating of how cold it “feels.” The model numbers AMD uses with the new Athlon XP are like a “speed factor,” which is supposed to tell you how fast the processor “feels” compared to a Pentium 4. (However, AMD does insist its performance rating numbers are not meant to be directly associated with the Pentium 4.)

AMD’s marketing problem is real: How do you market a chip that performs faster than your rival when both are running at the same clock speed? An AMD Athlon XP with an actual clock speed of 2GHz is significantly faster than a 2GHz Pentium 4 and in fact performs about equal to a 2.4GHz Pentium 4 (hence, AMD calls this model the Athlon XP 2400+). This apparent disparity in performance is because the P4 uses a different architecture that utilizes a deeper instruction pipeline with more stages. The Pentium 4 has a 20-stage pipeline, which compares to a 10-stage pipeline in the Athlon and a 10-stage pipeline in the Pentium III/Celeron (see Table 3.15).

Table 3.15 Number of Pipelines per CPU

Processor	Pipeline Depth	Processor	Pipeline Depth
Pentium III	10-stage	Athlon 64/64 FX	12-stage
Pentium M	10-stage	Pentium 4	20-stage
Athlon/XP	10-stage	Pentium 4 Prescott	31-stage

A deeper pipeline effectively breaks instructions down into smaller microsteps, which allows overall higher clock rates to be achieved using the same silicon technology. However, it also means that overall fewer instructions can be executed in a single cycle as compared with the Athlon (or Pentium III). This is because, if a branch prediction or speculative execution step fails (which happens fairly frequently inside the processor as it attempts to line up instructions in advance), the entire pipeline has to be flushed and refilled. Thus, if you compared an Athlon to a Pentium III to a Pentium 4 all running at the same clock speed, the Athlon and Pentium III would both beat the Pentium 4 running typical benchmarks because they would execute more instructions in the same number of cycles.

Although this would sound bad for the Pentium 4, it really isn’t. In fact, it is part of the design. Intel’s reasoning is that even though the deeper pipeline might be 30% less efficient overall, it more than makes up for this by allowing at least 50% greater clock speeds than the Athlon or Pentium III with shorter pipelines. The deeper 20- or 31-stage pipeline in the P4 architecture enables significantly higher clock speeds to be achieved using the same silicon die process as other chips. As an example, the Athlon XP and Pentium 4 were originally made using the same 0.18-micron process (which describes the line width of components etched on the chips). The P4’s 20-stage pipeline enabled the 0.18-micron die process to result in chips running up to 2.0GHz, whereas the same process achieves only 1.73GHz in the 10-stage Athlon XP and only 1.13GHz in the 10-stage Pentium III/Celeron. Using the newer 0.13-micron process, the Pentium 4 currently runs up to 3.4GHz and the Athlon XP tops out at 2.2GHz (3200+ model) in the same introduction timeframe. Even though the Pentium 4 executes fewer instructions in each cycle, the overall higher cycling speeds make up for the loss of efficiency. So, for the initial crop of Athlon XP and Pentium 4 processors, in the end, higher clock speed versus more efficient processing effectively cancel each other out.

Many systems display the clock speed of the processor during the initial boot cycle. Windows XP also displays the CPU clock speed on the General tab of the System Properties sheet. AMD would prefer that systems no longer indicate processor speed directly. In fact, *AMD does not recommend or validate motherboards using the Athlon XP if they display the processor’s actual clock speed.* In the future, the curious will need to use a third-party program such as SiSoft Sandra or the Intel Frequency ID Utility to find out the true clock speed of their processors after it is installed.

Note

If you want to determine the designed clock speed for any type of Athlon processor (the actual clock speed could vary according to motherboard overclocking, underclocking, or power management clock speed adjustments), go to AMD's Web site and download the Data Sheet for the processor model you are interested in. You will find a table in each data sheet that lists the actual MHz (divide by 1,000 for the GHz) for each model. The latest Athlon XPs are Model 10, and earlier models are Model 8 and Model 6.

One thing is clear in all of this confusion: Raw MHz (or GHz) is not always a good way to compare chips, and generating pseudo-MHz numbers can only make things more confusing for the uninitiated. Even Intel is now moving away from using clock speed as its primary marketing designation. It still notes the speeds of its chips, but it is adding a new model number to the later Pentium 4 and Celeron processors to indicate a relative difference between them. This relative difference is based not just on speed, but also on architectural and other differences.

Overclocking

In some systems, the processor speed can be set higher than the rating on the chip; this is called *overclocking* the chip. In many cases, you can get away with a certain amount of overclocking because Intel, AMD, and others often build safety margins into their ratings. So, a chip rated for, say, 800MHz might in fact run at 900MHz or more but instead be down-rated to allow for a greater margin of reliability. By overclocking, you are using this margin and running the chip closer to its true maximum speed. I don't normally recommend overclocking for a novice, but if you are comfortable playing with your system settings, and you can afford and are capable of dealing with any potential consequences, overclocking might enable you to get 10%–20% or more performance from your system.

Overclocking Pitfalls

If you are intent on overclocking, there are several issues to consider. One is that most Intel processors since the Pentium II are multiplier-locked before they are shipped out. Therefore, the chip ignores any changes to the multiplier setting on the motherboard. Actually, both Intel and AMD lock the multipliers on most of their newer processors, but the AMD processors use solder bridges on top of the chip that can be manipulated if you are careful and somewhat mechanically inclined. Although originally done to prevent re-markers from fraudulently relabeling processors (creating "counterfeit" chips), this has impacted the computing performance enthusiast, leaving tweaking the motherboard bus speed as the only easy way (or in some cases, the only way possible) to achieve a clock speed higher than standard.

You can run into problems increasing motherboard bus speed, as well. Most older Intel motherboards, for example, simply don't support clock speeds other than the standard 66MHz, 100MHz, 133MHz, 400MHz, 533MHz or 800MHz settings. Newer Intel boards have a "burn-in" feature that allows you to increase the default processor bus speed (and also the speed of the processor core) by up to 4%. That is relatively mild, but easily achievable with most chips you might have. Most other brands of motherboards allow changing the bus speeds by even greater amounts.

Even if you could trick the processor into accepting a different clock multiplier setting, the jump from 66MHz to 100MHz or from 100MHz to 133MHz is a large one, and many processors will not make that much of a jump reliably. For example, a Pentium III 800E runs at a 100MHz bus speed with an 8x multiplier. Bumping the motherboard speed to 133MHz causes the processor to try to run at 8x133, or 1066MHz. It is not certain that the chip would run reliably at that speed. Likewise, a Celeron 600E runs at 9x66MHz. Raising the bus speed to 100MHz causes the chip to try and run at 9x100MHz, or 900MHz, another potentially unsuccessful change.

A board that supports intermediate speed settings and allows the settings to be changed in smaller increments is necessary. This is because a given chip is generally overclockable by a certain percentage. The smaller the steps you can take when increasing speed, the more likely that you'll be able to come close

to the actual maximum speed of the chip without going over. For example, the Asus P3V4X motherboard supports frontside bus speed settings of 66MHz, 75MHz, 83MHz, 90MHz, 95MHz, 100MHz, 103MHz, 105MHz, 110MHz, 112MHz, 115MHz, 120MHz, 124MHz, 133MHz, 140MHz, and 150MHz. By setting the 800MHz Pentium III to increments above 100MHz, you'd have the following:

Multiplier (Fixed)	Bus Speed	Processor Speed
8x	100MHz	800MHz
8x	103MHz	824MHz
8x	105MHz	840MHz
8x	110MHz	880MHz
8x	112MHz	896MHz
8x	115MHz	920MHz
8x	120MHz	960MHz
8x	124MHz	992MHz
8x	133MHz	1066MHz

Likewise, using this motherboard with a Celeron 600, you could try settings above the standard 66MHz bus speed as follows:

Multiplier (Fixed)	Bus Speed	Processor Speed
9x	66MHz	600MHz
9x	75MHz	675MHz
9x	83MHz	747MHz
9x	90MHz	810MHz
9x	95MHz	855MHz
9x	100MHz	900MHz

Typically, a 10%–20% increase is successful, so with this motherboard, you are likely to get your processor running 100MHz or faster than it was originally designed for.

An issue when it comes to increasing CPU bus speeds is that the other buses in the system will typically be similarly affected. Thus, if you increase the CPU bus speed by 10%, you might also be increasing the PCI or AGP bus by the same amount, and your video, network, or other cards might not be able to keep up. This is something that varies from board to board, so you have to consider each example as a potentially unique case.

Overclocking Socket A Processors

The AMD Athlon and Duron processors in the FC-PGA (flip-chip pin grid array) format, which plugs into Socket A, have special solder bridges on the top face of the chip that can be modified to change or remove the lock from the internal multiplier on the chip. This can increase the speed of the chip without changing the motherboard bus speed, thus affecting other buses or cards.

The selected multiplier is set or locked by very small solder connections between solder dots (contacts) on the surface of the chip. You can completely unlock the chip by bridging or disconnecting the appropriate dots. Unfortunately, it is somewhat difficult to add or remove these bridges; you usually have to mask off the particular bridge you want to create and, rather than dripping solder onto it, literally paint the bridge with silver or copper paint. For example, you can use the special copper paint sold in small vials at any auto parts store for repairing the window defogger grids. The real problem is that the contacts are very small, and if you bridge to adjacent rather than opposite contacts, you can render the chip

nonfunctional. An Xacto knife or razor blade can be used to remove the bridges if desired. If you are not careful, you can easily damage a processor worth several hundred dollars. If you are leery of making such changes, you should try bus overlocking instead because this is done in the BIOS Setup and can easily be changed or undone without any mechanical changes to the chip.

CPU Voltage Settings

Another trick used by overclockers is playing with the voltage settings for the CPU. All modern CPU sockets and slots, including Slot 1, Slot A, Socket 8, Socket 370, Socket 423, Socket 478, and Socket A, have automatic voltage detection. With this detection, the system detects and sets the correct voltage by reading certain pins on the processor. Some motherboards, such as those made by Intel, do not allow any manual changes to these settings. Other motherboards, such as the Asus P3V4X mentioned earlier, allow you to tweak the voltage settings from the automatic setting up or down by tenths of a volt. Some experimenters have found that by either increasing or decreasing voltage slightly from the standard, a higher speed of overclock can be achieved with the system remaining stable.

My recommendation is to be careful when playing with voltages because you can damage the chip in this manner. Even without changing voltage, overclocking with an adjustable bus speed motherboard is very easy and fairly rewarding. I do recommend you make sure you are using a high-quality board, good memory, and especially a good system chassis with additional cooling fans and a heavy-duty power supply. See Chapter 21, "Power Supply and Chassis/Case," for more information on upgrading power supplies and chassis. Especially when overclocking, it is essential that the system components and the CPU remain properly cooled. Going a little bit overboard on the processor heatsink and adding extra cooling fans to the case never hurts and in many cases helps a great deal when hotrodding a system in this manner.

Note

One good source of online overclocking information is located at <http://www.tomshardware.com>. It includes, among other things, fairly thorough overclocking FAQs and an ongoing survey of users who have successfully (and sometimes unsuccessfully) overclocked their CPUs. Note that many of the newer Intel processors incorporate fixed bus multiplier ratios that effectively prevent or certainly reduce the ability to overclock. Unfortunately, this can be overridden with a simple hardware fix, and many counterfeit processor vendors are selling re-marked (overclocked) chips.

Cache Memory

As processor core speeds increased, memory speeds could not keep up. How could you run a processor faster than the memory from which you feed it without having performance suffer terribly? The answer was cache. In its simplest terms, *cache memory* is a high-speed memory buffer that temporarily stores data the processor needs, allowing the processor to retrieve that data faster than if it came from main memory. But there is one additional feature of a cache over a simple buffer, and that is intelligence. A cache is a buffer with a brain.

A buffer holds random data, usually on a first in, first out, or first in, last out basis. A cache, on the other hand, holds the data the processor is most likely to need in advance of it actually being needed. This enables the processor to continue working at either full speed or close to it without having to wait for the data to be retrieved from slower main memory. Cache memory is usually made up of static RAM (SRAM) memory integrated into the processor die, although older systems with cache also used chips installed on the motherboard.

- ▶▶ See "Cache Memory: SRAM," p. 461.

Two levels of processor/memory cache are used in a modern PC, called Level 1 (L1) and Level 2 (L2) (some server processors such as the Itanium series from Intel also have Level 3 cache). These caches and how they function are described in the following sections.

Internal Level 1 Cache

All modern processors starting with the 486 family include an integrated L1 cache and controller. The integrated L1 cache size varies from processor to processor, starting at 8KB for the original 486DX and now up to 32KB, 64KB, or more in the latest processors.

To understand the importance of cache, you need to know the relative speeds of processors and memory. The problem with this is that processor speed usually is expressed in MHz or GHz (millions or billions of cycles per second), whereas memory speeds are often expressed in nanoseconds (billionths of a second per cycle). Most newer types of memory express the speed in either MHz or in megabyte per second (MBps) bandwidth (throughput).

Both are really time- or frequency-based measurements, and a chart comparing them can be found in Table 6.3 in Chapter 6, "Memory." In this table, you will note that a 233MHz processor equates to 4.3-nanosecond cycling, which means you would need 4ns memory to keep pace with a 200MHz CPU. Also note that the motherboard of a 233MHz system typically runs at 66MHz, which corresponds to a speed of 15ns per cycle and requires 15ns memory to keep pace. Finally, note that 60ns main memory (common on many Pentium-class systems) equates to a clock speed of approximately 16MHz. So, a typical Pentium 233 system has a processor running at 233MHz (4.3ns per cycle), a motherboard running at 66MHz (15ns per cycle), and main memory running at 16MHz (60ns per cycle). This might seem like a rather dated example, but in a moment, you will see that the figures listed here make it easy for me to explain how cache memory works.

Because L1 cache is always built into the processor die, it runs at the full-core speed of the processor internally. By full-core speed, I mean this cache runs at the higher clock multiplied internal processor speed rather than the external motherboard speed. This cache basically is an area of very fast memory built into the processor and is used to hold some of the current working set of code and data. Cache memory can be accessed with no wait states because it is running at the same speed as the processor core.

Using cache memory reduces a traditional system bottleneck because system RAM is almost always much slower than the CPU; the performance difference between memory and CPU speed has become especially large in recent systems. Using cache memory prevents the processor from having to wait for code and data from much slower main memory, therefore improving performance. Without the L1 cache, a processor would frequently be forced to wait until system memory caught up.

Cache is even more important in modern processors because it is often the only memory in the entire system that can truly keep up with the chip. Most modern processors are clock multiplied, which means they are running at a speed that is really a multiple of the motherboard into which they are plugged. The Pentium 4 2.8GHz, for example, runs at a multiple of 5.25 times the true motherboard speed of 533MHz. The main memory is one half this speed (266MHz) because the Pentium 4 uses a quad-pumped memory bus. Because the main memory is plugged into the motherboard, it can run only at 266MHz maximum. The only 2.8GHz memory in such a system is the L1 and L2 caches built into the processor core. In this example, the Pentium 4 2.8GHz processor has 20KB of integrated L1 cache (8KB data cache and 12KB execution trace cache) and 512KB of L2, all running at the full speed of the processor core.

▶▶ See "Memory Module Speed," p. 497.

If the data the processor wants is already in the internal cache, the CPU does not have to wait. If the data is not in the cache, the CPU must fetch it from the Level 2 cache or (in less sophisticated system designs) from the system bus, meaning main memory directly.

How Cache Works

To learn how the L1 cache works, consider the following analogy.

This story involves a person (in this case you) eating food to act as the processor requesting and operating on data from memory. The kitchen where the food is prepared is the main memory (SIMM/DIMM) RAM. The cache controller is the waiter, and the L1 cache is the table at which you are seated.

Okay, here's the story. Say you start to eat at a particular restaurant every day at the same time. You come in, sit down, and order a hot dog. To keep this story proportionately accurate, let's say you normally eat at the rate of one bite (byte? <g>) every four seconds (233MHz = about 4ns cycling). It also takes 60 seconds for the kitchen to produce any given item that you order (60ns main memory).

So, when you first arrive, you sit down, order a hot dog, and you have to wait for 60 seconds for the food to be produced before you can begin eating. After the waiter brings the food, you start eating at your normal rate. Pretty quickly you finish the hot dog, so you call the waiter over and order a hamburger. Again you wait 60 seconds while the hamburger is being produced. When it arrives, you again begin eating at full speed. After you finish the hamburger, you order a plate of fries. Again you wait, and after it is delivered 60 seconds later, you eat it at full speed. Finally, you decide to finish the meal and order cheesecake for dessert. After another 60-second wait, you can eat cheesecake at full speed. Your overall eating experience consists of mostly a lot of waiting, followed by short bursts of actual eating at full speed.

After coming into the restaurant for two consecutive nights at exactly 6 p.m. and ordering the same items in the same order each time, on the third night the waiter begins to think, "I know this guy is going to be here at 6 p.m., order a hot dog, a hamburger, fries, and then cheesecake. Why don't I have these items prepared in advance and surprise him? Maybe I'll get a big tip." So you enter the restaurant and order a hot dog, and the waiter immediately puts it on your plate, with no waiting! You then proceed to finish the hot dog and right as you are about to request the hamburger, the waiter deposits one on your plate. The rest of the meal continues in the same fashion, and you eat the entire meal, taking a bite every four seconds, and never have to wait for the kitchen to prepare the food. Your overall eating experience this time consists of all eating, with no waiting for the food to be prepared, due primarily to the intelligence and thoughtfulness of your waiter.

This analogy exactly describes the function of the L1 cache in the processor. The L1 cache itself is the table that can contain one or more plates of food. Without a waiter, the space on the table is a simple food buffer. When stocked, you can eat until the buffer is empty, but nobody seems to be intelligently refilling it. The waiter is the cache controller who takes action and adds the intelligence to decide which dishes are to be placed on the table in advance of your needing them. Like the real cache controller, he uses his skills to literally guess which food you will require next, and if and when he guesses right, you never have to wait.

Let's now say on the fourth night you arrive exactly on time and start off with the usual hot dog. The waiter, by now really feeling confident, has the hot dog already prepared when you arrive, so there is no waiting.

Just as you finish the hot dog, and right as he is placing a hamburger on your plate, you say "Gee, I'd really like a bratwurst now; I didn't actually order this hamburger." The waiter guessed wrong, and the consequence is that this time you have to wait the full 60 seconds as the kitchen prepares your brat. This is known as a *cache miss*, in which the cache controller did not correctly fill the cache with the data the processor actually needed next. The result is waiting, or in the case of a sample 233MHz Pentium system, the system essentially throttles back to 16MHz (RAM speed) whenever a cache miss occurs.

According to Intel, the L1 cache in most of its processors has approximately a 90% hit ratio (some processors, such as the Pentium 4, are slightly higher). This means that the cache has the correct data 90% of the time, and consequently the processor runs at full speed—233MHz in this example—90% of the time. However, 10% of the time the cache controller guesses wrong and the data has to be retrieved out of the significantly slower main memory, meaning the processor has to wait. This essentially throttles the system back to RAM speed, which in this example was 60ns or 16MHz.

In this analogy, the processor was 14 times faster than the main memory. Memory speeds have increased from 16MHz (60ns) to 333MHz (3.0ns) or faster in the latest systems, but processor speeds have also risen to 3GHz and beyond, so even in the latest systems, memory is still 7.5 or more times *slower* than the processor. Cache is what makes up the difference.

The main feature of L1 cache is that it has always been integrated into the processor core, where it runs at the same speed as the core. This, combined with the hit ratio of 90% or greater, makes L1 cache very important for system performance.

Level 2 Cache

To mitigate the dramatic slowdown every time an L1 cache miss occurs, a secondary (L2) cache is employed.

Using the restaurant analogy I used to explain L1 cache in the previous section, I'll equate the L2 cache to a cart of additional food items placed strategically in the restaurant such that the waiter can retrieve food from the cart in only 15 seconds (versus 60 seconds from the kitchen). In an actual Pentium class (Socket 7) system, the L2 cache is mounted on the motherboard, which means it runs at motherboard speed—66MHz, or 15ns in this example. Now, if you ask for an item the waiter did not bring in advance to your table, instead of making the long trek back to the kitchen to retrieve the food and bring it back to you 60 seconds later, he can first check the cart where he has placed additional items. If the requested item is there, he will return with it in only 15 seconds. The net effect in the real system is that instead of slowing down from 233MHz to 16MHz waiting for the data to come from the 60ns main memory, the data can instead be retrieved from the 15ns (66MHz) L2 cache. The effect is that the system slows down from 233MHz to 66MHz.

Newer processors have integrated L2 cache that runs at the same speed as the processor core, which is also the same speed as the L1 cache. For the analogy to describe these newer chips, the waiter would simply place the cart right next to the table you were seated at in the restaurant. Then, if the food you desired wasn't on the table (L1 cache miss), it would merely take a longer reach over to the adjacent L2 cache (the cart, in this analogy) rather than a 15-second walk to the kitchen as with the older designs.

Cache Performance and Design

Just as with the L1 cache, most L2 caches have a hit ratio also in the 90% range; therefore, if you look at the system as a whole, 90% of the time it will be running at full speed (233MHz in this example) by retrieving data out of the L1 cache. Ten percent of the time it will slow down to retrieve the data from the L2 cache. Ninety percent of the time the processor goes to the L2 cache, the data will be in the L2, and 10% of that time it will have to go to the slow main memory to get the data because of an L2 cache miss. So, by combining both caches, our sample system runs at full processor speed 90% of the time (233MHz in this case), at motherboard speed 9% (90% of 10%) of the time (66MHz in this case), and at RAM speed about 1% (10% of 10%) of the time (16MHz in this case). You can clearly see the importance of both the L1 and L2 caches; without them the system uses main memory more often, which is significantly slower than the processor.

This brings up other interesting points. If you could spend money doubling the performance of either the main memory (RAM) or the L2 cache, which would you improve? Considering that main memory is used directly only about 1% of the time, if you doubled performance there, you would double the speed of your system only 1% of the time! That doesn't sound like enough of an improvement to justify much expense. On the other hand, if you doubled L2 cache performance, you would be doubling system performance 9% of the time, a much greater improvement overall. I'd much rather improve L2 than RAM performance.

The processor and system designers at Intel and AMD know this and have devised methods of improving the performance of L2 cache. In Pentium (P5) class systems, the L2 cache usually was found on the motherboard and had to therefore run at motherboard speed. Intel made the first dramatic improvement by migrating the L2 cache from the motherboard directly into the processor and initially running it at the same speed as the main processor. The cache chips were made by Intel and mounted next to the main processor die in a single chip housing. This proved too expensive, so with the Pentium II, Intel began using cache chips from third-party suppliers such as Sony, Toshiba, NEC, Samsung, and others. Because these were supplied as complete packaged chips and not raw die, Intel mounted them on a circuit board alongside the processor. This is why the Pentium II was designed as a cartridge rather than what looked like a chip.

One problem was the speed of the available third-party cache chips. The fastest ones on the market were 3ns or higher, meaning 333MHz or less in speed. Because the processor was being driven in speed above that, in the Pentium II and initial Pentium III processors Intel had to run the L2 cache at half the processor speed because that is all the commercially available cache memory could handle. AMD followed suit with the Athlon processor, which had to drop L2 cache speed even further in some models to two-fifths or one-third the main CPU speed to keep the cache memory speed less than the 333MHz commercially available chips.

Then a breakthrough occurred, which first appeared in Celeron processors 300A and above. These had 128KB of L2 cache, but no external chips were used. Instead, the L2 cache had been integrated directly into the processor core just like the L1. Consequently, both the L1 and L2 caches now would run at full processor speed, and more importantly scale up in speed as the processor speeds increased in the future. In the newer Pentium III, as well as all the Xeon and Celeron processors, the L2 cache runs at full processor core speed, which means there is no waiting or slowing down after an L1 cache miss. AMD also achieved full-core speed on-die cache in its later Athlon and Duron chips. Using on-die cache improves performance dramatically because 9% of the time the system would be using the L2, it would now remain at full speed instead of slowing down to one-half or less the processor speed or, even worse, slow down to motherboard speed as in Socket 7 designs. Another benefit of on-die L2 cache is cost, which is less because now fewer parts are involved.

Let's revisit the restaurant analogy using a modern Pentium 4 2GHz. You would now be taking a bite every half second (2GHz = 0.5ns cycling). The L1 cache would also be running at that speed, so you could eat anything on your table at that same rate (the table = L1 cache). The real jump in speed comes when you want something that isn't already on the table (L1 cache miss), in which case the waiter reaches over to the cart (which is now directly adjacent to the table) and nine out of ten times is able to find the food you want in only one-half second (L2 speed = 2GHz or 0.5ns cycling). In this more modern system, you would run at 2GHz 99% of the time (L1 and L2 hit ratios combined) and slow down to RAM speed (wait for the kitchen) only 1% of the time as before. With faster memory running at 400MHz (2.5ns), you would have to wait only 2.5 seconds for the food to come from the kitchen. If only restaurant performance would increase at the same rate processor performance has!

Cache Organization

You know that cache stores copies of data from various main memory addresses. Because the cache cannot hold copies of the data from all the addresses in main memory simultaneously, there has to be a way to know which addresses are currently copied into the cache so that, if we need data from those addresses, it can be read from the cache rather than from the main memory. This function is performed by Tag RAM, which is additional memory in the cache that holds an index of the addresses that are copied into the cache. Each line of cache memory has a corresponding address tag that stores the main memory address of the data currently copied into that particular cache line. If data from a particular main memory address is needed, the cache controller can quickly search the address tags to see whether the requested address is currently being stored in the cache (a *hit*) or not (a *miss*). If the data is there, it can be read from the faster cache; if it isn't, it has to be read from the much slower main memory.

Various ways of organizing or mapping the tags affect how cache works. A cache can be mapped as fully associative, direct-mapped, or set associative.

In a fully associative mapped cache, when a request is made for data from a specific main memory address, the address is compared against all the address tag entries in the cache tag RAM. If the requested main memory address is found in the tag (a *hit*), the corresponding location in the cache is returned. If the requested address is not found in the address tag entries, a *miss* occurs and the data must be retrieved from the main memory address instead of the cache.

In a direct-mapped cache, specific main memory addresses are preassigned to specific line locations in the cache where they will be stored. Therefore, the tag RAM can use fewer bits because when you know which main memory address you want, only one address tag needs to be checked and each tag

needs to store only the possible addresses a given line can contain. This also results in faster operation because only one tag address needs to be checked for a given memory address.

A set associative cache is a modified direct-mapped cache. A direct-mapped cache has only one set of memory associations, meaning a given memory address can be mapped into (or associated with) only a specific given cache line location. A two-way set associative cache has two sets, so that a given memory location can be in one of two locations. A four-way set associative cache can store a given memory address into four different cache line locations (or sets). By increasing the set associativity, the chance of finding a value increases; however, it takes a little longer because more tag addresses must be checked when searching for a specific location in the cache. In essence, each set in an n-way set associative cache is a subcache that has associations with each main memory address. As the number of subcaches or sets increases, eventually the cache becomes fully associative—a situation in which any memory address can be stored in any cache line location. In that case, an n-way set associative cache is a compromise between a fully associative cache and a direct-mapped cache.

In general, a direct-mapped cache is the fastest at locating and retrieving data from the cache because it has to look at only one specific tag address for a given memory address. However, it also results in more misses overall than the other designs. A fully associative cache offers the highest hit ratio but is the slowest at locating and retrieving the data because it has many more address tags to check through. An n-way set associative cache is a compromise between optimizing cache speed and hit ratio, but the more associativity there is, the more hardware (tag bits, comparator circuits, and so on) is required, making the cache more expensive. Obviously, cache design is a series of tradeoffs, and what works best in one instance might not work best in another. Multitasking environments such as Windows are good examples of environments in which the processor needs to operate on different areas of memory simultaneously and in which an n-way cache can improve performance.

The organization of the cache memory in the 486 and MMX Pentium family is called a *four-way set associative cache*, which means that the cache memory is split into four blocks. Each block also is organized as 128 or 256 lines of 16 bytes each. The following table shows the associativity of various processor L1 and L2 caches.

Processor	L1 Cache Associativity	L2 Cache Associativity
486	Four-way	Not in CPU
Pentium (non-MMX)	Two-way	Not in CPU
Pentium MMX	Four-way	Not in CPU
Pentium Pro/II/III	Four-way	Four-way (off-die)
Pentium III/4	Four-way	Eight-way (on-die)

The contents of the cache must always be in sync with the contents of main memory to ensure that the processor is working with current data. For this reason, the internal cache in the 486 family is a *write-through* cache. Write-through means that when the processor writes information out to the cache, that information is automatically written through to main memory as well.

By comparison, the Pentium and later chips have an internal write-back cache, which means that both reads and writes are cached, further improving performance. Even though the internal 486 cache is write-through, the system can employ an external write-back cache for increased performance. In addition, the 486 can buffer up to 4 bytes before actually storing the data in RAM, improving efficiency in case the memory bus is busy.

Another feature of improved cache designs is that they are nonblocking. This is a technique for reducing or hiding memory delays by exploiting the overlap of processor operations with data accesses. A *nonblocking* cache enables program execution to proceed concurrently with cache misses as long as certain dependency constraints are observed. In other words, the cache can handle a cache miss much better and enable the processor to continue doing something nondependent on the missing data.

The cache controller built into the processor also is responsible for watching the memory bus when alternative processors, known as *bus masters*, are in control of the system. This process of watching the bus is referred to as *bus snooping*. If a bus master device writes to an area of memory that also is stored in the processor cache currently, the cache contents and memory no longer agree. The cache controller then marks this data as invalid and reloads the cache during the next memory access, preserving the integrity of the system.

All PC processor designs that support cache memory include a feature known as a translation look-aside buffer (TLB) to improve recovery from cache misses. The TLB is a table inside the processor that stores information about the location of recently accessed memory addresses. The TLB speeds up the translation of virtual addresses to physical memory addresses. To improve TLB performance, several recent processors have increased the number of entries in the TLB, as AMD did when it moved from the Athlon Thunderbird core to the Palomino core. Pentium 4 processors that support HT Technology have a separate instruction TLB (iTLB) for each virtual processor thread.

- See “Hyper-Threading Technology,” p. 79.

As clock speeds increase, cycle time decreases. Newer systems don’t use cache on the motherboard any longer because the faster DDR-SDRAM or RDRAM used in modern Pentium 4/Celeron or Athlon systems can keep up with the motherboard speed. Modern processors all integrate the L2 cache into the processor die just like the L1 cache. This enables the L2 to run at full-core speed because it is now a part of the core. Cache speed is always more important than size. The rule is that a smaller but faster cache is always better than a slower but bigger cache. Table 3.16 illustrates the need for and function of L1 (internal) and L2 (external) caches in modern systems.

Table 3.16 CPU Speeds Relative to Cache, RAM, and Motherboard

CPU Type	Pentium	Pentium Pro	Pentium II
CPU speed	233MHz	200MHz	450MHz
L1 cache speed	4.3ns (233MHz)	5.0ns (200MHz)	2.2ns (450MHz)
L1 cache size	16K	32K	32K
L2 cache type	onboard	on-chip	on-chip
L2 speed ratio	2/7	1/1	1/2
L2 cache speed	15ns (66MHz)	5ns (200MHz)	4.4ns (225MHz)
L2 cache size	varies ¹	256KB ²	512KB
CPU bus speed	66MHz	66MHz	100MHz
Memory bus speed	60ns (16MHz)	60ns (16MHz)	10ns (100MHz)
CPU Type	AMD K6-2	AMD K6-3	Pentium III
CPU speed	550MHz	450MHz	1.4GHz
L1 cache speed	1.8ns (550MHz)	2.2ns (450MHz)	0.71ns (1.4GHz)
L1 cache size	64K	64K	32K
L2 cache type	onboard	on-die	on-die
L2 speed ratio	2/11	1/1	1/1
L2 cache speed	10ns (100MHz)	2.2ns (450MHz)	0.71ns (1.4GHz)
L2 cache size	varies ¹	256KB	512KB
CPU bus speed	100MHz	100MHz	133MHz
Memory bus speed	10ns (100MHz)	10ns (100MHz)	7.5ns (133MHz)

Table 3.16 Continued

CPU Type	Athlon XP	Athlon 64	Pentium 4
CPU speed	2.2GHz	2.4GHz	4.0GHz
L1 cache speed	0.45ns (2.2GHz)	0.42ns (2.4GHz)	0.25ns (4.0GHz)
L1 cache size	128K	128K	28K
L2 cache type	on-die	on-die	on-die
L2 speed ratio	1/1	1/1	1/1
L2 cache speed	0.45ns (2.2GHz)	0.42ns (2.4GHz)	0.25ns (4.0GHz)
L2 cache size	512KB	1024KB	1024KB
CPU bus speed	400MHz	400MHz	800MHz
Memory bus speed	2.5ns (400MHz)	2.5ns (400MHz)	2.5ns (400MHz) ³

1. The L2 cache is on the motherboard, and the amount depends on which board is chosen and how much is installed.
2. The Pentium Pro was also available with 512KB and 1024KB L2 cache.
3. Dual-channel memory uses two banks simultaneously, doubling the throughput.

As you can see, having two levels of cache between the very fast CPU and the much slower main memory helps minimize any wait states the processor might have to endure, especially those with the on-die L2. This enables the processor to keep working closer to its true speed.

Processor Features

As new processors are introduced, new features are continually added to their architectures to help improve everything from performance in specific types of applications to the reliability of the CPU as a whole. The next few sections take a look at some of these technologies, including System Management Mode (SMM), Superscalar Execution, MMX, SSE, 3DNow!, and HT Technology.

SMM (Power Management)

Spurred on primarily by the goal of putting faster and more powerful processors in laptop computers, Intel has created power-management circuitry. This circuitry enables processors to conserve energy use and lengthen battery life. This was introduced initially in the Intel 486SL processor, which is an enhanced version of the 486DX processor. Subsequently, the power-management features were universalized and incorporated into all 75MHz and faster Pentium and later processors. This feature set is called SMM, which stands for *system management mode*.

SMM circuitry is integrated into the physical chip but operates independently to control the processor's power use based on its activity level. It enables the user to specify time intervals after which the CPU will be partially or fully powered down. It also supports the Suspend/Resume feature that allows for instant power on and power off, used mostly with laptop PCs. These settings are typically controlled via system BIOS settings.

Superscalar Execution

The fifth-generation Pentium and newer processors feature multiple internal instruction execution pipelines, which enable them to execute multiple instructions at the same time. The 486 and all preceding chips can perform only a single instruction at a time. Intel calls the capability to execute more than one instruction at a time *superscalar* technology. This technology provides additional performance compared with the 486.

- ▶▶ See "Pentium Processors," p. 125.

Superscalar architecture usually is associated with high-output Reduced Instruction Set Computer (RISC) chips. A RISC chip has a less complicated instruction set with fewer and simpler instructions. Although each instruction accomplishes less, overall the clock speed can be higher, which can usually increase performance. The Pentium is one of the first Complex Instruction Set Computer (CISC) chips to be considered superscalar. A CISC chip uses a richer, fuller-featured instruction set, which has more complicated instructions. As an example, say you wanted to instruct a robot to screw in a light bulb. Using CISC instructions, you would say

1. Pick up the bulb.
2. Insert it into the socket.
3. Rotate clockwise until tight.

Using RISC instructions, you would say something more along the lines of

1. Lower hand.
2. Grasp bulb.
3. Raise hand.
4. Insert bulb into socket.
5. Rotate clockwise one turn.
6. Is bulb tight? If not, repeat step 5.
7. End.

Overall, many more RISC instructions are required to do the job because each instruction is simpler (reduced) and does less. The advantage is that there are fewer overall commands the robot (or processor) has to deal with and it can execute the individual commands more quickly, and thus in many cases execute the complete task (or program) more quickly as well. The debate goes on whether RISC or CISC is really better, but in reality there is no such thing as a pure RISC or CISC chip—it is all just a matter of definition, and the lines are somewhat arbitrary.

Intel and compatible processors have generally been regarded as CISC chips, although the fifth- and sixth-generation versions have many RISC attributes and internally break CISC instructions down into RISC versions.

MMX Technology

MMX technology was originally named for multimedia extensions, or matrix math extensions, depending on whom you ask. Intel officially states that it is actually not an abbreviation and stands for nothing other than the letters MMX (not being an abbreviation was apparently required so that the letters could be trademarked); however, the internal origins are probably one of the preceding. MMX technology was introduced in the later fifth-generation Pentium processors as a kind of add-on that improves video compression/decompression, image manipulation, encryption, and I/O processing—all of which are used in a variety of today's software.

MMX consists of two main processor architectural improvements. The first is very basic; all MMX chips have a larger internal L1 cache than their non-MMX counterparts. This improves the performance of any and all software running on the chip, regardless of whether it actually uses the MMX-specific instructions.

The other part of MMX is that it extends the processor instruction set with 57 new commands or instructions, as well as a new instruction capability called single instruction, multiple data (SIMD).

Modern multimedia and communication applications often use repetitive loops that, while occupying 10% or less of the overall application code, can account for up to 90% of the execution time. SIMD enables one instruction to perform the same function on multiple pieces of data, similar to a teacher telling an entire class to “sit down,” rather than addressing each student one at a time. SIMD enables the chip to reduce processor-intensive loops common with video, audio, graphics, and animation.

Intel also added 57 new instructions specifically designed to manipulate and process video, audio, and graphical data more efficiently. These instructions are oriented to the *highly parallel* and often repetitive sequences frequently found in multimedia operations. *Highly parallel* refers to the fact that the same processing is done on many data points, such as when modifying a graphic image. The main drawbacks to MMX were that it worked only on integer values and used the floating-point unit for processing, so time was lost when a shift to floating-point operations was necessary. These drawbacks were corrected in the additions to MMX from Intel and AMD.

Intel licensed the MMX capabilities to competitors such as AMD and Cyrix, who were then able to upgrade their own Intel-compatible processors with MMX technology.

SSE, SSE2, and SSE3

In February 1999, Intel introduced the Pentium III processor and included in that processor an update to MMX called Streaming SIMD Extensions (SSE). These were also called Katmai New Instructions (KNI) up until their debut because they were originally included on the Katmai processor, which was the codename for the Pentium III. The Celeron 533A and faster Celeron processors based on the Pentium III core also support SSE instructions. The earlier Pentium II and Celeron 533 and lower (based on the Pentium II core) do not support SSE.

SSE includes 70 new instructions for graphics and sound processing over what MMX provided. SSE is similar to MMX; in fact, besides being called KNI, SSE was also called MMX-2 by some before it was released. In addition to adding more MMX style instructions, the SSE instructions allow for floating-point calculations and now use a separate unit within the processor instead of sharing the standard floating-point unit as MMX did.

SSE2 was introduced in November 2000, along with the Pentium 4 processor, and adds 144 additional SIMD instructions. SSE2 also includes all the previous MMX and SSE instructions.

SSE3 was introduced in February 2004, along with the Pentium 4 Prescott processor, and adds 13 new SIMD instructions to improve complex math, graphics, video encoding, and thread synchronization. SSE3 also includes all the previous MMX, SSE, and SSE2 instructions.

The Streaming SIMD Extensions consist of new instructions, including SIMD floating-point, additional SIMD integer, and cacheability control instructions. Some of the technologies that benefit from the Streaming SIMD Extensions include advanced imaging, 3D video, streaming audio and video (DVD playback), and speech-recognition applications. The benefits of SSE include the following:

- Higher resolution and higher quality image viewing and manipulation for graphics software
- High-quality audio, MPEG2 video, and simultaneous MPEG2 encoding and decoding for multimedia applications
- Reduced CPU utilization for speech recognition, as well as higher accuracy and faster response times when running speech-recognition software

The SSEx instructions are particularly useful with MPEG2 decoding, which is the standard scheme used on DVD video discs. SSE-equipped processors should therefore be more capable of performing MPEG2 decoding in software at full speed without requiring an additional hardware MPEG2 decoder card. SSE-equipped processors are much better and faster than previous processors when it comes to speech recognition, as well.

One of the main benefits of SSE over plain MMX is that it supports single-precision floating-point SIMD operations, which have posed a bottleneck in the 3D graphics processing. Just as with plain MMX, SIMD enables multiple operations to be performed per processor instruction. Specifically, SSE supports up to four floating-point operations per cycle; that is, a single instruction can operate on four pieces of data simultaneously. SSE floating-point instructions can be mixed with MMX instructions with no performance penalties. SSE also supports data *prefetching*, which is a mechanism for reading data into the cache before it is actually called for.

Note that for any of the SSE instructions to be beneficial, they must be encoded in the software you are using, so SSE-aware applications must be used to see the benefits. Most software companies writing graphics- and sound-related software today have updated those applications to be SSE aware and use the features of SSE. For example, high-powered graphics applications such as Adobe Photoshop support SSE instructions for higher performance on processors equipped with SSE. Microsoft includes support for SSE in its DirectX 6.1 and later video and sound drivers, which are included with Windows 98 Second Edition, Windows Me, Windows NT 4.0 (with service pack 5 or later), Windows 2000, and Windows XP.

SSE is an extension to MMX; SSE2 is an extension to SSE; and SSE3 is an extension to SSE2. Therefore, processors that support SSE3 also support the SSE2 instructions, processors that support SSE2 also support SSE, and processors that support SSE also support the original MMX instructions. This means that standard MMX-enabled applications run as they did on MMX-only processors.

3DNow!, Enhanced 3DNow!, and Professional 3DNow!

3DNow! technology was originally introduced as AMD's alternative to the SSE instructions in the Intel processors. Actually, 3DNow! was first introduced in the K6 series before Intel released SSE in the Pentium III, and then AMD added Enhanced 3DNow! to the Athlon and Duron processors. The latest version, Professional 3DNow!, was introduced in the first Athlon XP processors. AMD licensed MMX from Intel, and all its K6 series, Athlon, Duron, and later processors include full MMX instruction support. Not wanting to additionally license the SSE instructions being developed by Intel, AMD first came up with a different set of extensions beyond MMX called 3DNow!. Introduced in May 1998 in the K6-2 processor and enhanced when the Athlon was introduced in June 1999, 3DNow!, and Enhanced 3DNow! are sets of instructions that extend the multimedia capabilities of the AMD chips beyond MMX. This enables greater performance for 3D graphics, multimedia, and other floating-point-intensive PC applications.

3DNow! technology is a set of 21 instructions that uses SIMD techniques to operate on arrays of data rather than single elements. Enhanced 3DNow! adds 24 more instructions (19 SSE and 5 DSP/communications instructions) to the original 21 for a total of 45 new instructions. Positioned as an extension to MMX technology, 3DNow! is similar to the SSE found in the Pentium III and Celeron processors from Intel. According to AMD, 3DNow! provides approximately the same level of improvement to MMX as did SSE, but in fewer instructions with less complexity. Although similar in capability, they are not compatible at the instruction level, so software specifically written to support SSE does not support 3DNow!, and vice versa. The latest version of 3DNow!, 3DNow! Professional, adds 51 SSE commands to 3DNow! Enhanced, meaning that 3DNow! Professional now supports all SSE commands, meaning that AMD chips now essentially have SSE capability. Unfortunately, AMD includes SSE2 only on the Athlon 64, Athlon 64FX, and Opteron 64-bit processors.

Just as with SSE, 3DNow! also supports single precision floating-point SIMD operations and enables up to four floating-point operations per cycle. 3DNow! floating-point instructions can be mixed with MMX instructions with no performance penalties. 3DNow! also supports data prefetching.

Also like SSE, 3DNow! is well supported by software, including Windows 9x, Windows NT 4.0, and all newer Microsoft operating systems. 3DNow!-specific support is no longer a big issue if you are using an Athlon XP or Athlon 64 processor because they now fully support SSE through their support of 3DNow! Professional.

Dynamic Execution

First used in the P6 or sixth-generation processors, dynamic execution enables the processor to execute more instructions on parallel, so tasks are completed more quickly. This technology innovation is comprised of three main elements:

- *Multiple branch prediction.* Predicts the flow of the program through several branches
- *Dataflow analysis.* Schedules instructions to be executed when ready, independent of their order in the original program
- *Speculative execution.* Increases the rate of execution by looking ahead of the program counter and executing instructions that are likely to be necessary

Branch Prediction

Branch prediction is a feature formerly found only in high-end mainframe processors. It enables the processor to keep the instruction pipeline full while running at a high rate of speed. A special fetch/decode unit in the processor uses a highly optimized branch prediction algorithm to predict the direction and outcome of the instructions being executed through multiple levels of branches, calls, and returns. It is similar to a chess player working out multiple strategies in advance of game play by predicting the opponent's strategy several moves into the future. By predicting the instruction outcome in advance, the instructions can be executed with no waiting.

Dataflow Analysis

Dataflow analysis studies the flow of data through the processor to detect any opportunities for out-of-order instruction execution. A special dispatch/execute unit in the processor monitors many instructions and can execute these instructions in an order that optimizes the use of the multiple superscalar execution units. The resulting out-of-order execution of instructions can keep the execution units busy even when cache misses and other data-dependent instructions might otherwise hold things up.

Speculative Execution

Speculative execution is the processor's capability to execute instructions in advance of the actual program counter. The processor's dispatch/execute unit uses dataflow analysis to execute all available instructions in the instruction pool and store the results in temporary registers. A retirement unit then searches the instruction pool for completed instructions that are no longer data dependent on other instructions to run or which have unresolved branch predictions. If any such completed instructions are found, the results are committed to memory by the retirement unit or the appropriate standard Intel architecture in the order they were originally issued. They are then retired from the pool.

Dynamic execution essentially removes the constraint and dependency on linear instruction sequencing. By promoting out-of-order instruction execution, it can keep the instruction units working rather than waiting for data from memory. Even though instructions can be predicted and executed out of order, the results are committed in the original order so as not to disrupt or change program flow. This enables the P6 to run existing Intel architecture software exactly as the P5 (Pentium) and previous processors did—just a whole lot more quickly!

Dual Independent Bus Architecture

The Dual Independent Bus (DIB) architecture was first implemented in the sixth-generation processors from Intel and AMD. DIB was created to improve processor bus bandwidth and performance. Having two (dual) independent data I/O buses enables the processor to access data from either of its buses simultaneously and in parallel, rather than in a singular sequential manner (as in a single-bus system). The main (often called front-side) processor bus is the interface between

the processor and the motherboard or chipset. The second (back-side) bus in a processor with DIB is used for the L2 cache, enabling it to run at much greater speeds than if it were to share the main processor bus.

Two buses make up the DIB architecture: the L2 cache bus and the main CPU bus, often called FSB (front-side bus). The P6 class processors from the Pentium Pro to the Celeron, Pentium II/III/4, and Athlon/Duron processors can use both buses simultaneously, eliminating a bottleneck there. The dual bus architecture enables the L2 cache of the newer processors to run at full speed inside the processor core on an independent bus, leaving the main CPU bus (FSB) to handle normal data flowing in and out of the chip. The two buses run at different speeds. The front-side bus or main CPU bus is coupled to the speed of the motherboard, whereas the back-side or L2 cache bus is coupled to the speed of the processor core. As the frequency of processors increases, so does the speed of the L2 cache.

The key to implementing DIB was to move the L2 cache memory off the motherboard and into the processor package. L1 cache always has been a direct part of the processor die, but L2 was larger and originally had to be external. By moving the L2 cache into the processor, the L2 cache could run at speeds more like the L1 cache, much faster than the motherboard or processor bus.

DIB also enables the system bus to perform multiple simultaneous transactions (instead of singular sequential transactions), accelerating the flow of information within the system and boosting performance. Overall, DIB architecture offers up to three times the bandwidth performance over a single-bus architecture processor.

Hyper-Threading Technology

Computers with two or more physical processors have long had a performance advantage over single-processor computers when the operating system supported multiple processors, as is the case with Windows NT 4.0, 2000, XP Professional, and Linux. However, dual-processor motherboards and systems have always been more expensive than otherwise-comparable single processor systems, and upgrading a dual-processor-capable system to dual-processor status can be difficult with only one processor because of the need to match processor speeds and specifications. However, Intel's new Hyper-Threading (HT) Technology allows a single processor to handle two independent sets of instructions at the same time. In essence, HT Technology converts a single physical processor into two virtual processors.

Intel originally introduced HT Technology in its line of Xeon processors for servers in March 2002. HT Technology enables multiprocessor servers to act as if they had twice as many processors installed. HT Technology was introduced on Xeon workstation-class processors with a 533MHz system bus and later found its way into PC processors, with the Pentium 4 3.06GHz processor in November 2002. HT Technology is also present in all Pentium 4 processors with 800MHz CPU bus speed (2.4GHz up through 3.4GHz).

How Hyper-Threading Works

Internally, an HT-enabled processor has two sets of general-purpose registers, control registers, and other architecture components, but both logical processors share the same cache, execution units, and buses. During operations, each logical processor handles a single thread (see Figure 3.2).

Although the sharing of some processor components means that the overall speed of an HT-enabled system isn't as high as a true dual-processor system would be, speed increases of 25% or more are possible when multiple applications or a single multithreaded application is being run.

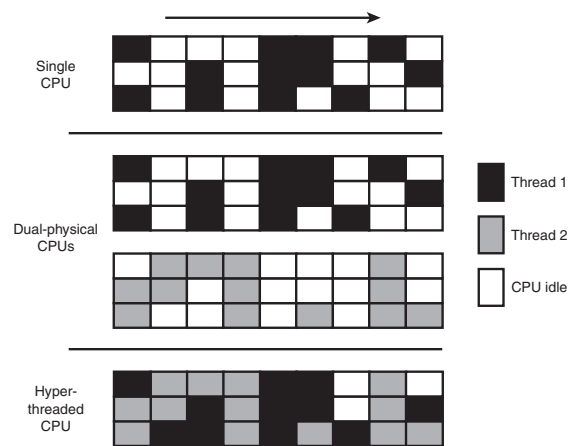

Figure 3.2 A processor with HT Technology enabled can fill otherwise-idle time with a second process, improving multitasking and performance of multithreading single applications.

Hyper-Threading Requirements

The first HT-enabled processor is the Intel Pentium 4 3.06GHz. All 3.06GHz and faster Pentium 4 models support HT Technology, as do all processors 2.4GHz and faster that use the 800MHz bus. However, an HT-enabled P4 processor by itself can't bring the benefits of HT Technology to your system. You also need the following:

- *A compatible motherboard (chipset).* It might need a BIOS upgrade.
- *BIOS support to enable/disable HT Technology.* If your operating system doesn't support HT Technology, you should disable this feature.
- *A compatible operating system such as Windows XP Home or Professional Editions.* When hyper-threading is enabled on these operating systems, the Device Manager shows two processors.

Intel's newer chipsets for the Pentium 4 support HT Technology; see the listing in Chapter 4 for details. However, if your motherboard or computer was released before HT Technology was introduced, you will need a BIOS upgrade from the motherboard or system vendor to be able to use HT Technology. Although Windows NT 4.0 and Windows 2000 are designed to use multiple physical processors, HT Technology requires specific operating system optimizations to work correctly. Linux distributions based on kernel 2.4.18 and higher also support HT Technology.

Processor Manufacturing

Processors are manufactured primarily from silicon, the second most common element on the planet (only the element oxygen is more common). Silicon is the primary ingredient in beach sand; however, in that form it isn't pure enough to be used in chips.

The manner in which silicon is formed into chips is a lengthy process that starts by growing pure silicon crystals via what is called the Czochralski method (named after the inventor of the process). In this method, electric arc furnaces transform the raw materials (primarily quartz rock that is mined) into metallurgical-grade silicon. Then to further weed out impurities, the silicon is converted to a liquid, distilled, and then redeposited in the form of semiconductor-grade rods, which are 99.999999% pure. These rods are then mechanically broken up into chunks and packed into quartz crucibles, which are loaded into electric crystal pulling ovens. There the silicon chunks are melted at more than 2,500° Fahrenheit. To prevent impurities, the ovens usually are mounted on very thick concrete cubes—often on a suspension to prevent any vibration, which would damage the crystal as it forms.

After the silicon is melted, a small seed crystal is inserted into the molten silicon and slowly rotated (see Figure 3.3). As the seed is pulled out of the molten silicon, some of the silicon sticks to the seed and hardens in the same crystal structure as the seed. By carefully controlling the pulling speed (10–40 millimeters per hour) and temperature (approximately 2,500°F), the crystal grows with a narrow neck that then widens into the full desired diameter. Depending on the chips being made, each ingot is 200mm (approximately 8") or 300mm (12") in diameter and more than 5 feet long, weighing hundreds of pounds.

Figure 3.3 Growing a pure silicon ingot in a high-pressure, high-temperature oven.

The ingot is then ground into a perfect 200mm- (8") or 300mm-diameter (12") cylinder, with a small, flat cut on one side for positioning accuracy and handling. Each ingot is then cut with a high-precision diamond saw into more than a thousand circular wafers, each less than a millimeter thick (see Figure 3.4). Each wafer is then polished to a mirror-smooth surface.

Chips are manufactured from the wafers using a process called *photolithography*. Through this photographic process, transistors and circuit and signal pathways are created in semiconductors by depositing different layers of various materials on the chip, one after the other. Where two specific circuits intersect, a transistor or switch can be formed.

The photolithographic process starts when an insulating layer of silicon dioxide is grown on the wafer through a vapor deposition process. Then a coating of photoresist material is applied, and an image of that layer of the chip is projected through a mask onto the now light-sensitive surface.

Doping is the term used to describe chemical impurities added to silicon (which is naturally a nonconductor), creating a material with semiconductor properties. The projector uses a specially created mask, which is essentially a negative of that layer of the chip etched in chrome on a quartz plate. Modern processors have 20 or more layers of material deposited and partially etched away (each requiring a mask) and up to six or more layers of metal interconnects.

As the light passes through a mask, the light is focused on the wafer surface, exposing the photoresist with the image of that layer of the chip. Each individual chip image is called a *die*. A device called a *stepper* then moves the wafer over a little bit, and the same mask is used to imprint another chip die

immediately next to the previous one. After the entire wafer is imprinted with a layer of material and photoresist, a caustic solution washes away the areas where the light struck the photoresist, leaving the mask imprints of the individual chip circuit elements and pathways. Then, another layer of semiconductor material is deposited on the wafer with more photoresist on top, and the next mask is used to expose and then etch the next layer of circuitry. Using this method, the layers and components of each chip are built one on top of the other until the chips are completed.

Figure 3.4 Slicing a silicon ingot into wafers with a diamond saw.

Some of the masks are used to add the *metallization* layers, which are the metal interconnects used to tie all the individual transistors and other components together. Most chips use aluminum interconnects, although during 2002 many moved to copper. The first commercial PC processor chip to use copper was the 0.18-micron Athlon made in AMD's Dresden fab, and Intel has shifted the Pentium 4 to copper with the 0.13-micron Northwood version (see Figure 3.5). Copper is a better conductor than aluminum and allows smaller interconnects with less resistance, meaning smaller and faster chips can be made. The reason copper hadn't been used until recently is that there were difficult corrosion problems to overcome during the manufacturing process that were not as much of a problem with aluminum. Now that these problems have been solved, more and more chips will be fabricated with copper interconnects.

Note

The Pentium III and Celeron chips with the "coppermine" (codename for the 0.18-micron die used in those chips) die used aluminum and not copper metal interconnects as many people assume. In fact, the chip name had nothing to do with metal; the codename instead came from the Coppermine River in the Northwest Territory of Canada. Intel has long had a fondness for using codenames based on rivers (and sometimes, other geological features), especially those in the northwest region of the North American continent. For example, an older version of the Pentium III (0.25-micron die) was code-named Katmai, after an Alaskan river. Intel codenames read like the travel itinerary of a whitewater rafting enthusiast: Deerfield, Foster, Northwood, Tuolatin, Gallatin, McKinley, and Madison are all rivers in Oregon, California, Alaska, Montana, and—in the case of Deerfield—Massachusetts and Vermont.

A completed circular wafer has as many chips imprinted on it as can possibly fit. Because each chip usually is square or rectangular, there are some unused portions at the edges of the wafer, but every attempt is made to use every square millimeter of surface.

The industry is going through several transitions in chip manufacturing. The trend in the industry is to use both larger wafers and a smaller chip die process. *Process* refers to the size and spacing of the individual circuits and transistors on the chip. In late 2001 and into 2002, chip manufacturing processes began moving from the 0.18-micron to the 0.13-micron process, the metal interconnects on

the die began moving from aluminum to copper, and wafers began moving from 200mm (8") to 300mm (12") in diameter. The larger 300mm wafers alone enable more than double the number of chips to be made, compared to the 200mm used previously. The smaller 0.13-micron process enables more transistors to be incorporated into the die while maintaining a reasonable die size and allowing for a sufficient yield. This means the trend for incorporating more and more cache within the die will continue, and transistor counts will rise to 1 billion per chip or more by 2010.

Figure 3.5 200mm wafer of the 0.13-micron Pentium 4 processors.

As an example of how this can affect a particular chip, let's look at the Pentium 4. The standard wafer size used in the industry for many years was 200mm in diameter, or just under 8". This results in a wafer of about 31,416 square millimeters in area. The first version of the Pentium 4 with the Willamette core used a 0.18-micron process with aluminum interconnects on a die that was 217 square millimeters in area, had 42 million transistors, and was made on 200mm wafers. Therefore, up to 145 of these chips could fit on a 200mm (8") wafer.

The newer Pentium 4 processors with the Northwood core use a smaller 0.13-micron process with copper interconnects on a die that is 131 square millimeters in area with 55 million transistors. Northwood has double the on-die L2 cache (512KB) as compared to Willamette, which is why the transistor count is significantly higher. Even with the higher transistor count, the smaller 0.13-micron process results in a die that is more than 60% smaller, allowing up to 240 chips to fit on the same 200mm (8") wafer that could hold only 145 Willamette die.

Starting in early 2002, Intel began producing Northwood on the larger 300mm wafers, which have a surface area of 70,686 square millimeters. These wafers have 2.25 times the surface area of the smaller 200mm wafers, enabling more than double the number of chips to be produced per wafer. In the case of the Pentium 4 Northwood, up to 540 chip dies fit on a 300mm wafer. By combining the smaller die with the larger wafer, Pentium 4 production has increased by more than 3.7 times since the chip was first introduced. This is one reason newer chips are often more plentiful and less expensive than older ones.

In 2004, the industry began moving to the 90-nanometer (0.09-micron) process, allowing even smaller and faster chips to be made. In 2007, we'll see a move toward a 65-nanometer process, and we'll see a 45-nanometer process in 2010. These advancements in process will allow 1 billion transistors per chip in 2010! All these will still be made on 300mm wafers because the next wafer transition isn't expected until 2013, when a transition to 450mm wafers is being considered. Table 3.17 lists the CPU process transitions.

Table 3.17 Past, Current, and Future CPU Process Transitions

Date:	1989	1991	1993	1995	1997	1999	2001	2004	2007	2010	2013	2016
Process (micron):	1.0	0.8	0.5	0.35	0.25	0.18	0.13	0.09	0.065	0.045	0.032	0.022
Process (nm):	1000	800	500	350	250	180	130	90	65	45	32	22

Note that not all the chips on each wafer will be good, especially as a new production line starts. As the manufacturing process for a given chip or production line is perfected, more and more of the chips will be good. The ratio of good to bad chips on a wafer is called the *yield*. Yields well under 50% are common when a new chip starts production; however, by the end of a given chip's life, the yields are normally in the 90% range. Most chip manufacturers guard their yield figures and are very secretive about them because knowledge of yield problems can give their competitors an edge. A low yield causes problems both in the cost per chip and in delivery delays to their customers. If a company has specific knowledge of competitors' improving yields, it can set prices or schedule production to get higher market share at a critical point.

After a wafer is complete, a special fixture tests each of the chips on the wafer and marks the bad ones to be separated out later. The chips are then cut from the wafer using either a high-powered laser or diamond saw.

After being cut from the wafers, the individual dies are then retested, packaged, and retested again. The packaging process is also referred to as *bonding* because the die is placed into a chip housing in which a special machine bonds fine gold wires between the die and the pins on the chip. The package is the container for the chip die, and it essentially seals it from the environment.

After the chips are bonded and packaged, final testing is done to determine both proper function and rated speed. Different chips in the same batch often run at different speeds. Special test fixtures run each chip at different pressures, temperatures, and speeds, looking for the point at which the chip stops working. At this point, the maximum successful speed is noted and the final chips are sorted into bins with those that tested at a similar speed. For example, the Pentium 4 2.0A, 2.2, 2.26, 2.4, and 2.53GHz are all exactly the same chip made using the same die. They were sorted at the end of the manufacturing cycle by speed.

One interesting thing about this is that as a manufacturer gains more experience and perfects a particular chip assembly line, the yield of the higher-speed versions goes way up. So, of all the chips produced from a single wafer, perhaps more than 75% of them check out at the highest speed and only 25% or less run at the lower speeds. The paradox is that Intel often sells a lot more of the lower-priced, lower-speed chips, so it just dips into the bin of faster ones, labels them as slower chips, and sells them that way. People began discovering that many of the lower-rated chips actually ran at speeds much higher than they were rated, and the business of overclocking was born.

Processor Re-marking

An interesting problem then arose: Unscrupulous vendors began re-marking slower chips and reselling them as if they were faster. Often the price between the same chip at different speed grades can be substantial—in the hundreds of dollars—so by changing a few numbers on the chip, the potential profits can be huge. Because most of the Intel and AMD processors are produced with a generous safety margin—that is, they typically run well past their rated speeds—the re-marked chips would seem to work fine in most cases. Of course, in many cases they wouldn't work fine, and the system would end up crashing or locking up periodically.

At first, the re-marked chips were just a case of rubbing off the original numbers and restamping with new official-looking numbers. These were easy to detect, though. Re-markers then resorted to manufacturing completely new processor housings, especially for the plastic-encased Slot 1 and Slot A processors from Intel and AMD. Although it might seem to be a huge bother to make a custom plastic case and swap it with the existing case, because the profits can be huge, criminals find it very lucrative. This type of re-marking is a form of organized crime and isn't just some kid in his basement with sandpaper and a rubber stamp.

Intel and AMD have seen fit to put a stop to some of the re-marking by building overclock protection in the form of a multiplier lock into most of their newer chips. This is usually done in the bonding or

cartridge manufacturing process, where the chips are intentionally altered so they won't run at any speeds higher than they are rated. Usually this involves changing the bus frequency (BF) pins or traces on the chip, which control the internal multipliers the chip uses. Even so, enterprising individuals have found ways to run their motherboards at bus speeds higher than normal, so even though the chip won't allow a higher multiplier, you can still run it at a speed higher than it was designed for.

Be Wary of PII and PIII Slot 1 Overclocking Fraud

If you're still interested in purchasing Slot 1 processors, note that unscrupulous individuals have devised a small logic circuit that bypasses the multiplier lock, enabling the chip to run at higher multipliers. This small circuit can be hidden in the PII or PIII cartridge, and then the chip can be re-marked or relabeled to falsely indicate it is a higher-speed version. This type of chip re-marking fraud is far more common in the industry than people want to believe. In fact, if you purchase your system or processor from a local computer flea market show, you have an excellent chance of getting a re-marked chip. I recommend purchasing processors only from more reputable direct distributors or dealers. You can contact Intel, AMD, or VIA for a list of them.

The real problem with the overclock protection as implemented by Intel and AMD is that the professional counterfeiter has often been able to figure out a way around it by modifying the chip physically. Socketed processors are much more immune to these re-marking attempts, but it is still possible, particularly because the evidence can be hidden under a heatsink. To protect yourself from purchasing a fraudulent chip, verify the specification numbers and serial numbers with Intel and AMD before you purchase. Also beware where you buy your hardware. Purchasing over online auction sites can be extremely dangerous because defrauding the purchaser is so easy. Also, traveling computer show/flea market arenas can be a hotbed of this type of activity. Finally, I recommend purchasing only "boxed" or retail-packaged versions of the Intel and AMD processors, rather than the raw OEM versions. The boxed versions are shrink-wrapped and contain a high-quality heatsink, documentation, and a 3-year warranty with the manufacturer.

Fraudulent computer components are not limited to processors. I have seen fake memory (SIMMs/DIMMs), fake mice, fake video cards, fake SCSI cards, fake cache memory, counterfeit operating systems and applications, and even fake motherboards. The hardware that is faked usually works but is of inferior quality to the type it is purporting to be. For example, one of the most highly counterfeited pieces of hardware at one time was the Microsoft mouse. They originally sold for \$35 wholesale, yet I could purchase cheap mice from overseas manufacturers for as little as \$2.32 each. It didn't take somebody long to realize that if they made the \$2 mouse look like a \$35 Microsoft mouse, they could sell it for \$20 and people would think they were getting a genuine article for a bargain, while the thieves ran off with a substantial profit.

PGA Chip Packaging

Variations on the pin grid array (PGA) chip packaging have been the most commonly used chip packages over the years. They were used starting with the 286 processor in the 1980s and are still used today for Pentium and Pentium Pro processors. PGA takes its name from the fact that the chip has a grid-like array of pins on the bottom of the package. PGA chips are inserted into sockets, which are often of a zero insertion force (ZIF) design. A ZIF socket has a lever to allow for easy installation and removal of the chip.

Most Pentium processors use a variation on the regular PGA called staggered pin grid array (SPGA), in which the pins are staggered on the underside of the chip rather than in standard rows and columns. This was done to move the pins closer together and decrease the overall size of the chip when a large number of pins is required. Figure 3.6 shows a Pentium Pro that uses the dual-pattern SPGA (on the right) next to an older Pentium 66 that uses the regular PGA. Note that the right half of the Pentium Pro shown here has additional pins staggered among the other rows and columns.

Figure 3.6 PGA on Pentium 66 (left) and dual-pattern SPGA on Pentium Pro (right).

Older PGA variations had the processor die mounted in a cavity underneath the substrate, with the top surface facing up if you turned the chip upside down. The die was then wire-bonded to the chip package with hundreds of tiny gold wires connecting the connections at the edge of the chip with the internal connections in the package. After the wire bonding, the cavity was sealed with a metal cover. This was an expensive and time-consuming method of producing chips, so cheaper and more efficient packaging methods were designed.

Most modern processors are built on a form of flip-chip pin grid array (FC-PGA) packaging. This type still plugs into a PGA socket, but the package itself is dramatically simplified. With FC-PGA, the raw silicon die is mounted face down on the top of the chip substrate, and instead of wire bonding, the connections are made with tiny solder bumps around the perimeter of the die. The edge is then sealed with a fillet of epoxy. With the original versions of FC-PGA, you could see the backside of the raw die sitting on the chip.

Unfortunately, there were some problems with attaching the heatsink to an FC-PGA chip. The heatsink sat on the top of the die, which acted as a pedestal. If you pressed down on one side of the heatsink excessively during the installation process (such as when you were attaching the clip), you risked cracking the silicon die and destroying the chip. This was especially a problem as heatsinks became larger and heavier and the force applied by the clip became greater.

AMD decreased the risk of damage by adding rubber spacers to each corner of the chip substrate, thus preventing the heatsink from tilting excessively during installation. Still, these bumpers could compress, and it was all too easy to crack the die. The Athlon XP currently uses FC-PGA with spacers at each corner of the substrate, and some aftermarket vendors sell specially designed shims that help provide additional protection. The Athlon 64 uses a different heatsink design, which attaches the heatsink to a clip. The clip is then screwed to the motherboard, which helps prevent damage to the processor.

Intel revised its packaging with a newer FC-PGA2 version used in the newer Pentium III and all Pentium 4 processors. This incorporates an integrated protective metal cap called a heat spreader that sits on top of the die, enabling larger and heavier heatsinks to be installed without any potential damage to the processor core. Ironically, the first processor for PCs to use a heat spreader was made by AMD (the K6 family).

Future packaging directions are headed toward what is called BBUL (bumpless build-up layer) packaging. This will embed the die completely in the package; in fact, the package layers will be built up around and on top of the die, fully encapsulating it within the package. This will embed the chip die and allow for a full flat surface for attaching the heatsink, as well as shorter internal interconnections within the package.

Single Edge Contact and Single Edge Processor Packaging

Intel and AMD used cartridge- or board-based packaging for some of their processors from 1997 through 2000. This packaging was called single edge contact cartridge (SECC) or single edge processor package (SEPP) and consisted of the CPU and optional separate L2 cache chips mounted on a circuit board that looked similar to an oversized memory module and that plugged into a slot. In some cases, the boards were covered with a plastic cartridge cover.

The SEC cartridge is an innovative—if a bit unwieldy—package design that incorporates the back-side bus and L2 cache internally. It was used as a cost-effective method for integrating L2 cache into the processor before it was feasible to include the cache directly inside the processor die.

A less expensive version of the SEC is called the single edge processor (SEP) package. The SEP package is basically the same circuit board containing processor and (optional) cache, but without the fancy plastic cover. This was used mainly by the lower-cost early Celeron processors. The SEP package plugs directly into the same Slot 1 connector used by the standard Pentium II or III. Four holes on the board enable the heatsink to be installed.

Slot 1, as shown in Figure 3.7, is the connection to the motherboard and has 242 pins. AMD used the same physical slot but rotated it 180° and called it Slot A. The SEC cartridge or SEP processor is plugged into the slot and secured with a processor-retention mechanism, which is a bracket that holds it in place. There also might be a retention mechanism or support for the processor heatsink. Figure 3.8 shows the parts of the cover that make up the SEC package. Note the large thermal plate used to aid in dissipating the heat from this processor. The SEP package is shown in Figure 3.9.

Figure 3.7 Pentium II Processor Slot 1 dimensions (metric/English).

Figure 3.8 Pentium II Processor SEC package parts.

Figure 3.9 Celeron Processor SEP package front-side view.

With the Pentium III, Intel introduced a variation on the SEC packaging called single edge contact cartridge version 2 (SECC2). This new package covered only one side of the processor board with plastic and enables the heatsink to directly attach to the chip on the other side. This more direct thermal interface allowed for better cooling, and the overall lighter package was cheaper to manufacture. A newer Universal Retention System, consisting of a plastic upright stand, was required to hold the SECC2 package in place on the board. The Universal Retention System also worked with the older SEC package as used on most Pentium II processors, as well as the SEP package used on the slot-based Celeron processors. This made it the ideal retention mechanism for all Slot 1-based processors. AMD Athlon Slot A processors used the same retention mechanisms as Intel. Figure 3.10 shows the SECC2 package.

Figure 3.10 SECC2 packaging used in newer Pentium II and III processors.

The main reason for switching to the SEC and SEP packages in the first place was to be able to move the L2 cache memory off the motherboard and onto the processor in an economical and scalable way. This was necessary because, at the time, it was not feasible to incorporate the cache directly into the CPU core die. After building the L2 directly into the CPU die became possible, the cartridge and slot packaging were unnecessary. Because virtually all modern processors incorporate the L2 cache on-die, the processor packaging has gone back to the PGA socket form.

Processor Socket and Slot Types

Intel and AMD have created a set of socket and slot designs for their processors. Each socket or slot is designed to support a different range of original and upgrade processors. Table 3.18 shows the designations for the various 486 and newer processor sockets/slots and lists the chips designed to plug into them.

Table 3.18 CPU Socket and Slot Types and Specifications

Chip Class	Socket	Pins	Layout	Voltage	Supported Processors	Introduced
Intel/AMD 486 class	Socket 1	169	17×17 PGA	5V	486 SX/SX2, DX/DX2, DX4 OD	Apr. '89
	Socket 2	238	19×19 PGA	5V	486 SX/SX2, DX/DX2, DX4 OD, 486 Pentium OD	Mar. '92
	Socket 3	237	19×19 PGA	5V/3.3V	486 SX/SX2, DX/DX2, DX4, 486 Pentium OD, AMD 5x86	Feb. '94
	Socket 6 ¹	235	19×19 PGA	3.3V	486 DX4, 486 Pentium OD	Feb. '94
Intel/AMD 586 (Pentium) class	Socket 4	273	21×21 PGA	5V	Pentium 60/66, OD	Mar. '93
	Socket 5	320	37×37 SPGA	3.3V/3.5V	Pentium 75-133, OD	Mar. '94
	Socket 7	321	37×37 SPGA	VRM	Pentium 75-233+, MMX, OD, AMD K5/K6, Cyrix M1/II	June '95

Table 3.18 Continued

Chip Class	Socket	Pins	Layout	Voltage	Supported Processors	Introduced
Intel 686 (Pentium II/III) class	Socket 8	387	Dual-pattern SPGA	Auto VRM	Pentium Pro, OD	Nov. '95
	Slot 1 (SC242)	242	Slot	Auto VRM	Pentium II/III, Celeron SECC	May '97
	Socket 370	370	37×37 SPGA	Auto VRM	Celeron/Pentium III PPGA/ FC-PGA	Nov. '98
Intel Pentium 4 class	Socket 423	423	39×39 SPGA	Auto VRM	Pentium 4 FC-PGA	Nov. '00

	Socket 603	603	31×25 mPGA	Auto VRM	Xeon (P4)	May '01
	Socket 604	604	31×25 mPGA	Auto VRM	Xeon (P4)	Oct. '03
	Socket PAC418	418	38×22	Auto VRM split SPGA	Itanium	May '01
	Socket PAC611	611	25×28	Auto VRM mPGA	Itanium 2	July '02
	Socket 940	940	31×31 mPGA	Auto VRM	AMD Athlon 64FX, Opteron	Apr. '03

1. Socket 6 was never actually implemented in any systems.

FC-PGA = Flip-chip pin grid array

FC-PGA2 = FC-PGA with an Integrated Heat Spreader (IHS)

OD = OverDrive (retail upgrade processors)

PAC = Pin array cartridge

PGA = Pin grid array

PPGA = Plastic pin grid array

SC242 = Slot connector, 242 pins

SC330 = Slot connector, 330 pins

SECC = Single edge contact cartridge

SPGA = Staggered pin grid array

mPGA = Micro pin grid array

VRM = Voltage regulator module with variable voltage output determined by module type or manual jumpers

Auto VRM = Voltage regulator module with automatic voltage selection determined by processor Voltage ID (VID) pins

Sockets 1, 2, 3, and 6 are 486 processor sockets and are shown together in Figure 3.11 so you can see the overall size comparisons and pin arrangements between these sockets. Sockets 4, 5, 7, and 8 are Pentium and Pentium Pro processor sockets and are shown together in Figure 3.12 so you can see the overall size comparisons and pin arrangements between these sockets. More detailed drawings of each socket are included throughout the remainder of this section with thorough descriptions of the sockets.

Figure 3.11 486 processor sockets.

Figure 3.12 Pentium and Pentium Pro processor sockets.

Zero Insertion Force

When the Socket 1 specification was created, manufacturers realized that if users were going to upgrade processors, they had to make the process easier. The socket manufacturers found that 100 lbs. of insertion force is required to install a chip in a standard 169-pin screw Socket 1 motherboard. With this much force involved, you easily could damage either the chip or the socket during removal or reinstallation. Because of this, some motherboard manufacturers began using low insertion force (LIF) sockets, which required only 60 lbs. of insertion force for a 169-pin chip. With the LIF or standard socket, I usually advise removing the motherboard—that way you can support the board from behind when you insert the chip. Pressing down on the motherboard with 60–100 lbs. of force can crack the board if it is not supported properly. A special tool is also required to remove a chip from one of these sockets. As you can imagine, even the low insertion force was relative, and a better solution was needed if the average person was ever going to replace his CPU.

Manufacturers began using ZIF sockets in Socket 1 designs, and all processor sockets from Socket 2 and higher have been of the ZIF design. ZIF is required for all the higher-density sockets because the insertion force would simply be too great otherwise. ZIF sockets almost eliminate the risk involved in installing or removing a processor because no insertion force is necessary to install the chip and no tool is needed to extract one. Most ZIF sockets are handle-actuated: You lift the handle, drop the chip into the socket, and then close the handle. This design makes installing or removing a processor an easy task.

Socket 1

The original OverDrive socket, now officially called Socket 1, is a 169-pin PGA socket. Motherboards that have this socket can support any of the 486SX, DX, and DX2 processors and the DX2/OverDrive versions. This type of socket is found on most 486 systems that originally were designed for OverDrive upgrades. Figure 3.13 shows the pinout of Socket 1.

The original DX processor draws a maximum 0.9 amps of 5V power in 33MHz form (4.5 watts) and a maximum 1 amp in 50MHz form (5 watts). The DX2 processor, or OverDrive processor, draws a maximum 1.2 amps at 66MHz (6 watts). This minor increase in power requires only a passive heatsink consisting of aluminum fins that are glued to the processor with thermal transfer epoxy. Passive heatsinks don't have any mechanical components like fans. Heatsinks with fans or other devices that use power are called *active* heatsinks. OverDrive processors rated at 40MHz or less do not have heatsinks.

Socket 2

When the DX2 processor was released, Intel was already working on the new Pentium processor. The company wanted to offer a 32-bit, scaled-down version of the Pentium as an upgrade for systems that originally came with a DX2 processor. Rather than just increasing the clock rate, Intel created an all-new chip with enhanced capabilities derived from the Pentium.

The chip, called the Pentium OverDrive processor, plugs into a processor socket with the Socket 2 or Socket 3 design. These sockets hold any 486 SX, DX, or DX2 processor, as well as the Pentium OverDrive. Because this chip is essentially a 32-bit version of the (normally 64-bit) Pentium chip, many have taken to calling it a Pentium-SX. It was available in 25/63MHz and 33/83MHz versions. The first number indicates the base motherboard speed; the second number indicates the actual operating speed of the Pentium OverDrive chip. As you can see, it is a clock-multiplied chip that runs at 2.5 times the motherboard speed. Figure 3.14 shows the pinout configuration of the official Socket 2 design.

Figure 3.13 Intel Socket 1 pinout.

Figure 3.14 238-pin Intel Socket 2 configuration.

Notice that although the new chip for Socket 2 is called Pentium OverDrive, it is not a full-scale (64-bit) Pentium. Intel released the design of Socket 2 a little prematurely and found that the chip ran too hot for many systems. The company solved this problem by adding a special active heatsink to the Pentium OverDrive processor. This active heatsink is a combination of a standard heatsink and a built-in electric fan. Unlike the aftermarket glue-on or clip-on fans for processors that you might have seen, this one actually draws 5V power directly from the socket to drive the fan. No external connection to disk drive cables or the power supply is required. The fan/heatsink assembly clips and plugs directly into the processor and provides for easy replacement if the fan fails.

Another requirement of the active heatsink is additional clearance—no obstructions for an area about 1.4" off the base of the existing socket to allow for heatsink clearance. The Pentium OverDrive upgrade is difficult or impossible in systems that were not designed with this feature.

Another problem with this particular upgrade is power consumption. The 5V Pentium OverDrive processor draws up to 2.5 amps at 5V (including the fan) or 12.5 watts, which is more than double the 1.2 amps (6 watts) drawn by the DX2 66 processor.

Note

Intel no longer markets OverDrive processors, but it maintains technical information about them at <http://www.intel.com/support/processors/overdrive/index.htm>.

Socket 3

Because of problems with the original Socket 2 specification and the enormous heat the 5V version of the Pentium OverDrive processor generates, Intel came up with an improved design. The new processor is the same as the previous Pentium OverDrive processor, except that it runs on 3.3V and draws a maximum 3.0 amps of 3.3V (9.9 watts) and 0.2 amp of 5V (1 watt) to run the fan—a total of 10.9 watts. This configuration provides a slight margin over the 5V version of this processor. The fan is easy to remove from the OverDrive processor for replacement, should it ever fail.

Intel had to create a new socket to support both the DX4 processor, which runs on 3.3V, and the 3.3V Pentium OverDrive processor. In addition to the new 3.3V chips, this new socket supports the older 5V SX, DX, DX2, and even the 5V Pentium OverDrive chip. The design, called Socket 3, is the most flexible upgradeable 486 design. Figure 3.15 shows the pinout specification of Socket 3.

Notice that Socket 3 has one additional pin and several others plugged in compared with Socket 2. Socket 3 provides for better keying, which prevents an end user from accidentally installing the processor in an improper orientation. However, one serious problem exists: This socket can't automatically determine the type of voltage that is provided to it. You will likely find a jumper on the motherboard near the socket to enable selecting 5V or 3.3V operation.

Caution

Because this jumper must be manually set, a user could install a 3.3V processor in this socket when it is configured for 5V operation. This installation instantly destroys the chip when the system is powered on. So, it is up to the end user to ensure that this socket is properly configured for voltage, depending on which type of processor is installed. If the jumper is set in 3.3V configuration and a 5V processor is installed, no harm will occur, but the system will not operate properly unless the jumper is reset for 5V.

Socket 4

Socket 4 is a 273-pin socket designed for the original Pentium processors. The original Pentium 60MHz and 66MHz version processors had 273 pins and plugged into Socket 4. It is a 5V-only socket because all the original Pentium processors run on 5V. This socket accepts the original Pentium 60MHz or 66MHz processor and the OverDrive processor. Figure 3.16 shows the pinout specification of Socket 4.

Somewhat amazingly, the original Pentium 66MHz processor consumes up to 3.2 amps of 5V power (16 watts), not including power for a standard active heatsink (fan). The 66MHz OverDrive processor that replaced it consumes a maximum 2.7 amps (13.5 watts), including about 1 watt to drive the fan. Even the original 60MHz Pentium processor consumes up to 2.91 amps at 5V (14.55 watts). It might seem strange that the replacement processor, which is twice as fast, consumes less power than the original, but this has to do with the manufacturing processes used for the original and OverDrive processors.

Although both processors run on 5V, the original Pentium processor was created with a circuit size of 0.8 micron, making that processor much more power-hungry than the 0.6-micron circuits used in the OverDrive and the other Pentium processors. Shrinking the circuit size is one of the best ways to decrease power consumption. Although the OverDrive processor for Pentium-based systems draws less power than the original processor, additional clearance might have to be allowed for the active heatsink assembly that is mounted on top. As in other OverDrive processors with built-in fans, the power to run the fan is drawn directly from the chip socket, so no separate power-supply connection is required. Also, the fan is easy to replace should it ever fail.

Figure 3.15 237-pin Intel Socket 3 configuration.

Figure 3.16 273-pin Intel Socket 4 configuration.

Socket 5

When Intel redesigned the Pentium processor to run at 75MHz, 90MHz, and 100MHz, the company went to a 0.6-micron manufacturing process and 3.3V operation. This change resulted in lower power consumption: only 3.25 amps at 3.3V (10.725 watts). Therefore, the 100MHz Pentium processor used far less power than even the original 60MHz version. This resulted in lower power consumption and enabled the extremely high clock rates without overheating.

The Pentium 75 and higher processors actually have 296 pins, although they plug into the official Intel Socket 5 design, which calls for a total of 320 pins. The additional pins are used by the Pentium OverDrive for Pentium processors. This socket has the 320 pins configured in a staggered PGA, in which the individual pins are staggered for tighter clearance.

Several OverDrive processors for existing Pentiums were available. These usually were later design chips with integral voltage regulators to enable operating on the higher voltages the older chips originally required. Intel no longer sells these; however, companies such as Evergreen and PowerLeap do still sell upgrade chips for older systems. Figure 3.17 shows the standard pinout for Socket 5.

The Pentium OverDrive for Pentium processors has an active heatsink (fan) assembly that draws power directly from the chip socket. The chip requires a maximum 4.33 amps of 3.3V to run the chip (14.289 watts) and 0.2 amp of 5V power to run the fan (one watt), which results in a total power consumption of 15.289 watts. This is less power than the original 66MHz Pentium processor requires, yet it runs a chip that is as much as four times faster!

Socket 6

The last 486 socket was designed for the 486 DX4 and the 486 Pentium OverDrive processor. Socket 6 was intended as a slightly redesigned version of Socket 3 and had an additional 2 pins plugged for proper chip keying. Socket 6 has 235 pins and accepts only 3.3V 486 or OverDrive processors. Although Intel went to the trouble of designing this socket, it never was built or implemented in any systems. Motherboard manufacturers instead stuck with Socket 3.

Socket 7 (and Super7)

Socket 7 is essentially the same as Socket 5 with one additional key pin in the opposite inside corner of the existing key pin. Socket 7, therefore, has 321 pins total in a 37×37 SPGA arrangement. The real difference with Socket 7 is not with the socket itself, but with the companion voltage regulator module (VRM) circuitry on the motherboard that must accompany it.

The VRM is either a small circuit board or a group of circuitry embedded in the motherboard that supplies the proper voltage level and regulation of power to the processor.

The main reason for the VRM is that Intel and AMD wanted to drop the voltages the processors would use from the 3.3V or 5V supplied to the motherboard by the power supply. Rather than require custom power supplies for different processors, the VRM converts the 3.3V or 5V to the proper voltage for the particular CPU you are using. Intel released different versions of the Pentium and Pentium-MMX processors that ran on 3.3V (called VR), 3.465V (called VRE), or 2.8V. Equivalent processors from AMD, Cyrix, and others used voltages from 3.3V to 1.8V. Because of the variety of voltages that might be required to support different processors, most motherboard manufacturers started including VRM sockets or building adaptable VRMs into their Pentium motherboards.

Figure 3.18 shows the Socket 7 pinout.

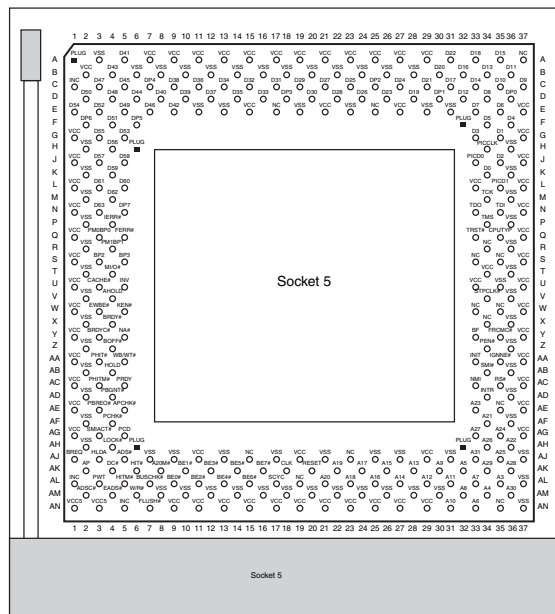

Figure 3.17 320-pin Intel Socket 5 configuration.

Figure 3.18 Socket 7 (Pentium) pinout (top view).

AMD, along with Cyrix and several chipset manufacturers, pioneered an improvement or extension to the Intel Socket 7 design called Super Socket 7 (or Super7), taking it from 66MHz to 95MHz and 100MHz. This enabled faster Socket 7-type systems to be made, supporting processors up to 500MHz, which are nearly as fast as some of the newer Slot 1- and Socket 370-type systems using Intel processors. Super7 systems also have support for the AGP video bus, as well as Ultra DMA hard disk controllers and advanced power management.

Major third-party chipset suppliers—including Acer Laboratories, Inc. (ALi); VIA Technologies; and Silicon Integrated Systems (SiS)—all released chipsets for Super7 boards. Most of the major motherboard manufacturers made Super7 boards in both Baby-AT and ATX form factors.

Socket 8

Socket 8 is a special SPGA socket featuring a whopping 387 pins! This was specifically designed for the Pentium Pro processor with the integrated L2 cache. The additional pins are to enable the chipset to control the L2 cache integrated in the same package as the processor. Figure 3.19 shows the Socket 8 pinout.

Socket 370 (PGA-370)

In November 1998, Intel introduced a new socket for P6 class processors. The socket was called Socket 370 or PGA-370 because it has 370 pins and originally was designed for lower-cost PGA versions of the Celeron and Pentium III processors. Socket 370 was originally designed to directly compete in the lower-end system market along with the Super7 platform supported by AMD and Cyrix. However, Intel later used it for the Pentium III processor. Initially all the Celeron and Pentium III processors were made in SECC or SEPP format. These are essentially circuit boards containing the processor and separate L2 cache chips on a small board that plugs into the motherboard via Slot 1. This type of design was necessary when the L2 cache chips were made a part of the processor but were not directly integrated into the processor die. Intel did make a multiple-die chip package for the Pentium Pro, but this proved to be a very expensive way to package the chip, and a board with separate chips was cheaper, which is why the Pentium II looks different from the Pentium Pro.

Starting with the Celeron 300A processor introduced in August 1998, Intel began combining the L2 cache directly on the processor die; it was no longer in separate chips. With the cache fully integrated into the die, there was no longer a need for a board-mounted processor. Because it costs more to make a Slot 1 board or cartridge-type processor instead of a socketed type, Intel moved back to the socket design to reduce the manufacturing cost—especially with the Celeron, which at that time was competing on the low end with Socket 7 chips from AMD and Cyrix.

The Socket 370 (PGA-370) pinout is shown in Figure 3.20.

Figure 3.19 Socket 8 (Pentium Pro) pinout showing power pin locations.

Figure 3.20 Socket 370 (PGA-370) Pentium III/Celeron pinout (top view).

The Celeron was gradually shifted over to PGA-370, although for a time both were available. All Celeron processors at 333MHz and lower were available only in the Slot 1 version. Celeron processors from 366MHz to 433MHz were available in both Slot 1 and Socket 370 versions; all Celeron processors from 466MHz and up through 1.4GHz are available only in the Socket 370 version.

Starting in October 1999, Intel also introduced Pentium III processors with integrated cache that plug into Socket 370. These use a packaging called flip chip pin grid array (FC-PGA), in which the raw die is mounted on the substrate upside down. The slot version of the Pentium III was more expensive and no longer necessary because of the on-die L2 cache.

Note that because of some voltage changes and one pin change, many original Socket 370 motherboards do not accept the later FC-PGA Socket 370 versions of the Pentium III and Celeron. Pentium III processors in the FC-PGA form have two RESET pins and require VRM 8.4 specifications. Prior motherboards designed only for the older versions of the Celeron are referred to as *legacy motherboards*, and the newer motherboards supporting the second RESET pin and VRM 8.4 specification are referred to as *flexible motherboards*. Contact your motherboard or system manufacturer for information to see whether your socket is the flexible version. Some motherboards, such as the Intel CA810, do support the VRM 8.4 specifications and supply proper voltage, but without Vtt support the Pentium III processor in the FC-PGA package will be held in RESET#. The last versions of the Pentium III and Celeron III use the Tualatin core design, which also requires a revised socket to operate. Motherboards that can handle Tualatin-core processors are known as *Tualatin-ready* and use different chipsets from those not designed to work with the Tualatin-core processor. Companies that sell upgrade processors offer products that enable you to install a Tualatin-core Pentium III or Celeron III processor into a motherboard that lacks built-in Tualatin support.

Installing a Pentium III processor in the FC-PGA package into an older motherboard is unlikely to damage the motherboard. However, the processor itself could be damaged. Pentium III processors in the 0.18-micron process operate at either 1.60V or 1.65V, whereas the Intel Celeron processors operate at 2.00V. The motherboard could be damaged if the motherboard BIOS fails to recognize the voltage identification of the processor. Contact your PC or motherboard manufacturer before installation to ensure compatibility.

A motherboard with a Slot 1 can be designed to accept almost any Celeron, Pentium II, or Pentium III processor. To use the socketed Celerons and Pentium III processors, several manufacturers have made available a low-cost slot-to-socket adapter sometimes called a *slot-*ket**. This is essentially a Slot 1 board containing only a Socket 370, which enables you to use a PGA processor in any Slot 1 board. A typical slot-*ket* adapter is shown in the “Celeron” section later in this chapter.

▶▶ See “Celeron,” p. 150.

Socket 423

Socket 423 is a ZIF-type socket introduced in November 2000 for the original Pentium 4. Figure 3.21 shows Socket 423.

Socket 423 supports a 400MHz processor bus, which connects the processor to the Memory Controller Hub (MCH), which is the main part of the motherboard chipset and similar to the North Bridge in earlier chipsets. Pentium 4 processors up to 2GHz were available for Socket 423; all faster versions require Socket 478 instead.

Socket 423 uses a unique heatsink mounting method that requires standoffs attached either to the chassis or to a special plate that mounts underneath the motherboard. This was designed to support the weight of the larger heatsinks required for the Pentium 4. Because of this, many Socket 423 motherboards require a special chassis that has the necessary additional standoffs installed. Fortunately, the need for these standoffs was eliminated with the newer Socket 478 for Pentium 4 processors.

The processor uses five voltage ID (VID) pins to signal the VRM built into the motherboard to deliver the correct voltage for the particular CPU you install. This makes the voltage selection completely automatic and foolproof. Most Pentium 4 processors for Socket 423 require 1.7V. A small triangular mark indicates the pin-1 corner for proper orientation of the chip.

Socket 478

Socket 478 is a ZIF-type socket for the Pentium 4 and Celeron 4 (Celerons based on the Pentium 4 core) introduced in October 2001. It was specially designed to support additional pins for future Pentium 4 processors and speeds over 2GHz. The heatsink mounting is different from the previous Socket 423, allowing larger heatsinks to be attached to the CPU. Figure 3.22 shows Socket 478.

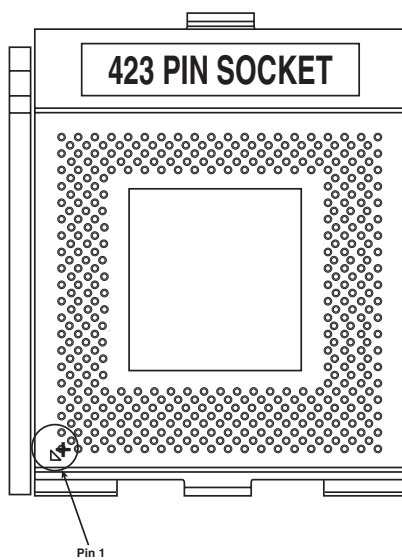

Figure 3.21 Socket 423 (Pentium 4) showing pin 1 location.

Figure 3.22 Socket 478 (Pentium 4) showing pin 1 location.

Socket 478 supports a 400MHz, 533MHz, or 800MHz processor bus that connects the processor to the memory controller hub (MCH), which is the main part of the motherboard chipset.

Socket 478 uses a new heatsink attachment method that clips the heatsink directly to the motherboard, and not the CPU socket or chassis (as with Socket 423). Therefore, any standard chassis can be used, and the special standoffs used by Socket 423 boards are not required. The new heatsink attachment allows for a much greater clamping load between the heatsink and processor, which aids cooling.

Socket 478 processors use five VID pins to signal the VRM built into the motherboard to deliver the correct voltage for the particular CPU you install. This makes the voltage selection completely automatic and foolproof. A small triangular mark indicates the pin-1 corner for proper orientation of the chip.

Socket A (Socket 462)

AMD introduced Socket A, also called Socket 462, in June 2000 to support the PGA versions of the Athlon and Duron processors. It is designed as a replacement for Slot A used by the original Athlon processor. Because the Athlon has now moved to incorporate L2 cache on-die, and the new low-cost Duron is available only in an on-die cache version, there was no longer a need for the expensive cartridge packaging the original Athlon processors used.

Socket A has 462 pins and 11 plugs oriented in an SPGA form (see Figure 3.23). Socket A has the same physical dimensions and layout as Socket 370; however, the location and placement of the plugs prevent Socket 370 processors from being inserted. Socket A supports 31 voltage levels from 1.100V to 1.850V in 0.025V increments, controlled by the VID0-VID4 pins on the processor. The automatic voltage regulator module circuitry typically is embedded on the motherboard.

There are 11 total plugged holes, including 2 of the outside pin holes at A1 and AN1. These are used to allow for keying to force the proper orientation of the processor in the socket. The pinout of Socket A is shown in Figure 3.24.

Figure 3.23 Socket A (Socket 462) Athlon/Duron layout.

Figure 3.24 Socket A (Socket 462) Athlon/Duron pinout (top view).

After the introduction of Socket A, AMD moved all Athlon (including all Athlon XP) processors to this form factor, phasing out Slot A. In addition, for a time AMD also sold a reduced L2 cache version of the Athlon called the Duron in this form factor. The Athlon 64 uses a different processor socket called Socket 754.

Caution

Just because a chip can plug into a socket doesn't mean it will work. The newer Athlon XP processors require different voltages, BIOS, and chipset support than earlier Socket A Athlon and Duron processors. As always, make sure your motherboard supports the processor you intend to install.

Socket 603

Socket 603 is used with the Intel Xeon processor in DP (dual processor) and MP (multiple processor) configurations. These are typically used in motherboards designed for use in network file servers. Figure 3.25 shows Socket 603.

Socket 754

Socket 754 is used with the new AMD Athlon 64 processor Socket 754 version, which is AMD's first 64-bit processor for desktop computers. This socket supports single-channel unbuffered DDR SDRAM. Figure 3.26 shows an overhead view of this socket.

Figure 3.25 Socket 603 is used by the Intel Xeon processor.

Figure 3.26 Socket 754. The large cutout corner at the lower left indicates pin 1.

Socket 939 and 940

Socket 939 is used with the Socket 939 versions of the AMD Athlon 64 and 64 FX (see Figure 3.27). Motherboards using this socket support conventional unbuffered DDR SDRAM modules in either single- or dual-channel mode, rather than the server-oriented (more expensive) registered modules required by Socket 940 motherboards. Sockets 939 and 940 have different pin arrangements and processors for each and are not interchangeable.

Socket 940 is used with the Socket 940 version of the AMD Athlon 64 FX, as well as all AMD Opteron processors (see Figure 3.28). Motherboards using this socket support only registered DDR SDRAM modules in dual-channel mode. Because the pin arrangement is different, Socket 939 processors do not work in Socket 940, and vice versa.

Socket T

Socket T (LGA775) is used by the latest versions of the Intel Pentium 4 Prescott processor. The first-generation Prescott processors used Socket 478. Socket T is unique in that it uses a land grid array format, so the pins are on the socket, rather than the processor. The first LGA processors were the Pentium II and Celeron processors in 1997; in those processors LGA packaging was used for the chip mounted on the Slot-1 cartridge.

LGA uses gold pads (called *lands*) on the bottom of the substrate to replace the pins used in PGA packages. In socketed form, it allows for much greater clamping forces and therefore greater stability and improved thermal transfer (better cooling). LGA is really just a recycled version of what was previously called LCC (leadless chip carrier) packaging. This was used way back on the 286 processor in

'84, which had gold lands around the edge only (there were far fewer pins back then). In other ways LGA is simply a modified version of ball grid array (BGA), with gold lands replacing the solder balls, making it more suitable for socketed (rather than soldered) applications. The early LCC packages were ceramic, whereas the first Pentium II LGA packages were plastic, with the package soldered to a cartridge substrate. These days (and for the future) the LGA package is organic and directly socketed instead. On a technical level, the Pentium 4 LGA chips combine several packaging technologies that have all been used in the past, including organic land grid array (OLGA) for the substrate and controlled collapse chip connection (C4) flip-chip for the actual processor die.

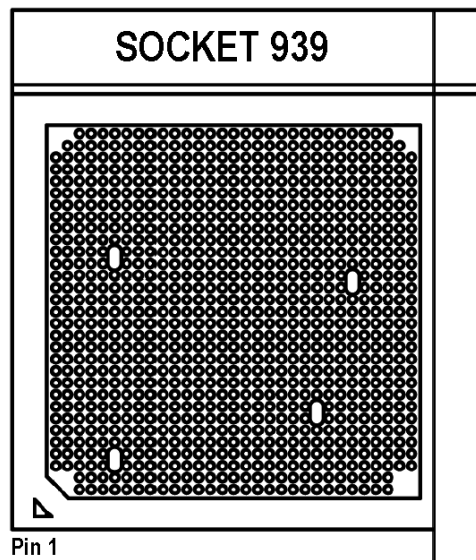

Figure 3.27 Socket 939. The cutout corner and triangle at the lower left indicate pin 1.

Figure 3.28 Socket 940. The cutout corner and triangle at the lower left indicate pin 1.

Processor Slots

After introducing the Pentium Pro with its integrated L2 cache, Intel discovered that the physical package it chose was very costly to produce. Intel was looking for a way to easily integrate cache and possibly other components into a processor package, and it came up with a cartridge or board design as the best way to do this. To accept its new cartridges, Intel designed two types of slots that could be used on motherboards.

Slot 1 is a 242-pin slot designed to accept Pentium II, Pentium III, and most Celeron processors. Slot 2, on the other hand, is a more sophisticated 330-pin slot designed for the Pentium II Xeon and Pentium III Xeon processors, which are primarily for workstations and servers. Besides the extra pins, the biggest difference between Slot 1 and Slot 2 is the fact that Slot 2 was designed to host up to four-way or more processing in a single board. Slot 1 allows only single or dual processing functionality.

Note that Slot 2 is also called SC330, which stands for slot connector with 330 pins. Intel later discovered less-expensive ways to integrate L2 cache into the processor core and no longer produces Slot 1 or Slot 2 processors. Both Slot 1 and Slot 2 processors are now obsolete, and many systems using these processors have been retired or upgraded with socket-based motherboards.

Slot 1 (SC242)

Slot 1, also called SC242 (slot connector 242 pins), is used by the SEC design that is used with the cartridge-type Pentium II/III and Celeron processors (see Figure 3.29).

◀◀ See "Single Edge Contact and Single Edge Processor Packaging," p. 86.

Figure 3.29 Slot 1 connector dimensions and pin layout.

Slot 2 (SC330)

Slot 2, otherwise called SC330 (slot connector 330 pins), is used on high-end motherboards that support the Pentium II and III Xeon processors. Figure 3.30 shows the Slot 2 connector.

Figure 3.30 Slot 2 (SC330) connector dimensions and pin layout.

The Pentium II Xeon and Pentium III Xeon processors are designed in a cartridge similar to, but larger than, that used for the standard Pentium II/III. Figure 3.31 shows the Xeon cartridge.

Figure 3.31 Pentium II/III Xeon cartridge.

Slot 2 motherboards were used in higher-end systems such as workstations or servers based on the Pentium II Xeon or Pentium III Xeon. These versions of the Xeon differ from the standard Pentium II and slot-based Pentium III mainly by virtue of having full-core speed L2 cache, and in some versions more of it. The additional pins allow for additional signals needed by multiple processors.

CPU Operating Voltages

One trend that is clear to anybody who has been following processor design is that the operating voltages have gotten lower and lower. The benefits of lower voltage are threefold. The most obvious is that with lower voltage comes lower overall power consumption. By consuming less power, the system is less expensive to run, but more importantly for portable or mobile systems, it runs much longer on existing battery technology. The emphasis on battery operation has driven many of the advances in lowering processor voltage because this has a great effect on battery life.

The second major benefit is that with less voltage and therefore less power consumption, less heat is produced. Processors that run cooler can be packed into systems more tightly and last longer.

The third major benefit is that a processor running cooler on less power can be made to run faster. Lowering the voltage has been one of the key factors in enabling the clock rates of processors to go higher and higher. This is because the lower the voltage, the shorter the time needed to change a signal from low to high.

Until the release of the mobile Pentium and both desktop and mobile Pentium MMX, most processors used a single voltage level to power both the core as well as run the input/output circuits. Originally, most processors ran both the core and I/O circuits at 5V, which was later reduced to 3.5V or 3.3V to lower power consumption. When a single voltage is used for both the internal processor core power as well as the external processor bus and I/O signals, the processor is said to have a single or unified power plane design.

When originally designing a version of the Pentium processor for mobile or portable computers, Intel came up with a scheme to dramatically reduce the power consumption while still remaining

compatible with the existing 3.3V chipsets, bus logic, memory, and other components. The result was a dual-plane or split-plane power design in which the processor core ran off a lower voltage while the I/O circuits remained at 3.3V. This originally was called voltage reduction technology (VRT) and first debuted in the Mobile Pentium processors released in 1996. Later, this dual-plane power design also appeared in desktop processors such as the Pentium MMX, which used 2.8V to power the core and 3.3V for the I/O circuits. Now most recent processors, whether for mobile or desktop use, feature a dual-plane power design. Some of the more recent Mobile Pentium II processors run on as little as 1.6V for the core while still maintaining compatibility with 3.3V components for I/O.

Knowing the processor voltage requirements is not a big issue with Socket 8, Socket 370, Socket 478, Socket A, Socket 604, Socket 754, Socket 940, Pentium Pro (Socket 8), or Pentium II (Slot 1 or Slot 2) processors because these sockets and slots have special VID pins the processor uses to signal to the motherboard the exact voltage requirements. This enables the voltage regulators built into the motherboard to be automatically set to the correct voltage levels by merely installing the processor.

Unfortunately, this automatic voltage setting feature was not available on Super7, Socket 7, and earlier motherboard and processor designs. Therefore, you usually must set jumpers or otherwise configure the motherboard according to the voltage requirements of the processor you are installing. Pentium (Socket 4, 5, or 7) processors have run on a number of voltages, but the most recent MMX versions all use 2.8V—except for mobile Pentium processors, which are as low as 1.8V. Table 3.19 lists the voltage settings used by Intel Pentium (non-MMX) Socket 7 processors that use a single power plane and a dual power plane. A single power plane means that both the CPU core and the I/O pins run at the same voltage, whereas a dual power plane means that the core and I/O voltage values are different.

Table 3.19 Socket 7 Single- and Dual-Plane Processor Voltages

Voltage Setting	Processor	Core Voltage	I/O Voltage	Voltage Planes
VRE (3.5V)	Intel Pentium	3.5V	3.5V	Single
STD (3.3V)	Intel Pentium	3.3V	3.3V	Single
MMX (2.8V)	Intel MMX Pentium	2.8V	3.3V	Dual
VRE (3.5V)	AMD K5	3.5V	3.5V	Single
3.2V	AMD-K6	3.2V	3.3V	Dual
2.9V	AMD-K6	2.9V	3.3V	Dual
2.4V	AMD-K6-2/K6-3	2.4V	3.3V	Dual
2.2V	AMD-K6/K6-2	2.2V	3.3V	Dual
VRE (3.5V)	Cyrix 6x86	3.5V	3.5V	Single
2.9V	Cyrix 6x86MX/M-II	2.9V	3.3V	Dual
MMX (2.8V)	Cyrix 6x86L	2.8V	3.3V	Dual
2.45V	Cyrix 6x86LV	2.45V	3.3V	Dual

Generally, the acceptable range is plus or minus 5% from the nominal intended setting.

Most Socket 7 and later Pentium motherboards supply several voltages (such as 2.5V, 2.7V, 2.8V, and 2.9V) for compatibility with future devices. A voltage regulator built into the motherboard converts

the power supply voltage into the various levels the processor core requires. Check the documentation for your motherboard and processor to find the appropriate settings.

The Pentium Pro and Pentium II processors were the first to automatically determine their voltage settings by controlling the motherboard-based voltage regulator through built-in VID pins. Those are explained in more detail later in this chapter.

- ▶▶ See "Pentium Pro Processors," p. 136.
- ▶▶ See "Pentium II Processors," p. 140.

Note that on the STD or VRE settings, the core and I/O voltages are the same; these are single-plane voltage settings. Any time a voltage other than STD or VRE is set, the motherboard defaults to a dual-plane voltage setting where the core voltage can be specifically set, while the I/O voltage remains constant at 3.3V no matter what.

Socket 5 was designed to supply only STD or VRE settings, so any processor that can work at those settings can work in Socket 5 as well as Socket 7. Older Socket 4 designs can supply only 5V, and they have a completely different pinout (fewer pins overall), so using a processor designed for Socket 7 or Socket 5 in Socket 4 is not possible.

Most Socket 7 and later Pentium motherboards supply several voltages (such as 2.2V, 2.4V, 2.5V, 2.7V, 2.8V, and 2.9V as well as the older STD or VRE settings) for compatibility with many processors. A voltage regulator built into the motherboard converts the power supply voltage into the various levels required by the processor core. Check the documentation for your motherboard and processor to find the appropriate settings.

Starting with the Pentium Pro, all newer processors (Celeron, Pentium II/III/4, AMD Athlon, Duron, Athlon XP, and Athlon 64) automatically determine their voltage settings by controlling the motherboard-based voltage regulator. That's done through built-in VID pins.

For hotrodding purposes, many newer motherboards for these processors have override settings that allow for manual voltage adjustment if desired. Many people have found that when attempting to overclock a processor, increasing the voltage by a tenth of a volt or so often helps. Of course, this increases the heat output of the processor and must be accounted for with adequate heatsinking and case cooling.

Heat and Cooling Problems

Heat can be a problem in any high-performance system. The higher-speed processors consume more power and therefore generate more heat. The processor is usually the single most power-hungry chip in a system, and in most situations, the fan inside your computer case is incapable of handling the load without some help.

To ensure a constant flow of air and more consistent performance, most processors include some form of heatsink, which is designed to draw heat away from the processor. Additionally, most heatsinks incorporate fans so they don't have to rely on the airflow within the system. Heatsinks with fans are referred to as *active* heatsinks (see Figure 3.32). Active heatsinks have a power connection. Older ones often used a spare disk drive power connector, but most recent heatsinks plug in to dedicated heatsink power connections found on the newer motherboards.

Processor cooling, including heatsinks, is covered in detail in Chapter 23, "Extreme Modifications: Overclocking, Cooling, Chassis, and Lighting."

Figure 3.32 Active heatsink suitable for a Pentium 4 processor using Socket 478.

Math Coprocessors (Floating-Point Units)

This section covers the floating-point unit (FPU) contained in the processor, which was formerly a separate external math coprocessor in the 386 and older chips. Older central processing units designed by Intel (and cloned by other companies) used an external math coprocessor chip. However, when Intel introduced the 486DX, it included a built-in math coprocessor, and every processor built by Intel (and AMD and Cyrix, for that matter) since then includes a math coprocessor. Coprocessors provide hardware for floating-point math, which otherwise would create an excessive drain on the main CPU. Math chips speed your computer's operation only when you are running software designed to take advantage of the coprocessor. All the subsequent fifth- and sixth-generation Intel and compatible processors (such as those from AMD and Cyrix) have featured an integrated floating-point unit.

Math chips (as coprocessors sometimes are called) can perform high-level mathematical operations—long division, trigonometric functions, roots, and logarithms, for example—at 10–100 times the speed of the corresponding main processor. The operations performed by the math chip are all operations that make use of noninteger numbers (numbers that contain digits after the decimal point). The need to process numbers in which the decimal is not always the last character leads to the term *floating point* because the decimal (point) can move (float), depending on the operation. The integer units in the primary CPU work with integer numbers, so they perform addition, subtraction, and multiplication operations. The primary CPU is designed to handle such computations; these operations are not offloaded to the math chip.

The instruction set of the math chip is different from that of the primary CPU. A program must detect the existence of the coprocessor and then execute instructions written explicitly for that coprocessor; otherwise, the math coprocessor draws power and does nothing else. Fortunately, most modern programs that can benefit from the use of the coprocessor correctly detect and use the

coprocessor. These programs usually are math intensive: spreadsheet programs, database applications, statistical programs, and graphics programs, such as computer-aided design (CAD) software. Word processing programs do not benefit from a math chip and therefore are not designed to use one. Table 3.20 summarizes the coprocessors available for the Intel family of processors.

Table 3.20 Math Coprocessor Summary

Processor	Coprocessor	Processor	Coprocessor
8086	8087	486DX2	Built-in FPU
8088	8087	486DX4/5x86	Built-in FPU
286	287	Intel Pentium/Pentium MMX	Built-in FPU
386SX	387SX	Cyrix 6x86/MI/MII	Built-in FPU
386DX	387DX	AMD K5/K6/Athlon/Duron	Built-in FPU
486SX	487SX, DX2/OverDrive ¹	Pentium II/III/Celeron/Xeon	Built-in FPU
487SX ¹	Built-in FPU	Pentium 4	Built-in FPU
486SX2	DX2/OverDrive ²	Athlon 64	Built-in FPU
486DX	Built-in FPU	Itanium/Itanium II	Built-in FPU

FPU = Floating-point unit

1. The 487SX chip is a modified pinout 486DX chip with the math coprocessor enabled. When you plug in a 487SX chip, it disables the 486SX main processor and takes over all processing.
2. The DX2/OverDrive is equivalent to the SX2 with the addition of a functional FPU.

Although virtually all processors since the 486 series have built-in floating-point units, they vary in performance. Historically, the Intel processor FPUs have dramatically outperformed those from AMD and Cyrix, although AMD and Cyrix are achieving performance parity in their newer offerings.

Within each of the original 8087 group, the maximum speed of the math chips varies. A suffix digit after the main number, as shown in Table 3.21, indicates the maximum speed at which a system can run a math chip.

Table 3.21 Maximum Math Chip Speeds

Part	Speed	Part	Speed
8087	5MHz	287	6MHz
8087-3	5MHz	287-6	6MHz
8087-2	8MHz	287-8	8MHz
8087-1	10MHz	287-10	10MHz

The 387 math coprocessors and the 486 or 487 and Pentium processors always indicate their maximum speed ratings in MHz in the part number suffix. A 486DX2-66, for example, is rated to run at 66MHz. Some processors incorporate clock multiplication, which means they can run at different speeds compared with the rest of the system.

Most systems that use the 386 or earlier processors are socketed for a math coprocessor as an option, but they do not include a coprocessor as standard equipment. A few systems on the market at that time didn't even have a socket for the coprocessor because of cost and size considerations. These systems were usually low-cost or portable systems, such as older laptops, the IBM PS/1, and the PCjr. For more specific information about math coprocessors, see the discussions of the specific chips—8087, 287, 387, and 487SX—in the later sections. Table 3.22 shows the specifications of the various math coprocessors.

Table 3.22 Older Intel Math Coprocessor Specifications

Name	Power Consumption	Case Minimum Temperature	Case Maximum Temperature	No. of Transistors	Date Introduced
8087	3 watts	0°C, 32°F	85°C, 185°F	45,000	1980
287	3 watts	0°C, 32°F	85°C, 185°F	45,000	1982
287XL	1.5 watts	0°C, 32°F	85°C, 185°F	40,000	1990
387SX	1.5 watts	0°C, 32°F	85°C, 185°F	120,000	1988
387DX	1.5 watts	0°C, 32°F	85°C, 185°F	120,000	1987

Most often, you can learn which CPU and math coprocessor are installed in a particular system by checking the markings on the chip.

Processor Bugs

Processor manufacturers use specialized equipment to test their own processors, but you have to settle for a little less. The best processor-testing device to which you have access is a system that you know is functional; you then can use the diagnostics available from various utility software companies or your system manufacturer to test the motherboard and processor functions.

Perhaps the most infamous of these bugs is the floating-point division math bug in the early Pentium processors. This and a few other bugs are discussed in detail later in this chapter.

Because the processor is the brain of a system, most systems don't function with a defective processor. If a system seems to have a dead motherboard, try replacing the processor with one from a functioning motherboard that uses the same CPU chip. You might find that the processor in the original board is the culprit. If the system continues to play dead, however, the problem is elsewhere, most likely in the motherboard, memory, or power supply. See the chapters that cover those parts of the system for more information on troubleshooting those components. I must say that in all my years of troubleshooting and repairing PCs, I have rarely encountered defective processors.

A few system problems are built in at the factory, although these bugs or design defects are rare. By learning to recognize these problems, you can avoid unnecessary repairs or replacements. Each processor section describes several known defects in that generation of processors, such as the infamous floating-point error in the Pentium. For more information on these bugs and defects, see the following sections, and check with the processor manufacturer for updates.

Processor Update Feature

All processors can contain design defects or errors. Many times, the effects of any given bug can be avoided by implementing hardware or software workarounds. Intel documents these bugs and workarounds well for its processors in its processor Specification Update manual; this manual is available from Intel's Web site. Most of the other processor manufacturers also have bulletins or tips on their Web sites listing any problems or special fixes or patches for their chips.

Previously, the only way to fix a processor bug was to work around it or replace the chip with one that had the bug fixed. Now, a new feature built into the Intel P6 and P7 processors, including the Pentium Pro through Pentium III, Celeron, and Pentium 4, can allow many bugs to be fixed by altering the *microcode* in the processor. Microcode is essentially a set of instructions and tables in the processor that control how the processor operates. These processors incorporate a new feature called *reprogrammable microcode*, which enables certain types of bugs to be worked around via microcode updates. The microcode updates reside in the motherboard ROM BIOS and are loaded into the processor by the motherboard BIOS during the POST. Each time the system is rebooted, the fix code is reloaded, ensuring that it will have the bug fix installed anytime the processor is operating.

The updated microcode for a given processor is provided by Intel to the motherboard manufacturer so it can incorporate the microcode into the flash ROM BIOS for the board. This is one reason it is important to install the most recent motherboard BIOS anytime you install a new processor. If your processor is newer than your motherboard ROM BIOS code, it probably doesn't include updated microcode to support your processor. In that case, you should visit the Web site of your motherboard manufacturer so you can download and install the latest BIOS update for your motherboard.

Processor Codenames

Intel, AMD, and Cyrix have always used codenames when talking about future processors. The codenames usually are not supposed to become public, but they typically do. They can often be found in online and print news and magazine articles talking about future-generation processors. Sometimes, they even appear in motherboard manuals because the manuals are written before the processors are officially introduced. Table 3.23 lists processor codenames for reference purposes.

Table 3.23 Processor Codenames

AMD Codename	Description
X5	5x86-133 [Socket 3]
SSA5	K5 (original PR75-PR100) [Socket 5, 7]
5k86	K5 (newer PR120-PR200) [Socket 7]
K6	Original AMD K6 core; canceled
NX686	NexGen K6 core; became the K6 [Socket 7]
Little Foot	0.25 μ m K6 [Socket 7]
Chompers	K6-2 [Socket 7, Super7]
Sharptooth	K6-3 [Super7]
Argon	Formerly K7
K7	Athlon [Slot A]
K75	0.18 μ m Athlon [Slot A]
K76	0.18 μ m Athlon (copper interconnects) [Slot A]
K8	Athlon 64
Thunderbird	Athlon [Slot A, Socket A]
Mustang	Athlon w/large L2; canceled
Corvette	Former mobile Athlon (now Palomino)
Palomino	0.18 μ m Athlon XP/MP, Mobile Athlon 4 [Socket A]
Thoroughbred	0.13 μ m Athlon XP/MP [Socket A]
Barton	0.13 μ m Athlon XP/MP w/512K L2 [Socket A]
Spitfire	Duron [Socket A]
Camaro	Former Morgan
Morgan	Mobile Duron and Model 7 Duron [Socket A]
Appaloosa	0.13 μ m Morgan [Socket A]
ClawHammer	Athlon 64 (64-bit CPU) [Socket 754]
ClawHammer DP	Early name for Opteron DP [Socket 940]
San Diego	0.09 μ Athlon 64
Odessa	0.09 μ mobile Athlon 64
SledgeHammer	Opteron w/large L2 [Socket 940]

VIA/Cyrix Codename	Description
M6	486DX [Socket 1, 2, 3]
M7	486DX2/DX4 [Socket 3]
M9	5x86 [Socket 3]
M1sc	5x86 [Socket 3]
Chili	5x86 project
M1	6x86 (3.3V/3.52V) [Socket 7]
M1L	6x86L (2.8V) [Socket 7]
M1R	6x86 on IBM 5M process
M2	6x86MX/M-II [Socket 7, Super7]
Cayenne	MXi and Gobi
Jedi	Former Joshua (before Gobi)
Gobi	Former Joshua
Joshua	Former Cyrix III (canceled)
MXi	Proprietary integrated CPU
Jalapeno	Former Mojave
Mojave	M3 [Socket 370]
Serrano	M4
C5	Samuel (Winchip-4)
C5B	0.15 μ m Samuel 2
C5C	0.13 μ m Ezra
C5M	Ezra-T
C5N	Ezra-T (copper interconnects)
Samuel	C3 [Socket 370]
Samuel 2	0.15 μ m C3 [Socket 370]
Ezra	0.13 μ m C3 [Socket 370]
Ezra-T	Ezra 1.25V [Socket 370]
C5X	Nehemiah
C5XL	Nehemiah (low power, small L2)
C5YL	Esther
Nehemiah	C3 [Socket 370] with encryption
Esther	C4 [Socket 370]
CZA	0.10 μ m Socket 478 CPU
Matthew	Proprietary integrated CPU
Intel Codename	Description
P23	486SX [Socket 1, 2, 3]
P23S	486SX SL-enhanced [Socket 1, 2, 3]
P23N	487SX (coprocessor) [Socket 1]
P4	486DX [Socket 1, 2, 3]
P4S	486DX SL-enhanced [Socket 1, 2, 3]
P24	486DX2 [Socket 1, 2, 3]

Table 3.23 Continued

Intel Codename	Description
P24S	486DX2 SL-enhanced [Socket 1, 2, 3]
P24D	486DX2 (write-back cache) [Socket 3]
P24C	486DX4 [Socket 3]
P23T	486DXODP (486 OverDrive) [Socket 3]
P4T	486DXODPR (486 OverDrive) [Socket 1, 2, 3]
P24T	PODP5V (Pentium OverDrive) [Socket 2, 3]
P24CT	Pentium OverDrive 3.3V [Socket 2, 3]
P5	Pentium 60/66MHz [Socket 4]
P5T	Pentium OverDrive 120/133MHz [Socket 4]
P54C	Pentium 75MHz–120MHz [Socket 5, 7]
P54CQS	Pentium 120MHz–133MHz [Socket 5, 7]
P54CS	Pentium 120MHz–200MHz [Socket 7]
P54CT(A)	Pentium OverDrive [Socket 5, 7]
P55C	Pentium MMX [Socket 7]
P54CTB	Pentium OverDrive MMX [Socket 5, 7]
Tillamook	Mobile Pentium MMX [Mobile Module]
P6	Pentium Pro [Socket 8]
P6T	Pentium II OverDrive [Socket 8]
Klamath	0.35 μ m Pentium II [Slot 1]
Deschutes	0.25 μ m Pentium II [Slot 1]
Drake	0.25 μ m Pentium II Xeon [Slot 2]

Shavano	Future Itanium family chip

Note that the codenames and information listed in these tables are used before the processor is officially introduced. After a chip is introduced, the codename is dropped and the chip is thereafter referred to by the marketing name used at the time of the introduction. Because many of these names refer to chips that are not yet officially released, the names or specifications might change. For chipset codenames, see Chapter 4.

Intel-Compatible Processors (AMD and Cyrix)

Several companies—mainly AMD and Cyrix—have developed processors that are compatible with Intel processors. These chips are fully Intel compatible, so they emulate every processor instruction in the Intel chips. Many of the chips are also pin compatible, which means that they can be used in any system designed to accept an Intel processor; others require a custom motherboard design. Any hardware or software that works on Intel-based PCs will work on PCs made with these third-party CPU chips. A number of companies currently offer Intel-compatible chips, and some of the most popular ones are discussed here.

AMD Processors

Advanced Micro Devices (AMD) has become a major player in the Pentium-compatible chip market with its own line of Intel-compatible processors. AMD ran into trouble with Intel several years ago because its 486-clone chips used actual Intel microcode. These differences have been settled, and AMD now has a cross-license agreement with Intel. In 1996, AMD finalized a deal to absorb NexGen, another maker of Intel-compatible CPUs. NexGen had been working on a chip it called the Nx686, which was renamed the K6 and introduced by AMD. AMD refined the design in the form of the K6-2 and K6-3. Its more recent chips, called the Athlon XP and Duron, are designed similarly to the Pentium III/4 and Celeron that have used both a similar but not identical slot and socket design. The newer AMD Athlon and Duron processors as well as the Athlon XP are designed to use Socket A, also called Socket 462. The newest AMD processor, the Athlon 64, is the first 64-bit processor designed for desktop computers. It uses the new Socket 754.

For a summary of the AMD processors, see Table 3.2 earlier in this chapter.

Cyrix

Cyrix was purchased by National Semiconductor in November 1997 and by VIA Technologies in 1999. Prior to that, it had been a fabless company, meaning it had no chip-manufacturing capability. All the Cyrix chips were manufactured for Cyrix first by Texas Instruments and then mainly by IBM up through the end of 1998. Starting in 1999, National Semiconductor took over manufacturing of the Cyrix processors. More recently, National has been purchased by VIA Technologies.

All Cyrix chips were manufactured by other companies such as IBM (who also marketed some of the 6x86 chips under its own name), National Semiconductor, and now VIA Technologies. See Table 3.2 earlier in this chapter, which summarizes the Cyrix and VIA processors.

P1 (086) First-Generation Processors

The first generation of processors represents the series of chips from Intel that were found in the first PCs. IBM, as the architect of the PC at the time, chose Intel processors and support chips to build the PC motherboard, setting a standard that would hold for many subsequent processor generations to come.

8088 and 8086 Processors

Intel introduced the 8086 back in June 1978. The 8086 was one of the first 16-bit processor chips on the market; at the time, virtually all other processors were 8-bit designs. The 8086 had 16-bit internal registers and could run a new class of software using 16-bit instructions. It also had a 16-bit external data path, so it could transfer data to memory 16 bits at a time.

The address bus was 20 bits wide, which enabled the 8086 to address a full 1MB (2^{20}) of memory. This was in stark contrast to most other chips of that time that had 8-bit internal registers, an 8-bit external data bus, and a 16-bit address bus allowing a maximum of only 64KB of RAM (2^{16}).

Unfortunately, most of the personal computer world at the time was using 8-bit processors, which ran 8-bit CP/M (Control Program for Microprocessors) operating systems and software. The board and circuit designs at the time were largely 8-bit, as well. Building a full 16-bit motherboard and memory system was costly, pricing such a computer out of the market.

The cost was high because the 8086 needed a 16-bit data bus rather than a less expensive 8-bit bus. Systems available at that time were 8-bit, and slow sales of the 8086 indicated to Intel that people weren't willing to pay for the extra performance of the full 16-bit design. In response, Intel introduced a kind of crippled version of the 8086, called the 8088. The 8088 essentially deleted 8 of the 16 bits on the data bus, making the 8088 an 8-bit chip as far as data input and output were concerned. However, because it retained the full 16-bit internal registers and the 20-bit address bus, the 8088 ran 16-bit software and was capable of addressing a full 1MB of RAM.

For these reasons, IBM selected the 8-bit 8088 chip for the original IBM PC. Years later, IBM was criticized for using the 8-bit 8088 instead of the 16-bit 8086. In retrospect, it was a very wise decision. IBM even covered up the physical design in its ads, which at the time indicated its new PC had a "high-speed 16-bit microprocessor." IBM could say that because the 8088 still ran the same powerful 16-bit software the 8086 ran, just a little more slowly. In fact, programmers universally thought of the 8088 as a 16-bit chip because there was virtually no way a program could distinguish an 8088 from an 8086. This enabled IBM to deliver a PC capable of running a new generation of 16-bit software, while retaining a much less expensive 8-bit design for the hardware. Because of this, the IBM PC was actually priced less at its introduction than the most popular PC of the time, the Apple II. For the trivia buffs out there, the IBM PC listed for \$1,265 and included only 16KB of RAM, whereas a similarly configured Apple II cost \$1,355.

Even though the 8088 was introduced in June 1979, the original IBM PC that used the processor did not appear until August 1981. Back then, a significant lag time often occurred between the introduction of a new processor and systems that incorporated it. That is unlike today, when new processors and systems using them often are released on the same day.

The 8088 in the IBM PC ran at 4.77MHz; the average instruction on the 8088 took 12 cycles to complete.

Computer users sometimes wonder why a 640KB conventional-memory barrier exists if the 8088 chip can address 1MB of memory. The conventional-memory barrier exists because IBM reserved 384KB of the upper portion of the 1024KB (1MB) address space of the 8088 for use by adapter cards and system BIOS. The lower 640KB is the conventional memory in which DOS and software applications execute.

80186 and 80188 Processors

After Intel produced the 8086 and 8088 chips, it created versions of these chips with some of the required support components integrated within the processor.

The relationship between the 80186 and 80188 is the same as that of the 8086 and 8088; the 80188 is essentially an 8-bit interface version of the 80186. The advantage of the 80186 and 80188 is that they combine on a single chip 15–20 of the 8086–8088 series system components—a fact that can greatly reduce the number of components in a computer design. The 80186 and 80188 chips were used for highly intelligent peripheral adapter cards of that age, such as network adapters.

8087 Coprocessor

The math coprocessor or floating-point unit that was paired with the 8086 chip was called the 8087 numeric data processor (NDP), the math coprocessor, or simply the math chip. The 8087 is designed to perform high-level math operations at many times the speed of the main processor. The primary advantage of using this chip is the increased execution speed in number-crunching programs, such as spreadsheet applications.

P2 (286) Second-Generation Processors

The second generation of PC processors allowed for a great leap in system speed and processing efficiency. With these chips we went from moving 8 bits of data around to moving 16 bits at a time. The following section details the second-generation PC processor, the 286.

286 Processors

The Intel 80286 (normally abbreviated as 286) processor did not suffer from the compatibility problems that damned the 80186 and 80188. The 286 chip, first introduced in 1982, is the CPU behind the original IBM PC AT (Advanced Technology). Other computer makers manufactured what came to be known as IBM clones, with many of these manufacturers calling their systems AT-compatible or AT-class computers.

When IBM developed the AT, it selected the 286 as the basis for the new system because the chip provided compatibility with the 8088 used in the PC and the XT. Therefore, software written for those chips should run on the 286. The 286 chip is many times faster than the 8088 used in the XT, and at the time it offered a major performance boost to PCs used in businesses. The processing speed, or throughput, of the original AT (which ran at 6MHz) is five times greater than that of the PC running at 4.77MHz. The die for the 286 is shown in Figure 3.33.

286 systems are faster than their predecessors for several reasons. The main reason is that 286 processors are much more efficient in executing instructions. An average instruction takes 12 clock cycles on the 8086 or 8088, but takes an average of only 4.5 cycles on the 286 processor. Additionally, the 286 chip can handle up to 16 bits of data at a time through an external data bus twice the size of the 8088.

The 286 chip has two modes of operation: real mode and protected mode. The two modes are distinct enough to make the 286 resemble two chips in one. In real mode, a 286 acts essentially the same as an 8086 chip and is fully *object-code compatible* with the 8086 and 8088. (A processor with object-code compatibility can run programs written for another processor without modification and execute every system instruction in the same manner.)

In the protected mode of operation, the 286 was truly something new. In this mode, a program designed to take advantage of the chip's capabilities believes that it has access to 1GB of memory (including virtual memory). The 286 chip, however, can address only 16MB of hardware memory. A significant failing of the 286 chip is that it cannot switch from protected mode to real mode without a hardware reset (a warm reboot) of the system. (It can, however, switch from real mode to protected mode without a reset.) A major improvement of the 386 over the 286 is that software can switch the 386 from real mode to protected mode, and vice versa. See the section "Processor Modes," earlier in this chapter for more information.

Figure 3.33 286 Processor die. *Photograph used by permission of Intel Corporation.*

Only a small amount of software that took advantage of the 286 chip was sold until Windows 3.0 offered standard mode for 286 compatibility; by that time, the hottest-selling chip was the 386. Still, the 286 was Intel's first attempt to produce a CPU chip that supported multitasking, in which multiple programs run at the same time.

80287 Coprocessor

The 80287, internally, is the same math chip as the 8087, although the pins used to plug them into the motherboard are different. Both the 80287 and the 8087 operate as though they are identical.

In most systems, the 80286 internally divides the system clock by 2 to derive the processor clock. The 80287 internally divides the system-clock frequency by 3. For this reason, most AT-type computers run the 80287 at one-third the system clock rate, which also is two-thirds the clock speed of the 80286. Because the 286 and 287 chips are asynchronous, the interface between the 286 and 287 chips is not as efficient as with the 8088 and 8087.

P3 (386) Third-Generation Processors

The third generation represents perhaps the most significant change in processors since the first PC. The big deal was the migration from processors that handled 16-bit operations to true 32-bit chips. The third-generation processors were so far ahead of their time, it took fully 10 years before 32-bit operating systems and software became mainstream, and by that time the third-generation chips had become a memory. The following section details the third-generation processors.

386 Processors

The Intel 80386 (usually abbreviated as 386) caused quite a stir in the PC industry because of the vastly improved performance it brought to the personal computer. Compared with 8088 and 286 systems, the 386 chip offered greater performance in almost all areas of operation.

The 386 is a full 32-bit processor optimized for high-speed operation and multitasking operating systems. Intel introduced the chip in 1985, but the 386 appeared in the first systems in late 1986 and

early 1987. The Compaq Deskpro 386 and systems made by several other manufacturers introduced the chip; somewhat later, IBM used the chip in its PS/2 Model 80.

The 386 can execute the real-mode instructions of an 8086 or 8088, but in fewer clock cycles. The 386 was as efficient as the 286 in executing instructions—the average instruction took about 4.5 clock cycles. In raw performance, therefore, the 286 and 386 actually seemed to be at almost equal clock rates. The 386 offered greater performance in other ways, mainly because of additional software capability (modes) and a greatly enhanced memory management unit (MMU). The die for the 386 is shown in Figure 3.34.

Figure 3.34 386 processor die. *Photograph used by permission of Intel Corporation.*

The 386 can switch to and from protected mode under software control without a system reset—a capability that makes using protected mode more practical. In addition, the 386 includes a new mode, called virtual real mode, which enables several real-mode sessions to run simultaneously under protected mode.

The protected mode of the 386 is fully compatible with the protected mode of the 286. The protected mode for both chips often is called their native mode of operation because these chips are designed for advanced operating systems such as Windows NT/2000/XP, which run only in protected mode. Intel extended the memory-addressing capabilities of 386 protected mode with a new MMU that provided advanced memory paging and program switching. These features were extensions of the 286 type of MMU, so the 386 remained fully compatible with the 286 at the system-code level.

The 386 chip's virtual real mode was also new. In virtual real mode, the processor could run with hardware memory protection while simulating an 8086's real-mode operation. Multiple copies of DOS and other operating systems, therefore, could run simultaneously on this processor, each in a protected area of memory. If the programs in one segment crashed, the rest of the system was protected.

Numerous variations of the 386 chip exist, some of which are less powerful and some of which are less power hungry. The following sections cover the members of the 386-chip family and their differences.

386DX Processors

The 386DX chip was the first of the 386 family members that Intel introduced. The 386 is a full 32-bit processor with 32-bit internal registers, a 32-bit internal data bus, and a 32-bit external data bus. The 386 contains 275,000 transistors in a very large scale integration (VLSI) circuit. The chip comes in a 132-pin package and draws approximately 400 milliamperes (ma), which is less power than even the 8086 requires. The 386 has a smaller power requirement because it is made of Complementary Metal-Oxide Semiconductor (CMOS) materials. The CMOS design enables devices to consume extremely low levels of power.

The Intel 386 chip was available in clock speeds ranging from 16MHz–33MHz; other manufacturers, primarily AMD and Cyrix, offered comparable versions with speeds up to 40MHz.

The 386DX can address 4GB of physical memory. Its built-in virtual memory manager enables software designed to take advantage of enormous amounts of memory to act as though a system has 64TB of memory. (A terabyte, or TB, is 1,099,511,627,776 bytes of memory, or about 1000GB.)

386SX Processors

The 386SX was designed for systems designers looking for 386 capabilities at 286 system prices. Similar to the 286, the 386SX is restricted to only 16 bits when communicating with other system components, such as memory. Internally, however, the 386SX is identical to the DX chip; the 386SX has 32-bit internal registers and can therefore run 32-bit software. The 386SX uses a 24-bit memory-addressing scheme like that of the 286, rather than the full 32-bit memory address bus of the standard 386. The 386SX, therefore, can address a maximum 16MB of physical memory rather than the 4GB of physical memory the 386DX can address. Before it was discontinued, the 386SX was available in clock speeds ranging from 16MHz to 33MHz.

The 386SX signaled the end of the 286 because of the 386SX chip's superior MMU and the addition of the virtual real mode. Under a software manager such as Windows or OS/2, the 386SX can run numerous DOS programs at the same time. The capability to run 386-specific software is another important advantage of the 386SX over any 286 or older design. For example, Windows 3.1 runs nearly as well on a 386SX as it does on a 386DX.

386SL Processors

The 386SL is another variation on the 386 chip. This low-power CPU had the same capabilities as the 386SX, but it was designed for laptop systems in which low power consumption was necessary. The SL chips offered special power-management features that were important to systems that ran on batteries. The SL chip also offered several sleep modes to conserve power.

The chip included an extended architecture that contained a System Management Interrupt (SMI), which provided access to the power-management features. Also included in the SL chip was special support for LIM (Lotus Intel Microsoft) expanded memory functions and a cache controller. The cache controller was designed to control a 16KB–64KB external processor cache.

These extra functions account for the higher transistor count in the SL chips (855,000) compared with even the 386DX processor (275,000). The 386SL was available in 25MHz clock speed.

Intel offered a companion to the 386SL chip for laptops called the 82360SL I/O subsystem. The 82360SL provided many common peripheral functions, such as serial and parallel ports, a direct memory access (DMA) controller, an interrupt controller, and power-management logic for the 386SL processor. This chip subsystem worked with the processor to provide an ideal solution for the small size and low power-consumption requirements of portable and laptop systems.

80387 Coprocessor

Although the 80387 chips ran asynchronously, 386 systems were designed so that the math chip ran at the same clock speed as the main CPU. Unlike the 80287 coprocessor, which was merely an 8087 with different pins to plug into the AT motherboard, the 80387 coprocessor was a high-performance math chip specifically designed to work with the 386.

All 387 chips used a low power-consumption CMOS design. The 387 coprocessor had two basic designs: the 387DX coprocessor, which was designed to work with the 386DX processor, and the 387SX coprocessor, which was designed to work with the 386SX, SL, or SLC processor.

Intel originally offered several speeds for the 387DX coprocessor. But when the company designed the 33MHz version, a smaller mask was required to reduce the lengths of the signal pathways in the chip. This increased the performance of the chip by roughly 20%.

Note

Because Intel lagged in developing the 387 coprocessor, some early 386 systems were designed with a socket for a 287 coprocessor. Performance levels associated with that union, however, leave much to be desired.

Installing a 387DX is easy, but you must be careful to orient the chip in its socket properly; otherwise, the chip will be destroyed. The most common cause of burned pins on the 387DX is incorrect installation. In many systems, the 387DX was oriented differently from other large chips. Follow the manufacturer's installation instructions carefully to avoid damaging the 387DX; Intel's warranty does not cover chips that are installed incorrectly.

Several manufacturers developed their own versions of the Intel 387 coprocessors, some of which were touted as being faster than the original Intel chips. The general compatibility record of these chips was very good.

P4 (486) Fourth-Generation Processors

The third generation had been a large change from the previous generations of processors. With the fourth generation, more refinement than complete redesign was accomplished. Even so, Intel, AMD, and others managed to literally double processor performance with their fourth-generation processors. The following section defines the fourth-generation processors from Intel, AMD, and others.

486 Processors

In the race for more speed, the Intel 80486 (normally abbreviated as 486) was another major leap forward. The additional power available in the 486 fueled tremendous growth in the software industry. Tens of millions of copies of Windows, and millions of copies of OS/2, have been sold largely because the 486 finally made the GUI of Windows and OS/2 a realistic option for people who work on their computers every day.

Four main features make a given 486 processor roughly twice as fast as an equivalent MHz 386 chip. These features are

- *Reduced instruction-execution time.* A single instruction in the 486 takes an average of only two clock cycles to complete, compared with an average of more than four cycles on the 386. Clock-multiplied versions, such as the DX2 and DX4, further reduced this to about two cycles per instruction.
- *Internal (Level 1) cache.* The built-in cache has a hit ratio of 90%–95%, which describes how often zero-wait-state read operations occur. External caches can improve this ratio further.
- *Burst-mode memory cycles.* A standard 32-bit (4-byte) memory transfer takes two clock cycles. After a standard 32-bit transfer, more data up to the next 12 bytes (or three transfers) can be transferred with only one cycle used for each 32-bit (4-byte) transfer. Thus, up to 16 bytes of contiguous memory data can be transferred in as little as five cycles instead of eight cycles or more. This effect can be even greater when the transfers are only 8 bits or 16 bits each.
- *Built-in (synchronous) enhanced math coprocessor (some versions).* The math coprocessor runs synchronously with the main processor and executes math instructions in fewer cycles than previous designs did. On average, the math coprocessor built into the DX-series chips provides two to three times greater math performance than an external 387 chip.

The 486 chip is about twice as fast as the 386, so a 386DX-40 is about as fast as a 486SX-20. This made the 486 a much more desirable option, primarily because it could more easily be upgraded to a DX2 or DX4 processor at a later time. You can see why the arrival of the 486 rapidly killed off the 386 in the marketplace.

Most of the 486 chips were offered in a variety of maximum speed ratings, varying from 16MHz up to 133MHz. Additionally, 486 processors have slight differences in overall pin configurations. The DX, DX2, and SX processors have a virtually identical 168-pin configuration, whereas the OverDrive chips have either the standard 168-pin configuration or a specially modified 169-pin OverDrive (sometimes also called 487SX) configuration. If your motherboard has two sockets, the primary one likely supports the standard 168-pin configuration, and the secondary (OverDrive) socket supports the 169-pin OverDrive configuration. Most of the later 486-based motherboards with a single ZIF socket support any of the 486 processors except the DX4. The DX4 is different because it requires 3.3V to operate instead of 5V, like most other chips up to that time.

A processor rated for a given speed always functions at any of the lower speeds. A 100MHz-rated 486DX4 chip, for example, runs at 75MHz if it is plugged into a 25MHz motherboard. Note that the DX2/OverDrive processors operate internally at two times the motherboard clock rate, whereas the DX4 processors operate at two, two-and-one-half, or three times the motherboard clock rate. Table 3.24 shows the various speed combinations that can result from using the DX2 or DX4 processors with different motherboard clock speeds.

Table 3.24 Intel DX2 and DX4 Operating Speeds Versus CPU Bus (Motherboard) Clock Speeds

CPU Bus Speed	DX2/DX4 Speed (2× Mode)	DX4 Speed (2.5× Mode)	DX4 Speed (3× Mode)
16MHz	32MHz	40MHz	48MHz
20MHz	40MHz	50MHz	60MHz
25MHz	50MHz	63MHz	75MHz
33MHz	66MHz	83MHz	100MHz
40MHz	80MHz	100MHz	120MHz
50MHz	100MHz	n/a	n/a

The internal multiplier of the DX4 processor is controlled by the CLKMUL (clock multiplier) signal at pin R-17 (Socket 1) or S-18 (Socket 2, 3, or 6). In most cases, one or two jumpers will be on the board near the processor socket to control the settings for these pins. The motherboard documentation should cover these settings if they can be changed.

One interesting capability here is to run the DX4-100 chip in a doubled mode with a 50MHz motherboard speed. This gives you a very fast memory bus, along with the same 100MHz processor speed, as if you were running the chip in a 33/100MHz tripled mode.

Many VL-Bus motherboards can run the VL-Bus slots in a buffered mode, add wait states, or even selectively change the clock only for the VL-Bus slots to keep them compatible. In most cases, they don't run properly at 50MHz. Consult your motherboard—or even better, your chipset documentation—to see how your board is set up.

Caution

When upgrading an existing system, you should be sure that your socket supports the chip you are installing. This was especially true when putting a DX4 processor in an older system. In that scenario, you needed some type of adapter to regulate the voltage down to 3.3V. Putting the DX4 in a 5V socket destroys the chip! See the earlier section on processor sockets for more information.

486DX Processors

The original Intel 486DX processor was introduced on April 10, 1989, and systems using this chip first appeared during 1990. The first chips had a maximum speed rating of 25MHz; later versions of the 486DX were available in 33MHz- and 50MHz-rated versions. The 486DX originally was available only in a 5V, 168-pin PGA version, but later became available in 5V, 196-pin plastic quad flat pack (PQFP) and 3.3V, 208-pin small quad flat pack (SQFP). These latter form factors were available in SL enhanced versions, which were intended primarily for portable or laptop applications in which saving power is important.

Two main features separate the 486 processor from its predecessors:

- The 486DX integrates functions such as the math coprocessor, cache controller, and cache memory into the chip.
- The 486 also was designed with easy installation and upgradeability in mind; double-speed OverDrive upgrades were available for most systems.

The 486DX processor is fabricated with low-power CMOS technology. The chip has a 32-bit internal register size, a 32-bit external data bus, and a 32-bit address bus. These dimensions are equal to those of the 386DX processor. The internal register size is where the “32-bit” designation used in advertisements comes from. The 486DX chip contains 1.2 million transistors on a piece of silicon no larger than your thumbnail. This figure is more than four times the number of components on 386 processors and should give you a good indication of the 486 chip’s relative power. The die for the 486 is shown in Figure 3.35.

Figure 3.35 486 processor die. *Photograph used by permission of Intel Corporation.*

The standard 486DX contains a processing unit, floating-point unit (math coprocessor), memory-management unit, and cache controller with 8KB of internal-cache RAM. Due to the internal cache and a more efficient internal processing unit, the 486 family of processors can execute individual instructions in an average of only 2 processor cycles. Compare this figure with the 286 and 386 families, both of which execute an average 4.5 cycles per instruction. Compare it also with the original 8086 and 8088 processors, which execute an average 12 cycles per instruction. At a given clock rate (MHz), therefore, a 486 processor is roughly twice as efficient as a 386 processor; a 16MHz 486SX is roughly equal to a 33MHz 386DX system; and a 20MHz 486SX is equal to a 40MHz 386DX system. Any of the faster 486s are way beyond the 386 in performance.

The 486 is fully instruction-set-compatible with previous Intel processors, such as the 386, but offers several additional instructions (most of which have to do with controlling the internal cache).

Similar to the 386DX, the 486 can address 4GB of physical memory and manage as much as 64TB of virtual memory. The 486 fully supports the three operating modes introduced in the 386: real mode, protected mode, and virtual real mode:

- *Real mode.* In this mode, the 486 (similar to the 386) runs unmodified 8086-type software.
- *Protected mode.* In this mode, the 486 (similar to the 386) offers sophisticated memory paging and program switching.
- *Virtual real mode.* In this mode, the 486 (similar to the 386) can run multiple copies of DOS or other operating systems while simulating an 8086's real-mode operation. Under an operating system such as Windows or OS/2, therefore, both 16-bit and 32-bit programs can run simultaneously on this processor with hardware memory protection. If one program crashes, the rest of the system is protected, and you can reboot the blown portion through various means, depending on the operating software.

The 486DX series has a built-in math coprocessor that sometimes is called an MCP (math coprocessor) or FPU. This series is unlike previous Intel CPU chips, which required you to add a math coprocessor if you needed faster calculations for complex mathematics. The FPU in the 486DX series is 100% software-compatible with the external 387 math coprocessor used with the 386, but it delivers more than twice the performance. It runs in synchronization with the main processor and executes most instructions in half as many cycles as the 386.

486SL

The 486SL was a short-lived, standalone chip. The SL enhancements and features became available in virtually all the 486 processors (SX, DX, and DX2) in what are called SL enhanced versions. SL enhancement refers to a special design that incorporates special power-saving features.

The SL enhanced chips originally were designed to be installed in laptop or notebook systems that run on batteries, but they found their way into desktop systems, as well. The SL-enhanced chips featured special power-management techniques, such as sleep mode and clock throttling, to reduce power consumption when necessary. These chips were available in 3.3V versions, as well.

Intel designed a power-management architecture called system management mode (SMM). This mode of operation is totally isolated and independent from other CPU hardware and software. SMM provides hardware resources such as timers, registers, and other I/O logic that can control and power down mobile-computer components without interfering with any of the other system resources. SMM executes in a dedicated memory space called system management memory, which is not visible and does not interfere with operating system and application software. SMM has an interrupt called system management interrupt (SMI), which services power-management events and is independent from—and a higher priority than—any of the other interrupts.

SMM provides power management with flexibility and security that were not available previously. For example, an SMI occurs when an application program tries to access a peripheral device that is powered down for battery savings, which powers up the peripheral device and re-executes the I/O instruction automatically.

Intel also designed a feature called Suspend/Resume in the SL processor. The system manufacturer can use this feature to provide the portable computer user with instant on-and-off capability. An SL system typically can resume (instant on) in 1 second from the suspend state (instant off) to exactly where it left off. You do not need to reboot, load the operating system, or load the applications and their data. Instead, simply push the Suspend/Resume button and the system is ready to go.

The SL CPU was designed to consume almost no power in the suspend state. This feature means that the system can stay in the suspend state possibly for weeks and yet start up instantly right where it

left off. An SL system can keep working data in normal RAM memory safe for a long time while it is in the suspend state, but saving to a disk still is prudent.

486SX

The 486SX, introduced in April 1991, was designed to be sold as a lower-cost version of the 486. The 486SX is virtually identical to the full DX processor, but the chip does not incorporate the FPU or math coprocessor portion.

As you read earlier in this chapter, the 386SX was a scaled-down (some people would say crippled) 16-bit version of the full-blown 32-bit 386DX. The 386SX even had a completely different pinout and was not interchangeable with the more powerful DX version. The 486SX, however, is a different story. The 486SX is, in fact, a full-blown 32-bit 486 processor that is basically pin compatible with the DX. A few pin functions are different or rearranged, but each pin fits into the same socket.

The 486SX chip is more a marketing quirk than new technology. Early versions of the 486SX chip actually were DX chips that showed defects in the math-coprocessor section. Instead of being scrapped, the chips were packaged with the FPU section disabled and sold as SX chips. This arrangement lasted for only a short time; thereafter, SX chips got their own mask, which is different from the DX mask. (A *mask* is the photographic blueprint of the processor and is used to etch the intricate signal pathways into a silicon chip.) The transistor count dropped to 1.185 million (from 1.2 million) to reflect this new mask.

The 486SX was available in 16MHz-, 20MHz-, 25MHz-, and 33MHz-rated speeds, and a 486 SX/2 was also available that ran at up to 50MHz or 66MHz. The 486SX typically comes in a 168-pin version, although other surface-mount versions are available in SL-enhanced models.

Despite what Intel's marketing and sales information implies, no technical provision exists for adding a separate math coprocessor to a 486SX system; neither was a separate math coprocessor chip ever available to plug in. Instead, Intel wanted you to add a new 486 processor with a built-in math unit and disable the SX CPU that already was on the motherboard. If this situation sounds confusing, read on because this topic brings you to the most important aspect of 486 design: upgradeability.

487SX

The 487SX math coprocessor, as Intel calls it, really is a complete 25MHz 486DX CPU with an extra pin added and some other pins rearranged. When the 487SX is installed in the extra socket provided in a 486SX CPU-based system, the 487SX turns off the existing 486SX via a new signal on one of the pins. The extra key pin actually carries no signal itself and exists only to prevent improper orientation when the chip is installed in a socket.

The 487SX takes over all CPU functions from the 486SX and also provides math coprocessor functionality in the system. At first glance, this setup seems rather strange and wasteful, so perhaps further explanation is in order. Fortunately, the 487SX turned out to be a stopgap measure while Intel prepared its real surprise: the OverDrive processor. The DX2/OverDrive speed-doubling chips, which are designed for the 487SX 169-pin socket, have the same pinout as the 487SX. These upgrade chips are installed in exactly the same way as the 487SX; therefore, any system that supports the 487SX also supports the DX2/OverDrive chips.

Although in most cases you can upgrade a system by removing the 486SX CPU and replacing it with a 487SX (or even a DX or DX2/OverDrive), Intel originally discouraged this procedure. Instead, Intel recommended that PC manufacturers include a dedicated upgrade (OverDrive) socket in their systems because several risks were involved in removing the original CPU from a standard socket. (The following section elaborates on those risks.) Now Intel recommends—or even insists on—the use of a single processor socket of a ZIF design, which makes upgrading an easy task physically.

◀◀ See "Zero Insertion Force," p. 90.

DX2/OverDrive and DX4 Processors

On March 3, 1992, Intel introduced the DX2 speed-doubling processors. On May 26, 1992, Intel announced that the DX2 processors also would be available in a retail version called OverDrive. Originally, the OverDrive versions of the DX2 were available only in 169-pin versions, which meant that they could be used only with 486SX systems that had sockets configured to support the rearranged pin configuration.

On September 14, 1992, Intel introduced 168-pin OverDrive versions for upgrading 486DX systems. These processors could be added to existing 486 (SX or DX) systems as an upgrade, even if those systems did not support the 169-pin configuration. When you use this processor as an upgrade, you install the new chip in your system, which subsequently runs twice as fast.

The DX2/OverDrive processors run internally at twice the clock rate of the host system. If the motherboard clock is 25MHz, for example, the DX2/OverDrive chip runs internally at 50MHz; likewise, if the motherboard is a 33MHz design, the DX2/OverDrive runs at 66MHz. The DX2/OverDrive speed doubling has no effect on the rest of the system; all components on the motherboard run the same as they do with a standard 486 processor. Therefore, you do not have to change other components (such as memory) to accommodate the double-speed chip. The DX2/OverDrive chips have been available in several speeds. Three speed-rated versions have been offered:

- 40MHz DX2/OverDrive for 16MHz or 20MHz systems
- 50MHz DX2/OverDrive for 25MHz systems
- 66MHz DX2/OverDrive for 33MHz systems

Notice that these ratings indicate the maximum speed at which the chip is capable of running. You could use a 66MHz-rated chip in place of the 50MHz- or 40MHz-rated parts with no problem, although the chip will run only at the slower speeds. The actual speed of the chip is double the motherboard clock frequency. When the 40MHz DX2/OverDrive chip is installed in a 16MHz 486SX system, for example, the chip functions only at 32MHz—exactly double the motherboard speed. Intel originally stated that no 100MHz DX2/OverDrive chip would be available for 50MHz systems—which technically has not been true because the DX4 could be set to run in a clock-doubled mode and used in a 50MHz motherboard (see the discussion of the DX4 processor in this section).

The only part of the DX2 chip that doesn't run at double speed is the bus interface unit, a region of the chip that handles I/O between the CPU and the outside world. By translating between the differing internal and external clock speeds, the bus interface unit makes speed doubling transparent to the rest of the system. The DX2 appears to the rest of the system to be a regular 486DX chip, but one that seems to execute instructions twice as fast.

DX2/OverDrive chips are based on the 0.8-micron circuit technology that was first used in the 50MHz 486DX. The DX2 contains 1.2 million transistors in a three-layer form. The internal 8KB cache, integer, and floating-point units all run at double speed. External communication with the PC runs at normal speed to maintain compatibility.

Besides upgrading existing systems, one of the best parts of the DX2 concept was the fact that system designers could introduce very fast systems by using cheaper motherboard designs, rather than the more costly designs that would support a straight high-speed clock. Therefore, a 50MHz 486DX2 system was much less expensive than a straight 50MHz 486DX system. The system board in a 486DX-50 system operates at a true 50MHz. The 486DX2 CPU in a 486DX2-50 system operates internally at 50MHz, but the motherboard operates at only 25MHz.

You might be thinking that a true 50MHz DX processor-based system still would be faster than a speed-doubled 25MHz system, and this generally is true. But, the differences in speed actually are very slight—a real testament to the integration of the 486 processor and especially to the cache design.

When the processor has to go to system memory for data or instructions, for example, it must do so at the slower motherboard operating frequency (such as 25MHz). Because the 8KB internal cache of the 486DX2 has a hit rate of 90%–95%, however, the CPU must access system memory only 5%–10% of the time for memory reads. Therefore, the performance of the DX2 system can come very close to that of a true 50MHz DX system and cost much less. Even though the motherboard runs at only 33.33MHz, a system with a DX2 66MHz processor ends up being faster than a true 50MHz DX system, especially if the DX2 system has a good L2 cache.

Many 486 motherboard designs also include a secondary cache that is external to the cache integrated into the 486 chip. This external cache allows for much faster access when the 486 chip calls for external-memory access. The size of this external cache can vary anywhere from 16KB to 512KB or more. When you add a DX2 processor, an external cache is even more important for achieving the greatest performance gain. This cache greatly reduces the wait states the processor must add when writing to system memory or when a read causes an internal cache miss. For this reason, some systems perform better with the DX2/OverDrive processors than others, usually depending on the size and efficiency of the external-memory cache system on the motherboard. Systems that have no external cache still enjoy a near-doubling of CPU performance, but operations that involve a great deal of memory access are slower.

This brings us to the DX4 processor. Although the standard DX4 technically was not sold as a retail part, it could be purchased from several vendors, along with the 3.3V voltage adapter needed to install the chip in a 5V socket. These adapters have jumpers that enable you to select the DX4 clock multiplier and set it to 2x, 2.5x, or 3x mode. In a 50MHz DX system, you could install a DX4/voltage-regulator combination set in 2x mode for a motherboard speed of 50MHz and a processor speed of 100MHz! Although you might not be able to take advantage of certain VL-Bus adapter cards, you will have one of the fastest 486-class PCs available.

Intel also sold a special DX4 OverDrive processor that included a built-in voltage regulator and heatsink that are specifically designed for the retail market. The DX4 OverDrive chip is essentially the same as the standard 3.3V DX4 with the main exception that it runs on 5V because it includes an on-chip regulator. Also, the DX4 OverDrive chip runs only in the tripled speed mode, and not the 2x or 2.5x modes of the standard DX4 processor.

Note

Intel has discontinued all 486 and DX2/DX4/OverDrive processors, including the so-called Pentium OverDrive processor.

Pentium OverDrive for 486SX2 and DX2 Systems

The Pentium OverDrive Processor became available in 1995. An OverDrive chip for 486DX4 systems had been planned, but poor marketplace performance of the SX2/DX2 chip resulted in it never seeing the light of day. One thing to keep in mind about the 486 Pentium OverDrive chip is that although it is intended primarily for SX2 and DX2 systems, it should work in any upgradeable 486SX or DX system that has a Socket 2 or Socket 3. If in doubt, check Intel's online upgrade guide for compatibility.

The Pentium OverDrive processor is designed for systems that have a processor socket that follows the Intel Socket 2 specification. This processor also works in systems that have a Socket 3 design, although you should ensure that the voltage is set for 5V rather than 3.3V. The Pentium OverDrive chip includes a 32KB internal L1 cache and the same superscalar (multiple instruction path) architecture of the real Pentium chip. Besides a 32-bit Pentium core, these processors feature increased clock-speed operation due to internal clock multiplication and incorporate an internal write-back cache (standard with the Pentium). If the motherboard supports the write-back cache function, increased performance is realized. Unfortunately, most motherboards, especially older ones with the Socket 2 design, support only write-through cache.

Most tests of these OverDrive chips show them to be only slightly ahead of the DX4-100 and behind the DX4-120 and true Pentium 60, 66, or 75. Based on the relative affordability of low-end "real" Pentiums (in their day), it was hard not to justify making the step up to a Pentium system.

AMD 486 (5x86)

AMD made a line of 486-compatible chips that installed into standard 486 motherboards. In fact, AMD made the fastest 486 processor available, which it called the Am5x86(TM)-P75. The name was a little misleading because the 5x86 part made some people think that this was a fifth-generation Pentium-type processor. In reality, it was a fast clock-multiplied (4x clock) 486 that ran at four times the speed of the 33MHz 486 motherboard you plugged it into.

The 5x86 offered high-performance features such as a unified 16KB write-back cache and 133MHz core clock speed; it was approximately comparable to a Pentium 75, which is why it was denoted with a P-75 in the part number. It was the ideal choice for cost-effective 486 upgrades, where changing the motherboard is difficult or impossible.

Not all 486 motherboards support the 5x86. The best way to verify that your motherboard supports the chip is by checking with the documentation that came with the board. Look for keywords such as “Am5X86,” “AMD-X5,” “clock-quadrupled,” “133MHz,” or other similar wording. Another good way to determine whether your motherboard supports the AMD 5x86 is to look for it in the listed models on AMD’s Web site.

There are a few things to note when installing a 5x86 processor into a 486 motherboard:

- *The operating voltage for the 5x86 is 3.45V +/- 0.15V.* Not all motherboards have this setting, but most that incorporate a Socket 3 design should. If your 486 motherboard is a Socket 1 or 2 design, you cannot use the 5x86 processor directly. The 3.45V processor does not operate in a 5V socket and can be damaged. To convert a 5V motherboard to 3.45V, processors with adapters could be purchased from several vendors, such as Kingston, PowerLeap, and Evergreen. These companies and others sold the 5x86 complete with a voltage regulator adapter attached in an easy-to-install package. These versions are ideal for older 486 motherboards that don’t have a Socket 3 design and might still be available in the surplus or closeout market. If not, you can create your own upgrade kit with a processor, voltage adapter, and heatsink/fan.
- *It is generally better to purchase a new motherboard, processor, and RAM than to buy one of these adapters.* Buying a new motherboard is also better than using an adapter because the older BIOS might not understand the requirements of the processor as far as speed is concerned. BIOS updates often are required with older boards.
- *Most Socket 3 motherboards have jumpers, enabling you to set the voltage manually.* Some boards don’t have jumpers, but have voltage autodetect instead. These systems check the VOLDET pin (pin S4) on the microprocessor when the system is powered on.
- *The VOLDET pin is tied to ground (Vss) internally to the microprocessor.* If you cannot find any jumpers for setting voltage, you can check the motherboard as follows: Switch the PC off, remove the microprocessor, connect pin S4 to a Vss pin on the ZIF socket, power on, and check any Vcc pin with a voltmeter. This should read 3.45 ([pm] 0.15) volts. See the previous section on CPU sockets for the pinout.
- *The 5x86 requires a 33MHz motherboard speed, so be sure the board is set to that frequency.* The 5x86 operates at an internal speed of 133MHz. Therefore, the jumpers must be set for “clock-quadrupled” or “4x clock” mode. By setting the jumpers correctly on the motherboard, the CLKMUL pin (pin R17) on the processor will be connected to ground (Vss). If there is no 4x clock setting, the standard DX2 2x clock setting should work.
- *Some motherboards have jumpers that configure the internal cache in either write-back (WB) or write-through (WT) mode.* They do this by pulling the WB/WT pin (pin B13) on the microprocessor to logic High (Vcc) for WB or to ground (Vss) for WT. For best performance, configure your system in WB mode; however, reset the cache to WT mode if problems running applications occur or the floppy drive doesn’t work right (DMA conflicts).
- *The 5x86 runs hot, so a heatsink is required.* It normally must have a fan, and most upgrade kits included a fan.

In addition to the 5x86, the AMD-enhanced 486 product line included 80MHz; 100MHz; and 120MHz CPUs. These are the A80486DX2-80SV8B (40MHz×2), A80486DX4-100SV8B (33MHz×3), and A80486DX4-120SV8B (40MHz×3).

Cyrix/TI 486

The Cyrix 486DX2/DX4 processors were available in 100MHz, 80MHz, 75MHz, 66MHz, and 50MHz versions. Similar to the AMD 486 chips, the Cyrix versions are fully compatible with Intel's 486 processors and work in most 486 motherboards.

The Cx486DX2/DX4 incorporates an 8KB write-back cache, an integrated floating-point unit, advanced power management, and SMM, and was available in 3.3V versions.

Note

TI originally made all the Cyrix-designed 486 processors, and under the agreement it also sold them under the TI name. They are essentially the same as the Cyrix chips.

P5 (586) Fifth-Generation Processors

After the fourth-generation chips such as the 486, Intel and other chip manufacturers went back to the drawing board to come up with new architectures and features that they would later incorporate into what they called fifth-generation chips. This section defines the fifth-generation processors from Intel, AMD, and others.

Pentium Processors

On October 19, 1992, Intel announced that the fifth generation of its compatible microprocessor line (codenamed P5) would be named the Pentium processor rather than the 586, as everybody had assumed. Calling the new chip the 586 would have been natural, but Intel discovered that it could not trademark a number designation, and the company wanted to prevent other manufacturers from using the same name for any clone chips they might develop. The actual Pentium chip shipped on March 22, 1993. Systems that used these chips were only a few months behind.

The Pentium is fully compatible with previous Intel processors, but it differs from them in many ways. At least one of these differences is revolutionary: The Pentium features twin data pipelines, which enable it to execute two instructions at the same time. The 486 and all preceding chips can perform only a single instruction at a time. Intel calls the capability to execute two instructions at the same time superscalar technology. This technology provides additional performance compared with the 486.

With superscalar technology, the Pentium can execute many instructions at a rate of two instructions per cycle. Superscalar architecture usually is associated with high-output RISC chips. The Pentium is one of the first CISC chips to be considered superscalar. The Pentium is almost like having two 486 chips under the hood. Table 3.25 shows the Pentium processor specifications.

Table 3.25 Pentium Processor Specifications

Introduced	March 22, 1993 (first generation); March 7, 1994 (second generation)
Maximum rated speeds	60/66MHz (first generation); 75/90/100/120/133/150/166/200MHz (second generation)
CPU clock multiplier	1x (first generation); 1.5x–3x (second generation)
Register size	32-bit
External data bus	64-bit
Memory address bus	32-bit
Maximum memory	4GB
Integral-cache size	8KB code; 8KB data

Table 3.25 Continued

Integral-cache type	Two-way set associative; write-back data
Burst-mode transfers	Yes
Number of transistors	3.1 million (first generation); 3.3 million (second generation)
Circuit size	0.8 micron (60/66MHz); 0.6 micron (75MHz–100MHz); 0.35 micron (120MHz and up)
External package	273-pin PGA; 296-pin SPGA; tape carrier
Math coprocessor	Built-in FPU
Power management	SMM; enhanced in second generation
Operating voltage	5V (first generation); 3.465V, 3.3V, 3.1V, 2.9V (second generation)

PGA = Pin grid array

SPGA = Staggered pin grid array

The two instruction pipelines within the chip are called the *u*- and *v*-pipes. The *u*-pipe, which is the primary pipe, can execute all integer and floating-point instructions. The *v*-pipe is a secondary pipe that can execute only simple integer instructions and certain floating-point instructions. The process of operating on two instructions simultaneously in the different pipes is called *pairing*. Not all sequentially executing instructions can be paired, and when pairing is not possible, only the *u*-pipe is used. To optimize the Pentium's efficiency, you can recompile software to enable more instructions to be paired.

The Pentium processor has a branch target buffer (BTB), which employs a technique called branch prediction. It minimizes stalls in one or more of the pipes caused by delays in fetching instructions that branch to nonlinear memory locations. The BTB attempts to predict whether a program branch will be taken and then fetches the appropriate instructions. The use of branch prediction enables the Pentium to keep both pipelines operating at full speed. Figure 3.36 shows the internal architecture of the Pentium processor.

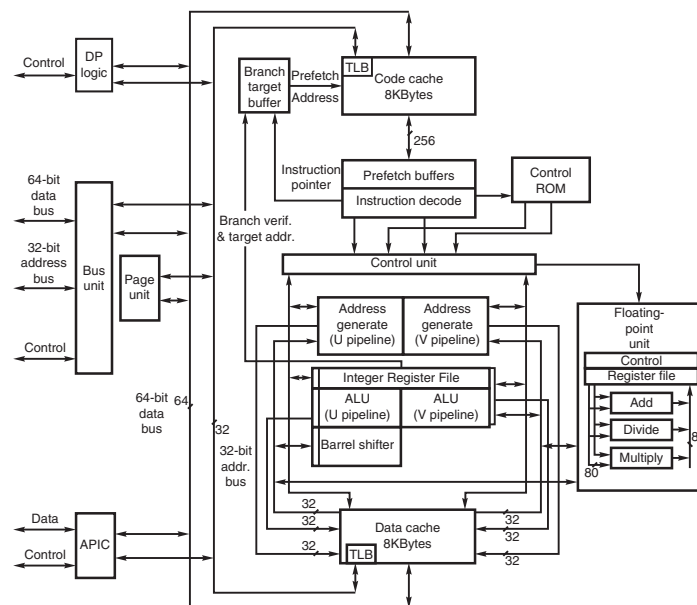

Figure 3.36 Pentium processor internal architecture.

The Pentium has a 32-bit address bus width, giving it the same 4GB memory-addressing capabilities as the 386DX and 486 processors. But the Pentium expands the data bus to 64 bits, which means it can move twice as much data into or out of the CPU, compared with a 486 of the same clock speed. The 64-bit data bus requires that system memory be accessed 64 bits wide, so each bank of memory is 64 bits.

On most motherboards, memory is installed via SIMMs or DIMMs. SIMMs are available in 8-bit-wide and 32-bit-wide versions, whereas DIMMs are 64 bits wide. In addition, versions are available with additional bits for parity or error correcting code (ECC) data. Most Pentium systems use the 32-bit-wide SIMMs—two of these SIMMs per bank of memory. Most Pentium motherboards have at least four of these 32-bit SIMM sockets, providing for a total of two banks of memory. Later Pentium systems and most Pentium II systems still in use today use DIMMs, which are 64 bits wide—just like the processor's external data bus, so only one DIMM is used per bank. This makes installing or upgrading memory much easier because DIMMs can go in one at a time and don't have to be matched up in pairs.

- See "SIMMs, DIMMs, and RIMMs," p. 477, and "Memory Banks," p. 496.

Even though the Pentium has a 64-bit data bus that transfers information 64 bits at a time into and out of the processor, the Pentium has only 32-bit internal registers. As instructions are being processed internally, they are broken down into 32-bit instructions and data elements and processed in much the same way as in the 486. Some people thought that Intel was misleading them by calling the Pentium a 64-bit processor, but 64-bit transfers do indeed take place. Internally, however, the Pentium has 32-bit registers that are fully compatible with the 486.

The Pentium has two separate internal 8KB caches, compared with a single 8KB or 16KB cache in the 486. The cache-controller circuitry and the cache memory are embedded in the CPU chip. The cache mirrors the information in normal RAM by keeping a copy of the data and code from different memory locations. The Pentium cache also can hold information to be written to memory when the load on the CPU and other system components is less. (The 486 makes all memory writes immediately.)

The separate code and data caches are organized in a two-way set associative fashion, with each set split into lines of 32 bytes each. Each cache has a dedicated translation lookaside buffer (TLB) that translates linear addresses to physical addresses. You can configure the data cache as write-back or write-through on a line-by-line basis. When you use the write-back capability, the cache can store write operations and reads, further improving performance over read-only write-through mode. Using write-back mode results in less activity between the CPU and system memory—an important improvement because CPU access to system memory is a bottleneck on fast systems. The code cache is an inherently write-protected cache because it contains only execution instructions and not data, which is updated. Because burst cycles are used, the cache data can be read or written very quickly.

Systems based on the Pentium can benefit greatly from secondary processor caches (L2), which usually consist of up to 512KB or more of extremely fast (15ns or less) SRAM chips. When the CPU fetches data that is not already available in its internal processor (L1) cache, wait states slow the CPU. If the data already is in the secondary processor cache, however, the CPU can go ahead with its work without pausing for wait states.

The Pentium uses a Bipolar Complementary Metal-Oxide Semiconductor (BiCMOS) process and super-scalar architecture to achieve the high level of performance expected from the chip. BiCMOS adds about 10% to the complexity of the chip design, but adds about 30%–35% better performance without a size or power penalty.

All 75MHz and faster Pentium processors are SL enhanced—they incorporate the SMM to provide full control of power-management features, which helps reduce power consumption. The second-generation Pentium processors (75MHz and faster) incorporate a more advanced form of SMM that includes processor clock control. This enables you to throttle the processor up or down to control power use. You can even stop the clock with these more advanced Pentium processors, putting the processor in a state of suspension that requires very little power. The second-generation Pentium processors run on 3.3V power (instead of 5V), reducing power requirements and heat generation even further.

Many Pentium motherboards supply either 3.465V or 3.3V. The 3.465V setting is called VRE (voltage reduced extended) by Intel and is required by some versions of the Pentium, particularly some of the 100MHz versions. The standard 3.3V setting is called STD (standard), which most of the second-generation Pentiums use. STD voltage means anything in a range from 3.135V to 3.465V with 3.3V nominal. Additionally, a special 3.3V setting called VR (voltage reduced) reduces the range from 3.300V to 3.465V with 3.38V nominal. Some of the processors require this narrower specification, which most motherboards provide. Here is a summary:

Voltage Specification	Nominal	Tolerance	Minimum	Maximum
STD (standard)	3.30V	±0.165	3.135V	3.465V
VR (voltage reduced)	3.38V	±0.083	3.300V	3.465V
VRE (VR extended)	3.50V	±0.100	3.400V	3.600V

For even lower power consumption, Intel introduced special Pentium processors with voltage reduction technology in the 75 to 266MHz family; the processors were intended for mobile computer applications. They did not use a conventional chip package and were instead mounted using a new format called tape carrier packaging (TCP). The tape carrier packaging does not encase the chip in ceramic or plastic as with a conventional chip package, but instead covers the actual processor die directly with a thin, protective plastic coating. The entire processor is less than 1mm thick, or about half the thickness of a dime, and weighs less than 1 gram. They were sold to system manufacturers in a roll that looks very much like a filmstrip.

The TCP processor is directly affixed (soldered) to the motherboard by a special machine, resulting in a smaller package, lower height, better thermal transfer, and lower power consumption. Special solder plugs on the circuit board located directly under the processor draw heat away and provide better cooling in the tight confines of a typical notebook or laptop system—no cooling fans are required. For more information on mobile processors and systems, see the chapter “Portable PCs” included on the disc accompanying this book.

The Pentium, like the 486, contains an internal math coprocessor or FPU. The FPU in the Pentium was rewritten to perform significantly better than the FPU in the 486 yet still be fully compatible with the 486 and 387 math coprocessors. The Pentium FPU is estimated to be two to as much as ten times faster than the FPU in the 486. In addition, the two standard instruction pipelines in the Pentium provide two units to handle standard integer math. (The math coprocessor handles only more complex calculations.) Other processors, such as the 486, have only a single-standard execution pipe and one integer math unit. Interestingly, the Pentium FPU contains a flaw that received widespread publicity. See the discussion in the section “Pentium Defects,” later in this chapter.

First-Generation Pentium Processor

The Pentium has been offered in three basic designs, each with several versions. The first-generation design, which is no longer available, came in 60MHz and 66MHz processor speeds. This design used a 273-pin PGA form factor and ran on 5V power. In this design, the processor ran at the same speed as the motherboard—in other words, a 1x clock was used.

The first-generation Pentium was created through a 0.8-micron BiCMOS process. Unfortunately, this process, combined with the 3.1 million transistor count, resulted in a die that was overly large and complicated to manufacture. As a result, reduced yields kept the chip in short supply; Intel could not make them fast enough. The 0.8-micron process was criticized by other manufacturers, including Motorola and IBM, which had been using 0.6-micron technology for their most advanced chips. The huge die and 5V operating voltage caused the 66MHz versions to consume up to an incredible 3.2 amps or 16 watts of power, resulting in a tremendous amount of heat and problems in some systems that did not employ conservative design techniques. Fortunately, adding a fan to the processor solved most cooling problems, as long as the fan kept running.

Much of the criticism leveled at Intel for the first-generation Pentium was justified. Some people realized that the first-generation design was just that; they knew that new Pentium versions, made in a more advanced manufacturing process, were coming. Many of those people advised against purchasing any Pentium system until the second-generation version became available.

Tip

A cardinal rule of computing is never buy the first generation of any processor. Although you can wait forever because something better always will be on the horizon, a little waiting is worthwhile in many cases.

Those who purchased first-generation Pentiums still had a way out, however. As with previous 486 systems, Intel released OverDrive upgrade chips that effectively doubled the processor speed of the Pentium 60 or 66. These are a single-chip upgrade, meaning they replace the existing CPU. Because subsequent Pentiums are incompatible with the Pentium 60/66 Socket 4 arrangement, these OverDrive chips and comparable upgrades available from some third-party sources were the only way to upgrade an existing first-generation Pentium without replacing the motherboard.

Generally, it was better to consider a complete motherboard replacement, which would accept a newer design processor that would potentially be many times faster, than to upgrade using just an OverDrive processor, that might only be twice as fast.

Second-Generation Pentium Processor

Intel announced the second-generation Pentium on March 7, 1994. This new processor was introduced in 90MHz and 100MHz versions, with a 75MHz version not far behind. Eventually, 120MHz, 133MHz, 150MHz, 166MHz, and 200MHz versions were also introduced. The second-generation Pentium uses 0.6-micron (75/90/100MHz) BiCMOS technology to shrink the die and reduce power consumption. The newer, faster 120MHz (and higher) second-generation versions incorporate an even smaller die built on a 0.35-micron BiCMOS process. These smaller dies are not changed from the 0.6-micron versions; they are basically a photographic reduction of the P54C die. The die for the Pentium is shown in Figure 3.37. Additionally, these new processors run on 3.3V power. The 100MHz version consumes a maximum of 3.25 amps of 3.3V power, which equals only 10.725 watts. Further up the scale, the 150MHz chip uses 3.5 amps of 3.3V power (11.6 watts); the 166MHz unit draws 4.4 amps (14.5 watts); and the 200MHz processor uses 4.7 amps (15.5 watts).

Figure 3.37 Pentium processor die. *Photograph used by permission of Intel Corporation.*

The second-generation Pentium processors come in a 296-pin SPGA form factor that is physically incompatible with the first-generation versions. The only way to upgrade from the first generation to the second is to replace the motherboard. The second-generation Pentium processors also have 3.3 million transistors—more than the earlier chips. The extra transistors exist because additional clock-control SL enhancements were added, along with an on-chip advanced programmable interrupt controller (APIC) and dual-processor interface.

The APIC and dual-processor interfaces are responsible for orchestrating dual-processor configurations in which two second-generation Pentium chips can process on the same motherboard simultaneously. Many of the Pentium motherboards designed for file servers come with dual Socket 7 specification sockets, which fully support the multiprocessing capability of the new chips. Software support for what usually is called symmetric multiprocessing (SMP) is being integrated into operating systems such as Windows NT and OS/2.

The second-generation Pentium processors use clock-multiplier circuitry to run the processor at speeds faster than the bus. The 150MHz Pentium processor, for example, can run at 2.5 times the bus frequency, which normally is 60MHz. The 200MHz Pentium processor can run at a 3x clock in a system using a 66MHz bus speed.

Virtually all Pentium motherboards had three speed settings: 50MHz, 60MHz, and 66MHz. Pentium chips were available with a variety of internal clock multipliers that caused the processor to operate at various multiples of these motherboard speeds. Refer to Table 3.7 for a list of the speeds of Pentium processors and motherboards.

The core-to-bus frequency ratio or clock multiplier is controlled in a Pentium processor by two pins on the chip labeled BF1 and BF2. Table 3.26 shows how the state of the BFx pins affects the clock multiplication in the Pentium processor.

Table 3.26 Pentium BFx Pins and Clock Multipliers

BF1	BF2	Clock Multiplier	Bus Speed (MHz)	Core Speed (MHz)
0	1	3x	66	200
0	1	3x	60	180
0	1	3x	50	150
0	0	2.5x	66	166
0	0	2.5x	60	150
0	0	2.5x	50	125
1	0	2x/4x	66	133/266 ¹
1	0	2x	60	120
1	0	2x	50	100
1	1	1.5x/3.5x	66	100/233 ¹
1	1	1.5x	60	90
1	1	1.5x	50	75

1. The 233MHz and 266MHz processors have modified the 1.5x and 2x multipliers to 3.5x and 4x, respectively.

Not all chips support all the bus frequency (BF) pins or combinations of settings. In other words, some of the Pentium processors operate only at specific combinations of these settings or might even be fixed at one particular setting. Many of the later Pentium motherboards included jumpers or switches that enabled you to control the BF pins and, therefore, alter the clock-multiplier ratio within the chip. In theory, you could run a 75MHz-rated Pentium chip at 133MHz by changing jumpers on

the motherboard. This is called overclocking and is discussed in the section “Overclocking,” earlier in this chapter. What Intel has done to discourage overclockers in its most recent Pentiums is discussed near the end of the “Processor Manufacturing” section of this chapter.

Intel also offered a single-chip OverDrive upgrade for second-generation Pentiums. These OverDrive chips are fixed at a 3x multiplier; they replace the existing Socket 5 or 7 CPU, increase processor speed up to 200MHz (with a 66MHz motherboard speed), and add MMX capability. Simply stated, a Pentium 100, 133, or 166 system equipped with the OverDrive chip has a processor speed of 200MHz. Perhaps the best feature of these Pentium OverDrive chips is that they incorporate MMX technology. MMX provides greatly enhanced performance while running the multimedia applications that are so popular today.

If you have a Socket 7 motherboard, you might not need the special OverDrive versions of the Pentium processor that have built-in voltage regulators. Instead, you can purchase a standard Pentium or Pentium-compatible chip and replace the existing processor with it. You must be sure to set the multiplier and voltage settings so that they are correct for the new processor.

Pentium-MMX Processors

A third generation of Pentium processors (codenamed P55C) was released in January 1997, and incorporates what Intel calls MMX technology into the second-generation Pentium design (see Figure 3.38). These Pentium-MMX processors are available in clock rates of 66/166MHz, 66/200MHz, and 66/233MHz and in a mobile-only version, which is 66/266MHz. The MMX processors have a lot in common with other second-generation Pentiums, including superscalar architecture, multiprocessor support, on-chip local APIC controller, and power-management features. New features include a pipelined MMX unit, 16KB code, write-back cache (versus 8KB in earlier Pentiums), and 4.5 million transistors. Pentium-MMX chips are produced on an enhanced 0.35-micron CMOS silicon process that allows for a lower 2.8V voltage level. The newer mobile 233MHz and 266MHz processors are built on a 0.25-micron process and run on only 1.8V. With this newer technology, the 266 processor actually uses less power than the non-MMX 133.

Figure 3.38 Pentium MMX. The left side shows the underside of the chip with the cover plate removed exposing the processor die. *Photograph used by permission of Intel Corporation.*

To use the Pentium-MMX, the motherboard must be capable of supplying the lower (2.8V or less) voltage these processors use. To enable a more universal motherboard solution with respect to these changing voltages, Intel has come up with the Socket 7 with VRM. The VRM is a socketed module that plugs in next to the processor and supplies the correct voltage. Because the module is easily replaced, reconfiguring a motherboard to support any of the voltages required by the newer Pentium processors is easy.

Of course, lower voltage is nice, but MMX is what this chip is really all about. MMX incorporates a process Intel calls single instruction multiple data (SIMD), which enables one instruction to perform

the same function on many pieces of data. Fifty-seven new instructions designed specifically to handle video, audio, and graphics data have been added to the chip.

To add maximum upgradeability to the MMX Pentiums, a Pentium motherboard needs 321-pin processor sockets that fully meet the Intel Socket 7 specification. These also would include the VRM socket. If you have dual sockets, you can add a second Pentium processor to take advantage of SMP support in operating systems that support this feature.

Pentium Defects

Probably the most famous processor bug in history is the now legendary flaw in the Pentium FPU. It has often been called the FDIV bug because it affects primarily the FDIV (floating-point divide) instruction, although several other instructions that use division are also affected. Intel officially refers to this problem as Errata No. 23, titled "Slight precision loss for floating-point divides on specific operand pairs." The bug has been fixed in the D1 or later steppings of the 60/66MHz Pentium processors, as well as the B5 and later steppings of the 75/90/100MHz processors. The 120MHz and higher processors are manufactured from later steppings, which do not include this problem. Tables listing all the variations of Pentium processors and steppings and how to identify them appear later in this chapter.

This bug caused a tremendous fervor when it first was reported on the Internet by a mathematician in October 1994. Within a few days, news of the defect had spread nationwide, and even people who did not have computers had heard about it. The Pentium incorrectly performed floating-point division calculations with certain number combinations, with errors anywhere from the third digit on up.

By the time the bug was publicly discovered outside of Intel, the company had already incorporated the fix into the next stepping of both the 60/66MHz and the 75/90/100MHz Pentium processor, along with the other corrections Intel had made.

After the bug was made public and Intel admitted to already knowing about it, a fury erupted. As people began checking their spreadsheets and other math calculations, many discovered they had also encountered this problem and did not know it. Others who had not encountered the problem had their faith in the core of their PCs very shaken. People had come to put so much trust in the PC that they had a hard time coming to terms with the fact that it might not even be capable of doing math correctly!

One interesting result of the fervor surrounding this defect is that people are less likely to implicitly trust their PCs and are therefore doing more testing and evaluating of important results. The bottom line is that if your information and calculations are important enough, you should implement some results tests. Several math programs were found to have problems. For example, a bug was discovered in the yield function of Excel 5.0 that some were attributing to the Pentium processor. In this case, the problem turned out to be the software (which has been corrected in versions 5.0c and later).

Intel finally decided that in the best interest of the consumer and its public image, it would begin a lifetime replacement warranty on the affected processors. Therefore, if you ever encounter one of the Pentium processors with the Errata 23 floating-point bug, Intel will replace the processor with an equivalent one without this problem. Usually, all you have to do is call Intel and ask for the replacement. It will ship you a new part matching the ratings of the one you are replacing in an overnight shipping box. The replacement is free, including all shipping charges. You merely remove your old processor, replace it with the new one, and put the old one back in the box. Then you call the overnight service, who picks it up and sends it back. Intel will take a credit card number when you first call for the replacement only to ensure that the original defective chip is returned. As long as it gets the original CPU back within a specified amount of time, there will be no charges to you. Intel has indicated that these defective processors will be destroyed and will not be remarketed or resold in another form.

Testing for the FPU Bug

Testing a Pentium for this bug is relatively easy. All you have to do is execute one of the test division cases cited here and see whether your answer compares to the correct result.

The division calculation can be done in a spreadsheet (such as Lotus 1-2-3, Microsoft Excel, or any other), the Microsoft Windows built-in calculator, or any other calculating program that uses the FPU. Make sure that for the purposes of this test the FPU has not been disabled. That typically requires some special command or setting specific to the application and, of course, ensures that the test comes out correct, regardless of whether the chip is flawed.

The most severe Pentium floating-point errors occur as early as the third significant digit of the result. Here is an example of one of the more severe instances of the problem:

$$962,306,957,033 / 11,010,046 = 87,402.6282027341 \text{ (correct answer)}$$

$$962,306,957,033 / 11,010,046 = 87,399.5805831329 \text{ (flawed Pentium)}$$

Note

Note that your particular calculator program might not show the answer to the number of digits shown here. Most spreadsheet programs limit displayed results to 13 or 15 significant digits.

As you can see in the previous case, the error turns up in the third most significant digit of the result. In an examination of more than 5,000 integer pairs in the 5- to 15-digit range found to produce Pentium floating-point division errors, errors beginning in the sixth significant digit were the most likely to occur.

Several workarounds are available for this bug, but they extract a performance penalty. Because Intel has agreed to replace any Pentium processor with this flaw under a lifetime warranty replacement program, the best workaround is a free replacement!

Power Management Bugs

Starting with the second-generation Pentium processors, Intel added functions that enable these CPUs to be installed in energy-efficient systems. These are usually called *Energy Star systems* because they meet the specifications imposed by the EPA Energy Star program, but they are also unofficially called *green PCs* by many users.

Unfortunately, there have been several bugs with respect to these functions, causing them to either fail or be disabled. These bugs are in some of the functions in the power-management capabilities accessed through SMM. These problems are applicable only to the second-generation 75/90/100MHz processors because the first-generation 60/66MHz processors do not have SMM or power-management capabilities, and all higher-speed (120MHz and up) processors have the bugs fixed.

Most of the problems are related to the STPCLK# pin and the HALT instruction. If this condition is invoked by the chipset, the system will hang. For most systems, the only workaround for this problem is to disable the power-saving modes, such as suspend or sleep. Unfortunately, this means that your green PC won't be so green anymore! The best way to repair the problem is to replace the processor with a later stepping version that does not have the bug. These bugs affect the B1 stepping version of the 75/90/100MHz Pentiums, and they were fixed in the B3 and later stepping versions.

Pentium Processor Models and Steppings

We know that like software, no processor is truly ever perfect. From time to time, the manufacturers gather up what problems they have found and put into production a new stepping, which consists of a new set of masks that incorporate the corrections. Each subsequent stepping is better and more refined than the previous ones. Although no microprocessor is ever perfect, they come closer to perfection with each stepping. In the life of a typical microprocessor, a manufacturer might go through half a dozen or more such steppings.

See *Upgrading and Repairing PCs, Tenth Anniversary Edition*, which is included on the disc, for tables showing the Pentium processor steppings and revisions. This information is also available online from Intel via its Web site.

To determine the specifications of a given processor, you must look up the S-spec number in the table of processor specifications. To find your S-spec number, you have to read it off the chip directly. It can be found printed on both the top and bottom of the chip. If your heatsink is glued on, remove the chip and heatsink from the socket as a unit and read the numbers from the bottom of the chip. Then, you can look up the S-spec number in the Specification Guide Intel publishes (via its Web site); it tells you the specifications of that particular processor. Intel is introducing new chips all the time, so visit its Web site and search for the Pentium processor “Quick Reference Guide” in the developer portion of its site. There you will find a complete listing of all current processor specifications by S-spec number.

One interesting item to note is that several subtly different voltages are required by different Pentium processors. Table 3.27 summarizes the various processors and their required voltages.

Table 3.27 Pentium Processor Voltages

Model	Stepping	Voltage Spec.	Voltage Range
1	—	Std.	4.75V–5.25V
1	—	5V1	4.90V–5.25V
1	—	5V2	4.90V–5.40V
1	—	5V3	5.15V–5.40V
2+	B1-B5	Std.	3.135V–3.465V
2+	C2+	Std.	3.135V–3.600V
2+	—	VR	3.300V–3.465V
2+	B1-B5	VRE	3.45V–3.60V
2+	C2+	VRE	3.40V–3.60V
4+	—	MMX	2.70V–2.90V
4	3	Mobile	2.285V–2.665V
4	3	Mobile	2.10V–2.34V
8	1	Mobile	1.850V–2.150V
8	1	Mobile	1.665V–1.935V

Many of the newer Pentium motherboards have jumpers that allow for adjustments to the different voltage ranges. If you are having problems with a particular processor, it might not be matched correctly to your motherboard voltage output.

If you are purchasing an older, used Pentium system today, I recommend using only Model 2 (second-generation) or later version processors that are available in 75MHz or faster speeds. You should definitely get stepping C2 or later. Virtually all the important bugs and problems were fixed in the C2 and later releases. The newer Pentium processors have no serious bugs to worry about.

AMD-K5

The AMD-K5 is a Pentium-compatible processor developed by AMD and available as the PR75, PR90, PR100, PR120, PR133, PR166, and PR200. Because it is designed to be physically and functionally compatible, any motherboard that properly supports the Intel Pentium should support the AMD-K5. However, a BIOS upgrade might be required to properly recognize the AMD-K5. The K5 has the following features:

- 16KB instruction cache, 8KB write-back data cache
- Dynamic execution—branch prediction with speculative execution
- Five-stage, RISC-like pipeline with six parallel functional units

- High-performance floating-point unit
- Pin-selectable clock multiples of 1.5x, 1.75x, and 2x

The K5 is sold under the P-Rating system, which means that the number on the chip does not indicate true clock speed, only apparent speed when running certain applications.

Note that the actual clock speeds of several of these processors are not the same as their apparent rated speeds. For example, the PR-166 version actually runs at only 117 true MHz. Sometimes this can confuse the system BIOS, which might report the true speed rather than the P-Rating, which compares the chip against an Intel Pentium of that speed. AMD's assertion is that because of architecture enhancements over the Pentium, they do not need to run the same clock frequency to achieve that same performance. Even with such improvements, AMD marketed the K5 as a fifth-generation processor, just like the Pentium.

The AMD-K5 operates at 3.52V (VRE setting). Some older motherboards default to 3.3V, which is below specification for the K5 and could cause erratic operation. Because of the relatively low clock speeds and compatibility issues some users experienced with the K5, AMD replaced it with the K6 family of processors.

Intel P6 (686) Sixth-Generation Processors

The P6 (686) processors represent a new generation with features not found in the previous generation units. The P6 processor family began when the Pentium Pro was released in November 1995. Since then, Intel has released many other P6 chips, all using the same basic P6 core processor as the Pentium Pro. Table 3.28 shows the variations in the P6 family of processors.

Table 3.28 Intel P6 Processor Variations

Pentium Pro	Original P6 processor, includes 256KB, 512KB, or 1MB of full-core speed L2 cache
Pentium II	P6 with 512KB of half-core speed L2 cache
Pentium II Xeon	P6 with 512KB, 1MB, or 2MB of full-core speed L2 cache
Celeron	P6 with no L2 cache
Celeron-A	P6 with 128KB of on-die full-core speed L2 cache
Pentium III	P6 with SSE (MMX2), 512KB of half-core speed L2 cache
Pentium IIPE	P6 with 256KB of full-core speed L2 cache
Pentium IIIE	P6 with SSE (MMX2) plus 256KB or 512KB of full-core speed L2 cache
Pentium III Xeon	P6 with SSE (MMX2), 512KB, 1MB, or 2MB of full-core speed L2 cache

The main new feature in the fifth-generation Pentium processors was the superscalar architecture, in which two instruction execution units could execute instructions simultaneously in parallel. Later fifth-generation chips also added MMX technology to the mix, as well. So then what did Intel add in the sixth generation to justify calling it a whole new generation of chip? Besides many minor improvements, the real key features of all sixth-generation processors are Dynamic Execution and the Dual Independent Bus (DIB) architecture, plus a greatly improved superscalar design.

Dynamic Execution

Dynamic execution enables the processor to execute more instructions on parallel, so tasks are completed more quickly. This technology innovation is comprised of three main elements:

- *Multiple branch prediction.* Predict the flow of the program through several branches
- *Dataflow analysis.* Schedules instructions to be executed when ready, independent of their order in the original program
- *Speculative execution.* Increases the rate of execution by looking ahead of the program counter and executing instructions that are likely to be necessary

Dual Independent Bus

The other main P6 architecture feature is known as the Dual Independent Bus. This refers to the fact that the processor has two data buses: one for the system (motherboard) and the other just for cache. This enables the cache memory to run at speeds previously not possible.

Other Sixth-Generation Improvements

Finally, the P6 architecture upgrades the superscalar architecture of the P5 processors by adding more instruction execution units and by breaking down the instructions into special micro-ops. This is where the CISC instructions are broken down into more RISC commands. The RISC-level commands are smaller and easier for the parallel instruction units to execute more efficiently. With this design, Intel has brought the benefits of a RISC processor—high-speed dedicated instruction execution—to the CISC world. Note that the P5 had only two instruction units, whereas the P6 has at least six separate dedicated instruction units. It is said to be three-way superscalar because the multiple instruction units can execute up to three instructions in one cycle.

Other improvements in efficiency also are included in the P6 architecture: built-in multiprocessor support, enhanced error detection and correction circuitry, and optimization for 32-bit software.

Rather than just being a faster Pentium, the Pentium Pro, Pentium II/III, and other sixth-generation processors have many feature and architectural improvements. The core of the chip is very RISC-like, whereas the external instruction interface is classic Intel CISC. By breaking down the CISC instructions into several RISC instructions and running them down parallel execution pipelines, the overall performance is increased.

Compared to a Pentium at the same clock speed, the P6 processors are faster—as long as you're running 32-bit software. The P6 Dynamic Execution is optimized for performance primarily when running 32-bit software, such as Windows NT. If you are using 16-bit software, such as Windows 95 or 98 (which still operate part time in a 16-bit environment) and most older applications, the P6 does not provide as marked a performance improvement over similarly speed-rated Pentium and Pentium-MMX processors. That's because the Dynamic Execution capability is not fully exploited. Because of this, Windows NT/2000/XP often are regarded as the most desirable operating systems for use with Pentium Pro/II/III/Celeron processors. Although this is not exactly true (a Pentium Pro/II/III/Celeron runs fine under Windows 95/98), Windows NT/2000/XP does take better advantage of the P6's capabilities.

Note that it is really not so much the operating system but which applications you use. Software developers can take steps to gain the full advantages of the sixth-generation processors. This includes using modern compilers that can improve performance for all current Intel processors, writing 32-bit code where possible, and making code as predictable as possible to take advantage of the processor's Dynamic Execution multiple branch prediction capabilities.

Pentium Pro Processors

Intel's successor to the Pentium is called the Pentium Pro. The Pentium Pro was the first chip in the P6 or sixth-generation processor family. It was introduced in November 1995 and became widely available in 1996. The chip is a 387-pin unit that resides in Socket 8, so it is not pin compatible with earlier Pentiums. The new chip is unique among processors because it is constructed in a multichip module (MCM) physical format, which Intel calls a dual cavity PGA package. Inside the 387-pin chip carrier are two dies. One contains the actual Pentium Pro processor (shown in Figure 3.39), and the other contains a 256KB (the Pentium Pro with 256KB cache is shown in Figure 3.40), 512KB, or 1MB L2 cache. The processor die contains 5.5 million transistors, the 256KB cache die contains 15.5 million transistors, and the 512KB cache die(s) have 31 million transistors each—for a potential total of nearly 68 million transistors in a Pentium Pro with 1MB of internal cache! A Pentium Pro with 1MB cache has two 512KB cache die and a standard P6 processor die (see Figure 3.41).

Figure 3.39 Pentium Pro processor die. *Photograph used by permission of Intel Corporation.*

Figure 3.40 Pentium Pro processor with 256KB L2 cache (the cache is on the left side of the processor die). *Photograph used by permission of Intel Corporation.*

Figure 3.41 Pentium Pro processor with 1MB L2 cache (the cache is in the center and right portions of the die). *Photograph used by permission of Intel Corporation.*

The main processor die includes a 16KB split L1 cache with an 8KB two-way set associative cache for primary instructions and an 8KB four-way set associative cache for data.

Another sixth-generation processor feature found in the Pentium Pro is the DIB architecture, which addresses the memory bandwidth limitations of previous-generation processor architectures. Two buses make up the DIB architecture: the L2 cache bus (contained entirely within the processor package) and the processor-to-main memory system bus. The speed of the dedicated L2 cache bus on the Pentium Pro is equal to the full-core speed of the processor. This was accomplished by embedding the cache chips directly into the Pentium Pro package. The DIB processor bus architecture addresses processor-to-memory bus bandwidth limitations. It offers up to three times the performance bandwidth of the single-bus, "Socket 7" generation processors, such as the Pentium.

Table 3.29 shows Pentium Pro processor specifications, and Table 3.30 shows the specifications for each model within the Pentium Pro family because many variations exist from model to model.

Table 3.29 Pentium Pro Family Processor Specifications

Introduced	November 1995
Maximum rated speeds	150MHz, 166MHz, 180MHz, 200MHz
CPU clock	2x, 2.5x, 3x, 3.5x, 4x
Internal registers	32-bit
External data bus	64-bit
Memory address bus	36-bit
Addressable memory	64GB
Virtual memory	64TB
Integral L1 cache size	8KB code, 8KB data (16KB total)
Integrated L2 cache bus	64-bit, full-core speed
Socket/Slot	Socket 8
Physical package	387-pin dual cavity PGA
Package dimensions	2.46 (6.25cm)×2.66 (6.76cm)
Math coprocessor	Built-in FPU
Power management	SMM
Operating voltage	3.1V or 3.3V

Table 3.30 Pentium Pro Processor Specifications by Processor Model

<i>Pentium Pro Processor (200MHz) with 1MB Integrated Level 2 Cache</i>	
Introduction date	August 18, 1997
Clock speeds	200MHz (66MHz×3)
Number of transistors	5.5 million (0.35-micron process), plus 62 million in 1MB L2 cache (0.35-micron)
Cache memory	8K×2 (16KB) L1, 1MB core-speed L2
Die size	0.552" per side (14.0mm)
<i>Pentium Pro Processor (166/180/200MHz)</i>	
Introduction date	November 1, 1995
Clock speeds	200MHz (66MHz×3), 180MHz (60MHz×3), 166MHz (66MHz×2.5)
Number of transistors	5.5 million (0.35-micron process), plus 15.5 million in 256KB L2 cache (0.6-micron), or 31 million in 512KB L2 cache (0.35-micron)
Cache memory	8K×2 (16KB) L1, 256KB or 512KB core-speed L2
Die size	0.552" per side (14.0mm)
<i>Pentium Pro Processor (150MHz)</i>	
Introduction date	November 1, 1995
Clock speeds	150MHz (60MHz×2.5)
Number of transistors	5.5 million (0.6-micron process), plus 15.5 million in 256KB L2 cache (0.6-micron)
Cache memory	8K×2 (16KB) L1, 256KB core-speed L2
Die size	0.691" per side (17.6mm)

Performance comparisons on the iCOMP 2.0 Index rate a classic Pentium 200MHz at 142, whereas a Pentium Pro 200MHz scores an impressive 220. Just for comparison, note that a Pentium MMX 200MHz falls right about in the middle in regards to performance at 182. Keep in mind that using a Pentium Pro with any 16-bit software applications nullifies much of the performance gain shown by the iCOMP 2.0 rating.

Similar to the Pentium before it, the Pentium Pro runs clock multiplied on a 66MHz motherboard. The following table lists speeds for Pentium Pro processors and motherboards:

CPU Type/Speed	CPU Clock	Motherboard Speed
Pentium Pro 150	2.5x	60
Pentium Pro 166	2.5x	66
Pentium Pro 180	3x	60
Pentium Pro 200	3x	66

The integrated L2 cache is one of the really outstanding features of the Pentium Pro. By building the L2 cache into the CPU and getting it off the motherboard, the Pentium Pro can now run the cache at full processor speed rather than the slower 60MHz or 66MHz motherboard bus speed. In fact, the L2 cache features its own internal 64-bit back-side bus, which does not share time with the external 64-bit front-side bus used by the CPU. The internal registers and data paths are still 32-bit, as with the Pentium. By building the L2 cache into the system, motherboards can be cheaper because they no longer require separate cache memory. Some boards might still try to include cache memory in their designs, but the general consensus is that L3 cache (as it would be called) would offer less improvement with the Pentium Pro than with the Pentium.

One of the features of the built-in L2 cache is that multiprocessing is greatly improved. Rather than just SMP, as with the Pentium, the Pentium Pro supports a new type of multiprocessor configuration called the Multiprocessor Specification (MPS 1.1). The Pentium Pro with MPS enables configurations of up to four processors running together. Unlike other multiprocessor configurations, the Pentium Pro avoids cache coherency problems because each chip maintains a separate L1 and L2 cache internally.

Pentium Pro-based motherboards are pretty much exclusively PCI and ISA bus-based, and Intel has produced its own chipsets for these motherboards. Because of the greater cooling and space requirements, Intel designed the new ATX motherboard form factor to better support the Pentium Pro and other future processors, such as the Pentium II/III/4. Even so, the Pentium Pro can be found in all types of motherboard designs; ATX is not mandatory.

- ▶▶ See "Motherboard Form Factors," p. 202, and "Sixth-Generation (P6 Pentium Pro/Pentium II Class) Chipsets," p. 254.

The Pentium Pro system manufacturers were tempted to stick with the Baby-AT form factor. The big problem with the standard Baby-AT form factor is keeping the CPU properly cooled. The massive Pentium Pro processor consumes more than 25 watts and generates an appreciable amount of heat.

Four special VID pins are on the Pentium Pro processor. These pins can be used to support automatic selection of power supply voltage. Therefore, a Pentium Pro motherboard does not have voltage regulator jumper settings like most Pentium boards, which greatly eases the setup and integration of a Pentium Pro system. These pins are not actually signals, but are either an open circuit in the package or a short circuit to voltage. The sequence of opens and shorts defines the voltage the processor requires. In addition to allowing for automatic voltage settings, this feature was designed to support voltage specification variations on future Pentium Pro processors. The VID pins are named VID0 through VID3, and the definition of these pins is shown in Table 3.31. A 1 in this table refers to an open pin, and a 0 refers to a short to ground. The voltage regulators on the motherboard should supply the requested voltage or disable itself.

Table 3.31 Pentium Pro Voltage Identification Definition

VID [3:0]	Voltage Setting	VID [3:0]	Voltage Setting	VID [3:0]	Voltage Setting	VID [3:0]	Voltage Setting
0000	3.5	1000	2.7	0100	3.1	1100	2.3
0001	3.4	1001	2.6	0101	3.0	1101	2.2
0010	3.3	1010	2.5	0110	2.9	1110	2.1
0011	3.2	1011	2.4	0111	2.8	1111	No CPU present

Most Pentium Pro processors run at 3.3V, but a few run at 3.1V. Note that the 1111 (or all opens) ID can be used to detect the absence of a processor in a given socket.

The Pentium Pro never did become very popular on the desktop, but it did find a niche in file-server applications primarily because of the full-core speed high-capacity internal L2 cache. For a time, Intel offered an OverDrive upgrade processor for the Pentium Pro, but it no longer offers any OverDrive processors. PowerLeap offers several upgrades for Pentium Pro that use 700MHz-class Celeron PPGA processors in an adapter.

Pentium II Processors

Intel revealed the Pentium II in May 1997. Prior to its official unveiling, the Pentium II processor was popularly referred to by its codename, Klamath, and was surrounded by much speculation throughout the industry. The Pentium II is essentially the same sixth-generation processor as the Pentium Pro, with MMX technology added (which included double the L1 cache and 57 new MMX instructions); however, there are a few twists to the design. The Pentium II processor die is shown in Figure 3.42.

Figure 3.42 Pentium II Processor die. *Photograph used by permission of Intel Corporation.*

From a physical standpoint, it was a big departure from previous processors. Abandoning the chip in a socket approach used by virtually all processors up until this point, the Pentium II chip is characterized by its SEC cartridge design. The processor, along with several L2 cache chips, is mounted on a small circuit board (much like an oversized-memory SIMM) as shown in Figure 3.43, and the circuit board is then sealed in a metal and plastic cartridge. The cartridge is then plugged into the motherboard through an edge connector called Slot 1, which looks very much like an adapter card slot.

Figure 3.43 Pentium II processor board (normally found inside the SEC cartridge). *Photograph used by permission of Intel Corporation.*

The two variations on these cartridges are called SECC (single edge contact cartridge) and SECC2. Figure 3.44 shows a diagram of the SECC package; Figure 3.45 shows the SECC2 package.

Figure 3.44 SECC components showing an enclosed processor board.

Figure 3.45 SECC, rev. 2 components showing a half-enclosed processor board.

As you can see from these figures, the SECC2 version is cheaper to make because it uses fewer overall parts. It also allows for a more direct heatsink attachment to the processor for better cooling. Intel transitioned from SECC to SECC2 in the beginning of 1999; all later PII chips, and the Slot 1 PIII chips that followed, use the improved SECC2 design.

By using separate chips mounted on a circuit board, Intel could build the Pentium II much less expensively than the multiple die within a package used in the Pentium Pro. Intel could also use cache chips from other manufacturers and more easily vary the amount of cache in future processors compared to the Pentium Pro design.

Intel has offered Pentium II processors with the following speeds:

CPU Type/Speed	CPU Clock	Motherboard Speed
Pentium II 233MHz	3.5x	66MHz
Pentium II 266MHz	4x	66MHz
Pentium II 300MHz	4.5x	66MHz
Pentium II 333MHz	5x	66MHz
Pentium II 350MHz	3.5x	100MHz
Pentium II 400MHz	4x	100MHz
Pentium II 450MHz	4.5x	100MHz

The Pentium II processor core has 7.5 million transistors and is based on Intel's advanced P6 architecture. The Pentium II started out using a 0.35-micron process technology, although the 333MHz and faster Pentium IIs are based on 0.25-micron technology. This enables a smaller die, allowing increased core frequencies and reduced power consumption. At 333MHz, the Pentium II processor delivers a 75%–150% performance boost, compared to the 233MHz Pentium processor with MMX technology, and approximately 50% more performance on multimedia benchmarks. As shown earlier in Table 3.3, the iCOMP 2.0 Index rating for the Pentium II 266MHz chip is more than twice as fast as a classic Pentium 200MHz.

Aside from speed, the best way to think of the Pentium II is as a Pentium Pro with MMX technology instructions and a slightly modified cache design. It has the same multiprocessor scalability as the Pentium Pro, as well as the integrated L2 cache. The 57 new multimedia-related instructions carried over from the MMX processors and the capability to process repetitive loop commands more efficiently are included as well. Also included as a part of the MMX upgrade is double the internal L1 cache from the Pentium Pro (from 16KB total to 32KB total in the Pentium II).

Maximum power usage for the Pentium II is shown in the following table:

Core Speed	Power Draw	Process	Voltage
450MHz	27.1w	0.25-micron	2.0V
400MHz	24.3w	0.25-micron	2.0V
350MHz	21.5w	0.25-micron	2.0V
333MHz	23.7w	0.25-micron	2.0V
300MHz	43.0w	0.35-micron	2.8V
266MHz	38.2w	0.35-micron	2.8V
233MHz	34.8w	0.35-micron	2.8V

You can see that the highest speed 450MHz version of the Pentium II actually uses less power than the slowest original 233MHz version! This was accomplished by using the smaller 0.25-micron process and running the processor on a lower voltage of only 2.0V. Pentium III and subsequent processors used even smaller processes and lower voltages to continue this trend.

The Pentium II includes Dynamic Execution, which describes unique performance-enhancing developments by Intel and was first introduced in the Pentium Pro processor. Major features of Dynamic Execution include multiple branch prediction, which speeds execution by predicting the flow of the program through several branches; dataflow analysis, which analyzes and modifies the program order to execute instructions when ready; and speculative execution, which looks ahead of the program counter and executes instruction that are likely to be needed. The Pentium II processor expands on these capabilities in sophisticated and powerful new ways to deliver even greater performance gains.

Similar to the Pentium Pro, the Pentium II also includes DIB architecture. The term *Dual Independent Bus* comes from the existence of two independent buses on the Pentium II processor—the L2 cache bus and the processor-to-main-memory system bus. The Pentium II processor can use both buses simultaneously, thus getting as much as twice as much data in and out of the Pentium II processor as a single-bus architecture processor. The DIB architecture enables the L2 cache of the 333MHz Pentium II processor to run 2 1/2 times as fast as the L2 cache of Pentium processors. As the frequency of future Pentium II processors increases, so will the speed of the L2 cache. Also, the pipelined system bus enables simultaneous parallel transactions instead of singular sequential transactions. Together, these DIB architecture improvements offer up to three times the bandwidth performance over a single-bus architecture as with the regular Pentium.

Table 3.32 shows the general Pentium II processor specifications. Table 3.33 shows the specifications that vary by model.

Table 3.32 Pentium II General Processor Specifications

Bus speeds	66MHz, 100MHz
CPU clock multiplier	3.5x, 4x, 4.5x, 5x
CPU speeds	233MHz, 266MHz, 300MHz, 333MHz, 350MHz, 400MHz, 450MHz
Cache memory	16K×2 (32KB) L1, 512KB 1/2-speed L2
Internal registers	32-bit
External data bus	64-bit system bus w/ ECC; 64-bit cache bus w/ optional ECC
Memory address bus	36-bit
Addressable memory	64GB
Virtual memory	64TB
Physical package	Single edge contact cartridge (S.E), 242 pins
Package dimensions	5.505" (13.98cm) × 2.473" (6.28cm) × 0.647" (1.64cm)
Math coprocessor	Built-in FPU
Power management	SMM

Table 3.33 Pentium II Specifications by Model

<i>Pentium II MMX Processor (350MHz, 400MHz, and 450MHz)</i>	
Introduction date	April 15, 1998
Clock speeds	350MHz (100MHz×3.5), 400MHz (100MHz×4), and 450MHz (100MHz×4.5)
iCOMP Index 2.0 rating	386 (350MHz), 440 (400MHz), and 483 (450MHz)
Number of transistors	7.5 million (0.25-micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	4GB
Operating voltage	2.0V
Slot	Slot 1
Die size	0.400" per side (10.2mm)
<i>Mobile Pentium II Processor (266MHz, 300MHz, 333MHz, and 366MHz)</i>	
Introduction date	January 25, 1999
Clock speeds	266MHz, 300MHz, 333MHz, and 366MHz
Number of transistors	27.4 million (0.25-micron process), 256KB on-die L2 cache
Ball grid array (BGA)	Number of balls = 615
Dimensions	Width = 31mm; length = 35mm
Core voltage	1.6 volts
Thermal design power ranges by frequency	366MHz = 9.5 watts; 333MHz = 8.6 watts; 300MHz = 7.7 watts; 266MHz = 7.0 watts
<i>Pentium II MMX Processor (333MHz)</i>	
Introduction date	January 26, 1998
Clock speed	333MHz (66MHz×5)
iCOMP Index 2.0 rating	366
Number of transistors	7.5 million (0.25-micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Operating voltage	2.0V
Slot	Slot 1
Die size	0.400" per side (10.2mm)
<i>Pentium II MMX Processor (300MHz)</i>	
Introduction date	May 7, 1997
Clock speed	300MHz (66MHz×4.5)
iCOMP Index 2.0 rating	332
Number of transistors	7.5 million (0.35-micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Die size	0.560" per side (14.2mm)
<i>Pentium II MMX Processor (266MHz)</i>	
Introduction date	May 7, 1997
Clock speed	266MHz (66MHz×4)
iCOMP Index 2.0 rating	303
Number of transistors	7.5 million (0.35-micron process), plus 31 million in 512KB L2 cache

Table 3.33 Continued

<i>Pentium II MMX Processor (266MHz)</i>	
Cacheable RAM	512MB
Slot	Slot 1
Die size	0.560" per side (14.2mm)
<i>Pentium II MMX Processor (233MHz)</i>	
Introduction date	May 7, 1997
Clock speed	233MHz (66MHz×3.5)
iCOMP Index 2.0 rating	267
Number of transistors	7.5 million (0.35-micron process), plus 31 million in 512KB L2 cache
Cacheable RAM	512MB
Slot	Slot 1
Die size	0.560" per side (14.2mm)

The L1 cache always runs at full-core speeds because it is mounted directly on the processor die. The L2 cache in the Pentium II normally runs at half-core speed, which saves money and allows for less expensive cache chips to be used. For example, in a 333MHz Pentium II, the L1 cache runs at a full 333MHz, whereas the L2 cache runs at 167MHz. Even though the L2 cache is not at full-core speed as it was with the Pentium Pro, this is still far superior to having cache memory on the motherboard running at the 66MHz motherboard speed of most Socket 7 Pentium designs. Intel claims that the DIB architecture in the Pentium II enables up to three times the bandwidth of normal single-bus processors, such as the original Pentium.

By removing the cache from the processor's internal package and using external chips mounted on a substrate and encased in the cartridge design, Intel can now use more cost-effective cache chips and more easily scale the processor up to higher speeds. The Pentium Pro was limited in speed to 200MHz, largely due to the inability to find affordable cache memory that runs any faster. By running the cache memory at half-core speed, the Pentium II can run up to 400MHz while still using 200MHz-rated cache chips. To offset the half-core speed cache used in the Pentium II, Intel doubled the basic amount of integrated L2 cache from 256KB standard in the Pro to 512KB standard in the Pentium II.

Note that the tag RAM included in the L2 cache enables up to 512MB of main memory to be cacheable in PII processors from 233MHz to 333MHz. The 350MHz, 400MHz, and faster versions include an enhanced tag-RAM that allows up to 4GB of main memory to be cacheable. This is very important if you ever plan on adding more than 512MB of memory. In that case, you would definitely want the 350MHz or faster version; otherwise, memory performance would suffer.

The system bus of the Pentium II provides "glueless" support for up to two processors. This enables low-cost, two-way multiprocessing on the L2 cache bus. These system buses are designed especially for servers or other mission-critical system use where reliability and data integrity are important. All Pentium IIs also include parity-protected address/request and response system bus signals with a retry mechanism for high data integrity and reliability.

To install the Pentium II in a system, a special processor-retention mechanism is required. This consists of a mechanical support that attaches to the motherboard and secures the Pentium II processor in Slot 1 to prevent shock and vibration damage. Retention mechanisms should be provided by the motherboard manufacturer. (For example, the Intel Boxed AL440FX and DK440LX motherboards included a retention mechanism, plus other important system integration components.)

The Pentium II can generate a significant amount of heat that must be dissipated. This is accomplished by installing a heatsink on the processor. Many of the Pentium II processors use an active heatsink that incorporates a fan. Unlike heatsink fans for previous Intel boxed processors, the Pentium II fans draw power from a three-pin power header on the motherboard. Most motherboards provide several fan connectors to supply this power.

Special heatsink supports are necessary to furnish mechanical support between the fan heatsink and support holes on the motherboard. Normally, a plastic support is inserted into the heatsink holes in the motherboard next to the CPU, before installing the CPU/heatsink package. Most fan heatsinks have two components: a fan in a plastic shroud and a metal heatsink. The heatsink is attached to the processor's thermal plate and should not be removed. The fan can be removed and replaced if necessary—for example, if it has failed. Figure 3.46 shows the SEC assembly with fan, power connectors, mechanical supports, and the slot and support holes on the motherboard.

Figure 3.46 Pentium II/III processor and heatsink assembly.

The following tables show the specifications unique to certain versions of the Pentium II processor.

To identify exactly which Pentium II processor you have and what its capabilities are, look at the specification number printed on the SEC cartridge. You will find the specification number in the dynamic mark area on the top of the processor module. See Figure 3.47 to locate these markings.

After you have located the specification number (actually, it is an alphanumeric code), you can look it up in Table 3.34 to see exactly which processor you have.

For example, a specification number of SL2KA identifies the processor as a Pentium II 333MHz running on a 66MHz system bus, with an ECC L2 cache, and indicates that this processor runs on only 2.0V. The stepping is also identified, and by looking in the “Pentium II Specification Update Manual” published by Intel, you could figure out exactly which bugs were fixed in that revision.

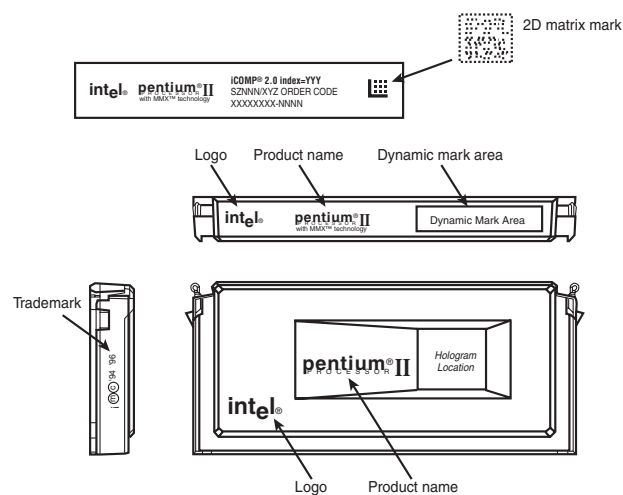

Figure 3.47 Pentium II/III SECC.

CPUID = The internal ID returned by the CPUID instruction

ECC = Error correcting code

OLGA = Organic land grid array

PLGA = Plastic land grid array

SECC = Single edge contact cartridge

SECC2 = Single edge contact cartridge revision 2

1. This is a boxed Pentium II processor with an attached fan heatsink.
2. These processors have an enhanced L2 cache, which can cache up to 4GB of main memory. Other standard PII processors can cache only up to 512MB of main memory.
3. These boxed processors might have packaging that incorrectly indicates ECC support in the L2 cache.
4. This is a boxed Pentium II OverDrive processor with an attached fan heatsink, designed for upgrading Pentium Pro (Socket 8) systems.
5. These parts operate only at the specified clock multiplier frequency ratio at which they were manufactured. They can be overlocked only by increasing the bus speed.

The two variations of the SECC2 cartridge vary by the type of processor core package on the board. The plastic land grid array (PLGA) is the older type of packaging used in previous SECC cartridges and was eventually phased out. A newer organic land grid array (OLGA), which is a processor core package that is smaller and easier to manufacture, took its place. It also enabled better thermal transfer between the processor die and the heatsink, which was attached directly to the top of the OLGA chip package. Figure 3.48 shows the open back side (where the heatsink would be attached) of SECC2 processors with PLGA and OLGA cores.

Figure 3.48 SECC2 processors with PLGA (top) and OLGA (bottom) cores.

Pentium II motherboards have an onboard voltage regulator circuit designed to power the CPU. Some Pentium II processors run at several different voltages, so the regulator must be set to supply the correct voltage for the specific processor you are installing. As with the Pentium Pro and unlike the older Pentium, no jumpers or switches must be set; the voltage setting is handled completely automatically through the VID pins on the processor cartridge. Table 3.35 shows the relationship between the pins and the selected voltage.

To ensure the system is ready for all Pentium II processor variations, the values in **bold** must be supported. Most Pentium II processors run at 2.8V, with some newer ones at 2.0V.

The Pentium II Mobile Module is a Pentium II for notebooks that includes the North Bridge of the high-performance 440BX chipset. This is the first chipset on the market that allows 100MHz processor bus operation, although that is currently not supported in the mobile versions. The 440BX chipset was released at the same time as the 350MHz and 400MHz versions of the Pentium II.

Newer variations on the Pentium II include the Pentium IIPE, which is a mobile version that includes 256KB of L2 cache directly integrated into the die. Therefore, it runs at full-core speed, making it faster than the desktop Pentium II because the desktop chips use half-speed L2 cache.

Table 3.35 Pentium II/III/Celeron Voltage ID Pin Definitions

VID4	VID3	VID2	VID1	VID0	Voltage	VID4	VID3	VID2	VID1	VID0	Voltage
0	1	1	1	1	1.30	1	1	1	1	1	No Core
0	1	1	1	0	1.35	1	1	1	1	0	2.1
0	1	1	0	1	1.40	1	1	1	0	1	2.2
0	1	1	0	0	1.45	1	1	1	0	0	2.3
0	1	0	1	1	1.50	1	1	0	1	1	2.4
0	1	0	1	0	1.55	1	1	0	1	0	2.5
0	1	0	0	1	1.60	1	1	0	0	1	2.6
0	1	0	0	0	1.65	1	1	0	0	0	2.7
0	0	1	1	1	1.70	1	0	1	1	1	2.8
0	0	1	1	0	1.75	1	0	1	1	0	2.9
0	0	1	0	1	1.80	1	0	1	0	1	3.0
0	0	1	0	0	1.85	1	0	1	0	0	3.1
0	0	0	1	1	1.90	1	0	0	1	1	3.2
0	0	0	1	0	1.95	1	0	0	1	0	3.3
0	0	0	0	1	2.00	1	0	0	0	1	3.4
0	0	0	0	0	2.05	1	0	0	0	0	3.5

0 = Processor pin connected to Vss.

VID0–VID3 used on Socket 370.

VID0–VID4 used on Slot 1.

1 = Open on processor.

Socket 370 supports 1.30–2.05V settings only.

Slot 1 supports 1.30–3.5V settings.

Celeron

The Celeron processor is a chameleon. It was originally a P6 with the same processor core as the Pentium II in the original two versions; later it came with the same core as the PIII; and more recently it uses the Pentium 4 core. It is designed mainly for lower-cost PCs.

Most of the features for the Celeron are the same as the Pentium II, III, or 4 because it uses the same internal processor cores. The main differences are in packaging, L2 cache amount, and CPU bus speed.

The first version of the Celeron was available in a package called the single edge processor package (SEPP or SEP package). The SEP package is basically the same Slot 1 design as the SECC used in the Pentium II/III, with the exception of the fancy plastic cartridge cover. This cover is deleted in the Celeron, making it cheaper to produce and sell. Essentially, the original Celeron used the same circuit board as is inside the Pentium II package.

◀◀ See “Single Edge Contact and Single Edge Processor Packaging,” p. 86.

Even without the plastic covers, the Slot 1 packaging was more expensive than it should have been. This was largely due to the processor retention mechanisms (stands) required to secure the processor into Slot 1 on the motherboard, as well as the larger and more complicated heatsinks required. This, plus competition from the lower-end Socket 7 systems using primarily AMD processors, led Intel to introduce the Celeron in a socketed form. The socket is called PGA-370 or Socket 370 because it has 370 pins. The processor package designed for this socket is called the plastic pin grid array (PPGA) package (see Figure 3.49) or flip chip PGA (FC-PGA). Both the PPGA and FC-PGA packages plug into the 370 pin socket and allow for lower-cost, lower-profile, and smaller systems because of the less expensive processor retention and cooling requirements of the socketed processor.

◀◀ See “Socket 370 (PGA-370),” p. 95.

Figure 3.49 Celeron processors in the FC-PGA, PPGA, and SEP packages.

All Celeron processors at 433MHz and lower have been available in the SEPP that plugs into the 242-contact slot connector (Slot 1). The 300MHz and higher versions also are available in the PPGA package. This means that the 300MHz to 433MHz have been available in both packages, whereas the 466MHz and higher-speed versions are available only in the PPGA. The fastest Celeron processor for Socket 370 runs at 1.4GHz; faster Celerons use Socket 478 and are based on the Pentium 4 design.

Motherboards that include Socket 370 can accept the PGA versions of both the Celeron and Pentium III in most cases. If you want to use a Socket 370 version of the Celeron in a Slot 1 motherboard, slot-to-socket adapters (usually called slot-kets) are available for about \$10–\$20 that plug into Slot 1 and incorporate a Socket 370 on the card. Figure 3.50 shows a typical slot-ket adapter.

Figure 3.50 Slot-ket adapter for installing PPGA processors in Slot 1 motherboards.

Highlights of the Celeron include the following:

- Available at 300MHz (300A) and higher core frequencies with 128KB on-die L2 cache; 300MHz and 266MHz core frequencies without L2 cache
- L2 cache supports up to 4GB RAM address range and ECC
- Uses same P6 core processor as the Pentium II (266MHz through 533MHz) and now the Pentium III (533A MHz and higher) and Pentium 4 (1.7GHz and higher)
- Dynamic execution microarchitecture
- Operates on a 66MHz, 100MHz, or 400MHz CPU bus depending on the version
- Specifically designed for lower-cost value PC systems
- Includes MMX technology; Celeron 533A and higher include SSE; Celeron 1.7GHz and higher include SSE2
- More cost-effective packaging technology, including SEP, PPGA, and FC-PGA or FC-PGA2 packages
- Integrated L1 and L2 cache on most models, with amount and type depending on the version; typically, the Celeron has half the L2 cache of the processor core it is patterned after
- Integrated thermal diode for temperature monitoring

The Intel Celeron processors from the 300A and higher include integrated 128KB L2 cache. The core for the 300A through 533MHz versions that are based on the Pentium II core include 19 million transistors because of the addition of the integrated 128KB L2 cache. The 533A and faster versions are based on the Pentium III core and incorporate 28.1 million transistors. The 1.7GHz and faster versions are based on the Pentium 4 core with 42 million transistors. The Pentium III and Pentium 4-based versions actually have 256KB of L2 cache on the die; however, 128KB is disabled, leaving 128KB of functional L2 cache. This was done because it was cheaper for Intel to simply make the Celeron using the same die as the Pentium III or 4 and just disable part of the cache on the Celeron versions, rather than coming up with a unique die for the newer Celerons. The Pentium III-based Celeron processors also support the SSE in addition to MMX instructions, whereas the Pentium 4-based versions support SSE2 instructions. The older Celerons based on the Pentium II core support only MMX.

All the Celerons in SEPP and PPGA form are manufactured using the 0.25-micron process, whereas those in FC-PGA and FC-PGA2 form are made using an even better 0.18-micron process. The smaller process reduces processor heat and enables higher speeds.

What Exactly Is a Celeron?

The name *Celeron* is the general name Intel has used for its economy line of processors going all the way back to the Pentium II. In short, a *Celeron* is a Pentium II, Pentium III, or Pentium 4 processor with some features reduced or removed. Celerons are basically designed as less-expensive, stripped-down, economy versions of Intel's main processors. Although the specific details have varied over the years, Celerons have normally differed from Intel's Pentium II, Pentium III, or current Pentium 4 processors in the following ways:

- Lower CPU clock speeds
- Lower CPU bus speeds
- Smaller L2 cache

These differences have made Celeron processors less powerful than the particular Pentium II/III/4 they are based on, but these differences also make Celeron processors and Celeron-based systems less expensive. If you're looking for a low-cost system that's "Intel inside," a Celeron-based system is one way to get there.

A Brief Celeron History

The original Celerons were economy versions of the Intel Pentium II processor. Intel figured that by taking a Pentium II and deleting the separate L2 cache chips mounted inside the processor cartridge (and also deleting the cosmetic cover), it could create a "new" processor that was basically just a slower version of the Pentium II. As such, the first 266MHz and 300MHz Celeron models didn't include any L2 cache. Unfortunately, this proved to have far too great a crippling effect on performance, so starting with the 300A versions, the Celeron received 128KB of on-die full-speed L2 cache, which was actually faster and more advanced than the 512KB of half-speed cache used in the Pentium II it was based on! In fact, the Celeron was the first PC processor to receive on-die L2 cache. It wasn't until the Coppermine version of the Pentium III appeared that on-die L2 cache migrated to Intel's main processors.

Needless to say, this caused a lot of confusion in the marketplace about the Celeron. Considering that the Celeron started out as a "crippled" Pentium II and then was revised so as to actually be superior in some ways to the Pentium II on which it was based (all the while selling for less), many didn't know just where the Celeron stood in terms of performance. Fortunately, the crippling lack of L2 cache existed only in the earliest Celeron versions; all of those at speeds greater than 300MHz have on-die full-speed L2 cache.

The earliest Celerons from 266MHz up through 400MHz were produced in a SEPP design that physically looked like a circuit board and that was designed to fit into Slot 1. This is the same slot the Pentium II used, meaning the Celeron SEPP plugged into any Pentium II Slot-1 motherboard. As the Celeron continued to develop, the form factor was changed to correspond with changes in the Pentium II-, III-, and 4-class processors from which it was adapted. Starting with the 300A processor (300MHz Celeron with 128KB of on-die Level 2 cache), Celerons were produced in a PPGA package using the Socket 370 interface. This socket, with differences in voltage, was later used for most versions of the Pentium III. Celerons using Socket 370 range in speed from 300MHz all the way up to 1.4GHz. Along the way, the packaging changed from PPGA to FC-PGA and FC-PGA2. The latter added a metal heat spreader on top of the die offering better protection for the fragile die.

The latest Celerons are based on Pentium 4 processors. They are produced in an FC-PGA2 package that fits into the same Socket 478 that recent Pentium 4 processors use; the Celeron was never produced in the short-lived Socket 423 form factor the original Pentium 4 processors used.

As this very brief history shows, the name *Celeron* has never meant anything more specific than a reduced-performance version of Intel's current mainstream processor. Before you can decide whether a particular Celeron processor is a suitable choice, you need to know what its features are and especially on which processor it is based. At least eight discrete variations of the Celeron processor exist, which are detailed in Table 3.36.

Table 3.36 Celeron CPU Variations

Celeron Version	Based On	Codename	Process (Micron)	L2 Cache (KB)	Multimedia Support
Celeron	Pentium II Deschutes	Covington	0.25	0	MMX
Celeron A	Pentium II Deschutes	Mendocino	0.25	128	MMX
Celeron A-PGA	Pentium II Deschutes	Mendocino	0.25	128	MMX
Celeron III	Pentium III Coppermine	Coppermine-128	0.18	128	SSE
Celeron IIIA	Pentium III Tualatin	Tualatin-256	0.13	256	SSE
Celeron 4	Pentium 4 Willamette	Willamette-128	0.18	128	SSE2
Celeron 4A	Pentium 4 Northwood	Northwood-128	0.13	128	SSE2
Celeron D	Pentium 4 Prescott	Prescott-256	0.09	256	SSE3

*All Celeron III below 800MHz use the 66MHz CPU bus; all Celeron III from 800MHz through 1.1GHz use the 100MHz bus.

SEPP = Single edge processor package

FC-PGA = Flip chip pin grid array

FC-PGA2 = FC-PGA with added heat spreader

MMX = Multimedia extensions; 57 additional instructions for graphics and sound processing

SSE = Streaming SIMD (single instruction multiple data) extensions; MMX plus 70 additional instructions for graphics and sound processing

Figure 3.51 shows the various Celeron package types.

Figure 3.51 Processors released under the Celeron brand. *Photos courtesy of Intel.*

As you can see, there is a wide range of what is called a Celeron, and you could consider the Celeron as a family of different core processor models in several package variations.

The following sections discuss the differences between these Celeron processors.

Physical Interface	Package	CPU Bus Speed	Min. Speed	Max. Speed
Slot-1	SEPP	66MHz	266MHz	300MHz
Slot-1	SEPP	66MHz	300MHz	433MHz
Socket 370	PPGA	66MHz	300MHz	533MHz
Socket 370	FC-PGA	66/100MHz*	533MHz	1.1GHz
Socket 370	FC-PGA2	100MHz	900MHz	1.4GHz
Socket 478	FC-PGA2	400MHz	1.7GHz	1.8GHz
Socket 478	FC-PGA2	400MHz	2.0GHz	2.8GHz
Socket 478/Socket T (LGA775)	FC-PGA2	533MHz	2.53GHz	3.2GHz

SSE2 = Streaming SIMD extensions 2; SSE plus 144 additional instructions for graphics and sound processing

The "Celeron Version" names listed here are not official; I made them up as a way to clearly identify the different Celeron processors.

The Celeron 4A version is not out yet, but it will be introduced during the third quarter of 2004.

Minimum and maximum speeds indicate the slowest and fastest rated speeds of each variation offered.

Socket 370 Versus Socket 478 Celerons

Although both Socket 370 and Socket 478 processors bear the name Celeron, enormous differences in internal design exist between Celeron processors in these form factors. These differences directly relate to which Intel Pentium-class processor a particular Celeron processor is based on.

Socket 370 Celerons are based on various versions of the Pentium II and Pentium III architecture, whereas Socket 478 Celerons are based on the Pentium 4 architecture. This discussion focuses on the Celeron IIIA, Celeron 4, and Celeron 4A versions because the previous versions have been discontinued.

Intel offers Celeron IIIA versions for new Socket 370 motherboards in speeds from 900MHz to 1.4GHz, Celeron 4 versions for Socket 478 motherboards in speeds from 1.7GHz to 1.8GHz, and faster Celeron 4A models in speeds from 2.0GHz to 2.8GHz. It also offers new Prescott-based Celeron D models in both Socket 478 and Socket T (LGA775) versions in speeds from 2.53GHz to 3.2GHz.

What are the differences in these processors, other than clock speed?

- All Celeron IIIA Celerons have a CPU bus (sometimes called front-side-bus [FSB]) speed of 100MHz, whereas all Socket 478 Celerons have a CPU bus speed of 400MHz.
- Celeron IIIA versions based on the Pentium III Tualatin core have 256KB of L2 cache, whereas those based on the earlier Pentium III Coppermine core or Pentium II Deschutes core have 128KB of L2 cache. All current Socket 478 Celerons based on the Pentium 4 Willamette core have 128KB of L2 cache, and newer versions based on the Northwood core also will have 128KB of L2 cache.

How Tualatin, Willamette, and Northwood Improve the Celeron

Compared to Celerons based on the previous Pentium III Coppermine core, Tualatin-based Celerons have the following differences:

- Larger L2 memory cache (256KB versus 128KB)
- Improved L2 cache design for better performance
- FC-PGA2 packaging, which includes a metal heat spreader over the fragile CPU core to protect it when attaching a heatsink

However, these improvements come at a cost in compatibility. Like the Tualatin-core versions of the Pentium III, Celerons based on the Tualatin core don't work in motherboards designed for older Pentium III or Celeron chips. Socket 370 is physically the same, but the Tualatin core redefines 10 pins in the socket, which require corresponding changes in the chipset and motherboard. So, if you're looking for a way to speed up an older Celeron by installing a Tualatin-core Celeron IIIA, make sure the motherboard is Tualatin-ready. Also note that Tualatin-core Celerons use the FC-PGA2 packaging, which includes a heat spreader on top of the CPU die. This requires a compatible heatsink.

Because of the variations in packaging, which require different heatsink solutions, I normally recommend only purchasing boxed versions of the processors, which include a compatible high-quality heatsink in the box. That way, you are assured of having the proper heatsink, clips, thermal interface material, and other items necessary for the chip to operate properly and safely in your system. The boxed processors also feature a three-year warranty direct with Intel, which is not available with raw or OEM processors.

The more recent Celeron 4 processors are designed to provide a low-cost alternative to users of Socket 478 and Socket T (LGA775) motherboards (the form factor used by recent and current Pentium 4 processors). Socket 478 Celerons currently use the Willamette core found in the original Pentium 4, but newer Celeron 4A versions use the Northwood core and the Celeron D models use the Prescott core found in most Pentium 4 models. The only difference between the latest Celeron processors and the Pentium 4 models on which they are based is that the Celeron versions have less L2 cache and run at lower bus speeds when compared to the corresponding Pentium 4 version. Compared to earlier Pentium III-based Celerons, the Pentium 4-based Celerons have the following improvements:

- Faster clock speeds (up to 3.2GHz and climbing).
- 400MHz or 533MHz CPU bus for data and memory transfers up to 4.266GBps (depending on the memory used on the motherboard).
- Support for SSE2 instructions, which include the SSE instructions found in the Pentium III-based Celerons plus 144 additional instructions for graphics and sound processing. Celeron D models support SSE3, which includes 13 additional instructions over SSE2.
- Deeper 20-stage or 31-stage (Celeron D) internal pipeline.
- 256-bit wide L2 cache.
- All other Pentium 4 architectural features.

Celerons have less cache than the Pentium 4 processors on which they are based. Even though the Celeron processors have less cache, the improvements in the cache architecture and CPU and bus speeds allow them to outperform previous-generation processors that might have even more cache. Celeron 4A CPUs have 256KB of L2 and perform even better than the current Celeron 4.

All the newer Celeron chips use Intel's FC-PGA2 design. This design adds a metal heat spreader to the top of the processor to improve heat transfer to the heatsink. This integrated heat spreader also prevents physical damage to the CPU during the processor and heatsink installation. Think of it as a metal protective cap over the CPU die.

Because Intel has offered Celerons in many distinctive variations, it's easy to get confused as to which is which, or which is available at a specific speed. By reading the spec number off a particular chip and looking up the number on the Intel developer Web site (developer.intel.com), you can find out the exact specification including socket type, voltage, stepping, cache size, and other information about the chip.

Pentium III

The Pentium III processor, shown in Figure 3.52, was first released in February 1999 and introduced several new features to the P6 family. It is essentially the same core as a Pentium II with the addition of SSE instructions and integrated on-die L2 cache in the later versions. SSE consists of 70 new instructions that dramatically enhance the performance and possibilities of advanced imaging, 3D, streaming audio, video, and speech-recognition applications.

Figure 3.52 Pentium III processor in SECC2 (Slot 1) and FC-PGA (Socket 370) packages.

Originally based on Intel's advanced 0.25-micron CMOS process technology, the PIII core started out with more than 9.5 million transistors. In late 1999, Intel shifted to a 0.18-micron process die (code-named Coppermine) and added 256KB of on-die L2 cache, which brought the transistor count to 28.1 million. The latest version of the Pentium III (codenamed Tualatin) uses a 0.13-micron process and has 44 million transistors; motherboards made before the Tualatin-core versions of the Pentium III generally do not support this processor because of logical pinout changes. The Pentium III also became available in speeds from 450MHz through 1.4GHz, as well as server versions with larger or faster cache called Xeon. The Pentium III also incorporates advanced features such as a 32KB L1 cache and either half-core speed 512KB L2 cache or full-core speed on-die 256KB or 512KB L2 with cacheability for up to 4GB of addressable memory space. The PIII also can be used in dual-processing systems with up to 64GB of physical memory. A self-reportable processor serial number gives security, authentication, and system management applications a powerful new tool for identifying individual systems. Because of privacy concerns when the processor was released, you can disable this feature in the system BIOS on most systems that use the Pentium III or Celeron III processors.

Pentium III processors were first made available in Intel's SECC2 form factor, which replaced the more expensive older SEC packaging. The SECC2 package covers only one side of the chip and allows for better heatsink attachment and less overall weight. Architectural features of the Pentium III processor include

- *Streaming SIMD extensions.* Seventy new instructions for dramatically faster processing and improved imaging, 3D streaming audio and video, Web access, speech recognition, new user interfaces, and other graphics and sound-rich applications.
- *Intel processor serial number.* The processor serial number serves as an electronic serial number for the processor and, by extension, its system or user. This feature can be enabled or disabled as desired in the BIOS Setup. The serial number enables the system/user to be identified by company internal networks and applications. The processor serial number can be used in applications that benefit from stronger forms of system and user identification, such as:
 - *Applications using security capabilities.* Managed access to new Internet content and services; electronic document exchange.
 - *Manageability applications.* Asset management; remote system load and configuration.

Although the initial release of Pentium III processors was made in the improved SECC2 packaging, Intel later switched to the FC-PGA package, which is even less expensive to produce and enables a more direct attachment of the heatsink to the processor core for better cooling. The FC-PGA version plugs into Socket 370 but can be used in Slot 1 with a slot-ket adapter.

All Pentium III processors have either 512KB or 256KB of L2 cache, which runs at either half-core or full-core speed. Pentium III Xeon versions have 512KB, 1MB, or 2MB of L2 cache that runs at full-core speed. The Pentium III Xeon is a more expensive version of the Pentium III designed for servers and workstations. All PIII processor L2 caches can cache up to 4GB of addressable memory space and include ECC capability.

Pentium III processors can be identified by their markings, which are found on the top edge of the processor cartridge. Figure 3.53 shows the format and meaning of the markings.

Table 3.37 shows variations of the Pentium III, indicated by the S-specification number.

SECC = Single edge contact cartridge

SECC2 = Single edge contact cartridge revision 2

Pentium III processors are all clock multiplier locked. This is a means to prevent processor fraud and over-clocking by making the processor work only at a given clock multiplier. Unfortunately, this feature can be bypassed by making modifications to the processor under the cartridge cover, and unscrupulous individuals have been selling lower-speed processors re-marked as higher speeds. It pays to purchase your systems or processors from direct Intel distributors or high-end dealers who do not engage in these practices.

Pentium II/III Xeon

The Pentium II and III processors are available in special high-end versions called Pentium II Xeon and Pentium III Xeon processors (Intel now uses the term *Xeon* by itself to refer to Xeon processors based on the Pentium 4). Originally introduced in June 1998 in Pentium II versions, later Pentium III versions were introduced in March 1999. These differ from the standard Pentium II and III in three ways: packaging, cache size, and cache speed.

Pentium II/III Xeon processors use a larger SEC cartridge than the standard PII/III processors, mainly to house a larger internal board with more cache memory.

Besides the larger package, the Xeon processors also include more L2 cache. They were produced in three variations, with 512KB, 1MB, or 2MB of L2 cache.

Even more significant than the size of the cache is its speed. All the cache in the Xeon processors run at the full-core speed. This is difficult to do considering that the cache chips are separate chips on the board; up until recently they were not integrated into the processor die. The original Pentium II Xeon processors had 7.5 million transistors in the main processor die, whereas the later Pentium III Xeon came with 9.5 million. When the Pentium III versions with on-die cache were released, the transistor count went up to 28.1 million transistors in the 256KB cache version, 84 million transistors in the 1MB cache version, and a whopping 140 million transistors in the latest 2MB cache version, setting an industry record at the time. The high transistor counts are due to the on-die L2 cache, which is very transistor intensive. The L2 cache in all Pentium II and III Xeon processors has a full 64GB RAM address range and supports ECC.

Later versions of the Xeon processor were designed for Socket 370, and even newer versions based on the Pentium 4 are designed for Socket 603 and Socket 604.

Other Sixth-Generation Processors

Besides Intel, many other manufacturers have produced P6-type processors, but often with a difference. Most of them were designed to interface with P5 class motherboards for the lower-end markets. AMD later offered up the Athlon and Duron processors, which were true sixth-generation designs using their own proprietary connections to the system.

This section examines the various sixth-generation processors from manufacturers other than Intel.

NexGen Nx586

NexGen was founded by Thampy Thomas, who hired some of the people formerly involved with the 486 and Pentium processors at Intel. At NexGen, developers created the Nx586, a processor that was functionally the same as the Pentium but not pin compatible. As such, it was always supplied with a motherboard; in fact, it was usually soldered in. NexGen did not manufacture the chips or the motherboards they came in; for that it hired IBM Microelectronics. Later NexGen was bought by AMD, right before it was ready to introduce the Nx686—a greatly improved design by Greg Favor and a true competitor for the Pentium. AMD took the Nx686 design and combined it with a Pentium electrical interface to create a drop-in Pentium-compatible chip called the K6, which actually outperformed the original from Intel.

The Nx586 had all the standard fifth-generation processor features, such as superscalar execution with two internal pipelines and a high-performance integral L1 cache with separate code and data caches. One advantage is that the Nx586 includes separate 16KB instruction and 16KB data caches compared to 8KB each for the Pentium. These caches keep key instruction and data close to the processing engines to increase overall system performance.

The Nx586 also includes branch prediction capabilities, which are one of the hallmarks of a sixth-generation processor. Branch prediction means the processor has internal functions to predict program flow to optimize the instruction execution.

The Nx586 processor also featured a RISC core. A translation unit dynamically translates x86 instructions into RISC86 instructions. These RISC86 instructions were designed specifically with direct support for the x86 architecture while obeying RISC performance principles. They are thus simpler and easier to execute than the complex x86 instructions. This type of capability is another feature normally found only in P6 class processors.

The Nx586 was discontinued after the merger with AMD, which then took the design for the successor Nx686 and released it as the AMD-K6.

AMD-K6 Series

The AMD-K6 processor is a high-performance sixth-generation processor that is physically installable in a P5 (Pentium) motherboard. It essentially was designed for AMD by NexGen and was first known as the Nx686. The NexGen version never appeared because it was purchased by AMD before the chip was due to be released. The AMD-K6 delivers performance levels somewhere between the Pentium and Pentium II processor as a result of its unique hybrid design. Because it is designed to install in Socket 7, which is a fifth-generation processor socket and motherboard design, it can't quite perform as a true sixth-generation chip because the Socket 7 architecture severely limits cache and memory performance. However, with this processor, AMD gave Intel a lot of competition in the low- to mid-range market, where the Pentium was still popular.

The K6 processor contains an industry-standard, high-performance implementation of the new multimedia instruction set, enabling a high level of multimedia performance. The K6-2 introduced an upgrade to MMX that AMD calls 3DNow!, which adds even more graphics and sound instructions. AMD designed the K6 processor to fit the low-cost, high-volume Socket 7 infrastructure. Initially, it used AMD's 0.35-micron, five-metal layer process technology; more recent variations used the 0.25-micron processor to increase production quantities because of reduced die size, as well as to decrease power consumption.

AMD-K6 processor technical features include:

- Sixth-generation internal design, fifth-generation external interface
- Internal RISC core, translates x86 to RISC instructions
- Superscalar parallel execution units (seven)
- Dynamic execution
- Branch prediction
- Speculative execution
- Large 64KB L1 cache (32KB instruction cache plus 32KB write-back dual-ported data cache)
- Built-in floating-point unit
- Industry-standard MMX instruction support
- System Management Mode
- Ceramic pin grid array (CPGA) Socket 7 design
- Manufactured using 0.35-micron and 0.25-micron, five-layer designs

The K6-2 adds the following:

- Higher clock speeds
- Higher bus speeds of up to 100MHz (Super7 motherboards)
- 3DNow!; 21 new graphics and sound processing instructions

The K6-3 adds the following:

- 256KB of on-die full-core speed L2 cache

The addition of the full-speed L2 cache in the K6-3 was significant. It enables the K6 series to fully compete with the Intel Pentium II processors and the Celeron processors based on the Pentium II. The 3DNow! capability added in the K6-2/3 was also exploited by newer graphics programs, making these processors ideal for lower-cost gaming systems.

The AMD-K6 processor architecture is fully x86 binary code compatible, which means it runs all Intel software, including MMX instructions. To make up for the lower L2 cache performance of the Socket 7 design, AMD beefed up the internal L1 cache to 64KB total, twice the size of the Pentium II or III. This, plus the dynamic execution capability, enabled the K6 to outperform the Pentium and come close to the Pentium II and III in performance for a given clock rate. The K6-3 was even better with the addition of full-core speed L2 cache; however, this processor ran very hot and was discontinued after a relatively brief period.

Both the AMD-K5 and AMD-K6 processors are Socket 7 bus compatible. However, certain modifications might be necessary for proper voltage setting and BIOS revisions. To ensure reliable operation of the AMD-K6 processor, the motherboard must meet specific voltage requirements.

The AMD processors have specific voltage requirements. Most older split-voltage motherboards default to 2.8V Core/3.3V I/O, which is below specification for the AMD-K6 and could cause erratic operation. To work properly, the motherboard must have Socket 7 with a dual-plane voltage regulator supplying 2.9V or 3.2V (233MHz) to the CPU core voltage (Vcc2) and 3.3V for the I/O (Vcc3). The voltage regulator must be capable of supplying up to 7.5A (9.5A for the 233MHz) to the processor. When used with a 200MHz or slower processor, the voltage regulator must maintain the core voltage within 145mV of nominal (2.9V \pm 145mV). When used with a 233MHz processor, the voltage regulator must maintain the core voltage within 100mV of nominal (3.2V \pm 100mV).

If the motherboard has a poorly designed voltage regulator that cannot maintain this performance, unreliable operation can result. If the CPU voltage exceeds the absolute maximum voltage range, the processor can be permanently damaged. Also note that the K6 can run hot. Make sure your heatsink is securely fitted to the processor and that the thermally conductive grease or pad is properly applied.

The motherboard must have an AMD-K6 processor-ready BIOS with support for the K6 built in. Award has that support in its March 1, 1997 or later BIOS; AMI had K6 support in any of its BIOSs with CPU Module 3.31 or later; and Phoenix supports the K6 in version 4.0, release 6.0, or release 5.1 with build dates of 4/7/97 or later.

Because these specifications can be fairly complicated, AMD keeps a list of motherboards that have been verified to work with the AMD-K6 processor on its Web site. All the motherboards on that list have been tested to work properly with the AMD-K6. So, unless these requirements can be verified elsewhere, it is recommended that you use only a motherboard from that list with the AMD-K6 processor.

The multiplier, bus speed, and voltage settings for the K6 are shown in Table 3.38. You can identify which AMD-K6 you have by looking at the markings on this chip, as shown in Figure 3.54.

Table 3.38 AMD-K6 Processor Speeds and Voltages

Processor	Core Speed	Clock Multiplier	Bus Speed	Core Voltage	I/O Voltage
K6-3	450MHz	4.5x	100MHz	2.4V	3.3V
K6-3	400MHz	4x	100MHz	2.4V	3.3V
K6-2	475MHz	5x	95MHz	2.4V	3.3V
K6-2	450MHz	4.5x	100MHz	2.4V	3.3V
K6-2	400MHz	4x	100MHz	2.2V	3.3V
K6-2	380MHz	4x	95MHz	2.2V	3.3V
K6-2	366MHz	5.5x	66MHz	2.2V	3.3V
K6-2	350MHz	3.5x	100MHz	2.2V	3.3V
K6-2	333MHz	3.5x	95MHz	2.2V	3.3V
K6-2	333MHz	5.0x	66MHz	2.2V	3.3V
K6-2	300MHz	3x	100MHz	2.2V	3.3V
K6-2	300MHz	4.5x	66MHz	2.2V	3.3V

Table 3.38 Continued

Processor	Core Speed	Clock Multiplier	Bus Speed	Core Voltage	I/O Voltage
K6-2	266MHz	4x	66MHz	2.2V	3.3V
K6	300MHz	4.5x	66MHz	2.2V	3.45V
K6	266MHz	4x	66MHz	2.2V	3.3V
K6	233MHz	3.5x	66MHz	3.2V	3.3V
K6	200MHz	3x	66MHz	2.9V	3.3V
K6	166MHz	2.5x	66MHz	2.9V	3.3V

**Figure 3.54** AMD Athlon processor for Slot A (cartridge form factor).

Older motherboards achieve the 3.5x setting by setting jumpers for 1.5x. The 1.5x setting for older motherboards equates to a 3.5x setting for the AMD-K6 and newer Intel parts. Getting the 4x and higher setting requires a motherboard that controls three BF pins, including BF2. Older motherboards can control only two BF pins. The settings for the multipliers are shown in Table 3.39.

Table 3.39 AMD-K6 Multiplier Settings

Multiplier Setting	BF0	BF1	BF2	Multiplier Setting	BF0	BF1	BF2
2.5x	Low	Low	High	4.5x	Low	Low	Low
3x	High	Low	High	5x	High	Low	Low
3.5x	High	High	High	5.5x	High	High	Low
4x	Low	High	Low				

These settings usually are controlled by jumpers on the motherboard. Consult your motherboard documentation to see where they are and how to set them for the proper multiplier and bus speed settings.

Unlike Cyrix and some of the other Intel competitors, AMD is a manufacturer and a designer. Therefore, it designs and builds its chips in its own fabs. Similar to Intel, AMD has migrated to 0.25-micron process technology and beyond (the AMD Athlon XP is built on a 0.13-micron process). The original K6 has 8.8 million transistors and is built on a 0.35-micron, five-layer process. The die is 12.7mm on each side, or about 162 square mm. The K6-3 uses a 0.25-micron process and incorporates 21.3 million transistors on a die only 10.9mm on each side, or about 118 square mm.

Because of its performance and compatibility with the Socket 7 interface, the K6 series is often looked at as an excellent processor upgrade for motherboards using older Pentium or Pentium MMX processors. Although they do work in Socket 7, the AMD-K6 processors have different voltage and bus speed requirements from the Intel processors. Before attempting any upgrades, you should check the board documentation or contact the manufacturer to see whether your board meets the necessary requirements. In some cases, a BIOS upgrade also is necessary.

AMD Athlon, Duron, and Athlon XP

The Athlon is AMD's successor to the K6 series (refer to Figure 3.60). The Athlon is a whole new chip from the ground up and does not interface via the Socket 7 or Super7 sockets like its previous chips. In the initial Athlon versions, AMD used a cartridge design, called Slot A, almost exactly like that of the Intel Pentium II and III. This was due to the fact that the original Athlons used 512KB of external L2 cache, which was mounted on the processor cartridge board. The external cache ran at one-half core, two-fifths core, or one-third core depending on which speed processor you had. In June 2000, AMD introduced a revised version of the Athlon (codenamed Thunderbird) that incorporates 256KB of L2 cache directly on the processor die. This on-die cache runs at full-core speed and eliminates a bottleneck in the original Athlon systems. Along with the change to on-die L2 cache, the Athlon was also introduced in a PGA or chip Socket A version, which replaced the Slot A cartridge version. The most recent Athlon version, called the Athlon XP, has several enhancements such as 3DNow! Professional instructions, which also include the Intel SSE instructions. The latest Athlon XP models have also returned to the use of 512KB L2 cache, but this time at full processor speed.

Although the Slot A cartridge looks a lot like the Intel Slot 1, and the Socket A looks like Intel's Socket 370, the pinouts are completely different and the AMD chips do not work in the same motherboards as the Intel chips. This was by design because AMD was looking for ways to improve its chip architecture and distance itself from Intel. Special blocked pins in either socket or slot design prevent accidentally installing the chip in the wrong orientation or wrong slot. Figure 3.55 shows the Athlon in the Slot A cartridge. Socket A versions of the Athlon closely resemble the Duron.

Figure 3.55 AMD Athlon XP 0.13-micron processor for Socket A (PGA form factor).

AMD-K7900MNR53B	Model 2	900	100x2	9x	512KB
AMD-K7950MNR53B	Model 2	950	100x2	9.5x	512KB

The Athlon is available in speeds from 500MHz up to 1.4GHz and uses a 200MHz or 266MHz processor (front-side) bus called the EV6 to connect to the motherboard North Bridge chip as well as other processors. Licensed from Digital Equipment, the EV6 bus is the same as that used for the Alpha 21264 processor, now owned by Compaq. The EV6 bus uses a clock speed of 100MHz or 133MHz but double-clocks the data, transferring data twice per cycle, for a cycling speed of 200MHz or 266MHz. Because the bus is 8 bytes (64 bits) wide, this results in a throughput of 8 bytes times 200MHz/266MHz, which amounts to 1.6Gbps or 2.1Gbps. This bus is ideal for supporting PC1600 or PC2100 DDR memory, which also runs at those speeds. The AMD bus design eliminates a potential bottleneck between the chipset and processor and enables more efficient transfers compared to other processors. The use of the EV6 bus is one of the primary reasons the Athlon and Duron chips perform so well.

The Athlon has a very large 128KB of L1 cache on the processor die and one-half, two-fifths, or one-third core speed 512KB L2 cache in the cartridge in the older versions; 256KB of full-core speed cache in Socket A Athlon and most Athlon XP models; and 512KB of full-core speed cache in the latest Athlon XP models. All PGA socket A versions have the full-speed cache. The Athlon also has support for MMX and the Enhanced 3DNow! instructions, which are 45 new instructions designed to support graphics and sound processing. 3DNow! is very similar to Intel's SSE in design and intent, but the specific instructions are different and require software support. The Athlon XP adds the Intel SSE instructions, which it calls 3DNow! Professional. Fortunately, most companies producing graphics software have decided to support the 3DNow! instructions along with the Intel SSE instructions, with only a few exceptions.

The initial production of the Athlon used 0.25-micron technology, with newer and faster versions being made on 0.18-micron and 0.13-micron processes. The latest versions are even built using copper metal technology, a first in the PC processor business. Eventually all other processors will follow because copper connects allow for lower power consumption and faster operation.

Table 3.40 shows detailed information on the Slot A version of the Athlon processor.

In most benchmarks the AMD Athlon compares as equal, if not superior, to the Intel Pentium III. AMD beat Intel to the 1GHz mark by introducing its 1GHz Athlon two days before Intel introduced the 1GHz Pentium III.

Table 3.41 shows information on the PGA or Socket A version of the AMD Athlon processor. All Socket A processors are Model 4.

L2 Speed (MHz)	Voltage	Max. Power (W)	Process (Microns)	Transistors	Introduced

AMD Duron

The AMD Duron processor (originally code named Spitfire) was announced in June 2000 and is a derivative of the AMD Athlon processor in the same fashion as the Celeron is a derivative of the Pentium II and III. Basically, the Duron is an Athlon with less L2 cache; all other capabilities are essentially the same. It is designed to be a lower-cost version with less cache but only slightly less performance. In keeping with the low-cost theme, Duron contains 64KB on-die L2 cache and is designed for Socket A, a socket version of the Athlon Slot A (see Figure 3.56). Except for the Duron markings, the Duron is almost identical externally to the Socket A versions of the original Athlon.

Essentially, the Duron was designed to compete against the Intel Celeron in the low-cost PC market, just as the Athlon was designed to compete in the higher-end Pentium III market. The Duron has

L2 Speed (MHz)	Voltage	Max. Power (W)	Process (Microns)	Transistors	Introduced
333	1.80V	65W	0.18	22M	Mar. 2000
650	1.70V	36.1W	0.18	37M	Jun. 2000
700	1.70V	38.3W	0.18	37M	Jun. 2000
750	1.70V	40.4W	0.18	37M	Jun. 2000
800	1.70V	42.6W	0.18	37M	Jun. 2000
850	1.70V	44.8W	0.18	37M	Jun. 2000
900	1.75V	49.7W	0.18	37M	Jun. 2000
950	1.75V	52.0W	0.18	37M	Jun. 2000
1000	1.75V	54.3W	0.18	37M	Jun. 2000

Voltage	Max. Power (W)	Process (Microns)	Transistors
1.75V	38.5W	0.18	37M
1.75V	40.3W	0.18	37M
1.75V	43.8W	0.18	37M
1.75V	45.5W	0.18	37M
1.75V	47.3W	0.18	37M
1.75V	50.8W	0.18	37M
1.75V	52.5W	0.18	37M
1.75V	54.3W	0.18	37M
1.75V	54.3W	0.18	37M
1.75V	59.5W	0.18	37M
1.75V	63.0W	0.18	37M
1.75V	66.5W	0.18	37M
1.75V	66.5W	0.18	37M
1.75V	68.3W	0.18	37M
1.75V	70.0W	0.18	37M
1.75V	72.0W	0.18	37M

since been discontinued, but most systems that use the Duron processor can use AMD Athlon or, in some cases Athlon XP, processors as an upgrade.

Because the Duron processor is derived from the Athlon core, it includes the Athlon 200MHz front-side system bus (interface to the chipset) as well as enhanced 3DNow! instructions in Model 3. Model 7 processors include 3DNow! Professional instructions (which include a full implementation of SSE instructions).

Table 3.42 shows information on the PGA or Socket A version of the AMD Duron processor. Durons that require 1.6V are Model 3 processors, whereas those that require 1.75V are Model 7 processors. The Model 7 version was originally code named Morgan.

Figure 3.56 AMD Duron processor.

1800	266	64KB	1.5V	53.0W	0.13	37.2M

AMD Athlon XP

As mentioned earlier, the newest version of the Athlon is called the Athlon XP. This is basically an improved version of the previous Athlon, with improvements in the instruction set so it can execute Intel SSE instructions and a new marketing scheme that directly competes with the Pentium 4. The latest Athlon XP models have also adopted a larger (512KB) full-speed on-die cache.

AMD uses the term "QuantiSpeed" (a marketing term, not a technical term) to refer to the architecture of the Athlon XP. AMD defines this as including the following:

- *A nine-issue superscalar, fully pipelined microarchitecture.* This provides more pathways for instructions to be sent into the execution sections of the CPU and includes three floating-point execution units, three integer units, and three address calculation units.
- *A superscalar, fully pipelined floating-point calculation unit.* This provides faster operations per clock cycle and cures a long-time deficiency of AMD processors versus Intel processors.
- *A hardware data prefetch.* This gathers the data needed from system memory and places it in the processor's Level 1 cache to save time.
- *Improved translation look-aside buffers (TLBs).* These enable the storage of data where the processor can access it more quickly without duplication or stalling for lack of fresh information.

These design improvements wring more work out of each clock cycle, enabling a "slower" Athlon XP to beat a "faster" Pentium 4 processor in doing actual work (and play).

The first models of the Athlon XP used the Palomino core, which is also shared by the Athlon 4 mobile (laptop) processor. Later models have used the Thoroughbred core, which was later revised to improve thermal characteristics. The different Thoroughbred cores are sometimes referred to as Thoroughbred-A and Thoroughbred-B. The latest Athlon XP processors use a new core with 512KB on-die full-speed L2 cache known as Barton. Additional features include

- 3DNow! Professional multimedia instructions (adding compatibility with the 70 additional SSE instructions in the Pentium III but not the 144 additional SSE2 instructions in the Pentium 4)
- 266MHz or 333MHz FSB
- 128KB Level 1 and 256KB or 512KB on-die Level 2 memory caches running at full CPU speed
- Copper interconnects (instead of aluminum) for more electrical efficiency and less heat

Also new to the Athlon XP is the use of a thinner, lighter organic chip packaging compound similar to that used by recent Intel processors. Figure 3.57 shows the latest Athlon XP processors that use the Barton core.

Figure 3.57 AMD Athlon XP 0.13-micron processor with 512KB of L2 cache for Socket A (PGA form factor). Photo courtesy of Advanced Micro Devices, Inc.

This packaging allows for a more efficient layout of electrical components. The latest versions of the Athlon XP are made using a new 0.13-micron die process that results in a chip with a smaller die that uses less power, generates less heat, and is capable of running faster as compared to the previous models. The newest 0.13-micron versions of the Athlon XP run at actual clock speeds exceeding 2GHz. Table 3.43 provides detailed information about the Athlon XP.

Table 3.43 AMD Athlon XP Processor Information

P-Rating	Actual Speed (MHz)	Bus Speed (MHz)	Multiplier	L2 Cache	Voltage	Max. Power (W)	Process (Microns)	Transistors

Athlon MP

The Athlon MP is AMD's first processor designed for multiprocessor support. Thus, it can be used in servers and workstations that demand multiprocessor support. The Athlon MP comes in the following three versions, which are similar to various Athlon and Athlon XP models:

- **Model 6 (1GHz, 1.2GHz).** This model is similar to the Athlon Model 4.
- **Model 6 OPGA (1500+ through 2100+).** This model is similar to the Athlon XP Model 6.
- **Model 8 (2000+, 2200+, 2400+, 2600+).** This model is similar to the Athlon XP Model 8.
- **Model 10 (2500+, 2800+, 3000+).** This model is similar to the Athlon XP Model 8, but with 512KB of L2 cache.

All Athlon MP processors use the same Socket A interface used by later models of the Athlon and all Duron and Athlon XP processors.

For more details about the Athlon MP, see the AMD Web site.

Cyrix/IBM 6x86 (M1) and 6x86MX (MII)

The Cyrix 6x86 processor family consists of the now-discontinued 6x86 and the newer 6x86MX processors. They are similar to the AMD-K5 and K6 in that they offer sixth-generation internal designs in a fifth-generation P5 Pentium-compatible Socket 7 exterior.

The Cyrix 6x86 and 6x86MX (renamed MII) processors incorporate two optimized superpipelined integer units and an on-chip floating-point unit. These processors include the dynamic execution capability that is the hallmark of a sixth-generation CPU design. This includes branch prediction and speculative execution.

The 6x86MX/MII processor is compatible with MMX technology to run MMX games and multimedia software. With its enhanced memory-management unit, a 64KB internal cache, and other advanced architectural features, the 6x86MX processor achieves higher performance and offers better value than competitive processors.

Features and benefits of the 6x86 processors include

- *Superscalar architecture.* Two pipelines to execute multiple instructions in parallel
- *Branch prediction.* Predicts with high accuracy the next instructions needed
- *Speculative execution.* Enables the pipelines to continuously execute instructions following a branch without stalling the pipelines
- *Out-of-order completion.* Lets the faster instruction exit the pipeline out of order, saving processing time without disrupting program flow

The 6x86 incorporates two caches: a 16KB dual-ported unified cache and a 256-byte instruction line cache. The unified cache is supplemented with a small, quarter-K-size, high-speed, fully associative instruction line cache. The improved 6x86MX design quadruples the internal cache size to 64KB, which significantly improves performance.

The 6x86MX also includes the 57 MMX instructions that speed up the processing of certain computing-intensive loops found in multimedia and communication applications.

All 6x86 processors feature support for SMM. This provides an interrupt that can be used for system power management or software transparent emulation of I/O peripherals. Additionally, the 6x86 supports a hardware interface that enables the CPU to be placed into a low-power suspend mode.

The 6x86 is compatible with x86 software and all popular x86 operating systems, including Windows 95/98/Me, Windows NT/2000, OS/2, DOS, Solaris, and Unix. Additionally, the 6x86 processor has been certified Windows 95 compatible by Microsoft.

As with the AMD-K6, there are some unique motherboard and BIOS requirements for the 6x86 processors. The 6x86 processor has been discontinued since Cyrix was absorbed into VIA, but the 6x86MX (MII) design is still sold and supported by VIA. Check motherboard compatibility with the 6x86MX or MII processors before integrating one into an existing Socket 7/Super7 system. A BIOS update might be necessary in some cases. When installing or configuring a system with the 6x86 processors, you have to set the correct motherboard bus speed and multiplier settings. The Cyrix processors are numbered based on a P-Rating scale, which is not the same as the true megahertz clock speed of the processor.

See the section “Cyrix Processor Speeds,” earlier in this chapter, for the correct and true speed settings for the Cyrix 6x86 processors.

Note that because of the use of the P-Rating system, the actual speed of the chip is not the same number at which it is advertised. For example, the 6x86MX-PR300 is not a 300MHz chip; it actually runs at only 263MHz or 266MHz, depending on exactly how the motherboard bus speed and CPU clock multipliers are set. Cyrix says it runs as fast as a 300MHz Pentium, hence the P-Rating. Personally, I wish it would label the chip at the correct speed and then say that it runs faster than a Pentium at the same speed.

To install the 6x86 processors in a motherboard, you also must set the correct voltage. Normally, the markings on top of the chip indicate which voltage setting is appropriate. Various versions of the 6x86 run at 3.52V (use VRE setting), 3.3V (VR setting), or 2.8V (MMX) settings. The MMX versions use the standard split-plane 2.8V core 3.3V I/O settings.

The Cyrix MII is now sold by VIA Technologies.

VIA C3

The VIA C3 was originally known as the VIA Cyrix III and was designed to fit into the same Socket 370 used by the Pentium III and Celeron III. The initial versions of the C3, code named Joshua and Samuel, had 128KB L1 cache but didn't contain any L2 cache. As a consequence, they had much lower performance than similar 500MHz-class processors. The original Cyrix III/C3, code named Joshua, was developed by former Cyrix engineers after VIA bought Cyrix in late 1998, but the Samuel and subsequent versions are based on the Centaur Winchip (VIA purchased Centaur in 1999). The Samuel was built with a .18-micron process, whereas the Samuel 2 is a development of the Samuel with 64KB of L2 cache on board and is built on a .15-micron process. The Ezra core was the first .13-micron process C3 processor, but it, like previous C3 processors, was not compatible with Tualatin (late Pentium III-compatible) motherboards. The Ezra-T core was the first C3 to reach 1GHz and the first to support Tualatin motherboards. The latest C3 uses the Nehemiah core and features clock speeds over 1GHz and built-in encryption. C3 models feature 100MHz FSB (750MHz and 900MHz models) or 133MHz FSB (733MHz, 800MHz, 866MHz, 933MHz, and higher).

The C3 is fully software compatible with other x86 processors, including Pentium III and Celeron, but its microarchitecture is designed to enhance the performance of most frequently used instructions while reducing the performance of seldom-used instructions. This design feature significantly reduces the die size needed for C3 processors, but it also reduces performance in multimedia and graphics operations. By reducing the die size, the C3 in its Nehemiah version offers typical power consumption of only 11.25 watts, making it the coolest running processor available for Socket 370 applications.

Because of its low power consumption, cool operation, and relatively low performance compared to the Intel Celeron, the C3 processor should be considered primarily for computing appliances, set-top boxes, and portable computers in which small size and low power/cooling requirements (rather than performance) are paramount.

The C3 is also available in an enhanced ball grid array (EBGA) package called the E-series. E-series C3 processors are used for permanent installation on motherboards such as the Mini-ITX ultra-compact form factor designs also produced by VIA.

For more details about various versions of the C3, refer to Table 3.2 or the VIA Technologies Web site.

Intel Pentium 4 (Seventh-Generation) Processors

The Pentium 4 was introduced in November 2000 and represented a new generation in processors (see Figure 3.58). If this one had a number instead of a name, it might be called the 786 because it represents a generation beyond the previous 686 class processors. Three main variations on the Pentium 4 have been released, based on the processor die and architecture. They are called the Willamette, Northwood, and Prescott. The processor dies are shown in Figure 3.59.

Figure 3.58 Pentium 4 FC-PGA2 processor.

The main technical details for the Pentium 4 include

- Speeds range from 1.3GHz to 4GHz and beyond.
- 42 million transistors, 0.18-micron process, 217 sq. mm die (Willamette).
- 55 million transistors, 0.13-micron process, 131 sq. mm die (Northwood).
- 125 million transistors, 0.09-micron process, 112 sq. mm die (Prescott).
- Software compatible with previous Intel 32-bit processors.
- Processor (front-side) bus runs at 400MHz, 533MHz, or 800MHz.
- Arithmetic logic units (ALUs) run at twice the processor core frequency.
- Hyper-pipelined (20-stage or 31-stage) technology.
- Hyper-threading technology support in all 2.4GHz and faster processors running an 800MHz bus and all 3.06GHz and faster processors running a 533MHz bus.
- Very deep out-of-order instruction execution.
- Enhanced branch prediction.
- 8KB or 16KB L1 cache plus 12K micro-op execution trace cache.
- 256KB, 512KB, or 1MB of on-die, full-core speed 256-bit-wide L2 cache with eight-way associativity.
- L2 cache can handle up to 4GB RAM and supports ECC.
- 2MB of on-die, full-speed L3 cache (Extreme Edition).
- SSE2—SSE plus 144 new instructions for graphics and sound processing (Willamette and Northwood).
- SSE3—SSE2 plus 13 new instructions for graphics and sound processing (Prescott).
- Enhanced floating-point unit.
- Multiple low-power states.

Intel abandoned Roman numerals for a standard Arabic numeral 4 designation. Internally, the Pentium 4 introduces a new architecture Intel calls NetBurst microarchitecture, which is a marketing term and not a technical term. Intel uses NetBurst to describe hyper-pipelined technology, a rapid execution engine, a high-speed (400MHz, 533MHz, or 800MHz) system bus, and an execution trace cache. The hyper-pipelined technology doubles or triples the instruction pipeline depth as compared to the Pentium III (or Athlon/Athlon 64), meaning more and smaller steps are required to execute instructions. Even though this might seem less efficient, it enables much higher clock speeds to be more easily attained. The rapid

execution engine enables the two integer arithmetic logic units (ALUs) to run at twice the processor core frequency, which means instructions can execute in half a clock cycle. The 400MHz/533MHz/800MHz system bus is a quad-pumped bus running off a 100MHz/133MHz/200MHz system clock transferring data four times per clock cycle. The execution trace cache is a high-performance Level 1 cache that stores approximately 12k decoded micro-operations. This removes the instruction decoder from the main execution pipeline, increasing performance.

Figure 3.59 The CPU dies for the Pentium 4 CPU based on the Willamette, Northwood, and Prescott cores.

Of these, the high-speed processor bus is most notable. Technically speaking, the processor bus is a 100MHz, 133MHz, or 200MHz quad-pumped bus that transfers four times per cycle (4x), for a 400MHz, 533MHz, or 800MHz effective rate. Because the bus is 64 bits (8 bytes) wide, this results in a throughput rate of 3200MBps, 4266MBps, or 6400MBps.

Table 3.44 shows how this transfer rate compares to dual-channel RDRAM and DDR SDRAM.

Table 3.44 Pentium 4 Processor Bus and RDRAM Speed Comparison

Pentium 4 Processor Bus Speed	Throughput (Processor Bus×8)	Dual-channel RIMM Throughput	Dual-channel DDR DIMM Throughput
400MHz	3200MBps	3200MBps	3200MBps
533MHz	4266MBps	4266MBps	4266MBps
800MHz	6400MBps	6400MBps	6400MBps

As you can see from Table 3.44, the throughput of the Pentium 4's processor bus is an exact match for the most common types of RDRAM and DDR SDRAM memory. The use of dual-channel memory means that modules must be added in matched pairs. Dual banks of PC1600, PC2100, or PC3200 DDR SDRAM are less expensive than equivalent RDRAM solutions, which is why virtually all newer chipsets—including the 865 (Springdale) and 875 (Canterwood)—support DDR SDRAM only for the Pentium 4.

In the new 20-stage or 31-stage pipelined internal architecture, individual instructions are broken down into many more substages, making this almost like a RISC processor. Unfortunately, this can add to the number of cycles taken to execute instructions if they are not optimized for this processor. Early benchmarks running existing software showed that existing Pentium III or AMD Athlon processors could easily keep pace with or even exceed the Pentium 4 in specific tasks; however, this is

changing now that applications are being recompiled to work smoothly with the Pentium 4's deep pipelined architecture.

Another important architectural advantage is hyper-threading technology, which can be found in all Pentium 4 2.4GHz and faster processors running an 800MHz bus and all 3.06GHz and faster processors running a 533MHz bus. Hyper-threading enables a single processor to run two threads simultaneously, thereby acting as if it were two processors instead of one. For more information on hyper-threading technology, see the section "Hyper-Threading Technology," earlier in this chapter.

The Pentium 4 initially used Socket 423, which has 423 pins in a 39x39 SPGA arrangement. Later versions used Socket 478; recent versions use Socket T (LGA775), which has additional pins for future and faster variations of the chip. The Celeron was never designed to work in Socket 423, but Celeron versions are available for Socket 478 and Socket T (LGA775), allowing for lower-cost systems compatible with the Pentium 4. Voltage selection is made via an automatic voltage regulator module installed on the motherboard and wired to the socket.

Pentium 4 Extreme Edition

In November 2003, Intel introduced the Extreme Edition of the Pentium 4, which is notable for being the first desktop PC processor to incorporate L3 cache. The Extreme Edition (or Pentium 4EE) is basically a revamped version of the Prestonia core Xeon workstation/server processor, which has used L3 cache since November 2002. The Pentium 4EE has 2MB of L3 cache, which increases the transistor count to 178 million transistors and makes the die significantly larger than the standard Pentium 4. Because of the large die based on the 130-nanometer process, this chip is expensive to produce and the extremely high selling price reflects that. The Extreme Edition is targeted toward the gaming market, where people are willing to spend extra money for additional performance. The additional cache doesn't help standard business applications as well as it helps power-hungry 3D games.

Although the L3 cache found in the Pentium 4 Extreme Edition is unique today, in the future many processors will likely incorporate L3 cache as they strive for more and more performance and take advantage of industry reductions in process size. Expect to see an Extreme Edition of the Pentium 4 based on the Prescott core in 2005.

Memory Requirements

Pentium 4-based motherboards use either RDRAM or DDR SDRAM memory, depending on the chipset; however, most use DDR SDRAM. The RDRAM boards use the same Rambus RDRAM RIMM modules introduced for use with some of the chipsets used in Pentium III motherboards; however, the dual RDRAM channels the Pentium 4 uses require you to install pairs of identical modules (called RIMMs). Pentium 4 motherboards that use RDRAM accept either one or two pairs of RIMMs. Both pairs of memory must be the same speed, but need not be the same size.

Whereas most initial Pentium 4 motherboard chipsets supported only RDRAM memory, most newer chipsets are available that support more standard memory, such as SDRAM or DDR SDRAM. Since Intel's contract with RAMBUS expired in 2001, DDR SDRAM has become Intel's preferred memory type for mainstream systems.

Power Supply Issues

The Pentium 4 requires a lot of electrical power, and because of this, most Pentium 4 motherboards use a new design voltage regulator module that is powered from 12V instead of 3.3V or 5V, as with previous designs. By using the 12V power, more 3.3V and 5V power is available to run the rest of the system, and the overall current draw is greatly reduced with the higher voltage as a source. PC power supplies generate a more than adequate supply of 12V power, but the ATX motherboard and power supply design originally allotted only one pin for 12V power (each pin is rated for only 6 amps), so additional 12V lines were necessary to carry this power to the motherboard.

The fix appears in the form of a third power connector, called the ATX12V connector. This new connector is used in addition to the standard 20-pin ATX power supply connector and 6-pin auxiliary (3.3/5V) connector. Fortunately, the power supply itself won't need a redesign; there is more than enough 12V power available from the drive connectors. To utilize this, companies such as PC Power and Cooling sell an inexpensive (\$8) adapter that converts a standard Molex-type drive power connector to the ATX12V connector. Typically, a 300-watt (the minimum recommended) or larger power supply has more than adequate levels of 12V power for both the drives and the ATX12V connector.

Table 3.45 Pentium 4 Processor Information

If your power supply is less than the 300-watt minimum recommended, you need to purchase a replacement; some vendors now sell an off-the-shelf ATX12V ready model or one that uses the adapter mentioned previously.

The various Pentium 4 versions, including thermal and power specifications, are shown in Table 3.45.

Cooling a high-wattage unit such as the Pentium 4 requires a large active heatsink. These heavy (sometimes more than 1 lb.) heatsinks can damage a CPU or destroy a motherboard when subjected to vibration or shock, especially during shipping. To prevent this, Intel's specifications for Socket 423 added four standoffs to the ATX chassis design flanking the Socket 423 to support the heatsink retention brackets. These standoffs enabled the chassis to support the weight of the heatsink instead of depending on the motherboard, as with older designs. Vendors also used other means to reinforce the CPU location without requiring a direct chassis attachment. For example, Asus's P4T motherboard was supplied with a metal reinforcing plate to enable off-the-shelf ATX cases to work with the motherboard.

Socket 478 systems do not require any special standoffs or reinforcement plates; instead they use a unique scheme in which the CPU heatsink attaches directly to the motherboard rather than to the

CPU socket or chassis. Motherboards with Socket 478 can be installed into any ATX chassis—no special standoffs are required.

Pentium 4 processors use special heatsinks that, as noted previously, have different designs. If you purchase the shrink-wrapped or “boxed” processor, you get an Intel-specified high-quality heatsink in the box with the process. In addition, you get a 3-year warranty with Intel, making the boxed version ideal for upgraders and system builders.

Because of the included heatsink and warranty, I highly recommend purchasing only boxed processors instead of raw OEM processors for upgrades or building a new system.

Intel Processor Model Numbers

Most people associate clock speed with the processor, and Intel has always used the raw clock speed of its processors to market them. This has led many people to believe that faster-speed processors always result in faster or better systems, but that is not always the case. Processor architectures have a major effect on the performance of a processor, and it is entirely possible that a slower clock speed processor can handily outperform a faster one when running actual programs or doing real work. Unfortunately, this message is hard to convey when the main attribute used to market a chip is its raw clock speed.

AMD has long been marketing its chips with model numbers, which in this case do relate to speed—but not directly. Intel has now decided to go the model number route, but its model numbering scheme is distinctly different from AMD's. Whereas AMD uses model numbers that equate to "Pentium 4 equivalent" speed, Intel has decided to use a BMW-esque numbering scheme, with 7xx models as the top of the line, 5xx models as the mainstream, and 3xx models on the low end.

When creating the specific model number for a chip, Intel takes into account not only the raw clock speed of the chip, but also the internal architecture, cache sizes, bus speeds, and other features. In general, the higher the number, the more feature-rich the processor. In addition, within each series, the higher numbers are generally faster chips.

Examples of the model numbers currently assigned are shown in Table 3.46.

Table 3.46 Intel Processor Model Numbers and Meanings

Processor	Model No.	Clock Speed	Bus Speed	L2 Cache	Hyper-Threading
Pentium M	755	2.0GHz	400MHz	2MB	No
	745	1.8GHz	400MHz	2MB	No
	735	1.7GHz	400MHz	2MB	No
Pentium 4	720	3.73GHz	1066MHz	2MB	Yes
	580	4.0GHz	800MHz	1MB	Yes
	570	3.8GHz	800MHz	1MB	Yes
	560	3.6GHz	800MHz	1MB	Yes
	550	3.4GHz	800MHz	1MB	Yes
	540	3.2GHz	800MHz	1MB	Yes
	530	3.0GHz	800MHz	1MB	Yes
	520	2.8GHz	800MHz	1MB	Yes
Celeron D	350	3.2GHz	533MHz	256KB	No
	345	3.06GHz	533MHz	256KB	No
	340	2.93GHz	533MHz	256KB	No
	335	2.80GHz	533MHz	256KB	No
	330	2.66GHz	533MHz	256KB	No
	325	2.53GHz	533MHz	256KB	No

Note that not all 7xx chips are faster than 5xx chips, and not all 5xx chips are faster than 3xx chips. The model numbers are not strictly comparisons of speed and certainly don't pertain to speed comparisons outside the model line. For example, using the BMW automobile analogy from which these numbers seem to be derived, some 3-series cars are faster than some 5-series cars, and some 5-series cars are faster than some 7-series cars. However, as you go up in the series numbers, the higher-numbered series generally have more features or are premium models. Although not the most powerful chip it offers, Intel considers the Pentium M mobile processor a full-featured "executive-type" chip and the Celeron more of a "bargain-type" chip. Within the series, the model numbers do give somewhat of an indication of speed, in that a Pentium 4 580 is faster than a Pentium 4 570, and so on.

It will be interesting to see how these model numbers play out in the marketplace. I can say one thing, though—I wouldn't purchase either an Intel or an AMD chip without knowing what the *real* or true clock speeds are, as well as knowing the cache sizes and other features in the chip. The model numbers don't strictly tell that and are useful only for a rough comparison.

Beyond the Pentium 4

The Pentium 4 architecture is reaching the end of the line with the current Prescott die. Beyond that, simply using a smaller process and adding more features seems to have a diminishing return on the investment. Based on the current architecture, power consumption and heat generation are skyrocketing, and a new approach is necessary. Intel has learned a lot from the work it did on the Pentium M laptop processor, which was based mostly on the Pentium III design with some extremely creative power management tricks added. Many rumors are swirling around about the future, but Intel has made several things clear: Its future desktop processors will use many of the power conservation lessons learned from its mobile processors, such as the Pentium M, and future chips might use multiple cores. The latter is somewhat surprising—rather than creating new chip architectures, the best approach to increasing performance is simply to combine multiple processors into a single chip. Hyper-threading technology was actually the beginning of this, and one could have foretold the future by studying that alone. As more and more software is being designed to work using multiple threads of execution, having a hyper-threaded or multiple-core processor makes perfect sense. It might be a year or so before processors with multiple cores are introduced, but it seems as if that will be a natural extension of the existing hyper-threading technology.

Eighth-Generation (64-Bit Register) Processors

As of 2001, it had been about 15 years since PCs had begun to support 32-bit processors (all processors from the 80386 up through the Intel Pentium 4 and AMD Athlon XP). However, in 2001, Intel introduced the first 64-bit processor for servers—the Itanium—followed in 2002 by the improved Itanium 2. In 2003, AMD introduced the first 64-bit processor for desktop computers—the Athlon 64—followed by its first 64-bit server processor, the Opteron. The following sections discuss the major features of these processors and the different approaches taken by Intel and AMD to bring 64-bit computing to the PC server and desktop.

Intel Itanium and Itanium 2

Introduced on May 29, 2001, the Itanium was the first processor in Intel's IA-64 (Intel Architecture 64-bit) product family, and it incorporated innovative performance-enhancing architecture techniques, such as prediction and speculation. It and its newer sibling, the Itanium 2 (introduced in June 2002), are the highest-end processors from Intel and are designed mainly for the server market.

If Intel was still using numbers to designate its processors, the Itanium family might be called the 886 because the Itanium and Itanium 2 are the eighth-generation processors in the Intel family, and they represent the most significant processor architecture advancement since the 386.

Intel's IA-64 product family is designed to expand the capabilities of the Intel architecture to address the high-performance server and workstation market segments.

As with previous new processor introductions, the Itanium and Itanium 2 are not designed to replace the Pentium 4 or III. They feature an all-new design that is initially expensive and is found only in the highest-end systems such as file servers or workstations.

The Itanium's technical details are listed in Table 3.47.

Table 3.47 Intel Itanium and Itanium 2 Technical Details

Processor	Processor Speed	L2 Cache	L3 Cache Size	FSB Speed	Memory Bus Width	Bandwidth	Number of Transistors
Itanium	733MHz 800MHz	96KB	2MB ¹ or 4MB ¹	266MHz	64-bit	2.1GBps	25 million (core) 150 or 300 million (cache)
Itanium 2	900MHz 1GHz	256KB	3MB ²	400MHz	128-bit	6.4GBps	221 million
Itanium 2	1.4GHz 1.5GHz	256KB	6MB ²	400MHz	128-bit	6.4GBps	410 million

1. On-cartridge, full-speed unified 128-bit wide

2. On-die, full-speed unified 128-bit wide

As noted in Table 3.47, the Itanium and Itanium 2 are the first Intel processors with three levels of integrated cache. Even though a few previous system designs featured L3 cache, the L3 cache was located on the motherboard and was therefore much slower. By building L3 cache in to the cartridge (Itanium) or on the processor die (Itanium 2), all three cache levels run at the full processor speed.

The following features apply to both Itanium and Itanium 2 processors:

- 16TB (terabytes) physical memory addressing (44-bit address bus).
- Full 32-bit instruction compatibility in hardware.
- EPIC (explicitly parallel instruction computing) technology, which enables up to 20 operations per cycle.
- Two integer and two memory units that can execute four instructions per clock.
- Two FMAC (floating-point multiply accumulate) units with 82-bit operands.
- Each FMAC unit is capable of executing two floating-point operations per clock.
- Two additional MMX units are capable of executing two single-precision FP operations each.
- A total of eight single-precision FP operations can be executed every cycle.
- 128 integer registers, 128 floating-point registers, 8 branch registers, 64 predicate registers.

The Itanium 2 also features

- 400MHz CPU Bus (versus 266MHz for Itanium)
- 128-bit-wide CPU Bus (versus 64-bit-wide for Itanium)

Intel and Hewlett-Packard began jointly working on the Itanium processor in 1994. In October 1997, more than three years after they first disclosed their plan to work together on a new microprocessor architecture, Intel and HP officially announced some of the new processor's technical details.

Itanium is the first microprocessor based on the Intel architecture-64 (IA-64) specification, which is also supported by Itanium 2. IA-64 is a completely different processor design that uses Very Long Instruction Words (VLIW), instruction prediction, branch elimination, speculative loading, and other advanced processes for enhancing parallelism from program code. The Itanium series features elements of both CISC and RISC design.

The Itanium series incorporates a new architecture Intel calls explicitly parallel instruction computing (EPIC), which enables the processor to execute *parallel instructions*—several instructions at the same time. In the Itanium and Itanium 2, three instructions can be encoded in one 128-bit word, so that each instruction has a few more bits than today's 32-bit instructions. The extra bits let the chip address more registers and tell the processor which instructions to execute in parallel. This approach simplifies the design of processors with many parallel-execution units and should let them run at higher clock rates. In other words, besides being capable of executing several instructions in parallel within the chip, the Itanium can be linked to other Itanium chips in a parallel processing environment. The Itanium 2 also supports parallel processing.

Besides having new features and running a completely new 64-bit instruction set, Itanium and Itanium 2 feature full backward compatibility with the current 32-bit Intel x86 software. In this way, they support 64-bit instructions while retaining full compatibility with today's 32-bit applications. Full backward compatibility means it will run all existing applications as well as any new 64-bit applications. Unfortunately, because this is not the native mode for the processor, performance is not as good when executing 32-bit instructions as it is in the Pentium 4 and earlier chips.

To use the IA-64 instructions, programs must be recompiled for the new instruction set. This is similar to what happened in 1985, when Intel introduced the 386, the first 32-bit PC processor. The 386 gave us a platform for an advanced 32-bit operating system that tapped this new power. To ensure immediate acceptance, the 386 and future 32-bit processors still ran 16-bit code. To take advantage of the 32-bit capability first found in the 386, new software would have to be written. Unfortunately, software evolves much more slowly than hardware. It took Microsoft a full 10 years after the 386 debuted to release Windows 95, the first mainstream 32-bit operating system for Intel processors.

That won't happen with the Itanium and Itanium 2, which already have support from four operating systems, including Microsoft Windows (XP 64-bit Edition and 64-bit Windows Advanced Server Limited Edition 2002), Linux (from four distributor companies: Red Hat, SuSE, Caldera, and Turbo Linux), and two Unix versions (Hewlett-Packard's HP-UX and IBM's AIX).

Despite the immediate OS support, it will likely take several years before the mainstream software market shifts to 64-bit operating systems and software. The installed base of 32-bit processors is simply too great. The backward compatible 32-bit mode of the Itanium family enables them to run 32-bit software because 32-bit instructions are handled directly in the hardware rather than through software emulation. Still, this does not perform as well as a native 32-bit chip.

Itanium and Itanium 2 were initially based on 0.18-micron technology; however, current versions of the Itanium 2 are based on 0.13-micron, allowing for higher speeds and larger caches.

Itaniums come in a new package called the pin array cartridge (PAC). This cartridge includes L3 cache and plugs into a PAC418 (418-pin for Itanium) or PAC611 (611-pin for Itanium 2) socket on the motherboard and not a slot. The package is about the size of a standard index card, weighs about 6oz. (170g), and has an alloy metal on its base to dissipate the heat (see Figure 3.60). Itanium has clips on its sides, enabling four of them to be hung from a motherboard, both below and above.

The first Itanium 2 was codenamed McKinley and officially introduced in June 2002. The current version uses the 0.13-micron Madison core, which has a whopping 410 million transistors and up to 6MB of on-die L3 cache. Because the Itanium 2 has a significantly higher CPU bus bandwidth (6.4GBps), higher clock speeds, larger caches, and a processor FSB twice as wide (128 bits) as the original Itanium, the Itanium 2 is significantly faster in overall processing. The Itanium 2 integrates all three levels of cache inside the processor die, so a cartridge is unnecessary (see Figure 3.61). The Itanium and Itanium 2 are not interchangeable and are supported by different sockets and chipsets.

Itanium Cartridge Features

AMD Athlon 64 and 64 FX

The AMD Athlon 64 and 64 FX, introduced in September 2003, are the first 64-bit processors for desktop (and not server) computers. Originally code named ClawHammer, the Athlon 64 and 64 FX are the desktop element of AMD's 64-bit processor family, which also includes the Opteron (code named SledgeHammer) server processor. The Athlon 64 and 64 FX (shown in Figure 3.62) are essentially Opteron chips but are designed for single-processor systems, and in some cases have decreased cache or memory bandwidth capabilities.

Besides support for 64-bit instructions, the biggest difference between the Athlon 64 and 64 FX and other processors is the fact that their memory controller is built in. The memory controller is normally part of the motherboard chipset North Bridge or memory controller hub, but with the Athlon 64 and 64 FX, the memory controller is now built into the processor. This means that the typical CPU bus architecture is different with these chips. In a conventional design, the processor talks to the chipset North Bridge, which then talks to the memory and all other components in the system.

Because the Athlon 64 and 64 FX have integrated memory controllers, they talk to memory directly, and also talk to the North Bridge for other system communications. Separating the memory traffic from the CPU bus allows for greatly improved performance not only in memory transfers, but also in CPU bus transfers. The main difference in the Athlon 64 and 64 FX is in the different configurations of cache sizes and memory bus widths.

Figure 3.62 AMD Athlon 64 FX (Socket 940 version). *Photo courtesy of AMD.*

The major features of the Athlon 64 and 64 FX design include

- Speeds ranging from 1.8GHz to 2.4GHz and beyond
- 105.9 million transistors, 0.13-micron process, 193 sq. mm die
- 12-stage pipeline
- Single- or dual-channel 72-bit (64-bit plus ECC support) memory interface integrated into the processor (instead of the North Bridge or MCP, as in other recent chipsets)
- 128KB L1 cache
- 512KB or 1MB of on-die full-speed L2 cache
- Actual clock speeds of 1.6GHz–2.4GHz or faster
- Support for IA-32e (also called AMD64, x86-64, or EM64T) 64-bit extension technology (extends 32-bit x86 architecture)
- 3.2GBps or 4GBps Hypertransport link to chipset North Bridge
- Addressable memory size up to 1TB, greatly exceeding the 4GB or 64GB limit imposed by 32-bit processors
- SSE2 (SSE plus 144 new instructions for graphics and sound processing)
- Multiple low-power states

Although AMD has been criticized by many, including me, for its confusing performance-rating processor names in the Athlon XP series, AMD also uses this naming scheme with the Athlon 64. As I suggest with the Athlon XP, you should look at the actual performance of the processor with the applications you use most to determine whether the Athlon 64 is right for you and which model is best suited to your needs. The integrated memory bus in the Athlon 64 means that the Athlon 64 connects to memory more directly than any 32-bit chip and makes North Bridge design simpler. AMD offers its own chipsets for the Athlon 64, but most Athlon 64 motherboards and systems use third-party chipsets from the same vendors that now produce Athlon XP chipsets. See Chapter 4 for details.

The various models and features of the Athlon 64 and 64 FX are summed up in Tables 3.48 and 3.49.

Table 3.48 Athlon 64 Processor Information

Table 3.49 Athlon 64 FX Processor Information

Part Number	Model Number	CPU Speed	Bus Speed (GBps)	CPUID
ADAFX51CEP5AK	FX-51	2.2GHz	3.2	0F58h
ADAFX51CEP5AT	FX-51	2.2GHz	3.2	0F5Ah
ADAFX53CEP5AT	FX-53	2.4GHz	3.2	0F5Ah
ADAFX53DEP5AS	FX-53	2.4GHz	4.0	0F7Ah

The Athlon 64 and 64 FX are available in three socket versions (see Table 3.50). The Athlon 64 is available in Socket 754 and Socket 939 versions, whereas the 64 FX is available in Socket 939 and Socket 940 versions. Socket 754 supports only a single-channel memory bus, whereas Sockets 939 and 940 both support dual-channel memory for double the memory bandwidth. Socket 939 also supports faster and cheaper unbuffered DDR SDRAM DIMMs; Socket 940 supports slower and more expensive registered DIMMs. Because of this, you should avoid any Socket 940 processors or motherboards because they require registered modules that are both slower and more expensive than unbuffered types. Socket 754 versions of the Athlon 64 are also designed to use more affordable unbuffered modules, but only in single-channel mode.

Table 3.50 AMD Athlon 64 and 64 FX Socket and Memory Types

Socket	Processor	Channels	Type
754	Athlon 64	Single-channel	Unbuffered
939	Athlon 64 Athlon 64 FX	Dual-channel	Unbuffered
940	Athlon 64 FX	Dual-channel	Registered

L2 Cache	Max. Temp	Voltage	Power	Socket	Process	Transistors
512K	70°C	1.5V	89W	754	130nm	105.9M
512K	70°C	1.5V	89W	754	130nm	105.9M
512K	70°C	1.5V	89W	754	130nm	105.9M
512K	70°C	1.5V	89W	754	130nm	105.9M
1M	70°C	1.5V	89W	754	130nm	105.9M
1M	70°C	1.5V	89W	754	130nm	105.9M
512K	70°C	1.5V	89W	754	130nm	105.9M
1M	70°C	1.5V	89W	754	130nm	105.9M
1M	70°C	1.5V	89W	754	130nm	105.9M
512K	70°C	1.5V	89W	939	130nm	105.9M
1M	70°C	1.5V	89W	754	130nm	105.9M
512K	70°C	1.5V	89W	939	130nm	105.9M

L2 Cache	Max. Temp	Voltage	Power	Socket	Process	Transistors
1M	70°C	1.5V	89W	940	130nm	105.9M
1M	70°C	1.5V	89W	940	130nm	105.9M
1M	70°C	1.5V	89W	940	130nm	105.9M
1M	70°C	1.5V	89W	939	130nm	105.9M

The Athlon 64 essentially comes in two versions: a Socket 754 version that has only a single-channel memory bus and an improved Socket 939 version that has a dual-channel memory bus. The Athlon 64 FX is also available in two versions: a Socket 940 version that uses expensive (and slower) registered memory and an improved Socket 939 version that uses unbuffered memory. The Socket 939 versions of the Athlon 64 and 64 FX are essentially the same chip, differing only in the amount of L2 cache included. For example, the Athlon 64 3800+ and Athlon 64 FX-53 both run at 2.4GHz and run dual-channel memory. The only difference is that the 3800+ has only 512KB of L2 cache whereas the FX-53 has 1MB of L2. Because the 64 and 64 FX chips are essentially the same, you need to read the fine print to determine the minor differences in configuration.

The Athlon 64 and 64 FX can draw up to 89W or more of power, which is high but still somewhat less than the more power-hungry Pentium 4 processors. As with the Pentium 4, motherboards for the Athlon 64 and 64 FX require the ATX12V connector to provide adequate 12V power to run the processor voltage regulator module.

The initial version of the Athlon 64 is built on a 0.13-micron (130-nanometer) process (see Figure 3.63). The second version—code named San Diego (desktop version) and Odessa (portable version)—is due in 2004 and will be AMD's first processor to use the .09-micron process.

Figure 3.63 AMD Athlon 64 die (130-nanometer process, 106 million transistors, 193 sq. mm). *Photo courtesy of AMD.*

AMD Opteron

The AMD Opteron is the workstation and server counterpart to the AMD Athlon 64, supporting the same x86-64 architecture as the Athlon 64. The Opteron was introduced in the spring of 2003.

The following are the major features of the Opteron:

- 128KB L1 cache
- 1MB L2 cache
- Initial clock speeds of 1.8GHz–2GHz
- Three 3.2MBps Hypertransport links to chipset
- Socket 940
- Integrated memory controller
- 128-bit plus ECC dual-channel memory bus
- Maximum addressable memory of 1 terabyte (40-bit physical) and 256 terabytes (48-bit virtual)
- x86-64 architecture

Unlike the Itanium series, which has been supported primarily by Intel chipsets, the Opteron has broad third-party chipset support from companies such as VIA, SiS, ALi, NVIDIA, and ATI (just like the Athlon 64 does).

Processor Upgrades

Since the 486, processor upgrades have been relatively easy for most systems. With the 486 and later processors, Intel designed in the capability to upgrade by designing standard sockets that would take a variety of processors. Thus, if you have a motherboard with Socket 3, you can put virtually any 486 processor in it; if you have a Socket 7 motherboard, it should be capable of accepting virtually any Pentium processor (or Socket 7–based third-party processor). This trend has continued to the present, with most motherboards being designed to handle a range of processors in the same family (Pentium III/Celeron III, Athlon/Duron/Athlon XP, Pentium 4/Celeron 4, and so forth).

To maximize your motherboard, you can almost always upgrade to the fastest processor your particular board will support. Because of the varieties of processor sockets and slots—not to mention voltages, speeds, and other potential areas of incompatibility—you should consult with your motherboard manufacturer to see whether a higher-speed processor will work in your board. Usually, that can be

determined by the type of socket or slot on the motherboard, but other things such as the voltage regulator and BIOS can be deciding factors as well.

For example, if your motherboard uses Socket 370, you might be able to upgrade to the fastest 1.4GHz version of the Pentium III. Before purchasing a new CPU, you should verify that the motherboard has proper bus speed, voltage settings, and ROM BIOS support for the new chip.

Caution

If you are trying to upgrade the processor in a low-cost micro-ATX system from a company such as HP, you might have very few processor upgrade options. This is because many of the motherboards in low-cost computers don't provide much in the way of adjustments for clock speed or voltage.

If you are unable to install a faster processor directly into your system, a variety of third-party solutions are available, including adapters that can help first-generation Socket 423 Pentium 4 motherboards use Socket 478 processors, faster Socket 370 processors for older Slot 1 motherboards, and so on. Rather than purchasing processors and adapters separately, I usually recommend you purchase them together in a module from companies such as Evergreen or PowerLeap (see the Vendor List on the disc).

Upgrading the processor can, in some cases, double the performance of a system. However, if you already have the fastest processor that will fit a particular socket, you need to consider other alternatives. In that case, you really should look into a complete motherboard change, which would let you upgrade to a Pentium 4, Athlon XP, or Athlon 64 processor at the same time. If your chassis design is not proprietary and your system uses an industry-standard ATX motherboard design, I normally recommend changing the motherboard and processor rather than trying to find an upgrade processor that will work with your existing board.

OverDrive Processors

Intel at one time offered special OverDrive processors for upgrading systems. Often these were repackaged versions of the standard processors, sometimes including necessary voltage regulators and fans. Unfortunately, they frequently were overpriced, even when compared against purchasing a complete new motherboard and processor. They have all been withdrawn, and Intel has not announced any new versions. I don't recommend the OverDrive processors unless the deal is too good to pass up.

Processor Benchmarks

People love to know how fast (or slow) their computers are. We have always been interested in speed; it is human nature. To help us with this quest, various benchmark test programs can be used to measure different aspects of processor and system performance. Although no single numerical measurement can completely describe the performance of a complex device such as a processor or a complete PC, benchmarks can be useful tools for comparing different components and systems.

However, the only truly accurate way to measure your system's performance is to test the system using the actual software applications you use. Although you think you might be testing one component of a system, often other parts of the system can have an effect. It is inaccurate to compare systems with different processors, for example, if they also have different amounts or types of memory, different hard disks, video cards, and so on. All these things and more will skew the test results.

Benchmarks can typically be divided into two types: component or system tests. *Component* benchmarks measure the performance of specific parts of a computer system, such as a processor, hard disk, video card, or CD-ROM drive, whereas system benchmarks typically measure the performance of the entire computer system running a given application or test suite.

Benchmarks are, at most, only one kind of information you can use during the upgrading or purchasing process. You are best served by testing the system using your own set of software operating systems and applications and in the configuration you will be running.

Several companies specialize in benchmark tests and software. The following table lists the companies and the benchmarks they are known for. You can contact these companies via the information in the Vendor List on the disc.

Company	Benchmarks Published	Benchmark Type
Futuremark (formerly MadOnion.com)	SysMark PCMark Pro 3DMark	System System 3D graphics
Lionbridge (Veritest) (PC Magazine benchmarks)	Winstone WinBench CD WinBench NetBench WebBench	System System CD/DVD drives Network Web server
Business Applications Performance Corporation (BAPCo)	MobileMark	Notebook battery life
Standard Performance Evaluation Corporation	SPECint	Processor Integer
SiSoftware	SPECfp Sandra	Processor Floating-Point System, memory, processor, multimedia

Processor Troubleshooting Techniques

Processors are normally very reliable. Most PC problems are with other devices, but if you suspect the processor, there are some steps you can take to troubleshoot it. The easiest thing to do is to replace the microprocessor with a known-good spare. If the problem goes away, the original processor is defective. If the problem persists, the problem is likely elsewhere.

Table 3.51 provides a general troubleshooting checklist for processor-related PC problems.

Table 3.51 Troubleshooting Processor-Related Problems

Problem Identification	Possible Cause	Resolution
System is dead, no cursor, no beeps, no fan.	Power cord failure.	Plug in or replace power cord. Power cords can fail even though they look fine.
	Power supply failure.	Replace the power supply. Use a known-good spare for testing.
	Motherboard failure.	Replace motherboard. Use a known-good spare for testing.
	Memory failure.	Remove all memory except 1 bank and retest. If the system still won't boot replace bank 1.
System is dead, no beeps, or locks up before POST begins.	All components either not installed or incorrectly installed.	Check all peripherals, especially memory and graphics adapter. Reseat all boards and socketed components.
System beeps on startup, fan is running, no cursor on screen.	Improperly seated or failing graphics adapter.	Reseat or replace graphics adapter. Use known-good spare for testing.
System powers up, fan is running, no beep or cursor.	Processor not properly installed.	Reseat or remove/reinstall processor and heatsink.

Table 3.51 Continued

Problem Identification	Possible Cause	Resolution
Locks up during or shortly after POST.	Poor heat dissipation.	Check CPU heatsink/fan; replace if necessary, use one with higher capacity.
	Improper voltage settings.	Set motherboard for proper core processor voltage.
	Wrong motherboard bus speed.	Set motherboard for proper speed.
	Wrong CPU clock multiplier.	Jumper motherboard for proper clock multiplier.
Improper CPU identification during POST.	Old BIOS.	Update BIOS from manufacturer.
	Board not configured properly.	Check manual and jumper board accordingly to proper bus and multiplier settings.
System won't start after new processor is installed.	Processor not properly installed.	Reseat or remove/reinstall processor and heatsink.
	BIOS doesn't support new processor.	Update BIOS from system or motherboard manufacturer.
	Motherboard can't use new processor.	Verify motherboard support.
Operating system will not boot.	Poor heat dissipation.	Check CPU fan; replace if necessary; it might need a higher-capacity heatsink or heatsink/fan on the North Bridge chip.
	Improper voltage settings.	Jumper motherboard for proper core voltage.
	Wrong motherboard bus speed.	Jumper motherboard for proper speed.
	Wrong CPU clock multiplier.	Jumper motherboard for proper clock multiplier.
	Applications will not install or run.	Improper drivers or incompatible hardware; update drivers and check for compatibility issues.
System appears to work, but no video is displayed.	Monitor turned off or failed.	Check monitor and power to monitor. Replace with known-good spare for testing.

If during the POST the processor is not identified correctly, your motherboard settings might be incorrect or your BIOS might need to be updated. Check that the motherboard is jumpered or configured correctly for your processor, and make sure you have the latest BIOS for your motherboard.

If the system seems to run erratically after it warms up, try setting the processor to a lower speed setting. If the problem goes away, the processor might be defective or overclocked.

Many hardware problems are really software problems in disguise. Be sure you have the latest BIOS for your motherboard, as well as the latest drivers for all your peripherals. Also, it helps to use the latest version of your given operating system because there usually will be fewer problems.

CHAPTER 4

Motherboards and Buses

Motherboard Form Factors

Without a doubt, the most important component in a PC system is the main board or motherboard. Some companies refer to the motherboard as a system board or planar. The terms *motherboard*, *main board*, *system board*, and *planar* are interchangeable, although I prefer the *motherboard* designation. This chapter examines the various types of motherboards available and those components typically contained on the motherboard and motherboard interface connectors.

Several common form factors are used for PC motherboards. The *form factor* refers to the physical dimensions (size and shape) as well as certain connector, screw hole, and other positions that dictate into which type of case the board will fit. Some are true standards (meaning that all boards with that form factor are interchangeable), whereas others are not standardized enough to allow for interchangeability. Unfortunately, these nonstandard form factors preclude any easy upgrade or inexpensive replacement, which generally means they should be avoided. The more commonly known PC motherboard form factors include the following:

Obsolete Form Factors

- Baby-AT
- Full-size AT
- LPX (semiproprietary)
- WTX (no longer in production)
- ITX (FlexATX variation, never produced)

Modern Form Factors

- BTX
- microBTX
- picoBTX
- ATX
- microATX
- flexATX
- Mini-ITX (FlexATX variation)
- NLX

All Others

- Fully proprietary designs (certain Compaq, Packard Bell, Hewlett-Packard, notebook/portable systems, and so on)

Motherboards have evolved over the years from the original Baby-AT form factor boards used in the original IBM PC and XT to the current BTX and ATX boards used in most full-size desktop and tower systems. ATX has a number of variants, including microATX (which is a smaller version of the ATX form factor used in the smaller systems) and FlexATX (an even smaller version for the lowest-cost home PCs). The newest form factor, BTX, relocates major components to improve system cooling and incorporates a thermal module. BTX also has smaller microBTX and picoBTX variations. Another small form factor called Mini-ITX is also available; it's really just a minimum-size version of FlexATX designed for very small systems. NLX is designed for corporate desktop-type systems; WTX was designed for workstations and medium-duty servers, but never became popular. Table 4.1 shows the modern industry-standard form factors and their recommended uses.

Table 4.1 Common Industry-Standard Motherboard Form Factors

Form Factor	Use	Max. Slots
BTX	New-generation tower and desktop systems; likely to be the most common form factor from 2005 and beyond; supports high-end systems	7
microBTX	Smaller version of BTX; used in new-generation mid-range systems; fits the microBTX or BTX chassis	4
picoBTX	Smallest version of BTX; used in low-end small form factor, entertainment, or appliance systems; fits the picoBTX, microBTX, or BTX chassis	1
ATX	Standard tower and desktop systems; most common form factor from mid-1996 through 2004; supports high-end systems	7

Table 4.1 Continued

Form Factor	Use	Max. Slots
Mini-ATX	A slightly smaller version of ATX that fits the ATX chassis; many ATX motherboards are sold as Mini-ATX motherboards	6
microATX	Smaller version of ATX; used in mid-range systems; fits the microATX or ATX chassis	4
FlexATX	Smallest version of ATX; used in low-end small form factor, entertainment, or appliance systems; fits the FlexATX, microATX, or ATX chassis	3
Mini-ITX	Minimum-size FlexATX version; used in set-top boxes and compact/small form factor systems; highly integrated with one PCI expansion slot; fits in the Mini-ITX, FlexATX, microATX, or ATX chassis	1
NLX	Corporate slim desktop or mini-tower systems; fast and easy serviceability; slots on riser card	Varies

Although the Baby-AT, Full-size AT, and LPX boards were once popular, they have been replaced by more modern and interchangeable form factors. The modern form factors are true standards that provide improved interchangeability within each type. This means one brand of ATX boards can interchange with other brand ATX boards, BTX with other BTX, and so on. The additional features found on these boards as compared to the obsolete form factors, combined with true interchangeability, has made the migration to these newer form factors quick and easy. Today I recommend purchasing only systems with one of the modern industry-standard form factors. Each of these form factors, however, is discussed in more detail in the following sections.

Anything that does not fit into one of the industry-standard form factors should be considered proprietary. Unless there are special circumstances, I do not recommend purchasing systems with proprietary board designs. They will be virtually impossible to upgrade and very expensive to repair later because the motherboard, case, and often power supply will not be interchangeable with other models. I call proprietary form factor systems “disposable” PCs because that’s what you must normally do with them when they are too slow or need repair out of warranty.

Caution

“Disposable” PCs might be more common than ever. Some estimate that as much as 60% of all PCs sold today are disposable models, not so much because of the motherboards used, but because of the tiny power supplies and cramped micro-tower cases that are favored on most retail-market PCs today. Although low-cost PCs using small chassis and power supplies are theoretically more upgradeable than past disposable type systems, you’ll still hit the wall over time if you need more than three expansion slots or want to use more than two or three internal drives. Because mini-tower systems are so cramped and limited, I consider them to be almost as disposable as the LPX systems they have largely replaced.

You also need to watch out for systems that only appear to meet industry standards, such as certain Dell computer models built from 1996 to the present—especially the XPS line of systems. These computers often use rewired versions of the ATX power supply (or even some that are completely nonstandard in size and shape) and modified motherboard power connectors, which makes both components completely incompatible with standard motherboards and power supplies. In some of the systems, the power supply has a completely proprietary shape as well and the motherboards are not fully standard ATX either. If you want to upgrade the power supply, you must use a special Dell-compatible power supply. And if you want to upgrade the motherboard (assuming you can find one that fits), you must buy a standard power supply to match. The best alternative is to replace the motherboard, power supply, and possibly the case with industry-standard components simultaneously. For more details about how to determine whether your Dell computer uses nonstandard power connectors, see Chapter 21, “Power Supply and Chassis/Case.”

If you want to have a truly upgradeable system, insist on systems that use ATX or BTX motherboards in a mid-tower or larger case with at least five drive bays.

PC and XT

The first popular PC motherboard was, of course, the original IBM PC released in August 1981. Figure 4.1 shows how this board looked. IBM followed the PC with the XT motherboard in March 1983, which had the same size and shape as the PC board but had eight slots instead of five. Both the IBM PC and XT motherboards were 9"×13" in size. Also, the slots were spaced 0.8" apart in the XT instead of 1" apart as in the PC (see Figure 4.2). The XT also eliminated the little-used cassette port in the back, which was supposed to be used to save BASIC programs on cassette tape instead of the much more expensive (at the time) floppy drive.

Figure 4.1 IBM PC motherboard (circa 1981).

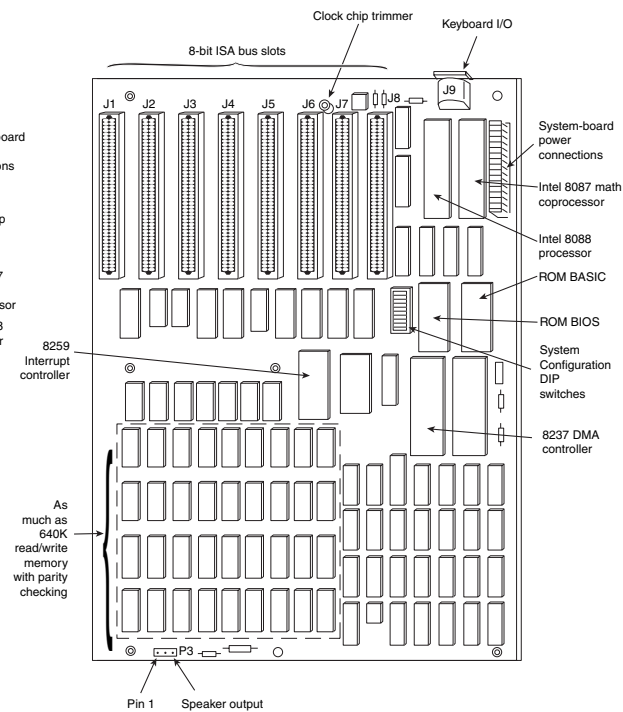

Figure 4.2 IBM PC-XT motherboard (circa 1983).

Note

The Technical Reference section of the disc accompanying this book contains detailed information on the PC (5150) and XT (5160). All the information there is printable.

The minor differences in the slot positions and the deleted cassette connector on the back required a minor redesign of the case. In essence, the XT was a mildly enhanced PC, with a motherboard that was the same overall size and shape, used the same processor, and came in a case that was identical except for slot bracketry and the lack of a hole for the cassette port. Eventually, the XT motherboard design became very popular, and many other PC motherboard manufacturers of the day copied IBM's XT design and produced similar boards.

Full-Size AT

The full-size AT motherboard form factor matches the original IBM AT motherboard design. This allows for a very large board of up to 12" wide by 13.8" deep. The full-size AT board first debuted in August 1984, when IBM introduced the Personal Computer AT (advanced technology). To accommodate the 16-bit 286 processor and all the necessary support components at the time, IBM needed more room than the original PC/XT-sized boards could provide. So for the AT, IBM increased the size of the motherboard but retained the same screw hole and connector positions of the XT design. To accomplish this, IBM essentially started with a PC/XT-sized board and extended it in two directions (see Figure 4.3).

Figure 4.3 IBM AT motherboard (circa 1984).

Note

The Technical Reference section of the disc enclosed with this book contains detailed coverage of the AT and the XT Model 286.

A little more than a year after being introduced, the appearance of chipsets and other circuit consolidation allowed the same motherboard functionality to be built using fewer chips, so the board was redesigned to make it slightly smaller. Then, it was redesigned again as IBM shrank the board down to XT-size in a system it called the XT-286 (introduced in September 1986). The XT-286 board was virtually identical in size and shape to the original XT, a form factor which would later be known as Baby-AT.

The keyboard connector and slot connectors in the full-size AT boards still conformed to the same specific placement requirements to fit the holes in the XT cases already in use, but a larger case was still required to fit the larger board. Because of the larger size of the board, a full-size AT motherboard only fits into full-size AT desktop or tower cases. Because these motherboards do not fit into the smaller Baby-AT or mini-tower cases, and because of advances in component miniaturization, they are no longer being produced by most motherboard manufacturers—except in some cases for dual processor server applications.

The important thing to note about the full-size AT systems is that you can always replace a full-size AT motherboard with a Baby-AT (or XT-size) board, but the opposite is not true unless the case is large enough to accommodate the full-size AT design.

Baby-AT

After IBM released the AT in August 1984, component consolidation allowed subsequent systems to be designed using far fewer chips and requiring much less in the way of motherboard real estate. Therefore, all the additional circuits on the 16-bit AT motherboard could fit into boards using the smaller XT form factor.

IBM was one of the first to use the smaller boards when it introduced a system called the XT-286 in September 1986. Unfortunately the “XT” designation in the name of that system caused a lot of confusion, and many people did not want to buy a system they thought used older and slower technology. Sales of the XT-286 were dismal. By this time, other companies had also developed XT-size AT class systems. However, they decided that rather than calling these boards XT-size, which seemed to make people think they were 8-bit designs, they would refer to them as “Baby-AT” designs. The intention was to make people understand that these new boards had AT technology in a smaller form factor and were not souped-up versions of older technology as was seemingly implied by IBM’s XT-286 moniker.

Thus, the Baby-AT form factor is essentially the same form factor as the original IBM XT motherboard. The only difference is a slight modification in one of the screw hole positions to fit into an AT-style case. These motherboards also have specific placement of the keyboard and slot connectors to match the holes in the case. Note that virtually all full-size AT and Baby-AT motherboards use the standard 5-pin DIN type connector for the keyboard. Baby-AT motherboards can be used to replace full-size AT motherboards and will fit into several case designs. Because of its flexibility, from 1983 into early 1996, the Baby-AT form factor was the most popular motherboard type. Starting in mid-1996, Baby-AT was replaced by the superior ATX motherboard design, which is not directly interchangeable. Most systems sold since 1996 have used the improved ATX, microATX, or NLX design, and Baby-AT is getting harder and harder to come by (surplus computer hardware outlets are your best bet for Baby-AT). Figure 4.5 shows the onboard features and layout of a late-model Baby-AT motherboard. Older Baby-AT motherboards have the same general layout but lack advanced features, such as USB connectors, DIMM memory sockets, and the AGP slot.

Any case that accepts a full-size AT motherboard will also accept a Baby-AT design. PC motherboards using the Baby-AT design have been manufactured to use virtually any processor from the original 8088 to the Pentium III or Athlon, although the pickings are slim where the newer processors are concerned. As such, systems with Baby-AT motherboards were the original upgradeable systems. Because any Baby-AT motherboard can be replaced with any other Baby-AT motherboard, this is an interchangeable design. Even though the Baby-AT design (shown in Figure 4.4) is now obsolete, ATX carries on its philosophy of interchangeability. Figure 4.5 shows a more modern Baby-AT motherboard, which includes USB compatibility, SIMM and DIMM sockets, and even a supplemental ATX power supply connection.

The easiest way to identify a Baby-AT form factor system without opening it is to look at the rear of the case. In a Baby-AT motherboard, the cards plug directly into the board at a 90° angle; in other words, the slots in the case for the cards are perpendicular to the motherboard. Also, the Baby-AT motherboard has only one visible connector directly attached to the board, which is the keyboard connector. Typically, this connector is the full-size 5-pin DIN type connector, although some Baby-AT systems use the smaller 6-pin mini-DIN connector (sometimes called a PS/2 type connector) and might even have a mouse connector. All other connectors are mounted on the case or on card edge brackets and are attached to the motherboard via cables. The keyboard connector is visible through an appropriately placed hole in the case.

▶▶ See “Keyboard/Mouse Interface Connectors,” p. 1031.

Baby-AT boards all conform to specific widths and screw hole, slot, and keyboard connector locations, but one thing that can vary is the length of the board. Versions have been built that are smaller than the full 9"×13" size; these are often called mini-AT, micro-AT, or even things such as 2/3-Baby or 1/2-Baby. Even though they might not be the full size, they still bolt directly into the same case as a standard Baby-AT board and can be used as a direct replacement for one.

Figure 4.4 Baby-AT motherboard form factor dimensions.

Figure 4.5 A late-model Baby-AT motherboard, the Tyan Trinity 100AT (S1590). *Photo courtesy of Tyan Computer Corporation.*

LPX

The LPX and mini-LPX form factor boards were a semiproprietary design that Western Digital originally developed in 1987 for some of its motherboards. The *LP* in LPX stands for Low Profile, which is so named because these boards incorporate slots that are parallel to the main board, enabling the expansion cards to install sideways. This allows for a slim or low-profile case design and overall a smaller system than the Baby-AT.

Although Western Digital no longer produces PC motherboards, the form factor lives on, and many other motherboard manufacturers have duplicated the design. Unfortunately, because the specifications were never laid out in exact detail—especially with regard to the bus riser card portion of the design—these boards are termed semiproprietary and are not interchangeable between manufacturers. Some vendors, such as IBM and HP, for example, have built LPX systems that use a T-shaped riser card that allows expansion cards to be mounted at the normal 90° angle to the motherboard but still above the motherboard. This lack of standardization means that if you have a system with an LPX board, in most cases you can't replace the motherboard with a different LPX board later. You essentially have a system you can't upgrade or repair by replacing the motherboard with something better. In other words, you have what I call a disposable PC, something I would not normally recommend that anybody purchase.

Most people were not aware of the semiproprietary nature of the design of these boards, and they were extremely popular in what I call “retail store” PCs from the late 1980s through the late 1990s. This would include primarily Compaq and Packard Bell systems, as well as many others who used this form factor in their lower-cost systems. These boards were most often used in low-profile or Slimline case systems but were found in tower cases, too. These were often lower-cost systems such as those sold at retail electronics superstores. Although scarce even in retail chains today, because of their proprietary nature, I recommend staying away from any system that uses an LPX motherboard.

Purchasing LPX Motherboards

Normally, I would never recommend upgrading an LPX system—they simply aren't worth the expense. However, a few vendors do sell LPX motherboards, so if it's absolutely necessary, an upgrade might be possible. The problem is the riser card, which is typically sold separately from the motherboard itself. It is up to you to figure out which riser card will work in your existing case, and often, if you choose the wrong riser card, you're stuck with it.

If you must locate LPX-compatible products, try these Web sites and vendors:

- Unicorn Computers (Taiwan): www.unicorn-computer.com.tw
- Hong Faith America (Taiwan): america.hongfaith.com
- FriendTech's LPX Zone: www.friendtech.com/LPX_Zone/LPX_Zone.htm

Note that the FriendTech Web site has links to other vendors and is developing a comprehensive knowledge base of LPX-related information and possible upgrades.

LPX boards are characterized by several distinctive features (see Figure 4.6). The most noticeable is that the expansion slots are mounted on a bus riser card that plugs into the motherboard. In most designs, expansion cards plug sideways into the riser card. This sideways placement allows for the low-profile case design. Slots are located on one or both sides of the riser card depending on the system and case design. Vendors who use LPX-type motherboards in tower cases sometimes use a T-shaped riser card instead, which puts the expansion slots at the normal right angle to the motherboard but on a raised shelf above the motherboard itself.

Another distinguishing feature of the LPX design is the standard placement of connectors on the back of the board. An LPX board has a row of connectors for video (VGA 15-pin), parallel (25-pin), two serial ports (9-pin each), and mini-DIN PS/2 style mouse and keyboard connectors. All these connectors are mounted across the rear of the motherboard and protrude through a slot in the case. Some LPX motherboards might have additional connectors for other internal ports, such as network or SCSI adapters. Because LPX systems use a high degree of motherboard port integration, many vendors of LPX motherboards, cases, and systems often refer to LPX products as having an “all-in-one” design.

The standard form factor used for LPX and mini-LPX motherboards in many typical low-cost systems is shown in Figure 4.7.

Figure 4.6 Typical LPX system chassis and motherboard.

Figure 4.7 LPX motherboard dimensions.

I am often asked, “How can I tell whether a system has an LPX board without opening the cover?” Because of the many variations in riser card design, and because newer motherboards such as NLX also use riser cards, the most reliable way to distinguish an LPX motherboard from other systems is to look at the connector signature (the layout and pattern of connectors on the back of the board). As you can see in Figure 4.8, all LPX motherboards—regardless of variations in riser card shape, size, or location—place all external ports along the rear of the motherboard. By contrast, Baby-AT motherboards use case-mounted or expansion slot-mounted connectors for serial, parallel, PS/2 mouse, and USB ports, whereas ATX-family motherboards group all external ports together to the left side of the expansion slots.

On an LPX board, the riser is placed in the middle of the motherboard, whereas NLX boards have the riser to the side (the motherboard actually plugs into the riser in NLX).

Figure 4.8 shows two typical examples of the connectors on the back of LPX boards. Note that not all LPX boards have the built-in audio, so those connectors might be missing. Other ports (such as USB) might be missing from what is shown in these diagrams, depending on exactly which options are included on a specific board; however, the general layout will be the same.

Figure 4.8 LPX motherboard back panel connectors.

The connectors along the rear of the board would interfere with locating bus slots directly on the motherboard, which accounts for why riser cards are used for adding expansion boards.

Although the built-in connectors on the LPX boards were a good idea, unfortunately the LPX design was semiproprietary (not a fully interchangeable standard) and thus, not a good choice. Newer motherboard form factors such as ATX, microATX, and NLX have both built-in connectors and use a standard board design. The riser card design of LPX allowed system designers to create a low-profile desktop system, a feature now carried by the much more standardized NLX form factor. In fact, NLX was developed as the modern replacement for LPX.

ATX

The ATX form factor was the first of a dramatic evolution in motherboard form factors. ATX is a combination of the best features of the Baby-AT and LPX motherboard designs, with many new enhancements and features thrown in. The ATX form factor is essentially a Baby-AT motherboard turned sideways in the chassis, along with a modified power supply location and connector. The most important thing to know initially about the ATX form factor is that it is physically incompatible with either the previous Baby-AT or LPX design. In other words, a different case and power supply are required to match the ATX motherboard. These case and power supply designs have become common and are found in most new systems.

Intel initially released the official ATX specification in July 1995. It was written as an open specification for the industry. ATX boards didn't hit the market in force until mid-1996, when they rapidly began replacing Baby-AT boards in new systems. The ATX specification was updated to version 2.01 in February 1997, 2.03 in May 2000, 2.1 in June 2002, and 2.2 in February 2004. Intel publishes these

detailed specifications so other manufacturers can use the interchangeable ATX design in their systems. The current specifications for ATX and other current motherboard types are available online from the Desktop Form Factors site: www.formfactors.org. ATX is the most popular motherboard form factor for new systems through 2004. An ATX system will be upgradeable for many years to come, exactly like Baby-AT was in the past.

ATX improved on the Baby-AT and LPX motherboard designs in several major areas:

- **Built-in double high external I/O connector panel.** The rear portion of the motherboard includes a stacked I/O connector area that is 6 1/4" wide by 1 3/4" tall. This enables external connectors to be located directly on the board and negates the need for cables running from internal connectors to the back of the case as with Baby-AT designs.
 - **Single main keyed internal power supply connector.** This is a boon for the average end user who always had to worry about interchanging the Baby-AT power supply connectors and subsequently blowing the motherboard. The ATX specification includes a keyed and shrouded main power connector that is easy to plug in and can't be installed incorrectly. This connector also features pins for supplying 3.3V to the motherboard, so ATX motherboards do not require built-in voltage regulators that are susceptible to failure. The ATX specification was extended to include two additional optional keyed power connectors called the Auxiliary Power connector (3.3V and 5V) and the ATX12V connector for systems that require more power than the original specification would allow.
- ▶▶ See "Motherboard Power Connectors," p. 1164.
- **Relocated CPU and memory.** The CPU and memory modules are relocated so they can't interfere with any bus expansion cards and can easily be accessed for upgrade without removing any of the installed bus adapters. The CPU and memory are relocated next to the power supply, which is where the primary system fan is located. The improved airflow concentrated over the processor, in the case of some older processors, eliminates the need for extra-cost CPU cooling fans (lower power configurations only). There is room for a CPU and a heatsink and fan combination of up to 2.8" in height, as well as more than adequate side clearance provided in that area.

Note

Most systems require cooling in addition to the fan in the power supply—from a secondary case-mounted fan or an active heatsink on the processor with an integral fan. Intel and AMD supply processors with attached high-quality (ball bearing) fans for CPUs sold to smaller vendors. These are so-called "boxed" processors because they are sold in single-unit box quantities instead of cases of 100 or more like the raw CPUs sold to the larger vendors. The included fan heatsink is an excellent form of thermal insurance because most smaller vendors and system self-assemblers lack the engineering knowledge necessary to perform thermal analysis, temperature measurements, and the testing required to select the properly sized passive heatsinks. The only thermal requirement spelled out for the boxed processors is that the temperature of the air entering the active heatsink (usually the same as the system interior ambient temperature) is kept to 45°C (113°F) or less in Pentium III or earlier models, or 40°C (104°F) or less in the Pentium 4 or later processors. By putting a high-quality fan on these "boxed" processors, Intel and AMD can put a warranty on the boxed processors that is independent of the system warranty. Larger vendors have the engineering talent to select the proper passive heatsink, thus reducing the cost of the system as well as increasing reliability. With an OEM non-boxed processor, the warranty is with the system vendor and not the processor manufacturer directly. Heatsink mounting instructions usually are included with a motherboard if non-boxed processors are used.

- **Relocated internal I/O connectors.** The internal I/O connectors for the floppy and hard disk drives are relocated to be near the drive bays and out from under the expansion board slot and drive bay areas. Therefore, internal cables to the drives can be much shorter, and accessing the connectors does not require card or drive removal.
- **Improved cooling.** The CPU and main memory are designed and positioned to improve overall system cooling. This can decrease—but not necessarily eliminate—the need for separate case or CPU cooling fans. Most higher-speed systems still need additional cooling fans for the CPU and

chassis. Note that the ATX specification originally specified that the ATX power supply fan blows into the system chassis instead of outward. This reverse flow, or positive pressure design, pressurizes the case and minimizes dust and dirt intrusion. More recently, the ATX specification was revised to allow the more normal standard flow, which negatively pressurizes the case by having the fan blow outward. Because the specification technically allows either type of airflow, and because some overall cooling efficiency is lost with the reverse flow design, most power supply manufacturers provide ATX power supplies with fans that exhaust air from the system, otherwise called a negative pressure design. See Chapter 21 for more detailed information.

- **Lower cost to manufacture.** The ATX specification eliminates the need for the rat's nest of cables to external port connectors found on Baby-AT motherboards, additional CPU or chassis cooling fans, or onboard 3.3V voltage regulators. Instead, ATX allows for shorter internal drive cables and no cables for standard external serial or parallel ports. These all conspire to greatly reduce the cost of the motherboard and the cost of a complete system—including the case and power supply.

Figure 4.9 shows the ATX system layout and chassis features, as you would see them looking in with the lid off on a desktop, or sideways in a tower with the side panel removed. Notice how virtually the entire motherboard is clear of the drive bays and how the devices such as CPU, memory, and internal drive connectors are easy to access and do not interfere with the bus slots. Also notice how the processor is positioned near the power supply.

Figure 4.9 When mounted inside the case, the ATX motherboard is oriented so that the CPU socket is near the power supply fan and case fan (if your case includes one).

The ATX motherboard shape is basically a Baby-AT design rotated sideways 90°. The expansion slots are now parallel to the shorter side dimension and do not interfere with the CPU, memory, or I/O connector sockets (see Figure 4.10). There are actually two basic sizes of standard ATX boards. In

addition to a full-size ATX layout, Intel also specified a MiniATX design, which is a fully compatible subset of ATX that fits into the same case:

- A full-size ATX board is 12" wide × 9.6" deep (305mm×244mm).
- The Mini-ATX board is 11.2"×8.2" (284mm×208mm).

Mini-ATX is not an official standard; instead it is simply referenced as a slightly smaller version of ATX. In fact, all references to Mini-ATX were removed from the ATX 2.1 and later specifications. Two smaller official versions of ATX exist, called microATX and FlexATX. They are discussed in the following sections.

Figure 4.10 ATX specification 2.2 motherboard dimensions.

Although the case holes are similar to the Baby-AT case, cases for Baby-AT and ATX are generally incompatible. The ATX power supply design is identical in physical size to the standard Slimline power supply used with Baby-AT systems; however, they also use different connectors and supply different voltages.

The ATX form factor's design advantages have swept Baby-AT and LPX motherboards off the market. Although other form factors are now available, I have been recommending only ATX (or compatible variations such as microATX or FlexATX) systems for new system purchases since late 1996 and will probably continue to do so for the next several years.

The best way to tell whether your system has an ATX-family motherboard design without removing the lid is to look at the back of the system. Two distinguishing features identify ATX. One is that the

expansion boards plug directly into the motherboard. There is usually no riser card as with LPX or NLX, so the slots are perpendicular to the plane of the motherboard. Also, ATX boards have a unique double-high connector area for all the built-in connectors on the motherboard (see Figure 4.11 and Table 4.2). This is found just to the side of the bus slot area and can be used to easily identify an ATX board.

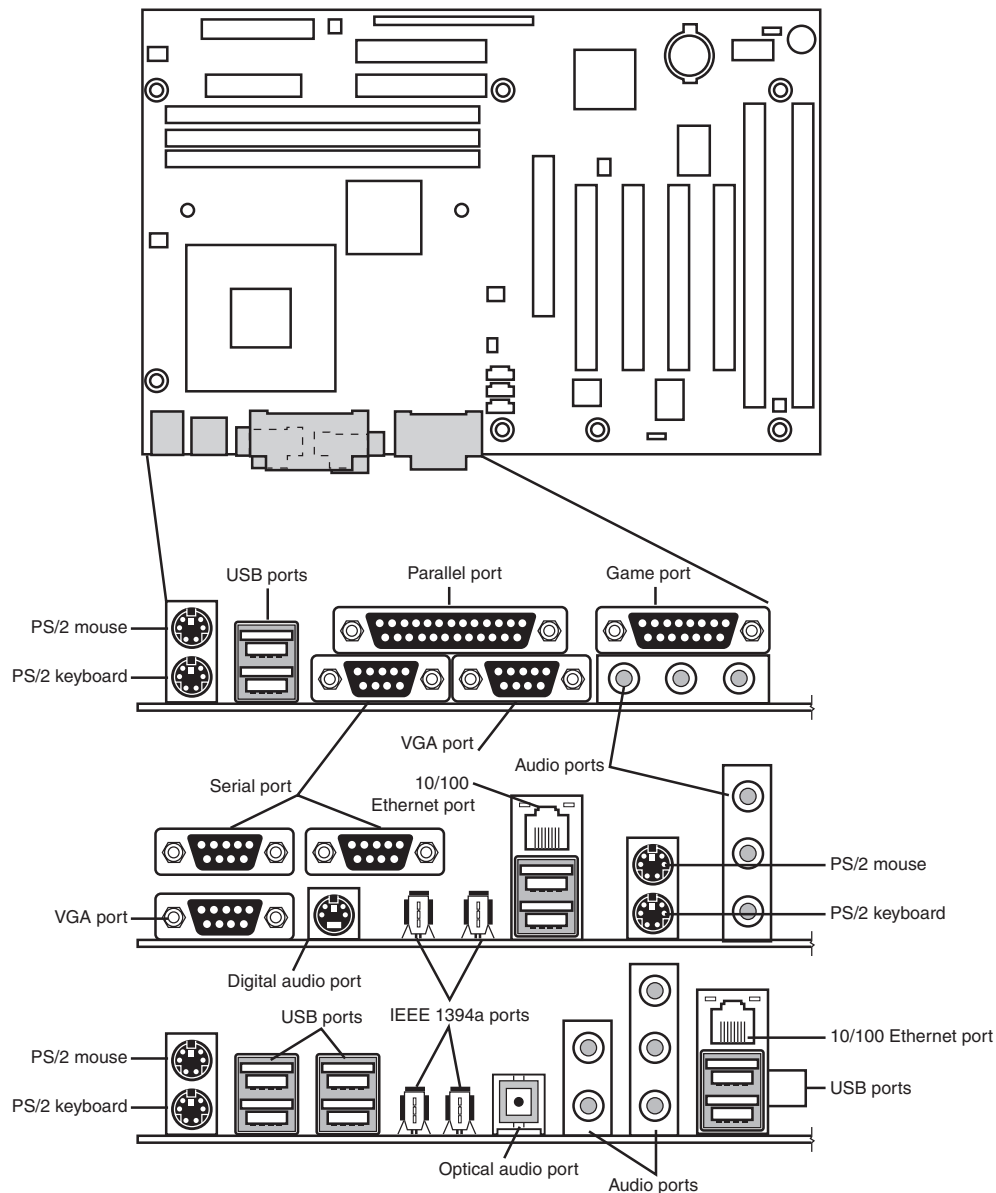

Figure 4.11 ATX motherboard and rear panel connections from systems with onboard sound and video (top and middle), networking and IEEE 1394/FireWire (middle and bottom), and a “legacy-free” system (bottom).

Table 4.2 Built-in Ports Usually Found on ATX Motherboards

Port Description	Connector Type	Connector Color
PS/2 mouse port	6-pin Mini-DIN	Green
PS/2 keyboard port	6-pin Mini-DIN	Purple
USB ports	Dual Stack USB	Black
Parallel port	25-pin D-Submini	Burgundy
Serial port	9-pin D-Submini	Teal
VGA analog video port	15-pin HD D-Submini	Dark blue
MIDI/Game port	15-pin D-Submini	Gold
Audio ports: L/R in, front L/R out, rear L/R out, center/LFE out, Microphone L/R in	1/8" (3.5mm) Mini-Phone	Light blue, lime green, black, black, pink
S-Video TV out	4-pin Mini-DIN	Black
IEEE 1394/FireWire port	6-pin IEEE 1394	Gray
10/100/1000 Ethernet LAN	8-pin RJ-45	Black
Optical S/PDIF audio out	TOSLINK	Black
DVI digital video out (not shown)	DDWG-DVI	White
Digital S/PDIF audio out (not shown)	RCA Jack	Orange
SCSI (not shown)	50/68-pin HD SCSI	Black
Modem (not shown)	4-pin RJ-11	Black
Composite Video out (not shown)	RCA Jack	Yellow

DIN = Deutsches Institut für Normung e.V.

USB = Universal serial bus

VGA = Video graphics array

HD = High density

MIDI = Musical Instrument Digital Interface

L/R = Left and right channel

LFE = Low frequency effects (subwoofer)

S-Video = Super Video

IEEE = Institute of Electrical and Electronics Engineers

LAN = Local area network

RJ = Registered jack

S/PDIF = Sony/Philips Digital Interface

TOSLINK = Toshiba optical link

DVI = Digital visual interface

DDWG = Digital Display Working Group

RCA = Radio Corporation of America

SCSI = Small computer system interface

Note

Most ATX motherboards feature connectors with industry-standardized color codes (shown in the previous table). This makes plugging in devices much easier and more foolproof: You merely match up the colors. For example, most keyboards have a cable with a purple plug, whereas most mice have a cable with a green plug. Even though the keyboard and mouse connectors on the motherboard appear the same (both are 6-pin Mini-DIN types), their color-coding matches the plugs on the respective devices. Thus, to plug them in properly, you merely insert the purple plug into the purple connector and the green plug into the green connector. This saves you from having to bend down to try to decipher small labels on the connectors to ensure you get them right.

The specification and related information about the ATX, Mini-ATX, microATX, FlexATX, or NLX form factor specifications are available from the Form Factors Web site at www.formfactors.org. The Form Factors site provides form factor specifications and design guides, as well as design considerations for new technologies, information on initiative supporters, vendor products, and a form factor discussion forum.

Note

Some motherboards, especially those used in server systems, come in nonstandard ATX variations collectively called *extended ATX*. This is a term applied to boards that are compatible with ATX but that are deeper. Standard ATX is 12"×9.6" (305mm×244mm), whereas extended ATX boards are up to 12"×13" (305mm×330mm). Because technically no official "extended ATX" standard exists, compatibility problems can exist with boards and chassis claiming to support extended ATX. When purchasing an extended ATX board, be sure it will fit in the chassis you intend to use. Dual Xeon processors fit in a standard ATX-size board, so choose a standard ATX-size board for maximum compatibility with the existing ATX chassis.

ATX Riser

In December 1999, Intel introduced a riser card design modification for ATX motherboards. The design includes the addition of a 22-pin (2×11) connector to one of the PCI slots on the motherboard, along with a two- or three-slot riser card that plugs in. The riser enables two or three PCI cards to be installed, but it does not support AGP.

ATX motherboards typically are found in vertically oriented tower-type cases, but often a horizontal desktop system is desired for a particular application. When ATX boards are installed in desktop cases, PCI cards can be as tall as 4.2", thus requiring a case that is at least 6"–7" tall. For Slimline desktop systems, most manufacturers now use the NLX format, but the more complex design and lower popularity of NLX makes that a more expensive alternative. A low-cost way to use an industry-standard ATX form factor board in a Slimline desktop case is therefore needed. The best long-term solution to this problem is the eventual adoption of a lower-profile PCI card design that is shorter than the current 4.2". The PCI Low-Profile specification was released for engineering review by the Peripheral Component Interconnect Special Interest Group (PCI SIG) on February 14, 2000, and some PCI card products have been produced in this shorter (2.5") form factor. Until Low-Profile PCI becomes widespread, Intel has suggested a riser card approach to enable standard-height PCI cards to be used in Slimline and rack-mount systems.

By adding a small 22-pin extension connector to one of the PCI slots on a motherboard, the necessary additional signals for riser card support could be implemented. The current design enables the use of a two- or three-slot riser that is either 2" or 2.8" tall, respectively. To this riser, you can attach full-length cards sideways in the system, and the motherboard can be used with or without the riser. The only caveat is that, if a riser card is installed, the remaining PCI slots on the motherboard can't be used. You can have expansion cards plugged in to only the riser or the motherboard, but not both. Also, the riser card supports only PCI cards—not AGP or ISA cards. A sample ATX board with a riser installed is shown in Figure 4.12.

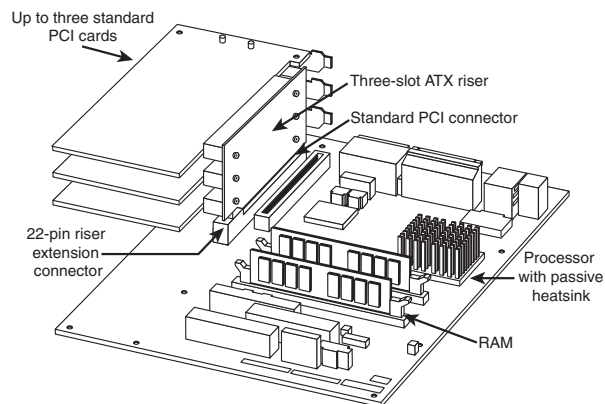

Figure 4.12 A three-slot ATX riser implementation on a microATX motherboard.

The 22-pin extension connector usually is installed in line with PCI slot 6, which is the second one from the right; the slots are usually numbered from right to left (facing the board) starting with 7 as the one closest to the processor. Some boards number the slots from right to left starting with 1; in that case, the extension connector is on PCI slot 2. The pinout of the ATX 22-pin riser extension connector is shown in Figure 4.13.

Signal	Pin	Pin	Signal
Ground	B1	A1	PCI_GNT1#
PCI_CLK1	B2	A2	Ground
Ground	B3	A3	PCI_GNT2#
PCI_REQ1#	A4	B4	Ground
Ground	A5	B5	PCI_CLK3
PCI_CLK2	A6	B6	RISER_ID1
Ground	A7	B7	Reserved
PCI_REQ2#	A8	B8	RISER_ID2
Ground	A9	B9	NOGO
PC/PCI_DREQ#	A10	B10	+12V
PC/PCI_DGNT#	A11	B11	SER_IRQ

Figure 4.13 An ATX 22-pin riser extension connector pinout.

The PCI connector that is in line with the riser extension connector is just a standard PCI slot; none of the signals are changed.

Systems that use the riser generally are low-profile designs. Therefore, they don't fit normal PCI or AGP cards in the remaining (nonriser-bound) slots. Although the ATX riser standard originally was developed for use with low-end boards—which have integrated video, sound, and network support—many rack-mounted servers are also using the ATX riser because these boards also have most of their required components already integrated. In fact, the ATX riser appears to be more popular for rack-mounted servers than for the originally intended target market of Slimline desktop systems.

ATX riser cards, compatible cases, and compatible motherboards are available from a variety of vendors, allowing you to build your own Slimline ATX system.

microATX

microATX is a motherboard form factor Intel originally introduced in December 1997, as an evolution of the ATX form factor for smaller and lower-cost systems. The reduced size as compared to standard ATX allows for a smaller chassis, motherboard, and power supply, thereby reducing the cost of the entire system. The microATX form factor is also backward-compatible with the ATX form factor and can be used in full-size ATX cases. Of course, a microATX case doesn't take a full-size ATX board. This form factor has become popular in the low-cost PC market. Currently, mini-tower chassis systems dominate the low-cost PC market, although their small sizes and cramped interiors severely limit future upgradeability.

The main differences between microATX and standard or Mini-ATX are as follows:

- Reduced width motherboard (9.6" [244mm] instead of 12" [305mm] or 11.2" [284mm])
- Fewer I/O bus expansion slots (four maximum, although most boards feature only three)
- Smaller power supply optional (SFX/TFX form factors)

The microATX motherboard maximum size is only 9.6"×9.6" (244mm×244mm) as compared to the full-size ATX size of 12"×9.6" (305mm×244mm) or the Mini-ATX size of 11.2"×8.2" (284mm×208mm). Even smaller boards can be designed as long as they conform to the location of the mounting holes,

connector positions, and so on, as defined by the standard. Fewer slots aren't a problem for typical home or small-business PC users because more components such as sound and video are usually integrated on the motherboard and therefore don't require separate slots. This higher integration reduces motherboard and system costs. External buses, such as USB, 10/100 Ethernet, and optionally SCSI or 1394 (FireWire), can provide additional expansion out of the box. The specifications for microATX motherboard dimensions are shown in Figure 4.14.

Figure 4.14 microATX specification 1.2 motherboard dimensions.

Smaller form factor (called SFX or TFX) power supplies have been defined for optional use with microATX systems, although the standard ATX supply also works fine because the connectors are the same. The smaller size SFX/TFX power supplies encourage flexibility in choosing mounting locations within the chassis and allows for smaller systems that consume less power overall. Although the smaller supplies can be used, they may lack sufficient power output for faster or more fully configured systems. Because of the high power demands of most modern systems, most third-party microATX chassis are designed to accept standard ATX power supplies, although microATX systems sold by vendors such as Compaq, HP, and eMachines typically use some type of SFX or TFX power supply to reduce costs.

▶▶ See "Power Supply Form Factors" p. 1155.

The microATX form factor is similar to ATX for compatibility. The similarities include the following:

- Standard ATX 20-pin power connector
- Standard ATX I/O panel
- Mounting holes and dimensions are a subset of ATX

These similarities ensure that a microATX motherboard can easily work in a standard ATX chassis with a standard ATX power supply, as well as the smaller microATX chassis and SFX/TFX power supply.

The overall system size for a microATX is very small. A typical case is only 12"–14" tall, about 7" wide, and 12" deep. This results in a kind of micro-tower or desktop size. A typical microATX motherboard is shown in Figure 4.15.

Figure 4.15 A typical microATX motherboard's dimensions are 9.6"×9.6".

As with ATX, Intel released microATX to the public domain to facilitate adoption as a de facto standard. The specification and related information on microATX are available through the Desktop Form Factors site (www.formfactors.org).

FlexATX

In March 1999, Intel released the FlexATX addendum to the microATX specification. This added a new and even smaller variation of the ATX form factor to the motherboard scene. FlexATX's smaller design is intended to allow a variety of new PC designs, especially extremely inexpensive, smaller, consumer-oriented, appliance-type systems. Some of these designs might not even have expansion slots, allowing expansion only through USB or IEEE 1394/FireWire ports.

FlexATX defines a board that is up to 9"×7.5" (229mm×191mm) in size, which is the smallest of the ATX family boards. In all other ways, FlexATX is the same as ATX and microATX, making FlexATX fully backward compatible with ATX or microATX by using a subset of the mounting holes and the same I/O and power supply connector specifications (see Figure 4.16).

Most FlexATX systems likely use SFX/TFX (small or thin form factor) type power supplies (introduced in the microATX specification), although if the chassis allows it, a standard ATX power supply can also be used.

Form Factor	Mounting Hole Locations	Notes
• FlexATX	B, C, F, H, J, S	
• microATX	B, C, F, H, J, L, M, R, S	Holes R and S were added for microATX form factor. Hole B was defined in full-AT format.
• ATX	A, C, F, G, H, J, K, L, M	Hole F must be implemented in all ATX 2.03-compliant chassis assemblies. The hole was optional in the ATX 1.1 specification.

Figure 4.16 Size and mounting hole comparison between ATX, microATX, and FlexATX motherboards.

With the addition of FlexATX, the family of ATX boards has now grown to include four definitions of size (three are the official standards), as shown in Table 4.3.

Table 4.3 ATX Motherboard Form Factors

Form Factor	Max. Width	Max. Depth	Max. Area	Size Comparison
ATX	12.0" (305mm)	9.6" (244mm)	115 sq. in. (743 sq. cm)	—
Mini-ATX	11.2" (284mm)	8.2" (208mm)	92 sq. in. (593 sq. cm)	20% smaller
microATX	9.6" (244mm)	9.6" (244mm)	92 sq. in. (595 sq. cm)	20% smaller
Flex ATX	9.0" (229mm)	7.5" (191mm)	68 sq. in. (435 sq. cm)	41% smaller

Note that these dimensions are the maximums allowed. Making a board smaller in any given dimension is always possible as long as it conforms to the mounting hole and connector placement requirements detailed in the respective specifications. Each board has the same basic screw hole and connector placement requirements, so if you have a case that fits a full-size ATX board, you could also mount a microATX, or FlexATX board in that same case. Obviously, if you have a smaller case designed for microATX or FlexATX, you won't be able to put the larger Mini-ATX or full-size ATX boards in that case.

ITX and Mini-ITX

FlexATX is the smallest industry-standard form factor specification, and it defines a board that is *up to* 9"×7.5" in size. Note the *up to* part of the dimensions, which means that, even though those dimensions are the maximums, less is also allowed. Therefore, a FlexATX board can be smaller than that, but how much smaller? By analyzing the FlexATX specification—and, in particular, studying the required mounting screw locations—you can see that a FlexATX board could be made small enough to use only four mounting holes (C, E, H, and J). Refer to Figure 4.16 for the respective hole locations.

According to the FlexATX standard, the distance between holes H and J is 6.2", and the distance between hole J and the right edge of the board is 0.25". By leaving the same margin from hole H to the left edge, you could make a board with a minimum width of 6.7" (0.25" + 6.2" + 0.25") that would conform to the FlexATX specification. Similarly, the distance between holes C and H is 6.1", and the distance between hole C and the back edge of the board is 0.4". By leaving a minimum 0.2" margin from hole H to the front edge, you could make a board with a minimum depth of 6.7" (0.4" + 6.1" + 0.2") that would conform to the FlexATX specification. By combining the minimum width and depth, you can see that the minimum board size that would conform to the FlexATX specification is 6.7"×6.7" (170mm×170mm).

VIA Technologies Platform Solutions Division wanted to create a motherboard as small as possible, yet not define a completely new and incompatible form factor. To accomplish this, in March 2001 VIA created a board that was slightly narrower in width (8.5" instead of 9") but still the same depth as FlexATX, resulting in a board that was 6% smaller and yet still conformed to the FlexATX specification. VIA called this ITX but then realized that the size savings were simply too small to justify developing it further, so it was discontinued before any products were released.

In April 2002, VIA created an even smaller board that featured the absolute minimum width and depth dimensions allowed by FlexATX. It called it Mini-ITX. In essence, all Mini-ITX boards are simply FlexATX boards that are limited to the minimum allowable dimensions. All other aspects, including the I/O aperture size and location, screw hole locations, and power supply connections, are pure FlexATX. A Mini-ITX board fits in any chassis that accepts a FlexATX board; however, larger boards will not fit into a Mini-ITX chassis.

The Mini-ITX form factor was designed by VIA especially to support VIA's low-power embedded Eden and C3 E-Series processors. Only a very small number of motherboards is available in this form factor, and only from VIA and one or two other manufacturers. Because the processors used on these boards are substantially less powerful than even the Intel Celeron 4 or AMD Duron entry-level processors, the Mini-ITX form factor is intended for use mainly in nontraditional settings such as set-top boxes and computing appliances. The size of the ITX and Mini-ITX boards relate to FlexATX as shown in Table 4.4.

Table 4.4 Comparing the FlexATX, ITX, and Mini-ITX Form Factors

Form Factor	Max. Width	Max. Depth	Max. Area	Size Comparison
Flex ATX	9.0" (229mm)	7.5" (191mm)	68 sq. in. (435 sq. cm)	—
ITX	8.5" (215mm)	7.5" (191mm)	64 sq. in. (411 sq. cm)	6% smaller
Mini-ITX	6.7" (170mm)	6.7" (170mm)	45 sq. in. (290 sq. cm)	34% smaller

Again, I must point out that technically any ITX or Mini-ITX board conforms to the FlexATX specification. In particular, the Mini-ITX is the smallest board that can conform. Although the still-born ITX format was virtually the same as FlexATX in size (which is probably why it was discontinued before any were sold), Mini-ITX motherboards are 170mm×170mm (6.7"×6.7"), which is 34% smaller than the maximum allowed by FlexATX.

To take advantage of the smaller Mini-ITX format, several chassis makers are producing very small chassis to fit these boards. Most are the shape of a small cube, with one floppy and one optical drive bay visible from the front. The layout of a typical Mini-ITX motherboard, the VIA EPIA-V, is shown in Figure 4.17.

Figure 4.17 Top and rear views of the VIA EPIA-V motherboard, a typical Mini-ITX motherboard. *Photo courtesy VIA Technologies, Inc.*

As Figure 4.17 makes clear, Mini-ITX motherboards can offer a full range of input-output ports. However, several differences exist between the Mini-ITX motherboards and other ATX designs:

- The processor on a Mini-ITX motherboard is usually permanently soldered to the board, making future processor upgrades or replacements impossible.
- Most Mini-ITX chassis use TFX power supplies, for which there are currently only a few suppliers. Consequently, replacements for them are more expensive and more difficult to find.
- The available TFX power supplies are rated for less output than larger supplies, typically up to 240 watts maximum.
- There is no provision for replacing onboard video with an AGP video card.

Because Mini-ITX boards and chassis are made by only a small number of suppliers, future upgrades or parts replacements are limited. However, Mini-ITX boards are actually FlexATX boards, so they can be installed in any standard FlexATX, microATX, or full-size ATX chassis and use the corresponding power supplies. The only caveats are that the smaller Mini-ITX chassis will not accept larger FlexATX, microATX, or full-size ATX boards and most Mini-ITX chassis accept only TFX power supplies. When you select a Mini-ITX system, you must be sure to select the appropriate processor type and speed necessary for the task you need it to perform because processor replacements or upgrades almost always require changing the entire motherboard.

Both the VIA C3 E-series and the VIA Eden are x86-compatible processors, so they run the same operating systems and applications as typical AMD and Intel processors, including Windows and Linux. However, the C3 and Eden processors are significantly slower than the Celeron 4, Pentium 4, and Athlon XP processors found in typical desktop and notebook computers. Table 4.5 provides technical information about these processors.

Table 4.5 VIA C3 E-Series and Eden Processors

Processor Model	Clock Speed	FSB Speed	Voltage	L1 Cache	L2 Cache
Eden ESP 4000	400MHz	100MHz	1.05V	128KB	64KB
Eden ESP 5000	533MHz	133MHz	1.20V	128KB	64KB
Eden ESP 6000	600MHz	133MHz	1.20V	128KB	64KB
Eden ESP 8000	800MHz	133MHz	1.20V	128KB	64KB
Eden ESP 10000	1GHz	133MHz	1.20V	128KB	64KB
C3 E-series	733MHz	133MHz	1.35V	64KB	128KB
C3 E-series	800MHz	133MHz	1.35V	64KB	128KB
C3 E-series	866MHz	133MHz	1.35V	64KB	128KB
C3 E-series	933MHz	133MHz	1.35V	64KB	128KB
C3 E-series	1GHz	133MHz	1.35V	64KB	128KB
C3 E-series	1.1GHz	133MHz	1.35V	64KB	128KB

The Eden ESP series of processors uses a simplified design optimized for the most common operations. Eden ESP processors are an excellent choice for set-top boxes and Internet clients, but they are not as powerful in features or clock speed as the C3 E-series. VIA recommends Eden processors for embedded systems because the processor can be operated without a fan by using a passive heatsink for cooling. For more traditional computer tasks in a small footprint, VIA recommends the C3 E-series because it has performance similar to Intel Celeron processors running at similar speeds. C3 E-series processors can also be run with a passive heatsink, but they run hotter than Eden-series processors because they use higher voltages. VIA recommends a cooling fan for C3 E-series processors unless the case is specially designed to provide adequate cooling for the processor.

VIA uses varying combinations of the following North Bridge and South Bridge chips in its Mini-ITX motherboards. The North Bridge uses either the PLE133 or CLE266 chips, whereas the South Bridge uses either the VT8231 or VT8235 chips.

The PLE133 North Bridge chip features built-in Trident AGP 4x video and support for PC100 and PC133 SDRAM memory. The CLE266, on the other hand, features built-in S3 Savage 4 4x AGP video, a built-in MPEG2 decoder for excellent DVD playback, and support for DDR266 SDRAM memory.

The VT8231 South Bridge chip features AC'97 audio, MC'97 modem, an ATA-100 host adapter, and four USB 1.1 ports. Additional capabilities can be added through optional chips. The VT8235 South Bridge chip features six-channel audio, an ATA-133 host adapter, USB 2.0 ports, 10/100 Ethernet, PCI controller, and MC'97 modem. It also supports the new 8X V-Link interface with the North Bridge.

VIA offers a handful of Mini-ITX motherboards through its VIA Platform Solutions Division (VPSD), including the following:

- EPIA
- EPIA V (refer to Figure 4.17)
- EPIA M
- EPIA CL
- EPIA TC
- EPIA MII
- EPIA PD

Table 4.6 summarizes the differences in these motherboards.

Table 4.6 VPSD Mini-ITX Motherboards

Feature	EPIA	EPIA V	EPIA M	EPIA CL	EPIA TC	EPIA MII	EPIA PD*
North Bridge	PL133	PL133	CLE266	CLE266	CLE266	CLE266	CLE266
South Bridge	VT8231	VT8231	VT8235	VT8235	VT8235	VT8235	VT8235
RAM (#)	PC100, 133 (2)	PC133 (2)	DDR266 (1)	DDR266 (1)	DDR266 (1)	DDR266 (1)	DDR266 (1)
ATA (#)	100, 66 (1)	100, 66 (2)	133, 100, 66 (2)	133, 100, 66 (2)	133, 100, 66 (2)	133, 100, 66 (2)	133, 100, 66 (2)
USB (#)	1.1 (4)	1.1 (2)	2.0 (2)	2.0 (4)	2.0 (6)	2.0 (6)	2.0 (6)
FireWire	No	No	Yes (2)	No	No	Yes	No
Floppy controller	No	Yes	Yes	Yes	No	Yes	No
Ethernet	Yes	Yes	Yes	Yes	Yes	Yes	Yes

*EPIA PD has four serial ports; other models feature one serial port.

The EPIA MII motherboard is the most sophisticated of the models listed and is the best choice for digital multimedia because of its faster memory subsystem, Hi-Speed USB (USB 2.0) and IEEE 1394a ports, and optimized DVD playback. The EPIA PD motherboard is a suitable choice for point-of-sale (POS) systems because it has four serial ports (often used for POS printers).

Obviously, with top performance only on par with sub-1GHz Celeron systems, Mini-ITX motherboards are not intended for power user applications. However, if you need a compact system for specialized uses such as home entertainment centers or for small-footprint computers for office suites and Internet access and don't mind investing in a small form factor that might make future upgrades or repairs extremely difficult, these tiny systems can be useful.

Note

The official site for ITX information is www.via.com.tw/en/VInternet/mini_itx.jsp. The site www.mini-itx.com is often mistaken for an official site, but it is actually a vendor that specializes in ITX systems and component sales.

BTX

Balanced Technology Extended (BTX) is a motherboard form factor specification Intel originally released in September 2003. A 1.0a update was released in February 2004. BTX is designed to eventually replace the venerable ATX form factor while addressing ever-increasing component power and cooling requirements, as well as enabling improved circuit routing and more flexible chassis designs.

BTX represents a completely new form factor that is not backward-compatible with ATX or other designs. A full-size BTX board is 17% larger than ATX, allowing room for more integrated components onboard.

The I/O connectors, slots, and mounting holes are in different locations than with ATX, requiring new chassis designs. However, the power supply interface connectors are the same as in the latest ATX12V specifications, and newer ATX, TFX, SFX, CFX, and LFX power supplies can be used. The latter two power supply form factors were specifically created to support compact and low-profile BTX systems.

The primary advantages to BTX include

- *Optimized inline component layout and routing.* Signals are aligned front to back, allowing connections between components and I/O connectors to run unobstructed.
- *Optimized airflow path.* Allows for a condensed system design and an optimized, unobstructed airflow path for efficient system cooling with fewer fans and lower acoustics.
- *Support and retention module (SRM).* Offers mechanical support for heavy heatsinks. It also helps to prevent board flexing or damaging board components and traces during shipping and handling.
- *Scalable board dimensions.* Flexible board sizes enable developers to use the same components for a variety of system sizes and configurations.
- *Low-profile options.* Component keep-out specifications enable lower profiles, making it easier to design slim-line or small form factor systems.
- *Flexible, compatible power supply designs.* Connectors are shared with recent ATX designs; smaller, more efficient power supply form factors can be used for small form factor systems, whereas standard ATX12V power supplies can be used for larger tower configurations.

BTX includes three definitions of motherboard size, as shown in Table 4.7.

Table 4.7 BTX Motherboard Form Factors

Form Factor	Max. Width	Depth	Max. Area	Size Versus BTX
BTX	12.8" (325mm)	10.5" (267mm)	134 sq. in. (867 sq. cm)	—
microBTX	10.4" (264mm)	10.5" (267mm)	109 sq. in. (705 sq. cm)	19% smaller
PicoATX	8.0" (203mm)	10.5" (267mm)	84 sq. in. (542 sq. cm)	37% smaller

Each board has the same basic screw hole and connector placement requirements. So, if you have a case that fits a full-size BTX board, you can also mount a microBTX or picoBTX board in that same case (see Figure 4.18). Obviously, if you have a smaller case designed for MicroBTX or picoBTX, you won't be able to put the larger microBTX or BTX boards in that case.

BTX requires up to 10 mounting holes and supports up to seven slots, depending on the size, as shown in Table 4.8.

Table 4.8 BTX Motherboard Mounting Holes

Board Size	Mounting Holes	Max. Slots
BTX	A,B,C,D,E,F,G,H,J,K	7
microBTX	A,B,C,D,E,F,G	4
picoBTX	A,B,C,D	1

BTX also clearly specifies volumetric zones around the motherboard to prevent any interference from the chassis or internal components such as drives, which allows for maximum interchangeability without physical interference or fit problems.

Figure 4.18 BTX specification 1.0a motherboard dimensions.

With processors exceeding 100W in thermal output, as well as voltage regulators, motherboard chipsets, and video cards adding to the thermal load in a system, BTX was designed to allow all the high-heat-producing core components to be mounted inline from front to back, so that a single high-efficiency thermal module (heatsink) can cool the system. This eliminates the need for an excessive number of fans. The thermal module includes a heatsink for the processor, a high-efficiency fan, and a duct to direct airflow through the system. Extra support for the thermal module is provided under the board via a support and retention module (SRM), which provides structural support for heatsinks that are much heavier than allowed in ATX designs (see Figure 4.19).

Figure 4.19 BTX thermal module containing a processor heatsink and fan.

BTX uses the same power connectors as in the latest power supply form factor specifications, including a 24-pin main connector for the board and a 4-pin ATX12V connector for the CPU voltage regulator module. The particular power supply form factor used depends mostly on the chassis selected.

A typical tower system has components arranged as shown in Figure 4.20.

Figure 4.20 BTX tower chassis layout.

From Figure 4.20, you can see that the main heat-producing core components are centrally located inline from front to rear, allowing the most efficient thermal design. Air flows from front to rear through the center, cooling the processor, motherboard chipset, memory, and video card.

To support the heavy processor heatsink and thermal module assembly, an SRM is mounted under the board. The SRM is essentially a metal plate affixed to the chassis under the board, and the thermal module is bolted directly to the SRM instead of to the motherboard. This helps carry the weight of the module and prevents excessive loads from being applied to the processor and motherboard, especially during the shipping and handling of the system.

The BTX I/O connector area is similar to ATX, except that it is at the opposite side of the rear of the board. The size of the area is slightly shorter but wider than ATX, allowing a large number of interfaces and connectors to be built in to the motherboard.

NLX

NLX is a low-profile form factor designed to replace the nonstandard LPX design used in previous low-profile systems. First introduced in November 1996 by Intel, NLX was a popular form factor in the late 1990s for Slimline corporate desktop systems from vendors such as Compaq, HP, Toshiba, and others. Since 2000, many Slimline systems have used variations on the FlexATX motherboard instead.

NLX is similar in initial appearance to LPX, but with numerous improvements designed to enable full integration of the latest technologies. NLX is basically an improved version of the proprietary LPX design, but, unlike LPX, NLX is fully standardized, which means you should be able to replace one NLX board with another from a different manufacturer—something that was not possible with LPX.

Another limitation of LPX boards is the difficulty in handling the larger physical size of the newer processors and their larger heatsinks, as well as newer bus structures such as AGP for video. The NLX form factor has been designed specifically to address these problems (see Figure 4.21). In fact, NLX provides enough room for some vendors to support dual Slot 1 Pentium III processors in this form factor.

Figure 4.21 NLX motherboard and riser combination.

The main characteristic of an NLX system is that the motherboard plugs into the riser, unlike LPX where the riser plugs into the motherboard. Therefore, the motherboard can be removed from the system without disturbing the riser or any of the expansion cards plugged into it. In addition, the motherboard in a typical NLX system literally has no internal cables or connectors attached to it! All devices that normally plug into the motherboard—such as drive cables, the power supply, the front panel light, switch connectors, and so on—plug into the riser instead (see Figure 4.21). By using the riser card as a connector concentration point, you can remove the lid on an NLX system and literally slide the motherboard out the left side of the system without unplugging a single cable or connector on the inside. This allows for unbelievably quick motherboard changes; in fact, I have swapped motherboards in less than 30 seconds on NLX systems!

As Figure 4.22 shows, by using different sizes and types of riser cards, a system designer can customize the features of a given NLX system.

Such a design is a boon for the corporate market, where ease and swiftness of servicing is a major feature. Not only can components be replaced with lightning speed, but because of the industry-standard design, motherboards, power supplies, and other components can be interchanged even among different systems.

Specific advantages of the NLX form factor include

- *Support for all desktop system processor technologies.* This is especially important because, since the NLX form factor was developed, both AMD and Intel adopted and then abandoned bulkier slot-based processors and returned to more compact socketed processors. NLX can handle both types of processors.
- *Flexibility in the face of rapidly changing processor technologies.* Backplane-like flexibility has been built in to the form by allowing a new motherboard to be easily and quickly installed without tearing your entire system to pieces. But unlike traditional backplane systems, many industry leaders, such as Compaq, Toshiba, and HP, have sold NLX-based systems.
- *Support for newer technologies.* This includes Accelerated Graphics Port (AGP) high-performance graphic solutions, Universal Serial Bus (USB), and memory modules in DIMM or RIMM form.
- *Ease and speed of servicing and repair.* Compared to other industry-standard interchangeable form factors, NLX systems are by far the easiest to work on and allow component swaps or other servicing in the shortest amount of time.

Figure 4.22 Typical NLX riser cards. Although most NLX systems use a low-profile riser card similar to the top riser card, others use a taller riser card to provide more slots for add-on cards.

Furthermore, with the importance of multimedia applications, connectivity support for such things as video playback, enhanced graphics, and extended audio has been built in to the motherboard. This should represent a good cost savings over expensive daughterboard arrangements that have been necessary for many advanced multimedia uses in the past. Although ATX also has this support, LPX and Baby-AT don't have the room for these additional connectors.

Figure 4.23 shows the basic NLX system layout. Notice that, similar to ATX, the motherboard is clear of the drive bays and other chassis-mounted components. Also, the motherboard and I/O cards (which, like the LPX form factor, are mounted parallel to the motherboard) can easily be slid in to and out of the side of the chassis, leaving the riser card and other cards in place. The processor can be easily accessed and enjoys greater cooling than in a more closed-in layout.

Note the position of the optional AGP slot shown in Figure 4.23. It is mounted on the motherboard itself, not on the riser card as with PCI or ISA slots. This location was necessary because AGP was developed well after the NLX form factor was introduced. Most NLX motherboards use chipset-integrated or motherboard-based video instead of a separate AGP card, but you must remove an AGP card installed in an NLX system before you can remove the motherboard for servicing. Also, the AGP card used in an NLX system must have a different form factor to enable it to clear the rear connector shield at the back of the NLX motherboard (see Figure 4.24).

Figure 4.23 NLX system chassis layout and cooling airflow.

Figure 4.24 An AGP card that can be installed in either a standard ATX/Baby-AT system or an NLX system. This is because of the shape, which leaves room for the NLX motherboard's rear connector shield. *Photo courtesy Elsa AG.*

The NLX motherboard is specified in three lengths, front to back: 13.6", 11.2", or 10" total (see Figure 4.25). With proper bracketry, the shorter boards can go into a case designed for a longer board.

As with most of the form factors, you can identify NLX via the unique I/O shield or connector area at the back of the board (see Figure 4.26). You only need a quick look at the rear of any given system to determine which type of board is contained within. Figure 4.26 shows the unique stepped design of the NLX I/O connector area. This allows for a row of connectors all along the bottom and has room for double-stacked connectors on one side.

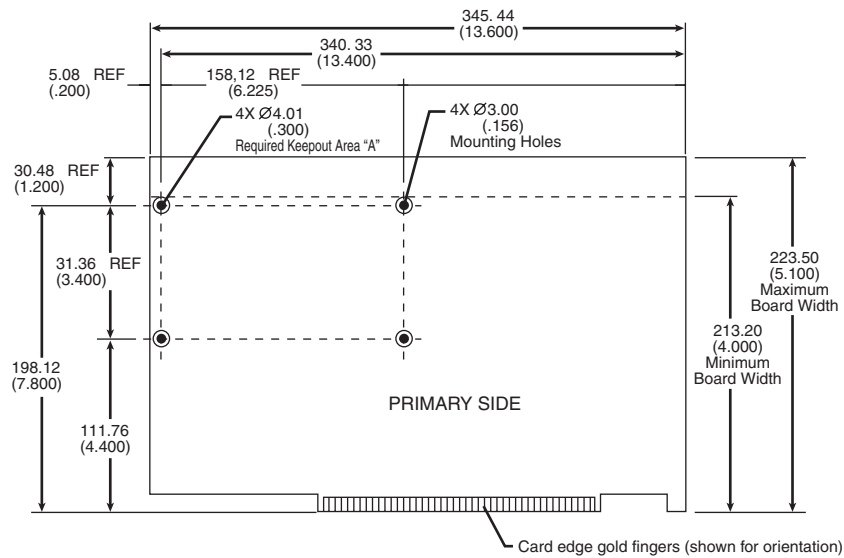

Figure 4.25 NLX form factor. This shows a 13.6" long NLX board. The NLX specification also allows shorter 11.2" and 10" versions.

Figure 4.26 Typical NLX motherboard rear connector layout.

As you can see, the NLX form factor has been designed for maximum flexibility and space efficiency. Even extremely long I/O cards will fit easily without getting in the way of other system components—a problem with Baby-AT form factor systems.

The specification and related information about the NLX form factor are available at the Desktop Form Factor site located at www.formfactors.org (specify NLX in the search tool). Although NLX is a standard form factor—just as the ATX family is—most NLX products have been sold as part of complete systems aimed at the corporate market. Very few aftermarket motherboards have been developed in this form factor. Thus, although NLX makes swapping motherboards easy, you are more likely to encounter it in a corporate environment than in a home or small-business computer. The microATX and FlexATX form factors have largely superseded NLX in the markets formerly dominated by LPX. Overall, one of the ATX variants is still the best choice for most new systems where expandability, upgradeability, low cost, and ease of service are of prime importance. In the future, picoBTX is likely to eventually replace both the NLX and FlexATX form factors.

WTX

WTX was a board and system form factor developed for the mid-range workstation market; however, most vendors making workstations and servers have used the ATX form factor. WTX went beyond ATX and defined the size and shape of the board and the interface between the board and chassis, as well as required chassis features.

WTX was first released in September 1998 (1.0) and updated in February 1999 (1.1). The specification and other information on WTX used to be available at www.wtx.org; however, WTX has been officially discontinued and there will be no further updates.

Figure 4.27 shows a typical WTX system with the cover removed. Note that easy access is provided to internal components via pull-out drawers and swinging side panels.

Figure 4.27 Typical WTX system chassis showing internal layout and ease of access.

WTX motherboards have a maximum width of 14" (356mm) and a maximum length of 16.75" (425 mm), which is significantly larger than ATX. There are no minimum dimensions, so board designers are free to design smaller boards as long as they meet the mounting criteria. The additional space

provided by the WTX form factor provides room for two or more processors and other onboard equipment needed in a workstation or server design. Although WTX is no longer an official form factor, a number of server and workstation motherboard vendors, such as Tyan, MSI, and SuperMicro, continue to build products that use it.

The WTX specification offers flexibility by leaving motherboard mounting features and locations undefined. Instead of defining exact screw hole positions, WTX motherboards must mount to a standard mounting adapter plate, which must be supplied with the board. The WTX chassis is designed to accept the mounting plate with attached motherboard and not just a bare board alone.

WTX motherboards use different power connectors than ATX motherboards. Originally, WTX motherboards used a 24-pin power connector that supplied only 5V and 3.3V power to the motherboard and a separate 22-pin power connector that supplied 12V power. Modern WTX motherboards still use a 24-pin primary power connector, but the connector might use the EPS12V (also known as the Superset ATX or SSI) standard or the older ATX-GES standard. Both ATX-GES and EPS12V provide 3.3V, 5V, and 12V power to the motherboard, but the pinouts are completely different. EPS12V motherboards also use an 8-pin power connector to provide additional 12V power to the processor(s). Table 4.9 compares the pinouts of the ATX-GES and EPS12V 24-pin primary power connectors.

Caution

Keep in mind that motherboards using the WTX, ATX-GES, and EPS12V power supply standards all use the same connector (the 24-pin Molex 39-01-2240 connector, a longer version of the 20-pin Molex connector used by ATX power supplies). However, they use different voltages on almost every wire. If you mismatch the motherboard and power supply, you will destroy one or both of them!

Table 4.9 ATX-GES and EPS12V 24-Pin Primary Power Connector Pinouts

Pin #	ATX-GES	EPS12V	Pin #	ATX-GES	EPS12V
1	+5V red	+3.3V orange	13	+5V red	+3.3V orange and brown
2	+5V red	+3.3V orange	14	+5V red	-12V blue
3	GND black	GND black	15	GND black	GND black
4	GND black	+5V red	16	+5V SB purple	PS-On green
5	PS-On green	GND black	17	-12V blue	GND black
6	GND black	+5V red	18	GND black	GND black
7	+3.3V orange + orange	GND black	19	+3.3V orange	GND black
8	+3.3V orange	Pwr-OK gray	20	+3.3V orange	-5V white
9	GND black	+5V SB purple	21	+3.3V orange	+5V red
10	GND black	+12V yellow	22	GND black	+5V red
11	+12V yellow	+12V yellow	23	GND black	+5V red
12	+12V yellow	+3.3V orange	24	+12V yellow	GND black

Proprietary Designs

Motherboards that are *not* one of the industry standard form factors, such as AT/Baby-AT, NLX, or any of the ATX formats, are deemed *proprietary* or *semiproprietary*. LPX, ITX, and Mini-ITX systems fall into the semiproprietary category for example, while other companies have fully proprietary systems that only they manufacture. Most people purchasing PCs should avoid proprietary designs because they do not allow for a future motherboard, power supply, or case upgrade, which limits future use and serviceability of the system. To me, proprietary systems are disposable PCs because you can neither upgrade them nor

easily repair them. The problem is that the proprietary parts can come only from the original system manufacturer, and they usually cost much more than nonproprietary parts. Therefore, after your proprietary system goes out of warranty, not only is it not upgradeable, but it is also essentially no longer worth repairing. If the motherboard or any component on it goes bad, you will be better off purchasing a completely new standard system than paying five times the normal price for a new proprietary motherboard. In addition, a new motherboard in a standard form factor system would be one or more generations newer and faster than the one you would be replacing. In a proprietary system, the replacement board would not only cost way too much, but it would be the same as the one that failed.

Note that you might be able to perform limited upgrades to older systems with proprietary motherboards, in the form of custom (non-OEM) processor replacements with attached voltage regulators, usually called “overdrive” or “turbo” chips. Unfortunately, these often don’t perform up to the standards of a less expensive new processor and motherboard combination. Of course, I usually recommend upgrading the motherboard and processor together—but that is something that can’t be done with a proprietary system.

Until the late 1990s, the LPX motherboard design was at the heart of most proprietary systems. These systems were sold primarily in the retail store channel by Compaq, IBM’s Aptiva line, HP’s Vectra line, and Packard Bell (no longer in business in North America). As such, virtually all their systems have problems inherent with their proprietary designs.

If the motherboard in your current ATX form factor system dies, you can find any number of replacement boards that will bolt directly in—with your choice of processors and clock speeds—at great prices. You can also find replacements for Baby-AT motherboards, but this form factor doesn’t support the newest technologies and has not been used in new system designs for several years. However, if the motherboard dies in a proprietary form factor system, you’ll pay for a replacement available only from the original manufacturer, and you have little or no opportunity to select a board with a faster or better processor than the one that failed. In other words, upgrading or repairing one of these systems via a motherboard replacement is difficult and usually not cost-effective.

Systems sold by the leading mail-order suppliers, such as Gateway, Micron, Dell, and others, are available in industry-standard form factors such as ATX, microATX, FlexATX, and NLX. This allows for easy upgrading and system expansion in the future. These standard factors allow you to replace your own motherboards, power supplies, and other components easily and select components from any number of suppliers other than where you originally bought the system.

Backplane Systems

One type of design that has been used in some systems over the years is the *backplane system*. These systems do not have a motherboard in the true sense of the word. In a backplane system, the components typically found on a motherboard are located instead on an expansion adapter card plugged into a slot.

In these systems, the board with the slots is called a backplane, rather than a motherboard. Systems using this type of construction are called backplane systems.

Backplane systems come in two main types—passive and active. A *passive* backplane means the main backplane board does not contain any circuitry at all except for the bus connectors and maybe some buffer and driver circuits. All the circuitry found on a conventional motherboard is contained on one or more expansion cards installed in slots on the backplane. Some backplane systems use a passive design that incorporates the entire system circuitry into a single mothercard. The mothercard is essentially a complete motherboard designed to plug into a slot in the passive backplane. The passive backplane/mothercard concept enables the entire system to be easily upgraded by changing one or more cards. Because of the expense of the high-function mothercard, this type of system design is rarely found in standard PC systems today, although it was once favored by a few early 286/386 vendors such as Zenith Data Systems. The passive backplane design does enjoy popularity in industrial systems, which are often rack-mounted. Some high-end file servers also feature this design. Figure 4.28 shows a typical Pentium 4 single-board computer used in PICMG passive backplane systems. Figure 4.29 shows a rack-mount chassis with a passive backplane.

Figure 4.28 A typical Pentium 4 PICMG single-board computer. This single card provides PCI and ISA interfacing; integrated AGP video; two 10/100 Ethernet network interfaces; ATA RAID; and normal parallel, serial, ATA/IDE, USB, and floppy interfaces.

Figure 4.29 A rack-mount chassis with passive backplane.

Passive backplane systems with mothercards (often called single-board computers or SBCs) are by far the most popular backplane design. They are used in industrial or laboratory-type systems and are rack-mountable. They usually have a large number of slots and extremely heavy-duty power supplies; they also feature high-capacity, reverse flow cooling designed to pressurize the chassis with cool, filtered air. Many passive backplane systems, such as the one pictured in Figure 4.28, adhere to the PCI/ISA passive backplane and CompactPCI form factor standards set forth by the PCI Industrial Computer Manufacturers Group (PICMG). You can get more information about these standards from PICMG's Web site at www.picmg.org.

Note

Another popular standard for SBCs is the PISA standard developed by JUMPtEC and Kontron. The PISA standard uses a half-length SBC that plugs in to a backplane slot similar to the old EISA slot. PISA backplanes also support PCI and ISA cards. Learn more at <http://www.jumpotec.de/index-en.html>.

An *active* backplane means the main backplane board contains bus control and usually other circuitry as well. Most active backplane systems contain all the circuitry found on a typical motherboard except for what is then called the *processor complex*. The processor complex is the name of the circuit board that contains the main system processor and any other circuitry directly related to it, such as clock control, cache, and so forth. The processor's complex design enables the user to easily upgrade the system later to a new processor type by changing one card. In effect, it amounts to a modular motherboard with a replaceable processor section.

Many large PC manufacturers have built systems with an active backplane/processor complex. Both IBM and Compaq, for example, have used this type of design in some of their high-end (server class) systems. ALR (now owned by Gateway) once made a series of desktop and server PCs that also featured this design. This allows an easier and generally more affordable upgrade than the passive backplane/mothercard design because the processor complex board is usually much cheaper than a mothercard. Unfortunately, because no standards exist for the processor complex interface to the system, these boards are proprietary and can be purchased only from the system manufacturer. This limited market and availability causes the prices of these boards to be higher than most complete motherboards from other manufacturers.

The motherboard system design and the backplane system design have advantages and disadvantages. Most original PCs were designed as backplanes in the late 1970s. Apple and IBM shifted the market to the now traditional motherboard with a slot-type design because this kind of system generally is cheaper to mass-produce than one with the backplane design. In the late 1980s, Zenith Data manufactured a line of backplane-based 8088, 286, and 386-based systems but later abandoned this for a standard motherboard design similar to other vendors. The theoretical advantage of a backplane system, however, is that you can easily upgrade it to a new processor and level of performance by changing a single card. For example, you can upgrade a system's processor just by changing the card. In a motherboard-design system, you often must change the motherboard, a seemingly more formidable task. Unfortunately, the reality of the situation is that a backplane design is frequently much more expensive to upgrade. For example, because the bus remains fixed on the backplane, the backplane design precludes more comprehensive upgrades that involve adding local bus slots.

Another nail in the coffin of backplane designs is the upgradeable processor. Starting with the 486, Intel and AMD began standardizing the sockets or slots in which processors were to be installed, allowing a single motherboard to support a wider variety of processors and system speeds. Because board designs could be made more flexible, changing only the processor chip for a faster standard OEM type (not one of the kludgy "overdrive" chips) is the easiest and most cost-effective way to upgrade without changing the entire motherboard.

Because of the limited availability of the processor-complex boards or motherboards, they usually end up being more expensive than a complete new motherboard that uses an industry-standard form factor. The bottom line is that unless you have a requirement for a large-capacity industrial or laboratory-type system, especially one that would be rack-mounted, you are better off sticking with standard ATX form factor PCs. They will certainly be far less expensive.

Note

Some companies offer plug-in processor cards that essentially turn your existing motherboard into an active backplane, shutting down the main CPU and memory and having the card's processor and memory essentially take over. These are, unfortunately, much more expensive than a new motherboard and processor alone, use the more expensive SO-DIMM memory, don't provide AGP video, and are generally not recommended.

Motherboard Components

A modern motherboard has several components built in, including various sockets, slots, connectors, chips, and so on. This section examines the components found on a typical motherboard.

Most modern motherboards have at least the following major components on them:

- Processor socket/slot
- Chipset (North/South Bridge or memory and I/O controller hubs)
- Super I/O chip
- ROM BIOS (Flash ROM/firmware hub)
- SIMM/DIMM/RIMM (RAM memory) sockets
- ISA/PCI/AGP bus slots
- CPU voltage regulator
- Battery

Some motherboards also include integrated video, audio, networking, SCSI, Audio Modem Riser (AMR), Communications and Networking Riser (CNR) connectors, or other optional interfaces, depending on the individual board.

These standard components are discussed in the following sections.

Processor Sockets/Slots

The CPU is installed in either a socket or a slot, depending on the type of chip.

Starting with the 486 processors, Intel designed the processor to be a user-installable and replaceable part and developed standards for CPU sockets and slots that would allow different models of the same basic processor to plug in. One key was to use a zero insertion force (ZIF) socket design, which meant that the processor could be easily installed or removed with no tools. ZIF sockets use a lever to engage or release the grip on the chip, and with the lever released, the chip can be easily inserted or removed. The ZIF sockets were given a designation that was usually imprinted or embossed on the socket indicating what type it was. Different socket types accepted different families of processors. If you know the type of socket or slot on your motherboard, you essentially know which types of processors are designed to plug in.

◀◀ See "Processor Socket and Slot Types," p. 88.

Sockets for processors prior to the 486 were not ZIF designs and, as such, were not designed for easy processor installation or removal. In addition, interchangeability was limited. Table 4.10 shows the designations for the various 486 and newer processor sockets/slots and lists the chips designed to plug into them.

Table 4.10 CPU Socket Specifications

	Socket	Pins	Layout	Voltage	Supported Processors
Intel/AMD 486 class	Socket 1	169	17×17 PGA	5V	486 SX/SX2, DX/DX2, DX4 OD
	Socket 2	238	19×19 PGA	5V	486 SX/SX2, DX/DX2, DX4 OD, 486 Pentium OD
	Socket 3	237	19×19 PGA	5V/3.3V	486 SX/SX2, DX/DX2, DX4, 486 Pentium OD, AMD 5x86
	Socket 6 ¹	235	19×19 PGA	3.3V	486 DX4, 486 Pentium OD
Intel/AMD 586 (Pentium) class	Socket 4	273	21×21 PGA	5V	Pentium 60/66, OD
	Socket 5	320	37×37 SPGA	3.3V/ 3.5V	Pentium 75-133, OD
	Socket 7	321	37×37 SPGA	VRM	Pentium 75-233+, MMX, OD, AMD K5/K6, Cyrix M1/II
Intel 686 (Pentium II/III) class	Socket 8	387	Dual-pattern SPGA	Auto VRM	Pentium Pro, OD
	Slot 1 (SC242)	242	Slot	Auto VRM	Pentium II/III, Celeron SECC
	Socket 370	370	37×37 SPGA	Auto VRM	Celeron/Pentium III PPGA/FC-PGA
Pentium 4 class	Socket 423	423	39×39 SPGA	Auto VRM	Pentium 4 FC-PGA
	Socket 478	478	26×26 mPGA	Auto VRM	Pentium 4/Celeron FC-PGA2
	Socket T (LGA775)	775	30×33 LGA	Auto VRM	Pentium 4/Celeron LGA775
AMD K7 class	Slot A	242	Slot	Auto VRM	AMD Athlon SECC
	Socket A (462)	462	37×37 SPGA	Auto VRM	AMD Athlon/Athlon XP/Duron PGA/FC-PGA
AMD K8 class	Socket 754	754	29×29 mPGA	Auto VRM	AMD Athlon 64
	Socket 939	939	31×31 mPGA	Auto VRM	AMD Athlon 64 v.2
	Socket 940	940	31×31 mPGA	Auto VRM	AMD Athlon 64FX, Opteron
Intel/AMD Server and Workstation class	Slot 2 (SC330)	330	Slot	Auto VRM	Pentium II/III Xeon
	Socket 603	603	31×25 mPGA	Auto VRM	Xeon (P4)
	Socket PAC418	418	38×22 split SPGA	Auto VRM	Itanium
	Socket PAC611	611	25×28 mPGA	Auto VRM	Itanium 2
	Socket 940	940	31×31 mPGA	Auto VRM	AMD Athlon 64FX, Opteron

1. Socket 6 was never actually implemented in any systems.

FC-PGA = Flip-chip pin grid array

FC-PGA2 = FC-PGA with an integrated heat spreader (IHS)

OD = OverDrive (retail upgrade processors)

PAC = Pin array cartridge

PGA = Pin grid array

PPGA = Plastic pin grid array

SC242 = Slot connector, 242 pins

SC330 = Slot connector, 330 pins

SECC = Single edge contact cartridge

SPGA = Staggered pin grid array

mPGA = Micro pin grid array

VRM = Voltage regulator module with variable voltage output determined by module type or manual jumpers

Auto VRM = Voltage regulator module with automatic voltage selection determined by processor voltage ID (VID) pins

Originally, all processors were mounted in sockets (or soldered directly to the motherboard). With the advent of the Pentium II and original Athlon processors, both Intel and AMD temporarily shifted to a slot-based approach for their processors because the processors now incorporated built-in L2 cache, purchased as separate chips from third-party Static RAM (SRAM) memory chip manufacturers. Therefore, the processor then consisted not of one but of several chips, all mounted on a daughterboard that was then plugged into a slot in the motherboard. This worked well, but there were additional expenses in the extra cache chips, the daughterboard itself, the slot, optional casings or packaging, and the support mechanisms and physical stands and latches for the processor and heatsink. All in all, slot-based processors were expensive to produce compared to the previous socketed versions.

With the advent of the second-generation Celeron, Intel integrated the L2 cache directly into the processor die, meaning within the main CPU chip circuits with no extra chips required. The second-generation (code named Coppermine) Pentium III also received on-die L2 cache, as did the K6-3, Duron (code named Spitfire), and second-generation Athlon (code named Thunderbird) processors from AMD (some early Thunderbird Athlon CPUs were also made in the Slot A configuration). With on-die L2, the processor was back to being a single chip again, which also meant that mounting it on a separate board plugged into a slot was expensive and unnecessary. Because of on-die integrated L2 cache, processor packaging shifted back to sockets and will continue that way for the foreseeable future. All modern processors now have integrated L2 cache (some also have integrated L3 cache) and use the socket form. Besides allowing a return to socketed packaging, the on-die L2 cache runs at full processor speed, instead of the one-half or one-third speed of the previous integrated (but not on-die) L2 cache.

Chipsets

We can't talk about modern motherboards without discussing chipsets. The *chipset* is the motherboard; therefore, any two boards with the same chipsets are functionally identical unless the vendor has added features to those provided by the chipset or removed support for certain chipset features.

The chipset contains the processor bus interface (called front-side bus, or FSB), memory controllers, bus controllers, I/O controllers, and more. All the circuits of the motherboard are contained within the chipset. If the processor in your PC is like the engine in your car, the chipset represents the chassis. It is the framework in which the engine rests and is its connection to the outside world. The chipset is the frame, suspension, steering, wheels and tires, transmission, drive shaft, differential, and brakes. The chassis in your car is what gets the power to the ground, allowing the vehicle to start, stop, and corner. In the PC, the chipset represents the connection between the processor and everything else. The processor can't talk to the memory, adapter boards, devices, and so on without going through the chipset. The chipset is the main hub and central nervous system of the PC. If you think of the processor as the brain, the chipset is the spine and central nervous system.

Because the chipset controls the interface or connections between the processor and everything else, the chipset ends up dictating which type of processor you have; how fast it will run; how fast the buses will run; the speed, type, and amount of memory you can use; and more. In fact, the chipset might be the single most important component in your system, possibly even more important than the processor. I've seen systems with faster processors be outperformed by systems with slower processor but a better chipset, much like how a car with less power might win a race through better cornering and braking. When deciding on a system, I start by choosing the chipset first because the chipset decision then dictates the processor, memory, I/O, and expansion capabilities.

Chipset Evolution

When IBM created the first PC motherboards, it used several discrete (separate) chips to complete the design. Besides the processor and optional math coprocessor, many other components were required to complete the system. These other components included items such as the clock generator, bus controller, system timer, interrupt and DMA controllers, CMOS RAM and clock, and keyboard controller. Additionally, many other simple logic chips were used to complete the entire motherboard circuit, plus,

of course, things such as the actual processor, math coprocessor (floating-point unit), memory, and other parts. Table 4.11 lists all the primary chip components used on the original PC/XT and AT motherboards.

Table 4.11 Primary Chip Components on PC/XT and AT Motherboards

Chip Function	PC/XT Version	AT Version
Processor	8088	80286
Math Coprocessor (Floating-Point Unit)	8087	80287
Clock Generator	8284	82284
Bus Controller	8288	82288
System Timer	8253	8254
Low-order Interrupt Controller	8259	8259
High-order Interrupt Controller	—	8259
Low-order DMA Controller	8237	8237
High-order DMA Controller	—	8237
CMOS RAM/Real-Time Clock	—	MC146818
Keyboard Controller	8255	8042

In addition to the processor/coprocessor, a six-chip set was used to implement the primary motherboard circuit in the original PC and XT systems. IBM later upgraded this to a nine-chip design in the AT and later systems, mainly by adding more interrupt and DMA controller chips and the nonvolatile CMOS RAM/Real-Time Clock chip. All these motherboard chip components came from Intel or an Intel-licensed manufacturer, except the CMOS/Clock chip, which came from Motorola. To build a clone or copy of one of these IBM systems required all these chips plus many smaller discrete logic chips to glue the design together, totaling 100 or more individual chips. This kept the price of a motherboard high and left little room on the board to integrate other functions.

In 1986, a company called Chips and Technologies introduced a revolutionary component called the 82C206—the main part of the first PC motherboard chipset. This was a single chip that integrated into it all the functions of the main motherboard chips in an AT-compatible system. This chip included the functions of the 82284 Clock Generator, 82288 Bus Controller, 8254 System Timer, dual 8259 Interrupt Controllers, dual 8237 DMA Controllers, and even the MC146818 CMOS/Clock chip. Besides the processor, virtually all the major chip components on a PC motherboard could now be replaced by a single chip. Four other chips augmented the 82C206 acting as buffers and memory controllers, thus completing virtually the entire motherboard circuit with five total chips. This first chipset was called the CS8220 chipset by Chips and Technologies. Needless to say, this was a revolutionary concept in PC motherboard manufacturing. Not only did it greatly reduce the cost of building a PC motherboard, but it also made designing a motherboard much easier. The reduced component count meant the boards had more room for integrating other items formerly found on expansion cards. Later, the four chips augmenting the 82C206 were replaced by a new set of only three chips, and the entire set was called the New Enhanced AT (NEAT) CS8221 chipset. This was later followed by the 82C836 Single Chip AT (SCAT) chipset, which finally condensed all the chips in the set down to a single chip.

The chipset idea was rapidly copied by other chip manufacturers. Companies such as Acer, Erso, Opti, Suntac, Symphony, UMC, and VLSI each gained an important share of this market. Unfortunately for many of them, the chipset market has been a volatile one, and many of them have long since gone out of business. In 1993, VLSI had become the dominant force in the chipset market and had the vast majority of the market share; by the next year, VLSI (which later was merged into Philips Semiconductors), along with virtually everybody else in the chipset market, was fighting to stay alive. This is because a new chipset manufacturer had come on the scene, and within a year or so of getting

serious, it was totally dominating the chipset market. That company was Intel, and after 1994, it had a virtual lock on the chipset market. If you have a motherboard built since 1994 that uses or accepts an Intel processor, chances are good that it has an Intel chipset on it as well.

Intel struggled somewhat with chipsets from 1999 through 2001 because of its reliance on RDRAM memory. Intel originally signed a contract with Rambus back in 1996 declaring it would support this memory as its primary focus for desktop PC chipsets through 2001. I suspect this has turned out to be something Intel regrets (the contract has since expired). RDRAM memory had a significantly higher price than DDR SDRAM memory. Consequently, Intel introduced the 845 chipset (code named Brookdale), which supported DDR SDRAM with the Pentium 4. After that, all of Intel's Pentium 4 chipsets have supported either DDR or DDR2 memory. Intel is not alone in the Pentium 4 chipset business: VIA Technologies, Silicon Integrated Systems (SiS), ATI, and ALi Corporation all make chipsets for the Pentium 4. In addition, almost all these chipsets also support SDRAM or DDR-SDRAM (although SiS makes a few chipsets that use RDRAM).

Although AMD has developed its own chipsets for the K6 and Athlon family of processors, it now emphasizes encouraging third-party chipset developers to support its products. Today, VIA Technologies is the leading developer of chipsets for AMD processors. The popularity of AMD processors has encouraged NVIDIA, SiS, ATI, and ALi Corporation to develop chipsets for AMD-based systems as well.

It is interesting to note that the original PC chipset maker, Chips and Technologies, survived by changing course to design and manufacture video chips and found a niche in that market specifically for laptop and notebook video chipsets. Chips and Technologies was subsequently purchased by Intel in 1998 as a part of Intel's video strategy.

Intel Chipsets

You can't talk about chipsets today without discussing Intel because it currently owns the vast majority of the chipset market. It is interesting to note that we probably have Compaq to thank for forcing Intel into the chipset business in the first place!

The thing that really started it all was the introduction of the EISA bus designed by Compaq in 1989. At that time, it had shared the bus with other manufacturers in an attempt to make it a market standard. However, Compaq refused to share its EISA bus chipset—a set of custom chips necessary to implement this bus on a motherboard.

Enter Intel, who decided to fill the chipset void for the rest of the PC manufacturers wanting to build EISA bus motherboards. As is well known today, the EISA bus failed to become a market success except for a short-term niche server business, but Intel now had a taste of the chipset business and this it apparently wouldn't forget. With the introduction of the 286 and 386 processors, Intel became impatient with how long it took the other chipset companies to create chipsets around its new processor designs; this delayed the introduction of motherboards that supported the new processors. For example, it took more than two years after the 286 processor was introduced for the first 286 motherboards to appear and just over a year for the first 386 motherboards to appear after the 386 had been introduced. Intel couldn't sell its processors in volume until other manufacturers made motherboards that would support them, so it thought that by developing motherboard chipsets for a new processor in parallel with the new processor, it could jumpstart the motherboard business by providing ready-made chipsets for the motherboard manufacturers to use.

Intel tested this by introducing the 420 series chipsets along with its 486 processor in April 1989. This enabled the motherboard companies to get busy right away, and in only a few months the first 486 motherboards appeared. Of course, the other chipset manufacturers weren't happy; now they had Intel as a competitor, and Intel would always have chipsets for new processors on the market first!

Intel then realized that it made both processors *and* chipsets, which were 90% of the components on a typical motherboard. What better way to ensure that motherboards were available for its Pentium processor when it was introduced than by making its own motherboards as well and having these boards ready on the new processor's introduction date. When the first Pentium processor debuted in

1993, Intel also debuted the 430LX chipset as well as a fully finished motherboard. Now, besides the chipset companies being upset, the motherboard companies weren't too happy, either. Intel was not only the major supplier of parts needed to build finished boards (processors and chipsets), but was now building and selling the finished boards as well. By 1994, Intel dominated the processor and chipset markets and had cornered the motherboard market as well.

Now as Intel develops new processors, it develops chipsets and motherboards simultaneously, which means they can be announced and shipped in unison. This eliminates the delay between introducing new processors and waiting for motherboards and systems capable of using them, which was common in the industry's early days. For the consumer, this means no waiting for new systems. Since the original Pentium processor in 1993, we have been able to purchase ready-made systems on the same day a new processor is released.

In my seminars, I ask how many people in the class have Intel-brand PCs. Of course, Intel does not sell or market a PC under its own name, so nobody thinks they have an "Intel-brand" PC. But, if your motherboard was made by Intel, for all intents and purposes you sure seem to have an Intel-brand PC, at least as far as the components are concerned. Does it really matter whether Dell, Gateway, or Micron PC (now MPC Computers, LLC) put that same Intel motherboard into a slightly different-looking case with their name on it? If you look under the covers, you'll find that many, if not most, of the systems from the major manufacturers are really the same because they basically use the same parts. Although more and more major manufacturers are offering AMD-based systems as alternatives to Intel's, no single manufacturer dominates AMD motherboard sales the way Intel has dominated OEM sales to major system manufacturers.

To hold down pricing, many low-cost retail systems based on microATX motherboards use non-Intel motherboards (albeit with Intel chipsets in most cases). But, even though many companies make PC-compatible motherboards for aftermarket upgrades or local computer assemblers, Intel still dominates the major vendor OEM market for midrange and high-end systems.

Intel Chipset Model Numbers

Starting with the 486 in 1989, Intel began a pattern of numbering its chipsets as shown in Table 4.12.

Table 4.12 Intel Chipset Model Numbers

Chipset Number	Processor Family	Chipset Number	Processor Family
420xx	P4 (486)	450xx	P6 server (Pentium Pro/PII/PIII Xeon)
430xx	P5 (Pentium)	E72xx	Xeon workstation with hub architecture
440xx	P6 (Pentium Pro/PII/PIII)	E75xx	Xeon server with hub architecture
8xx	P6/P7 (PII/PIII/P4) with hub architecture	460xx	Itanium processor
9xx	P7 (Pentium 4) with PCI-Express	E88xx	Itanium 2 processor with hub architecture

The chipset numbers listed here are abbreviations of the actual chipset numbers stamped on the individual chips. For example, one of the popular Pentium II/III chipsets was the Intel 440BX chipset, which consisted of two components: the 82443BX North Bridge and the 82371EB South Bridge. Likewise, the 865G chipset supports the Pentium 4 and consists of two main parts: the 82865G graphics memory controller hub (GMCH; replaces the North Bridge and includes integrated video) and an 82801EB or 82801EBR I/O controller hub (ICH5 or ICH5R; replaces the South Bridge). By reading the logo (Intel or others) as well as the part number and letter combinations on the larger chips on your motherboard, you can quickly identify the chipset your motherboard uses.

Intel has used two distinct chipset architectures: a North/South Bridge architecture and a newer hub architecture. All its more recent 800 and 900 series chipsets use the hub architecture.

Tip

In many cases, the North Bridge/GMCH/MCH chip on recent motherboards is covered up with a heatsink, and some motherboards also use a heatsink on the South Bridge or ICH chip. To determine the chipset used in these systems, watch for motherboard information displayed at system startup by some systems or use a third-party hardware reporting program such as SiSoftware Sandra (download from <http://www.sisoftware.co.uk/>).

AMD Athlon/Duron Chipsets

AMD took a gamble with its Athlon family of processors (Athlon, Athlon XP, Athlon MP, and Duron). With these processors, AMD decided for the first time to create a chip that was Intel compatible with regard to software but not directly hardware or pin compatible. Whereas the K6 series would plug into the same Socket 7 that Intel designed for the Pentium processor line, the AMD Athlon and Duron would not be pin compatible with the Pentium II/III and Celeron chips. This also meant that AMD could not take advantage of the previously existing chipsets and motherboards when the Athlon and Duron were introduced; instead, AMD would have to either create its own chipsets and motherboards or find other companies who would.

The gamble seems to have paid off. AMD bootstrapped the market by introducing its own chipset, referred to as the AMD-750 chipset (code named Irongate). The AMD 750 chipset consists of the 751 System Controller (North Bridge) and the 756 Peripheral Bus Controller (South Bridge). AMD followed with the AMD-760 chipset for the Athlon/Duron processors, which was the first major chipset on the market supporting DDR SDRAM for memory. It consists of two chips—the AMD-761 System Bus Controller (North Bridge) and the AMD-766 Peripheral Bus Controller (South Bridge). Similarly, AMD established a new standard chipset architecture for its line of 64-bit processors—the Athlon 64 and Opteron—by developing the AMD-8000 chipset. AMD's pioneering efforts have inspired other companies, such as VIA Technologies, NVIDIA, Ali, and SiS, to develop chipsets specifically designed for the Slot A and current Socket A, Socket 754, Socket 939, and Socket 940 processors from AMD. This has enabled the motherboard companies to make a variety of boards supporting these chips and the Athlon family of processors to take a fair amount of market share away from Intel in the process.

Traditional North/South Bridge Architecture

Most of Intel's earlier chipsets (and, until recently, virtually all non-Intel chipsets) are broken into a multitiered architecture incorporating what are referred to as North and South Bridge components, as well as a Super I/O chip:

- *The North Bridge.* So named because it is the connection between the high-speed processor bus (400/266/200/133/100/66MHz) and the slower AGP (533/266/133/66MHz) and PCI (33MHz) buses. The North Bridge is what the chipset is named after, meaning that, for example, what we call the 440BX chipset is derived from the fact that the actual North Bridge chip part number for that set is 82443BX.
- *The South Bridge.* So named because it is the bridge between the PCI bus (66/33MHz) and the even slower ISA bus (8MHz).
- *The Super I/O chip.* It's a separate chip attached to the ISA bus that is not really considered part of the chipset and often comes from a third party, such as National Semiconductor or Standard Microsystems Corp. (SMSC). The Super I/O chip contains commonly used peripheral items all combined into a single chip. Note that most recent South Bridge chips now include Super I/O functions (such chips are known as Super-South Bridge chips), so that most recent motherboards no longer include a separate Super I/O chip.

►► See "Super I/O Chips," p. 328.

Figure 4.30 shows a typical AMD Socket A motherboard using North/South Bridge architecture with the locations of all chips and components.

Figure 4.30 A typical Socket A (AMD Athlon/Duron) motherboard showing component locations.

The North Bridge is sometimes referred to as the PAC (PCI/AGP Controller). It is essentially the main component of the motherboard and is the only motherboard circuit besides the processor that normally runs at full motherboard (processor bus) speed. Most modern chipsets use a single-chip North Bridge; however, some of the older ones actually consisted of up to three individual chips to make up the complete North Bridge circuit.

The South Bridge is the lower-speed component in the chipset and has always been a single individual chip. The South Bridge is a somewhat interchangeable component in that different chipsets (North Bridge chips) often are designed to use the same South Bridge component. This modular design of the chipset allows for lower cost and greater flexibility for motherboard manufacturers. Similarly, many vendors produce several versions of pin-compatible South Bridge chips with different features to enable more flexible and lower-cost manufacturing and design. The South Bridge connects to the 33MHz PCI bus and contains the interface or bridge to the 8MHz ISA bus (if present). It also typically contains dual ATA/IDE hard disk controller interfaces, one or more USB interfaces, and in later designs even the CMOS RAM and real-time clock functions. In older designs, the South Bridge contained all the components that make up the ISA bus, including the interrupt and DMA controllers. The third motherboard component, the Super I/O chip, is connected to the 8MHz ISA bus or the low pin count (LPC) bus and contains all the standard peripherals that are built in to a motherboard. For example, most Super I/O chips contain the serial ports, parallel port, floppy controller, and keyboard/mouse interface. Optionally, they might contain the CMOS RAM/Clock, IDE controllers, and game port interface as well. Systems that integrate IEEE 1394 and SCSI ports use separate chips for these port types.

Most recent motherboards that use North/South Bridge chipset designs incorporate a Super-South Bridge, which incorporates the South Bridge and Super I/O functions into a single chip.

Hub Architecture

The newer 800 series chips from Intel use hub architectures in which the former North Bridge chip is now called a Memory Controller Hub (MCH) and the former South Bridge is called an I/O Controller Hub (ICH). Rather than connect them through the PCI bus as in a standard North/South Bridge design, they are connected via a dedicated hub interface that is twice as fast as PCI. The hub design offers several advantages over the conventional North/South Bridge design:

- *It's faster.* The hub interface used by the 8xx series is a 4X (quad-clocked) 66MHz 8-bit ($4 \times 66\text{MHz} \times 1 \text{ byte} = 266\text{MBps}$) interface, which has twice the throughput of PCI ($33\text{MHz} \times 32 \text{ bits} = 133\text{MBps}$).
- *Reduced PCI loading.* The hub interface is independent of PCI and doesn't share or steal PCI bus bandwidth for chipset or Super I/O traffic. This improves performance of all other PCI bus-connected devices because the PCI bus is not involved in these transactions.
- *Reduced board wiring.* Although twice as fast as PCI, the accelerated hub interface (AHA) hub interface is only 8 bits wide and requires only 15 signals to be routed on the motherboard. By comparison, PCI requires no less than 64 signals be routed on the board, causing increased electromagnetic interference (EMI) generation, greater susceptibility to signal degradation and noise, and increased board manufacturing costs.

This hub interface design allows for a much greater throughput for PCI devices because there is no South Bridge chip (also carrying traffic from the Super I/O chip) hogging the PCI bus. Due to bypassing PCI, hub architecture also enables greater throughput for devices directly connected to the I/O Controller Hub (formerly the South Bridge), such as the higher-speed ATA-100, Serial ATA, and USB 2.0 interfaces.

The hub interface design is also very economical, being only 8 bits wide. Although this seems too narrow to be useful, there is a reason for the design. By making the interface only 8 bits wide, it uses only 15 signals, compared to the 64 signals required by the 32-bit-wide PCI bus interface used by North/South Bridge chip designs. The lower pin count means less circuit routing exists on the board, less signal noise and jitter occur, and the chips themselves have many fewer pins, making them smaller and more economical to produce.

Although it transfers only 8 bits at a time, the hub interface executes four transfers per cycle and cycles at 66MHz. This gives it an effective throughput of $4 \times 66\text{MHz} \times 1 \text{ byte} = 266\text{MB}$ per second (MBps). This is twice the bandwidth of PCI, which is 32 bits wide but runs only one transfer per 33MHz cycles for a total bandwidth of 133MBps. So, by virtue of a very narrow—but very fast—design, the hub interface achieves high performance with less cost and more signal integrity than with the previous North/South Bridge design.

The MCH interfaces between the high-speed processor bus (800/533/400/133/100/66MHz) and the hub interface (66MHz) and AGP bus (533/266/133/66MHz), whereas the ICH interfaces between the hub interface (66MHz) and the ATA (IDE) ports (66/100MHz), the SATA ports on the ICH5 (150MHz), and the PCI bus (33MHz).

The ICH also includes a new low-pin-count (LPC) bus, consisting basically of a stripped 4-bit wide version of PCI designed primarily to support the motherboard ROM BIOS and Super I/O chips. By using the same 4 signals for data, address, and command functions, only 9 other signals are necessary to implement the bus, for a total of only 13 signals. This dramatically reduces the number of traces connecting the ROM BIOS chip and Super I/O chips in a system as compared to the 98 ISA bus signals necessary for older North/South Bridge chipsets that used ISA as the interface to those devices. The LPC bus has a maximum bandwidth of 16.67MBps, which is much faster than ISA and more than enough to support devices such as ROM BIOS and Super I/O chips.

The 9xx series of chipsets uses a second-generation hub design with a new interconnect technology called direct media interface (DMI). DMI runs at 1Gbps, or four times faster than the advanced hub architecture (AHA) used by most Intel 8xx-series chipsets or the updated hub interface 1.5 (HI 1.5) used by the 865/875 chipsets.

Figure 4.31 shows a typical Intel motherboard that uses bus architecture—the Intel D875PVZ, which supports the Intel Pentium 4 processor. Unlike some of Intel’s less-expensive hub-based motherboards, the Intel D875PVZ’s 875 chipset doesn’t incorporate video.

High-Speed North-South Bridge Connections

As you learned in the previous section, Intel has developed a replacement for the traditional North Bridge/South Bridge architecture known as *hub architecture*. This 266Mbps interface provides a faster connection between the memory controller hub/graphics memory controller hub (North Bridge replacements) and the I/O controller hub (South Bridge replacements) in Intel 8xx-series chipsets for the Pentium III and Pentium 4 processor families. The 9xx-series chipsets for the Pentium 4 processor have adopted a second-generation hub architecture that boosts the connection speed to 1Gbps.

Intel is not alone in replacing the slow PCI bus connection between North and South Bridge-type chips with a faster architecture that bypasses the PCI bus. Other companies that have introduced high-speed chipset interconnects include

- **VIA.** VIA created the V-Link architecture to connect its North and South Bridge chips at speeds matching or exceeding Intel hub architecture. V-Link uses a dedicated 8-bit data bus and is currently implemented in three versions: 4x V-Link, 8x V-Link, and Ultra V-Link. 4x V-Link transfers data at 266MBps (4×66MHz), which is twice the speed of PCI and matches the speed of Intel's AHA and HI 1.5 hub architectures. 8x V-Link transfers data at 533MBps (4×133MHz), which is twice the speed of Intel's HI 1.5 hub architecture. Ultra V-Link transfers data at 1GBps, which is four times the speed of Intel's HI 1.5 hub architecture and equals the speed of Intel's new DMI hub architecture. All VIA South Bridge chips in the VT82xx series support V-Link. The first chipsets to use V-Link were VIA's 266-series chipsets for the Pentium III, Pentium 4, and Athlon processor families. VIA's newer chipsets also use V-Link.
- **SiS.** SiS's MuTIOL architecture provides performance comparable to VIA's 4x V-Link; the second-generation MuTIOL 1G provides performance comparable to VIA's Ultra V-Link or Intel's DMI architectures. Chipsets that support MuTIOL use separate address, DMA, input data, and output data buses for each I/O bus master. MuTIOL buffers and manages multiple upstream and downstream data transfers over a bidirectional 16-bit data bus. South Bridge chips in the SiS961 and 962 series support MuTIOL at a data transfer rate of 533MBps (4×133MHz), whereas the SiS963 and 964 series support the faster MuTIOL 1G, which supports data transfer rates exceeding 1GBps. The North Bridge chips that support MuTIOL are described in the sections listing SiS chipsets for Pentium 4 and Athlon-series processors.
- **ATI.** ATI uses a high-speed interconnect called A-Link in its 9100-series IGP integrated chipsets. A-Link runs at 266MBps, matching Intel's HI 1.5 hub architecture and first-generation V-Link and MuTIOL designs. An improved version called A-Link II is used by ATI's chipsets for the Athlon 64.
- **NVIDIA.** NVIDIA's nForce, nForce2, and nForce3 chipsets use the HyperTransport bus originally developed by AMD.

Table 4.13 compares the performance features and chipset support of major non-Intel high-speed chipset architectures.

Table 4.13 Non-Intel High-Speed Chipset Architectures

Vendor	Architecture (Performance)	Sample Chipsets	Desktop Processors Supported
Ali	HyperTransport (1.6GBps)	M1687	Athlon 64, Opteron
		M1685	
		M1683	Intel Pentium 4, Celeron
ATI	A-Link (266MBps)	9100 IGP series	Pentium 4, Celeron
	A-Link II	RS/RX480	Athlon 64
NVIDIA	HyperTransport (800MBps)	nForce, nForce2	Athlon, Athlon XP, Duron
SiS	MuTIOL 1G (1.2GBps)	SiS 656, 655, 648 series	
		SiS R659	
		SiS 661FX	Pentium 4, Celeron
		SiS 760, 756, 755 series	Athlon 64, Athlon 64 FX, Opteron
		SiS 748, 746, 741 series	Athlon XP, Duron
	MuTIOL (533MBps)	SiS 651, 650, 645 series	Pentium 4, Celeron
		SiS 740	Athlon XP, Duron

Table 4.13 Continued

Vendor	Architecture (Performance)	Sample Chipsets	Desktop Processors Supported
VIA	Ultra V-Link (1GBps)	PM880, PT880 K8T800Pro	Pentium 4, Celeron Athlon 64, Athlon 64 FX, Opteron
	8x V-Link (533MBps)	PT800, PM800, P4X533, P4X400, P4X333 KT800, KT600, KM400, KT400 series K8T800, K8M800	Pentium 4, Celeron Athlon XP, Duron
	4x V-Link (266MBps)	P4M266 series, P4X266 series KT333, KT266 series	Pentium 4, Celeron Athlon, AthlonXP, Duron

1. The speed for the A-Link II was unknown at print time.

Let's examine the popular chipsets, starting with those used in 486 motherboards and working all the way through to the latest Pentium III/Celeron, Pentium 4, Athlon XP, and Athlon 64 chipsets.

Intel's Early 386/486 Chipsets

Intel's first real PC motherboard chipset was the 82350 chipset for the 386DX and 486 processors. This chipset was not very successful, mainly because the EISA bus was not very popular and many other manufacturers were making standard 386 and 486 motherboard chipsets at the time. The market changed very quickly, and Intel dropped the EISA bus support and introduced follow-up 486 chipsets that were much more successful.

Table 4.14 shows the Intel 486 chipsets.

Table 4.14 Intel 486 Motherboard Chipsets

Chipset	420TX	420EX	420ZX
Code name	Saturn	Aries	Saturn II
Date introduced	Nov. 1992	March 1994	March 1994
Processor	5V 486	5V/3.3V 486	5V/3.3V 486
Bus speed	Up to 33MHz	Up to 50MHz	Up to 33MHz
SMP (dual CPUs)	No	No	No
Memory types	FPM	FPM	FPM
Parity/ECC	Parity	Parity	Parity
Max. memory	128MB	128MB	160MB
L2 cache type	Async	Async	Async
PCI support	2.0	2.0	2.1
AGP support	No	No	No

AGP = Accelerated graphics port

FPM = Fast page mode

PCI = Peripheral component interconnect

SMP = Symmetric multiprocessing (dual processors)

Note: PCI 2.1 supports concurrent PCI operations.

The 420 series chipsets were the first to introduce the North/South Bridge design that is still used in many chipsets today.

Fifth-Generation (P5 Pentium Class) Chipsets

With the advent of the Pentium processor in March 1993, Intel also introduced its first Pentium chipset: the 430LX chipset (code named Mercury). This was the first Pentium chipset on the market and set the stage as Intel took this lead and ran with it. Other manufacturers took months to a year or more to get their Pentium chipsets out the door. Since the debut of its Pentium chipsets, Intel has dominated the chipset market. Table 4.15 shows the Intel Pentium motherboard chipsets. Note that none of these chipsets support AGP; Intel first added support for AGP in its chipsets for the Pentium II/Celeron processors.

Table 4.15 Intel Pentium Motherboard Chipsets (North Bridge)

Chipset	430LX	430NX	430FX	430MX	430HX	430VX	430TX
Code name	Mercury	Neptune	Triton	Mobile Triton	Triton II	Triton III	n/a
Date introduced	March 1993	March 1994	Jan. 1995	Oct. 1995	Feb. 1996	Feb. 1996	Feb. 1997
CPU bus speed	66MHz	66MHz	66MHz	66MHz	66MHz	66MHz	66MHz
CPUs supported	P60/66	P75+	P75+	P75+	P75+	P75+	P75+
SMP (dual CPUs)	No	Yes	No	No	Yes	No	No
Memory types	FPM	FPM	FPM/EDO	FPM/EDO	FPM/EDO	FPM/EDO/SDRAM	FPM/EDO/SDRAM
Parity/ECC	Parity	Parity	Neither	Neither	Both	Neither	Neither
Max. memory	192MB	512MB	128MB	128MB	512MB	128MB	256MB
Max. cacheable	192MB	512MB	64MB	64MB	512MB	64MB	64MB

PCI support	2.0	2.0	2.0	2.0	2.1	2.1	2.1
AGP support	No	No	No	No	No	No	No
South Bridge	SIO	SIO	PIIX	MPIIX	PIIX3	PIIX3	PIIX4

EDO = Extended data out

FPM = Fast page mode

PIIX = PCI ISA IDE Xcelerator

SDRAM = Synchronous dynamic RAM

SIO = System I/O

SMP = Symmetric multiprocessing (dual processors)

Note

PCI 2.1 supports concurrent PCI operations, enabling multiple PCI cards to perform transactions at the same time for greater speed.

Table 4.16 shows the Intel South Bridge chips used with Intel chipsets for Pentium processors. South Bridge chips are the second part of the modern Intel motherboard chipsets.

Table 4.16 Intel South Bridge Chips

Chip Name	SIO	PIIX	PIIX3	PIIX4	PIIX4E	ICH0	ICH
Part number	82378IB/ZB	82371FB	82371SB	82371AB	82371EB	82801AB	82801AA
IDE support	None	BMIDE	BMIDE	UDMA-33	UDMA-33	UDMA-33	UDMA-66
USB support	None	None	Yes	Yes	Yes	Yes	Yes
CMOS/clock	No	No	No	Yes	Yes	Yes	Yes
Power SMM/ACPI management	SMM	SMM	SMM	SMM	SMM/ACPI	SMM/ACPI	

ACPI = Advanced configuration and power interface
 BMIDE = Bus master IDE (ATA)
 ICH = I/O Controller Hub
 IDE = Integrated Drive Electronics (AT attachment)
 PIIX = PCI ISA IDE Xcelerator

SIO = System I/O
 SMM = System management mode
 UDMA = Ultra-DMA IDE (ATA)
 USB = Universal serial bus

The Pentium chipsets listed in Tables 4.10 and 4.11 have been out of production for several years, and most computers that use these chipsets have been retired.

Intel 430LX (Mercury)

The 430LX was introduced in March 1993, concurrent with the introduction of the first Pentium processors. This chipset was used only with the original Pentiums, which came in 60MHz and 66MHz versions. These were 5V chips and were used on motherboards with Socket 4 processor sockets.

- ◀◀ See "Processor Socket and Slot Types," p. 88.
- ◀◀ See "First-Generation Pentium Processor," p. 128.

The 430LX chipset consisted of three total chips for the North Bridge portion. The main chip was the 82434LX system controller. This chip contained the processor-to-memory interface, cache controller, and PCI bus controller. There was also a pair of PCI bus interface accelerator chips, which were identical 82433LX chips.

The 430LX chipset was noted for the following:

- Single processor
- Support for up to 512KB of L2 cache
- Support for up to 192MB of standard DRAM

This chipset died off along with the 5V 60/66MHz Pentium processors.

Intel 430NX (Neptune)

Introduced in March 1994, the 430NX was the first chipset designed to run the new 3.3V second-generation Pentium processor. These were noted by having Socket 5 processor sockets and an onboard 3.3V/3.5V voltage regulator for both the processor and chipset. This chipset was designed primarily for Pentiums with speeds from 75MHz to 133MHz, although it was used mostly with 75MHz–100MHz systems. Along with the lower-voltage processor, this chipset ran faster, cooler, and more reliably than the first-generation Pentium processor and the corresponding 5V chipsets.

- ◀◀ See "CPU Operating Voltages," p. 102.
- ◀◀ See "Second-Generation Pentium Processor," p. 129.

The 430NX chipset consisted of three chips for the North Bridge component. The primary chip was the 82434NX, which included the cache and main memory (DRAM) controller and the control interface to the PCI bus. The actual PCI data was managed by a pair of 82433NX chips called local bus accelerators. Together, these two chips, plus the main 82434NX chip, constituted the North Bridge.

The South Bridge used with the 430NX chipset was the 82378ZB System I/O (SIO) chip. This component connected to the PCI bus and generated the lower-speed ISA bus.

The 430NX chipset introduced the following improvements over the Mercury (430LX) chipset:

- Dual processor support
- Support for 512MB of system memory (up from 192MB for the LX Mercury chipset)

This chipset rapidly became the most popular chipset for the early 75MHz–100MHz systems, overshadowing the older 60MHz and 66MHz systems that used the 430LX chipset.

Intel 430FX (Triton)

The 430FX (Triton) chipset rapidly became popular after it was introduced in January 1995. This chipset is noted for being the first to support extended data out (EDO) memory, which subsequently became very popular. EDO was about 21% faster than the standard fast page mode (FPM) memory that had been used up until that time but cost no more than the slower FPM. Unfortunately, although it was known for faster memory support, the Triton chipset was also known as the first Pentium chipset without support for parity checking for memory. This was somewhat of a blow to PC reliability and fault tolerance, even though many did not know it at the time.

- ▶▶ See "Extended Data Out RAM," p. 468.
- ▶▶ See "Parity and ECC," p. 500.

The Triton chipset lacked parity support from the previous 430NX chipset, but it also supported only a single CPU. The 430FX was designed as a low-end chipset for home or non-mission-critical systems. As such, it did not replace the 430NX, which carried on in higher-end network file servers and other more mission-critical systems.

The 430FX consisted of a three-chip North Bridge. The main chip was the 82437FX system controller that included the memory and cache controllers, CPU interface, and PCI bus controller, along with dual 82438FX data path chips for the PCI bus. The South Bridge was the first PIIX (PCI ISA IDE Xcelerator) chip that was a 82371FB. This chip not only acted as the bridge between the 33MHz PCI bus and the slower 8MHz ISA bus, but also incorporated for the first time a dual-channel IDE interface. By moving the IDE interface off the ISA bus and into the PIIX chip, it was now effectively connected to the PCI bus, enabling much faster Bus Master IDE transfers. This was key in supporting the ATA-2 or Enhanced IDE interface for better hard disk performance.

The major points on the 430FX are

- | | |
|---|---|
| ■ Support for EDO memory | ■ Lack of support for parity-checked memory |
| ■ Support for higher speed—pipelined burst L2 cache | ■ Only single CPU support |
| ■ PIIX South Bridge with high-speed Bus Master IDE | ■ Supported only 128MB of RAM, of which only 64MB could be cached |

That last issue is one that many people are not aware of. The 430FX chipset can cache only up to 64MB of main memory. So, if you install more than 64MB of RAM in your system, performance suffers greatly. At the time, many didn't think this would be that much of a problem—after all, they didn't usually run enough software to load past the first 64MB anyway. That is another misunderstanding because Windows 9x and NT/2000 (as well as all other protected-mode operating systems

including Linux and so on) load from the top down. So, for example, if you install 96MB of RAM (one 64MB and one 32MB bank), virtually all your software, including the main operating system, loads into the noncached region above 64MB. Needless to say, performance would suffer greatly. Try disabling the L2 cache via your CMOS Setup to see how slowly your system runs without it. That is the performance you can expect if you install more than 64MB of RAM in a 430FX-based system. Some thought this was a Windows limitation, but it is instead caused by the chipset design.

Intel 430HX (Triton II)

Intel created the Triton II 430HX chipset as a true replacement for the powerful 430NX chip. It added some of the high-speed memory features from the low-end 430FX, such as support for EDO memory and pipeline burst L2 cache. It also retained dual-processor support. In addition to supporting parity checking to detect memory errors, it added support for error correcting code (ECC) memory to detect and correct single bit errors on-the-fly. And the great thing was that this was implemented using plain parity memory.

The HX chipset's primary advantages over the FX are

- Symmetric multiprocessor (dual processor) support.
- Support for ECC and parity memory.
- 512MB maximum RAM support (versus 128MB).
- L2 cache functions over 512MB RAM versus 64MB (providing optional cache tag RAM is installed).
- Memory transfers in fewer cycles overall.
- PCI Level 2.1 compliance that allows concurrent PCI operations.
- PIIX3 supports different IDE/ATA transfer speed settings on a single channel.
- PIIX3 South Bridge component supports USB.

The memory problems with caching in the 430FX were corrected in the 430HX. This chipset allowed for the caching of the full 512MB of possible RAM as long as the correct amount of cache *tag* was installed. Tag is a small cache memory chip used to store the index to the data in the cache. Most 430HX systems shipped with a tag chip that could manage only 64MB of cached main memory, although you could optionally upgrade it to a larger capacity tag chip that would enable caching the full 512MB of RAM.

The 430HX chipset was a true one-chip North Bridge. It was also one of the first chips out in a ball-grid array (BGA) package, in which the chip leads are configured as balls on the bottom of the chip. This enabled a smaller chip package than the previous plastic quad flat pack (PQFP) packaging used on the older chips, and, because only one chip existed for the North Bridge, a very compact motherboard was possible. The South Bridge was the PIIX3 (82371SB) chip, which enabled independent timing of the dual IDE channels. Therefore, you could install two different speed devices on the same channel as master/slave and configure their transfer speeds independently. Previous PIIX chips allowed both devices on a single cable to work at the lowest common denominator speed supported by both. The PIIX3 also incorporated the USB for the first time on a PC motherboard. Unfortunately at the time, no devices were available to attach to USB, nor was there any operating systems or driver support for the bus. USB ports were a curiosity at the time, and nobody had a use for them.

▶▶ See "Universal Serial Bus," p. 983.

The 430HX supports the newer PCI 2.1 standard, which allowed for concurrent PCI operations and greater performance. Combined with the support for EDO and pipelined burst cache, this was perhaps the best Pentium chipset for the power user's system. It offered excellent performance, and with ECC memory it offered a truly reliable and stable system design.

The 430HX was the only modern Intel Pentium-class chipset to offer parity and error-corrected memory support. This made it the recommended Intel chipset at the time for mission-critical applications, such as file servers, database servers, business systems, and so on.

Intel 430VX (Triton III)

The 430VX was designed to be a replacement for the low-end 430FX chipset; it was not a replacement for the higher-powered 430HX chipset. As such, the VX has only one significant technical advantage over the HX, but in almost all other respects it is more like the 430FX than the HX.

The VX has the following features:

- Support for 66MHz SDRAM
- No parity or ECC memory support
- Single processor only
- Supports only 128MB RAM
- Supports caching for only 64MB RAM

Most notable was the support for SDRAM, which was about 27% faster than the more popular EDO memory used at the time. Although the support for SDRAM was a nice bonus, the actual improvement in system speed derived from such memory was somewhat limited. This was because with a normal L1/L2 cache combination, the processor read from the caches 99% of the time. A combined miss (both L1 and L2 missing) happened only about 1% of the time while reading/writing memory. Thus with SDRAM, the system would be up to 27% faster, but only about 1% of the time. Therefore, the cache performance was actually far more important than main memory performance. See the section “How Cache Works” in Chapter 3, “Microprocessor Types and Specifications,” for more information.

As with the 430FX, the VX has the limitation of being capable of caching only 64MB of main memory. Therefore, installing more than 64MB of memory actually slows down the system dramatically because none of the memory past that point can be cached. Because Windows loads from the top of memory down, installing any amount of memory greater than 64MB in a system using this chipset dramatically decreases performance.

The 430VX chipset was rapidly made obsolete in the market by the 430TX chipset that followed.

Intel 430TX

The 430TX was Intel’s final Pentium chipset. It was designed not only to be used in desktop systems, but to replace the 430MX mobile Pentium chipset for laptop and notebook systems.

The 430TX had some refinements over the 430VX, but, unfortunately, it still lacked support for parity or ECC memory and retained the 64MB cacheable RAM limitation of the older FX and VX chipsets. The 430TX was not designed to replace the more powerful 430HX chipset, which still remained the chipset of choice for Pentium class mission-critical systems.

The TX chipset features include the following:

- 66MHz SDRAM support
- Cacheable memory still limited to 64MB
- Support for Ultra-ATA, or Ultra-DMA 33 (UDMA) IDE transfers
- Lower power consumption for mobile use
- No parity or ECC memory support
- Single processor only

►► See “ATA/ATAPI-4,” p. 539.

Third-Party (Non-Intel) P5 Pentium Class Chipsets

The development of non-Intel Pentium-class chipsets was spurred by AMD’s development of its own equivalents to the Pentium processor—the K5 and K6 processor families. Although the K5 was not a successful processor, the K6 family was very successful in the low-cost (under \$1,000) market and as an upgrade for Pentium systems. AMD’s own chipsets aren’t used as often as other third-party chipsets, but AMD’s capability to support its own processors with timely chipset deliveries has helped make the K6 and its successors—the Athlon, Athlon XP, and Duron—into credible rivals for Intel’s Pentium MMX

and Pentium II/III/4/Celeron families and has spurred other vendors, such as VIA, Acer Laboratories, and SiS, to support AMD's processors. Major third-party chipsets for Pentium-class processors include

- AMD 640
- ALi Aladdin 4, Aladdin 5, and Aladdin 7
- VIA Apollo VP1, VP2, VPX, VP3, MVP3, and MVP4
- SiS SiS540, SiS530/5595, SiS5598, SiS5581, SiS5582, SiS5571, SiS5591, and SiS5592

Most computers that use these chipsets have been retired. For more detailed information about these chipsets, see *Upgrading and Repairing PCs, 14th Edition*, which is included on the disc packaged with this book.

Sixth-Generation (P6 Pentium Pro/II/III Class) Chipsets

Just as Intel clearly dominated the Pentium chipset world, it is also the leading vendor for chipsets supporting its P6 processor families. As discussed earlier, the biggest reason for this is that, since the Pentium first came out in 1993, Intel has been introducing new chipsets (and even complete ready-to-go motherboards) simultaneously with its new processors. This makes it hard for anybody else to catch up. Another problem for other chipset manufacturers is that they are required to license the CPU bus interface design before they can produce a matching chipset.

Note that because the Pentium Pro, Celeron, and Pentium II/III are essentially the same processor with different cache designs and minor internal revisions, the same chipset can be used for Socket 8 (Pentium Pro), Socket 370 (Celeron/Pentium III), and Slot 1 (Celeron/Pentium II/III) designs. Of course, the newer P6-class chipsets are optimized for the Socket 370 architecture and nobody is making any new designs for Socket 8 or Slot 1.

Table 4.17 shows the chipsets used on Pentium Pro motherboards.

Note

PCI 2.1 supports concurrent PCI operations.

Table 4.18 P6 Processor Chipsets Using North/South Bridge Architecture

SIO = System I/O

SMP = Symmetric multiprocessing (dual processors)

For the Celeron and Pentium II/III motherboards, Intel offers the chipsets in Table 4.18. 4xx series chipsets incorporate a North/South Bridge architecture, whereas 8xx series chipsets support the newer and faster hub architecture. P6/P7 (Pentium III/Celeron, Pentium 4, and Xeon) processor chipsets using hub architecture are shown in Table 4.19.

South Bridge (ICH)	82801AA/ AB (ICH/ICH0)	82801AA (ICH)	82801AA (ICH)	82801BA (ICH2)	82801BA (ICH2)

1. The 440ZX is available in a cheaper 440ZX-66 version that runs only at 66MHz.

2. These 810/815 chipsets have integral AGP 2x 3D video that is NOT upgradeable via an external AGP adapter.

3. The 815/815E chipsets have integral AGP 2x 3D video that IS upgradeable via an APG 4x slot.

4. The only difference between the 815 and 815E is in which I/O controller hub (South Bridge) is used.

AGP = Accelerated graphics port

Note

Pentium Pro, Celeron, and Pentium II/III CPUs have their secondary caches integrated into the CPU package. Therefore, cache characteristics for these machines are not dependent on the chipset but are quite dependent on the processor instead.

Most Intel chipsets are designed as a two-part system, using a North Bridge (MCH or GMCH in hub-based designs) and a South Bridge (ICH in hub-based designs) component. Often the same South Bridge or ICH component can be used with several different North Bridge (MCH or GMCH) chipsets. Table 4.20 shows a list of all the Intel South Bridge components used with P6-class processors and their capabilities. The ICH2 is also used as part of some of the first seventh-generation (Pentium 4/Celeron 4) Intel chipsets.

The following sections examine the chipsets for P6 processors up through the Celeron and Pentium III.

ISA = Industry standard architecture bus

LPC = Low pin count bus

SMM = System management mode

ACPI = Advanced configuration and power interface

Intel 450KX/GX (Orion Workstation/Server)

The first chipsets to support the Pentium Pro were the 450KX and GX, both code named Orion. The 450KX was designed for networked or standalone workstations; the more powerful 450GX was designed for file-servers. The GX server chipset was particularly suited to the server role because it supports up to four Pentium Pro processors for symmetric multiprocessing (SMP) servers, up to 8GB of four-way interleaved memory with ECC or parity, and two bridged PCI buses. The 450KX is the workstation or standalone user version of Orion and as such it supports fewer processors (one or two) and less memory (1GB) than the GX. The 450GX and 450KX both have full support for ECC memory—a requirement for server and workstation use.

The 450GX and 450KX North Bridge comprises four individual chip components—an 82454KX/GX PCI bridge, an 82452KX/GX data path (DP), an 82453KX/GX data controller (DC), and an 82451KX/GX memory interface controller (MIC). Options for QFP or BGA packaging were available on the PCI Bridge and the DP. BGA uses less space on a board.

The 450's high reliability is obtained through ECC from the Pentium Pro processor data bus to memory. Reliability is also enhanced by parity protection on the processor bus, control bus, and all PCI signals. In addition, single-bit error correction is provided, thereby avoiding server downtime because of spurious memory errors caused by cosmic rays.

Until the introduction of the following 440FX chipset, these were used almost exclusively in file servers. After the debut of the 440FX, the expensive Orion chips all but disappeared due to their complexity and high cost.

Intel 440FX (Natoma)

The first popular mainstream P6 (Pentium Pro or Pentium II) motherboard chipset was the 440FX, which was code named Natoma. Intel designed the 440FX to be a lower-cost and somewhat higher-performance replacement for the 450KX workstation chipset. It offered better memory performance through support of EDO memory, which the prior 450KX lacked.

The 440FX uses half the number of components that the previous Intel chipset used. It offers additional features, such as support for the PCI 2.1 (concurrent PCI) standard, support for USB, and reliability through ECC.

The concurrent PCI processing architecture maximizes system performance with simultaneous activity on the CPU, PCI, and ISA buses. Concurrent PCI provides increased bandwidth to better support 2D/3D graphics, video and audio, and processing for host-based applications. ECC memory support delivers improved reliability to business system users.

The main features of this chipset include

- Support for up to 1GB of EDO memory
- Support for USB
- Full 1GB cacheability (based on the processor because the L2 cache and tag are in the CPU)
- Support for Bus master IDE
- Support for full parity/ECC

The 440FX consists of a two-chip North Bridge. The main component is the 82441FX PCI Bridge and Memory controller, along with the 82442FX Data Bus accelerator for the PCI bus. This chipset uses the PIIX3 82371SB South Bridge chip that supports high-speed Bus Master DMA IDE interfaces and USB, and it acts as the bridge between the PCI and ISA buses.

Note that this was the first P6 chipset to support EDO memory, but it lacked support for the faster SDRAM. Also, the PIIX3 used with this chipset does not support the faster Ultra DMA IDE hard drives.

The 440FX was the chipset used on the first Pentium II motherboards, which have the same basic architecture as the Pentium Pro. The Pentium II was released several months before the chipset that was supposedly designed for it was ready, so early PII motherboards used the older 440FX chipset. This

chipset was never designed with the Pentium II in mind, whereas the newer 440LX was optimized specifically to take advantage of the Pentium II architecture. For that reason, I normally recommended that people stay away from the original 440FX-based PII motherboards and wait for Pentium II systems that used the forthcoming 440LX chipset. When the new chipset was introduced, the 440FX was quickly superseded by the improved 440LX design.

Intel 440LX

The 440LX quickly took over in the marketplace after it debuted in August of 1997. This was the first chipset to really take full advantage of the Pentium II processor. Compared to the 440FX, the 440LX chipset offers several improvements:

- Support for the (then-new) AGP video card bus
- Support for 66MHz SDRAM memory
- Support for the Ultra DMA IDE interface
- Support for USB

The 440LX rapidly became the most popular chip for all new Pentium II systems from the end of 1997 through the beginning of 1998.

Intel 440EX

The 440EX was designed to be a low-cost, lower-performance alternative to the 440LX chipset. It was introduced in April 1998, along with the Intel Celeron processor. The 440EX lacks several features found in the more powerful 440LX, including dual processor and ECC or parity memory support. This chipset is basically designed for low-end 66MHz bus-based systems that use the Celeron processor. Note that boards with the 440EX also fully support a Pentium II but lack some of the features of the more powerful 440LX or 440BX chipsets.

The main things to note about the 440EX are listed here:

- Designed with a feature set tuned for the low-end PC market
- Primarily for the Intel Celeron processor
- Supports AGP
- Does not support ECC or parity memory
- Single processor support only

The 440EX consists of an 82443EX PCI AGP Controller (PAC) North Bridge component and the new 82371EB (PIIX4E) South Bridge chip.

Note

The original 266MHz and 300MHz Celeron processors used with the 440EX chipset provided very low performance because these processors lacked any onboard Level 2 cache memory. Starting with the 300MHz Celeron 300A, Celeron added 128KB of Level 2 cache to its SEP packaging; all Socket 370 Celerons also include Level 2 cache. You should consider upgrading to a faster Celeron CPU with Level 2 cache if your 440EX-based system uses one of the original Celeron processors.

Intel 440BX

The Intel 440BX chipset was introduced in April 1998 and was the first chipset to run the processor host bus (often called the front-side bus, or FSB) at 100MHz. The 440BX was designed specifically to support the faster Pentium II/III processors at 350MHz and higher. A mobile version of this chipset is the first Pentium II/III chipset for notebook or laptop systems.

The main change from the previous 440LX to the BX is that the 440BX chipset improves performance by increasing the bandwidth of the system bus from 66MHz to 100MHz. Because the chipset can run at either 66MHz or 100MHz, it allows one basic motherboard design to support all Pentium II/III processor speeds based on either the 66MHz or 100MHz processor bus.

Here are the Intel 440BX highlights:

- Support for 100MHz SDRAM (PC100); the now-common PC133 RAM can also be installed, but it will still run at just 100MHz
- Support for both 100MHz and 66MHz system and memory bus designs
- Support for up to 1GB of memory in up to four banks (four DIMMs)
- Support for ECC memory
- Support for ACPI
- The first chipset to support the Mobile Intel Pentium II processor

The Intel 440BX consists of a single North Bridge chip called the 82443BX Host Bridge/Controller, which is paired with a new 82371EB PCI-ISA/IDE Xcelerator (PIIX4E) South Bridge chip. The new South Bridge adds support for the ACPI specification version 1.0. Figure 4.32 shows a typical system block diagram using the 440BX.

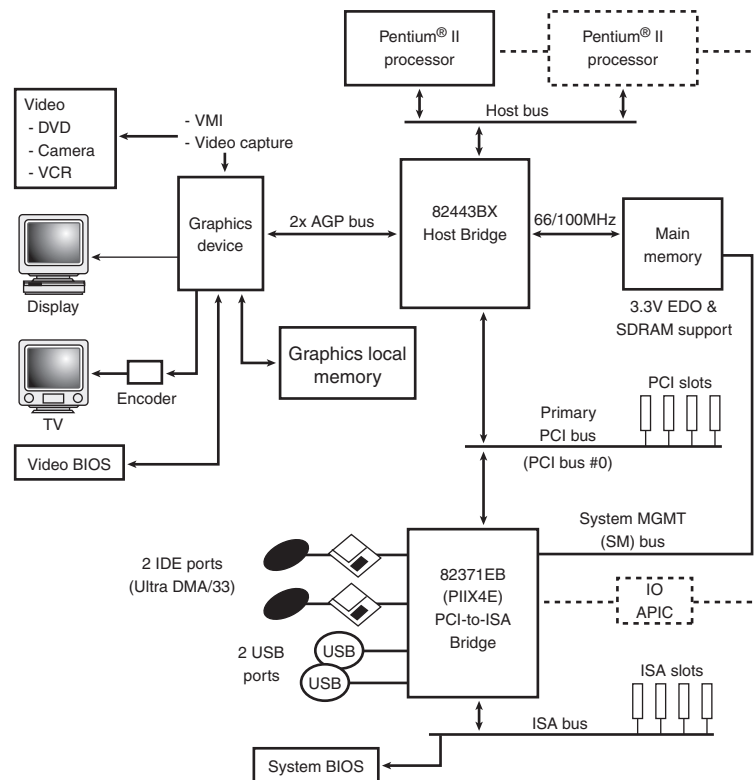

Figure 4.32 System block diagram using the Intel 440BX chipset.

The 440BX was a popular chipset during 1998 and into 1999. It offered superior performance and high reliability through the use of ECC, SDRAM, and DIMMs.

Intel 440ZX and 440ZX-66

The 440ZX was designed to be a low-cost version of the 440BX. The 440ZX brings 66MHz or 100MHz performance to entry-level Celerons (with or without Level 2 cache) and low-end Pentium II/III systems. The 440ZX is pin compatible with the more expensive 440BX, meaning existing 440BX motherboards can be easily redesigned to use this lower-cost chipset.

Note that two versions of the 440ZX are available: The standard one runs at 100MHz or 66MHz, and the 440ZX-66 runs only at the slower 66MHz.

The features of the 440ZX include the following:

- Support for Celeron and Pentium II/III processors at up to 100MHz bus speeds
- These main differences from the 440BX:
 - No parity or ECC memory support
 - Only two banks of memory (two DIMMs) supported
 - Maximum memory only 256MB

The 440ZX is not a replacement for the 440BX; instead, it was designed to be used in less expensive systems (such as those based on the microATX form factor), in which the greater memory capabilities, performance, and data integrity functions (ECC memory) of the 440BX are unnecessary.

Intel 440GX

The Intel 440GX AGP set is the first chipset optimized for high-volume midrange workstations and lower-cost servers. The 440GX is essentially a version of the 440BX that has been upgraded to support the Slot 2 (also called SC330) processor slot for the Pentium II/III Xeon processor. The 440GX can still be used in Slot 1 designs, as well. It also supports up to 2GB of memory, twice that of the 440BX. Other than these items, the 440GX is essentially the same as the 440BX. Because the 440GX is core compatible with the 440BX, motherboard manufacturers could quickly and easily modify their existing Slot 1 440BX board designs into Slot 1 or 2 440GX designs.

The main features of the 440GX include the following:

- Support for Slot 1 and Slot 2
- Support for 100MHz system bus
- Support for up to 2GB of SDRAM memory

This chipset allows for lower-cost, high-performance workstations and servers using the Slot 2-based Xeon processors.

Intel 450NX

The 450NX chipset is designed for multiprocessor systems and standard high-volume servers based on the Pentium II/III Xeon processor. The Intel 450NX chipset consists of four components: the 82454NX PCI Expander Bridge (PXB), 82451NX Memory and I/O Bridge Controller (MIOC), 82452NX RAS/CAS Generator (RCG), and 82453NX Data Path Multiplexor (MUX).

The 450NX supports up to four Pentium II/III Xeon processors at 100MHz. Two dedicated PCI Expander Bridges can be connected via the Expander Bus. Each PXB provides two independent 32-bit, 33MHz PCI buses, with an option to link the two buses into a single 64-bit, 33MHz bus.

Figure 4.33 shows a typical high-end server block diagram using the 450NX chipset.

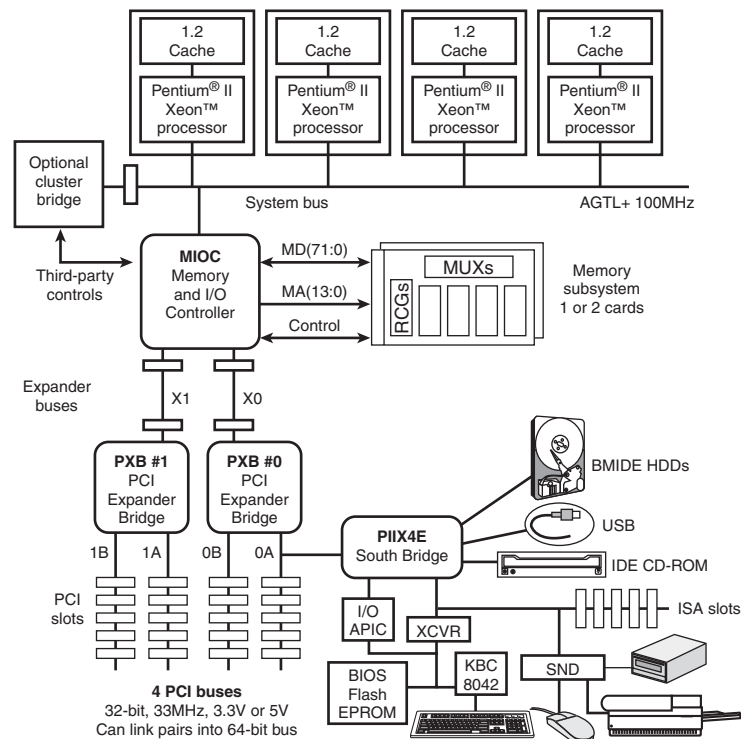

Figure 4.33 High-end server block diagram using the Intel 440NX chipset.

The 450NX supports one or two memory cards. Each card incorporates an RCG chip and two MUX chips, in addition to the memory DIMMs. Up to 8GB of memory is supported in total.

The primary features of the 450NX include the following:

- Slot 2 (SC330) processor bus interface at 100MHz
- Support for up to four-way processing
- Support for two dedicated PCI Expander Bridges
- Up to four 32-bit PCI buses or two 64-bit PCI buses

The 450NX chipset does not support AGP because high-end video is not an issue in network file servers.

Intel 810, 810E, and 810E2

Introduced in April 1999, the Intel 810 chipset (code named Whitney) represents a major change in chipset design from the standard North and South Bridges that have been used since the 486 days. The 810 chipset allows for improvements in system performance, all for less cost and system complexity. The 810 (which supports 66MHz and 100MHz processor buses) was later revised as the 810E with support for the 133MHz processor bus.

Note

The 810E2 uses the same 82810E GMCH as the 810E but pairs it with the 82801BA I/O Controller Hub (ICH2) used by the Intel 815E. For information about the 82801BA ICH2 chip, see the section "Intel 815 Family," later in this chapter.

The major features of the 810E chipset include

- 66/100/133MHz system bus
- Integrated AGP 2x Intel 3D graphics
- Efficient use of system memory for graphics performance
- Optional 4MB of dedicated display cache video memory
- Digital Video Out port compatible with DVI specification for flat-panel displays
- Software MPEG-2 DVD playback with hardware motion compensation
- 266MBps hub interface
- Support for ATA-66
- Integrated Audio-Codec 97 (AC'97) controller
- Support for low-power sleep modes
- Random number generator (RNG)
- Integrated USB controller
- LPC bus for Super I/O and Firmware Hub (ROM BIOS) connection
- Elimination of ISA bus

The 810E chipset consists of three major components:

- *82810E Graphics Memory Controller Hub (GMCH)*. 421 BGA package (the original 810 chipset used the 82810 GMCH).
- *82801 Integrated Controller Hub (ICH)*. 241 BGA package.
- *82802 Firmware Hub (FWH)*. In either 32-pin plastic leaded chip carrier (PLCC) or 40-pin thin small outline package (TSOP) packages. Although a functional part of the chipset, this component is actually sold separately by Intel to motherboard developers.

Compared to the previous North/South Bridge designs, there are some fairly significant changes in the 810 chipset. The previous system designs had the North Bridge acting as the memory controller, talking to the South Bridge chip via the PCI bus. This new design has the GMCH taking the place of the North Bridge, which talks to the ICH via a 66MHz dedicated interface called the accelerated hub architecture (AHA) bus instead of the previously used PCI bus. In particular, implementing a direct connection between the North and South Bridges in this manner was key in implementing the new UDMA-66 high-speed IDE interface for hard disks, DVD drives, and other IDE devices.

Figure 4.34 shows a system block diagram for the 810E chipset. With the 810 chipset family, ISA is finally dead.

The 82810E GMCH uses an internal Direct AGP (integrated AGP) interface to create 2D and 3D effects and images. The video capability integrated into the 82810E chip features hardware motion compensation to improve software DVD video quality; it also features both analog and direct digital video out ports, which enable connections to either traditional TVs (via an external converter module) or a direct digital flat panel display. The GMCH chip also incorporates the System Manageability Bus, which enables networking equipment to monitor the 810 chipset platform. Using ACPI specifications, the system manageability function enables low-power sleep mode and conserves energy when the system is idle.

The 82801 I/O Controller Hub employs AHA for a direct connection from the GMCH chip. This is twice as fast (266MBps) as the previous North/South Bridge connections that used the PCI bus, and it uses far fewer pins for reduced electrical noise. Plus, the AHA bus is dedicated, meaning that no other devices will be on it. The AHA bus also incorporates optimized arbitration rules allowing more functions to run concurrently, enabling better video and audio performance.

The ICH also integrates dual IDE controllers, which run up to either 33MBps (UDMA-33 or Ultra-ATA/33) or 66MBps (UDMA-66 or Ultra-ATA/66). Note that two versions of the ICH chip exist. The 82801AA (ICH) incorporates the 66MBps-capable ATA/IDE and supports up to six PCI slots, whereas the 82801AB (ICH0) supports only 33MBps ATA/IDE maximum and supports up to four PCI slots.

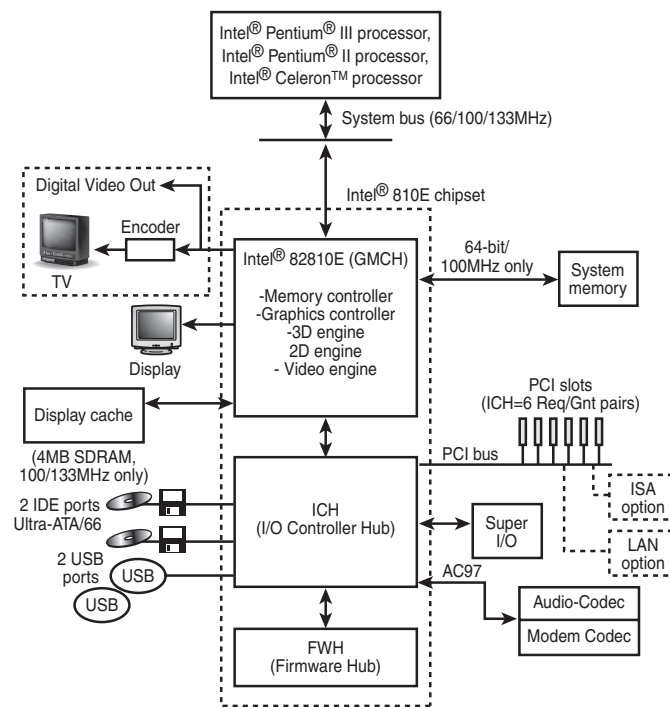

Figure 4.34 Intel 810E chipset system block diagram.

The ICH also integrates an interface to an Audio-Codesc 97 (AC'97) controller, dual USB ports, and the PCI bus with up to four or six slots. The Integrated Audio-Codesc 97 controller enables software audio and modem by using the processor to run sound and modem software via very simple digital-to-analog conversion circuits. Reusing existing system resources lowers the system cost by eliminating components.

The 82802 Firmware Hub (FWH) incorporates the system BIOS and video BIOS, eliminating a redundant nonvolatile memory component. The BIOS within the FWH is flash-type memory, so it can be field-updated at any time. In addition, the 82802 contains a hardware RNG. The RNG provides truly random numbers to enable fundamental security building blocks supporting stronger encryption, digital signing, and security protocols. Two versions of the FWH are available, called the 82802AB and 82802ACy. The AB version incorporates 512KB (4Mb) of Flash BIOS memory, and the AC version incorporates a full 1MB (8Mb) of BIOS ROM.

With the Intel 810 and 810E chipsets, Intel did something that many in the industry were afraid of: It integrated the video and graphics controller directly into the motherboard chipset with no means of upgrade. This means systems using the 810 chipset don't have an AGP slot and aren't capable of using conventional AGP video cards. For the low-end market for which this chipset is designed, lacking an AGP slot shouldn't be too much of a drawback. Higher-end systems, on the other hand, use the 815 or other chipsets that do support AGP slots. Intel calls the integrated interface Direct AGP, and it describes the direct connection between the memory and processor controllers with the video controller all within the same chip.

This means the video card as we know it will be reserved only for midrange and higher-end systems, as well as gaming-oriented systems. With the 810 as well as subsequent chipsets with integrated video, Intel has let it be known in a big way that it has entered the PC video business.

In fact, the theme with the 810 chipset is one of integration. The integrated video means no video cards are required; the integrated AC'97 interface means that conventional modems and sound cards are not required. Plus, there is an integrated CMOS/Clock chip (in the ICH), and even the BIOS is integrated in the FWH chip. All in all, the 810 should be taken as a sign for things to come in the PC industry, which means more integration, better overall performance for low-end and mainstream systems, and less overall cost.

Intel Random Number Generator

The 8xx chipset series features the Intel Random Number Generator (RNG). The RNG is built in to the 82802 FWH, which is the ROM BIOS component used on 8xx-based motherboards. The RNG provides software with true nondeterministic random numbers.

Most security routines, especially those providing authentication or encryption services, require random numbers for purposes such as key code generation. One method of cracking these types of codes is to predict the random numbers being used to generate the keys. Current methods that use system and user input as a seed to a conventional pseudorandom number generator have proven vulnerable to this type of attack. The Intel RNG uses thermal noise across a resistor contained in the FWH (that is, ROM BIOS in 8xx-based boards) to generate true nondeterministic, unpredictable random numbers. Therefore, “random” numbers generated by 8xx-series chipsets really are random.

Intel 815 Family

Introduced in June 2000, the 815 and 815E chipsets are mainstream PC chipsets with integral video that is also upgradeable via an AGP 4x slot. The *E* versions include the ICH2 I/O controller hub, which features two USB controllers (four ports) and ATA-100 support. The 815P and EP versions were introduced later and lacked the integrated video for lower cost. In September 2001, the last members of the family—the 815G and 815EG—were introduced. Note that the *G* indicates that these chipsets also include integrated video, which was superior to the video included with the original 815 and 815E.

The 815 chipsets are designed for Slot-1 or Socket-370 processors, such as the Celeron or Pentium III. These are the first chipsets from Intel designed to directly support PC133 SDRAM memory, allowing for a more affordable solution than other chipsets using RDRAM memory. Similar to the other 8xx series chipsets from Intel, the 815 uses hub architecture that provides a 266Mbps connection between the main chipset components and does not share the PCI bus like the prior North/South Bridge designs.

Although six variations on the 815 chipset are available, only five different parts are used to create the various members of the family: one memory controller hub (82815EP MCH: North Bridge replacement without integrated graphics), two graphics memory controller hubs (82815 or 82815G GMCH: North Bridge replacement with integrated graphics), and two I/O controller hubs (ICH and ICH2). Table 4.21 shows how these parts are combined to create the various members of the family.

Table 4.21 815 Chipset Family Components

Chipset Name	82815 GMCH	82815G GMCH	82815EP MCH	82801AA ICH	82801BA ICH2

815EG		*			*

Figure 4.33 illustrates one member of this chipset family, the 815E.

All 815 chipsets support the following features:

- 66/100/133MHz system bus
- 266MBps hub interface
- ATA-100 (815E/EP/EG) or ATA-66 (815/P/G)
- PC100 or PC133 CL-2 SDRAM (also PC66 with 815G/EG)
- Up to 512MB RAM
- Integrated Audio-Codec 97 (AC'97) controller
- Low-power sleep modes
- RNG for stronger security products
- One (815/P/G) or two (815E/EP/EG) integrated USB controllers with either two or four ports, respectively
- LPC bus for Super I/O and Firmware Hub (ROM BIOS) connection
- Elimination of ISA Bus

The 815/E/G/EG also support the following:

- Integrated Intel AGP 2x 3D graphics
- Efficient use of system memory for graphics performance
- Optional 4MB of dedicated display cache video memory
- Digital Video Out port compatible with DVI specification for flat panel displays
- Software MPEG-2 DVD playback with hardware motion compensation

The 815E/EP/EG uses the ICH2, which is most notable for providing ATA-100 support, allowing 100MBps drive performance. Of course, few drives can really take advantage of this much throughput, but in any case, there won't be a bottleneck there. The other notable feature is having two USB 1.1 controllers and four ports on board. This allows double the USB performance by splitting up devices over the two ports and can allow up to four connections before a hub is required.

Integrated Ethernet

Another important feature of the 815 series is the integration of a fast Ethernet controller directly into the chipset. The integrated LAN controller works with one of three new physical layer components from Intel and enables three distinct solutions for computer manufacturers. These include

- Enhanced 10/100Mbps Ethernet with Alert on LAN technology
- Basic 10/100Mbps Ethernet
- 1Mbps HomePNA (phone-line) home networking

These physical layer components can be placed directly on the PC motherboard (additional chips) or installed via an adapter that plugs into the CNR slot. The CNR slot and cards enable PC assemblers to build network-ready systems for several markets.

AGP Inline Memory Module

Although the 815/815E feature is essentially the same built-in AGP 2x 3D video that comes with the 810 chipset, the difference is upgradeability. The video can easily be upgraded by adding a graphics performance accelerator (GPA) card (see Figure 4.35) or an AGP 4x card for maximum 3D graphics and video performance. The GPA card (also called the AGP Inline Memory Module, or AIMM) is essentially a high-performance video memory card that works in the AGP 4x slot and improves the performance of the integrated video by up to 30%. Unfortunately, these are not commonly sold and are somewhat expensive. For even more performance, you can install a full 4x AGP card in the AGP 4x slot, which disables the integrated video. By having the video integrated, very low-cost systems with reasonable video performance can be assembled. By later installing either the GPA or a full 4x AGP card, you can improve video performance up to 100% or more.

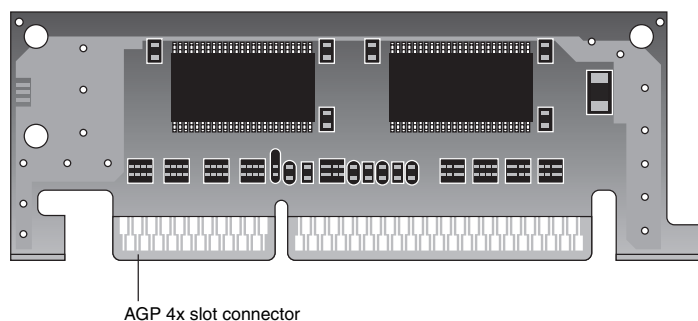

Figure 4.35 A typical 4MB GPA/AIMM module, which attaches to the AGP slot of a motherboard using the 815 or 815E chipset.

PC133 Memory Support

Another important feature of the 815 chipset is the support of PC133 memory. The 815 family also uses PC100 memory. With PC133 support, Intel has also officially set a standard for PC133 memory that was higher than some of the PC133 memory on the market at the time of introduction. To meet the Intel PC133 specification, the memory must support what is called 2-2-2 timing, sometimes also known as CAS-2 (column address strobe) or CL-2 timing. The numbers refer to the number of clock cycles for the following functions to complete:

- *Precharge command to Active command.* Charges the memory's storage capacitors to prepare them for data
- *Active command to Read command.* Selects rows and columns in memory array for reading
- *Read command to Data Out.* Reads data from selected rows and columns for transmission

Some of the PC133 memory on the market takes three cycles for each of these functions and would therefore be termed PC133 3-3-3, CAS-3, or CL-3 memory. Note that the faster PC133 CL-2 can be used in place of the slower CL-3 variety, but not the other way around.

As a result of the tighter cycling timing, PC133 CL-2 offers a lead-off latency of only 30ns, instead of the 45ns required by PC133 CL-3. This results in a 34% improvement in initial access due to the decreased latency.

The 815 chipset was a popular chipset for the mainstream PC market that didn't want to pay the higher prices for RDRAM memory. The 815 was essentially designed to replace the venerable 440BX chipset.

Intel 820 and 820E

The Intel 820 chipsets use the hub-based architecture like all the 800 series chips and are designed to support slot 1 or socket 370 processors, such as the Pentium III and Celeron. The 820 chipset supports RDRAM memory technology, 133MHz system bus, and 4x AGP.

The 82820 MCH provides the processor, memory, and AGP interfaces. Two versions are available: One supports a single processor (82820), whereas the other supports two processors (82820DP). Either is designed to work with the same 82801 ICH as used with the other 800 series chipsets, such as the 810 and 840. The 820 chipset also uses the 82802 FWH for BIOS storage and for the Intel RNG.

The connection between the MCH and ICH uses what is called the Intel Hub Architecture bus instead of the PCI bus as with prior North/South Bridge chipsets. The hub architecture bus provides twice the bandwidth of PCI at 266MB per second, enabling twice as much data to flow between them. The hub architecture bus also has optimized arbitration rules, allowing more functions to run concurrently, as well as far fewer signal pins, reducing the likelihood of encountering or generating noise and signal errors.

The 820 chipset is designed to use RDRAM memory, which has a maximum throughput of up to 1.6GBps. The 820 supports PC600, PC700, and PC800 RDRAM, delivering up to 1.6GBps of theoretical memory bandwidth in the PC800 version. PC800 RDRAM is a 400MHz bus running double-clocked and transferring 16 bits (2 bytes) at a time ($2 \times 400\text{MHz} \times 2 \text{ bytes} = 1.6\text{GBps}$). Two RIMM sockets are available to support up to 1GB of total system memory.

The AGP interface in the 820 enables graphics controllers to access main memory at AGP 4x speed, which is about 1GB per second—twice that of previous AGP 2x platforms. Figure 4.36 shows the 820 chipset architecture. Because the 820 was designed for midrange to higher-end systems, it does not include integrated graphics, relying instead on the AGP 4x slot to contain a graphics card.

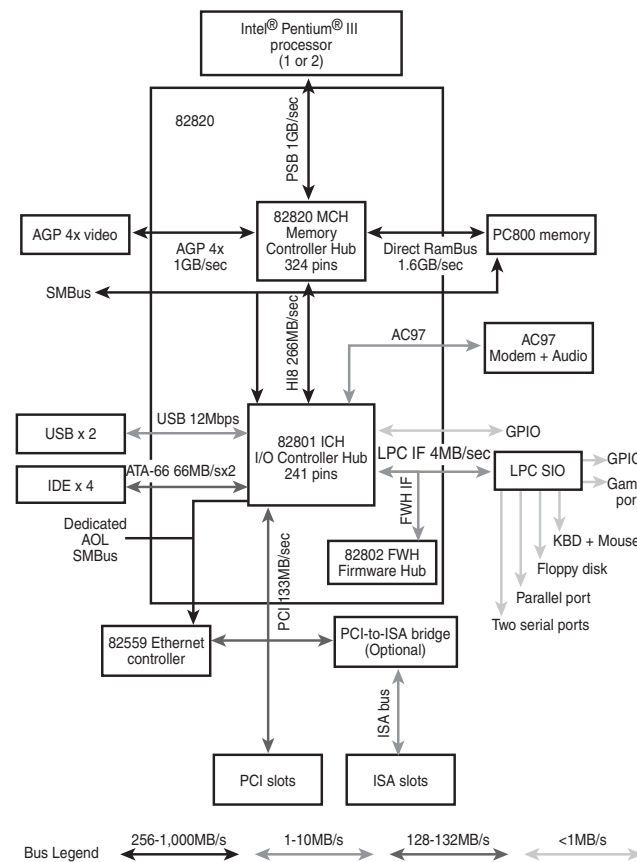

Figure 4.36 Intel 820 chipset architecture.

820 Chipset features include:

- 100/133MHz processor bus
- Intel 266Mbps hub interface
- PC800 RDRAM RIMM memory support
- AGP 4x support
- ATA-100 (820E) or ATA-66 interface
- Intel RNG
- LPC interface
- AC'97 controller
- One (820) or two (820E) USB buses with either two or four ports, respectively

The 820 chipset consists of three main components with a few optional extras. The main component is the 82820 (single-processor) or 82820DP (dual-processor) MCH, which is a 324 BGA chip. That is paired with an 82801 ICH, which is a 241 BGA chip, and finally it has the 82802 FWH, which is really just a fancy Flash ROM BIOS chip. Optionally, there can be an 82380AB PCI-ISA bridge that is used only if the board is equipped with ISA slots.

The newer 820E version uses an updated 82801BA ICH2, which supports ATA-100 and incorporates dual USB controllers with two ports each, for a total of four USB ports.

820 Chipset MTH Bug

The 820 chipset is designed to support RDRAM memory directly. However, because the market still demanded lower-cost SDRAM, Intel created an RDRAM-to-SDRAM translator chip called the Memory Translator Hub (MTH). This enabled them to produce 820 chipset motherboards that supported SDRAM instead of the more expensive RDRAM.

Because the design of the MTH was proven defective, the chip (and any board using it) was simply discontinued. On May 10, 2000, Intel officially announced that it would replace any motherboards using the MTH with a new board lacking the component. The MTH translates signals from SDRAM memory to the Intel 820 chipset and is used only with motherboards utilizing SDRAM and the Intel 820 chipset; boards using RDRAM don't have an MTH and were not affected. Intel found electrical noise issues with the MTH that can cause some systems to intermittently reset, reboot, or hang. In addition, the noise issue can, under extreme conditions, potentially cause data corruption.

The MTH bug forced Intel to recall and replace more than a million motherboards in mid-2000, with new versions lacking the MTH and thus supporting only RDRAM memory. The final bill for this recall was reported at about \$253 million, making it perhaps the most costly recall of computer components since the infamous Pentium math bug in 1994. I found it interesting that, due to the fact that Intel did more than \$24.4 billion in sales the previous year, at least one article classified the cost of this recall as "chump change" to the chip giant!

Intel has an MTH I.D. Utility at www.intel.com/support/mth that will tell you whether you have that component and whether your board is eligible for replacement, including a 128MB RDRAM RIMM. Again, note that the 820 chipset was really designed to support RDRAM as the native type of memory, and RDRAM-based systems are not affected because they don't use the memory translator hub component.

Intel 840

The Intel 840 is a high-end chipset designed for use in high-performance multiprocessor systems using Slot 1, Slot 2 (Xeon processor), or Socket 370 processors. The 840 chipset uses the same hub architecture and modular design as the rest of the 800 family chipsets, with some additional components enabling more performance. See Figure 4.37 for a photo of the Intel 840 chipset.

As with the other 800 series chipsets, the 840 has three main components:

- **82840 Memory Controller Hub.** Provides graphics support for AGP 2x/4x, dual RDRAM memory channels, and multiple PCI bus segments for high-performance I/O.
- **82801 I/O Controller Hub.** Equivalent to the South Bridge in older chipset designs, except it connects directly to the MCH component via the high-speed Intel Hub Architecture bus. The ICH supports 32-bit PCI, IDE controllers, and dual USB ports.
- **82802 Firmware Hub.** Basically an enhanced Flash ROM chip that stores system BIOS and video BIOS, as well as an Intel RNG. The RNG provides truly random numbers to enable stronger encryption, digital signing, and security protocols.

Figure 4.37 Intel 840 chipset showing the 82840 (MCH), 82801 (ICH), 82802 (FWH), 82803 (MRH-R), 82804 (MRH-S), and 82806 (P64H) chips. *Photograph used by permission of Intel Corporation.*

In addition to the core components, parts are available for scaling up to a more powerful design. Three additional components can be added:

- **82806 64-bit PCI Controller Hub (P64H).** Supports 64-bit PCI slots at speeds of either 33MHz or 66MHz. The P64H connects directly to the MCH using Intel Hub Architecture, providing a dedicated path for high-performance I/O. This is the first implementation of the 66MHz 66-bit PCI on a PC motherboard chipset, allowing for a PCI bus four times faster than the standard 32-bit 33MHz version.
- **82803 RDRAM-based Memory Repeater Hub (MRH-R).** Converts each memory channel into two memory channels for expanded memory capacity.
- **82804 SDRAM-based Memory Repeater Hub (MRH-S).** Translates the RDRAM protocol into SDRAM-based signals for system memory flexibility. This would be used only in 840 systems that supported SDRAM.

Figure 4.38 shows the 840 chipset architecture.

840 chipset features include

- 100/133MHz processor bus
- Dual RDRAM memory channels, operating simultaneously and providing up to 3.2GBps memory bandwidth
- 16-bit wide implementation of Intel Hub Architecture (HI16), which enables high-performance concurrent PCI I/O with the optional P64H component
- AGP 4x
- Prefetch cache, unique to the 840 chipset, which enables highly efficient data flow and helps maximize system concurrency

- Intel RNG (see the section “Intel Random Number Generator,” earlier in this chapter)
- USB support

Optionally, network interface and RAID controller interface chips can be added as well.

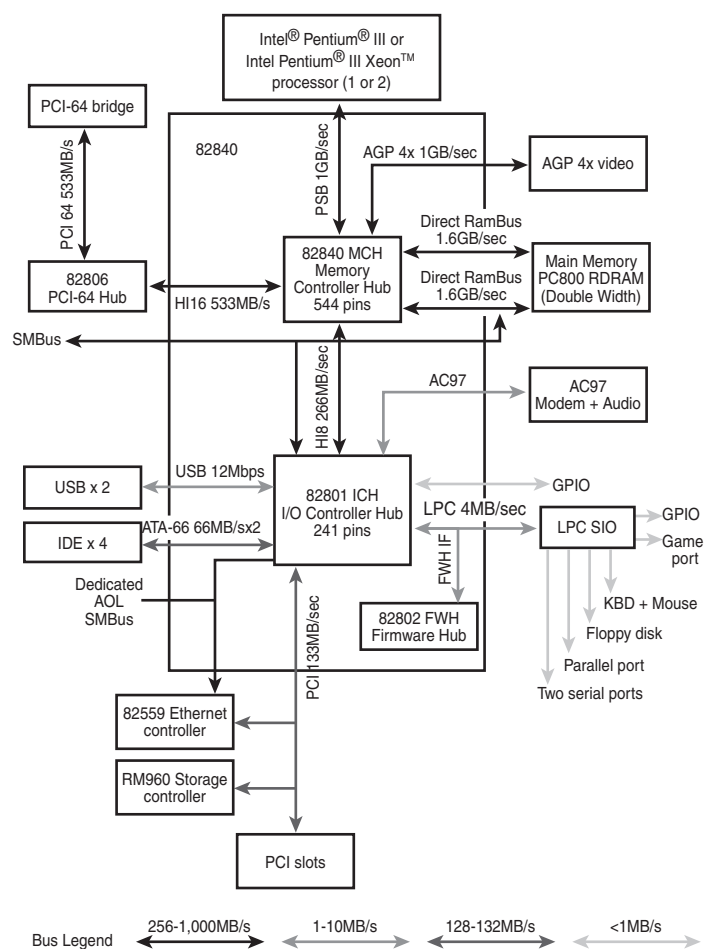

Figure 4.38 Intel 840 chipset architecture.

Third-Party (Non-Intel) P6-Class Chipsets

Several companies produce chipsets designed to support P6-class processors, including ALi Corporation (formerly known as Acer Laboratories), VIA Technologies, and SiS. The following sections discuss the offerings from these companies.

Ali Chipsets for P6-Class Processors

ALi has a variety of chipsets for the P6-class processors. Table 4.22 provides an overview of these chipsets.

Table 4.22 Ali Chipsets for Pentium Pro-II-III-Celeron

Chipset	Aladdin Pro II	Aladdin Pro 4	Aladdin TNT2	Aladdin Pro 5
Date introduced	1999	2000	1999	2000, 2001(T)
Part number	M1621	M1641/M1641B	M1631	M1651, M1651T

Seventh-Generation (Pentium 4) Chipsets

Because of its long-time integration of processor and chipset design, it's not surprising that Intel dominates the Pentium 4 chipset market as it has the markets for Pentium (P5) and Pentium II/III/Celeron (P6) markets in the past. Although Intel has licensed Socket 423 (used by early Pentium 4 processors) and the current Socket 478 to rival chipset vendors such as SiS, VIA, and ALi, Intel is still the leading developer of Pentium 4 chipsets. Third-party chipsets for Pentium 4 and Celeron 4 processors are discussed later in this chapter.

Because the Pentium 4 and Celeron processors using Socket 423 and those made for Socket 478 are essentially the same processors with different cache designs and minor internal revisions, the same chipset can be used for both processors.

Tables 4.27 and 4.28 show the 8xx-series chipsets made by Intel for Pentium 4 and Celeron 4 processors. These chipsets use Intel's hub architecture, providing an interconnect speed of 266MBps between the MCH/GMCH and the ICH chips.

Table 4.27 Pentium 4 8xx-Series Chipsets from Intel Introduced 2000–2002

Chipset	850	850E	845	845E
Code name	Tehama	Tehama-E	Brookdale	Brookdale-E
Date introduced	Nov. 2000	May 2002	Sept. 2001 (SDRAM); Jan. 2002 (DDR)	May 2002
Part number	82850	82850E	82845	82845E

SMM = System management mode

ACPI = Advanced configuration and power interface

Starting in mid-2004, Intel introduced a new 9xx series of chipset for the Pentium 4 and Celeron 4. These chipsets, codenamed Grantsdale and Alderwood before their introduction, are optimized for the Pentium 4 Prescott design introduced in early 2004. They are the first Intel chipsets to support several new technologies, including DDR-II memory and PCI-Express for both video and other high-speed I/O uses (such as Gigabit Ethernet). They also include support for the new Socket 775—the first LGA processor socket (also known as Socket-T).

Because of the greater performance needed to support these high-speed technologies, the 9xx-series chipsets use a faster version of the HI 1.5 hub architecture used by the 8xx-series chipsets. The new interconnect design, known as Direct Media Interface (DMI), runs at 1GBps in each direction, making it comparable to the latest non-Intel interconnects listed in Table 4.13. Table 4.30 lists the 9xx-series chipsets introduced in 2004, and Table 4.31 lists the ICH6 family of I/O controller hub chips used with these chipsets.

Intel 850 Family

The Intel 850 family contains two members, the original 850 and an enhanced version called the 850E. The 850 is the first chipset for the Intel Pentium 4 processor and thus is also the first chipset to support the NetBurst microarchitecture. The 850 is designed for high-performance desktop computers and workstations and uses the same hub architecture and modular design as the rest of Intel's 8xx family of chipsets. See Figure 4.39 for a photo of the Intel 850 chipset.

The 850 has two main components, down from three in earlier 800-series chipsets:

- **82850 Memory Controller Hub.** Provides support for dual 400MHz RDRAM memory channels with a 3.2GBps bandwidth and a 100MHz system bus. The 82850 MCH also supports 1.5V AGP 4x video cards at a bandwidth exceeding 1GBps.
- **82801BA I/O Controller Hub 2.** The ICH2 (an enhanced version of the 82801 used by other 800-series chipsets) supports 32-bit PCI rev. 2.2, dual UDMA 33/66/100 IDE host adapters, four USB ports, an integrated LAN controller, six-channel AC'97 audio/modem codec, FWH interface support, SMBus support, and Alert on LAN and Alert on LAN 2 support.

Optionally, the Intel 82562ET/82562EM Platform LAN communication chips can be added to the 850 chipset to provide support for 10BASE-T and Fast Ethernet networking, building on the LAN features in the 82801BA ICH2 chip.

The 850 chipset, similar to most recent Intel and non-Intel chipsets, also supports the CNR card for integrated audio, modem, and network capabilities. See Figure 4.40 for a diagram of the 850's chipset architecture.

Figure 4.39 The Intel 850 chipset. *Photo used by permission of Intel Corporation.*

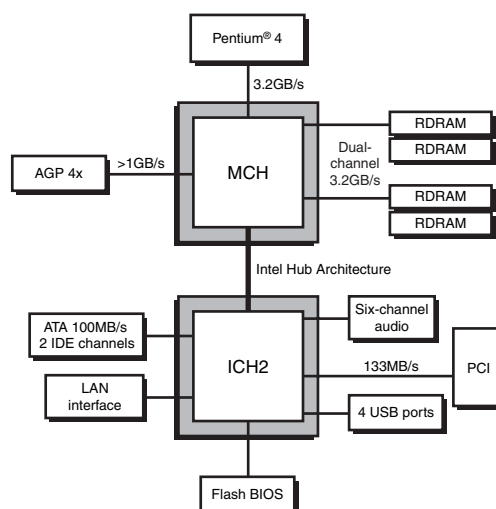

Figure 4.40 Architecture of the Intel 850 chipset.

The 850E is an enhanced version of the 850. Its 82850E MCH adds support for dual 533MHz Rambus RDRAM memory channels and support for PC1066 RIMM modules to the 850's standard features. It also uses the same ICH2 hub as the original 850.

Intel 845 Family

Unlike the 850 and 850E chipsets, the 845 family of chipsets is widely used by both Intel and third-party motherboard makers. If you purchased a Pentium 4 system from late 2001 through mid-2003, it probably uses some version of the 845 chipset. The 845, code named Brookdale during its development, was the first Pentium 4 chipset from Intel to support low-cost SDRAM instead of expensive RDRAM. Subsequent variations support DDR SDRAM at speeds up to DDR333, ATA/100, and USB 2.0.

The 845-series chipsets include the following models:

- 845
- 845GL
- 845GV
- 845G
- 845GE
- 845E
- 845PE

All members of the 845 family use the same hub-based architecture developed for the 845 family, but they also have onboard audio and support the communications and networking riser (CNR) card for integrated modem and 10/100 Ethernet networking. However, they differ in their support for different types and amounts of memory, integrated graphics, external AGP support, and which ICH chip they use.

Although the original version of the 845 supported only PC133 SDRAM memory, the so-called 845D model (a designation used by review sites but not by Intel) also supports 200/266MHz DDR SDRAM. The Intel 845's 82845 MCH supports Socket 478-based Celeron or Pentium 4 processors and can support up to two DDR SDRAM modules or three standard SDRAM modules (depending on the motherboard). When DDR SDRAM is used, the 845 supports either 200MHz (PC2100) or 266MHz (PC2700) memory speeds, with an FSB speed of 400MHz. The 845 also supports ECC error correction when parity-checked memory modules are used and offers an AGP 4x video slot, but it has no onboard video.

The 845 uses the same ICH2 I/O controller hub chip (82801-BA) used by the Intel 850 and 850E chipsets in Rambus-based systems and the 815EP in low-cost SDRAM-based systems. The ICH2 supports ATA/100 hard disk interfacing, basic AC'97 sound, and four USB 1.1 ports.

All G-series 845 models feature Intel Extreme Graphics integrated video, which has faster core speeds and adds 3D performance to the bare-bones integrated video used by the 810 and 815 chipset families. Two chipsets—the 845G and 845GE—also offer support for AGP 4x video cards.

The 845E is an updated version of the current 845 model with ECC error correction and support for 533MHz FSB, whereas the 845PE supports the 533MHz FSB, DDR 266, and 333MHz memory, but it doesn't support ECC error correction. All models except the 845 (845D) use the enhanced ICH4 I/O Controller Hub 82801DB, which offers six USB 2.0 ports as well as integrated networking. Additionally, all models except the 845 and 845GL offer enhanced 20-bit audio.

Figure 4.41 compares the system block diagrams of the 845 and 845GE models.

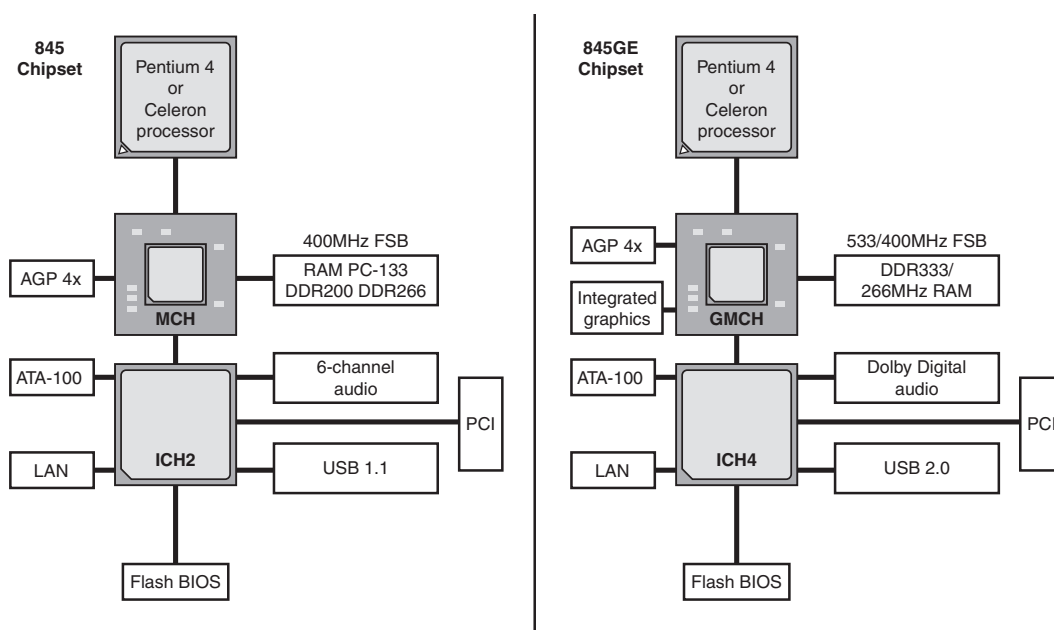

Figure 4.41 The 845GE (right) adds support for faster FSB speeds, memory, integrated graphics, and USB 2.0 to the basic 845 chipset architecture (left).

Intel Extreme Graphics Architecture

845-series chipsets with integrated video (845G-series models) support Intel's new Extreme Graphics Architecture, which supports 3D graphics and features the following four technologies to improve 3D rendering speed and quality:

- *Rapid Pixel and Texel Rendering Engine.* Uses pipelines to overlap 2D and 3D operations, provides 8x data compression to improve the use of memory bandwidth, and features a multitier cache for 3D operations
- *Zone Rendering.* Reduces memory bandwidth requirements by dividing the frame buffer into rectangular zones, sorting the triangles into memory by zone, and processing each zone to memory
- *Dynamic Video Memory Technology.* Manages memory sharing between the display, applications, and operating system depending on the memory requirements of the programs running
- *Intelligent Memory Management.* Improves memory addressing, display buffer implementation, and memory efficiency

Extreme Graphics Architecture improves 3D rendering compared to Intel's earlier integrated video chipsets (the 810 and 815-series chipsets, which have no 3D functions at all), but its performance and features still lag behind even current midrange video chipsets from NVIDIA and ATI. Extreme Graphics Architecture lacks hardware Transform and Lighting (T&L) features. T&L is a feature required by virtually all current games that support DirectX 7.0 and above. It offers frame rates which, at best, are at about the level of the now-obsolete NVIDIA GeForce 2 MX 200. Thus, even though you can play an occasional game with the G-series systems with integrated video, if you want serious game play, you'll need one of the 845 models that supports AGP 4x graphics cards and DDR333 memory, such as the 845GE or 845PE.

Intel 865 Family

The Intel 865 chipset family, code named Springdale, was released in May 2003. As the name might suggest, the 865 series is designed to replace the 845 series with chipsets that feature dual-channel memory support, the new communications streaming architecture (CSA) that provides a dedicated connection for the integrated network controller, faster performance, and support for the latest technologies (including optional Gigabit Ethernet and Serial ATA). The features of the 865 and 875 families are summarized in Table 4.28.

The 865 family includes the 865P, 865PE, 865G, and 865GV chipsets. The 865PE, 865G, and 865GV support single-channel or dual-channel DDR266, as well as dual-channel DDR333 and DDR400 SDRAM with FSB speeds up to 800MHz. Dual-channel memory provides a wider memory bandwidth for faster performance. The 865P model supports DDR266/333 and FSB speeds up to 533MHz. All models except the GV support AGP 8x, and the G and GV models include Intel Extreme Graphics 2—a faster version of the integrated graphics technology found in G-series versions of the 845 chipset family. Finally, an optional Gigabit Ethernet (GbE) port is connected to the MCH/GMCH and requires the use of an optional Intel 82547 Gigabit Ethernet controller chip on the motherboard.

All members of the 865 family use the new ICH5 or ICH5R I/O controller hub. A faster hub architecture called Hub Link 1.5 (HL 1.5) with 266Mbps bandwidth connects the MCH/GMCH and ICH together.

ICH5 and ICH5R

ICH5 and ICH5R (RAID) are the latest generation of Intel's I/O controller hub for its AHA and HI 1.5 hub-based architecture, which is the equivalent of the South Bridge in Intel's hub-based architecture introduced with the 800 series of chipsets.

ICH5 and ICH5R feature four USB 2.0 controllers with eight external ports, two ATA/100 ports, and two Serial ATA/150 ports. ICH5R models add support only for RAID 0 (striping) and RAID 1 (mirroring) on the SATA ports. ICH5/ICH5R also support the PCI 2.3 bus and include an integrated 10/100 Ethernet LAN controller.

Note

RAID 1 (mirroring) support for ICH5R-equipped motherboards requires the installation of the latest version of the Intel Application Accelerator RAID Edition. In some cases, you might also need to install the latest edition of the Intel RAID Option ROM first. For more information and to download driver and option ROM updates, go to http://support.intel.com/support/chipsets/iaa_raid/.

Intel 875P

The Intel 875P chipset, code named Canterwood during its development, was introduced in April 2003. The 875P chipset supports Intel's HT Technology (hyper-threading), so it fully supports 3.06GHz and faster Pentium 4s, including the newer Prescott (90nm) core versions.

For faster memory access, the 875P supports four standard or ECC memory modules (up to 4GB total) using DDR333 or DDR400 memory in a dual-channel mode, and it offers a new Turbo mode that uses a faster path between DDR400 memory and the MCH to boost enhanced performance. Because multiple memory modules aren't always the same size or type, the 875P also features a new dynamic mode that optimizes system memory when different types or sizes of memory are used at the same time.

The 875P also includes both Serial ATA and RAID support and uses the same ICH5/5R I/O controller hub family used by the 865 series.

Intel 915 Chipset Family

The Intel 915 chipset family, code named Grantsdale during its development, was introduced in 2004. The Grantsdale family comprises four members (915P, 915G, 915GV, and 915GL), all of which support the latest 90nm Pentium 4 Prescott core. These chipsets are the first to support the new Socket 775 processor interface outlined in Chapter 3. These chipsets are intended to replace the 865 Springdale family of chipsets.

The 915P, 915G, and 915GV models are all designed to support the HT Technology feature built in to most recent Pentium 4 processors and to support bus speeds up to 800MHz. All three chipsets support dual-channel DDR memory up to 400MHz and the new DDR-II memory standard. All three models also support PCI-Express x1 as well as PCI version 2.3 expansion slots.

The 915P uses a PCI-Express x16 slot for high-speed graphics, whereas the 915G has a PCI-Express x16 slot as well as integrated Intel Extreme Graphics 3. The 915GV uses Intel Extreme Graphics 3 but lacks a PCI-Express x16 slot. Extreme Graphics 3 is a partial implementation of DirectX 9, but it lacks the vertex shaders found on fully compatible DirectX 9 GPUs from ATI and NVIDIA.

The 915GL is the low-end member of the family, lacking support for DDR-II RAM, 800MHz bus speeds, HT Technology, and PCI-Express x16 video. The 915GL is designed to be matched with Intel Celeron processors to produce a low-cost system.

All 915-series MCH/GMCH chips use the new ICH6 family of South Bridge replacements detailed in Table 4.31.

Figure 4.42 shows which features of the 915 (Grantsdale) family are common to all versions and which vary by chipset and ICH6 version used.

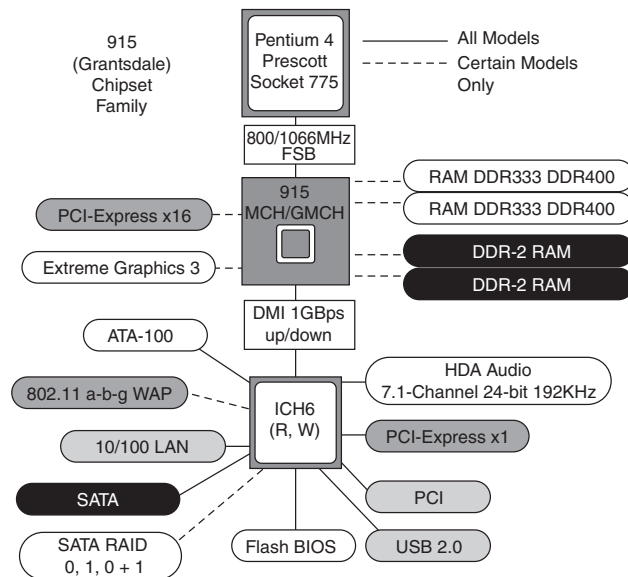

Figure 4.42 All versions of the 915 (Grantsdale) family support dual-channel memory, SATA, PCI-Express x1 slots, and 7.1-channel audio, but other features vary by model.

Intel 925X Chipset

The Intel 925X chipset, code named Alderwood before its release, was released in 2004. It is designed to replace the 875P Canterwood chipset. Unlike the 915 series of chipsets, which continue to support older DDR memory, the 925X supports only DDR-II memory. The 925X also supports ECC memory, providing a fast and accurate platform for mission-critical applications. To further improve performance, it uses an optimized memory controller design.

The 925X supports PCI-Express x1 and PCI-Express x16 (video) as well as PCI version 2.3 expansion slots. It supports the new LGA 775 processor socket and the new Intel Prescott Pentium 4 core and uses the new ICH6 family of South Bridge replacements detailed in Table 4.31.

Third-Party Pentium 4 Chipsets

SiS, the ALi Corporation, ATI, and VIA all produce chipsets for the Intel Pentium 4 and Celeron 4 processors.

Although Intel's chipsets for the Pentium 4 have dominated the market up to this point, many of these chipsets offer unique features that are worth considering. The following sections discuss these chipsets by vendor.

SiS Chipsets for Pentium 4

SiS offers several chipsets for the Pentium 4, including integrated chipsets, chipsets for use with discrete video accelerator cards, and some that support Rambus RDRAM. Details of SiS's chipsets for the Pentium 4 are available in Tables 4.32, 4.33, and 4.34. Unlike most of the chipsets SiS has created for the Pentium II/III/Celeron, the SiS chipsets for the Pentium 4 use one of several high-speed South Bridge equivalents (SiS 96x series Media I/O chips) instead of integrating North and South Bridge functions into a single chip. SiS North and South Bridge chips for the Pentium 4 use a high-speed 16-bit connection known as MuTIOL (Multi-Threaded I/O Link) instead of the slow PCI bus as with older chipsets.

Table 4.32 SiS North Bridge Chips for Pentium 4 Socket 478 (up to 533MHz Processor Bus Speed)

Chipset	SiS650	SiS651	SiS645	SiS645DX	SiS648	SiS655	SiS R658

SiS650/651 Chipsets

The SiS650 and 651 chipsets enable Pentium 4 system builders to create low-cost systems with onboard video that can be enhanced with AGP 4x video cards at a later date. The integrated video features support for high-quality DVD playback and the optional SiS301B video bridge for TV-out and DVI LCD panels.

Both chipsets also feature SiS's own MuTIOL technology for connecting the North Bridge and South Bridge chips with a three-layer high-speed (266MHz/533MBps bandwidth) data highway.

AC'97 2.2, 5.1 channel	Yes	No	Yes	No	533MBps
AC'97 2.2, 5.1 channel	Yes	No	Yes	No	1GBps
AC'97 2.2, 5.1 channel	Yes	No	Yes	No	1GBps
AC'97, 7.1 channel	Yes	Yes	Yes	No	1GBps
AC'97, 7.1 channel	Yes	No	Yes	No	1GBps

The 650 and 651 both support SDRAM and DDR SDRAM, and the 651 adds support for DDR333 memory, the 533MHz system bus of the latest Pentium 4 processors, and hyper-threading in its B-stepping version.

The 650's SiS961 South Bridge provides USB 1.1, ATA-100 (133 in its 961B version), AC'97 six-channel audio, and integrated Ethernet/HomePNA networking. The 651 also uses the newer SiS962 South Bridge, which provides ATA133 and USB 2.0 support.

SiS645/645DX

The 645 family of SiS chipsets does not include the integrated graphics of the 650/651 family, but they are otherwise similar. They support SDRAM and DDR SDRAM, AGP 4x, and the high-speed MuTIOL North Bridge/South Bridge interface. The 645DX supports DDR333 memory, the 533MHz system bus, and the HT technologies found in the most recent Pentium 4 processors.

Both the 645 and 645DX use the SiS961 South Bridge.

SiS648/648FX/655/655FX/655TX

The SiS648 chipset is a development of the 645DX chipset, with the following differences:

- Supports DDR memory only (up to DDR333)
- 8X AGP slot
- SiS963 South Bridge (USB 2.0, IEEE 1394a support)

The SiS655 chipset is essentially a dual-channel version of the 648, supporting up to 4GB of memory with DDR266/333 memory only.

The SiS648FX chipset is a development of the 648 that supports 800MHz bus speeds of the Pentium 4.

The SiS655FX is a development of the original SiS655 chipset with the following differences:

- Supports dual-channel DDR400 memory
- Supports 800MHz bus speeds of the Pentium 4
- Supports SiS's HyperStreaming Technology, SiS's marketing term for its method of reducing data latency through improved pipelining and splitting transactions
- Has SiS964 South Bridge (eight USB 2.0 ports, eight-channel audio, SATA, RAID)

The SiS655TX is based on the SiS655FX but uses second-generation Advanced HyperStreaming Technology.

SiS661FX

The SiS661FX is an integrated chipset with the following features:

- Support for Pentium 4 processors up to 800MHz processor bus with HT Technology
- Up to 2GB of DDR400 (two DIMMs) or up to 3GB of DDR333/266 (three DIMMS)
- AGP 8x video
- Integrated SiS Mirage Graphics (software compatible with DirectX9) with CRT, TV, LCD support; hardware acceleration for DVD playback; and shared memory of 32MB or 64MB
- SiS964 South Bridge

SiS656

The SiS656 is the first SiS chipset to support PCI-Express and DDR-II memory. Thus, it is roughly similar to the Intel 915 series of Pentium 4 chipsets (shown earlier). Other features include

- Support for Pentium 4 processors up to 800MHz FSB, including Prescott
- Dual-channel DDR400/333 or dual-channel DDR-II memory
- Maximum memory size of 4GB
- ECC memory support
- PCI-Express x16
- SiS965 South Bridge

SiS R658/R659

The SiS R658 is the first SiS chipset ever to support Rambus RDRAM. Other features include

- Support for Pentium 4 processors with 533MHz and HT (B-stepping only) features
- Dual-channel support for PC1066/PC800 RDRAM (requires identical pairs of memory)
- 4GB maximum memory size
- AGP 8x interface
- MuTIOL 1G (533MHz clock speed providing more than 1GBps throughput) interface to the SiS963 South Bridge

Essentially, the R658 is an RDRAM version of the 655 chipset, and, like the 655, it uses the SiS963 South Bridge.

The R659 is based on the R658 with the following differences:

- Support for 800MHz bus speeds of the Pentium 4
- SiS HyperStreaming Technology
- Quad-channel PC1200 RDRAM
- SiS964 South Bridge

ALi Corporation Chipsets for Pentium 4

ALi Corporation (formerly known as Acer Laboratories) has produced several chipsets for the Pentium 4 and Celeron 4 processors. Tables 4.35 and 4.36 provide an overview of these chipsets, which are discussed in the following sections.

Table 4.35 ALi Chipsets for Pentium 4

Chipset	ALADDiN-P4	M1681	M1683	M1685
North Bridge chip	M1671	M1681	M1563	M1563
Bus speed	400MHz	533/400MHz	800/533/400MHz	800/533/400MHz
Supports HT Technology	No	Yes	Yes	Yes
SMP (dual CPUs)	No	No	No	No
Memory types	PC100/133 DDR200/266/333	PC100/133 DDR200/266/333/400	PC133 DDR266/333/400	DDR266/333/400 DDR-II
Parity/ECC	Neither	Neither	Neither	Neither
Maximum memory	3GB	3GB	4GB	3.5GB
PCI support	2.2	2.3	2.3	2.3
PCI speed/width	33MHz, 32-bit	33MHz, 32-bit	33MHz, 32-bit	33MHz, 32-bit
Video slot	AGP 4x	AGP 8x	AGP 8x	PCI-Express x16
Integrated video	No	No	No	No
South Bridge	M1535 series	M1563	M1653	M1653
HyperTransport NB/ SB Link	N/A	400MBps	400MBps	400MBps

**Also supports hyper-threaded processors*

Table 4.36 provides an overview of the ALi South Bridge chips used in ALi Corporation's chipsets for the Pentium 4; ALi uses the same South Bridge chips for its chipsets for the Athlon XP.

Table 4.36 Ali South Bridge Chips for Pentium 4 and Athlon XP

South Bridge Chip	USB Support	Number of USB Ports	ATA Support	Audio	Soft Modem	10/100 Ethernet	Super I/O	HyperTransport Link Speed
M1535D	1.1	4	33/66	Stereo AC'97	Yes	No	Yes	N/A
M1535D+	1.1	6	33/66/100/133	Six-channel AC'97	Yes	No	Yes	N/A
M1563*	1.1, 2.0	6	66/100/133	Six-channel AC'97, SPDIF	Yes	Yes	Yes	400MBps

*Also incorporates SD and Memory Stick flash memory interfaces and supports AMD Athlon 64/Opteron/Mobile Athlon 64 processors.

Aladdin P4 (M1671)

The ALI Aladdin P4 was ALI's first Pentium 4-compatible chipset. Because it uses the same M1535-series South Bridge chips used by its earlier Pentium and Pentium II/III chipsets, the P4 is a traditional North Bridge/South Bridge solution. Thus, it relies on the slow (133MBps) PCI interface to carry data between the bridge chips.

The P4's major features include the following:

- 400MHz system bus
- Support for PC100/133 and DDR200/266/333 memory
- ATA-133 support (when used with the M1535D+ South Bridge)
- AGP 4x interface
- USB 1.1 ports
- ACPI power management

The P4 is also available in a version for notebook computers: the ALADDiN-P4M, which uses the D1535+ South Bridge.

M1681/M1683

ALI's M1681 chipset for the Pentium 4 processor brings ALI's offerings in line with the latest from other chipset vendors. In a break with ALI tradition, it uses the HyperTransport high-speed direct connection between North and South Bridge chips instead of relying on the PCI bus, as with previous designs.

Its major features include

- Support for hyper-threading and 533MHz system bus
- Support for DDR memory up to DDR400 and PC100/133 SDRAM
- ATA-133
- USB 2.0
- AGP 8x interface
- Memory Stick and SD (Secure Digital) flash memory device interfaces
- ACPI power management
- HyperTransport high-speed link between North and South Bridge chips, running at >400MBps bandwidth in each direction (800MBps total throughput)
- M1563 South Bridge chip

The M1683 chipset is based on the M1681 but supports the 800MHz system bus.

M1685

Although the M1685 chipset is numbered in series with ALi's earlier Pentium 4 chipsets, it represents a major departure from the M1681/M1683 generation. The M1685 is ALi's first chipset for the Pentium 4 to adopt PCI-Express and DDR-II memory. Its major features include

- Support for the 800MHz system bus
- Support for HT Technology processors
- DDR266/333/400 or DDR-II memory
- PCI-Express x16 video slot
- 3.5GB maximum memory size
- M1563 South Bridge chip

Although the M1685 North Bridge supports the same DDR-II memory and PCI-Express x16 technologies used by the latest Intel and SiS chipsets, the companion M1653 South Bridge lacks significant I/O support features, such as Serial ATA and ATA RAID. Thus, a motherboard using the M1685/M1563 chipset combination will not support the latest hard disks unless a discrete SATA host adapter chip is used.

ATI Chipsets for Pentium 4

ATI's original line of chipsets for the Pentium 4 integrate Radeon VE-level 3D graphics, DVD playback, and dual-display features with high-performance North Bridge and South Bridge designs. ATI uses its high-speed A-Link bus to connect its North and South Bridge chips.

The Radeon IGP North Bridge chips for Pentium 4 include the ATI A4 family, comprised of

- Radeon IGP 330
- Radeon IGP 340

The Radeon 9x00 IGP family is ATI's second generation of chipsets for the Pentium 4. The 9x00 IGP North Bridge chips feature Radeon 9200-level graphics with DirectX 8.1 hardware support and support for multiple monitors. On the other hand, the companion IXP 300 South Bridge supports Serial ATA and USB 2.0 as well as six-channel audio. The Radeon 9x00 IGP family includes

- Radeon 9100 IGP
- Radeon 9100 Pro IGP
- Radeon 9000 Pro IGP

ATI's South Bridge chips include

- IXP 150
- IXP 200
- IXP 250
- IXP 300
- IXP 400

Table 4.37 summarizes the major features of the North Bridge chips, and Table 4.38 summarizes the major features of the South Bridge chips used in ATI's integrated chipsets for the Pentium 4. The Radeon IGP 330 and 340 chipsets were not widely used in desktop computers and have now been discontinued.

Table 4.37 Radeon IGP (North Bridge) Chips for Pentium 4

North Bridge Chip	Radeon IGP 330	Radeon IGP 340	Radeon 9100/PRO ² IGP	Radeon 9000 PRO IGP
Bus speed	400MHz	400/533MHz	400/533/800MHz	400/533/800MHz
Hyper-Threading support	No	No	Yes	Yes
Memory types	DDR200/266	DDR200/266/333	DDR333/400 dual-channel	DDR333/400
Parity/ECC	Neither	Neither	Neither	Neither
Maximum memory	1GB	1GB	4GB	4GB
PCI support	2.2	2.2	2.3	2.3
PCI speed/width	33MHz/32-bit	33MHz/32-bit	33MHz/32-bit	33MHz/32-bit
AGP slot	4x	4x	8x	8x
Integrated video	Radeon VE ¹	Radeon VE ¹	Radeon 9200 ^{3,4}	Radeon 9200 ^{3,4}
NS/SB interconnect speed	266MBps	266MBps	266MBps	266MBps
NS/SB interconnect type	A-Link	A-Link	A-Link	A-Link

1. Same core as ATI Radeon 7000 with support for dual displays.

2. The PRO version features improved AGP 8x performance, better memory performance, and improved DDR400 memory compatibility.

3. Two graphics pipelines only; discrete Radeon 9200 GPU has four.

4. Supports ATI SurroundView, which allows a three-monitor setup when a dual-display ATI graphics card is connected to the AGP slot. Some motherboards might not support this feature.

Table 4.39 VIA Chipsets for Pentium 4 (up to 533MHz System Bus)

Chipset	P4X266	P4X266A	P4X266E
North Bridge chip	VT8753	VT8753A	VT8753E
Bus speed	400MHz	400MHz	400/533MHz
HT Technology support	No	No	No
SMP (dual CPUs)	No	No	No
Memory types	PC100/133, DDR200/266	PC100/133, DDR200/266	DDR200/266
Parity/ECC	Neither	Neither	Neither
Maximum memory	4GB	4GB	4GB
PCI support	2.2	2.2	2.2
PCI speed/width	33MHz/32-bit*	33MHz/32-bit*	33MHz/32-bit*
AGP slot	4x	4x	4x
Integrated video	No	No	No
South Bridge	VT8233, VT8233C, VT8233A	VT8233, VT8233C, VT8233A	VT8233, VT8233C, VT8233A, VT8235
V-Link speed	266MBps	266MBps	266MBps

*Supports 66MHz/64-bit PCI when an optional VPX-64 (VT8101) chip is used.

Table 4.38 ATI South Bridge Chips for Pentium 4

South Bridge Chip	USB Support	Number of USB Ports	ATA Support	Audio	10/100 Ethernet	High-speed Interconnect
IXP 150	2.0	6	ATA100	AC'97 2.3; 6-channel	3Com	A-Link
IXP 200/250 ¹	2.0	6	ATA100	AC'97 2.3; 6-channel	3Com	A-Link
IXP 300	2.0	8	ATA133, 2 SATA	AC'97 2.3; 6-channel	3Com	A-Link
IXP 400 (SB400)	2.0	8	ATA133, 4 SATA	AC'97 2.3; 6-channel	3Com	A-Link

1. IXP250 identical features to IXP200, plus it supports Wake On LAN (WOL), Desktop Management Interface (DMI), manage boot agent (MBA), and the Alert Standards Forum (ASF) mechanism.

VIA Chipsets for Pentium 4

Although VIA Technologies produces a line of chipsets for the Pentium 4, it initially lacked a license from Intel for the Socket 478 interface. This slowed acceptance of VIA's chipsets by motherboard makers until VIA and Intel reached an agreement in April 2003. Before VIA received a license to the Socket 478 interface, it used its VIA Platform Solutions Division (VPSD) to produce Pentium 4-compatible motherboards for sale under a variety of brand names. With the agreement between VIA and Intel, VIA's chipsets for the Pentium 4 are now being used by most of the major third-party motherboard makers.

Tables 4.39 and 4.40 provide an overview of VIA's chipsets for the Pentium 4, including ProSavage chipsets with integrated graphics.

P4M266	P4X400 (P4X333)	P4X400A	P4X533
VT8751	VT8754	VT8754CE	P4X533
400MHz	400/533MHz	400/533MHz	400/533MHz
No	No	Yes	Yes
No	No	No	No
PC100/133, DDR200/266	DDR200/266/333	DDR266/333/400	DDR200/266/333
Neither	ECC	ECC	ECC
4GB	16GB	16GB	16GB
2.2	2.2	2.2	2.2
33MHz/32-bit	33MHz/32-bit*	33MHz/32-bit*	33MHz/32-bit*
4x	8x	8x	8x
S3 Graphics ProSavage8 3D	No	No	No
VT8233, VT8233C, VT8233A	VT8235	VT8235	VT8237
266MBps	533MBps	533MBps	533MBps

Table 4.40 VIA Chipsets for Pentium 4 (800MHz System Bus)

Chipset	PT800	PM800	PT880	PM880
North Bridge chip	PT800	PM800	PT800	PM880
Bus speed	400/533/ 800MHz	400/533/ 800MHz	400/533/ 800MHz	400/533/ 800MHz
HT Technology support	Yes	Yes	Yes	Yes
SMP (dual CPUs)	No	No	No	No
Memory types	DDR266/ 333/400	DDR266/ 333/400	Dual-channel DDR266/333/400	Dual-channel DDR266/333/400
Parity/ECC	ECC	ECC	ECC	ECC
Maximum memory	16GB	16GB	16GB	16GB
PCI support	2.2	2.2	2.2	2.2
PCI speed/width	33MHz/32-bit*	33MHz/32-bit*	33MHz/32-bit*	33MHz/32-bit*
AGP slot	8x	8x	8x	8x
Integrated video	No	S3 UniChrome Pro [#]	No	S3 UniChrome Pro [#]
South Bridge	VT8237	VT8237	VT8237	VT8237
V-Link speed	533MBps	533MBps	1066MBps	1066MBps

The UniChrome Pro features dual-monitor support, 350MHz RAMDAC, enhanced DVD playback, and DirectX 7/8/9 3D graphics support.

* Supports 66MHz/64-bit PCI when optional VPX-64 (VT8101) chip is used.

Table 4.41 lists the major features of the VIA South Bridge chips used in VIA's chipsets for the Pentium 4. Note that these same chips are also used by VIA chipsets for the AMD Athlon family of processors. All chipsets that use these South Bridge chips use VIA's high-speed V-Link interface between North and South Bridge chips. These chipsets connect to the VT1211 LPC (low pin count) or equivalent Super I/O chip for support of legacy devices such as serial, IR, and parallel ports and the floppy drive.

Table 4.41 VIA South Bridge Chips for Pentium 4

South Bridge Chip	USB Support	Number of USB Ports	ATA Support	Audio	10/100 Ethernet	HomePNA	V-Link Throughput
VT8233	1.1	6	33/66/100	AC'97, 6-channel ¹	Yes	Yes	266MBps
VT8233A	1.1	6	33/66/100/133	AC'97, 6-channel ¹	Yes	No	266MBps
VT8233C	1.1	6	33/66/100	AC'97, 6-channel ¹	Yes ²	No	266MBps
VT8235	2.0	6	33/66/100/133	AC'97, 5.1 channel ¹	Yes	No	533MBps
VT8237 ⁵	2.0	8	33/66/100/133	AC'97, 5.1 channel ^{1,4}	Yes	No	1066MBps 2 (4) ³

1. Integrated audio requires separate audio codec chip on motherboard; it also supports MC'97 soft modem.

2. 3Com 10/100 Ethernet.

3. 4 SATA ports with optional SATALite interface.

4. 8-channel (7.1) audio when optional VIA Envy 24PT PCI audio controller is used.

5. Can also be used with North Bridge chips that support 533MBps interconnect speed. It also has support for RAID 0+1 with optional SATALite.

VIA Modular Architecture Platforms (V-MAP) for Pentium 4

VIA's North and South Bridge chips for the Pentium 4 support VIA's Modular Architecture Platforms (V-MAP) designs, which enable motherboard designers to convert quickly to more advanced versions of a chipset because of a common pinout. The North Bridge chips used in all VIA Pentium 4-compatible chipsets are all pin-compatible with each other, as are the 8233/8235/8237-series South Bridge chips. Thus, motherboards using these chipsets can be built in a variety of configurations. All these chipsets also support VIA's V-Link high-speed connection between the North and South Bridge chips.

VIA Apollo P4X266 Family

The VIA Apollo P4X266 is its first chipset for the Pentium 4 and Celeron 4 processors, supporting AGP 4x, 4GB of RAM, and the 400MHz system bus used by early Pentium 4/Celeron 4 processors. The P4X266A improves the memory interface and queues more instructions (up to 12) in the processor bus interface to reduce latency and improve performance. The P4X266E adds support for the 533MHz bus used in the 2.53GHz (and faster) Pentium 4 processors. It also supports both the VT8233 and newer VT8235 series of South Bridge chips.

ProSavage P4M266

The VIA ProSavage P4M266 integrates the S3 Graphics ProSavage8 2D/3D graphics accelerators with the features of the P4X266 chipset. Unlike some other chipsets with integrated graphics, the P4M266 retains an AGP 4x slot, so users can upgrade to faster AGP 4x graphics in the future.

The ProSavage8 core uses 32MB of system RAM for its frame buffer, supports AGP 8x bandwidth internally with 128-bit data paths, and features DVD DXVA Motion Compensation to improve the quality of DVD playback. In addition, it supports all members of the 8233 family of South Bridge chips.

Apollo P4X400, P4X400A, and P4X533

The VIA Apollo P4X400 chipset is an improved version of the short-lived P4X333. It's suitable for both server and workstation/desktop computer use, thanks to its support for up to 32GB of RAM and ECC memory. It also supports 400MHz and 533MHz system bus speeds and DDR memory up to 400MHz. It uses the VT8235 South Bridge, so it also supports the latest I/O standards (USB 2.0 and ATA-133).

The P4X400A chipset features improved timings and support for DDR400 memory, supports HT Technology processors, and uses the VT8235 South Bridge.

The P4X533 chipset is similar to the P4X400A but uses the VT8237 as its South Bridge chip, providing support for SATA and RAID as well as eight USB 2.0 ports and optional 7.1 audio.

All three processors use the 8x V-Link connection (533MBps) between North and South Bridge chips.

PT800/PM800/PT880/PM880

The PT8xx-series chipsets are the first VIA Technologies chipsets to support the 800MHz processor bus versions of the Pentium 4. They use the VT8237 South Bridge chips (eight USB 2.0 ports, SATA, RAID, and optional 7.1 audio).

The major differences between these chipsets include

- PT800 uses single-channel DDR 400 memory and AGP 8x video, with 8x V-Link (533MBps).
- PM800 adds S3 UniChrome Pro integrated graphics to the PT800 feature set.
- PT880 is a dual-channel version of the PT800 and uses Ultra V-Link (1066MBps).
- PM880 adds S3 UniChrome Pro integrated graphics to the PT880 feature set.

Figure 4.43 displays the architecture of the PM880 chipset when equipped with the optional VIA Envy 24PT audio controller for eight-channel audio (left) and VIA Gigabit Ethernet controller (bottom).

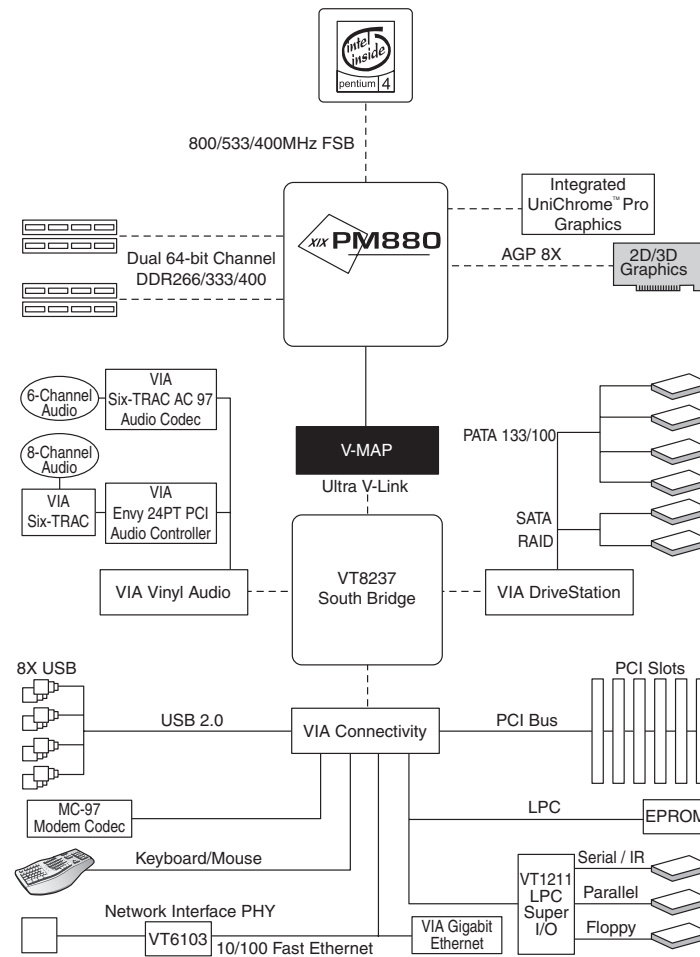

Figure 4.43 VIA's PM880 chipset for the Pentium 4 combines integrated graphics with support for AGP 8x and offers optional eight-channel audio (left) and Gigabit Ethernet (bottom). It uses a separate Super I/O chip (bottom right).

Athlon/Duron/Athlon XP Chipsets

The original AMD Athlon was a Slot A processor chip, but subsequent versions have used Socket A—as do the economical Duron and current Athlon XP. Although similar in some ways to the Pentium III and Celeron, the AMD chips use a different interface and require different chipsets. AMD was originally the only supplier for Athlon chipsets, but VIA Technology, ALi Corporation, SiS, and NVIDIA now provide a large number of chipsets with a wide range of features. These chipsets are covered in the following sections.

AMD Chipsets for Athlon/Duron Processors

AMD makes four chipsets for Athlon and Duron processors: the AMD-750 and AMD-760/MP/MPX. The major features of these chipsets are compared in Table 4.42 and described in greater detail in the following sections.

Table 4.42 AMD Athlon/Duron Processor Chipsets Using North/South Bridge Architecture

Chipset	AMD-750	AMD-760
Code name	Irongate	None
Date introduced	Aug. 1999	Oct. 2000
Part number	AMD-751	AMD-761
Bus speed	200MHz	200/266MHz
Supported processors	Athlon/Duron	Athlon/Duron
SMP (dual CPUs)	No	Yes
Memory type	SDRAM	DDR SDRAM
Memory speed	PC100	PC1600/PC2100
Parity/ECC	Both	Both
Maximum memory	768MB	2GB buffered, 4GB registered
PCI support	2.2	2.2
AGP support	AGP 2x	AGP 4x
South Bridge	AMD-756	AMD-766
ATA/IDE support	ATA-66	ATA-100
USB support	1C/4P	1C/4P
CMOS/clock	Yes	Yes
ISA support	Yes	No
LPC support	No	Yes
Power management	SMM/ACPI	SMM/ACPI

AGP = Accelerated graphics port

ATA = AT attachment (IDE) interface

DDR-SDRAM = Double data rate SDRAM

ECC = Error correcting code

ISA = Industry Standard Architecture

LPC = Low pin count bus

PCI = Peripheral component interconnect

SDRAM = Synchronous dynamic RAM

SMP = Symmetric multiprocessing (dual processors)

USB = Universal serial bus

AMD-750

AMD's first chipset for its own Slot A and Socket A processors, called the AMD-750, is a traditional North/South Bridge design specifically for the Athlon and Duron processors. The AMD-750 chipset consists of the AMD-751 North Bridge and the AMD-756 South Bridge.

The AMD-751 system controller connects between the AMD Athlon processor bus to the processor and features the memory controller, AGP 2x controller, and PCI bus controller. The AMD-756 South Bridge includes a PCI-to-ISA bridge, USB controller interface, and ATA 33/66 controller.

The AMD-750 chipset includes the following features:

- AMD Athlon 200MHz processor bus
- PCI 2.2 bus with up to six masters
- AGP 2x
- PC-100 SDRAM with ECC
- Up to 768MB of memory
- ACPI power management
- ATA-33/66 support
- USB controller
- ISA bus support
- Integrated 256-byte CMOS RAM with clock
- Integrated keyboard/mouse controller

AMD-760 Family

The AMD-760 chipset was introduced in October 2000 and is notable as the first chipset supporting DDR SDRAM memory. The AMD-760 chipset consists of the AMD-761 system controller (North Bridge) in a 569-pin plastic ball-grid array (PBGA) package and the AMD-766 peripheral bus controller (South Bridge) in a 272-pin PBGA package. See Figure 4.44 for details of the 760's block diagram.

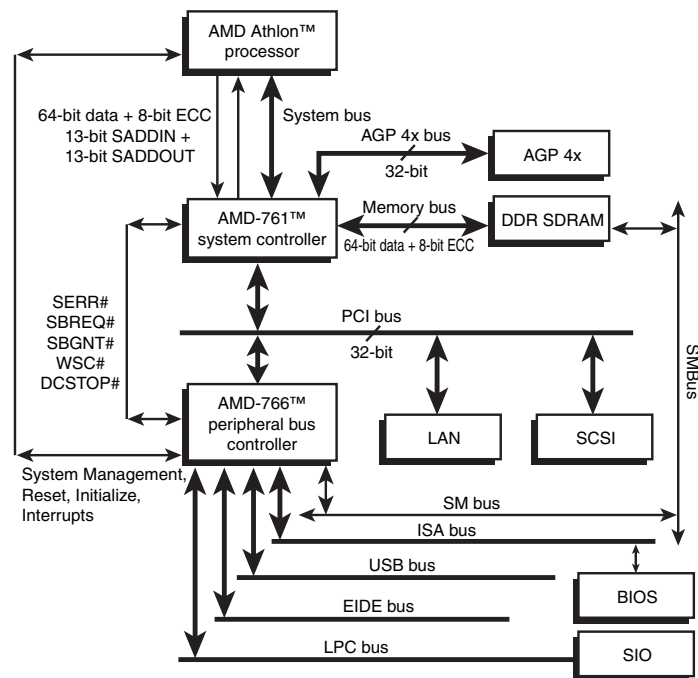

Figure 4.44 AMD-760 chipset block diagram.

The AMD-761 North Bridge features the AMD Athlon system bus, DDR-SDRAM system memory controller with support for either PC1600 or PC2100 memory, AGP 4x controller, and PCI bus controller. The 761 allows for 200MHz or 266MHz processor bus operation and supports the newer Athlon chips that use the 266MHz processor (also called front-side) bus.

The AMD-766 South Bridge includes a USB controller, dual UDMA/100 ATA/IDE interfaces, and the LPC bus for interfacing newer Super I/O and ROM BIOS components.

The AMD-760 chipset includes the following features:

- AMD Athlon 200/266MHz processor bus
- Dual processor support
- PCI 2.2 bus with up to six masters
- AGP 2.0 interface that supports 4x mode
- PC1600 or PC2100 DDR SDRAM with ECC
- Support for a maximum of 2GB buffered or 4GB registered DDR SDRAM
- ACPI power management
- ATA-100 support
- USB controller
- LPC bus for Super I/O support

The AMD-760MP chipset, which uses the AMD-762 North Bridge chip, is a development of the basic AMD-760 design that supports dual-processor Athlon MP systems. It differs from the standard 760 chipset in the following ways:

- Supports dual AMD Athlon MP processors with 200/266MHz processor bus speeds
- Up to 4GB PC2100 DDR (registered modules)
- Supports 33MHz PCI slots in 32-bit and 64-bit widths

The AMD-760MPX chipset uses the same AMD-762 North Bridge chip as the AMD-760MP to support multiple Athlon MP processors, but it uses the AMD-768 peripheral bus controller (South Bridge) chip. It differs from the 760MP chipset in the following ways:

- The AMD-762 North Bridge chip is used to support two 66MHz 32/64-bit PCI slots.
- The AMD-768 South Bridge chip is used to support 33MHz/32-bit PCI slots.

The 760MPX chipset is a better choice for a server because of its support for 66MHz and 64-bit PCI slots, whereas the 760MP is a suitable choice for a workstation.

None of these chipsets support USB 2.0, ATA-133, or DDR333 or faster memory. If you buy an Athlon, a Duron, or an Athlon XP desktop system, it's far more likely that your system will contain a third-party chipset than an AMD chipset; however, the 760MP and 760MPX chipsets continue to be popular choices for AMD-based workstations and servers. The following sections cover the third-party chipsets made for the Athlon, Duron, and Athlon XP processors.

VIA Chipsets for Athlon, Duron, and Athlon XP

VIA Technologies, Inc., is the largest chipset and processor supplier outside of Intel and AMD. Originally founded in 1987, VIA is based in Taipei, Taiwan, and is the largest integrated circuit design firm on the island. VIA is a fabless company, which means it farms out the manufacturing to other companies with chip foundry capability. Although it is best known for its chipsets, in 1999 VIA purchased the Cyrix processor division from National Semiconductor and the Centaur processor division from IDT, respectively, thereby becoming a supplier of processors in addition to chipsets. VIA has also formed a joint venture with SONICblue (formerly S3) as a means of integrating graphics capabilities into various chipset products. This joint venture is known as S3 Graphics, Inc.

VIA makes chipsets for Intel, AMD, and Cyrix (VIA) processors. Table 4.43 provides an overview of VIA's Athlon/Duron chipsets that use the traditional North/South Bridge architecture.

More recently, VIA has converted to an architecture called V-Link, which uses a fast dedicated connection between the North Bridge and South Bridge. V-Link is similar to Intel's hub architecture, as well as HyperTransport (used by ALi, NVIDIA, and ATI), MuTIOOL (used by SiS), and A-Link (used by ATI). V-Link is also used by VIA's Pentium 4 chipsets. Tables 4.43, 4.44, and 4.45 provide an overview of V-Link chipsets, which also support the VIA Modular Architecture Platform (V-MAP) design. As with VIA's chipsets for the Pentium 4, V-MAP uses identical pinouts for several ranges of V-Link North and South Bridge chips so vendors can reuse a motherboard design with more advanced chipsets as they are developed.

Both types of chipsets are discussed in the following sections.

Table 4.43 VIA Athlon/Duron/Athlon XP Processor Chipsets Using North/South Bridge Architecture

Chipset	Apollo KX133	Apollo KT133	Apollo KT133A	Apollo KLE133	ProSavage KM133
Introduced	Aug. 1999	June 2000	Dec. 2000	Mar. 2001	Sep. 2000

1. Integrated audio requires a separate audio codec chip on the motherboard; it also supports MC'97 soft modem.

2. 3Com 10/100 Ethernet.

3. 4 SATA ports with optional SATA Lite interface.

4. RAID 0+1 with optional SATA Lite.

5. 8-channel (7.1) audio when optional VIA Envy 24PT PCI audio controller is used.

6. Can also be used with North Bridge chips that support 1066MBps Ultra V-Link interconnect speed.

VIA Technologies Apollo KX133

The VIA Apollo KX133 chipset brings AGP 4x, PC133, a 200MHz FSB, and ATA-66 technologies to the AMD Athlon processor platform, exceeding the performance of AMD's own 750 chipset. It was the first chipset to support AGP 4x.

Key features include the following:

- 200MHz processor bus
- AGP 4x graphics bus
- PC133 SDRAM memory
- 2GB maximum RAM
- ATA-66 support
- Four USB ports
- AC'97 link for audio and modem
- Hardware monitoring
- Power management

The VIA Apollo KX133 is a two-chip set consisting of the VT8371 North Bridge controller and the VT82C686A South Bridge controller.

VIA Technologies Apollo KT133 and KT133A

The VIA Apollo KT133/A chipsets are designed to support the AMD Athlon and Duron processors in Socket-A (462) form. Based on the prior KX133 chipset, the KT133/A differ mainly in their support for Socket-A (462) over the previous Slot-A processor interface.

The VIA Apollo KT133 and KT133A are both two-chip sets consisting of the VT8363 North Bridge and the VT82C686A South Bridge (KT133) or the VT8363A North Bridge and the VT82C686B South Bridge (KT133A).

Both the KT133 and KT133A support the following standard features:

- Athlon/Duron Socket-A (462) processors
- 200MHz CPU (front-side) bus
- AGP 4x
- 2GB RAM maximum
- PC100/PC133MHz SDRAM
- PCI 2.2
- ATA-66
- USB support
- AC-97 audio
- Integrated Super I/O
- Integrated hardware monitoring
- ACPI power management

The KT133A (VT8363A North Bridge with VT82C686B South Bridge) adds the following features:

- 266MHz CPU (front-side) bus
- ATA-100

ProSavage KM133

The VIA ProSavage KM133 integrates S3 Graphics' S3 Savage 4 and S3 Savage 2000 3D and 2D graphics engines with the Apollo Pro KT133 chipset. The major features of the chipset are the same as for the Apollo Pro KT133, with the following additions:

- 2MB–32MB shared memory architecture integrated with Savage 4 3D and Savage 2000 2D video
- Z-buffering, 32-bit true-color rendering, massive 2K-by-2K textures, single-pass multiple textures, sprite antialiasing, and other 3D features

- Support for DVD playback, DVI LCD displays, and TV-out
- PCI 2.2 compliance

An optional AGP 4x interface enables the integrated AGP 4x video to be upgraded with an add-on card if desired. This two-chip chipset consists of the VT8365 North Bridge and VT8231 South Bridge.

The VT8231 South Bridge integrates the Super I/O and supports the LPC interface.

Apollo KT266 and KT266A

The Apollo KT266 is the first VIA chipset for Athlon-based systems to support VIA's high-speed V-Link system architecture. V-Link connects the 552-pin VT8366 North Bridge to the 376-pin VT8233 series South Bridge with a 266MBps data pathway, which is twice as fast as traditional PCI-based connections.

Major features of the KT266 include system bus speeds of 200/266MHz, AGP 2x/4x interface, and up to 4GB of DDR200/266 DDR SDRAM or PC100/133 SDRAM. Other features vary with the South Bridge (VT8233, VT8233A, or VT8233C) chip used with the VT8366.

The KT266A is a pin-compatible upgrade to the original KT266's North Bridge. The KT266A's VT8366A includes VIA's Performance Driven Design, which is not a technical term but a marketing term for the A-series' chips improved memory timing and deeper command queues to improve chipset performance. Basic features of the KT266A are otherwise similar to the KT266.

ProSavage KM266

The ProSavage KM266 combines the features of the KT266 with the graphics core of the S3 Graphics ProSavage 8 2D/3D accelerator. Unlike some other chipsets with integrated graphics, the KM266 retains an AGP 4x slot, so users can upgrade to faster AGP 4x graphics in the future.

The ProSavage8 core uses 32MB of system RAM for its frame buffer, supports AGP 8x bandwidth internally with 128-bit data paths, and features DVD DXVA Motion Compensation to improve the quality of DVD playback. It supports all members of the VT8233 family of South Bridge chips and has a 266MBps 4x V-Link connection between North and South Bridge chips.

Apollo KT333

The Apollo KT333 is a pin-compatible development of the KT266A, adding support for a 333MHz system bus, 333MHz memory bus, and DDR333 memory. Unlike the KT266A, the KT333 no longer supports PC100/133 memory, but it uses the same VT8233 family of South Bridge chips.

Apollo KT400/KM400

The Apollo KT400 is the first VIA chipset for the Athlon XP processor to offer AGP 8x and a second-generation 533MB/s V-Link connection to the South Bridge. It uses the VT8235 South Bridge, which is VIA's first South Bridge chip to support USB 2.0 as well as ATA-133.

The combination of faster video, fast memory and system bus speeds, and faster V-Link connections make the KT400 among the fastest Athlon XP chipsets.

The KM400 has the same basic features as the KT400 but adds integrated UniChrome 2D/3D graphics developed by S3 Graphics. The KM400 can be matched with the VT8235CE South Bridge chip or the top-of-the-line VT8237 South Bridge chip introduced by the KT400A (see the next section).

Apollo KT400A/KT600

In previous A-series chipsets from VIA, the North Bridge component was replaced with an improved chip and the South Bridge component was retained. However, the KT400A features new designs for both its North Bridge (VT8377A) and South Bridge (VT8237) chips. The major features of the VT8377A component include

- System bus support up to 333MHz
- DDR memory support up to DDR400
- Up to 4GB of memory
- An expanded array of prefetch buffers to reduce memory latency and improve throughput (FastStream64)
- AGP 8x interface

Some motherboard vendors use the older VT8235CE South Bridge chip (refer to Table 4.45) with the VT8377A North Bridge component. However, when the VT8237 South Bridge is used, the KT400A chipset has these new features:

- Integrated six-channel Surround Sound AC'97 audio
- Optional eight-channel audio
- Eight USB 2.0 ports
- Integrated MC'97 modem
- Integrated 10/100 Ethernet
- Serial ATA
- ATA RAID 0, 1 (0+1 with optional VIA SATAlite interface for two additional SATA ports)
- ATA 33/66/100/133
- ACPI/OnNow power management
- Optional VIA Velocity Gigabit Ethernet (PCI controller)

KT400A's FastStream64 enables the system to reach 3.2GBps memory transfer speeds without the need for more expensive dual-channel memory support.

Figure 4.45 shows the architecture of the KT400A (with VT8237) chipset.

The VIA KT600 is an improved version of the KT400A/VT3237 combo, adding support for the 400MHz CPU bus versions of the Athlon XP. Although a few motherboards pair the KT600's North Bridge with the older VT8235CE South Bridge, most motherboard vendors use the KT600/VT8237 combo to provide support for Serial ATA, SATA RAID, and other advanced features.

KT880

The VIA KT880 is VIA's first dual-channel chipset for the Athlon XP. Dual-channel memory support enables the system to reach very high memory transfer rates. It has the following features:

- System bus support up to 400MHz
- Dual-channel DDR memory support up to DDR400
- Up to 8GB of memory
- DualStream 64, which is VIA's marketing term for this chipset's combination of improved memory clock timings, larger on-chip branch table, and enhancements to the data prefetch protocol and memory branch predictions feature
- AGP 8x interface
- Integrated six-channel Surround Sound AC'97 audio with optional eight-channel audio
- Eight USB 2.0 ports
- Integrated MC'97 modem
- Integrated 10/100 Ethernet
- Serial ATA and SATA RAID 0, 1 (0+1 with optional VIA SATAlite interface for two additional SATA ports)
- ATA 33/66/100/133
- ACPI/OnNow power management

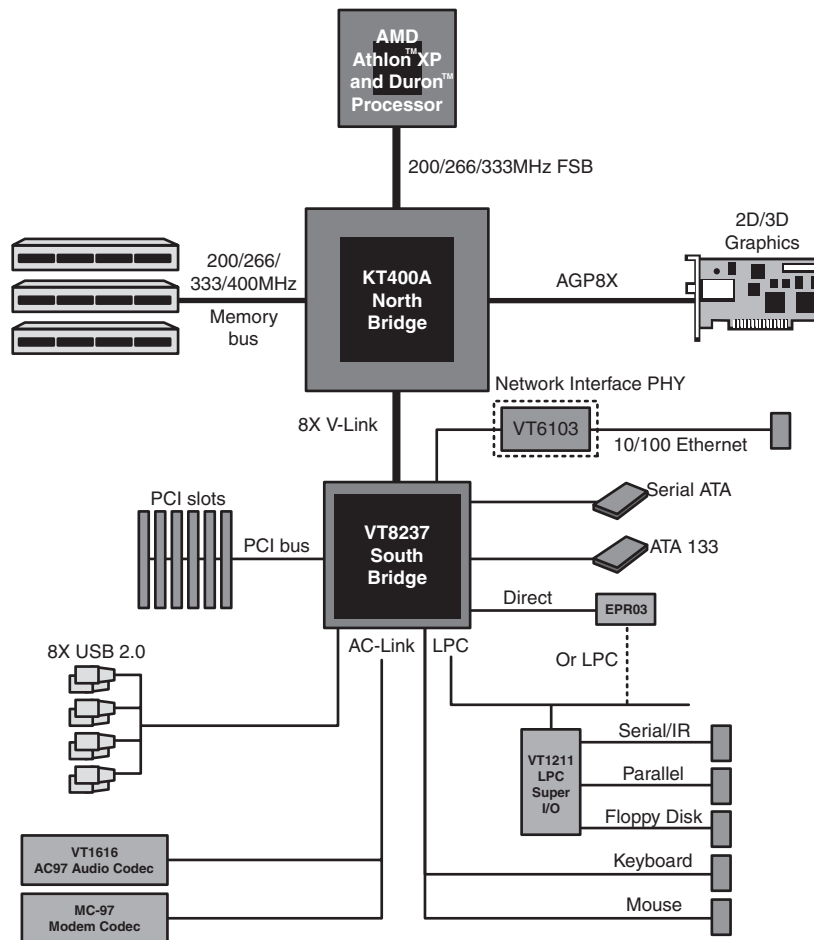

Figure 4.45 VIA KT400A block diagram.

Silicon Integrated Systems Chipsets for AMD Athlon/Duron Processors

SiS has a variety of chipsets for the Athlon, Duron, and Athlon XP processors. Tables 4.46 and 4.47 provide an overview of these chipsets, some of which use SiS's unique single-chip design and others of which use a high-speed two-chip design similar to other vendors' chipsets. These chipsets are discussed in the following sections.

Table 4.46 SiS Chipsets for Athlon/Duron/Athlon XP Processors

Chipset	SiS730S	SiS740	SiS733	SiS735	SiS745
Bus speed	200/266MHz	266MHz	200/266MHz	200/266MHz	266MHz
SMP (dual CPUs)	No	No	No	No	No

SiS MuTIOL High-Speed North/South Bridge Connection

The SiS96x-series South Bridge chips use a high-speed bus called MuTIOL to connect with compatible North Bridge chips. The original version of MuTIOL (supported by the SiS961- and 962-series chips) is a 16-bit wide 266MHz connection that provides 533MBps bandwidth, twice the speed of the Intel hub architecture used by Intel's 800-series chipsets.

The SiS963-, 964-, and 965-series and matching North Bridge chips use a second generation of MuTIOL called MuTIOL 1G, which supports a 16-bit-wide 533MHz connection to achieve bandwidths exceeding 1GBps.

When connected to the SiS746FX, SiS741GX, SiS748, or SiS741 North Bridge chips and newer models, the SiS963/964-series chips use a further development of MuTIOL called HyperStreaming, which integrates the following four technologies to further improve the speed of data transfer:

- *Single Stream with Low Latency Technology.* Improves performance by 5%–43% depending on the activity.
- *Multiple Stream with Pipelining and Concurrent Execution Technology.* Uses concurrent parallel data pipelines and simultaneous processing of nonsequential data. In file-copy operations, for example, performance increases as data file size increases.
- *Specific Stream with Prioritized Channel Technology.* Improves playback of Internet music, video, and applications such as IP telephony and videoconferencing.
- *Smart Stream Flow Control Technology.* Analyzes characteristics of different interfaces and improves performance.

SiS730S

The SiS730S is a high-performance, low-cost, single-chip chipset with integrated 2D/3D graphics and support for Socket A versions of the AMD Athlon and Duron.

The integrated video is based on a 128-bit graphic display interface with AGP 2x performance. In addition to providing a standard analog interface for CRT monitors, the SiS730S also provides the DFP for a digital flat panel monitor. An optional SiS301 video bridge supports NTSC/PAL TV output. The SiS730S also supports an AGP 4x slot, enabling users to upgrade to a separate AGP card in the future.

The SiS730S also includes integrated 10/100Mb Fast Ethernet as well as an AC'97-compliant interface that comprises a digital audio engine with 3D-hardware accelerator, on-chip sample rate converter, and professional wavetable along with separate modem DMA controller. SiS730S also incorporates the LPC interface for attaching newer Super I/O chips and a dual USB host controller with six USB ports. The SiS730S can also be used with ISA slots if an optional LPC/ISA bridge chip is used.

Features of the SiS730S include

- Support for AMD Athlon/Duron processors with 200/266MHz system bus
- Support for PC133 SDRAM
- Meets PC99 requirements
- PCI 2.2 compliant
- Four PCI masters
- Support for Ultra DMA100
- Integrated AGP 2x 2D/3D video/graphics accelerator
- Support for digital flat panel
- Hardware DVD decoding
- Built-in secondary CRT controller for independent secondary CRT, LCD, or TV digital output
- LPC interface
- Advanced PCI H/W audio (Sound Blaster 16 and DirectSound 3D compliant) and modem
- Meets ACPI 1.0, APM 1.2 requirements
- PCI Bus Power Management Interface Spec. 1.0
- Integrated keyboard/mouse controller
- Dual USB controller with six USB ports
- Integrated 10/100Mbps Ethernet controller

SiS733 and SiS735

The SiS733 and SiS735 are high-performance single-chip sets that support the AMD Athlon and Duron Socket A processors. Similar to other SiS single-chip sets, the SiS733 and SiS735 incorporate the features of a traditional North Bridge, South Bridge, and Super I/O chip into a single chip.

The SiS733 supports PC133 SDRAM and uses a 682-pin BGA package. The SiS735 supports either PC133 or DDR266 SDRAM and integrates 10/100 Fast Ethernet and HomePNA 1Mbps/10Mbps Home Network interfaces. The SiS735 also uses a 682-pin BGA package.

The SiS733 and SiS735 share the following features:

- Support for 4x AGP
- Up to six PCI masters
- Dual UDMA/100 IDE host adapters
- 1.5GB RAM maximum
- Six USB ports
- AC'97 audio and AMR support
- Integrated RTC
- LPC interface for support of MIDI, joystick, and legacy BIOS devices
- PC2001 compliant

SiS740

The SiS740 is a dual-chip design that provides a high-speed integrated video solution for Athlon-class processors. Its North Bridge and South Bridge chips use the high-speed MuTIOL connection to transfer data. Its major features include

- Integrated Real256 2D/3D graphics core with full DirectX 7 compatibility
- Up to 128MB of shared memory
- Hardware DVD playback
- DDR266 memory support

It is designed to use the SiS961- or 962-series South Bridge chips.

SiS745

The SiS745 is the first single-chip solution to integrate IEEE 1394a (FireWire 400) as part of its I/O. It is designed to provide a high-performance legacy-free solution. Its key features include the following:

- DDR266/333 memory support up to 3GB
- Support for Athlon XP processor as well as earlier models
- Six USB 1.1 ports
- Three IEEE 1394a ports
- Legacy keyboard, mouse, floppy, MIDI, and joystick interfaces
- ATA-100
- AC'97 audio and AMR (audio modem riser) support for a V.90 soft modem

SiS746 and SiS746FX

The SiS746 is the first Athlon/Duron/Athlon XP-compatible chipset on the market to feature an AGP 8x interface. It is a two-piece chipset designed to connect with the SiS963-series South Bridge chipsets. Major features include

- 266MHz processor bus
- DDR266/333 memory (the FX supports DDR400 memory)
- AGP 8x interface
- MuTIOL 1G second-generation connection to South Bridge (1GBps)
- SiS963 or SiS963L South Bridge

The companion SiS963L South Bridge chip adds the following features: ATA-133 support, six USB 2.0 ports, six-channel AC'97 audio, and MII interface for HomePNA or 10/100 Ethernet networking.

The SiS963 South Bridge chip adds IEEE 1394a (FireWire 400) support.

The SiS746FX North Bridge is an enhanced version of the SiS746, adding support for the 333MHz processor bus and approved DDR400 memory. It also uses the SiS963 series of South Bridge chips and uses SiS HyperStreaming technology to reduce latency in the MuTIOl interface.

SiS748

Like the SiS746FX, the SiS748 also uses the SiS963 series of South Bridge chips, as well as the SiS HyperStreaming technology for a lower-latency connection between the chips. Its other major features include

- Up to 400MHz system bus
- DDR266/333/400 memory support
- AGP 8x interface

Figure 4.46 shows the system architecture of the SiS748 chipset when using the SiS963L South Bridge chip. If the SiS963 South Bridge chip is used in place of the SiS963L pictured, three IEEE 1394a ports are also available.

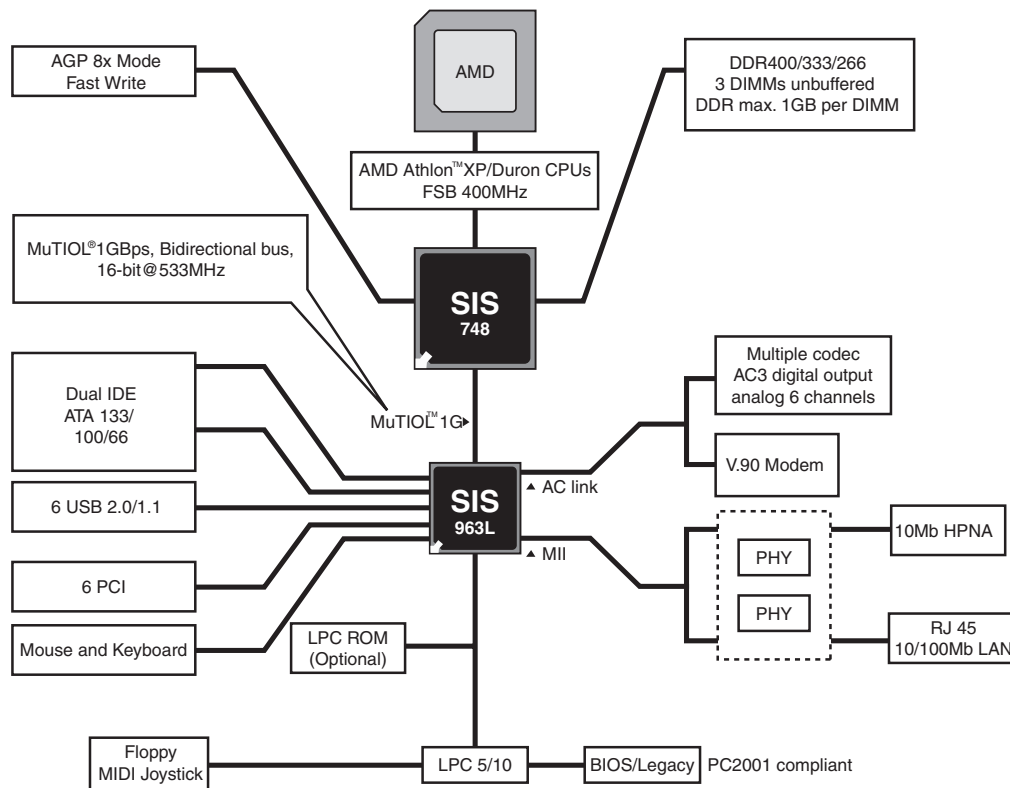

Figure 4.46 Block diagram for SiS748 chipset with SiS963L South Bridge.

SiS741/741GX

The SiS741 chipset includes integrated SiS Mirage Graphics. Its other features are similar to those of the SiS748 chipset. Major features include

- 400MHz system bus
- DDR400 memory support
- Up to 3GB of memory
- AGP 8x
- Integrated SiS Mirage Graphics with DirectX 8.1 support and 32MB or 64MB of shared memory
- Uses SiS963- or 964-series South Bridge

The SiS741GX also includes integrated SiS Mirage Graphics. Its other features are similar to those of the SiS746FX, but it is usually paired with the SiS964 South Bridge.

When paired with an SiS964-series South Bridge, the SiS741GX also supports the following:

- Serial ATA (two ports; 964 only)
- Serial ATA RAID (964 only)
- PCI version 2.3
- Up to eight USB 2.0 ports

ALiMagik1 for AMD Athlon/Duron Systems

ALi Corporation makes only one chipset for AMD Athlon/Duron processors: the ALiMagik1.

ALiMagik1 is a two-chip chipset that uses the M1647 Super North Bridge and the M1535D+ South Bridge (which is also used by its Pentium III/Celeron chipsets). The M1647 Super North Bridge is a 528-pin BGA chip.

The M1647 Super North Bridge supports SDRAM as well as DDR SDRAM at speeds of 200MHz or 266MHz. It supports up to 3GB of RAM but does not support ECC. Memory timing is x-1-1-1-1-1-1 in back-to-back SDRAM reads. Because the M1647 supports both conventional and DDR SDRAM, system manufacturers can use the same chipset for both memory types.

The M1647 supports AGP 4x video, PCI 2.2, up to six PCI masters beyond the North Bridge and PCI bridge, ACPI and Legacy green power management, PCI Mobile CLKRUN#, and AGP Mobile BUSY#/STOP#.

When combined with an M1535+ South Bridge chip, the chipset is called the MobileMagik1 and can be used on Athlon- or Duron-based portable systems.

Because this chipset, unlike others that use DDR memory, still uses the traditional 133MBps PCI bus connection between North and South Bridge chips, its performance is among the lowest of any Athlon chipset. This chipset is now discontinued.

NVIDIA nForce Chipsets for Athlon/Duron/Athlon XP

NVIDIA, although best known for its popular GeForce line of graphics chipsets, has also become a popular vendor of chipsets for the AMD Athlon/Duron/Athlon XP processor family with its nForce and nForce2 product families.

nForce's advanced features include

- 400MBps HyperTransport link between chipset components. nForce is the first PC chipset to use HyperTransport.
- Dual-channel crossbar memory controller to provide high-speed memory access when identical pairs of memory are used. It uses independent 64-bit memory controllers.
- nView multidisplay hardware (420 chipset with integrated video) supports dual displays with integrated video.
- AGP 4x interface.
- Dynamic adaptive speculative preprocessor (DASP) to reduce latency and improve prefetching of data.

- StreamThru architecture to improve isochronous (time-dependent) data transfers for network and broadband through the chipset's integrated 10/100 Ethernet port.
- Integrated GeForce2 MX video (420 chipset with integrated video) with support for DVI LCD flat panels.
- True hardware-based audio processing with support for Dolby Digital (AC-3) 5.1 channel audio (SoundStorm chipsets).

nForce2 improvements over nForce include the following:

- DualDDR improved dual-channel memory controller that supports up to DDR400 memory and allows dual-channel operation with two or three DIMMs
- Optional IEEE 1394a support

Table 4.48 nForce/nForce2 IGP/SPP (North Bridge) Chips

North Bridge Chip	nForce 420	nForce 415	nForce2 IGP	nForce2 SPP
Bus speed	200/266MHz	200/266MHz	200/266/ 333MHz	200/266MHz

nForce2 Gigabit MCP	1.1, 2.0	8	33/66/100/133	Yes	Yes
nForce2 RAID MCP	1.1, 2.0	8	33/66/100/133	Yes	Yes

1. Also known as NVIDIA SoundStorm

- Optional GeForce4 MX integrated video
- AGP 8x interface

Table 4.48 provides an overview of the North Bridge chips in the nForce and nForce2 families, and Table 4.49 provides an overview of the nForce/nForce2 South Bridge chips. Unlike most other chip makers, NVIDIA does not make Pentium 4-compatible chipsets; the nForce is a descendant of the custom chipset NVIDIA created for the Microsoft Xbox console game system.

nForce North Bridge chips with integrated graphics are known as *integrated graphics processors (IGPs)*, whereas those that require separate AGP video are known as *system platform processors (SPPs)*. All South Bridge chips are known as media and communications processors (MCP). IGP/SPP and MCP chips communicate over an 800MBps HyperTransport connection.

nForce2 400	nForce2 Ultra 400	nForce 2 Ultra 400R	nForce2 Ultra 400 Gb
200/266/ 333/400MHz	200/266/ 333/400MHz	200/266/ 333/400MHz	200/266/ 333/400MHz

2. Use only two identical memory modules to enable this mode.

Audio	10/100 Ethernet ²	Gigabit Ethernet	IEEE 1394	Hardware Firewall	Used with
AC'97, 5.1 channel	Yes	No	No	No	nForce IGP, SPP
AC'97, 5.1 channel	Yes	No	No	No	nForce IGP, SPP
AC'97, 6- channel, 20-bit, SPDIF out	Yes	No	No	No	nForce2 IGP, SPP, 400, Ultra 400
All features of MCP, plus Audio Processing Unit, Dolby Digital 5.1 channel, and DirectX 8 3D audio	Dual NVIDIA and 3Com	No	Yes	No	nForce2 IGP, SPP, 400, Ultra 400
AC'97, 6- channel, 20-bit, SPDIF out	Yes	Yes	No	Yes	nForce2 Ultra 400Gb
AC'97, 6- channel, 20-bit, SPDIF out	Yes	No	No	No	nForce2 Ultra 400R

2. Also supports HomePNA networking

The combination of advanced memory controllers, prefetch design, HyperTransport high-speed connection, and hardware audio processing in MCP-D and MCP-T chips makes the second-generation nForce2 chipsets among the fastest chipsets available for Athlon XP processors. The new Gigabit MCP and RAID MCP chips bring eight-port USB 2.0 and Serial ATA/ATA RAID support to nForce2-based systems. The Gigabit MCP is the first nForce2 MCP chip to offer integrated Gigabit Ethernet.

Figure 4.47 shows the architecture of the nForce2 IGP and MCP-T combination, which provides the greatest versatility. If the SPP North Bridge is used instead of the IGP, integrated video is not present. If the MCP South Bridge is used instead of the MCP-T, IEEE 1394a, hardware 5.1 Dolby Digital audio, and dual network ports are not available.

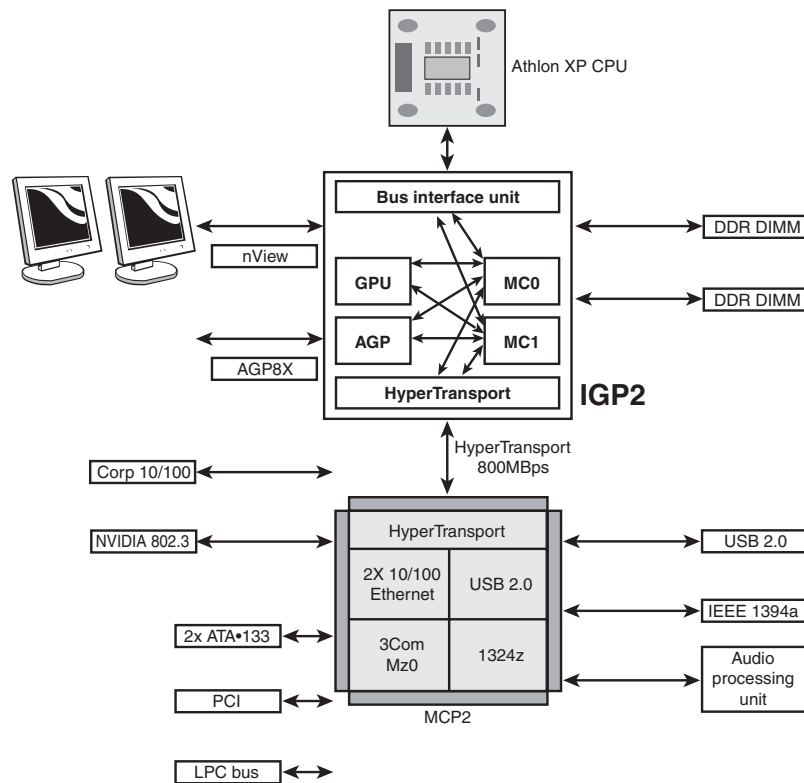

Figure 4.47 NVIDIA nForce2 IGP/MCP2 chipset architecture.

ATI Radeon IGP Chipsets for Athlon/Duron/Athlon XP

ATI made a series of chipsets for the Athlon series of processors that integrate Radeon VE-level 3D graphics, DVD playback, and dual-display features with high-performance North Bridge and South Bridge designs. These chipsets use ATI's high-speed A-Link bus to connect its North and South Bridge chips, but they also support connections to third-party South Bridge chips via the PCI bus. This has enabled system designers to create an all-ATI or a mix-and-match solution. Many of the first Radeon IGP-based systems on the market used ALi or VIA South Bridge chips. The Radeon IGP 320 North Bridge chip can be matched with either of ATI's South Bridge chips: the IXP 200 or IXP 250. Both of these chips support six USB 2.0 ports and ATA33/66/100. Although the mobile version of this chipset—the Radeon 320M IGP—is still available for use in laptop computers, the Radeon 320 IGP is now discontinued. Table 4.50 summarizes the major features of the IGP 320, and Table 4.51 summarizes the major features of the IXP 200 and 250.

Table 4.50 Radeon IGP (North Bridge) Chip for Athlon

North Bridge Chip	Radeon IGP 320	North Bridge Chip	Radeon IGP 320
Bus speed	200/266MHz	PCI support	2.2
SMP (dual CPUs)	No	PCI speed/width	33MHz/32-bit
Memory type	DDR200/266	AGP slot	4x
Parity/ECC	Neither	Integrated video	Radeon VE*
Maximum memory	1GB	A-Link speed	266MBps

*Same core as ATI Radeon 7000, with support for dual displays

Table 4.51 ATI South Bridge Chips for Athlon

South Bridge Chip	IXP 200/250*	South Bridge Chip	IXP 200/250*
USB Support	6 USB 2.0 ports	Ethernet LAN	3Com 10/100
ATA Support	ATA100	Super I/O	Yes
Audio Support	AC'97, S/PDIF	High Speed Interconnect	A-Link

*The IXP250 has identical features to IXP200; plus it supports Wake On LAN (WOL), Desktop Management Interface (DMI), manage boot agent (MBA), and the Alert Standards Forum (ASF) mechanism.

Intel Workstation Chipsets for Pentium 4 and Xeon

Intel has developed several chipsets for workstations based on the Pentium 4 and Xeon processors. The following sections describe these chipsets in detail; Table 4.52 provides a quick reference to their features.

Table 4.52 Workstation Chipsets

Chipset	860	E7205	E7505
Code name	Colusa	Granite Bay	Placer
Date introduced	May 2001	Dec. 2002	Dec. 2002
Part number	82860	E7205	E7505
Bus speeds	400MHz	533/400MHz	533/400MHz
Supported processors	Xeon	Pentium 4 ⁵	Xeon 533MHz FSB and 512KB L2 cache ⁵
SMP (dual CPUs)	Yes (2)	No	Yes (2)
Memory type	4 RDRAM PC800 ¹	DDR200/266 SDRAM (unbuffered)	DDR200/266 (in pairs)
Parity/ECC	Both	Both	Both
Maximum memory	4GB (with two MRHR chips)	4GB	16GB
Memory banks	Up to 4 ³	Up to 4	Up to 6 (registered memory) or 4 (unbuffered memory)
PCI support	2.2	2.2	2.2
PCI speed/width	32-bit/33MHz ²	32-bit/33MHz	32-bit/33MHz ⁴
AGP slot	AGP 4x/2x	AGP8x-1x	AGP8x-1x
Integrated video	None	None	None
South Bridge (Hub)	ICH2	ICH4	ICH4

1. Up to eight on motherboards with MRHR chips

2. 64-bit 33/66MHz on motherboards with P64H chips

3. Two banks when MRHR chip is not present

4. 64-bit 33/66MHz and PCI-X on motherboards with P64H2 chips

5. Supports HT Technology

Intel 860

The Intel 860 is a high-performance chipset designed for the Socket 602 (Pentium 4–based) Xeon processors for DP workstations. The 860 uses the same ICH2 as the Intel 850 but uses a different MCH—the 82860, which supports one or two Socket 602 (“Foster”) Xeon processors. The other major features of the 82860 are similar to those of the 82850, including support for dual 400MHz RDRAM memory channels with a 3.2GBps bandwidth and a 400MHz system bus. The 82860 MCH also supports 1.5V AGP 4x video cards at a bandwidth exceeding 1GBps.

The 860 chipset uses a modular design, in which its two core chips can be supplemented by the 82860AA (P64H) 66MHz PCI Controller Hub and the 82803AA MRHR. The 82860AA supports 64-bit PCI slots at either 33MHz or 66MHz, and the 82803AA converts each RDRAM memory channel into two, which doubles memory capacity. Thus, whether a particular 860-based motherboard offers 64-bit or 66MHz PCI slots or dual-channel RDRAM memory depends on whether these supplemental chips are used in its design.

Intel E7205

The Intel E7205 chipset, known as Granite Bay during its development, is designed to support both workstation and high-performance PC applications. It supports DDR200/266 SDRAM modules with a system bus speed up to 533MHz and uses the ICH4 I/O controller hub, just as some versions of the 845 chipset do. However, the E7205 supports ECC and parity-checked memory for better system reliability and supports all standard-voltage speeds of AGP from 1x to 8x with an AGP Pro slot (nonstandard 3.5V versions of AGP once sold by some vendors such as 3dfx will not work). It supports hyper-threading for use with the 3.06GHz and faster Pentium 4 processors.

Table 4.53 Chipsets for Athlon 64

Vendor	Chipset Model	Opteron Support	Chipset Connection	South Bridge	Optional Chipset Components	Video Support
AMD	8151	Yes	HyperTransport (16b/800MHz CPU/NB) ²	8111	8131 PCI-X tunnel ³	AGP 8x
Ali	M1687	Yes	HyperTransport (16b/800MHz CPU/NB)	M1653 ⁴	—	AGP 8x
Ali	M1689	Yes	HyperTransport (16b/800MHz CPU/NB)	— ⁵	—	AGP 8x
VIA	K8T800 Pro ⁶	Yes	HyperTransport (16b/1GHz CPU/NB); Ultra V-Link (NB/SB)	VT8251 (also supports VT8237)	Velocity Gigabit Ethernet (PCI); VIA Vinyl Gold 8-channel audio	AGP 8x
VIA	K8T800	Yes	HyperTransport (16b/800MHz CPU/NP); 8x V-Link (NB/SB)	VT8237	Velocity Gigabit Ethernet (PCI); SATAlite SATA/SATA RAID 0+1; VIA Vinyl Gold 8-channel audio	AGP 8x
VIA	K8M800	Yes	HyperTransport (16b/800MHz CPU/NP); 8x V-Link (NB/SB)	VT8237	Velocity Gigabit Ethernet; SATAlite SATA/SATA RAID 0+1; VIA Vinyl Gold 8-channel audio	Integrated UniChrome Pro; AGP 8x

Intel E7505

The Intel E7505 chipset, known as Placer during its development, is in some ways an updated version of the 860 chipset, adding support for faster processors and more advanced hardware than the 860 offers.

The E7505 supports a system bus of up to 533MHz, matching the single or dual Xeon 533MHz FSB and 512KB L2 cache processors it supports; it also supports the HT Technology included in these processors. The E7505 supports pairs of DDR200/266 memory up to 16GB total, four times as much as the E7205 and the 860. It can use up to six registered or four unbuffered memory modules and supports ECC. Its Intel x4 single-device data correction (SDDC) can correct up to four errors per memory module for better system reliability.

Its AGP Pro slot supports all speeds of AGP from 1x to 8x (except for the nonstandard 3.5V versions of AGP once sold by some vendors), and it uses the ICH4 I/O controller hub. To achieve 66MHz/64-bit PCI and 133MHz PCI-X support, the E7505 can be used with up to three optional P64H2 (82870P2) chips, an improved version of the P64H chip that is an optional part of the 860 chipset.

Chipsets for Athlon 64

The Athlon 64 processor requires a new generation of chipsets, both to support its 64-bit processor architecture and to allow for integration of the memory controller into the processor (the memory controller has traditionally been located in the North Bridge chip or equivalent). As a consequence, some vendors do not use the term *North Bridge* to refer to the chipset component that connects the processor to AGP video.

AMD, VIA Technologies, NVIDIA, ATI, SiS, and ALi Corporation have developed chipsets for the Athlon 64. Table 4.53 lists the major features of the chipsets developed for the Athlon 64.

PCI-Express x1 Slots	ATA/Serial ATA Support	USB Support (# of Ports)	Audio	LAN
None	ATA-133	1.1/2.0 (6)	AC'97 2.2 (6-channel)	10/100 Ethernet

Table 4.53 Continued

Vendor	Chipset Model	Opteron Support	Chipset Connection	South Bridge	Optional Chipset Components	Video Support
SiS	760GX	No	HyperTransport (800MHz CPU-NB); MuTIOIOL 1G with HyperStreaming (NB/SB)	SiS966 (also compatible with SiS965/L)	—	AGP 8x; integrated Mirage 1
SiS	761	Yes ¹⁰	HyperTransport (1GHz CPU-NB); MuTIOIOL 1G with HyperStreaming (NB/SB)	SiS966 (also compatible with SiS965/L)	—	PCI-Express x16; integrated Mirage 3
SiS	761GX	No ¹²	HyperTransport (1GHz CPU-NB); MuTIOIOL 1G with HyperStreaming (NB/SB)	SiS966 (also compatible with SiS965/L)	—	PCI-Express x16; integrated Mirage 1
ATI	RS480	Yes	HyperTransport (16b/800MHz CPU/NB); A-Link II	SB400	—	PCI-Express 16x; Integrated Radeon 9100
ATI	RX480	Yes	HyperTransport (16b/800MHz CPU/NB); A-Link II	SB400	—	PCI-Express 16x

1. This chipset is also referred to as the 8000. 8151 is the AGP 3.0 Graphics Tunnel, which performs the graphics interface functions normally performed by the North Bridge in other chipset architectures.
2. 8b = 8-bit-wide HyperTransport connection; 16b = 16-bit-wide connection.
3. This component provides two independent PCI-X bus bridges and uses HyperTransport.
4. For features of the M1653, see Table 4.36.
5. Single-chip chipset.
6. Features asynchronous bus architecture, which locks AGP and PCI buses at the correct speeds when FSB or clock multipliers are adjusted for faster performance.
7. With VT8251 South Bridge.

The following sections cover these chipsets in greater detail.

AMD 8000 (8151) Chipset

The AMD 8000 is AMD's first chipset designed for the Athlon 64 and Opteron families. Its architecture is substantially different from the North Bridge/South Bridge or hub-based architectures we are familiar with from the chipsets designed to support Pentium II/III/4/Celeron and AMD Athlon/Athlon XP/Duron processors.

The AMD-8000 chipset is often referred to as the AMD-8151 because the AMD-8151 provides the connection between the Athlon 64 or Opteron processor and the AGP video slot—the task usually performed by the North Bridge or MCH hub in other chipsets. The name of the North Bridge or MCH hub chip is usually applied to the chipset. However, AMD refers to the AMD-8151 chip as the AGP Graphics Tunnel chip because its only task is to provide a high-speed connection to the AGP slot on the motherboard. The other components of the AMD-8000 chipset include the AMD-8111 HyperTransport I/O hub (South Bridge) and the AMD-8131 PCI-X Tunnel chip.

Due to delays in the development of the AMD-8151 AGP Graphics Tunnel chip, most vendors through late 2003 used the AMD-8111 HyperTransport I/O hub alone or along with the AMD-8131

PCI-Express x1 Slots	ATA/Serial ATA Support	USB Support (# of Ports)	Audio	LAN
4 ¹¹	ATA-133, SATA, RAID 0, 1, 0+1 ¹³	1.1/2.0 (10) ¹³	AC'97 2.3 (6-channel); Intel HDA	10/100/1000 ¹³ Ethernet; HomePNA 2.0
4 ¹¹	ATA-133, SATA, RAID 0, 1, 0+1 ¹³	1.1/2.0 (10) ¹³	AC'97 2.3 (6-channel); Intel HDA ¹³	10/100/1000 ¹³ Ethernet; HomePNA 2.0
4 ¹¹	ATA-133, SATA, RAID 0, 1, 0+1 ¹³	1.1/2.0 (10) ¹³	AC'97 2.3 (6-channel); Intel HDA ¹³	10/100/1000 ¹³ Ethernet; HomePNA 2.0
2	ATA-133, SATA, SATA RAID 0, 1, 0+1	1.1/2.0 (8)	AC'97 2.2 (6-channel); Intel HDA	—
2	ATA-133, SATA, SATA RAID 0, 1, 0+1	1.1/2.0 (8)	AC'97 2.2 (6-channel); Intel HDA	—

8. Also incorporates an integrated firewall.

9. With SiS965 South Bridge.

10. Supports Athlon 64FX, Opteron processors only.

11. With SiS966 South Bridge.

12. Supports Athlon 64FX processors only.

13. Officially supports Athlon 64 Socket 939; some vendors also use it for motherboards with Socket 940 Opteron processors.

HDA = High-Definition Audio (previously code named Azalia); supports CE-quality (192KHz, 32-bit multichannel) audio with support for Dolby Pro Logic IIx (7.1 surround) and multiple codecs operating independently.

PCI-X Tunnel chip to provide a mixture of PCI and PCI-X slots on motherboards optimized as servers. Some recent systems have incorporated the AMD-8151 chip to provide AGP video, but the AMD-8000 chipset continues to be used primarily as a workstation/server chipset instead of as a desktop chipset.

The AMD-8151 AGP Graphics tunnel has the following major features:

- Supports AGP 2.0/3.0 (AGP 1x–8x) graphics cards
- 16-bit up/down HyperTransport connection to the processor
- 8-bit up/down HyperTransport connection to downstream chips

The AMD-8111 HyperTransport I/O hub (South Bridge) chip's major features include

- PCI 2.2-compliant PCI bus (32-bit, 33MHz) for up to eight devices
- AC'97 2.2 audio (six-channel)
- Six USB 1.1/2.0 ports (three controllers)
- Two ATA/IDE host adapters supporting up to ATA-133 speeds
- RTC

- Low-pin-count (LPC) bus
- Integrated 10/100 Ethernet
- 8-bit up/down HyperTransport connection to upstream chips

The AMD-8131 HyperTransport PCI-X tunnel chip's major features include

- Two PCI-X bridges (A and B) supporting up to five PCI bus masters each
- PCI-X transfer rates up to 133MHz
- PCI 2.2 33MHz and 66MHz transfer rates
- Independent operational modes and transfer rates for each bridge
- 8-bit up/down HyperTransport connection to upstream and downstream chips

Figure 4.48 shows the architecture of the AMD-8151 chipset for Athlon 64.

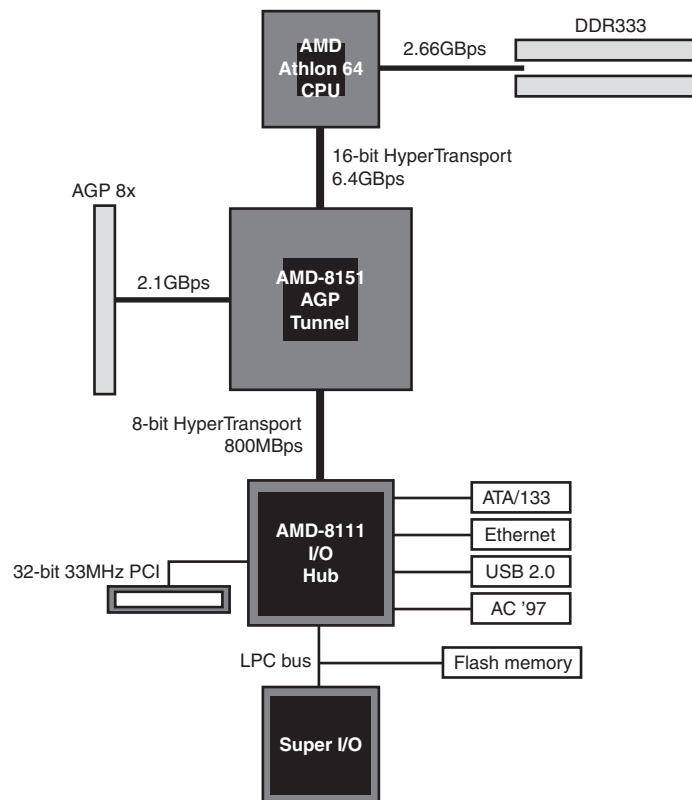

Figure 4.48 Block diagram of the AMD 8000 chipset for Athlon 64.

ALi Chipsets for Athlon 64

Although ALi has largely been absent from chipset development for the Athlon XP, it offers two chipsets for the Athlon 64 and Opteron processors: the M1687 and the M1689. The M1687 is a traditional two-chip design, whereas the M1689 is a one-chip design following in the footsteps of SiS and, more recently, NVIDIA.

ALi M1687

The M1687 uses the M1563 as its South Bridge, and the major features of this chipset are similar to the AMD-8151/AMD-8111 design:

- Support for AGP 2.0/3.0 (AGP 1x–8x) graphics cards
- 16-bit up/down HyperTransport connection between processor and M1687
- 8-bit up/down HyperTransport connection between M1687 North Bridge and M1563 South Bridge
- PCI 2.2–compliant PCI bus (32-bit, 33MHz) for up to six devices
- AC'97 2.2 audio (six-channel)
- Six USB 1.1/2.0 ports (three controllers)
- Two ATA/IDE host adapters supporting up to ATA-133 speeds
- RTC
- Low-pin-count (LPC) bus
- Integrated 10/100 Ethernet

Compared to the AMD-8151/AMD-8111, the major advantage of the ALi M1687 is the Secure Digital and Sony Memory Stick interfaces built in to the M1563.

ALi M1689

The ALi M1689 is a single-chip chipset for the Athlon 64 and Opteron processors, and it can also be used with the Mobile Athlon 64. It integrates several of the latest technologies, including Serial ATA, support for eight USB 2.0/1.1 ports, and AC'97 2.3 20-bit six-channel audio. Major features include

- AGP 1.5/3.0 (AGP 1x–8x)
- PCI 2.3 with support for up to seven bus masters
- Dual ATA-133 host adapters with support for 48-bit LBA drives
- Four USB host adapters and eight USB 1.1/2.0 ports
- 10/100 Ethernet
- AC'97 2.3 audio with 20-bit sampling
- Two Serial ATA host adapters

VIA Technologies Chipsets for Athlon 64

VIA Technologies has long been one of the leading developers of chipsets for AMD processors, and this pattern continues with the Athlon 64 and Opteron. VIA offers five chipsets for these processors:

- K8T800 Pro
- K8T800
- K8M800
- K8T890
- K8M890

The following sections cover these chipsets in more detail.

K8T800, K8T800 Pro, and K8M800

The K8T800 (originally known as the K8T400) was VIA's first chipset for the Athlon 64 and Opteron processors. It departs somewhat from the pattern established by AMD's and ALi's chipsets by using VIA's own 8x V-Link (533MBps) interconnect between the North and South Bridge chips instead of

HyperTransport (although HyperTransport is used, of course, to connect to the processor). The K8T800 uses the VT8237 South Bridge chip. Major features include

- HyperTransport 16-bit/800MHz link between the processor and North Bridge
- Support for AGP 4x/8x video cards
- PCI 2.23 with support for up to six bus masters
- Dual ATA-133 host adapters
- Eight USB 1.1/2.0 ports
- 10/100 Ethernet
- AC'97 5.1 audio
- Two Serial ATA/SATA RAID host adapters (RAID 0, 1, JBOD)

The K8T800 chipset family also includes the following optional chips, which can be used to add more features:

- SATAlite SATA (two additional ports, adding RAID 0+1)
- VPX2 expansion bridge (adds two PCI-X buses)
- VIA Vinyl Gold (7.1 surround sound via PCI bus)
- Gigabit Ethernet controller (via PCI bus)

The K8T800 Pro is based on the K8T800, but with the following improvements:

- HyperTransport 1GHz link between the processor and North Bridge
- Asynchronous operation of PCI and AGP slots
- Ultra V-Link (1GBps) connection between the North and South Bridges

The most significant of these features is the asynchronous operation of PCI and AGP slots. This feature enables the user to lock the frequency of these slots regardless of the processor bus and clock multiplier used by the processor, enabling more reliable overclocking. Many Athlon 64 chipsets lack this capability.

The K8M800 is based on the K8T800 but adds S3 UniChrome Pro integrated graphics. UniChrome Pro offers a 128-bit 2D/3D engine, dual pixel pipelines, hardware acceleration for MPEG-2 and MPEG-4 video, and support for HDTV up to 1080p and standard TV as well as LCD and CRT displays.

K8T890 and K8M890

The VIA K8T890 and K8M890 are the first Athlon 64/Opteron chipsets to support both the new PCI-Express x16 slot and the established AGP 8x slot for high-speed graphics. This support enables the user to upgrade to 64-bit computing now and upgrade to PCI-Express x16 at a later point. These chipsets use the 1GHz HyperTransport processor/NB connection and Ultra V-Link NB/SB connections.

These North Bridge chips actually have a 20-lane-wide PCI-Express interface, leaving 4 lanes available for PCI-Express x1 cards.

These chipsets are also designed to use the new VT8251 South Bridge, which includes several features that once required add-on chips:

- Four Serial ATA host adapters are included to support SATA RAID 0, 1, and 0+1.
- Support for Intel's new High-Definition Audio (HDA, formerly code named Azalia) standard. HDA provides Dolby Digital Iifx-compatible (7.1) surround sound and 24-bit/192KHz sampling rates for CE-quality sound.
- Two PCI-Express x1 slots, for a total of six possible (four connected to North Bridge and two to South Bridge).

Figure 4.49 displays the K8T890's block diagram.

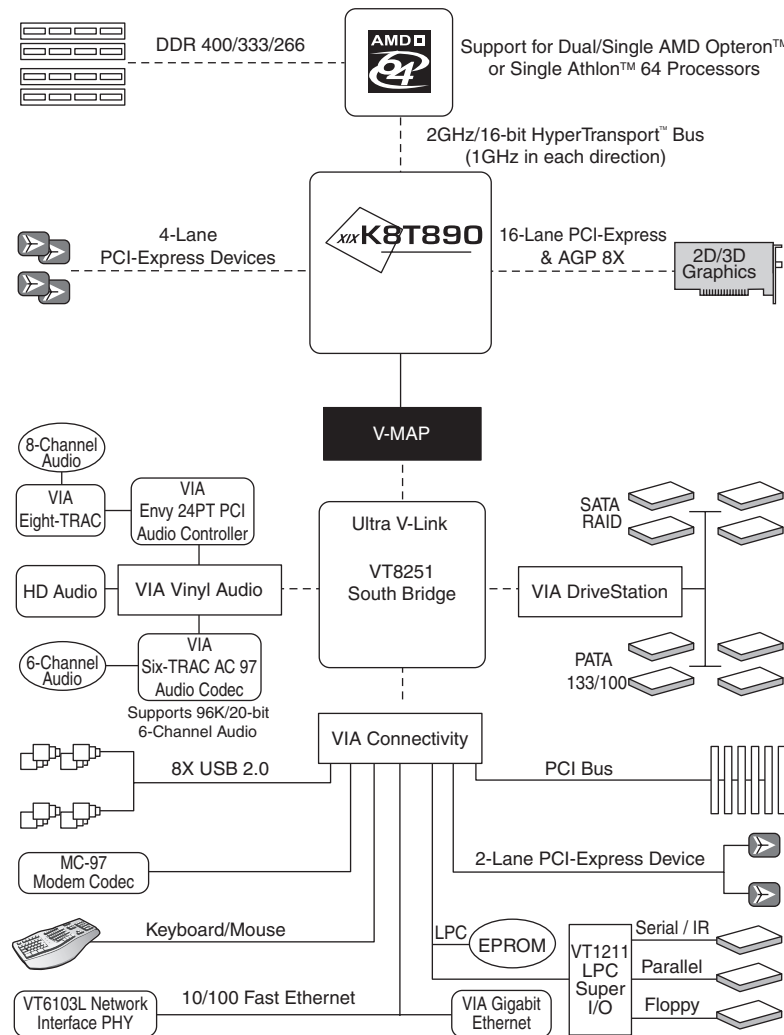

Figure 4.49 The VIA K8T890 is the first PCI-Express x16 chipset that also supports AGP 8x. It also supports two-lane and four-lane PCI-Express devices, HD Audio, and the 1GHz/each direction 16-bit HyperTransport bus.

The K8M890 adds integrated S3 Graphics DeltaChrome 2D/3D graphics with DirectX 9 graphics support to the features of the K8T890.

NVIDIA

NVIDIA offers four single-chip chipsets for the Athlon 64:

- nForce3 150
- nForce3 250
- nForce3 250Gb
- nForce3 250 Ultra

NVIDIA also offers two single-chip chipsets for the Opteron:

- nForce3 Pro 150
- nForce3 Pro 250

NVIDIA refers to these chips as *media and communications processors (MCPs)* because a single chip combines the functions of typical North and South Bridge chips. The following sections cover these chips in more detail.

nForce3 150 and nForce3 Pro 150

The NVIDIA nForce3 150 MCP was one of the first chipsets available for the Athlon 64 processor. Although it departs from the two-chip chipset standard used by most Athlon 64 chipsets by combining North Bridge and South Bridge functions, the nForce3 150 has a limited feature set. The short list of features reflects both this chipset's early development and its positioning as an entry-level chipset. The nForce3 150's major features include

- HyperTransport chipset-to-processor connection. However, it offers the standard 16-bit/800MHz speed only in the downstream (processor-to-chipset) direction. Data flowing from the chipset to the processor (upstream) runs in an 8-bit data path at only 600MHz.
- AGP 1x–8x video card support.
- Dual ATA-133 ATA/IDE hard disk host adapters.
- RAID 0, 1, and 0+1.
- AC'97 2.1 audio (six-channel) with 20-bit output and SPDIF support.
- Six USB 1.1/2.0 ports.
- 10/100 Ethernet.

The nForce3 Pro 150 has a similar feature set but is designed for use with the Opteron processor and NVIDIA's Quadro workstation graphics processor.

Note

Although some nForce3 150 and Pro 150 motherboards offer SATA and SATA RAID, this is *not* a function of the chipset; however, it can be performed with the use of an add-on SATA RAID chip.

nForce3 250, 250Gb, and 250 Ultra and nForce3 Professional 250

The nForce3 250 family of MCPs includes four members, all of which include several enhanced features over the original nForce3 150 and 150 Pro. The base model, nForce3 250, has the following major features:

- HyperTransport 16-bit/800MHz upstream/downstream connections between the processor and the MCP
- AGP 8x graphics card support
- Dual independent ATA-133 ATA/IDE host adapters with RAID 0, 1, and 0+1
- SATA and SATA RAID 0, 1, and 0+1
- Eight USB 1.1/2.0 ports
- 10/100 Ethernet with integrated hardware firewall
- AC'97 2.1 audio (six-channel) with 20-bit output and SPDIF support

The 250Gb model has the 250's features and adds support for 10/100/1000 Ethernet with integrated hardware firewall. The 250 Pro has the feature set of the 250 Gb but supports the Opteron workstation processor and the Athlon 64FX and is optimized to work with NVIDIA's Quadro workstation graphics processor.

The 250 Ultra model has the 250's features and adds support for both 10/100/1000 Ethernet with integrated hardware firewall and an Advanced 16-bit/1GHz HyperTransport upstream/downstream processor/MCP connection.

Note

The integrated firewall included in all nForce3 250-series chipsets is highly configurable and protects the computer as soon as it is turned on. Software firewalls, by contrast, cannot protect the computer until they are loaded, which is often late in the boot process.

SiS

SiS offers seven chipsets for 64-bit AMD processors. The following three chipsets require discrete graphics:

- 755
- 755FX
- 756

SiS also offers four chipsets with integrated graphics for AMD's 64-bit processors:

- 760
- 760GX
- 761
- 761GX

The following sections cover these chipsets in greater detail.

SiS755 and SiS755FX

The SiS 755 is the first SiS chipset to support the AMD Athlon 64, Opteron, and Athlon 64FX chipsets. It is a two-piece chipset that uses the SiS964 as its South Bridge component. Its major features include

- HyperTransport 16-bit/800MHz connection between the processor and North Bridge with HyperStreaming
- Support for AGP 8x graphics
- MuTIOL 1G connection between the North and South Bridge chips with HyperStreaming
- Dual ATA-133 host adapters
- Two Serial ATA ports with SATA RAID 0 and 1
- Eight USB 1.1/2.0 ports
- 10/100 Ethernet
- AC'97 version 2.3 8-channel audio

The 755FX North Bridge chip is pin-compatible with the 755; however, the preferred South Bridge chip for the 755FX—the SiS965—uses a larger 588-pin socket over the 505-pin socket used by the 964 family. The 755FX/965 chipset has the following major improvements over the 755/964 chipset:

- HyperTransport 16-bit/1GHz connection between the processor and North Bridge with HyperStreaming
- Support for two PCI-Express x1 slots
- Four Serial ATA ports with SATA RAID 0, 1, and 0+1 and JBOD (disk spanning)
- 10/100/1000 Ethernet

SiS756

The SiS756 chipset is designed specifically for use with the high-performance Athlon 64FX desktop processor. It is the first SiS chipset to support the PCI-Express x16 graphics interface. The SiS756 is usually paired with the SiS965 South Bridge. This chipset's major features include

- HyperTransport 16-bit/1GHz connection between the processor and North Bridge with HyperStreaming
- PCI-Express x16 graphics support
- Two PCI-Express x1 slots
- Eight USB 1.1/2.0 ports
- Four SATA ports with SATA RAID 0, 1, and 0+1 and JBOD
- 10/100/1000 Ethernet
- AC'97 2.3 eight-channel audio

Note

If the SiS965L is used in place of the SiS965, only two SATA ports with SATA RAID 0 and 1 are available. The other features are the same.

PCI-Express x16 replaces the AGP 8x video support found in earlier SiS chipsets.

Figure 4.50 shows the architecture of the SiS756 chipset with the SiS965 South Bridge.

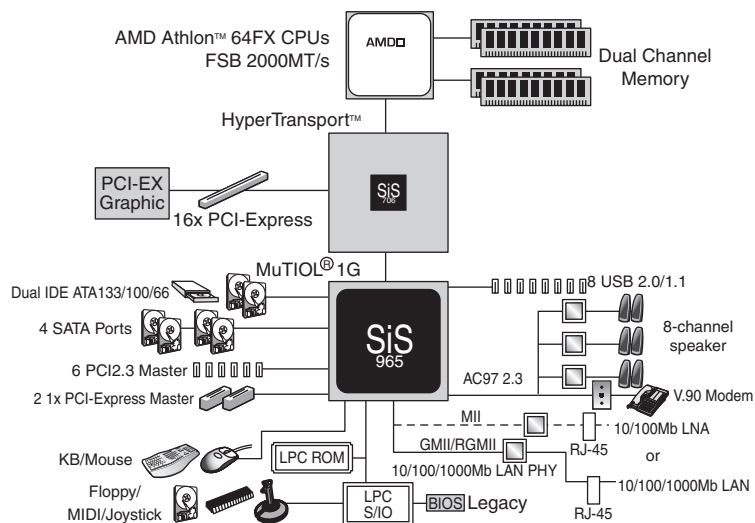

Figure 4.50 As with most Athlon 64 chipsets, the SiS756's North Bridge is used only for connection to discrete graphics (PCI-Express in this case), while a vast majority of the work is performed by the South Bridge.

SiS760 and SiS760GX

The SiS760 is the first SiS chipset with integrated graphics for the Athlon 64 and Opteron processors. Otherwise, its major features are similar to those of the SiS755. Both use the SiS964 South Bridge chip. Its features include

- HyperTransport 16-bit/800MHz connection between the processor and North Bridge with HyperStreaming

- Support for AGP 8x graphics
- MuTIOL 1G connection between the North and South Bridge chips with HyperStreaming
- Dual ATA-133 host adapters
- Two Serial ATA ports with SATA RAID 0 and 1
- Eight USB 1.1/2.0 ports
- 10/100 Ethernet
- AC'97 version 2.3 8-channel audio

The integrated SiS Mirage 2 (Ultra256) graphics features of the SiS760 include

- DirectX 8.1-compatible 3D graphics
- Dual-channel 256-bit 3D interface
- 128-bit 2D graphics
- Optional support for TV-out and a secondary CRT or LCD display
- Shared memory up to 128MB

The SiS760GX instead uses Mirage 1 single-channel (128-bit) graphics.

The SiS966 South Bridge is the preferred South Bridge for the SiS760GX, adding the following features:

- Four PCI-Express x1 slots
- SATA, SATA RAID 0, 1, and 0+1
- Ten USB 1.1/2.0 ports
- AC'97 2.3 audio with support for Intel's new High Definition Audio 7.1-channel audio
- 10/100/1000 Ethernet

SiS761 and SiS761GX

The SiS761 and SiS761GX integrated graphics chipsets support the high-performance Athlon 64FX processor family (the SiS761 can also be used with Opteron processors). Both chipsets use the SiS966 as their preferred South Bridge.

Note

The SiS966, SiS965, and SiS965L are pin compatible. Thus, some vendors might use the SiS965 or SiS965L in place of the SiS966.

Both the SiS761 and SiS761GX North Bridge chips have the following major features:

- HyperTransport 16-bit/800MHz connection between the processor and North Bridge with HyperStreaming
- Support for PCI-Express x16 graphics
- MuTIOL 1G connection between the North and South Bridge chips with HyperStreaming

When the SiS966 South Bridge chip is used, both chipsets also feature

- Four PCI-Express x1 slots
- SATA, SATA RAID 0, 1, and 0+1
- Ten USB 1.1/2.0 ports
- AC'97 2.3 six-channel audio with support for Intel's new High Definition Audio standard

Note

HDA, previously code named Azalia, provides Dolby Pro Logic IIx-compatible 7.1-channel CE-quality (192KHz, 32-bit multichannel) sound.

- 10/100/1000 Ethernet

The major difference between the SiS761GX and SiS761 is in the type of integrated graphics each North Bridge chip contains:

- The SiS761GX features conventional single-channel Mirage 1 integrated graphics.
- The SiS761 features dual-channel Mirage 3 integrated graphics.

ATI

ATI offers two two-piece chipsets for Athlon 64 processors: the RS480 (which includes Radeon 9200-equivalent DirectX 8.1 integrated graphics) and the RX480. Both chipsets use the SB400 (also known as the IXP400) South Bridge. Aside from the RS480's integrated graphics, both chipsets have the following major features:

- HyperTransport 16-bit/800MHz processor-to-North Bridge connection
- PCI-Express x16 graphics card support
- A-Link II connection between the North and South Bridge chips
- Four PCI-Express x1 slots
- Dual ATA-133 host adapters
- Four Serial ATA host adapters with SATA RAID 0, 1, and 0+1
- Eight USB 2.0 ports
- AC'97 2.3 six-channel audio with support for Intel's new HDA standard

Super I/O Chips

The third major chip seen on many PC motherboards is called the Super I/O chip. This is a chip that integrates devices formerly found on separate expansion cards in older systems.

Most Super I/O chips contain, at a minimum, the following components:

- Floppy controller
- One or two serial port controllers
- Parallel port controller

The floppy controllers on some Super I/O chips handle two drives, but some newer models can handle only one. Older systems often required a separate floppy controller card.

The serial port is another item that was formerly on one or more cards. Most of the better Super I/O chips implement a buffered serial port design known as a universal asynchronous receiver transmitter (UART), one for each port. Most mimic the standalone NS16550A high-speed UART, which was created by National Semiconductor. By putting the functions of these chips into the Super I/O chip, serial ports are essentially built in to the motherboard.

Virtually all Super I/O chips also include a high-speed multimode parallel port. Most recent models allow three modes: standard (bidirectional), Enhanced Parallel Port (EPP), and the Enhanced Capabilities Port (ECP) modes. The ECP mode is the fastest and most powerful, but selecting it also

causes your port to use an ISA bus 8-bit DMA channel—usually DMA channel 3. As long as you account for this and don't set anything else to that channel (such as a sound card and so on), the EPC mode parallel port should work fine. Some of the newer printers and scanners that connect to the system via the parallel port use ECP mode, which was invented by Hewlett-Packard.

The Super I/O chip can contain other components as well. For example, the Intel VC820 ATX motherboard uses an SMC (Standard Microsystems Corp.) LPC47M102 Super I/O chip. This chip incorporates the following functions:

- Floppy drive interface
- Two high-speed serial ports
- One ECP/EPP multimode parallel port
- 8042-style keyboard and mouse controller

This chip is typical of recent Super I/O chips in that it has an integrated keyboard and mouse controller. Older Super I/O chips lacked this feature.

One thing I've noticed over the years is that the role of the Super I/O chip has decreased more and more in the newer motherboards. This is primarily due to Intel and other chipset manufacturers moving Super I/O functions, such as IDE, directly into the chipset South Bridge or ICH component, where these devices can attach to the PCI bus (North/South Bridge architecture) or to the high-speed hub interface (hub architecture) rather than the ISA bus. One of the shortcomings of the Super I/O chip is that originally it was interfaced to the system via the ISA bus and shared all the speed and performance limitations of that 8MHz bus. Moving the IDE over to the PCI bus allowed higher-speed IDE drives to be developed that could transfer at the faster 33MHz PCI bus speed.

Newer Super I/O chips interface to the system via the LPC bus, an interface designed by Intel to offer a connection running at half the speed of PCI (up to about 16.67MBps) using only 13 signals. LPC is much more efficient than ISA.

Because high-speed devices such as IDE/ATA drives are now interfaced through the South Bridge chip, PCI bus, or hub architectures, nothing interfaced through the current Super I/O chips needs any greater bandwidth anyway.

As the chipset manufacturers combine more and more functions into the main chipset, and as USB- and IEEE 1394-based peripherals replace standard serial, parallel, and floppy controller-based devices, we will probably see the Super I/O chip continue to fade away in motherboard designs. More and more chipsets are combining the South Bridge and Super I/O chips into a single component (often referred to as a Super South Bridge chip) to save space and reduce parts count on the motherboard. Several of the SiS and NVIDIA chipsets even integrate all three chips (North Bridge, South Bridge, and Super I/O) into a single chip.

Motherboard CMOS RAM Addresses

In the original AT system, a Motorola 146818 chip was used as the RTC and Complementary Metal-Oxide Semiconductor (CMOS) RAM chip. This was a special chip that had a digital clock and stored 64 bytes of data. The clock used 14 bytes of RAM and an additional 50 more bytes of leftover RAM in which you could store anything you wanted. The designers of the IBM AT used these extra 50 bytes to store the system configuration.

Modern PC systems don't use the Motorola chip; instead, they incorporate the functions of this chip into the motherboard chipset (South Bridge) or Super I/O chip, or they use a special battery and NVRAM module from companies such as Dallas or Benchmarq.

- For more details on the CMOS RAM addresses, see "Motherboard CMOS RAM Addresses," p. 425.

Motherboard Connectors

There are a variety of connectors on a modern motherboard. Figure 4.51 shows connector locations on a typical motherboard. Several of these connectors, such as power supply connectors, serial and parallel ports, and keyboard/mouse connectors, are covered in other chapters.

This section has figures and tables showing the configurations and pinouts of most of the other interface and I/O connectors you will find.

- ▶▶ See "AT Power Supply Connectors," p. 1164.
- ▶▶ See "Serial Ports," p. 997, and "Parallel Ports," p. 1007.
- ▶▶ See "Keyboard/Mouse Interface Connectors," p. 1031.
- ▶▶ See "Universal Serial Bus," p. 983.
- ▶▶ See "Overview of the IDE Interface," p. 532.

Figure 4.51 Typical motherboard connectors.

One of the biggest problems many people overlook when building and upgrading systems is the front panel connections. Connectors that don't match between the motherboard and chassis are one of the small but frustrating things that can be problematic in an otherwise smooth upgrade or system build. Having dependable standards for these connections would help, but unfortunately no official standard for the front panel connectors existed until October 2000, when Intel published the "Front

Panel I/O Connectivity Design Guide.” This guide can be found, along with the motherboard form factor specifications, at www.formfactors.org.

Before this standard was published, no official standard existed (and anarchy ruled). In addition, even though most chassis gave you individual tiny connectors for each function, some of the bigger system builders (for example, Dell, Gateway, MicronPC [now MPC], and so on) began using specialized inline or dual-row header connectors so they could build systems more quickly and efficiently.

Coincidentally, most of those vendors used Intel boards, hence Intel’s development of a standard.

The front panel guide details a 10-pin keyed header connector for the main front panel switch/LED functions, as well as a 10-pin keyed USB header, a 10-pin keyed IEEE 1394 (FireWire/i.LINK) header, a 10-pin keyed audio header, and a 6-pin keyed IR header. The pinouts and configurations of these and other motherboard-based connectors are shown in the following figures and tables. Figure 4.52 details the front panel switch/LED header connector.

Figure 4.52 Front panel switch/LED header connector.

The pinout of the standard front panel switch/LED connector is shown in Table 4.54.

Table 4.54 Front Panel Switch/LED Connector Pinout

Signal	Description	Pin	Pin	Signal	Description
Hard Disk Activity LED			Power/Sleep/Message LED		
HD_LED+	Hard disk LED+	1	2	PWR_LED GRN+	Single-color LED+
HD_LED-	Hard disk LED-	3	4	PWR_LED_YEL+	Dual-color LED+
Reset Button			Power On/Off Button		
GND	Ground	5	6	FP_PWR	Power switch
FP_RESET	Reset switch	7	8	GND	Ground
Power			Not Connected		
+5V	Power	9	10	N/C	Not connected

Some chassis provide a single 10-pin header connector for the front panel switch/LED connections, but most provide individual 2-pin connectors for the various functions. If 2-pin connectors are used, they are connected as shown in Figure 4.53.

Figure 4.53 Standard front panel switch/LED connections using 2-pin connectors.

The 2-pin connections to a standard 10-pin front panel switch/LED connector are shown in Table 4.55.

Table 4.55 Front Panel Switch/LED Connections Using Multiple Connectors

Connector	Pins	Description
A	1 and 3	Hard disk activity LED
B	2 and 4	Power LED
C	5 and 7	Reset switch
D	6 and 8	Power switch

A chassis can use either a single-color or dual-color LED for the Power LED function. A dual-color LED can provide more information about the various power and message states the system might be in, including power on/off, sleep, and message-waiting indications. Table 4.56 shows the possible states and meanings for both single- and dual-color power LEDs.

Table 4.56 Power LED Indications

LED Type	LED State	Description	ACPI State
Single-color	Off	Power off or sleeping	S1, S3, S5
	Steady green	Running	S0
	Blinking green	Running, message waiting	S0
Dual-color	Off	Power off	S5
	Steady green	Running	S0
	Blinking green	Running, message waiting	S0
	Steady yellow	Sleeping	S1, S3
	Blinking yellow	Sleeping, message waiting	S1, S3

Many motherboards do not follow the industry-standard guidelines for front panel switch/LED connections, and many use alternative designs instead, one of which is shown in Figure 4.54.

Figure 4.54 Alternative front panel switch/LED connector configuration.

Some of Intel's older motherboards, as well as those made by other motherboard manufacturers, used a single-row pin header connector for the front panel connections, as shown in Figure 4.55.

Figure 4.55 Alternative single-row front panel connector configuration.

Table 4.57 shows the designations for the front panel motherboard connectors used on some motherboards.

Table 4.57 Alternative Single-Row Front Panel Connector Pinout

Connector	Pin	Signal Name
Speaker	27	SPKR
	26	PIEZO_IN
	25	Key (no pin)
	24	GND
Reset	23	FP_RESET
	22	GND
None	21	Key (no pin)
Sleep/Power LED	20	PWR_LED1 (green)
	19	Key (no pin)
	18	PWR_LED2 (yellow)
None	17	Key (no pin)
Hard Drive LED	16	HD_LED+
	15	HD_LED-
	14	Key (no pin)
	13	HD_LED+
None	12	Key (no pin)
IrDA	11	+5V
	10	Ir_TX
	9	GND
	8	Ir_RX
	7	Key (no pin)
	6	+5V
None	5	Key (no pin)
Sleep/Resume	4	GND
	3	SLEEP_REQ
Power On	2	GND
	1	SW_ON

To adapt the connectors in your chassis to those on your motherboard, in some cases you might need to change the connector ends by removing the terminals and reinserting them into different positions. For example, I had a chassis that used a three-pin power LED connection, while the motherboard only had a two-pin connection. I had to remove one of the terminals, reinsert it into the middle position on the three-pin connector, and then plug the connector into the motherboard so that two pins were mated and the third empty position was hanging off the end of the connector. Fortunately, the terminals are easy to remove by merely lifting a latch on the side of the connector and then sliding the terminal and wire back out. When the terminal is inserted, the latch automatically grabs the terminal and locks it into position.

Most motherboards include front panel USB connectors, which are designed to be connected to front-mounted USB connectors in the chassis. The standard uses a single 10-pin keyed connector to provide two USB connections. The pinout of a standard dual USB motherboard header connector is shown in Figure 4.56 and Table 4.58.

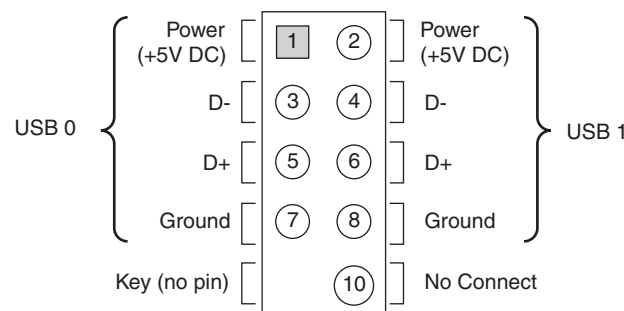

Figure 4.56 Front panel dual-USB header connector configuration.

Table 4.58 Front Panel USB Header Connector Pinout

Description	Signal Names	Pin	Pin	Signal Names	Description
Port 0 +5V	USB0_PWR	1	2	USB1_PWR	Port 1 +5V
Port 0 Data-	USB_D0-	3	4	USB_D1-	Port 1 Data-
Port 0 Data+	USB_D0+	5	6	USB_D1+	Port 1 Data+
Port 0 Ground	GND	7	8	GND	Port 1 Ground
No pin	Key	9	10	NC/Shield	No Connect/Shield

Many chassis includes multiple inline connectors for the dual-USB-to-front panel connection, instead of a single keyed connector. An example of this is shown in Figure 4.57.

Using the multiple individual connectors shown in the previous figure, you would have to plug each individual connector into the proper pin. Some internal chassis USB cables use two 5-pin inline connectors, in which case you just need to ensure that you don't put them on backward. Consult your motherboard and chassis manual for more information if you are unsure about your particular connections.

Caution

If your chassis uses multiple individual non-keyed connections, you must be sure to connect them properly to the connector on the motherboard. If you connect them improperly, you can cause a short circuit to occur that can damage the motherboard or any USB peripherals you plug into the front panel connectors. Higher-quality motherboards usually have self-healing fuses on the power signals, which can prevent damage if such a situation occurs.

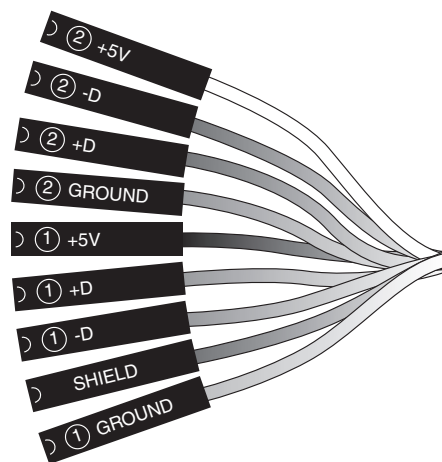

Figure 4.57 Front panel USB cable using multiple individual non-keyed connectors.

Although IEEE 1394 (FireWire/i.LINK) is not found on most motherboards, many boards do incorporate this feature or offer it as an option. FireWire can also be added via an expansion card, and many of the cards have header connectors for front panel connections similar to that found on a motherboard. Figure 4.58 and Table 4.59 show the pinout of the industry-standard FireWire header connector.

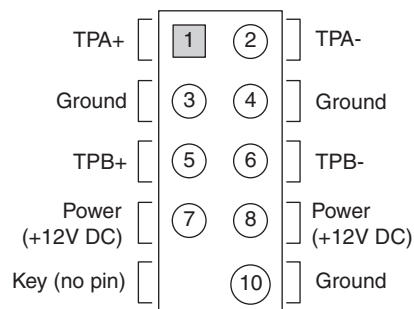

Figure 4.58 Front panel IEEE 1394 (FireWire/i.LINK) header connector configuration.

Table 4.59 Front Panel IEEE 1394 (FireWire/i.LINK) Connector Pinout

Pin	Signal Name	Pin	Signal Name
TPA+	1	2	TPA-
Ground	3	4	Ground
TPB+	5	6	TPB-
+12V (Fused)	7	8	+12V (Fused)
Key (no pin)	9	10	Ground

Note that the front panel FireWire header connector has the same physical configuration and keying as a front panel USB connector. This is unfortunate because it enables a USB front panel cable to be plugged into a FireWire connector, and vice versa. Either situation could cause a short circuit.

Caution

You must not plug a front panel USB cable into a FireWire header connector, or a front panel FireWire cable into a USB header connector. Doing so causes a short circuit that can damage the motherboard, as well as any peripherals you plug into the front panel connectors. Higher-quality motherboards usually have self-healing fuses on the power signals, which can prevent damage if such a situation occurs.

Motherboards that have integrated audio hardware usually feature a front panel audio header connector. The pinout of the industry-standard front panel audio header connector is shown in Figure 4.59 and Table 4.60.

Figure 4.59 Front panel audio header connector configuration.

Table 4.60 Front Panel Audio Connector Pinout

Description	Signal Name	Pin	Pin	Signal Name	Description
Microphone input	AUD_MIC	1	2	AUD_GND	Analog audio ground
Microphone power	AUD_MIC_BIAS	3	4	AUD_VCC	Filtered +5V for analog audio
Right channel audio	AUD_FPOUT_R	5	6	AUD_RET_R	Right channel return
Ground or headphone amplifier control	GND/HP_ON	7	8	KEY	No pin
Left channel audio	AUD_FPOUT_L	9	10	AUD_RET_L	Left channel return

Some motherboards include an infrared data connector that connects to an infrared optical transceiver on the chassis front panel. This enables communicating via infrared to cell phones, PDAs, laptops, printers, or other IrDA devices. The industry-standard pinout for IrDA connections on a motherboard are shown in Figure 4.60 and Table 4.61.

Figure 4.60 Infrared data front panel header connector configuration.

Other miscellaneous connectors might appear on motherboards as well; several are shown in Tables 4.62–4.70.

Table 4.61 Infrared Data Front Panel Connector Pinout

Description	Signal	Pin	Pin	Signal	Description

Pin	Signal Name	Pin	Signal Name
1	Left Line In	3	Ground
2	Ground	4	Right Line In (monaural)

Note

Some boards have a board-mounted piezo speaker. It is enabled by placing a jumper over pins 3 and 4, which routes the speaker output to the board-mounted speaker. Removing the jumper enables a conventional speaker to be plugged in.

Most modern motherboards have three or four fan connectors for use with the processor fan, rear chassis fan, front chassis fan, and voltage regulator (power) fan (see Table 4.71). They all generally use the same 3-pin connector, with the third pin providing a tachometer signal for optional speed monitoring. If the motherboard is capable of monitoring the fan speed, it can sound an alarm when the fans begin to slow down due to bearing failure or wear. The alarm sound can vary, but it normally comes from the internal speaker and might be an ambulance siren-type sound.

Table 4.71 Fan Power Connectors

Pin	Signal Name
1	Ground
2	+12V
3	Sense tachometer

Caution

Do not place a jumper on this connector; serious board damage will result if the 12V is shorted to ground.

System Bus Types, Functions, and Features

The heart of any motherboard is the various buses that carry signals between the components. A *bus* is a common pathway across which data can travel within a computer. This pathway is used for communication and can be established between two or more computer elements.

The PC has a hierarchy of different buses. Most modern PCs have at least three buses; some have four or more. They are hierarchical because each slower bus is connected to the faster one above it. Each device in the system is connected to one of the buses, and some devices (primarily the chipset) act as bridges between the various buses.

The main buses in a modern system are as follows:

- **Processor bus.** Also called the front-side bus (FSB), this is the highest-speed bus in the system and is at the core of the chipset and motherboard. This bus is used primarily by the processor to pass information to and from cache or main memory and the North Bridge of the chipset. The processor bus in a modern system runs at 66MHz, 100MHz, 133MHz, 200MHz, 266MHz, 400MHz, 533MHz, or 800MHz and is normally 64 bits (8 bytes) wide.
- **AGP bus.** This is a high-speed 32-bit bus specifically for a video card. It runs at 66MHz (AGP 1x), 133MHz (AGP 2x), 266MHz (AGP 4x), or 533MHz (AGP 8x), which allows for a bandwidth of up to 2133MBps. It is connected to the North Bridge or Memory Controller Hub of the chipset and is manifested as a single AGP slot in systems that support it.
- **PCI bus.** This is usually a 33MHz 32-bit bus found in virtually all newer 486 systems and Pentium and higher processor systems. Some newer systems include an optional 66MHz 64-bit version—mostly workstations or server-class systems. This bus is generated by either the chipset North Bridge in North/South Bridge chipsets or the I/O Controller Hub in chipsets using hub architecture. This bus is manifested in the system as a collection of 32-bit slots, normally white in color and numbering from four to six on most motherboards. High-speed peripherals, such as SCSI adapters, network cards, video cards, and more, can be plugged into PCI bus slots. PCI-X and PCI-Express are faster developments of the PCI bus. PCI-Express motherboards and systems began to appear in mid-2004.
- **ISA bus.** This is an 8MHz 16-bit bus that has disappeared from recent systems after first appearing in the original PC in 8-bit, 5MHz form and in the 1984 IBM AT in full 16-bit 8MHz form. It is a very slow-speed bus, but it was ideal for certain slow-speed or older peripherals. It has been used in the past for plug-in modems, sound cards, and various other low-speed peripherals. The ISA bus is created by the South Bridge part of the motherboard chipset, which acts as the ISA bus controller and the interface between the ISA bus and the faster PCI bus above it. The Super I/O chip usually was connected to the ISA bus on systems that included ISA slots.

Some newer motherboards feature a special connector called an Audio Modem Riser (AMR) or a Communications and Networking Riser (CNR). These are dedicated connectors for cards that are specific to the motherboard design to offer communications and networking options. They are *not* designed to be general-purpose bus interfaces, and few cards for these connectors are offered on the open market. Usually, they're offered only as an option with a given motherboard. They are designed such that a motherboard manufacturer can easily offer its boards in versions with and without communications options, without having to reserve space on the board for optional chips. Normal network and modem options offered publicly, for the most part, will still be PCI based because the AMR/CNR connection is somewhat motherboard specific. Figure 4.61 compares these connectors, and Figure 4.62 compares typical AMR and CNR riser cards.

Several hidden buses exist on modern motherboards—buses that don't manifest themselves in visible slots or connectors. I'm talking about buses designed to interface chipset components, such as the Hub Interface and the LPC bus. The Hub Interface is a quad-clocked (4x) 66MHz 8-bit bus that carries data between the MCH and ICH in hub architecture chipsets made by Intel. It operates at a bandwidth of 266MBps and was designed as a chipset component connection that is faster than PCI and yet uses fewer signals for a lower-cost design. Some recent workstation/server chipsets and the latest 9xx-series desktop computer chipsets from Intel use faster versions of the hub interface. The most recent chipsets from major third-party vendors also bypass the PCI bus with direct high-speed connections between chipset components.

◀◀ See "High-Speed North-South Bridge Connections," p. 246.

Figure 4.61 The AMR slot (top left) and CNR slot (top center) compared to PCI slots. When the AMR slot is used, the PCI slot paired with it cannot be used.

Figure 4.62 A typical AMR riser card (right) with connections for soft modem and 10/100 Ethernet ports. A typical CNR riser card (left) with analog and SPDIF digital audio ports.

In a similar fashion, the LPC bus is a 4-bit bus that has a maximum bandwidth of 16.67MBps; it was designed as an economical onboard replacement for the ISA bus. In systems that use LPC, it typically is used to connect Super I/O chip or motherboard ROM BIOS components to the main chipset. LPC is faster than ISA and yet uses far fewer pins and enables ISA to be eliminated from the board entirely.

The system chipset is the conductor that controls the orchestra of system components, enabling each to have its turn on its respective buses. Table 4.72 shows the widths, speeds, data cycles, and overall bandwidth of virtually all PC buses.

Table 4.72 Bandwidth (in MBps) and Detailed Comparison of Most PC Buses and Interfaces

Bus Type	Bus Width (Bits)	Bus Speed (MHz)	Data Cycles per Clock	Bandwidth (MBps)
8-bit ISA (PC/XT)	8	4.77	1/2	2.39

533MHz Pentium 4 FSB	64	133	4	4266
800MHz Pentium 4 FSB	64	200	4	6400
1066MHz Pentium 4 FSB	64	267	4	8533
266MHz Itanium FSB	64	133	2	2133
400MHz Itanium 2 FSB	128	100	4	6400

Note: ISA, EISA, VL-Bus, and MCA are no longer used in current motherboard designs.

MBps = Megabytes per second

ISA = Industry Standard Architecture, also known as the PC/XT (8-bit) or AT-Bus (16-bit)

LPC = Low Pin Count bus

DD Floppy = Double Density (360/720KB) Floppy

HD Floppy = High Density (1.2/1.44MB) Floppy

ED Floppy = Extra-high Density (2.88MB) Floppy

EISA = Extended Industry Standard Architecture (32-bit ISA)

VL-Bus = VESA (Video Electronics Standards Association) Local Bus (ISA extension)

MCA = MicroChannel Architecture (IBM PS/2 systems)

PC-Card = 16-bit PCMCIA (Personal Computer Memory Card International Association) interface

CardBus = 32-bit PC-Card

Hub Interface = Intel 8xx chipset bus

HyperTransport = AMD chipset bus

V-Link = VIA Technologies chipset bus

MuTIOL = Silicon Integrated System chipset bus

PCI = Peripheral Component Interconnect

AGP = Accelerated Graphics Port

RS-232 = Standard Serial port, 115.2Kbps

RS-232 HS = High Speed Serial port, 230.4Kbps

IEEE 1284 Parallel = Standard Bidirectional Parallel Port

IEEE 1284 EPP/ECP = Enhanced Parallel Port/Extended Capabilities Port

USB = Universal serial bus

IEEE 1394 = FireWire, also called i.LINK

ATA PIO = AT Attachment (also known as IDE) Programmed I/O

ATA-UDMA = AT Attachment Ultra DMA

SCSI = Small computer system interface

FPM = Fast Page Mode, based on X-3-3-3 (1/3 max) burst mode timing on a 66MHz bus

EDO = Extended Data Out, based on X-2-2-2 (1/2 max) burst mode timing on a 66MHz bus

SDRAM = Synchronous dynamic RAM

RDRAM = Rambus dynamic RAM

DDR = Double data rate SDRAM

DDR2 = Next-generation DDR

CPU FSB = Processor front-side bus

Note that many of the buses use multiple data cycles (transfers) per clock cycle to achieve greater performance. Therefore, the data transfer rate is higher than it would seem for a given clock rate, which allows for an easy way to take an existing bus and make it go faster in a backward-compatible way.

The following sections discuss the processor and other subset buses in the system and the main I/O buses mentioned in the previous table.

The Processor Bus (Front-Side Bus)

The processor bus (also called the front-side bus or FSB) is the communication pathway between the CPU and motherboard chipset, more specifically the North Bridge or Memory Controller Hub. This bus runs at the full motherboard speed—typically between 66MHz and 800MHz in modern systems, depending on the particular board and chipset design. This same bus also transfers data between the CPU and an external (L2) memory cache on Socket-7 (Pentium class) systems. Figure 4.63 shows how this bus fits into a typical Socket 7 PC system.

Figure 4.63 also shows where and how the other main buses, such as the PCI and ISA buses, fit into the system. As you can see, there is clearly a three-tier architecture with the fastest CPU bus on top, the PCI bus next, and the ISA bus at the bottom. Various components in the system are connected to one of these three main buses.

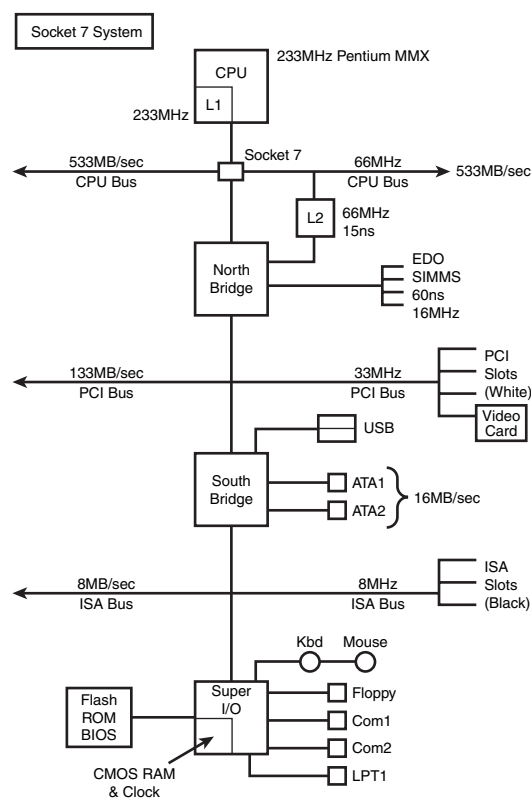

Figure 4.63 Typical Socket 7 (Pentium class) system architecture.

Socket 7 systems have an external (L2) cache for the CPU; the L2 cache is mounted on the motherboard and connected to the main processor bus that runs at the motherboard speed (usually between 66MHz and 100MHz). Thus, as the Socket 7 processors became available in faster and faster versions (through increasing the clock multiplier in the chip), the L2 cache unfortunately remained stuck on the motherboard running at the relatively slow (by comparison) motherboard speed. For example, the fastest Intel Socket 7 systems ran the CPU at 233MHz, which was 3.5x the CPU bus speed of 66MHz. Therefore, the L2 cache ran at only 66MHz. The fastest Socket 7 systems used the AMD K6-2 550 processor, which ran at 550MHz—5.5x a CPU bus speed of 100MHz. In those systems, the L2 cache ran at only 100MHz.

The problem of the slow L2 cache was first solved in the P6 class processors, such as the Pentium Pro, Pentium II, Celeron, Pentium III, and AMD Athlon and Duron. These processors used either Socket 8, Slot 1, Slot 2, Slot A, Socket A, or Socket 370. They moved the L2 cache off the motherboard and directly onto the CPU and connected it to the CPU via an on-chip back-side bus. Because the L2 cache bus was called the back-side bus, some in the industry began calling the main CPU bus the front-side bus. I still usually refer to it simply as the CPU bus.

By incorporating the L2 cache into the CPU, it can run at speeds up to the same speed as the processor itself. Most processors now incorporate the L2 cache directly on the CPU die, so the L2 cache runs at the same speed as the rest of the CPU. Others (mostly older versions) used separate die for the cache integrated into the CPU package, which ran the L2 cache at some lower multiple (one-half, two-fifth, or one-third) of the main CPU. Even if the L2 ran at half or one-third of the processor speed, it still was significantly faster than the motherboard-bound cache on the Socket 7 systems.

In a Slot-1 type system the L2 cache is built in to the CPU but running at only half the processor speed. This would also be the same for systems using Slot A. The CPU bus speed increased from 66MHz (used primarily in Socket 7 systems) to 100MHz, enabling a bandwidth of 800MBps. Note that most of these systems included AGP support. Basic AGP was 66MHz (twice the speed of PCI), but most of these systems incorporated AGP 2x, which operated at twice the speed of standard AGP and enabled a bandwidth of 533MBps. These systems also typically used PC-100 SDRAM DIMMs, which have a bandwidth of 800MBps, matching the processor bus bandwidth for the best performance.

Slot 1 was dropped in favor of Socket 370 for the Pentium III and Celeron systems. This was mainly because these newer processors incorporated the L2 cache directly into the CPU die (running at the full-core speed of the processor) and an expensive cartridge with multiple chips was no longer necessary. At the same time, processor bus speeds increased to 133MHz, which enabled a throughput of 1066MBps. Figure 4.64 shows a typical Socket 370 system design. AGP speed was also increased to AGP 4x, with a bandwidth of 1066MBps.

Note the use of what Intel calls “hub architecture” instead of the older North/South Bridge design. This moves the main connection between the chipset components to a separate 266MBps hub interface (which has twice the throughput of PCI) and enables PCI devices to use the full bandwidth of PCI without fighting for bandwidth with a South Bridge. Also note that the flash ROM BIOS chip is now referred to as a Firmware Hub and is connected to the system via the LPC bus instead of via the Super I/O chip as in older North/South Bridge designs. The ISA bus is no longer used in most of these systems, and the Super I/O is connected via the LPC bus instead of ISA. The Super I/O chip also can easily be eliminated in these designs. This is commonly referred to as a *legacy-free* system because the ports supplied by the Super I/O chip are now known as *legacy* ports. Devices that would have used legacy ports must then be connected to the system via USB instead, and such systems would feature two USB controllers, with up to four total ports (more can be added by attaching USB hubs).

AMD processor systems adopted a Socket A design, which is similar to Socket 370 except it uses faster processor and memory buses. Although early versions retained the older North/South Bridge design, more recent versions use a design similar to Intel’s hub architecture. Note the high-speed CPU bus running up to 333MHz (2667MBps throughput) and the use of DDR SDRAM DIMM modules that support a matching bandwidth of 2667MBps. It is always best for performance when the bandwidth of memory matches that of the processor. Finally, note how most of the South Bridge components include functions otherwise found in Super I/O chips; when these functions are included the chip is called a Super South Bridge.

The Pentium 4 uses a Socket 423 or Socket 478 design with hub architecture (see Figure 4.65). This design is most notable for including a 400MHz, 533MHz, or 800MHz CPU bus with a bandwidth of 3200MBps, 4266MBps, or 6400MBps. The 533MHz and 800MHz models are currently faster than anything else on the market. In this example, note the use of dual-channel PC3200 (DDR400) SDRAM. A single PC-3200 DIMM has a bandwidth of 3200MBps, but when running dual-channel (identical pairs

of memory) memory, it has a bandwidth of 6400MBps—which matches the bandwidth of the 800MHz CPU bus models of the Pentium 4 for best performance. Processors with the 533MHz CPU bus can use pairs of PC2100 (DDR266) or PC2700 (DDR333) memory modules in dual channel mode to match the 4266MBps throughput of this memory bus. It is always best when the throughput of the memory bus matches that of the processor bus.

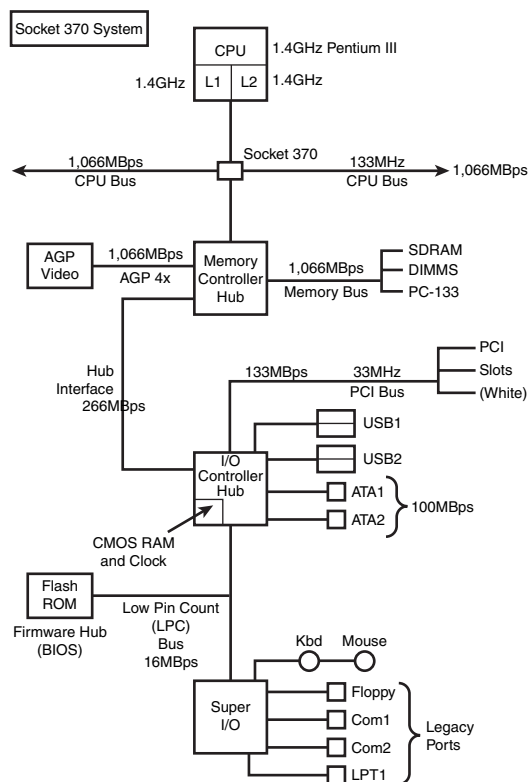

Figure 4.64 Typical Socket 370 (Pentium III/Celeron class) system architecture.

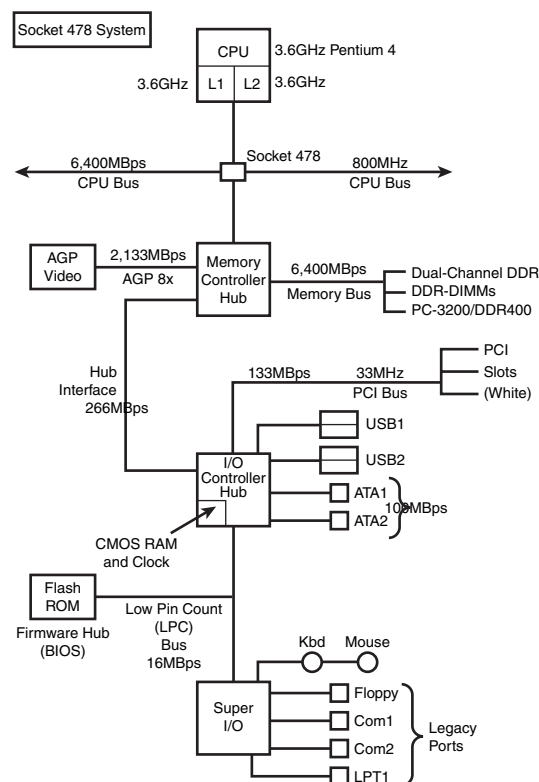

Figure 4.65 Typical Socket 478 (Pentium 4) system architecture.

The Athlon 64 uses the high-speed HyperTransport architecture to connect the North Bridge or AGP Graphics Tunnel chip to the processor (Socket 754, 939, or 940). Most Athlon 64 chipsets use the 16-bit/800MHz version, but the latest chipsets designed for the new Socket 939 Athlon 64 FX-53 use the faster 16-bit/1GHz version to support faster DDR-2 memory.

However, the Athlon 64's most significant departure from conventional computer architecture is the location of the memory controller. Rather than being located in the North Bridge/MCH/GMCH chip, the Athlon 64/FX/Opteron architecture places the memory controller in the processor itself. This eliminates slow-downs caused by the use of an external memory controller and helps boost performance.

One drawback to the design, however, is that new memory technologies, such as DDR-2, require that the processor itself be redesigned.

Figure 4.66 illustrates an Athlon 64 FX-53–based system that uses the new PCI-Express x1 and PCI-Express x16 expansion slot designs.

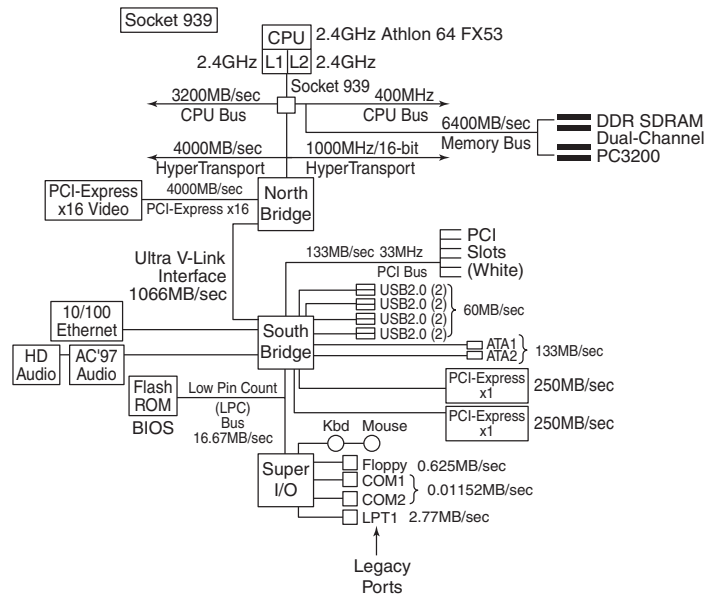

Figure 4.66 Typical Socket 939 (Athlon 64 FX-53) system architecture using PCI-Express slots.

Because the purpose of the processor bus is to get information to and from the CPU at the fastest possible speed, this bus typically operates at a rate faster than any other bus in the system. The bus consists of electrical circuits for data, addresses (the address bus, which is discussed in the following section), and control purposes. Most processors since the original Pentium have a 64-bit data bus, so they transfer 64 bits (8 bytes) at a time over the CPU bus.

The processor bus operates at the same base clock rate as the CPU does externally. This can be misleading because most CPUs these days run at a higher clock rate internally than they do externally. For example, an AMD Athlon 64 3800+ system has a processor running at 2.4GHz internally but only 400MHz externally, whereas a Pentium 4 3.4GHz runs at 3.4GHz internally but only 800MHz externally. In newer systems, the actual processor speed is some multiple (2x, 2.5x, 3x, and higher) of the processor bus.

◀◀ See "Processor Speed Ratings," p. 53.

The processor bus is tied to the external processor pin connections and can transfer 1 bit of data per data line every cycle. Most modern processors transfer 64 bits (8 bytes) of data at a time.

To determine the transfer rate for the processor bus, you multiply the data width (64 bits or 8 bytes for a Celeron/Pentium III/4 or Athlon/Duron/Athlon XP/Athlon 64) by the clock speed of the bus (the same as the base or unmultiplied clock speed of the CPU).

For example, if you are using a Pentium 4 3.6GHz processor that runs on an 800MHz processor bus, you have a maximum instantaneous transfer rate of roughly 6400MBps. You get this result by using the following formula:

$$800\text{MHz} \times 8 \text{ bytes (64 bits)} = 6400\text{MBps}$$

With slower versions of the Pentium 4, you get either

$$533.33\text{MHz} \times 8 \text{ bytes (64 bits)} = 4266\text{MBps}$$

or

$$400\text{MHz} \times 8 \text{ bytes (64 bits)} = 3200\text{MBps}$$

With Socket A (Athlon XP), you get

$$333.33\text{MHz} \times 8 \text{ bytes (64 bits)} = 2667\text{MBps}$$

or

$$266.66\text{MHz} \times 8 \text{ bytes (64 bits)} = 2133\text{MBps}$$

or

$$200\text{MHz} \times 8 \text{ bytes (64 bits)} = 1600\text{MBps}$$

With Socket 370 (Pentium III), you get

$$133.33\text{MHz} \times 8 \text{ bytes (64 bits)} = 1066\text{MBps}$$

or

$$100\text{MHz} \times 8 \text{ bytes (64 bits)} = 800\text{MBps}$$

This transfer rate, often called the *bandwidth* of the processor bus, represents the maximum speed at which data can move. Refer to Table 4.72 for a more complete list of various processor bus bandwidths.

The Memory Bus

The memory bus is used to transfer information between the CPU and main memory—the RAM in your system. This bus is connected to the motherboard chipset North Bridge or Memory Controller Hub chip. Depending on the type of memory your chipset (and therefore motherboard) is designed to handle, the North Bridge runs the memory bus at various speeds. The best solution is if the memory bus runs at the same speed as the processor bus. Systems that use PC133 SDRAM have a memory bandwidth of 1066MBps, which is the same as the 133MHz CPU bus. In another example, Athlon systems running a 266MHz processor bus also run PC2100 DDR-SDRAM, which has a bandwidth of 2133MBps—exactly the same as the processor bus in those systems. In addition, systems running a Pentium 4 with its 400MHz processor bus also use dual-channel RDRAM memory, which runs 1600MBps for each channel, or a combined bandwidth (both memory channels run simultaneously) of 3200MBps, which is exactly the same as the Pentium 4 CPU bus. Pentium 4 systems with the 533MHz bus run dual-channel DDR PC2100 or PC2700 modules, which match or exceed the throughput of the 4266MBps processor bus.

Running memory at the same speed as the processor bus negates the need for having cache memory on the motherboard. That is why when the L2 cache moved into the processor, nobody added an L3 cache to the motherboard. Some very high-end processors, such as the Itanium and Itanium 2 and the Intel Pentium 4 Extreme Edition, have integrated 2MB–4MB of full-core speed L3 cache into the CPU. Eventually, this should make it down to more mainstream desktop systems.

Note

Notice that the main memory bus must transfer data in the same width as the processor bus. This defines the size of what is called a *bank* of memory, at least when dealing with anything but RDRAM. Memory banks and their widths relative to processor buses are discussed in the section “Memory Banks” in Chapter 6.

The Need for Expansion Slots

The I/O bus or expansion slots enable your CPU to communicate with peripheral devices. The bus and its associated expansion slots are needed because basic systems can't possibly satisfy all the needs of all the people who buy them. The I/O bus enables you to add devices to your computer to expand its capabilities. The most basic computer components, such as sound cards and video cards, can be plugged into expansion slots; you also can plug in more specialized devices, such as network interface cards, SCSI host adapters, and others.

Note

In most modern PC systems, a variety of basic peripheral devices are built in to the motherboard. Most systems today have at least dual (primary and secondary) IDE interfaces, four USB ports, a floppy controller, two serial ports, a parallel port, keyboard, and mouse controller built directly into the motherboard. These devices are usually distributed between the motherboard chipset South Bridge and the Super I/O chip. (Super I/O chips are discussed earlier in this chapter.)

Many add even more items, such as a built-in sound card, video adapter, SCSI host adapter, network interface or IEEE 1394a port, that also are built in to the motherboard. Those items, however, might not be built in to the motherboard chipset or Super I/O chip; they are sometimes configured as additional chips installed on the board. Nevertheless, these built-in controllers and ports still use the I/O bus to communicate with the CPU. In essence, even though they are built in, they act as if they were cards plugged into the system's bus slots, including using system resources in the same manner.

Types of I/O Buses

Since the introduction of the first PC, many I/O buses have been introduced. The reason is simple: Faster I/O speeds are necessary for better system performance. This need for higher performance involves three main areas:

- Faster CPUs
- Increasing software demands
- Greater multimedia requirements

Each of these areas requires the I/O bus to be as fast as possible.

One of the primary reasons new I/O bus structures have been slow in coming is compatibility—that old catch-22 that anchors much of the PC industry to the past. One of the hallmarks of the PC's success is its standardization. This standardization spawned thousands of third-party I/O cards, each originally built for the early bus specifications of the PC. If a new high-performance bus system was introduced, it often had to be compatible with the older bus systems so the older I/O cards would not be obsolete. Therefore, bus technologies seem to evolve rather than make quantum leaps forward.

You can identify different types of I/O buses by their architectures. The main types of I/O buses are detailed earlier in this chapter.

The main differences among buses consist primarily of the amounts of data they can transfer at one time and the speeds at which they can do it. The following sections describe the various types of PC buses.

The ISA Bus

Industry Standard Architecture (ISA) is the bus architecture that was introduced as an 8-bit bus with the original IBM PC in 1981; it was later expanded to 16 bits with the IBM PC/AT in 1984. ISA is the basis of the modern personal computer and was the primary architecture used in the vast majority of PC systems until the late 1990s. It might seem amazing that such a presumably antiquated architecture was used for so long, but it provided reliability, affordability, and compatibility, plus this old bus is still faster than many of the peripherals we connect to it!

Note

The ISA bus has vanished from all recent desktop systems, and few companies make or sell ISA cards anymore. The ISA bus continues to be popular with industrial computer (PICMG) designs, but it is expected to eventually fade away from these as well.

Two versions of the ISA bus exist, based on the number of data bits that can be transferred on the bus at a time. The older version is an 8-bit bus; the newer version is a 16-bit bus. The original 8-bit version ran at 4.77MHz in the PC and XT, and the 16-bit version used in the AT ran at 6MHz and then 8MHz. Later, the industry as a whole agreed on an 8.33MHz maximum standard speed for 8/16-bit versions of the ISA bus

for backward-compatibility. Some systems have the capability to run the ISA bus faster than this, but some adapter cards will not function properly at higher speeds. ISA data transfers require anywhere from two to eight cycles. Therefore, the theoretical maximum data rate of the ISA bus is about 8MBps, as the following formula shows:

$$8.33\text{MHz} \times 2 \text{ bytes (16 bits) [db] } 2 \text{ cycles per transfer} = 8.33\text{MBps}$$

The bandwidth of the 8-bit bus would be half this figure (4.17MBps). Remember, however, that these figures are theoretical maximums. Because of I/O bus protocols, the effective bandwidth is much lower—typically by almost half. Even so, at about 8MBps, the ISA bus is still faster than many of the peripherals connected to it, such as serial ports, parallel ports, floppy controllers, keyboard controllers, and so on.

The 8-Bit ISA Bus

This bus architecture is used in the original IBM PC computers and was retained for several years in later systems. Although virtually nonexistent in new systems today, this architecture still exists in hundreds of thousands of PC systems in the field, including systems with 286 and 386 processors.

Physically, the 8-bit ISA expansion slot resembles the tongue-and-groove system furniture makers once used to hold two pieces of wood together. It is specifically called a *card/edge connector*. An adapter card with 62 contacts on its bottom edge plugs into a slot on the motherboard that has 62 matching contacts. Electronically, this slot provides 8 data lines and 20 addressing lines, enabling the slot to handle 1MB of memory.

Figure 4.67 describes the pinouts for the 8-bit ISA bus; Figure 4.68 shows how these pins are oriented in the expansion slot.

Figure 4.67 Pinouts for the 8-bit ISA bus.

Figure 4.68 The 8-bit ISA bus connector.

Although the design of the bus is simple, IBM waited until 1987 to publish full specifications for the timings of the data and address lines, so in the early days of PC compatibles, manufacturers had to do their best to figure out how to make adapter boards. This problem was solved, however, as PC-compatible personal computers became more widely accepted as the industry standard and manufacturers had more time and incentive to build adapter boards that worked correctly with the bus.

The dimensions of 8-bit ISA adapter cards are as follows:

4.2" (106.68mm) high

13.13" (333.5mm) long

0.5" (12.7mm) wide

The 16-Bit ISA Bus

IBM threw a bombshell on the PC world when it introduced the AT with the 286 processor in 1984. This processor had a 16-bit data bus, which meant communications between the processor and motherboard as well as memory would now be 16 bits wide instead of only 8. Although this processor could have been installed on a motherboard with only an 8-bit I/O bus, that would have meant a huge sacrifice in the performance of any adapter cards or other devices installed on the bus.

Rather than create a new I/O bus, at that time IBM instead came up with a system that could support both 8- and 16-bit cards by retaining the same basic 8-bit connector layout but adding an optional 16-bit extension connector. This first debuted on the PC/AT in August 1984, which is why we also refer to the ISA bus as the *AT-bus*.

The extension connector in each 16-bit expansion slot adds 36 connector pins (for a total of 98 signals) to carry the extra signals necessary to implement the wider data path. In addition, two of the pins in the 8-bit portion of the connector were changed. These two minor changes did not alter the function of 8-bit cards.

Figure 4.69 describes the pinouts for the full 16-bit ISA expansion slot, and Figure 4.70 shows how the additional pins are oriented in the expansion slot.

Because of physical interference with some ancient 8-bit card designs, IBM left 16-bit extension connectors off two of the slots in the AT. This was not a problem in newer systems, so any system with ISA slots would have all of them as full 16-bit versions.

The dimensions of a typical AT expansion board are as follows:

4.8" (121.92mm) high

13.13" (333.5mm) long

0.5" (12.7mm) wide

Two heights actually are available for cards commonly used in AT systems: 4.8" and 4.2" (the height of older PC-XT cards). The shorter cards became an issue when IBM introduced the XT Model 286. Because this model has an AT motherboard in an XT case, it needs AT-type boards with the 4.2" maximum height. Most board makers trimmed the height of their boards; most manufacturers who still make ISA cards now make only 4.2"-tall (or less) boards so they will work in systems with either profile.

32-Bit Buses

After 32-bit CPUs became available, it was some time before 32-bit bus standards became available. Before MCA and EISA specs were released, some vendors began creating their own proprietary 32-bit buses, which were extensions of the ISA bus. Fortunately, these proprietary buses were few and far between.

The expanded portions of the bus typically are used for proprietary memory expansion or video cards. Because the systems are proprietary (meaning that they are nonstandard), pinouts and specifications are not available.

Figure 4.69 Pinouts for the 16-bit ISA bus.

Figure 4.70 The ISA 16-bit bus connector.

The Micro Channel Bus

The introduction of 32-bit chips meant that the ISA bus could not handle the power of another new generation of CPUs. The 386DX chips could transfer 32 bits of data at a time, but the ISA bus can handle a maximum of only 16 bits. Rather than extend the ISA bus again, IBM decided to build a new bus; the result was the MCA bus. MCA (an abbreviation for microchannel architecture) is completely different from the ISA bus and is technically superior in every way.

IBM wanted not only to replace the old ISA standard, but also to require vendors to license certain parts of the technology. Many owed for licenses on the ISA bus technology that IBM also created, but because IBM had not been aggressive in its licensing of ISA, many got away without any license. Problems with licensing and control led to the development of the competing EISA bus (see the next section on the EISA bus) and hindered acceptance of the MCA bus.

MCA systems produced a new level of ease of use; they were plug-and-play before the official Plug and Play specification even existed. An MCA system had no jumpers and switches—neither on the motherboard nor on any expansion adapter. Instead you used a special Reference disk, which went with the particular system, and Option disks, which went with each of the cards installed in the system. After a card was installed, you loaded the Option disk files onto the Reference disk; after that, you didn't need the Option disks anymore. The Reference disk contained the special BIOS and system setup program necessary for an MCA system, and the system couldn't be configured without it.

For more information on the MCA bus, see the previous editions of this book on the included disc.

The EISA Bus

The Extended Industry Standard Architecture (EISA) standard was announced in September 1988 as a response to IBM's introduction of the MCA bus—more specifically, to the way IBM wanted to handle licensing of the MCA bus. Vendors did not feel obligated to pay retroactive royalties on the ISA bus, so they turned their backs on IBM and created their own buses.

The EISA standard was developed primarily by Compaq and was intended to be its way of taking over future development of the PC bus from IBM. Compaq knew that nobody would clone its bus if it was the only company that had it, so it essentially gave the design to other leading manufacturers.

Compaq formed the EISA committee, a nonprofit organization designed specifically to control development of the EISA bus. Very few EISA adapters were ever developed. Those that were developed centered mainly around disk array controllers and server-type network cards.

The EISA bus was essentially a 32-bit version of ISA. Unlike the MCA bus from IBM, you could still use older 8-bit or 16-bit ISA cards in 32-bit EISA slots, providing for full backward-compatibility. As with MCA, EISA also allowed for automatic configuration of EISA cards via software.

The EISA bus added 90 new connections (55 new signals plus grounds) without increasing the physical connector size of the 16-bit ISA bus. At first glance, the 32-bit EISA slot looks a lot like the 16-bit ISA slot. The EISA adapter, however, has two rows of stacked contacts. The first row is the same type used in 16-bit ISA cards; the other, thinner row extends from the 16-bit connectors. Therefore, ISA cards can still be used in EISA bus slots. Although this compatibility was not enough to ensure the popularity of EISA buses, it is a feature that was carried over into the VL-Bus standard that followed. The physical specifications of an EISA card are as follows:

- 5" (127mm) high
- 13.13" (333.5mm) long
- 0.5" (12.7mm) wide

The EISA bus can handle up to 32 bits of data at an 8.33MHz cycle rate. Most data transfers require a minimum of two cycles, although faster cycle rates are possible if an adapter card provides tight timing specifications. The maximum bandwidth on the bus is 33MBps, as the following formula shows:

$$8.33\text{MHz} \times 4 \text{ bytes (32 bits)} = 33\text{MBps}$$

Figure 4.71 describes the pinouts for the EISA bus. Figure 4.72 shows the locations of the pins; note how some pins are offset to allow the EISA slot to accept ISA cards. Figure 4.73 shows the card connector for the EISA expansion slot.

Local Buses

The I/O buses discussed so far (ISA, MCA, and EISA) have one thing in common: relatively slow speed. The next three bus types that are discussed in the following few sections all use the *local bus* concept explained in this section to address the speed issue. The three main local buses found in PC systems are

- VL-Bus (VESA local bus)
- PCI
- AGP

The speed limitation of ISA, MCA, and EISA is a carryover from the days of the original PC when the I/O bus operated at the same speed as the processor bus. As the speed of the processor bus increased, the I/O bus realized only nominal speed improvements, primarily from an increase in the bandwidth of the bus. The I/O bus had to remain at a slower speed because the huge installed base of adapter cards could operate only at slower speeds.

Figure 4.74 shows a conceptual block diagram of the buses in a computer system.

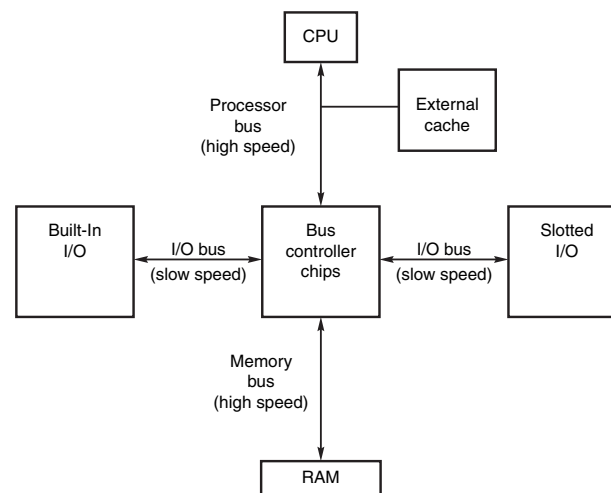

Figure 4.74 Bus layout in a traditional PC.

The thought of a computer system running more slowly than it could is very bothersome to some computer users. Even so, the slow speed of the I/O bus is nothing more than a nuisance in most cases. You don't need blazing speed to communicate with a keyboard or mouse—you gain nothing in performance. The real problem occurs in subsystems in which you need the speed, such as video and disk controllers.

The speed problem became acute when graphical user interfaces (such as Windows) became prevalent. These systems require the processing of so much video data that the I/O bus became a literal bottleneck for the entire computer system. In other words, it did little good to have a processor that was capable of 66MHz–450MHz or faster if you could put data through the I/O bus at a rate of only 8MHz.

An obvious solution to this problem is to move some of the slotted I/O to an area where it could access the faster speeds of the processor bus—much the same way as the external cache. Figure 4.75 shows this arrangement.

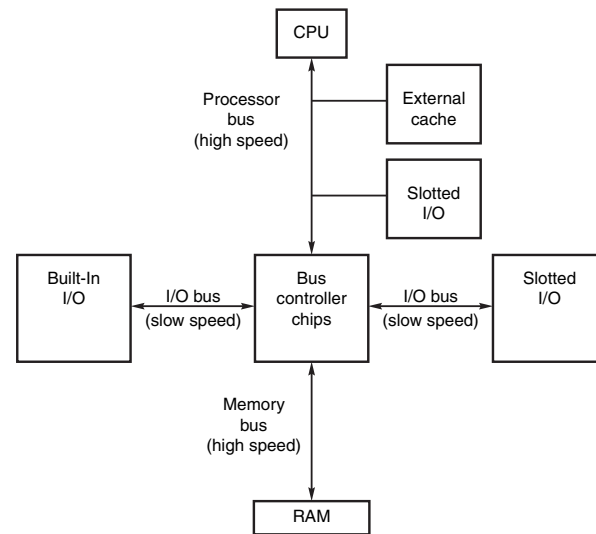

Figure 4.75 How a local bus works.

This arrangement became known as *local bus* because external devices (adapter cards) now could access the part of the bus that was local to the CPU—the processor bus. Physically, the slots provided to tap this new configuration would need to be different from existing bus slots to prevent adapter cards designed for slower buses from being plugged into the higher bus speeds, which this design made accessible.

It is interesting to note that the very first 8-bit and 16-bit ISA buses were a form of local bus architecture. These systems had the processor bus as the main bus, and everything ran at full processor speeds. When ISA systems ran faster than 8MHz, the main ISA bus had to be decoupled from the processor bus because expansion cards, memory, and so on could not keep up. In 1992, an extension to the ISA bus called the VESA local bus (VL-Bus) started showing up on PC systems, indicating a return to local bus architecture. Since then, the peripheral component interconnect (PCI) local bus has supplanted VL-Bus, and the AGP bus has been introduced to complement PCI.

Note

A system does not have to have a local bus expansion slot to incorporate local bus technology; instead, the local bus device can be built directly into the motherboard. (In such a case, the local bus-slotted I/O shown in Figure 4.75 would in fact be built-in I/O.) This built-in approach to local bus is the way the first local bus systems were designed.

Local bus solutions do not necessarily replace earlier standards, such as ISA; they are designed into the system as a bus that is closer to the processor in the system architecture. Older buses such as ISA were kept around for backward compatibility with slower types of adapters that didn't need any faster connection to the system (such as modems). Therefore, until recently a typical system might have AGP, PCI, and ISA slots. Older cards still are compatible with such a system, but high-speed adapter cards can take advantage of the AGP and PCI local bus slots as well. With the demise of ISA slots and the movement of traditionally ISA-based motherboard devices to the LPC interface, today's motherboards essentially use other buses or dedicated interfaces for most of the connections that would have previously used ISA.

The performance of graphical user interfaces such as Windows and graphical Linux interfaces such as KDE and GNOME have been tremendously improved by moving the video cards off the slow ISA bus and onto faster PCI and now AGP local buses.

VESA Local Bus

The Video Electronics Standards Association (VESA) local bus was the most popular local bus design from its debut in August 1992 through 1994. It was created by the VESA committee, a nonprofit organization originally founded by NEC to further develop video display and bus standards. In a similar fashion to how EISA evolved, NEC had done most of the work on the VL-Bus (as it would be called) and, after founding the nonprofit VESA committee, NEC turned over future development to VESA. At first, the local bus slot seemed designed to be used primarily for video cards. Improving video performance was a top priority at NEC to help sell its high-end displays as well as its own PC systems. By 1991, video performance had become a real bottleneck in most PC systems.

The VL-Bus can move data 32 bits at a time, enabling data to flow between the CPU and a compatible video subsystem or hard drive at the full 32-bit data width of the 486 chip. The maximum rated throughput of the VL-Bus is 133MBps. In other words, local bus went a long way toward removing the major bottlenecks that existed in earlier bus configurations.

Unfortunately, the VL-Bus did not seem to be a long-lived concept. The design was simple indeed—just take the pins from the 486 processor and run them out to a card connector socket. So, the VL-Bus is essentially the raw 486 processor bus. This allowed a very inexpensive design because no additional chipsets or interface chips were required. A motherboard designer could add VL-Bus slots to its 486 motherboards very easily and at a very low cost. This is why these slots appeared on virtually all 486 system designs overnight.

Problems arose with timing glitches caused by the capacitance introduced into the circuit by different cards. Because the VL-Bus ran at the same speed as the processor bus, different processor speeds meant different bus speeds, and full compatibility was difficult to achieve. Although the VL-Bus could be adapted to other processors—including the 386 or even the Pentium—it was designed for the 486 and worked best as a 486 solution only. Despite the low cost, after a new bus called PCI appeared, VL-Bus fell into disfavor very quickly. It never did catch on with Pentium systems, and there was little or no further development of the VL-Bus in the PC industry.

Physically, the VL-Bus slot was an extension of the slots used for whatever type of base system you have. If you have an ISA system, the VL-Bus is positioned as an extension of your existing 16-bit ISA slots. The VESA extension has 112 contacts and uses the same physical connector as the MCA bus.

The PCI Bus

In early 1992, Intel spearheaded the creation of another industry group. It was formed with the same goals as the VESA group in relation to the PC bus. Recognizing the need to overcome weaknesses in the ISA and EISA buses, the PCI Special Interest Group was formed.

The PCI bus specification was released in June 1992 as version 1.0 and since then has undergone several upgrades. Table 4.73 shows the various releases of PCI.

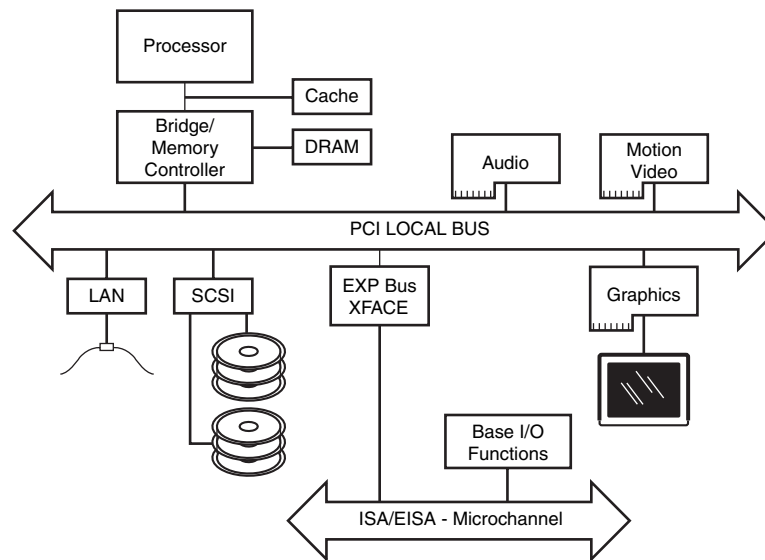

Table 4.73 PCI Specifications

PCI Specification	Released	Major Change
PCI 1.0	June 1992	Original 32/64-bit specification
PCI 2.0	April 1993	Defined connectors and expansion boards
PCI 2.1	June 1995	66MHz operation, transaction ordering, latency changes
PCI 2.2	Jan. 1999	Power management, mechanical clarifications
PCI-X 1.0	Sept. 1999	133MHz operation, addendum to 2.2
Mini-PCI	Nov. 1999	Small form factor boards, addendum to 2.2

Table 4.73 Continued

PCI Specification	Released	Major Change
PCI 2.3	March 2002	3.3V signaling, low-profile add-in cards
PCI-X 2.0	July 2002	266MHz and 533MHz operation, supports subdivision of 64-bit data bus into 32-bit or 16-bit segments for use by multiple devices, 3.3V/1.5V signaling
PCI-Express 1.0	July 2002	2.5GBps per lane per direction, using 0.8V signaling, resulting in 250MBps per lane; designed to eventually replace PCI 2.x in PC systems

PCI redesigned the traditional PC bus by inserting another bus between the CPU and the native I/O bus by means of bridges. Rather than tap directly into the processor bus, with its delicate electrical timing (as was done in the VL-Bus), a new set of controller chips was developed to extend the bus, as shown in Figure 4.76.

**Figure 4.76** Conceptual diagram of the PCI bus.

The PCI bus often is called a *mezzanine bus* because it adds another layer to the traditional bus configuration. PCI bypasses the standard I/O bus; it uses the system bus to increase the bus clock speed and take full advantage of the CPU's data path. Systems that integrate the PCI bus became available in mid-1993 and have since become a mainstay in the PC.

Information typically is transferred across the PCI bus at 33MHz and 32 bits at a time. The bandwidth is 133MBps, as the following formula shows:

$$33.33\text{MHz} \times 4 \text{ bytes (32 bits)} = 133\text{MBps}$$

Although 32-bit 33MHz PCI is the standard found in most PCs, there are now several variations on PCI as shown in Table 4.74.

Table 4.74 PCI Bus Types

PCI Bus Type	Bus Width (Bits)	Bus Speed (MHz)	Data Cycles per Clock	Bandwidth (Mbps)
PCI	32	33	1	133
PCI 66MHz	32	66	1	266
PCI 64-bit	64	33	1	266
PCI 66MHz/64-bit	64	66	1	533
PCI-X 64	64*	66	1	533
PCI-X 133	64*	133	1	1066
PCI-X 266	64*	133	2	2132
PCI-X 533	64*	133	4	4266
PCI-Express**	1	2500	0.8	250
PCI-Express**	16	2500	0.8	4000
PCI-Express**	32	2500	0.8	8000

*Bus width on PCI-X devices can be shared by multiple 32-bit or 16-bit devices.

**PCI-Express uses 8b/10b encoding, which transfers 8 bits for every 10 bits sent and can transfer 1–32 bits at a time, depending on how many lanes are in the implementation.

Currently, the 64-bit or 66MHz and 133MHz variations are used only on server- or workstation-type boards and systems. Aiding performance is the fact that the PCI bus can operate concurrently with the processor bus; it does not supplant it. The CPU can be processing data in an external cache while the PCI bus is busy transferring information between other parts of the system—a major design benefit of the PCI bus.

A PCI adapter card uses its own unique connector. This connector can be identified within a computer system because it typically is offset from the normal ISA, MCA, or EISA connectors found in older motherboards. See Figure 4.77 for an example. The size of a PCI card can be the same as that of the cards used in the system's normal I/O bus.

Figure 4.77 Typical configuration of 32-bit 33MHz PCI slots in relation to ISA or EISA and AGP slots.

The PCI specification identifies three board configurations, each designed for a specific type of system with specific power requirements; each specification has a 32-bit version and a longer 64-bit version. The 5V specification is for stationary computer systems (using PCI 2.2 or earlier versions), the 3.3V specification is

for portable systems (also supported by PCI 2.3), and the universal specification is for motherboards and cards that work in either type of system. 64-bit versions of the 5V and universal PCI slots are found primarily on server motherboards. The PCI-X 2.0 specifications for 266 and 533 versions support 3.3V and 1.5V signaling; this corresponds to PCI version 2.3, which supports 3.3V signaling.

Note

The pinouts for the 5V, 3.3V, and universal PCI slots can be found on the disc in the Technical Reference section.

Figure 4.78 compares the 32-bit and 64-bit versions of the standard 5V PCI slot to a 64-bit universal PCI slot. Figure 4.79 shows how the connector on a 64-bit universal PCI card compares to the 64-bit universal PCI slot.

Figure 4.78 A 32-bit, 33MHz PCI slot (top) compared to a 64-bit 33MHz PCI slot (center) and a 64-bit universal PCI slot that runs at 66MHz (bottom).

Figure 4.79 A 64-bit universal PCI card (top) compared to the 64-bit universal PCI slot (bottom).

Notice that the universal PCI board specifications effectively combine the 5V and 3.3V specifications. For pins for which the voltage is different, the universal specification labels the pin V I/O. This type of pin represents a special power pin for defining and driving the PCI signaling rail.

Another important feature of PCI is the fact that it was the model for the Intel PnP specification. Therefore, PCI cards do not have jumpers and switches and are instead configured through software. True PnP systems are capable of automatically configuring the adapters, whereas non-PnP systems with ISA slots must configure the adapters through a program that is usually a part of the system CMOS configuration. Starting in late 1995, most PC-compatible systems have included a PnP BIOS that allows the automatic PnP configuration.

PCI-Express

During 2001, a group of companies called the Arapahoe Work Group (led primarily by Intel) developed a draft of a new high-speed bus specification code named 3GIO (third-generation I/O). In August 2001, the PCI Special Interest Group (PCI-SIG) agreed to take over, manage, and promote the 3GIO architecture specification as the future generation of PCI. In April 2002, the 3GIO draft version 1.0 was completed, transferred to the PCI-SIG, and renamed PCI-Express. Finally in July 2002, the PCI-Express 1.0 specification was approved.

The original 3GIO code name was derived from the fact that this new bus specification was designed to initially augment and eventually replace the previously existing ISA/AT-Bus (first-generation) and PCI (second-generation) bus architectures in PCs. Each of the first two generations of PC bus architectures was designed to have a 10- to 15-year useful life in PCs. In being adopted and approved by the PCI-SIG, PCI-Express is now destined to be the dominant PC bus architecture designed to support the increasing bandwidth needs in PCs over the next 10–15 years.

The key features of PCI-Express are as follows:

- Compatibility with existing PCI enumeration and software device drivers.
- Physical connection over copper, optical, or other physical media to allow for future encoding schemes.
- Maximum bandwidth per pin allows small form factors, reduced cost, simpler board designs and routing, and reduced signal integrity issues.
- Embedded clocking scheme enables easy frequency (speed) changes as compared to synchronous clocking.
- Bandwidth (throughput) increases easily with frequency and width (lane) increases.
- Low latency suitable for applications requiring isochronous (time-sensitive) data delivery, such as streaming video.
- Hot plugging and hot swapping capabilities.
- Power management capabilities.

PCI-Express is another example of how the PC is moving from parallel to serial interfaces. Earlier generation bus architectures in the PC have been of a parallel design, in which multiple bits are sent simultaneously over several pins in parallel. The more bits sent at a time, the faster the bus throughput is. The timing of all the parallel signals must be the same, which becomes more and more difficult to do over faster and longer connections. Even though 32 bits can be transmitted simultaneously over a bus such as PCI or AGP, propagation delays and other problems cause them to arrive slightly skewed at the other end, resulting in a time difference between when the first and last of all the bits arrive.

A serial bus design is much simpler, sending 1 bit at a time over a single wire, at much higher rates of speed than a parallel bus would allow. By sending the bits serially, the timing of individual bits or the length of the bus becomes much less of a factor. By combining multiple serial data paths, even faster throughputs can be realized that dramatically exceed the capabilities of traditional parallel buses.

PCI-Express is a very fast serial bus design that is backward-compatible with current PCI parallel bus software drivers and controls. In PCI-Express, data is sent full duplex (simultaneously operating one-way paths) over two pairs of differentially signaled wires called a *lane*. Each lane allows for about 250MBps throughput in each direction initially, and the design allows for scaling from 1 to 2, 4, 8, 16, or 32 lanes. For example, a high-bandwidth configuration with 8 lanes allowing 8 bits to be sent in each direction simultaneously would allow up to 2000MBps bandwidth (each way) and use a total of only 40 pins (32 for the differential data pairs and 8 for control). Future increases in signaling speed could increase that to 8000MBps each way over the same 40 pins. This compares to PCI, which has only 133MBps bandwidth (one way at a time) and requires more than 100 pins to carry the signals.

For expansion cards, PCI-Express will take on the physical format of a smaller connector that appears adjacent to any existing PCI slots on the motherboard. Figure 4.80 compares the PCI-Express x1–x16 connectors, and Figure 4.81 shows how PCI-Express x1 and x16 slots compare to PCI slots on a typical motherboard implementation. Note that the PCI-Express x4 and x8 connectors shown in Figure 4.80 are intended primarily for use in servers.

Figure 4.80 PCI-Express x1, x4, x8, and x16 slots.

PCI-Express uses an IBM-designed 8-bit-to-10-bit encoding scheme, which allows for self-clocked signals that will easily allow future increases in frequency. The starting frequency is 2.5GHz, and the specification will allow increasing up to 10GHz in the future, which is about the limit of copper connections. By combining frequency increases with the capability to use up to 32 lanes, PCI-Express will be capable of supporting future bandwidths up to 32Gbps.

PCI-Express is designed to augment and eventually replace many of the buses currently used in PCs. It will not only be a supplement to (and the eventual replacement for) PCI slots, but can also be used to replace the existing Intel hub architecture, HyperTransport, and similar high-speed interfaces between motherboard chipset components. Additionally, it will replace video interfaces such as AGP and act as a mezzanine bus to attach other interfaces, such as Serial ATA, USB 2.0, 1394b (FireWire or i.LINK), Gigabit Ethernet, and more.

Because PCI-Express can be implemented over cables as well as onboard, it can be used to create systems constructed with remote “bricks” containing the bulk of the computing power. Imagine the motherboard, processor, and RAM in one small box hidden under a table, with the video, disk drives, and I/O ports in another box sitting out on a table within easy reach. This will enable a variety of flexible PC form factors to be developed in the future without compromising performance.

PCI-Express will not replace PCI or other interfaces overnight. System developers will continue to integrate PCI, AGP, and other bus architectures into system designs for several more years. Just as with PCI and the ISA/AT-Bus before, there will likely be a long period of time during which both buses will be found on motherboards. Gradually, though, fewer PCI and more PCI-Express connections will appear. Over time, PCI-Express will eventually become the preferred general-purpose I/O interconnect over PCI. I expect the move to PCI-Express will be similar to the transition from ISA/AT-Bus to PCI during the 1990s.

Although it will take some time for PCI-Express to replace PCI, many high-performance systems sold in the second half of 2004 and beyond will no longer feature AGP 8x video card slots. Instead,

PCI-Express x16 (a 16-lane-wide PCI-Express slot) will be used to provide video. Although a few systems will offer both PCI-Express x16 and AGP 8x slots, AGP is likely to be the first bus design replaced by PCI-Express.

The first desktop PCs using PCI-Express began to emerge in mid- to late 2004. These feature a mix of PCI and PCI-Express slots. After that, PCI-Express is expected to appear in portable devices and low-end servers and workstations by late 2004, and in high-end servers and workstations by late 2005. These are just estimates, of course, and might change according to the dynamics of the industry. The PCI-Express Bridge 1.0 and Mini PCI-Express Card specifications are designed to help bring PCI-Express products into being by using existing PCI technology. These specifications might help shorten the time-to-market for PCI-Express products.

For more information on PCI-Express, I recommend consulting the PCI-SIG Web site (www.pcisig.org).

Accelerated Graphics Port

Intel created AGP as a new bus specifically designed for high-performance graphics and video support. AGP is based on PCI, but it contains several additions and enhancements and is physically, electrically, and logically independent of PCI. For example, the AGP connector is similar to PCI, although it has additional signals and is positioned differently in the system. Unlike PCI, which is a true bus with multiple connectors (slots), AGP is more of a point-to-point high-performance connection designed specifically for a video card in a system because only one AGP slot is allowed for a single video card. Intel originally released the AGP specification 1.0 in July 1996 and defined a 66MHz clock rate with 1x or 2x signaling using 3.3V. AGP version 2.0 was released in May 1998 and added 4x signaling as well as a lower 1.5V operating capability.

The latest revision for the AGP specification for PCs is AGP 8x, also called AGP 3.0. AGP 8x defines a transfer speed of 2133MBps, which is twice that of AGP 4x. The AGP 8x specification was first publicly announced in November 2000. AGP 8x support is now widely available in motherboard chipsets and graphics chipsets from major vendors. Although AGP 8x has a maximum speed twice that of AGP 4x, the real-world differences between AGP 4x- and 8x-compatible devices with otherwise identical specifications are minimal. However, many 3D chipsets that support AGP 8x are also upgrading memory and 3D graphics core speeds and designs to better support the faster interface.

Most recent AGP video cards are designed to conform to the AGP 4X or AGP 8X specification, each of which runs on only 1.5 volts. Most older motherboards with AGP 2X slots are designed to accept only 3.3V cards. If you plug a 1.5V card into a 3.3V slot, both the card and motherboard could be damaged, so special keys have been incorporated into the AGP specification to prevent such disasters. Normally, the slots and cards are keyed such that 1.5V cards fit only in 1.5V sockets and 3.3V cards fit only in 3.3V sockets. However, universal sockets do exist that accept either 1.5V or 3.3V cards. The keying for the AGP cards and connectors is dictated by the AGP standard, as shown in Figure 4.81.

As you can see from Figure 4.81, AGP 4X or 8X (1.5V) cards fit only in 1.5V or universal (3.3V or 1.5V) slots. Due to the design of the connector and card keys, a 1.5V card cannot be inserted into a 3.3V slot. So, if your new AGP card won't fit in the AGP slot in your existing motherboard, consider that a good thing because if you were able to plug it in, you would fry both the card and possibly the board as well! In that case, you'd either have to return the 4X/8X card or get a new motherboard that supports the 4X/8X (1.5V) cards.

Caution

Some AGP 4x/8x-compatible motherboards require you to use 1.5V AGP 4x/8x cards only; be sure to check compatibility between the motherboard and the AGP card you want to buy to avoid problems. Some AGP 4x/8x-compatible slots use the card retention mechanism shown in Figure 4.81. Note that AGP 1x/2x slots have a visible divider not present on the newer AGP 4x slot. AGP 4x slots can also accept AGP 8x cards, and vice versa.

Figure 4.81 AGP 4X/8X (1.5V) card and AGP 3.3V, universal, and 1.5V slots.

Additionally, a newer specification was introduced as AGP Pro 1.0 in August 1998 and was revised in April 1999 as AGP Pro 1.1a. It defines a slightly longer slot with additional power pins at each end to drive bigger and faster AGP cards that consume more than 25 watts of power, up to a maximum of 110 watts. AGP Pro cards are likely to be used for high-end graphics workstations and are not likely to be found in any normal PCs. However, AGP Pro slots are backward-compatible, meaning a standard AGP card will plug in, and a number of motherboard vendors are using AGP Pro slots rather than AGP 4x slots in recent products. Because AGP Pro slots are longer, an AGP 1x/2x card can be incorrectly inserted into the slot, which could damage it, so some vendors supply a cover or an insert for the AGP Pro extension at the rear of the slot. This protective cover or insert should be removed only if you want to install an AGP Pro card.

The standard AGP 1x/2x, AGP 4x, and AGP Pro slots are compared to each other in Figure 4.82.

Figure 4.82 AGP standard (1x/2x), AGP 4x, and AGP Pro slots compared to each other. AGP 4x and AGP Pro can accept AGP 1x, 2x, and 4x cards. AGP 4x and AGP Pro slots can also accept AGP 8x cards.

AGP is a high-speed connection and runs at a base frequency of 66MHz (actually 66.66MHz), which is double that of standard PCI. In the basic AGP mode, called 1x, a single transfer is done every cycle. Because the AGP bus is 32 bits (4 bytes) wide, at 66 million times per second it would be capable of transferring data at a rate of about 266MBps! The original AGP specification also defines a 2x mode, in which two transfers are performed every cycle, resulting in 533MBps. Using an analogy in which every cycle is equivalent to the back-and-forth swing of a pendulum, the 1x mode is thought of as transferring information at the start of each swing. In 2x mode, an additional transfer would occur every time the pendulum completed half a swing, thereby doubling performance while technically maintaining the same clock rate, or in this case, the same number of swings per second. Although the earliest AGP cards supported only the AGP 1x mode, most vendors quickly shifted to the AGP 2x mode. The newer AGP 2.0 specification adds the capability for 4x transfers, in which data is transferred four times per cycle and equals a data transfer rate of 1066MBps. Most newer AGP cards now have support for the 4x standard as a minimum, and the latest graphics chipsets from NVIDIA and ATI support AGP 8x. Table 4.75 shows the differences in clock rates and data transfer speeds (bandwidth) for the various AGP modes.

Table 4.75 AGP Modes Showing Clock Speeds and Bandwidth

AGP Bus Type	Bus Width (Bits)	Bus Speed (MHz)	Data Cycles per Clock	Bandwidth (MBps)
AGP	32	66	1	266
AGP 2x	32	66	2	533
AGP 4x	32	66	4	1066
AGP 8x	32	66	8	2133

Because AGP is independent of PCI, using an AGP video card frees up the PCI bus for more traditional input and output, such as for IDE/ATA or SCSI controllers, USB controllers, sound cards, and so on.

Besides faster video performance, one of the main reasons Intel designed AGP was to allow the video card to have a high-speed connection directly to the system RAM, which would enable a reasonably fast and powerful video solution to be integrated at a lower cost. AGP allows a video card to have direct access to the system RAM, either enabling lower-cost video solutions to be directly built in to a motherboard without having to include additional video RAM or enabling an AGP card to share the main system memory. However, few AGP cards in recent years share main memory. Instead, they have their own high-speed memory (as much as 256MB in some recent models). Using dedicated memory directly on the video card is especially important when running high-performance 3D video applications. AGP enables the speed of the video card to pace the requirements for high-speed 3D graphics rendering as well as full-motion video on the PC.

Although AGP 8x (2133MBps) is 16 times faster than 32-bit 33MHz PCI (133MBps), AGP 8x is only about half as fast as PCI-Express x16 (4000MBps). Starting in mid-2004, motherboard and system vendors began to replace AGP 8x with PCI-Express x16 expansion slots in high-performance systems using Pentium 4 and Athlon 64 processors. This trend is likely to accelerate in 2005 and beyond and will eventually spell the end of AGP.

Note

If you want to purchase a motherboard that uses PCI-Express x16 but don't want to replace your AGP video card at the same time, look for motherboards that offer both AGP 8x and PCI-Express x16 slots. These are available for both Pentium 4 and AMD Athlon 64 processors.

System Resources

System resources are the communications channels, addresses, and other signals hardware devices use to communicate on the bus. At their lowest level, these resources typically include the following:

- Memory addresses
- IRQ (interrupt request) channels
- DMA (direct memory access) channels
- I/O port addresses

I have listed these roughly in the order you would experience problems with them. Memory conflicts are perhaps the most troublesome of these and certainly the most difficult to fully explain and overcome. These are discussed in Chapter 6. This chapter focuses on the others listed here in the order you will likely have problems with them.

IRQs cause more problems than DMAs because they are in much higher demand; virtually all cards use IRQ channels. Fewer problems exist with DMA channels because fewer cards use them, DMA channels are used only by the obsolete ISA standard, and there are usually more than enough channels to go around. I/O ports are used by all hardware devices on the bus, but there are technically 64KB of them, which means there are plenty to go around. With all these resources, you must ensure that a unique card or hardware function uses each resource; in most cases they cannot or should not be shared.

These resources are required and used by many components of your system. Adapter cards need these resources to communicate with your system and accomplish their purposes. Not all adapter cards have the same resource requirements. A serial communications port, for example, needs an IRQ channel and I/O port address, whereas a sound card needs these resources and at least one DMA channel. Most network cards use an IRQ channel and an I/O port address, and some also use a 16KB block of memory addresses.

As your system increases in complexity, the chance for resource conflicts increases. Modern systems with several additional devices can really push the envelope and become a configuration nightmare for the uninitiated. Sometimes under these situations the automatic configuration capability of Plug and Play can get confused or fail to optimally configure resources so that everything will work. Most adapter cards enable you to modify resource assignments by using the Plug and Play software that comes with the card or the Device Manager in Windows 9x and later, thus you can sometimes improve on a default configuration by making some changes. Even if the automatic configuration gets confused (which happens more often than it should), fortunately, in almost all cases a logical way to configure the system exists—once you know the rules.

Interrupts

Interrupt request channels, or hardware interrupts, are used by various hardware devices to signal the motherboard that a request must be fulfilled. This procedure is the same as a student raising his hand to indicate that he needs attention.

These interrupt channels are represented by wires on the motherboard and in the slot connectors. When a particular interrupt is invoked, a special routine takes over the system, which first saves all the CPU register contents in a stack and then directs the system to the interrupt vector table. This vector table contains a list of memory addresses that correspond to the interrupt channels. Depending on which interrupt was invoked, the program corresponding to that channel is run.

The pointers in the vector table point to the address of whatever software driver is used to service the card that generated the interrupt. For a network card, for example, the vector might point to the address of the network drivers that have been loaded to operate the card; for a hard disk controller, the vector might point to the BIOS code that operates the controller.

After the particular software routine finishes performing whatever function the card needed, the interrupt-control software returns the stack contents to the CPU registers, and the system then resumes whatever it was doing before the interrupt occurred.

Through the use of interrupts, your system can respond to external events in a timely fashion. Each time a serial port presents a byte to your system, an interrupt is generated to ensure that the system reads that byte before another comes in. Keep in mind that in some cases a port device—in particular, a modem with a 16550 or higher UART chip—might incorporate a byte buffer that allows multiple characters to be stored before an interrupt is generated.

Hardware interrupts are generally prioritized by their numbers; with some exceptions, the highest-priority interrupts have the lowest numbers. Higher-priority interrupts take precedence over lower-priority interrupts by interrupting them. As a result, several interrupts can occur in your system concurrently, with each interrupt nesting within another.

If you overload the system—in this case, by running out of stack resources (too many interrupts were generated too quickly)—an internal stack overflow error occurs and your system halts. The message usually appears as `Internal stack overflow - system halted` at a DOS prompt. If you experience this type of system error and run DOS, you can compensate for it by using the `STACKS` parameter in your `CONFIG.SYS` file to increase the available stack resources. Most people will not see this error in Windows 9x/Me or Windows NT/2000/XP.

The ISA bus uses *edge-triggered* interrupt sensing, in which an interrupt is sensed by a changing signal sent on a particular wire located in the slot connector. A different wire corresponds to each possible hardware interrupt. Because the motherboard can't recognize which slot contains the card that used an interrupt line and therefore generated the interrupt, confusion results if more than one card is set to use a particular interrupt. Each interrupt, therefore, is usually designated for a single hardware device. Most of the time, interrupts can't be shared.

Originally, IBM developed ways to share interrupts on the ISA bus, but few devices followed the necessary rules to make this a reality. The PCI bus inherently allows interrupt sharing; in fact, virtually all PCI cards are set to PCI interrupt A and share that interrupt on the PCI bus. The real problem is that there are technically two sets of hardware interrupts in the system: PCI interrupts and ISA interrupts. For PCI cards to work in a PC, the PCI interrupts are first mapped to ISA interrupts, which are then configured as non-shareable. Therefore, in many cases you must assign a nonconflicting interrupt for each card, even PCI cards. The conflict between assigning ISA IRQs for PCI interrupts caused many configuration problems for early users of PCI motherboards and continued to cause problems even after the development of Windows 95 and its Plug and Play technology.

The solution to the interrupt sharing problem for PCI cards was something called *PCI IRQ Steering*, which is supported in the more recent operating systems (starting with Windows 95 OSR 2.x) and BIOS. PCI IRQ Steering allows a plug-and-play operating system such as Windows to dynamically map or “steer” PCI cards (which almost all use PCI INTA#) to standard PC interrupts and allows several PCI cards to be mapped to the same interrupt. More information on PCI IRQ Steering is found in the section “PCI Interrupts,” later in this chapter.

Hardware interrupts are sometimes referred to as *maskable interrupts*, which means the interrupts can be masked or turned off for a short time while the CPU is used for other critical operations. It is up to the system BIOS and programs to manage interrupts properly and efficiently for the best system performance.

Because interrupts usually can't be shared in an ISA bus system, you often run into conflicts and can even run out of interrupts when you are adding boards to a system. If two boards or onboard devices use the same IRQ to signal the system, the resulting conflict prevents either board from operating properly. The following sections discuss the IRQs that any standard devices use, as well as what might be free in your system.

8-Bit ISA Bus Interrupts

The PC and XT (the systems based on the 8-bit 8086 CPU) provide for eight different external hardware interrupts. Table 4.76 shows the typical uses for these interrupts, which are numbered 0–7.

Table 4.76 8-Bit ISA Bus Default Interrupt Assignments

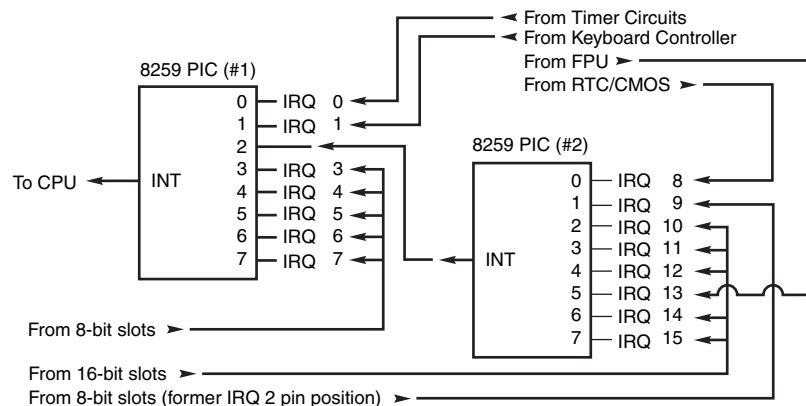

IRQ	Function	Bus Slot
0	System Timer	No
1	Keyboard Controller	No
2	Available	Yes (8-bit)
3	Serial Port 2 (COM2:)	Yes (8-bit)
4	Serial Port 1 (COM1:)	Yes (8-bit)
5	Hard Disk Controller	Yes (8-bit)
6	Floppy Disk Controller	Yes (8-bit)
7	Parallel Port 1 (LPT1:)	Yes (8-bit)

If you have a system that has one of the original 8-bit ISA buses, you will find that the IRQ resources provided by the system present a severe limitation. Installing several devices that need the services of system IRQs in a PC/XT-type system can be a study in frustration because the only way to resolve the interrupt-shortage problem is to remove the adapter board that you need the least.

16-Bit ISA, EISA, and MCA Bus Interrupts

The introduction of the AT, based on the 286 processor, was accompanied by an increase in the number of external hardware interrupts the bus would support. The number of interrupts was doubled to 16 by using two Intel 8259 interrupt controllers, piping the interrupts generated by the second one through the unused IRQ2 in the first controller. This arrangement effectively makes only 15 IRQ assignments available, and IRQ2 effectively became inaccessible.

By routing all the interrupts from the second IRQ controller through IRQ2 on the first, all these new interrupts are assigned a nested priority level between IRQ1 and IRQ3. Thus, IRQ15 ends up having a higher priority than IRQ3. Figure 4.83 shows how the two 8259 chips were wired to create the cascade through IRQ2 on the first chip.

**Figure 4.83** Interrupt controller cascade wiring.

To prevent problems with boards set to use IRQ2, the AT system designers routed one of the new interrupts (IRQ9) to fill the slot position left open after removing IRQ2. This means that any card you install in a modern system that claims to use IRQ2 is really using IRQ9 instead.

Table 4.77 shows the typical uses for interrupts in the 16-bit ISA and 32-bit PCI/AGP buses and lists them in priority order from highest to lowest. The obsolete EISA and MCA buses used a similar IRQ map.

Table 4.77 16/32-Bit ISA/PCI/AGP Default Interrupt Assignments

IRQ	Standard Function	Bus Slot	Card Type	Recommended Use
0	System Timer	No	—	—
1	Keyboard Controller	No	—	—
2	2nd IRQ Controller Cascade	No	—	—
8	Real-Time Clock	No	—	—
9	Avail. (as IRQ2 or IRQ9)	Yes	8/16-bit	Network Card
10	Available	Yes	16-bit	USB
11	Available	Yes	16-bit	SCSI Host Adapter
12	Mouse Port/Available	Yes	16-bit	Mouse Port
13	Math Coprocessor	No	—	—
14	Primary IDE	Yes	16-bit	Primary IDE (hard disks)
15	Secondary IDE	Yes	16-bit	2nd IDE (CD-ROM/Tape)
3	Serial 2 (COM2:)	Yes	8/16-bit	COM2:/Internal Modem
4	Serial 1 (COM1:)	Yes	8/16-bit	COM1:
5	Sound/Parallel 2 (LPT2:)	Yes	8/16-bit	Sound Card
6	Floppy Controller	Yes	8/16-bit	Floppy Controller
7	Parallel 1 (LPT1:)	Yes	8/16-bit	LPT1:

Notice that interrupts 0, 1, 2, 8, and 13 are not on the bus connectors and are not accessible to adapter cards. Interrupts 8, 10, 11, 12, 13, 14, and 15 are from the second interrupt controller and are accessible only by boards that use the 16-bit extension connector because this is where these wires are located. IRQ9 is rewired to the 8-bit slot connector in place of IRQ2, so IRQ9 replaces IRQ2 and, therefore, is available to 8-bit cards, which treat it as though it were IRQ2.

Note

Although the 16-bit ISA bus has twice as many interrupts as systems that have the 8-bit ISA bus, you still might run out of available interrupts because only 16-bit adapters can use most of the newly available interrupts. Any 32-bit PCI adapter can be mapped to any ISA IRQs.

The extra IRQ lines in a 16-bit ISA system are of little help unless the adapter boards you plan to use enable you to configure them for one of the unused IRQs. Some devices are hard-wired so they can use only a particular IRQ, and some of the early 16-bit ISA adapters weren't designed to use 16-bit IRQs (9–15). If you have a device that already uses that IRQ, you must resolve the conflict before installing the second adapter. If neither adapter enables you to reconfigure its IRQ use, chances are that you can't use the two devices in the same system.

PCI Interrupts

The PCI bus supports hardware interrupts (IRQs) that can be used by PCI devices to signal to the bus that they need attention. The four PCI interrupts are called INTA#, INTB#, INTC#, and INTD#. These INTx# interrupts are *level-sensitive*, which means that the electrical signaling enables them to be shared among PCI cards. In fact, all single device or single function PCI chips or cards that use only one interrupt must use INTA#. This is one of the rules in the PCI specification. If additional devices are within a chip or onboard a card, the additional devices can use INTB# through INTD#. Because there are very few multifunction PCI chips or boards, practically all the devices on a given PCI bus share INTA#.

For the PCI bus to function in a PC, the PCI interrupts must be mapped to ISA interrupts. Because ISA interrupts can't be shared, in most cases each PCI card using INTA# on the PCI bus must be mapped to a different non-shareable ISA interrupt. For example, you could have a system with four PCI slots and four PCI cards installed, each using PCI interrupt INTA#. These cards would each be mapped to a different available ISA interrupt request, such as IRQ9, IRQ10, IRQ11, or IRQ5 in most cases.

Finding unique IRQs for each device on both the ISA and PCI buses has always been a problem; there simply aren't enough free ones to go around. Setting two ISA devices to the same IRQ has never been possible (the so-called *IRQ sharing* of IRQ4 by COM1/3 and IRQ3 by COM2/4 didn't allow both COM ports to work at the same time), but on most newer systems sharing IRQs between multiple PCI devices might be possible. Newer system BIOSs as well as plug-and-play operating systems, such as Windows 95B (OSR 2) or later, Windows 98, and Windows 2000/XP, all support a function known as PCI IRQ Steering. For this to work, both your system BIOS and operating system must support IRQ Steering. Older system BIOSs and Windows 95 or 95A do not have support for PCI IRQ Steering.

Generally, the BIOS assigns unique IRQs to PCI devices. If your system supports PCI IRQ Steering and it is enabled, Windows assigns IRQs to PCI devices. Even when IRQ Steering is enabled, the BIOS still initially assigns IRQs to PCI devices. Although Windows has the capability to change these settings, it typically does not do so automatically, except where necessary to eliminate conflicts. If there are insufficient free IRQs to go around, IRQ Steering allows Windows to assign multiple PCI devices to a single IRQ, thus enabling all the devices in the system to function properly. Without IRQ Steering, Windows begins to disable devices after it runs out of free IRQs to assign.

To determine whether your Windows 9x/Me system is using IRQ Steering, you can follow these steps:

1. Open the Device Manager.
2. Double-click the System Devices branch.
3. Double-click the PCI Bus, and then click the IRQ Steering tab. There will be a check that displays IRQ Steering as either Enabled or Disabled. If enabled, it also specifies where the IRQ table has been read from.

Note that with Windows 2000 and XP, you can't disable IRQ steering and no IRQ Steering tab appears in the Device Manager.

IRQ Steering is controlled by one of four routing tables Windows attempts to read. Windows searches for the tables in order and uses the first one it finds. You can't control the order in which Windows searches for these tables, but by selecting or deselecting the Get IRQ Table Using check boxes, you can control which table Windows finds first by disabling the search for specific tables. Windows searches for the following tables:

- ACPI BIOS table
- MS Specification table
- Protected Mode PCIBIOS 2.1 table
- Real Mode PCIBIOS 2.1 table

Windows first tries to use the ACPI BIOS table to program IRQ Steering, followed by the MS Specification table, the Protected Mode PCIBIOS 2.1 table, and the Real Mode PCIBIOS 2.1 table. Windows 95 OSR2 and later versions offer only a choice for selecting the PCIBIOS 2.1 tables via a single check box, which is disabled by default. Under Windows 98, all IRQ table choices are selected by default, except the third one, which is the Protected Mode PCIBIOS 2.1 table.

If you are having a problem with a PCI device related to IRQ settings under Windows 95, try selecting the PCIBIOS 2.1 table and restarting. Under Windows 98, try clearing the ACPI BIOS table selection and restarting. If the problem persists, try selecting the Protected Mode PCIBIOS 2.1 table and restarting.

You should select Get IRQ Table from Protected Mode PCIBIOS 2.1 Call only if a PCI device is not working properly. To access these settings in the Windows 98 Device Manager, do the following:

1. Open the Device Manager.
2. Scroll down to the System Devices category, and double-click to open it.
3. Select PCI Bus and click Properties.
4. Click the IRQ Steering tab to see or change the current settings.

If IRQ Steering is shown as disabled in Device Manager, be sure the Use IRQ Steering check box is selected. After selecting this and restarting, if IRQ Steering is still showing as disabled, the IRQ routing table that must be provided by the BIOS to the operating system might be missing or contain errors. Check your BIOS Setup to ensure PCI IRQ Steering is enabled. If there is still no success, you might have to select the Get IRQ Table from Protected Mode PCIBIOS 2.1 Call check box, or your BIOS might not support PCI bus IRQ Steering. Contact the manufacturer of your motherboard or BIOS to see whether your board or BIOS supports IRQ Steering.

On systems that have support for IRQ Steering, an IRQ Holder for PCI Steering might be displayed when you view the System Devices branch of Device Manager. This indicates that an IRQ has been mapped to PCI and is unavailable for ISA devices, even if no PCI devices are currently using the IRQ. To view IRQs programmed for PCI-mode, follow these steps:

1. Select Start, Settings, Control Panel, and then double-click System.
2. Click the Device Manager tab.
3. Double-click the System Devices branch.
4. Double-click the IRQ Holder for PCI Steering you want to view, and then click the Resources tab.

I have found this interrupt steering or mapping to be the source of a great deal of confusion. Even though PCI interrupts (INTx#) can be (and are by default) shared, each card or device that might be sharing a PCI interrupt must be mapped or steered to a unique ISA IRQ, which in turn can't normally be shared. You can have several PCI devices mapped to the same ISA IRQ only if

- No ISA devices are using the IRQ.
- The BIOS and operating system support PCI IRQ Steering.
- PCI IRQ Steering is enabled.

Without PCI IRQ Steering support, the sharing capabilities of the PCI interrupts are of little benefit because all PCI-to-ISA IRQ assignments must then be unique. Without PCI IRQ Steering, you can easily run out of available ISA interrupts. If IRQ Steering is supported and enabled, multiple PCI devices will be capable of sharing a single IRQ, allowing for more system expansion without running out of available IRQs. Better support for IRQ Steering is one of the best reasons for upgrading to Windows 98 or newer versions, especially if you are using the original OSR1 release of 95.

Another source of confusion is that the interrupt listing shown in the Windows 9x Device Manager might show the PCI to ISA interrupt mapping as multiple entries for a given ISA interrupt. One entry would be for the device actually mapped to the interrupt—for example, a built-in USB controller—whereas the other entry for the same IRQ would say *IRQ Holder for PCI Steering*. This latter entry, despite claiming to use the same IRQ, does not indicate a resource conflict; instead it represents the chipset circuitry putting a reservation on that interrupt for mapping purposes. This is part of the plug-and-play capabilities of PCI and the modern motherboard chipsets. Windows 2000 and XP can also map multiple devices to the same IRQ, but they don't use the term *IRQ Holder* to avoid confusion.

Note that you can have internal devices on the PCI bus even though all the PCI slots are free. For example, most systems today have two IDE controllers and at least one USB controller as devices on the PCI bus. Normally, the PCI IDE controllers are mapped to ISA interrupts 14 (primary IDE) and 15 (secondary IDE), whereas the USB controller can be mapped to the available ISA interrupts 9, 10, 11, and 5. Many recent systems have two or more USB controllers (typically one per every two USB ports), so each USB controller needs to be mapped to an ISA interrupt.

- ▶▶ See "Universal Serial Bus," p. 983.

The PCI bus enables two types of devices to exist, called *bus masters* (initiators) and *slaves* (targets). A bus master is a device that can take control of the bus and initiate a transfer. The target device is the intended destination of the transfer. Most PCI devices can act as both masters and targets, and to be compliant with the PC'97 and newer system design guides, all PCI slots must support bus master cards.

The PCI bus is an arbitrated bus: A central arbiter (part of the PCI bus controller in the motherboard chipset) governs all bus transfers, giving fair and controlled access to all the devices on the bus. Before a master can use the bus, it must first request control from the central arbiter, and then it is granted control for only a specified maximum number of cycles. This arbitration allows equal and fair access to all the bus master devices, prevents a single device from hogging the bus, and also prevents deadlocks because of simultaneous multiple device access. In this manner, the PCI bus acts much like a local area network (LAN), albeit one that is contained entirely within the system and runs at a much higher speed than conventional external networks between PCs.

IRQ Conflicts

One of the more common IRQ conflicts is the potential one between the integrated COM2: port found in most modern motherboards and an internal (card-based) ISA modem. The problem stems from the fact that true PC card-based modems (not the so-called WinModems, which are software based) incorporate a serial port as part of the card's circuitry. This serial port is set as COM2: by default. Your PC sees this as having two COM2: ports, each using the same IRQ and I/O port address resources.

The solution to this problem is easy: Enter the system BIOS Setup and disable the built-in COM2: port in the system. While you are there, you might think about disabling the COM1: port too because you are unlikely to use it. Disabling unused COMx: ports is one of the best ways to free up a couple of IRQs for other devices to use.

Another common IRQ conflict also involves serial (COM) ports. You might have noticed in the preceding two sections that two IRQs are set aside for two COM ports. IRQ3 is used for COM2:, and IRQ4 is used for COM1:. The problem occurs when you have more than two serial ports in a system. When people add COM3: and COM4: ports, they often don't set them to nonconflicting interrupts, which results in a conflict and the ports not working.

Contributing to the problem are poorly designed COM port boards that do not allow IRQ settings other than 3 or 4. What happens is that they end up setting COM3: to IRQ4 (sharing it with COM1:), and COM4: to IRQ3 (sharing it with COM2:). This is not acceptable because it prevents you from using the two COM ports on any one of the interrupt channels simultaneously. This was somewhat acceptable under plain DOS because single-tasking (running only one program at a time) was the order of the day, but it is totally unacceptable with Windows and OS/2. If you must share IRQs, you can usually get away with sharing devices on the same IRQ as long as they use different COM ports. For instance, a scanner and an internal modem could share an IRQ, but if the two devices are used simultaneously, a conflict results. Fortunately, most devices that formerly used serial ports (such as mice and other pointing devices, label printers, external modems, and PDA cradles) have been redesigned to use USB ports. Thus, many users no longer have any devices that must be plugged into a serial port.

If you need to use serial ports, the best solution is to purchase a multiport serial I/O card that allows nonconflicting interrupt settings or an intelligent card with its own processor that can handle the multiple ports onboard and use only one interrupt in the system. Some older multiport serial cards

used the ISA slot, but PCI-slot cards have replaced these in recent systems and have the additional advantages of faster speed and a sharable interrupt.

▶▶ See "Serial Ports," p. 997.

If a device listed in the table is not present, such as the motherboard mouse port (IRQ12) or parallel port 2 (IRQ5), you can consider those interrupts as available. For example, a second parallel port is a rarity, and most systems have a sound card installed and set for IRQ5 (if it is used to emulate a SoundBlaster Pro or 16). Also, on most systems IRQ15 is assigned to a secondary IDE controller. If you do not have an IDE hard or optical drive connected to the secondary controller, you could disable the secondary IDE controller to free up that IRQ for another device.

Note that an easy way to check your interrupt settings is to use the Device Manager in Windows 95/98, Windows NT, or Windows 2000/XP. By double-clicking the Computer Properties icon in the Device Manager, you can get concise lists of all used system resources. Microsoft has also included a program called HWDIAG on Windows 95B; Windows 98 and above feature the System Information program. HWDIAG and System Information do an excellent job of reporting system resource usage, as well as details about device drivers and Windows Registry entries for each hardware component. If you are running Windows XP, a program called MSinfo32 will also give you a report of detailed system information.

To provide the maximum number of shareable interrupts in a recent system without ISA slots, I recommend performing the following steps in the system BIOS:

1. Disable any unused legacy ports in the system BIOS. For example, if you use USB ports instead of serial and parallel ports, disable the serial and parallel ports. This can free up as many as three IRQs.
2. Select the IRQs freed up in step 1 as available for PCI/PnP use. Depending on the BIOS, the screen to use might be known as the PnP/PCI Resource Exclusion screen or the PnP/PCI Configuration screen.
3. Enable the Reset Configuration Data option so the IRQ routing tables in the CMOS are cleared.
4. Save your changes and exit the BIOS setup program.

DMA Channels

Direct Memory Access (DMA) channels are used by communications devices that must send and receive information at high speeds. A serial or parallel port does not use a DMA channel, but an ISA-based sound card or SCSI adapter often does. DMA channels sometimes can be shared if the devices are not the type that would need them simultaneously. For example, you can have a network adapter and a tape backup adapter sharing DMA channel 1, but you can't back up while the network is running. To back up during network operation, you must ensure that each adapter uses a unique DMA channel.

Note

There are several types of DMA in a modern PC. The DMA channels referred to in this section involve the ISA bus. Other buses, such as the ATA/IDE bus used by hard drives, have different DMA uses. The DMA channels explained here don't involve your ATA/IDE drives, even if they are set to use DMA or Ultra DMA transfers.

8-Bit ISA Bus DMA Channels

In the 8-bit ISA bus, four DMA channels support high-speed data transfers between I/O devices and memory. Three of the channels are available to the expansion slots. Table 4.78 shows the typical uses of these DMA channels.

Table 4.78 8-Bit ISA Default DMA-Channel Assignments

DMA	Standard Function	Bus Slot
0	Dynamic RAM Refresh	No
1	Available	Yes (8-bit)
2	Floppy disk controller	Yes (8-bit)
3	Hard disk controller	Yes (8-bit)

Because most systems typically have both a floppy and hard disk drive, only one DMA channel is available in 8-bit ISA systems.

16-Bit ISA DMA Channels

Since the introduction of the 286 CPU, the ISA bus has supported eight DMA channels, with seven channels available to the expansion slots. Similar to the expanded IRQ lines described earlier in this chapter, the added DMA channels were created by cascading a second DMA controller to the first one. DMA channel 4 is used to cascade channels 0–3 to the microprocessor. Channels 0–3 are available for 8-bit transfers, and channels 5–7 are for 16-bit transfers only. Table 4.79 shows the typical uses for the DMA channels.

Table 4.79 16-Bit ISA Default DMA-Channel Assignments

DMA	Standard Function	Bus Slot	Card Type	Transfer	Recommended Use
0	Available	Yes	16-bit	8-bit	Sound
1	Available	Yes	8/16-bit	8-bit	Sound
2	Floppy Disk Controller	Yes	8/16-bit	8-bit	Floppy Controller
3	Available	Yes	8/16-bit	8-bit	LPT1: in ECP Mode
4	1st DMA Controller Cascade	No	—	16-bit	—
5	Available	Yes	16-bit	16-bit	Sound
6	Available	Yes	16-bit	16-bit	Available
7	Available	Yes	16-bit	16-bit	Available

Note that PCI adapters don't use these ISA DMA channels; these are only for ISA cards. However, some PCI cards emulate the use of these DMA channels (such as sound cards) to work with older software.

The only standard DMA channel used in all systems is DMA 2, which is universally used by the floppy controller. DMA 4 is not usable and does not appear in the bus slots. DMA channels 1 and 5 are most commonly used by ISA sound cards, such as the Sound Blaster 16, or by newer PCI sound cards that emulate an older one for backward compatibility. These cards use both an 8-bit and a 16-bit DMA channel for high-speed transfers. DMA 3 is used when a parallel port is configured to work in ECP mode or EPP/ECP mode. Some nonstandard systems, such as older Packard Bell computers, use DMA 1 instead of DMA 3 for the parallel port by default. However, a jumper block on the motherboard on many of these systems can be set to use DMA 3 for the parallel port and avoid conflicts with sound cards that use DMA 1.

Note

Although DMA channel 0 appears in a 16-bit slot connector extension and therefore can be used only by a 16-bit card, it performs only 8-bit transfers! Because of this, you generally don't see DMA 0 as a choice on 16-bit cards. Most 16-bit cards (such as SCSI host adapters) that use DMA channels have their choices limited to DMA 5–7.

I/O Port Addresses

Your computer's I/O ports enable communications between devices and software in your system. They are equivalent to two-way radio channels. If you want to talk to your serial port, you need to know on which I/O port (radio channel) it is listening. Similarly, if you want to receive data from the serial port, you need to listen on the same channel on which it is transmitting.

Unlike IRQs and DMA channels, our systems have an abundance of I/O ports. There are 65,535 ports to be exact—numbered from 0000h to FFFFh—which is an artifact of the Intel processor design more than anything else. Even though most devices use up to 8 ports for themselves, with that many to spare, you won't run out anytime soon. The biggest problem you have to worry about is setting two devices to use the same port.

Most modern plug-and-play systems resolve any port conflicts and select alternative ports for one of the conflicting devices.

One confusing issue is that I/O ports are designated by hexadecimal addresses similar to memory addresses. They are not memory; they are ports. The difference is that when you send data to memory address 1000h, it gets stored in your SIMM or DIMM memory. If you send data to I/O port address 1000h, it gets sent out on the bus on that "channel," and anybody listening in could then "hear" it. If nobody is listening to that port address, the data reaches the end of the bus and is absorbed by the bus terminating resistors.

Driver programs are primarily what interact with devices at the various port addresses. The driver must know which ports the device is using to work with it, and vice versa. That is not usually a problem because the driver and device come from the same company.

Motherboard and chipset devices usually are set to use I/O port addresses 0h–FFh, and all other devices use 100h–FFFFh. Table 4.80 shows the commonly used motherboard and chipset-based I/O port usage.

Table 4.80 Motherboard and Chipset-Based Device Port Addresses

Address (hex)	Size	Description
0000–000F	16 bytes	Chipset - 8237 DMA 1
0020–0021	2 bytes	Chipset - 8259 interrupt controller 1
002E–002F	2 bytes	Super I/O controller configuration registers
0040–0043	4 bytes	Chipset - Counter/Timer 1
0048–004B	4 bytes	Chipset - Counter/Timer 2
0060	1 byte	Keyboard/Mouse controller byte - reset IRQ
0061	1 byte	Chipset - NMI, speaker control
0064	1 byte	Keyboard/Mouse controller, CMD/STAT byte
0070, bit 7	1 bit	Chipset - Enable NMI
0070, bits 6:0	7 bits	MC146818 - Real-time clock, address
0071	1 byte	MC146818 - Real-time clock, data
0078	1 byte	Reserved - Board configuration

Table 4.80 Continued

Address (hex)	Size	Description
0079	1 byte	Reserved - Board configuration
0080-008F	16 bytes	Chipset - DMA page registers
00A0-00A1	2 bytes	Chipset - 8259 interrupt controller 2
00B2	1 byte	APM control port
00B3	1 byte	APM status port
00C0-00DE	31 bytes	Chipset - 8237 DMA 2
00F0	1 byte	Math Coprocessor Reset Numeric Error

To find out exactly which port addresses are being used on your motherboard, consult the board documentation or look up these settings in the Windows Device Manager.

Bus-based devices typically use the addresses from 100h on up. Table 4.81 lists the commonly used bus-based device addresses and some common adapter cards and their settings.

Table 4.81 Bus-Based Device Port Addresses

Address (hex)	Size	Description
0130-0133	4 bytes	Adaptec SCSI adapter (alternate)
0134-0137	4 bytes	Adaptec SCSI adapter (alternate)
0168-016F	8 bytes	Fourth IDE interface
0170-0177	8 bytes	Secondary IDE interface
01E8-01EF	8 bytes	Third IDE interface
01F0-01F7	8 bytes	Primary IDE/AT (16-bit) hard disk controller
0200-0207	8 bytes	Gameport or joystick adapter
0210-0217	8 bytes	IBM XT expansion chassis
0220-0233	20 bytes	Creative Labs Sound Blaster 16 audio (default)
0230-0233	4 bytes	Adaptec SCSI adapter (alternate)
0234-0237	4 bytes	Adaptec SCSI adapter (alternate)
0238-023B	4 bytes	MS bus mouse (alternate)
023C-023F	4 bytes	MS bus mouse (default)
0240-024F	16 bytes	SMC Ethernet adapter (default)
0240-0253	20 bytes	Creative Labs Sound Blaster 16 audio (alternate)
0258-025F	8 bytes	Intel above board
0260-026F	16 bytes	SMC Ethernet adapter (alternate)
0260-0273	20 bytes	Creative Labs Sound Blaster 16 audio (alternate)
0270-0273	4 bytes	Plug and Play I/O read ports
0278-027F	8 bytes	Parallel port 2 (LPT2)
0280-028F	16 bytes	SMC Ethernet adapter (alternate)
0280-0293	20 bytes	Creative Labs Sound Blaster 16 audio (alternate)
02A0-02AF	16 bytes	SMC Ethernet adapter (alternate)
02C0-02CF	16 bytes	SMC Ethernet adapter (alternate)

Table 4.81 Continued

Address (hex)	Size	Description
02E0-02EF	16 bytes	SMC Ethernet adapter (alternate)
02E8-02EF	8 bytes	Serial port 4 (COM4)
02EC-02EF	4 bytes	Video, 8514, or ATI standard ports
02F8-02FF	8 bytes	Serial port 2 (COM2)
0300-0301	2 bytes	MPU-401 MIDI port (secondary)
0300-030F	16 bytes	SMC Ethernet adapter (alternate)
0320-0323	4 bytes	XT (8-bit) hard disk controller
0320-032F	16 bytes	SMC Ethernet adapter (alternate)
0330-0331	2 bytes	MPU-401 MIDI port (default)
0330-0333	4 bytes	Adaptec SCSI adapter (default)
0334-0337	4 bytes	Adaptec SCSI adapter (alternate)
0340-034F	16 bytes	SMC Ethernet adapter (alternate)
0360-036F	16 bytes	SMC Ethernet adapter (alternate)
0366	1 byte	Fourth IDE command port
0367, bits 6:0	7 bits	Fourth IDE status port
0370-0375	6 bytes	Secondary floppy controller
0376	1 byte	Secondary IDE command port
0377, bit 7	1 bit	Secondary floppy controller disk change
0377, bits 6:0	7 bits	Secondary IDE status port
0378-037F	8 bytes	Parallel Port 1 (LPT1)
0380-038F	16 bytes	SMC Ethernet adapter (alternate)
0388-038B	4 bytes	Audio - FM synthesizer
03B0-03BB	12 bytes	Video, Mono/EGA/VGA standard ports
03BC-03BF	4 bytes	Parallel port 1 (LPT1) in some systems
03BC-03BF	4 bytes	Parallel port 3 (LPT3)
03C0-03CF	16 bytes	Video, EGA/VGA standard ports
03D0-03DF	16 bytes	Video, CGA/EGA/VGA standard ports
03E6	1 byte	Third IDE command port
03E7, bits 6:0	7 bits	Third IDE status port
03E8-03EF	8 bytes	Serial port 3 (COM3)
03F0-03F5	6 bytes	Primary floppy controller
03F6	1 byte	Primary IDE command port
03F7, bit 7	1 bit	Primary floppy controller disk change
03F7, bits 6:0	7 bits	Primary IDE status port
03F8-03FF	8 bytes	Serial port 1 (COM1)
04D0-04D1	2 bytes	Edge/level triggered PCI interrupt controller
0530-0537	8 bytes	Windows sound system (default)
0604-060B	8 bytes	Windows sound system (alternate)
0678-067F	8 bytes	LPT2 in ECP mode
0778-077F	8 bytes	LPT1 in ECP mode

Table 4.81 Continued

Address (hex)	Size	Description
0A20–0A23	4 bytes	IBM Token-Ring adapter (default)
0A24–0A27	4 bytes	IBM Token-Ring adapter (alternate)
0CF8–0CFB	4 bytes	PCI configuration address registers
0CF9	1 byte	Turbo and reset control register
0CFC–0CFF	4 bytes	PCI configuration data registers
FF00–FF07	8 bytes	IDE bus master registers
FF80–FF9F	32 bytes	Universal serial bus
FFA0–FFA7	8 bytes	Primary bus master IDE registers
FFA8–FFAF	8 bytes	Secondary bus master IDE registers

To find out exactly what your devices are using, again I recommend consulting the documentation for the device or looking up the device in the Windows Device Manager. Note that the documentation for some devices might list only the starting address instead of the full range of I/O port addresses used.

Virtually all devices on the system buses use I/O port addresses. Most of these are fairly standardized, meaning conflicts or problems won't often occur with these settings. In the next section, you learn more about working with I/O addresses.

Resolving Resource Conflicts

The resources in a system are limited. Unfortunately, the demands on those resources seem to be unlimited. As you add more and more adapter cards to your system, you will find that the potential for resource conflicts increases. If your system is fully PnP-compatible, potential conflicts should be resolved automatically, but often are not.

How do you know whether you have a resource conflict? Typically, one of the devices in your system stops working. Resource conflicts can exhibit themselves in other ways, though. Any of the following events could be diagnosed as a resource conflict:

- A device transfers data inaccurately.
- Your system frequently locks up.
- Your sound card doesn't sound quite right.
- Your mouse doesn't work.
- Garbage appears on your video screen for no apparent reason.
- Your printer prints gibberish.
- You can't format a floppy disk.
- The PC starts in Safe mode (Windows 9x/Me) or can start only in Last Known Good Configuration (Windows 2000/XP).

Windows 9x/Me and Windows 2000/XP also show conflicts by highlighting a device in yellow or red in the Device Manager representation. By using the Windows Device Manager, you can usually spot the conflicts quickly.

In the following sections, you learn some of the steps you can take to head off resource conflicts or track them down when they occur.

Caution

Be careful when diagnosing resource conflicts; a problem might not be a resource conflict at all, but a computer virus. Many computer viruses are designed to exhibit themselves as glitches or periodic problems. If you suspect a resource conflict, it might be worthwhile to run a virus check first to ensure that the system is clean. This procedure could save you hours of work and frustration.

One way to resolve conflicts is to help prevent them in the first place. Especially if you are building up a new system, you can take several steps to avoid problems. One is to avoid using older ISA devices. By definition, they cannot share IRQs, and that is the resource most in demand. PCI (and AGP) cards can share IRQs with IRQ Steering and as such are a much better choice.

Tip

The serial, PS/2 mouse, and parallel ports still found in most recent systems are all ISA devices that cannot share IRQs. If you no longer use these ports, you can use these devices' IRQs for other devices if you

- Disable the unused port in the system BIOS.
- Configure the system BIOS to use the IRQ formerly used by the device(s) for PnP configuration; this might be automatic in some systems.

Another way you can help is to install cards in a particular sequence, and not all at once. Modifying the installation sequence often helps because many cards can use only one or two out of a predefined selection of IRQs that is specific to each brand or model of card. By installing the cards in a controlled sequence, the plug-and-play software can more easily work around IRQ conflicts caused by the default configurations of different cards.

The first time you start up a new system you have assembled or done major upgrades on, the first thing you should check is the BIOS Setup. If you have a setting for PnP Operating System in your BIOS, be sure it is enabled if you are running an operating system with plug-and-play support, such as Windows 9x/Me/2000/XP. Otherwise, make sure it's disabled if you are running an OS that is not plug-and-play, such as Windows NT.

On initial startup I recommend a minimum configuration with only the graphics card, memory, and storage drives (floppy, hard disk, CD-ROM, and DVD). This allows for the least possibility of system conflicts in the initial configuration. If your motherboard came with a CD including drivers specific to the chipset or other built-in features of the board, now is the time to load or install them. Complete the configuration of all built-in devices before installing any other cards or external devices.

After the basic system has been configured (and after you have successfully loaded your operating system and any updates or patches), you can then begin adding one device at a time in a specific order. So, you will power down, install the new device, power up, and proceed to install any necessary drivers and configure the device. You'll probably have to restart your system after you are done to fully complete the configuration.

Tip

I sometimes recommend that between installing devices you enter the Device Manager in Windows and print out the resource settings as they are configured at the time. This way you have a record of how the configuration changes during the entire device installation and configuration process.

Here's the loading sequence for additional cards:

1. Sound card
2. Internal or external modem

3. Network card
4. Auxiliary video devices, such as MPEG decoders, 3D accelerators, and so on
5. SCSI adapter
6. Anything else

Normally, using this controlled sequence of configuring or building up your system results in easier integration with less conflicts and configuration hassles.

Resolving Conflicts Manually

In the past, the only way to resolve conflicts manually was to take the cover off your system and start changing switches or jumper settings on the adapter cards. Fortunately, this is a bit easier with plug-and-play because all the configuration is done via the Device Manager software included in the operating system. Although some early plug-and-play cards also had jumper switches or setup options to enable them to be configured manually, this feature was found primarily on ISA PnP-compatible cards.

Be sure you write down or print out your current system settings before you start making changes. That way, you will know where you began and can go back to the original configuration (if necessary).

Finally, dig out the manuals for all your adapter boards; you might need them, particularly if they can be configured manually or be switched to PnP mode. Additionally, you could look for more current information online at the manufacturers' Web sites.

Now you are ready to begin your detective work. As you try various resource settings, keep the following questions in mind; the answers will help you narrow down the conflict areas:

- *When did the conflict first become apparent?* If the conflict occurred after you installed a new adapter card, that new card probably is causing the conflict. If the conflict occurred after you started using new software, the software probably uses a device that is taxing your system's resources in a new way.
- *Are there two similar devices in your system that do not work?* For example, if your modem, integrated serial ports, or mouse—devices that use a COM port—do not work, chances are good that these devices are conflicting with each other.
- *Have other people had the same problem, and if so, how did they resolve it?* Public forums, such as those on CompuServe, Internet newsgroups, and America Online, are great places to find other users who might be able to help you solve the conflict.

Whenever you make changes in your system, reboot and see whether the problem persists. When you believe that you have solved the problem, be sure to test all your software. Fixing one problem often seems to cause another to crop up. The only way to ensure that all problems are resolved is to test everything in your system.

One of the best pieces of advice I can give you is to try changing one thing at a time, and then retest. That is the most methodical and the simplest way to isolate a problem quickly and efficiently.

As you attempt to resolve your resource conflicts, you should work with and update a system-configuration template, as discussed in the following section.

Using a System-Configuration Template

A *system-configuration template* is helpful because remembering something that is written down is easier than keeping it in your head. To create a configuration template, you need to start writing down which resources are used by which parts of your system. Then, when you need to make a change or add an adapter, you can quickly determine where conflicts might arise. You can also use the Windows 9x/Me/2000/XP Device Manager to list and print this information.

I like to use a worksheet split into three main areas—one for interrupts, another for DMA channels, and a middle area for devices that do not use interrupts. Each section lists the IRQ or DMA channel on the left and the I/O port device range on the right. This way, I get the clearest picture of which resources are used and which ones are available in a given system.

The next page shows the system-configuration template I have developed over the years and still use almost daily.

This type of configuration sheet is resource based instead of component based. Each row in the template represents a different resource and lists the component using the resource as well as the resources used. The chart has pre-entered all the fixed items in a modern PC for which the configuration cannot be changed.

To fill out this type of chart, you would perform the following steps:

1. Enter the default resources used by standard components, such as serial and parallel ports, disk controllers, and video. You can use the filled-out example I have provided to see how most standard devices are configured.
2. Enter the default resources used by additional add-on components, such as sound cards, SCSI cards, network cards, proprietary cards, and so on.
3. Change any configuration items that are in conflict. Try to leave built-in devices at their default settings, as well as sound cards. Other installed adapters might have their settings changed, but be sure to document the changes.

Of course, a template such as this is best used when first installing components, not after. After you have it completely filled out to match your system, you can label it and keep it with the system. Whenever you add more devices, the template will be your guide as to how any new devices should be configured if you need to configure devices manually.

Note

Thanks to plug-and-play configuration, the days of fixed IRQ and other hardware resources are receding into the past. Don't be surprised if your system has assigned different IRQ, I/O port address, or DMA settings after you install a new card. That's why I recommend recording information both before and after you add a new device to your system.

You also might want to track which PCI slot is used by a particular card because some systems convert PCI IRQs to different ISA IRQs depending on which slot is used for a card. Also, some systems pair PCI slots or might pair the AGP slot and a PCI slot, assigning cards installed in both paired slots to the same ISA IRQ.

Page 384 shows the same template filled out for a typical PC system with a mixture of PCI and ISA devices.

1. Represents a resource setting that had to be changed to resolve a conflict.

As you can see from this template, only one IRQ and two DMA channels remain available, and that would be *no* IRQs if I enabled the USB on the motherboard! As you can see, interrupt shortages are a big problem in modern systems, particularly when ISA and PCI devices are in use. In that case, I would probably find a way to recover one of the other interrupts; for example, I am not really using COM1, so I could disable that port and gain back IRQ4. In this sample configuration, the primary and secondary IDE connectors were built in to the motherboard:

- Floppy controller
- Two serial ports
- One parallel port

Whether these devices are built in to the motherboard or on a separate card makes no difference because the resource allocations are the same in either case. All default settings are typically used for these devices and are indicated in the completed configuration. Next, the accessory cards were configured. In this example, the following cards were installed:

- SVGA video card (ATI Mach 64)
- Sound card (Creative Labs Sound Blaster 16)
- SCSI host adapter (Adaptec AHA-1542CF)
- Network interface card (SMC EtherEZ)

It helps to install the cards in this order. Start with the video card; next, add the sound card. Because of problems with software that must be configured to the sound card, it is best to install it early and ensure that only default settings are used. It is better to change settings on cards other than the sound card.

After the sound card, the SCSI adapter was installed; however, the default I/O port addresses (330–331) and DMA channel (DMA 5) used were in conflict with other cards (mainly the sound card). These settings were changed to their next logical settings that did not cause a conflict.

Finally, the network card was installed, which also had default settings that conflicted with other cards. In this case, the Ethernet card came preconfigured to IRQ3, which was already in use by COM2:. The solution was to change the setting, and IRQ9 was the next logical choice in the card's configuration settings.

Even though this is a fully loaded configuration, only three individual items among all the cards had to be changed to achieve an optimum system configuration. As you can see, using a configuration template such as the one shown can make what would otherwise be a jumble of settings lay out in an easy-to-follow manner. The only real problems you will run into after you work with these templates are cards that do not allow for enough adjustment in their settings or cards that are lacking in documentation. As you can imagine, you will need the documentation for each adapter card, as well as the motherboard, to accurately complete a configuration table such as the one shown.

Tip

Do not rely too much on third-party DOS-based software diagnostics, such as MSD.EXE, which claim to be capable of showing hardware settings such as IRQ and I/O port settings. Even though they can be helpful in certain situations, they are often wrong with respect to at least some of the information they display about your system. One or two items shown incorrectly can be very troublesome if you believe the incorrect information and configure your system based on it!

Some third-party products such as AMIDiag and CheckIt do a better job, but a much better utility to view these settings is the Device Manager built in to Windows 9x/Me/2000/XP. With plug-and-play hardware, it not only reports settings, but it allows you to change them in some cases (sometimes this requires moving the card to another PCI slot). On older legacy hardware, you can view the settings but not change them. To change the settings of legacy (non-plug-and-play) hardware, you must manually move jumpers or switches and run the special configuration software that came with the card. Consult the card manufacturer or documentation for more information.

Heading Off Problems: Special Boards

A number of devices that you might want to install in a computer system require IRQ lines or DMA channels, which means that a world of conflict could be waiting in the box the device comes in. As mentioned in the preceding section, you can save yourself problems if you use a system-configuration template to keep track of the way your system is configured.

You also can save yourself trouble by carefully reading the documentation for a new adapter board before you attempt to install it, particularly if you are still using ISA boards. The documentation details the IRQ lines the board can use as well as its DMA-channel requirements. In addition, the documentation details the adapter's upper-memory needs for ROM and adapter.

Note

Although PCI cards also use all the resources discussed earlier except DMA channels, most are designed to use any available resource. Thus, the resources used by a particular PCI card are controlled less by the card's design than by the configuration of the particular system in use. For example, if IRQ3 or IRQ4 (normally set aside for use by COM2 and COM1) are not used by COM ports and are made available for PCI/PnP use on a given system, a PCI card might use one of these IRQs. However, on a system that has only IRQ9, IRQ10, and IRQ11 available for PCI/PnP configuration, the identical card might use one of these IRQs instead. In addition, some systems assign different IRQs to different PCI expansion slots.

The following sections describe some of the conflicts you might encounter when you install some popular adapter boards. Although the list of adapter boards covered in these sections is far from comprehensive, the sections serve as a guide to installing complex hardware with minimum hassle. Included are tips on soundboards, SCSI host adapters, and network adapters.

Sound Cards

Sound cards are probably the biggest single resource hog in your system. They typically use at least one IRQ, two DMA channels (in DOS emulation mode), and multiple I/O port address ranges. This is because a sound card is actually several different pieces of hardware all on one board. Most sound cards, including PCI-based models, emulate the Sound Blaster 16 from Creative Labs.

Table 4.82 shows the default resources used by a typical PCI sound card, the Creative Labs SB512. Because sound cards are multifunction devices, each function is listed separately as it appears in the Windows Device Manager.

Table 4.82 Default Resources Used by Creative Labs SB512

Device	IRQ	I/O Port Address	16-Bit DMA Channel	8-Bit DMA Channel
Sound Blaster 16 emulation	5	0220–022F 0330–0331 ¹ 0388–038B ²	5	1
Creative Multimedia Interface	N/A	D400–D407	n/a	n/a
Creative Gameport Joystick	N/A	0200–0207	n/a	n/a
Creative SB512	9 ³	C860–C87F	n/a	n/a

1. Used for MIDI interface

2. Used for FM Synthesis

3. Varies with system and PCI expansion slot used

Although other brands of sound cards might use a slightly different configuration, the pattern is the same; Sound Blaster emulation requires a large number of resources. Even if SB emulation isn't used (you might be able to disable it if you no longer play DOS games), the card still uses a single IRQ and several I/O port address ranges. If you take the time to read your soundboard's documentation and determine its communications-channel needs, compare those needs to the IRQ lines and DMA channels that already are in use in your system, and then change the settings of the other adapters to avoid conflicts with the sound card, your installation will go quickly and smoothly. Unfortunately, many vendors no longer provide detailed information on their plug-and-play-compatible cards. That's why you need to install the sound card first and use the system resource map to record which settings the card uses before you install other cards.

Tip

The best advice I can give you for installing a sound card is to put the sound card in before all other cards—except for video. In other words, let the sound card retain all its default settings if you can. Try to change the settings of other adapters when a conflict with the sound card arises. The problem here is that many older programs that use sound are very poorly written with respect to supporting alternative resource settings on sound cards. Save yourself some grief, and let the sound card have its way!

Even the latest sound cards can have problems if they're installed after other cards. I know a user who had to remove all his plug-and-play cards before his system would recognize his plug-and-play sound card.

If your system has integrated sound but you prefer to use a sound card, don't forget to use the BIOS configuration program to disable onboard sound before you install the sound card.

One example of a potential soundboard conflict is the combination of a Sound Blaster 16 and an Adaptec SCSI adapter, as I noted earlier in this chapter. The Sound and SCSI adapters conflict on DMA 5 as well as on I/O ports 330–331. Rather than changing the settings of the sound card, it is best to alter the SCSI adapter to the next available settings that will not conflict with the sound card or anything else. The reason to use the defaults for the sound card is that some older (mostly DOS-based) software often assumes default settings for sound hardware and won't work when alternative settings are used. However, devices that use SCSI ports can use any available setting. The final settings are shown in the previous configuration template.

The cards in question (Sound Blaster 16 and AHA-1542CF) are not singled out here because there is something wrong with them, but instead because they happen to be very popular cards of their respective types and, as such, often are paired together in older systems.

Most people would be using PCI versions of these cards today, but they still require the same types of resource settings with the only exception being DMA channels. Unfortunately, it wasn't DMA channels that we were really running out of! The interrupt shortage often continues even with PCI cards because for older real-mode applications or Windows 95 and earlier, they must be mapped to discrete ISA IRQs. The real solutions to the ISA IRQ problem are to use only PCI cards, use Windows 98 or newer (which support IRQ Steering), and have that support in your ROM BIOS. Then, full sharing is possible. Every desktop system sold today is equipped with a motherboard that lacks ISA slots and breaks ties with that bus forever. These motherboards free us of the interrupt restrictions we have been under for so many years.

Tip

The newer PCI sound cards are largely incompatible with older DOS-based software because they don't use DMA channels like their ISA counterparts. If you don't update your software to 32-bit Windows versions, you won't be able to use these newer PCI bus sound cards. Most of the newer PCI cards do include an emulation program that allows the card to work with older DMA-dependent software, but the results are often problematic. If you use integrated sound, the drivers for your motherboard might include a Sound Blaster emulation driver.

For the best results, use the PC/PCI connector found on some motherboards to connect a patch cable to a PC/PCI-compatible sound card. The PC/PCI connector enables the sound card to use ISA-style DMA channels without clumsy emulation software.

SCSI Adapter Boards

SCSI adapter boards use more resources than just about any other type of add-in device except perhaps a sound card. They often use resources that are in conflict with sound cards or network cards, especially if the card has an onboard BIOS for handling bootable drives. A typical ISA SCSI host adapter with onboard BIOS requires an IRQ line, a DMA channel, a range of I/O port addresses, plus a 16KB range of unused upper memory for its ROM and possible scratch-pad RAM use. Even a simple SCSI host adapter designed for use with scanners still requires an IRQ and a range of I/O port addresses. Fortunately, the typical SCSI adapter is also easy to reconfigure, and changing any of these settings should not affect performance or software operation. PCI-based SCSI host adapters require all of the preceding, except for the DMA channel.

Before installing a SCSI adapter, be sure to read the documentation for the card, and ensure that any IRQ lines, DMA channels, I/O ports, and upper memory the card needs are available. If the system resources the card needs are already in use, use your system-configuration template to determine how you can alter the settings on the SCSI card or other cards to prevent any resource conflicts before you attempt to plug in the adapter card.

Note

Some ISA-based SCSI and network cards can be configured to work in PnP mode or use manual configuration settings. With these cards, you can use the configuration method you prefer. If PnP doesn't work, set the card manually (through jumpers, DIP switches, or software).

Network Interface Cards

Networks are becoming more and more popular all the time, thanks to the rise of easy-to-configure small office/home office networks and the use of network cards to connect to broadband Internet devices such as cable and DSL modems. A typical network adapter does not require as many resources as some of the other cards discussed here, but it requires at least a range of I/O port addresses and an interrupt. Some network interface cards (NICs) also require a 16KB range of free upper memory to be used for the RAM transfer buffer on the network card. As with any other cards, be sure that all these resources are unique to the card and are not shared with any other devices. If your network adapter is built in to the motherboard, it still uses IRQ and I/O port address resources.

Multiple-COM-Port Adapters

A serial port adapter usually has two or more ports onboard. These COM ports require an interrupt and a range of I/O ports each. There aren't too many problems with the I/O port addresses because the ranges used by up to four COM ports in a system are fairly well defined. The real problem is with the interrupts. Most older installations of more than two serial ports have any additional ones sharing the same interrupts as the first two. This is incorrect and causes nothing but problems with software that runs under Windows or OS/2. With these older boards, ensure that each serial port in your system has a unique I/O port address range and, more importantly, a unique interrupt setting.

Many newer multiport adapter cards—such as those offered by Byte Runner Technologies—allow “intelligent” interrupt sharing among ports. In some cases, you can have up to 12 COM port settings without conflict problems. Check with your adapter card's manufacturer to determine whether it allows for automatic or “intelligent” interrupt sharing.

Although most people have problems incorrectly trying to share interrupts when installing more than two serial ports in a system, a fairly common problem exists with the I/O port addressing that should be mentioned. Many of the high-performance video chipsets, such as those from S3, Inc., and ATI, use some additional I/O port addresses that conflict with the standard I/O port addresses used by COM4:

In the sample system configuration just covered, you can see that the ATI video card uses some additional I/O port addresses, specifically 2EC–2EF. This is a problem because COM4: usually is configured as 2E8–2EF, which overlaps with the video card. The video cards that use these addresses are not normally adjustable for this setting, so you either must change the address of COM4: to a nonstandard setting or disable COM4: and restrict yourself to using only three serial ports in the system. If you do have a serial adapter that supports nonstandard I/O address settings for the serial ports, you must ensure that those settings are not used by other cards, and you must inform any software or drivers, such as those in Windows, of your nonstandard settings.

In many cases, USB or 10/100 Ethernet connections can be used to perform the tasks formerly handled by serial ports. If you no longer need serial ports for any devices in your system, I recommend that you disable the onboard serial ports, remove multiport serial cards, and assign the IRQs used by the serial ports in the BIOS to be available for PCI/AGP Plug and Play assignment. This helps eliminate any IRQ conflicts that could occur.

Universal Serial Bus

USB ports corresponding to USB 1.1 or USB 2.0 are now found on most motherboards, and Windows 98, Windows Me, Windows 2000, and Windows XP provide you with a wide range of operating systems that support them properly. One potential problem is that USB takes another interrupt from your system (in some cases, more than one), and many computers either don't have any free or are down to their last one. If your system supports PCI IRQ Steering, this shouldn't be much of a problem because the IRQ used by your USB controller should be sharable with other PCI devices. If you are out of interrupts, you should look at what other devices you can disable (such as COM or LPT ports) to gain back a necessary interrupt for other devices.

The big advantage of either type of USB from an IRQ or a resource perspective is that the USB bus uses only one IRQ no matter how many devices (up to 127) are attached or how many USB ports are installed on systems with a single USB controller. Some systems with multiple USB controllers use additional IRQs, but USB controllers can share IRQs with each other or with other PCI devices. Therefore, you can freely add or remove devices from the USB without worrying about running out of resources or having resource conflicts.

If you aren't using any USB devices, you should turn off the port using your motherboard CMOS Setup so that the IRQ it was using will be freed. As we continue to move to USB-based keyboards, mice, modems, printers, and so on, the IRQ shortage will be less of a problem. As we have already seen, the elimination of the ISA bus in our systems will also go a long way toward solving this problem.

For the best performance—especially with high-capacity removable media, CD/DVD rewriteable drives, scanners, and printers—look for motherboards that have USB 2.0 (High-speed USB) ports. These ports are also completely backward compatible with USB 1.1 devices and provide better performance when several USB devices are in use simultaneously. You can also add a USB 2.0 card to an existing motherboard to provide the same benefits to an existing system.

Miscellaneous Boards

Some video cards ship with advanced software that allows special video features, such as oversized desktops, custom monitors, switch modes on-the-fly, and so on. Unfortunately, this software requires that the card be configured to use an IRQ. If your video card doesn't require an IRQ, I suggest you dispense with this unnecessary software and configure the card to free up the interrupt for other devices. However, keep in mind that many of the latest 3D accelerators must use an IRQ to enable their bus-mastering feature to work correctly. See your video card's manual for details.

Also related to video is the use of an MPEG decoder add-on card that works in addition to your normal graphics adapter. These are used more in specialized video production and editing and in playing DVD movies; however, they do use additional system resources that must be available. If your CPU

runs at speeds above 300MHz and you have an AGP video card, you can probably use your video card for DVD playback and remove the MPEG decoder card. You will need a DVD player program, which might be supplied with your video card. See your video card's manual for details.

Plug-and-Play Systems

Plug and Play (PnP) represents a major revolution in interface technology. PnP first came on the market in 1995, and most motherboards and adapter cards since 1996 take advantage of it. Prior to that, PC users were forced to muddle through a nightmare of DIP switches and jumpers every time they wanted to add new devices to their systems. The results, all too often, were system resource conflicts and nonfunctioning cards.

PnP was not an entirely new concept. It was a key design feature of MCA and EISA interfaces that preceded it by almost 10 years, but the limited appeal of MCA and EISA meant that they never became true de facto industry standards. Therefore, mainstream PC users still had to worry about I/O addresses, DMA channels, and IRQ settings. Early PCI-based systems also used a form of PnP configuration, but because there was no provision for managing conflicts between PCI and ISA cards, many users still had configuration problems. But now that PnP has become prevalent, worry-free hardware setup is available to all computer buyers.

For PnP to work, the following components are desired:

- PnP hardware
- PnP BIOS
- PnP operating system

Each of these components needs to be PnP-compatible, meaning that it complies with the PnP specifications.

The Hardware Component

The *hardware component* refers to both computer systems and adapter cards. The term does not mean, however, that you can't use your older ISA adapter cards (referred to as *legacy cards*) in a PnP system. You can use these cards; in fact, your PnP BIOS automatically reassigns PnP-compatible cards around existing legacy components. Also, many late-model ISA cards can be switched into PnP-compatible mode.

PnP adapter cards communicate with the system BIOS and the operating system to convey information about which system resources are necessary. The BIOS and operating system, in turn, resolve conflicts (wherever possible) and inform the adapter card which specific resources it should use. The adapter card then can modify its configuration to use the specified resources.

The BIOS Component

The BIOS component means that most users of pre-1996 PCs need to update their BIOSs or purchase new machines that have PnP BIOSs. For a BIOS to be compatible, it must support 13 additional system function calls, which can be used by the OS component of a PnP system. The PnP BIOS specification was developed jointly by Compaq, Intel, and Phoenix Technologies.

The PnP features of the BIOS are implemented through an expanded POST. The BIOS is responsible for identification, isolation, and possible configuration of PnP adapter cards. The BIOS accomplishes these tasks by performing the following steps:

1. Disables any configurable devices on the motherboard or on adapter cards
2. Identifies any PnP PCI or ISA devices
3. Compiles an initial resource-allocation map for ports, IRQs, DMAs, and memory
4. Enables I/O devices

5. Scans the ROMs of ISA devices
6. Configures initial program-load (IPL) devices, which are used later to boot the system
7. Enables configurable devices by informing them which resources have been assigned to them
8. Starts the bootstrap loader
9. Transfers control to the operating system

The Operating System Component

The operating system component is found in most modern operating systems, such as Windows 9x/Me/2000/XP. In some cases system manufacturers have provided extensions to the operating system for their specific hardware. Such is especially true for notebook systems, for example. Be sure you load these extensions if they are required by your system.

It is the responsibility of the operating system to inform users of conflicts that can't be resolved by the BIOS. Depending on the sophistication of the operating system, the user then could configure the offending cards manually (onscreen) or turn off the system and set switches on the physical cards. When the system is restarted, the system is checked for remaining (or new) conflicts, any of which are brought to the user's attention. Through this repetitive process, all system conflicts are resolved.

Note

Because of revisions in some of the Plug and Play specifications, especially the ACPI specification, it can help to ensure you are running the latest BIOS and drivers for your system. With the Flash ROM used in most PnP systems, you can download the new BIOS image from the system vendor or manufacturer and run the supplied BIOS update program.

Motherboard Selection Criteria (Knowing What to Look For)

I am often asked to make a recommendation for purchases. Without guidance, many individuals don't have any rhyme or reason to their selections and instead base their choices solely on magazine reviews or, even worse, on some personal bias. To help eliminate this haphazard selection process, I have developed a simple checklist that will help you select a system. This list takes into consideration several important system aspects overlooked by most checklists. The goal is to ensure that the selected system truly is compatible and has a long life of service and upgrades ahead.

It helps to think like an engineer when you make your selection. Consider every aspect and detail of the motherboards in question. For instance, you should consider any future uses and upgrades. Technical support at a professional (as opposed to a user) level is extremely important. What support will be provided? Is there documentation, and does it cover everything else?

In short, a checklist is a good idea. Here is one for you to use in evaluating any PC-compatible system. A system might not have to meet every one of these criteria for you to consider purchasing it, but if it misses more than a few, consider staying away from that system. The items at the top of the list are the most important, and the items at the bottom are perhaps of lesser importance (although I think each item is important). The rest of this chapter discusses in detail the criteria in this checklist:

- **Motherboard chipset.** Motherboards should use a high-performance chipset that supports DDR or DDR-2 SDRAM DIMMs or RDRAM RIMMs—preferably one that allows ECC memory as well if you are concerned about catching possible memory errors before they corrupt your data. Also look for AGP 4x or faster video support and ATA-100 or faster hard drive support. The motherboard chipset is the backbone of a system and is perhaps the single most important part you'll consider. I spend the most time deciding on my next chipset because it affects and influences virtually every other component in the system.

- **Processor.** A modern system should use a socket-based processor with on-die L2 cache. Evaluate the processor choices you have, and try to get the one with the highest-speed CPU bus (front-side bus). Don't get too hung up on L2 cache size; a little cache goes a long way. It is more important that the cache run at full core speed (which it will if it is on-die). Current processors such as the Athlon XP, Pentium 4, Celeron 4, and Athlon 64 all meet this criteria. I usually recommend only "boxed" processors as sold by Intel and AMD, which include a high-quality active heatsink as well as installation instructions and a 3-year warranty direct with the manufacturer.
- **Processor sockets.** For maximum upgradeability and performance, you should stick with a system that uses a socket for the CPU. The main sockets in use today on new systems include Socket A (Socket 462) for the Duron/Athlon/Athlon XP, Socket 478 (which has replaced the original Socket 423) for the Pentium 4 and Celeron 4, and Socket 754 for the Athlon 64 or Socket 939 (which is replacing Socket 940) for the Athlon 64FX. As long as your motherboard has one of these sockets, you should be in good shape.
- **Motherboard speed.** The motherboard typically offers a choice of speeds, including anywhere from 200MHz to 400MHz for the Duron/Athlon/Athlon XP-based boards, or from 400MHz to 800MHz for the Pentium 4-based boards. Check to ensure the board you are buying runs at the speeds necessary to support the processors you want to install.
- **Cache memory.** All modern systems use processors with integral cache, most of them now having the cache directly on the processor die for maximum speed. As such, there won't be any cache memory on the motherboard in a modern system. The tip is to make sure you are using a processor with full core speed on-die L2 cache because this offers the maximum in performance. All the modern processors now incorporate full-speed on-die L2 cache.
- **SIMM/DIMM/RIMM memory.** SIMMs are obsolete by today's standards, so stay away from any boards that use them. Your board should support either standard or DDR DIMMs or RIMMs that contain SDRAM, DDR SDRAM, or RDRAM, respectively. What you use depends mainly on your motherboard chipset, so choose the chipset and board that accepts the memory type you want to use. Currently, DDR and DDR-2 SDRAM and RDRAM are the fastest types of memory available, with RDRAM being by far the most costly. SDRAM is now much more expensive than DDR SDRAM because current systems no longer use SDRAM.

Mission-critical systems should use ECC memory and ensure that the motherboard fully supports ECC operation. Note that many of the low-end chipsets from Intel and others do not support ECC and should not be used for mission-critical applications. This is something you should know before purchasing the system.

Finally, note that most motherboards support either three or four DIMM sockets, or two or three RIMM sockets. Be sure that you populate them wisely so you don't have to resort to removing memory later to add more, which is not very cost-effective.

- **Bus type.** No recent desktop motherboards incorporate ISA bus slots, so if you have any ISA cards, you'll have to discard them or use them in older systems. Instead you should find anywhere from one to five or more PCI local bus slots. Be sure the PCI slots conform to the PCI 2.1 or later revision (primarily based on the chipset). Take a look at the layout of the slots to ensure that cards inserted in them will not block access to memory sockets or be blocked by other components in the case. Systems without onboard video should also feature one AGP 4x or 8x slot for a high-performance AGP video card. Some very high-performance systems use the new PCI-Express x16 slot instead of (or sometimes along with) an AGP 4x/8x slot. Some boards also feature AMR (audio modem riser) or CNR (communications networking riser) slots for special cards that are included with the board to provide sound, modem, or other similar features. If a motherboard has an AMR or a CNR slot but doesn't include the riser card, you should check with the vendor to determine whether riser cards are available with the features you want.

- **BIOS.** The motherboard should use an industry-standard BIOS, such as those from AMI, Phoenix, or Award. The BIOS should be of a Flash ROM or EEPROM design for easy updating. Look for a BIOS Recover jumper or mode setting, as well as possibly a Flash ROM write-protect jumper on some systems.
- **Form factor.** For maximum flexibility, performance, reliability, and ease-of-use, the ATX form factor (including microATX and FlexATX) cannot be beat. ATX has several distinct performance and functional advantages over Baby-AT and is vastly superior to any proprietary designs, such as LPX. Additionally, the NLX form factor might be a consideration for low-profile or low-cost desktop systems, although FlexATX is also becoming popular for these designs. The newest form factor, BTX, offers superior cooling but is more expensive than ATX and requires a new power supply and case design.
- **Built-in interfaces.** Ideally, a motherboard should contain as many built-in standard controllers and interfaces as possible (except perhaps video). There is a trend toward legacy-free PCs that lack the conventional Super I/O component and therefore have only USB and sometimes IEEE 1394 for external expansion. Legacy-free PCs lack the conventional keyboard and mouse ports, serial and parallel ports, and possibly even the internal floppy controller. Systems that use an integrated Super I/O component have these interfaces.

Built-in 10/100 or 10/100/1000 Ethernet network adapters are also handy, especially if you are using a cable modem or DSL connection to the Internet. A built-in sound card is a great feature, usually offering full Sound Blaster compatibility and functions, and possibly offering additional features such as 5.1 (six-channel) or 7.1 (eight-channel) surround sound and SPDIF connections to a home theater system. If your sound needs are more demanding, you might find the built-in solutions less desirable, and you might want to have a separate sound card in your system. Built-in video adapters are also a bonus in some situations, but because there are many video chipset and adapter designs from which to choose, generally you'll find better choices in external local bus video adapters. This is especially true if you need the highest performance video available.

Built-in devices usually can be disabled to allow future add-ons, but problems can result.

- **Onboard IDE interfaces.** All motherboards on the market have included onboard IDE interfaces for some time now, but not all IDE interfaces are equal. Your motherboard should support at least UDMA/66 (ATA-66) speeds, which matches the best real-world performance currently available from IDE drives. UDMA/66, UDMA/100, and UDMA/133 actually exceed the real-world performance of current drives using these standards and thus provide you with headroom for future drives. For even greater speed, consider motherboards with onboard IDE RAID controllers. These motherboards can be configured to perform data striping for extra speed or data mirroring for extra reliability when two or more identical IDE drives are used. These motherboards are based on a variety of standard chipsets with RAID functions added by RAID chipsets from AMI, HighPoint, or Promise. Many recent systems now include Serial ATA drive interfaces, some of which include RAID functions. SATA is even faster than ATA-133 and exceeds the real-world performance of current (first-generation) SATA drives by a wide margin.

Tip

With a never-ending stream of motherboards coming onto the market, finding motherboards with the features you want can be difficult. Motherboard Homeworld's Mobot search engine helps you find motherboards based on your choice of form factor, platform, chipset, CPU type, processor, manufacturer, memory type, slot types, built-in ports, and more. Check it out at iceberg.pchomeworld.com/cgi-win/mobotGen/mobot.asp.

- **Power management.** The motherboard should fully support the latest standard for power management, which is ACPI. An Energy Star-compliant system is also a bonus because it uses less than 30 watts of electrical energy when in sleep mode, saving energy as well as your electric bill.

- **Documentation.** Good technical documentation is a requirement. Documents should include information on any and all jumpers and switches found on the board, connector pinouts for all connectors, specifications for other plug-in components, and any other applicable technical information. Most vendors provide this information in electronic form (using the Adobe Reader PDF format) on their Web sites, so you can preview the information available for a given motherboard before you buy.
- **Technical support.** Good online technical support goes beyond documentation. It includes driver and BIOS updates, FAQs, updated tables of processor and memory compatibility, and utility programs to help you monitor the condition of your system. In addition to these online support features, make sure the vendor can be contacted through email and by phone.

You might notice that these selection criteria seem fairly strict and might disqualify many motherboards on the market, including what you already have in your system! These criteria will, however, guarantee you the highest-quality motherboard offering the latest in PC technology that will be upgradeable, be expandable, and provide good service for many years.

Most of the time I recommend purchasing boards from better-known motherboard manufacturers such as Intel, Acer, ABIT, AsusTek, SuperMicro, Tyan, FIC, and others. These boards might cost a little more, but there is some safety in the more well-known brands. That is, the more boards they sell, the more likely that any problems will have been discovered by others and solved long before you get yours. Also, if service or support is necessary, the larger vendors are more likely to be around in the long run.

Documentation

As mentioned, documentation is an important factor to consider when you're planning to purchase a motherboard. Most motherboard manufacturers design their boards around a particular chipset, which actually counts as the bulk of the motherboard circuitry. Many manufacturers, such as Intel, VIA, ALi, SiS, and others, offer chipsets. I recommend obtaining the data book or other technical documentation on the chipset directly from the chipset manufacturer.

For example, one of the more common questions I hear about a system relates to the BIOS Setup program. People want to know what the "Advanced Chipset Setup" features mean and what the effects of changing them will be. Often they go to the BIOS manufacturer thinking that the BIOS documentation will offer help. Usually, however, people find that there is no real coverage of what the chipset setup features are in the BIOS documentation. You will find this information in the data book provided by the chipset manufacturer. Although these books are meant to be read by the engineers who design the boards, they contain all the detailed information about the chipset's features, especially those that might be adjustable. With the chipset data book, you will have an explanation of all the controls in the Advanced Chipset Setup section of the BIOS Setup program.

Besides the main chipset data books, I also recommend collecting any data books on the other major chips in the system. This includes any floppy or IDE controller chips, Super I/O chips, and of course the main processor. You will find an incredible amount of information on these components in the data books.

Caution

Most chipset manufacturers make a particular chip for only a short time, rapidly superseding it with an improved or changed version. The data books are available only during the time the chip is being manufactured, so if you wait too long, you will find that such documents might no longer be available. The time to collect documentation on your motherboard is *now!*

Using Correct Speed-Rated Parts

Some vendors use substandard parts in their systems to save money. Because the CPU is one of the most expensive components on the motherboard and motherboards are sold to system assemblers without the CPU installed, it is tempting for the assembler to install a CPU rated for less than the actual operating speed. A system could be sold as a 2.4GHz system, for example, but when you look under the hood, you might find it's rated for only 2GHz. This is called *overclocking*, and many vendors have practiced this over the last few years. Some even go so far as to re-mark the CPUs, so that even if you look, the part appears to have the correct rating. The best way to stop this is to purchase systems from known, reliable vendors and purchase processors from distributors that are closely connected with the manufacturer. Overclocking is fine if you want to do it yourself and understand the risks, but when I purchase a new system, I expect that all the parts included will be rated to run at the speed to which they are set.

◀◀ See "Processor Speed Ratings," p. 53.

When a chip is run at a speed higher than it is rated for, it runs hotter than it would normally. This can cause the chip to occasionally overheat, which would appear as random lockups, glitches, and frustration. I highly recommend that you check to ensure you are getting the right speed-rated parts you are paying for.

Also be sure to use the recommended heatsink compound (thermal grease). This can improve the efficiency of your heatsink by up to 30%.

This practice is easy to fall into because the faster-rated chips cost more money. Intel and other chip manufacturers usually rate their chips very conservatively. Over the years, I have overclocked many processors, running them sometimes well beyond their rated speeds. Although I might purchase a Pentium 4 2.4GHz and run it at 2.6GHz, if I were to experience lockups or glitches in operation, I would immediately return it to the original speed and retest. If I purchase a 2.6GHz system from a vendor, I fully expect it to have a 2.6GHz part, not slower parts running past their rated speeds!

Overclocking has been made more difficult by Intel and AMD, who have both started locking the bus multipliers in their chips to prevent easy overclocking by changing the multiplier setting on the motherboard. This is done mainly to combat re-marking CPUs and deceiving customers, although it unfortunately can also prevent those who want to from hotrodding their chips. Still, you can overclock most chips by increasing the CPU bus (front-side bus) speed within certain tolerances. Many of the motherboards on the market have tweakable CPU bus speeds specifically designed to allow overclocking. Check with your motherboard manual, or download the documentation from the manufacturer's Web site. You might find that your board is capable of things you didn't realize.

If you purchase a processor or system, verify that the markings are the original Intel or AMD markings and that the speed rating on the chip is what you really paid for.

The bottom line: If the price is too good to be true, ask before you buy. Are the parts really manufacturer-rated for the system speed?

To determine the rated speed of a CPU chip, look at the writing on the chip. See Chapter 3 for details on how to interpret the marks to see what the rating on the chip actually is.

Caution

Be careful when running software to detect processor speed. Most programs can only estimate at what speed the chip is currently running, not what the true original rating is. The current speed of the processor might not be its actual rated speed, either because of overclocking or because some recent systems reduce processor speed when the system is not heavily tasked. One exception to this is the Intel Processor Frequency ID Utility, which can determine whether an Intel processor is operating at the correct and rated frequency intended. Although it gives only basic information about any Intel processor, it can uniquely identify the original speed ratings of the Pentium III, third-generation Celeron (Coppermine-based), and any newer processors, accurately determining whether they have been overclocked. You can download the Intel Processor Frequency ID Utility from developer.intel.com/support/processors/tools/frequencyid/download.htm.

Older system chassis with speed markings or even indicator lights are usually no indication of the actual or rated speed of the processor inside. Those displays can literally be set via jumpers to read any speed you desire! They have no true relation to actual system speed.

Most of the better diagnostics on the market, such as Norton Utilities from Symantec or SiSoftware Sandra, read the processor ID and stepping information, as well as show current operating (but not rated) speed. You can consult the processor manufacturer or Chapter 3 for tables listing the various processor steppings to see exactly how yours stacks up.

CHAPTER 5

BIOS

BIOS Basics

It is often difficult for people to understand the difference between hardware and software in a PC system. The differences can be difficult because they are both very much intertwined in the system design, construction, and operation. Understanding these differences is essential to understanding the role of the BIOS in the system.

BIOS is a term that stands for *basic input/output system*, which consists of low-level software that controls the system hardware and acts as an interface between the operating system and the hardware. Most people know the term BIOS by another name—*device drivers*, or just *drivers*. In other words, the BIOS is drivers, meaning all of them. BIOS is essentially the link between hardware and software in a system.

When the PC was first introduced, the BIOS software containing all the device drivers for the entire system was collectively burned into one or more nonvolatile (meaning they retain their data even when the power is turned off) read-only memory (ROM) chips and placed on the motherboard. In essence, the drivers were self-contained, preloaded into memory, and accessible anytime the PC was powered on.

This ROM chip also contained a power on self test (POST) program and a bootstrap loader. The bootstrap program was designed to initiate the loading of an OS by checking for and loading the boot sector from a floppy disk and, if one was not present, a hard disk. After the OS was loaded, it could call on the low-level routines (device drivers) in the BIOS to interact with the system hardware. In the early days, all the necessary device drivers were in the BIOS stored in the motherboard ROM. This included drivers for the keyboard, MDA/CGA video adapters, serial/parallel ports, floppy controller, hard disk controller, joystick, and clock.

When the OS loaded, you didn't have to load a driver to interact with those pieces of hardware because the drivers were already preloaded in the ROM. That worked great as long as you didn't add any new hardware for which there wasn't a driver in ROM. If you did, you then had two choices: If the hardware you were adding was an adapter card, that card could have a ROM onboard containing the necessary device drivers. The motherboard ROM was preprogrammed to scan a predetermined area of memory looking for any adapter card ROMs and, if any were found, their code was tested and subsequently executed, essentially linking them into and adding their functionality to the existing BIOS. In essence, the motherboard ROM "assimilated" any adapter card ROMs, adding to the "collective" functionality.

This method of adding drivers was required for certain items, such as video cards, that needed to be functional immediately when the PC was powered on. The BIOS code in the motherboard ROM had drivers only for the IBM monochrome display adapter (MDA) and color graphics adapter (CGA) video cards. If you added any card that was different from that, the drivers in the motherboard ROM would not work. That wouldn't be a problem if the new video card had its own onboard drivers in a ROM that would be linked into the BIOS immediately upon throwing the power switch.

If the device did not use an adapter card, there had to be another way to add the necessary driver to the BIOS collective. A scheme was devised whereby during the early stages of loading, the OS startup file (`IO.SYS`) checked for a configuration file (called `CONFIG.SYS`) that specified any additional drivers to load to support new hardware. The `CONFIG.SYS` file, along with any drivers named within, would be placed on the boot drive. Then, when the `IO.SYS` program read them, it loaded the specified drivers into memory and linked them into the rest of the BIOS, again adding their functionality to the collective whole. In essence, these drivers were loaded from disk into RAM and linked into the BIOS so they could be called on when necessary.

At this point, the BIOS had grown from being entirely contained in the motherboard ROM, to having additional drivers linked in from adapter card ROMs, to having even more drivers linked in after being loaded into RAM during the early stages of the boot process. The BIOS was now constructed of programs located in three different physical locations in the system, and yet it functioned as a single entity because all the programs were linked together via the BIOS subroutine calling system-of-software interrupts. The OS or an application program needing to talk to a specific piece of hardware (for example, to read from the CD-ROM drive) would make a call to a specific software interrupt, and the

interrupt vector table would then route the call to the specific part of the BIOS (meaning the specific driver) for the device being called. It did not matter whether that driver was in the motherboard ROM, adapter ROM, or RAM. As far as the system was concerned, memory is memory, and as long as the routine existed at a memory address, it could be called.

The combination of the motherboard BIOS, adapter card BIOS, and device drivers loaded from disk contributed to the BIOS as a whole. The portion of the BIOS contained in ROM chips, both on the motherboard and in some adapter cards, is sometimes called *firmware*, which is a name given to software stored in chips rather than on disk. Of course, after you turned off the system, the drivers in nonvolatile ROM would remain intact but those in volatile RAM would instantly vanish. That was not a problem, however, because the next time the system was turned back on, it went through the boot process and again loaded the necessary supplemental drivers from disk all over again.

As the PC has evolved, more and more accessories and new hardware have been devised to add to the system. This means that more and more drivers have needed to be loaded to support this hardware. Adding new drivers to the motherboard ROM has been extremely difficult because ROM chips were relatively fixed (difficult to change) and limited space was available. The PC architecture allotted only 128KB for the motherboard ROM, and most of it was already used by the existing drivers, POST, BIOS Setup program, and of course the bootstrap loader. Putting the driver on an adapter card ROM is also difficult and expensive, and only 128KB is allocated for all adapter card ROMs to exist, not to mention the fact that the video cards have already stolen 32KB of that. So, most companies developing new hardware for the PC simply wrote a driver that was designed to be loaded into RAM during boot.

As time went on, more and more drivers were being loaded from disk—in some cases, even drivers that were replacing those in the motherboard. For example, Windows 95 introduced a new hard disk driver that used 32-bit code, which shut down the existing 16-bit driver that existed in the motherboard ROM. At that point, the hard disk driver in the motherboard ROM was used for only a few seconds after the system was turned on, and after the 32-bit driver was loaded into RAM during the boot process, the vector table was changed to point to that one instead of the one in the ROM. Windows 95, 98, and Me allowed the use of both 16-bit and 32-bit drivers, easing the transition to full 32-bit operation.

This has progressed to today, when 32-bit drivers have been designed to be loaded from disk to replace *all* the drivers in the motherboard ROM. This is the case for any system today running Windows NT, 2000, or XP. Those operating systems cannot use any of the 16-bit drivers found in either the motherboard ROMs or any adapter card ROMs and must use only 32-bit drivers. The 16-bit code in the motherboard ROM is used only to get the system functioning long enough to get the initial 32-bit drivers and OS loaded, at which point they take over and the 16-bit code is shut down.

The same issue is true for 64-bit versions of Windows, which require all 64-bit drivers and cannot use any 32-bit or 16-bit drivers. In fact, the all-or-nothing approach requiring all 64-bit drivers will delay the acceptance of systems running 64-bit Windows for some time.

When running 32-bit Windows XP, for example, after XP is loaded, no more calls are made to any of the 16-bit routines in the motherboard or adapter ROMs. Instead, only 32-bit device drivers loaded into RAM are called. So, the instant the PC is powered on, the BIOS might be mostly in ROM, but after XP is loaded, the BIOS resides entirely in RAM.

That is most likely the way things will continue for the future. The motherboard ROM exists only to get the system started, to initialize specific hardware, to offer security in the way of power-on passwords and such, and to perform some basic initial configuration. However, after the OS is loaded, a whole new set of drivers takes over.

A PC system can be described as a series of layers—some hardware and some software—that interface with each other. In the most basic sense, you can break a PC down into four primary layers, each of which can be broken down further into subsets. Figure 5.1 shows the four layers in a typical PC.

The purpose of the layered design is to enable a given operating system and applications to run on different hardware. Figure 5.1 shows how two different machines with different hardware can each

use different sets of drivers (BIOS) to interface the unique hardware to a common operating system and applications. Thus, two machines with different processors, storage media, video display units, and so on can run the same OS and applications.

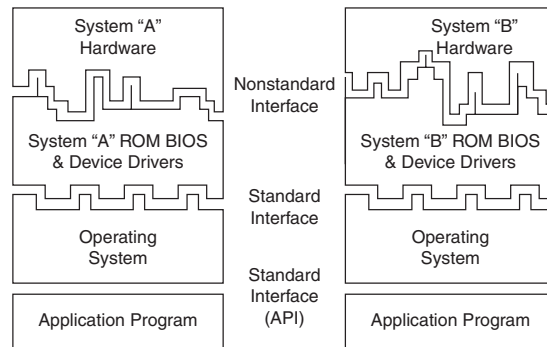

Figure 5.1 PC system layers.

In this layered architecture, the application software programs talk to the operating system via what is called an Application Program Interface (API). The API varies according to the operating system you are using and consists of the various commands and functions the operating system can perform for an application. For example, an application can call on the operating system to load or save a file. This prevents the application itself from having to know how to read the disk, send data to a printer, or perform any other of the many functions the operating system can provide. Because the application is completely insulated from the hardware, you can essentially run the same applications on different machines; the application is designed to talk to the operating system rather than the hardware.

The operating system then interfaces with or talks to the BIOS or driver layer. The BIOS consists of all the individual driver programs that operate between the operating system and the actual hardware. As such, the operating system never talks to the hardware directly; instead, it must always go through the appropriate drivers. This provides a consistent way to talk to the hardware. It is usually the responsibility of the hardware manufacturer to provide drivers for its hardware. Because the drivers must act between both the hardware and the operating system, the drivers typically are operating system specific. Thus, the hardware manufacturer must offer different drivers so that its hardware works under DOS, Windows 9x, Windows 2000, Windows XP, OS/2, Linux, and so on. Because many operating systems use the same internal interfaces, some drivers can work under multiple operating systems. For example, a driver that works under Windows Me will usually also work under Windows 98 and 95, and a driver that works under Windows XP will also often work under Windows 2000 and NT (and vice versa). This is because Windows 95, 98, and Me are essentially variations on the same OS, as are Windows NT, 2000, and XP.

Because the BIOS layer looks the same to the operating system no matter what hardware is above it (or underneath, depending on your point of view), the same operating system can run on a variety of systems. For example, you can run Windows XP on two systems with different processors, hard disks, video adapters, and so on, yet Windows XP will look and feel pretty much the same on both of them. This is because the drivers provide the same basic functions no matter which specific hardware is used.

As you can see from Figure 5.1, the application and operating systems layers can be identical from system to system, but the hardware can differ radically. Because the BIOS consists of software drivers that act to interface the hardware to the software, the BIOS layer adapts to the unique hardware on one end but looks consistently the same to the operating system at the other end.

The hardware layer is where most differences lie between various systems. It is up to the BIOS to mask the differences between unique hardware so that the given operating system (and subsequently the application) can be run. This chapter focuses on the BIOS layer of the PC.

BIOS Hardware/Software

The BIOS itself is software running in memory that consists of all the various drivers that interface the hardware to the operating system. The BIOS is unique compared to normal software in that it doesn't all load from disk; some of it is preloaded into memory chips (read-only memory, or ROM) installed in the system or on adapter cards.

The BIOS in a PC comes from three possible sources:

- Motherboard ROM
- Adapter card ROM (such as that found on a video card)
- Loaded into RAM from disk (device drivers)

The motherboard ROM BIOS is most often associated with hardware rather than software. This is because the BIOS on the motherboard is contained in a ROM chip on the board, which contains the initial software drivers needed to get the system running. Years ago, when only DOS was running on basic PCs, this was enough, so no other drivers were needed—the motherboard BIOS had everything that was necessary. The motherboard BIOS usually includes drivers for all the basic system components, including the keyboard, floppy drive, hard drive, serial and parallel ports, and more. As systems became more complex, new hardware was added for which no motherboard BIOS drivers existed. These included devices such as newer video adapters, CD-ROM drives, SCSI hard disks, USB ports, and so on.

Rather than requiring a new motherboard BIOS that would specifically support the new devices, it was far simpler and more practical to copy any new drivers that were necessary onto the system hard disk and configure the operating system to load them at boot time. This is how most CD-ROM drives, sound cards, scanners, printers, PC Card (PCMCIA) devices, and so on are supported. Because these devices don't need to be active during boot time, the system can boot up from the hard disk and wait to load the drivers during the initial operating system load.

Some drivers, however, must be active during boot time. For example, how could you boot from a hard disk if the drivers necessary to make the disk interface work must be loaded from that disk? Obviously, the hard disk drivers must be preloaded into ROM either on the motherboard or on an adapter card.

How will you be able to see anything onscreen if your video card doesn't have a set of drivers in a ROM? The solution to this could be to provide a motherboard ROM with the appropriate video drivers built in; however, this is impractical because of the variety of video cards, each needing its own drivers. You would end up with hundreds of different motherboard ROMs, depending on which video card you had. Instead, when IBM designed the original PC, it created a better solution. It designed the PC's motherboard ROM to scan the slots looking for adapter cards with ROMs on them. If a card was found with a ROM on it, the ROM was executed during the initial system startup phase, before the system began loading the operating system from the hard disk.

By putting the ROM-based drivers right on the card, you didn't have to change your motherboard ROM to have built-in support for new devices, especially those that needed to be active during boot time. A few cards (adapter boards) almost always have a ROM onboard, including the following:

- *Video cards.* All have an onboard BIOS.
- *SCSI adapters.* Those that support booting from SCSI hard drives or CD-ROMs have an onboard BIOS. Note that, in most cases, the SCSI BIOS does not support any SCSI devices other than a hard disk; if you use a SCSI CD-ROM, scanner, Zip drive, and so on, you still need to load the appropriate drivers for those devices from your hard disk. Most newer SCSI adapters support booting from a SCSI CD-ROM, but CD-ROM drivers are still necessary to access the CD-ROM when booting from another drive or device.

- **Network cards.** Those that support booting directly from a file server have what is usually called a boot ROM or IPL (initial program load) ROM onboard. This enables PCs to be configured on a LAN as diskless workstations—also called Net PCs, NCs (network computers), thin clients, or even smart terminals.
- **ATA or floppy upgrade boards.** Boards that enable you to attach more or different types of drives than what is typically supported by the motherboard alone. These cards require an onboard BIOS to enable these drives to be bootable.
- **Y2K boards.** Boards that incorporate BIOS fixes to update the century byte in the CMOS RAM. These boards have a small driver contained in a BIOS, which monitors the year byte for a change from 99 to 00. When this is detected, the driver updates the century byte from 19 to 20, correcting a flaw in some older motherboard ROM BIOS. Although it might seem strange to list Y2K boards because the century changed a few years ago, if installed these boards often remain in use until the systems using them are retired.

BIOS and CMOS RAM

Some people confuse BIOS with the CMOS RAM in a system. This confusion is aided by the fact that the Setup program in the BIOS is used to set and store the configuration settings in the CMOS RAM. They are, in fact, two totally separate components.

The BIOS on the motherboard is stored in a fixed ROM chip. Also on the motherboard is a chip called the RTC/NVRAM chip, which stands for real-time clock/nonvolatile memory. This is where the BIOS Setup information is stored, and it is actually a digital clock chip with a few extra bytes of memory thrown in. It is usually called the CMOS chip because it is made using CMOS (complementary metal-oxide semiconductor) technology.

The first example of this ever used in a PC was the Motorola MC146818 chip, which had 64 bytes of storage, of which 14 bytes were dedicated to the clock function, leaving 50 bytes to store BIOS Setup settings. Although it is called non-volatile, it is actually volatile, meaning that without power, the time/date settings and the data in the RAM portion will in fact be erased. It is considered *nonvolatile* by many because it is designed using CMOS technology, which results in a chip that still requires power but very little compared to other chips. A battery in the system, rather than the AC wall current, provides that power. This is also why most people call this chip the CMOS RAM chip; although not technically accurate (almost all modern chips use a form of CMOS technology), the term has stuck. Most RTC/NVRAM chips run on as little as 1 micro amp (millionth of an amp), so they use very little battery power to run. Most lithium coin cell batteries can last up to 5 years or more before the battery runs out and the information stored (as well as the date and time) is lost. Some systems use special versions of these chips made by Dallas Semiconductor, Benchmarq, or Odin (such as the DS12885 and DS12887) that include both the RTC/NVRAM chip and the battery in a single component.

When you enter your BIOS Setup, configure your hard disk parameters or other BIOS Setup settings, and save them, these settings are written to the storage area in the RTC/NVRAM (otherwise called CMOS RAM) chip. Every time your system boots up, it reads the parameters stored in the CMOS RAM chip to determine how the system should be configured. A relationship exists between the BIOS and CMOS RAM, but they are two distinctly different parts of the system.

Motherboard BIOS

All motherboards must have a special chip containing software called the ROM BIOS. This ROM chip contains the startup programs and drivers used to get the system running and act as the interface to the basic hardware in the system. When you turn on a system, the power on self test (POST) in the BIOS also tests the major components in the system. Additionally, you can run a setup program to store system configuration data in the CMOS memory, which is powered by a battery on the motherboard. This CMOS RAM is often called NVRAM (nonvolatile RAM) because it runs on about 1 millionth of an amp of electrical current and can store data for years when powered by a tiny lithium battery.

The BIOS is a collection of programs embedded in one or more chips, depending on the design of your computer. That collection of programs is the first thing loaded when you start your computer, even before the operating system. Simply put, the BIOS in most PCs has four main functions:

- *POST (power on self test)*. The POST tests your computer's processor, memory, chipset, video adapter, disk controllers, disk drives, keyboard, and other crucial components.
- *Setup*. The system configuration and setup program is usually a menu-driven program activated by pressing a special key during the POST, and it enables you to configure the motherboard and chipset settings along with the date and time, passwords, disk drives, and other basic system settings. You also can control the power-management settings and boot-drive sequence from the BIOS Setup, and on some systems, you can also configure CPU timing and clock-multiplier settings. Some older 286 and 386 systems did not have the Setup program in ROM and required that you boot from a special setup disk, and some newer systems use a Windows-based application to access BIOS Setup settings.
- *Bootstrap loader*. A routine that reads the first physical sector of various disk drives looking for a valid master boot record (MBR). If one meeting certain minimum criteria (ending in the signature bytes 55AAh) is found, the code within is executed. The MBR program code then continues the boot process by reading the first physical sector of the bootable volume, which is the start of the volume boot record (VBR). The VBR then loads the first operating system startup file, which is usually IO.SYS (DOS/Windows 9x/Me) or NTLDR (Windows NT/2000/XP), upon which the operating system is then in control and continues the boot process.
- *BIOS (basic input/output system)*. This refers to the collection of actual drivers used to act as a basic interface between the operating system and your hardware when the system is booted and running. When running DOS or Windows in safe mode, you are running almost solely on ROM-based BIOS drivers because none are loaded from disk.

ROM Hardware

Read-only memory (ROM) is a type of memory that can permanently or semipermanently hold data. It is called read-only because it is either impossible or difficult to write to. ROM is also often called nonvolatile memory because any data stored in ROM remains even if the power is turned off. As such, ROM is an ideal place to put the PC's startup instructions—that is, the software that boots the system (the BIOS).

Note that ROM and RAM are not opposites, as some people seem to believe. In fact, ROM is technically a subset of the system's RAM. In other words, a portion of the system's random access memory address space is mapped into one or more ROM chips. This is necessary to contain the software that enables the PC to boot up; otherwise, the processor would have no program in memory to execute when it is powered on.

For example, when a PC is turned on, the processor automatically jumps to address FFFF0h, expecting to find instructions to tell the processor what to do. This location is exactly 16 bytes from the end of the first megabyte of RAM space, as well as the end of the ROM itself. If this location were mapped into regular RAM chips, any data stored there would have disappeared when the power was previously turned off, and the processor would subsequently find no instructions to run the next time the power was turned on. By placing a ROM chip at this address, a system startup program can be permanently loaded into the ROM and will be available every time the system is turned on.

- ▶▶ For more information about Dynamic RAM, see "DRAM," p. 460.

Normally, the system ROM starts at address E0000h or F0000h, which is 128KB or 64KB prior to the end of the first megabyte. Because the ROM chip usually is up to 128KB in size, the ROM programs are allowed to occupy the entire last 128KB of the first megabyte, including the critical FFFF0h startup instruction address, which is located 16 bytes from the end of the BIOS space. Some motherboard ROM chips are larger, up to 256KB or 512KB in size. The additional code in these is configured to act as a video card ROM (addresses C0000h–C7FFFh) on motherboards with built-in video and might even contain additional ROM drivers configured anywhere from C8000h to DFFFFh to support additional onboard devices, such as SCSI or network adapters.

Adapter card ROMs, such as those used for video, SCSI, add-on ATA cards, and network cards for diskless workstations, are automatically scanned and read by the motherboard ROM during the early part of the boot process—during the POST. The motherboard ROM scans a special area of RAM reserved for adapter ROMs (addresses C0000–DFFFFh) looking for 55AAh signature bytes that indicates the start of a ROM.

All adapter ROMs must start with 55AAh; otherwise, the motherboard won't recognize them. The third byte indicates the size of the ROM in 512-byte units called *paragraphs*, and the fourth byte is the actual start of the driver programs. The size byte is used by the motherboard ROM for testing purposes. The motherboard ROM adds all the bytes in the ROM and divides the sum by the number of bytes. The result should produce a remainder of 100h. Thus, when creating a ROM for an adapter, the programmer typically uses a “fill” byte at the end to get the checksum to come out right. Using this checksum, the motherboard tests each adapter ROM during the POST and flags any that appear to have been corrupted.

The motherboard BIOS automatically runs the programs in any adapter ROMs it finds during the scan. You see this in most systems when you turn on your system, and during the POST you see the video card BIOS initialize and announce its presence.

ROM Shadowing

ROM chips by their natures are very slow, with access times of 150ns (nanoseconds, or billionths of a second), compared to DRAM access times of less than 10ns on the newest systems. Because of this, in virtually all systems the ROMs are *shadowed*, which means they are copied into DRAM chips at startup to allow faster access during normal operation. The shadowing procedure copies the ROM into RAM and then assigns that RAM the same address as the ROM originally used, disabling the actual ROM in the process. This makes the system seem as though it has ROM running at the same speed as RAM.

The performance gain from shadowing is often very slight, and it can cause problems if not set up properly. Therefore, in most cases, it is wise to shadow only the motherboard (and maybe the video card BIOS) and leave the others alone.

Typically, shadowing is useful only if you are running 16-bit operating systems, such as DOS or Windows 3.x. If you are running a 32-bit operating system, such as Windows 9x, Windows Me, Windows 2000, Windows NT, or Windows XP, shadowing is virtually useless because those operating systems do not use the 16-bit ROM code while running. Instead, those operating systems load 32-bit drivers into RAM, which replace the 16-bit BIOS code used only during system startup.

Shadowing controls are found in the CMOS Setup program in the motherboard ROM, which is covered in more detail later in this chapter.

ROM Chip Types

The four main types of ROM chips that have been used in PCs are as follows:

- *ROM*. Read-only memory
- *PROM*. Programmable ROM
- *EPROM*. Erasable PROM
- *EEPROM*. Electrically erasable PROM, also sometimes called a flash ROM

No matter which type of ROM your system uses, the data stored in a ROM chip is nonvolatile and remains indefinitely unless intentionally erased or overwritten (in those cases where that is possible).

Table 5.1 lists the identifying part numbers typically used for each type of ROM chip, along with any other identifying information.

Table 5.1 ROM Chip Part Numbers

ROM Type	Part Number
ROM	No longer in use
PROM	27xxxx
EPROM*	27xxxx
EEPROM/Flash	28xxxx or 29xxxx

xxxx = numbers normally indicating capacity in K-bits or M-bits

*Has a clear quartz window over the internal chip die allowing UV (ultraviolet) exposure to erase the chip

ROM (True or Mask ROM)

Originally, most ROMs were manufactured with the binary data (0s and 1s) already “cast in” or integrated into the die. The die represents the actual silicon chip itself. These are called Mask ROMs because the data is formed into the mask from which the ROM die is photolithographically produced. This type of manufacturing method is economical if you are making hundreds of thousands of ROMs with the same information. If you must change a single bit, however, you must remake the mask, which is an expensive proposition. Because of costs and inflexibility, nobody uses Mask ROMs anymore.

Mask ROMs are exactly analogous to prerecorded CD-ROMs. Some people think a CD-ROM is first manufactured as a blank and then the data is written to it by a laser, but that is not true. A CD-ROM is literally a piece of plastic that is stamped in a press, and the data is directly molded in, not written. The only actual recording is done with the master disc from which the molds or stamps are made.

PROM

PROMs are a type of ROM that is blank when new and that must be programmed with whatever data you want. The PROM was invented in the late 1970s by Texas Instruments and has been available in sizes from 1KB (8Kb) to 2MB (16Mb) or more. They can be identified by their part numbers, which usually are 27nnnn—where the 27 indicates the TI type PROM and the nnnn indicates the size of the chip in kilobits (not bytes). For example, most PCs that used PROMs came with 27512 or 271000 chips, which indicate 512Kb (64KB) or 1Mb (128KB).

Note

Since 1981, all cars sold in the United States have used onboard computers with some form of ROM containing the control software. For example, my 1989 Pontiac Turbo Trans Am came with an onboard computer containing a 2732 PROM, which was a 32Kb (4KB) chip in the ECM (electronic control module or vehicle computer) under the dash. This chip contained the vehicle operating software as well as all the data tables describing spark advance, fuel delivery, and other engine and vehicle operating parameters. Many devices with integrated computers use PROMs to store their operating programs.

Although we say these chips are blank when new, they are technically preloaded with binary 1s. In other words, a 1Mb ROM chip used in a PC would come with 1 million (actually 1,048,576) bit locations, each containing a binary 1. A blank PROM can then be programmed, which is the act of writing to it. This usually requires a special machine called a device programmer, ROM programmer, or ROM burner (see Figure 5.3).

Programming the ROM is sometimes referred to as *burning* it because that is technically an apt description of the process. Each binary 1 bit can be thought of as a fuse, which is intact. Most chips run on 5 volts, but when a PROM is programmed, a higher voltage (normally 12 volts) is placed at the various addresses within the chip. This higher voltage actually blows or burns the fuses at the desired locations, thus turning any given 1 into a 0. Although you can turn a 1 into a 0, you should note that the process is irreversible; that is, you can't turn a 0 back into a 1.

The device programmer examines the program you want to write into the chip and then selectively changes only the 1s to 0s where necessary in the chip.

Figure 5.3 Typical gang (multisocket) device programmer (PROM burner).

PROM chips are often referred to as OTP (one-time programmable) chips for this reason. They can be programmed once and never erased. Most PROMs are very inexpensive—about \$3 for a typical PC motherboard PROM—so if you want to change the program in a PROM, you discard it and program a fresh one with the new data.

The act of programming a PROM takes anywhere from a few seconds to a few minutes, depending on the size of the chip and the algorithm used by the programming device. Figure 5.3 shows an illustration of a typical PROM programmer that has multiple sockets. This is called a *gang programmer* and can program several chips at once, saving time if you have several chips to write with the same data. Less expensive programmers are available with only one socket, which is fine for most individual use.

I use and recommend a very inexpensive programmer from a company called Andromeda Research Labs (www.ar1abs.com). Besides being economical, its unit has the advantage of connecting to a PC via the parallel port for fast and easy data transfer of files between the PC and programming unit. The unit is also portable and comes built into a convenient carrying case. It is operated by a menu-driven program you install on the connected PC. The program contains several features, including a function that enables you to read the data from a chip and save it in a file on your system, as well as write a chip from a data file, verify that a chip matches a file, and verify that a chip is blank before programming begins. A low-cost BIOS backup option makes backing up the flash BIOS chip in your system easy (if it is removable) as a safeguard against disaster.

Custom Programming of PROM Chips

I even used my PROM programmer to reprogram the chip in my 1989 Turbo Trans Am, changing the factory preset speed and rpm limiters, turbocharger boost, torque converter lockup points, spark advance, fuel delivery, idle speed, and much more! I also incorporated a switch box under the dash that enables me to switch among four different chips, even while the vehicle is running. One chip I created I call the “valet chip,” which, when engaged, cuts off the fuel injectors at 36 miles per hour and restarts them when the vehicle coasts down to 35mph. By rewriting the chip, I could set the cutoff/restore speeds anywhere from 0mph to 255mph. I imagine this type of modification would be useful for those with teenage drivers because you could set the mph or engine rpm limit to whatever you want! Another chip I created cuts off fuel to the engine altogether, which I engage for security purposes when the vehicle is parked. No matter how clever, a thief will not be able to steal this car unless he tows it away. If you are interested in such a chip-switching device or custom chips for your Turbo Trans Am or Buick Grand National, contact Casper’s Electronics at www.casperselectronics.com. For other vehicles with replaceable PROMs, companies such as Fastchip (www.fastchip.com), Superchips (www.superchips.com), Hypertech (www.hypertech.com), and Mopar Performance (www.mopar.com/perf.html) offer custom PROMs or vehicle powertrain control modules (PCMs) for improved performance (see the Vendor List on the DVD packaged with this book). I installed a Mopar Performance PCM in my 5.9L Jeep Grand Cherokee, and it made a noticeable improvement in engine operation and vehicle performance.

EPROM

One variation of the PROM that has been very popular is the EPROM. An *EPROM* is a PROM that is erasable. An EPROM chip can be easily recognized by the clear quartz crystal window set in the chip package directly over the die (see Figure 5.4). You can actually see the die through the window! EPROMs have the same 27xxxx part-numbering scheme as the standard PROM, and they are functionally and physically identical except for the clear quartz window above the die.

Figure 5.4 An EPROM showing the quartz window for ultraviolet erasing.

The purpose of the window is to allow ultraviolet light to reach the chip die because the EPROM is erased by exposure to intense UV light. The window is quartz crystal because regular glass blocks UV light. You can't get a suntan through a glass window!

Note

The quartz window makes the EPROMs more expensive than the OTP PROMs. This extra expense is needless if erasability is not important.

The UV light erases the chip by causing a chemical reaction, which essentially melts the fuses back together. Thus, any binary 0s in the chip become 1s, and the chip is restored to a new condition with binary 1s in all locations. To work, the UV exposure must be at a specific wavelength (2,537 angstroms), at a fairly high intensity (12,000 uw/cm²), in close proximity (2cm–3cm, or about 1"), and last for between 5 and 15 minutes duration. An EPROM eraser is a device that contains a UV light source (usually a sunlamp-type bulb) above a sealed compartment drawer in which you place the chip or chips (see Figure 5.5).

Figure 5.5 shows a professional-type EPROM eraser that can handle up to 50 chips at a time. I use a much smaller and less expensive one called the DataRase by Walling Co. This device erases up to four chips at a time and is both economical and portable. The current version is called DataRase II; the DataRase II and similar products are sold by DigiKey (www.digikay.com) and other sources of EPROM programming equipment.

The quartz crystal window on an EPROM typically is covered by tape, which prevents accidental exposure to UV light. UV light is present in sunlight, of course, and even in standard room lighting, so that over time a chip exposed to the light can begin to degrade. For this reason, after a chip is programmed, you should put a sticker over the window to protect it.

Figure 5.5 A professional EPROM eraser.

EEPROM/Flash ROM

A newer type of ROM is the *EEPROM*, which stands for electrically erasable PROM. These chips are also called flash ROMs and are characterized by their capability to be erased and reprogrammed directly in the circuit board they are installed in, with no special equipment required. By using an EEPROM, or flash ROM, you can erase and reprogram the motherboard ROM in a PC without removing the chip from the system or even opening up the system chassis.

With a flash ROM or EEPROM, you don't need a UV eraser or device programmer to program or erase chips. Not only do virtually all PC motherboards built since 1994 use flash ROMs or EEPROMs, but most automobiles built since then use them as well. For example, my 1994 Chevy Impala SS had a PCM with an integral flash ROM, as do virtually all 1993 and newer vehicles.

The EEPROM or flash ROM can be identified by a 28xxxx or 29xxxx part number, as well as by the absence of a window on the chip. Having an EEPROM or a flash ROM in your PC motherboard means you now can easily upgrade the motherboard ROM without having to swap chips. In most cases, you download the updated ROM from the motherboard manufacturer's Web site and then run a special program it provides to update the ROM. This procedure is described in more detail later in this chapter.

I recommend that you periodically check with your motherboard manufacturer to see whether an updated BIOS is available for your system. An updated BIOS might contain bug fixes or enable new features not originally found in your system. You might find fixes for ATA hard drive support over 8.4GB or new drivers to support booting from LS-120 (120MB floppy) drives or USB drives.

Non-PC ROM Upgrades

For the auto enthusiasts out there, you might want to do the same for your car; that is, check to see whether ROM upgrades are available for your vehicle's computer. Now that updates are so easy and inexpensive, vehicle manufacturers are releasing bug-fix ROM upgrades that correct operational problems or improve vehicle performance. In most cases, you must check with your dealer to see whether any new vehicle ROMs are available. If you have a GM car, GM has a Web site where you can get information about the BIOS revisions available for your car, which it calls Vehicle Calibrations. The GM Vehicle Calibration Information site address is <http://calid.gm.com>.

When you enter your VIN (vehicle identification number), this page displays the calibration history for the vehicle, which is a list of all the different flash ROM upgrades (calibrations) developed since the vehicle was new. For example, when I entered the VIN on the 1994 Impala SS I had, I found that five flash ROM calibrations had been released over the years, and my car had only the second revision installed originally, meaning there had been three newer ROMs than the one I had! The fixes in the various calibration updates are also listed. A trip to the dealer with this information enabled them to use their diagnostic computer to connect to my car and reflash the PCM with the latest software, which, in my case, fixed several problems, including the engine surging under specific conditions, shift clunks, erroneous "check engine" light warnings, and several other minor problems.

With the flash ROM capability, I began experimenting with running calibrations originally intended for other vehicles. For example, I ran a modified Camaro '94 calibration in the '94 Impala SS. The spark-advance curve and fuel delivery parameters were much more aggressive in the Camaro calibration, as were the transmission shift points and other features. If you are interested in having a custom program installed in your flash ROM-equipped vehicle, I recommend you contact Fastchip at www.fastchip.com or Superchips at www.superchips.com. If you want to write and program your own vehicle calibrations, see www.diy-efi.org for more information.

These days, many objects with embedded computers controlling them are using flash ROMs. Pretty soon you'll be downloading flash ROM upgrades into your toaster as well!

- ▶▶ See the section "Upgrading the BIOS," p. 415, for more information on updating your PC motherboard flash ROMs.

Many other devices have flash ROMs; for example, I have updated the flash ROM code (often called *firmware*) in my network routers, wireless access points, and even some digital cameras. Installing flash ROM or firmware upgrades is as easy as downloading a file from the device manufacturer Web site and running the update program included in the file.

Flash ROM updates can also be used to add new capabilities to existing peripherals, such as modems or rewriteable DVD or CD drives, to the latest standards; for example, updating a modem from X2 or K56Flex to V.90 or V.92 or adding support for the latest types of media to a rewriteable drive.

ROM BIOS Manufacturers

Several popular BIOS manufacturers in the market today supply the majority of motherboard and system manufacturers with the code for their ROMs. This section discusses the various available versions.

Several companies have specialized in the development of a compatible ROM BIOS product. The three major companies that come to mind in discussing ROM BIOS software are American Megatrends, Inc. (AMI); Phoenix Technologies; and Award Software (now owned by Phoenix Technologies). Each company licenses its ROM BIOS to motherboard manufacturers so those manufacturers can worry about the hardware rather than the software. To obtain one of these ROMs for a motherboard, the original equipment manufacturer (OEM) must answer many questions about the design of the system so that the proper BIOS can be either developed or selected from those already designed. Combining a ROM BIOS and a motherboard is not a haphazard task. No single, generic, compatible ROM exists, either. AMI, Award, Microid Research (MR BIOS), and Phoenix ship many variations of their BIOS code to different board manufacturers, each one custom tailored to that specific motherboard.

Over the years, some major changes have occurred in the BIOS industry. Intel, the largest BIOS customer, has gone from using mostly Phoenix to using AMI, back to Phoenix, and now back to AMI for most of its motherboards. Intel originally used the Phoenix BIOS core in its motherboards up through 1995, when it changed to an AMI core. It then used AMI until 1997, when it switched back to Phoenix. More recently in 1999 Intel switched again, this time back to AMI. In all these cases, Intel takes the core BIOS from Phoenix or AMI and highly customizes it for its particular motherboards. It is always a big deal which BIOS Intel uses because Intel manufactures more motherboards than any other company. What that basically means is that if you purchase a PC today, you have a good chance of receiving an Intel-made motherboard with AMI BIOS.

Another major development in BIOS occurred in late 1998, when Phoenix bought Award. For several years, Phoenix continued to sell the Award BIOS as a separate product line. However, in March 2002, Phoenix introduced two new product lines based on the previous BIOS. The Phoenix FirstBIOS is based on Award 6.x code, and the Phoenix FirstBIOS Pro is based on Phoenix 4.x code.

Currently, the BIOS market is divided between AMI and Phoenix; however, Phoenix not only develops the BIOS for many systems, but is also the primary BIOS developer responsible for new BIOS development and new BIOS standards.

Another development in recent years has been the creation of separate BIOS products for 32-bit and 64-bit desktop systems, mobile systems, 32-bit and 64-bit servers, and embedded devices. Although all BIOS chips must perform some of the same tasks, a BIOS product optimized for a mobile computer often needs additional support for features such as docking modules, advanced battery power management, as well as bootable USB and removable Flash memory devices, whereas a BIOS optimized for a server needs support for features such as advanced hardware monitoring and 64-bit PCI slots. By creating customized BIOS versions for different platforms, BIOS vendors provide support for the features needed by a particular computing platform and provide better performance and stability.

OEMs

Although most use either the AMI or Phoenix offerings, some OEMs have developed their own compatible BIOS ROMs independently. Companies such as Compaq, AT&T, and Acer have developed their own BIOS products that are comparable to those offered by AMI and Phoenix. These companies also offer upgrades to newer versions that often can provide more features and improvements or fix problems with the older versions. If you use a system with a proprietary ROM, ensure that it is from a larger company with a track record and one that will provide updates and fixes as necessary. Ideally, upgrades should be available for download from the Internet.

Most OEMs have their BIOS written for them by a third-party company. For example, IBM and Hewlett-Packard contract with Phoenix to develop the motherboard BIOS for some HP PCs. Note that even though Phoenix might have done the development, you still must get upgrades or fixes from the OEM. This is really true for all systems because all motherboard manufacturers customize the BIOS for their boards.

AMI

Although AMI customizes the ROM code for a particular system, it does not sell the ROM source code to the OEM. An OEM must obtain each new release as it becomes available. Because many OEMs don't need or want every new version developed, they might skip several version changes before licensing a new one. The AMI BIOS is currently the most popular BIOS in PC systems. Some versions of the AMI BIOS are called Hi-Flex because of the high flexibility found in the BIOS configuration program. The AMI Hi-Flex BIOS products are used in Intel, AMI, and many other manufacturers' motherboards. One special AMI feature is that it is the only third-party BIOS manufacturer to make its own motherboards and other hardware devices.

During power up, the BIOS ID string is displayed on the lower-left part of the screen. This string tells you valuable information about which BIOS version you have and about certain settings that are determined by the built-in setup program.

Tip

A good trick to help you view the BIOS ID string is to shut down and either unplug your keyboard or hold down a key as you power back on. This causes a keyboard error, and the string remains displayed.

You also can download the AMI Motherboard ID Utility program (AMIMBID) from AMI's Web site (www.ami.com/support/mbid.cfm) and run it to determine the contents of ID String 1.

The primary BIOS Identification string (ID String 1) is displayed by any AMI BIOS during the POST in the bottom-left corner of the screen, below the copyright message. Two additional BIOS ID strings (ID Strings 2 and 3) can be displayed by the AMI Hi-Flex BIOS by pressing the Insert key during the POST. These additional ID strings display the options installed in the BIOS.

The general BIOS ID String 1 format for older AMI BIOS versions is shown in Table 5.2. In addition, the BIOS ID String 1 format for AMI Hi-Flex BIOS versions is shown in Table 5.3, the AMI Hi-Flex BIOS ID String 2 in Table 5.4, and the AMI Hi-Flex BIOS ID String 3 in Table 5.5.

Table 5.2 The ABBB-NNNN-mmddyy-KK String 1 Format for Older AMI BIOS Versions

Position	Description
A	BIOS Options: D = Diagnostics built in S = Setup built in E = Extended Setup built in
BBB	Chipset or Motherboard Identifier: C&T = Chips & Technologies chipset NET = C&T NEAT 286 chipset 286 = Standard 286 motherboard SUN = Suntac chipset PAQ = Compaq motherboard INT = Intel motherboard AMI = AMI motherboard G23 = G2 chipset 386 motherboard
NNNN	The manufacturer license code reference number
mmddyy	The BIOS release date, mm/dd/yy
KK	The AMI keyboard BIOS version number

Table 5.3 The AB-CCcc-DDDDDD-EFGHIJKL-mmddyy-MMMMMMMM-N String 1 Format for the AMI Hi-Flex BIOS

Position	Description
A	Processor Type: 0 = 8086 or 8088 2 = 286 3 = 386 4 = 486 5 = Pentium 6 = Pentium Pro/II/III/Celeron/Athlon/Duron
B	Size of BIOS: 0 = 64KB BIOS 1 = 128KB BIOS 2 = 256KB BIOS
CCcc	Major and minor BIOS version number
DDDDDD	Manufacturer license code reference number 0036xx = AMI 386 motherboard, xx = Series # 0046xx = AMI 486 motherboard, xx = Series # 0056xx = AMI Pentium motherboard, xx = Series # 0066xx = AMI Pentium Pro motherboard, xx = Series #
E	1 = Halt on POST Error
F	1 = Initialize CMOS every boot
G	1 = Block pins 22 and 23 of the keyboard controller
H	1 = Mouse support in BIOS/keyboard controller
I	1 = Wait for <F1> key on POST errors
J	1 = Display floppy error during POST

Table 5.3 Continued

Position	Description
K	1 = Display video error during POST
L	1 = Display keyboard error during POST
mmddy	BIOS Date, mm/dd/yy
MMMMMMMM	Chipset identifier or BIOS name
N	Keyboard controller version number

Table 5.4 The AAB-C-DDDD-EE-FF-GGGG-HH-II-JJJ Format for the AMI Hi-Flex BIOS String 2

Position	Description
AA	Keyboard controller pin number for clock switching
B	Keyboard controller clock switching pin function: H = High signal switches clock to high speed L = High signal switches clock to low speed
C	Clock switching through chipset registers 0 = Disable 1 = Enable
DDDD	Port address to switch clock high
EE	Data value to switch clock high
FF	Mask value to switch clock high
GGGG	Port address to switch clock low
HH	Data value to switch clock low
II	Mask value to switch clock low
JJJ	Pin number for Turbo Switch Input

Table 5.5 The AAB-C-DDD-EE-FF-GGGG-HH-II-JJ-K-L Format for the AMI Hi-Flex BIOS ID String 3

Position	Description
AA	Keyboard controller pin number for cache control.
B	Keyboard controller cache control pin function: H = High signal enables the cache. L = High signal disables the cache.
C	1 = High signal is used on the keyboard controller pin.
DDD	Cache control through chipset registers: 0 = Cache control off. 1 = Cache control on.
EE	Port address to enable cache.
FF	Data value to enable cache.
GGGG	Mask value to enable cache.
HH	Port address to disable cache.

Table 5.5 Continued

Position	Description
II	Data value to disable cache.
JJ	Mask value to disable cache.
K	Pin number for resetting the 82335 memory controller.
L	BIOS Modification Flag: 0 = The BIOS has not been modified. 1–9, A–Z = Number of times the BIOS has been modified.

The AMI BIOS has many features, including a built-in setup program activated by pressing the Delete or Esc key in the first few seconds of booting up your computer. The BIOS prompts you briefly as to which key to press and when to press it. The AMI BIOS offers user-definable hard disk types, essential for optimal use of many ATA or ESDI drives. The 1995 and newer BIOS versions also support enhanced ATA drives and autoconfigure the drive parameters.

A unique feature of some of the AMI BIOS versions was that in addition to the setup, they had a built-in, menu-driven diagnostics package—essentially a very limited version of the standalone AMIDIAG product. The internal diagnostics are not a replacement for more comprehensive disk-based programs, but they can help in a pinch. The menu-driven diagnostics do not do extensive memory testing, for example, and the hard disk low-level formatter works only at the BIOS level rather than at the controller register level. These limitations often have prevented it from being capable of formatting severely damaged disks. Most newer AMI BIOS versions no longer include the full diagnostics.

AMI doesn't produce BIOS documentation; it leaves that up to the motherboard manufacturers who include their BIOS on the motherboard. However, AMI has published a detailed version of its documentation called the *Programmer's Guide to the AMIBIOS: Includes Descriptions of PCI, APM, and Socket Services BIOS Functions*, published by Windcrest/McGraw-Hill, ISBN 0-07-001561-9. This book, written by AMI engineers, describes all the BIOS functions, features, error codes, and more. Unfortunately, this book is out of print. If you can locate it (try searching with Google or at Amazon.com), I recommend this book for users with an AMI BIOS in their systems because this provides a complete version of the documentation for which they might have been looking.

The AMI BIOS is sold through distributors, a list of which is available at its Web site. However, keep in mind that you can't buy upgrades and replacements directly from AMI, and AMI produces upgrades only for its own motherboards. If you have a non-AMI motherboard with a customized AMI BIOS, you must contact the motherboard manufacturer for an upgrade or use a third-party BIOS upgrade vendor such as those discussed later in this chapter.

Award

Phoenix now refers to the Award BIOS as FirstBIOS. The FirstBIOS has all the features you expect, including a built-in setup program activated by pressing Ctrl+Alt+Esc or a particular key on startup (usually prompted on the screen). This setup offers user-definable drive types, required to fully use ATA or ESDI hard disks. The POST is good, although the few beep codes supported means that a POST card is necessary if you want to diagnose most power-on problems. Phoenix provides technical support on its Web site at www.phoenix.com. eSupport.com (formerly Unicore Software) provides limited Award BIOS upgrades for end users.

Phoenix

The Phoenix BIOS (now sold by Phoenix as FirstBIOS Pro) for many years has been a standard of compatibility by which others are judged. It was one of the first third-party companies to legally reverse-engineer the IBM BIOS using a *clean-room* approach. In this approach, a group of engineers studied the IBM BIOS and wrote a specification for how that BIOS should work and what features should be incorporated.

This information then was passed to a second group of engineers who had never seen the IBM BIOS. They could then legally write a new BIOS to the specifications set forth by the first group. This work was then unique and not a copy of IBM's BIOS; however, it functioned the same way.

The Phoenix (FirstBIOS Pro) BIOS excels in two areas that put it high on my list of recommendations. One is that the POST is excellent. The BIOS outputs an extensive set of beep codes that can be used to diagnose severe motherboard problems that would prevent normal operation of the system. In fact, with beep codes alone, this POST can isolate memory failures in Bank 0 right down to the individual SIMM or DIMM module. The Phoenix BIOS also has an excellent setup program free from unnecessary frills, but one that offers all the features the user would expect, such as user-definable drive types and so on. The built-in setup is activated by pressing Ctrl+Alt+S; Ctrl+Alt+Esc; or a particular key on startup, such as F1 or F2 on most newer systems, depending on the version of BIOS you have.

The second area in which Phoenix excels is the documentation. Not only are the manuals you get with the system detailed, but Phoenix has also written a set of BIOS technical reference manuals that are a standard in the industry. The original set consists of three books, titled *System BIOS for IBM PC/XT/AT Computers and Compatibles*, *CBIOS for IBM PS/2 Computers and Compatibles*, and *ABIOS for IBM PS/2 Computers and Compatibles*; an updated version is called *System BIOS for IBM PCs, Compatibles, and EISA Computers: The Complete Guide to ROM-Based System Software*. In addition to being excellent references for the Phoenix BIOS, these books serve as an outstanding overall reference to the BIOS in general. These are out of print but might be available through bookfinder services such as Amazon.com.

Phoenix has extensive technical support and documentation on its Web site at www.phoenix.com, and you can also find documentation on the Micro Firmware site (www.firmware.com) as well as the eSupport site (www.esupport.com). You also can check the phone numbers listed in the Vendor List on the disc packaged with this book. Micro Firmware and eSupport offer upgrades to some older systems with an AMI or a Phoenix/Award BIOS, including many Packard Bell, Gateway (with Micronics motherboards), Micron Technologies, and other systems. For most systems, especially newer ones, you need to get any BIOS updates from the system or motherboard manufacturer.

These companies' products are established as ROM BIOS standards in the industry, and frequent updates and improvements ensure that a system containing these ROMs will have a long life of upgrades and service.

Microid Research BIOS

Microid Research (MR) is an interesting BIOS supplier. It primarily markets upgrade BIOS for older Pentium and 486 motherboards that were abandoned by their original manufacturers. As such, it is an excellent upgrade for adding new features and performance to an older system. Microid Research BIOS upgrades are sold through eSupport.com.

Tip

If you support several BIOS types, consider adding Phil Croucher's *The BIOS Companion* to your bookshelf or PDF file collection. This book provides detailed BIOS options and configuration information for today's leading BIOS. You can purchase various editions from Amazon.com and other bookstores, but for the most up-to-date (and least expensive) edition, I suggest ordering the PDF (Adobe Acrobat) version of *The BIOS Companion* from Electrocution.com.

Upgrading the BIOS

In this section, you learn how ROM BIOS upgrades can improve a system in many ways. You also learn why upgrades can be difficult and can require much more than plugging in a generic set of ROM chips.

The ROM BIOS provides the crude brains that get your computer's components working together. A simple BIOS upgrade can often give your computer better performance and more features.

The BIOS is the reason various operating systems can operate on virtually any PC-compatible system despite hardware differences. Because the drivers in the BIOS communicate with the hardware, the BIOS must be specific to the hardware and match it completely. As discussed earlier, instead of creating their own BIOS, many computer makers buy a BIOS from specialists such as American Megatrends, Inc. (AMI) or Phoenix Technologies Ltd. A motherboard manufacturer that wants to license a BIOS must tailor the BIOS code to the hardware. This is what makes upgrading a BIOS somewhat problematic; the BIOS usually resides on ROM chips on the motherboard and is specific to that motherboard model or revision. In other words, you must get your BIOS upgrades from your motherboard manufacturer or from a BIOS upgrade company that supports the motherboard you have, rather than directly from the BIOS developer.

Often, in older systems, you must upgrade the BIOS to take advantage of some other upgrade. To install some of the larger and faster Integrated Drive Electronics (IDE) hard drives and LS-120 (120MB) floppy drives in older machines, for example, you might need a BIOS upgrade. Some of the machines you have might be equipped with older BIOSs that do not support hard drives larger than 8GB, for example.

The following list shows some of the primary functions of a ROM BIOS upgrade; the exact features and benefits of a particular BIOS upgrade depend on your system:

- Added support for newer-type and faster-speed processors
- Support for bootable ATAPI CD-ROM drives (called the El Torito specification)
- Support for bootable LS-120 (120MB) SuperDisk floppy or Iomega Zip drive support
- Support for bootable USB drives
- Fast POST for decreasing boot times
- Support for Ultra-DMA/100 or Ultra-DMA/133 ATA drives
- Support for ATA hard drives greater than 8.4GB or 137GB (48-bit LBA)
- Support for Serial ATA (SATA) drives
- Support for a preboot environment and recovery software in the host protected area (HPA)
- Plug and Play (PnP) support and compatibility
- Correction of calendar-related and leap-year bugs
- Correction of known bugs or compatibility problems with certain hardware and application or operating system software
- Support for ACPI power management
- Support for temperature monitoring and fan speed monitoring and control
- Support for legacy USB devices (keyboards and mice)
- Support for chassis intrusion detection

Part of the PC 2001 standard published by Intel and Microsoft requires something called Fast POST to be supported. Fast POST means that the time it takes from turning on the power until the system starts booting from disk must be 12 seconds or less (for systems not using SCSI as the primary storage connection). This time limit includes the initialization of the keyboard, video card, and ATA bus. For systems containing adapters with onboard ROMs, an additional 4 seconds are allowed per ROM. Intel calls the Fast POST feature Rapid BIOS Boot (RBB), and it is supported in all its motherboards from 2001 and beyond—some of which can begin booting from power-on in as little as 6 seconds or less.

If you install newer hardware or software and follow all the instructions properly, but you can't get it to work, specific problems might exist with the BIOS that an upgrade can fix. This is especially true for newer operating systems. Many systems need to have a BIOS update to properly work with the

Plug and Play features of Windows 9x, Me, XP, and 2000. Because these problems are random and vary from board to board, it pays to periodically check the board manufacturer's Web site to see whether any updates are posted and what problems they fix. Because new hardware and software that are not compatible with your system could cause it to fail, I recommend you check the BIOS upgrades available for your system before you install new hardware or software, particularly processors.

You can use the BIOS Wizard utility available from eSupport.com (formerly Unicore) to test your BIOS for compatibility with popular BIOS features, such as Zip/LS-120 booting, ACPI power management, PCI IRQ routing, and more. Download it from www.esupport.com/techsupport/award/awardutils.htm.

Where to Get Your BIOS Update

For most BIOS upgrades, you must contact the motherboard manufacturer by phone or download the upgrade from its Web site. The BIOS manufacturers do not offer BIOS upgrades because the BIOS in your motherboard did not actually come from them. In other words, although you think you have a Phoenix, AMI, or Award BIOS, you really don't! Instead, you have a custom version of one of these BIOS, which was licensed by your motherboard manufacturer and uniquely customized for its board. As such, you must get any BIOS upgrades from the motherboard or system manufacturer because they must be customized for your board or system as well.

In the case of Phoenix or Award, another option might exist. A company called eSupport (formerly Unicore) specializes in providing Award BIOS upgrades. eSupport might be able to help you if you can't find your motherboard manufacturer or if it is out of business. Phoenix has a similar deal with Micro Firmware, a company it has licensed to provide various BIOS upgrades. If you have a Phoenix or an Award BIOS and your motherboard manufacturer can't help you, contact one of these companies for a possible solution. Microid Research (sold through eSupport, formerly Unicore) is another source of BIOS upgrades for a variety of older and otherwise obsolete boards. These upgrades are available for boards that originally came with AMI, Award, or Phoenix BIOS, and they add new features to older boards that have been abandoned by their original manufacturers. Contact eSupport for more information.

Determining Your BIOS Version

When seeking a BIOS upgrade for a particular motherboard (or system), you need to know the following information:

- The make and model of the motherboard (or system)
- The version of the existing BIOS
- The type of CPU (for example, Pentium MMX, AMD K6, Cyrix/IBM 6x86MX, MII, Pentium II, Pentium III and later, AMD Athlon, Athlon XP, and so on)

You usually can identify the BIOS you have by watching the screen when the system is first powered up. It helps to turn on the monitor first because some take a few seconds to warm up and the BIOS information is often displayed for only a few seconds.

Note

Many newer PCs now do not display the typical POST screen. Instead, many show a logo for the motherboard or PC manufacturer, which is usually referred to as a *splash screen*. To enter BIOS Setup, you must press a key or keys (specific to the BIOS manufacturer). See the section "Running or Accessing the CMOS Setup Program," later in this chapter, for more information. You might hear some in the industry refer to displaying a manufacturer's logo instead of the default POST screen as a *quiet boot*. Often you can change these BIOS splash screens to your own liking, even including your own company logo or graphic of choice. Intel has free software at developer.intel.com/design/motherbd/gen_indx.htm that enables you to change or restore the splash screen on Intel motherboards.

Tip

Look for any copyright notices or part number information. Sometimes you can press the Pause key on the keyboard to freeze the POST, allowing you to take your time to write down the information. Pressing any other key then causes the POST to resume.

In addition, you often can find the BIOS ID information in the BIOS Setup screens. eSupport also offers a downloadable BIOS Agent that can be used to determine this information, as well as the motherboard chipset and Super I/O chip used by your motherboard. After you have this information, you should be able to contact the motherboard manufacturer to see whether a new BIOS is available for your system. If you go to the Web site, check to see whether a version exists that is newer than the one you have. If so, you can download it and install it in your system.

Most BIOS display version information onscreen when the system is first powered up. In some cases, the monitor takes too long to warm up, and you might miss this information because it is displayed for only a few seconds. Try turning on your monitor first, and then your system, which makes this information easier to see. You usually can press the Pause key on the keyboard when the BIOS ID information is being displayed, which freezes it so you can record the information. Pressing any other key allows the system startup to resume.

Checking the BIOS Date

One method of determining the relative age and capabilities of your motherboard ROM is to check the date. The BIOS date is stored in virtually all PCs as an 8-byte text string at memory address FFFF5h. The date generally indicates when the BIOS code was last updated or compiled by the motherboard manufacturer. Knowing the date of a particular BIOS might give you some clue as to which features might or might not be present. You can use the DEBUG command-line utility supplied with Windows and DOS to view these addresses. DEBUG is a command-line program that presents a - prompt of its own, to which you can enter various commands. For example, the ? command displays help information. To find the BIOS date, open a command-prompt window (or boot to a DOS floppy) and execute the DEBUG command. Then at the DEBUG - prompt, enter **D FFFF:5 L 8**, which instructs DEBUG to display memory at FFFF5 for a length of 8 bytes. DEBUG then displays both the hexadecimal and ASCII codes found at those addresses. When the - prompt returns, you can enter **Q** to quit DEBUG and return to the command prompt. Figure 5.6 shows how this looked when I ran it on my system.

```

C:\>DEBUG
-D FFFF:5 L 8
FFFF:0000          31 31 2F-30 37 2F 30 33          11/07/03
-Q
C:\>_

```

Figure 5.6 Using DEBUG to display the motherboard ROM BIOS date.

In this example, the system shows a motherboard ROM BIOS date of 11/07/03.

Backing Up Your BIOS

One often-overlooked benefit of an EPROM programmer is that you can use it to essentially back up your ROMs in case they are later damaged. Many hardware vendors do not sell preprogrammed ROM chips for their systems, and the only way to repair an older motherboard or card with a damaged ROM is to burn a new copy from a backup. The backup can be in the form of another EPROM or flash ROM chip with the original program burned in or even in the form of a disk file. I keep files containing images of the ROMs in each of my motherboards and expansion cards in case I have to burn a new copy to repair one of my systems. A file-based backup of your ROMs can also prove interesting for snooping around because you can look for the copyright and other strings, disassemble the code to see how it works, and otherwise check it out.

To create a disk-file copy of your motherboard ROM BIOS, you can place the ROM in an EPROM programmer and use the function provided by the device to read the EPROM into a disk file, or you can use the DOS DEBUG program to read your ROM BIOS from memory and transfer it to disk as a file. Because most ROMs are soldered in, removal is difficult at best, so the DEBUG routine is much easier.

The ROM code in a PC normally consumes 128KB of RAM in two 64KB segments, E0000–EFFFF and F0000–FFFFF. Video and other auxiliary BIOS routines normally reside in C0000–CFFFF and D0000–DFFFF. Because of the nature of DEBUG, each 64KB segment must be saved separately.

To use DEBUG to save segments E000 and F000 in this manner, follow these instructions:

```
C:\>DEBUG                ;Run DEBUG
-R BX                    ;Change BX register (high-order file size)
BX 0000                  ; from 0
:1                        ; to 1 (indicates 64K file)
-N SEG-E.ROM             ;Name the file
-M E000:0 FFFF CS:0      ;Move 64K of BIOS data to current code segment
-W 0                     ;Write file from offset 0 in code segment
Writing 10000 bytes      ; 10000h = 64K
-N SEG-F.ROM             ;Name the file
-M F000:0 FFFF CS:0      ;Move 64K of BIOS data to current code segment
-W 0                     ;Write file from offset 0 in code segment
Writing 10000 bytes      ; 10000h = 64K
-Q                        ;Quit DEBUG
```

Figure 5.7 shows how this will look when entered in a Windows XP command-prompt window.

```

C:\>DEBUG
-R BX
BX 0000
:1
-N SEG-E.ROM
-M E000:0 FFFF CS:0
-W 0
Writing 10000 bytes
-N SEG-F.ROM
-M F000:0 FFFF CS:0
-W 0
Writing 10000 bytes
-Q

```

Figure 5.7 Using DEBUG to save E0000–EFFFF and F0000–FFFFF as files.

These instructions effectively save the 64K segment ranges E0000–EFFFF and F0000–FFFFF as files by first setting up the size of the file to be saved, then setting up the name of the file, and then moving (essentially, copying) the ROM BIOS code to the current code segment when DEBUG was loaded. The data then can be written to the disk.

If you want to save the segments including the video BIOS and other possible adapter card ROMs in your system, repeat the previous procedure but use C000:0 and D000:0 as the starting addresses in the DEBUG commands. Be sure to use different file names as well. Note that the video BIOS might not use all of the C0000 segment; also, you might not have any other adapters using ROM in the remainder of the C0000 and D0000 segments, in which case Windows can sometimes use this area for other code.

One important quirk of this procedure is that the commands should be entered in the relative order indicated here. In particular, the Name command must precede the Move command; otherwise, some of the data at the beginning of the current code-segment area will be trashed.

Backing Up Your BIOS's CMOS Settings

A motherboard BIOS upgrade usually wipes out the BIOS Setup settings in the CMOS RAM. Therefore, you should record these settings, especially the important ones such as hard disk parameters. Some software programs, such as the Norton Utilities, can save and restore CMOS settings, but unfortunately, these types of programs are often useless in a BIOS upgrade situation. This is because sometimes the new BIOS offers new settings or changes the positions of the stored data in the CMOS RAM, which means you don't want to do an exact restore. Also, with the variety of BIOS available, I have yet to find a CMOS RAM backup and restore program that works on more than just a few specific systems.

You are better off manually recording your BIOS Setup parameters, or possibly connecting a printer to your system and using the Shift+Prtsc (Print Screen) function to print each of the setup screens. Turn on your printer, start your computer normally, and restart it without turning off the system to initialize the printer to try this option. Some shareware programs could print or even save and restore the BIOS Setup settings stored in the CMOS RAM, but these were BIOS version specific and would not work on any other system. Most of these programs were useful during the 286/386 era, but most systems released since—especially those with Plug and Play capabilities—have rendered most of these older programs useless.

Tip

If you are unable to print your screens, use a digital camera to take a picture of each BIOS setup screen. Be sure to set the camera to its close-up mode, and use the LCD display rather than the optical viewfinder to ensure you get the entire screen in the photo.

Keyboard Controller Chips

In addition to the main system ROM, older AT-class (286 and later) computers also have a keyboard controller or keyboard ROM, which is a keyboard-controller microprocessor with its own built-in ROM. This often is found in the Super I/O or South Bridge chips on most newer boards. The keyboard controller was originally an Intel 8042 microcontroller, which incorporates a microprocessor, RAM, ROM, and I/O ports. This was a 40-pin chip that often had a copyright notice identifying the BIOS code programmed into the chip. Modern motherboards have this function integrated into the chipset, specifically the Super I/O or South Bridge chips, so you won't see the old 8042 chip anymore.

The keyboard controller controls the reset and A20 lines and also deciphers the keyboard scan codes. The A20 line is used in extended memory and other protected-mode operations. In many systems, one of the unused ports is used to select the CPU clock speed. Because of the tie-in with the keyboard controller and protected-mode operation, many problems with keyboard controllers became evident on these older systems when upgrading from DOS to Windows 95/98, NT, or 2000.

Problems with the keyboard controller were solved in most systems in the early 1990s, so you shouldn't have to deal with this issue in systems newer than that. With older systems, when you upgraded the BIOS in the system, the BIOS vendor often included a new keyboard controller.

Using a Flash BIOS

Virtually all PCs built since 1996 include a flash ROM to store the BIOS. A flash ROM is a type of EEPROM chip you can erase and reprogram directly in the system without special equipment. Older EPROMs required a special ultraviolet light source and an EPROM programmer device to erase and reprogram them, whereas flash ROMs can be erased and rewritten without even removing them from the system. On many recent systems, the flash ROM is not a separate chip but might be incorporated into the South Bridge chip.

Using flash ROM enables you to download ROM upgrades from a Web site or receive them on disk; you then can load the upgrade into the flash ROM chip on the motherboard without removing and replacing the chip. Normally, these upgrades are downloaded from the manufacturer's Web site, and then an included utility is used to create a bootable floppy with the new BIOS image and update

program. It is important to run this procedure from a boot floppy so that no other software or drivers are in the way that might interfere with the update. This method saves time and money for both the system manufacturer and end user.

Sometimes the flash ROM in a system is write-protected, and you must disable the protection before performing an update—usually by means of a jumper or switch that controls the lock on the ROM update. Without the lock, any program that knows the correct instructions can rewrite the ROM in your system—not a comforting thought. Without the write-protection, virus programs could be written that copy themselves directly into the ROM BIOS code in your system. Even without a physical write-protect lock, modern flash ROM BIOSs have a security algorithm that helps prevent unauthorized updates. This is the technique Intel uses on its motherboards.

Note that motherboard manufacturers will not notify you when they upgrade the BIOS for a particular board. You must periodically log on to their Web sites to check for updates. Usually, any flash updates are free.

Before proceeding with a BIOS upgrade, you first must locate and download the updated BIOS from your motherboard manufacturer. Consult the Vendor List on the accompanying DVD to find the Web site address or other contact information for your motherboard manufacturer. Log on to its Web site, and follow the menus to the BIOS updates page; then select and download the new BIOS for your motherboard.

Note

If a flash BIOS upgrade is identified as being for only certain board revisions of a particular model, be sure you determine that it will work with your motherboard before you install it. You might need to open your system and look for a revision number on the motherboard or for a particular component. Check the vendor's Web site for details.

The BIOS upgrade utility is contained in a self-extracting archive file that can initially be downloaded to your hard drive, but it must be extracted and copied to a floppy before the upgrade can proceed. Different motherboard manufacturers have slightly different procedures and programs to accomplish a flash ROM upgrade, so you should read the directions included with the update. I include instructions here for Intel motherboards because they are by far the most common.

Intel and other typical flash BIOS upgrades fit on a bootable floppy disk; some recent BIOS upgrades from Intel and other vendors can also be run from within the Windows GUI. Older Intel and some other flash BIOS upgrades also provide the capability to save and verify the current BIOS version before replacing it with the new version and also provide the capability to install alternative languages for BIOS messages and the BIOS setup utility.

Tip

Before you start the flash BIOS upgrade process, you should disconnect all USB devices except for your keyboard and mouse. On some systems, leaving USB drives connected prevents a BIOS upgrade from working properly.

If you have Byte Merge enabled in an Award BIOS or a FirstBIOS-based system, disable this feature before you perform the BIOS upgrade. On some systems, leaving byte merge enabled during a BIOS upgrade can destroy your BIOS. You can re-enable this feature after you complete the upgrade.

If the BIOS setup is performed with a bootable floppy disk, the first step in the upgrade after downloading the new BIOS file is to enter the CMOS Setup and write down or record your existing CMOS settings because they will be erased during the upgrade. Then, you create a DOS boot floppy and uncompress or extract the BIOS upgrade files to the floppy from the file you downloaded. Next, you reboot on the newly created upgrade disk and follow the menus for the actual reflash procedure.

The iFlash procedure covered in this section is similar to the BIOS update process used by most non-Intel motherboards and must be used for systems running Windows 95, MS-DOS, or non-Windows

operating systems such as Linux. Intel's Express BIOS update (for Windows 98, Windows NT 4, and current Windows versions) uses the InstallShield loader program familiar to Windows users to install BIOS upgrades within the Windows GUI. Here is a step-by-step procedure for the process using Intel's iFlash (DOS-based) BIOS update:

1. Save your CMOS RAM setup configuration. You can do so by pressing the appropriate key during boot to start the BIOS setup program (usually F1 with an AMI BIOS and F2 with a Phoenix BIOS) and writing down all your current CMOS settings. You also might be able to print the screens if you have a printer connected, using the PrtScr key on the keyboard. You must reset these settings after you have upgraded to the latest BIOS. Write down all the settings that are unique to the system. These settings will be needed later to reconfigure the system. Pay special attention to any hard drive settings for geometry (Cylinder/Head/Sectors per track) and translation (LBA, Large, CHS); these are very important. If you fail to restore these properly, you might not be able to boot from the drive or access the data on it.
2. Exit the BIOS Setup and restart the system. Allow the system to fully start Windows and bring up a DOS prompt window or boot directly to a DOS prompt via the Windows Start menu (for example, press F8 when you see Starting Windows, and select Command Prompt).
3. Place a formatted blank floppy disk in the A: floppy drive. If the disk contains data, format the floppy using the normal format command:

```
C:\>FORMAT A:
```

You also can use Windows Explorer to format the floppy disk.

4. The file you originally downloaded from the Intel Web site is a self-extracting compressed archive that includes other files that need to be extracted. Put the file in a temporary directory, and then from within this directory, double-click the BIOS file you downloaded or type the file-name of the file and press Enter. This causes the file to self-extract. For example, if the file you downloaded is called CB-P06.EXE (for the Intel D810E2CB motherboard), you would enter the following command:

```
C:\TEMP>CB-P06 <enter>
```
5. The extracted files are stored in the same temporary folder as the downloaded BIOS. Recent Intel flash BIOS upgrades contain the following files: Desc.txt, License.txt, Readme.txt, Run.bat (which is run to create the bootable floppy), and SW.EXE (which contains the BIOS code).
6. To create the bootable floppy disk, open Run.bat—which extracts files from SW.EXE—and transfer the necessary files to the blank disk in Drive A:
7. Now you can restart the system with the bootable floppy in drive A: containing the new BIOS files you just extracted. Upon booting from this disk, the iFlash program automatically starts and updates the BIOS boot block and the main BIOS area.
8. When you're told that the BIOS has been successfully loaded, remove the bootable floppy from the drive and press Enter to reboot the system.
9. Press F1 or F2 to enter Setup. On the first screen within Setup, check the BIOS version to ensure that it is the new version.
10. In Setup, load the default values. If you have an AMI BIOS, press the F5 key. With a Phoenix BIOS, go to the Exit submenu and highlight Load Setup Defaults, and then press Enter.

Caution

If you do not set the values back to default, the system might function erratically.

11. If the system had unique settings, reenter those settings now. Press F10 to save the values, exit Setup, and restart the system. Your system should now be fully functional with the new BIOS.

Note

If you encounter a CMOS checksum error or other problems after rebooting, try rebooting the system again. CMOS checksum errors require that you enter Setup, check and save your settings, and exit Setup a second time.

Note

The procedure for older Intel BIOS upgrades differs from that described previously. If your BIOS upgrade contains the BIOS.EXE program, see the BIOS upgrade description contained in *Upgrading and Repairing PCs, 12th Edition*, included in electronic form on the DVD packaged with this book.

Flash BIOS Recovery

When you performed the flash reprogramming, you should have seen a warning message onscreen similar to the following:

```
The BIOS is currently being updated. DO NOT REBOOT OR POWER DOWN until the update
is completed (typically within three minutes)...
```

If you fail to heed this warning or something interrupts the update procedure, you will be left with a system that has a corrupted BIOS. This means you will not be able to restart the system and redo the procedure, at least not easily. Depending on the motherboard, you might have to replace the flash ROM chip with one that was preprogrammed by the motherboard manufacturer or from a vendor such as BIOSWorld (www.biosworld.com), which provides replacement BIOS chips containing the same BIOS code as that provided by your motherboard vendor. This is an unfortunate necessity because your board will be nonfunctional until a valid ROM is present. This is why I still keep my trusty ROM burner around; it is very useful for those motherboards with socketed flash ROM chips. In minutes, I can use the ROM burner to reprogram the chip and reinstall it in the board. If you need a ROM programmer, I recommend Andromeda Research Labs (see the Vendor List on the accompanying DVD).

In many of the latest systems, the flash ROM is soldered into the motherboard so it can't be replaced, rendering the reprogramming idea moot. However, this doesn't mean the only way out is a complete motherboard replacement. Most motherboards with soldered-in flash ROMs have a special BIOS Recovery procedure that can be performed. This hinges on a special nonerasable part of the flash ROM that is reserved for this purpose.

In the unlikely event that a flash upgrade is interrupted catastrophically, the BIOS might be left in an unusable state. Recovering from this condition requires the following steps. A minimum of a power supply, a speaker, and a floppy drive configured as drive A: should be attached to the motherboard for this procedure to work:

1. Change the Flash Recovery jumper to the recovery mode position. Virtually all Intel motherboards and many third-party motherboards have a jumper or switch for BIOS recovery, which in most cases is labeled "Recover/Normal." Figure 5.8 shows this jumper on a typical motherboard.
2. Install the bootable BIOS upgrade disk you previously created to do the flash upgrade into drive A: and reboot the system.

Because of the small amount of code available in the nonerasable flash boot block area, no video prompts are available to direct the procedure. So, you will see nothing onscreen. In fact, it is not even necessary for a video card to be connected for this procedure to work. The procedure can be monitored by listening to the speaker and looking at the floppy drive LED. When the system beeps and the floppy drive LED is lit, the system is copying the BIOS recovery code into the flash device.

Figure 5.8 Motherboard BIOS recovery jumper.

3. As soon as the drive LED goes off and the system beeps (normally twice), the recovery should be complete. Sometimes there might be pauses where the drive stops reading during the recovery process; however, the process might not be complete. Be sure to wait for a minute or so to ensure a complete recovery before turning off the system. When you are sure the recovery is complete and there is no further activity, power off the system.
4. Change the flash recovery jumper back to the default position for normal operation.

When you power the system back on, the new BIOS should be installed and functional. However, you might want to leave the BIOS upgrade floppy in drive A: and check to see that the proper BIOS version was installed.

Note

Note that this BIOS recovery procedure is often the fastest way to update a large number of machines, especially if you are performing other upgrades at the same time. This is how it is typically done in a system assembly or production environment.

Using IML System Partition BIOS

IBM and Compaq used a scheme similar to a flash ROM, called Initial Microcode Load (IML), in some of their older Pentium and 486 systems. IML is a technique in which the BIOS code is installed on the hard disk in a special hidden-system partition and is loaded every time the system is powered up. Of course, the system still has a core BIOS on the motherboard, but all that BIOS does is locate and load updated BIOS code from the system partition. This technique enabled Compaq and IBM to distribute ROM updates on disk for installation in the system partition. The IML BIOS is loaded every time the system is reset or powered on.

Along with the system BIOS code, the system partition contains a complete copy of the Setup and Diagnostics or Reference Disk, which provides the option of running the setup and system-configuration software at any time during a reboot operation. This option eliminates the need to boot from this disk to reconfigure the system and gives the impression that the entire Setup and Diagnostics or Reference Disk is contained in ROM.

One drawback to this technique is that the BIOS code is installed on the hard disk; the system can't function properly without the correctly set-up hard disk connected. You can always boot from the Reference Disk floppy should the hard disk fail or become disconnected, but you can't boot from a standard floppy disk.

Although this might seem similar to newer systems using the host protected area (reserved space past the "end" of the hard disk), it is not quite the same thing. Systems using the HPA use it only for recovery, diagnostic, and backup applications. The BIOS itself, as well as the BIOS Setup, is still contained in the actual ROM (flash ROM) chip.

Motherboard CMOS RAM Addresses

In the original IBM AT system, a Motorola 146818 chip was used as the real-time clock (RTC) and CMOS RAM chip. This special chip had a simple digital clock that used 14 bytes of RAM and an additional 50 more bytes of leftover RAM in which you could store anything you wanted. The designers of the IBM AT used these extra 50 bytes to store the system configuration.

Modern PC systems don't use the Motorola chip; instead, they incorporate the functions of this chip into the motherboard chipset (South Bridge) or Super I/O chip, or they use a special battery and NVRAM module from companies such as Dallas or Benchmark.

Table 5.6 shows the standard format of the information stored in the 64-byte standard CMOS RAM module. This information controls the configuration of the system and is read and written by the system setup program.

Table 5.6 CMOS RAM Addresses

Offset (hex)	Offset (dec)	Field Size	Function
00h	0	1 byte	Current second in BCD (00–59)
01h	1	1 byte	Alarm second in BCD
02h	2	1 byte	Current minute in BCD (00–59)
03h	3	1 byte	Alarm minute in BCD
04h	4	1 byte	Current hour in BCD (00–23)
05h	5	1 byte	Alarm hour in BCD
06h	6	1 byte	Current day of week in BCD (00–06)
07h	7	1 byte	Current day of month in BCD (00–31)
08h	8	1 byte	Current month in BCD (00–12)
09h	9	1 byte	Current year in BCD (00–99)
0Ah	10	1 byte	Status register A
0Bh	11	1 byte	Status register B
0Ch	12	1 byte	Status register C
0Dh	13	1 byte	Status register D
0Eh	14	1 byte	Diagnostic status
0Fh	15	1 byte	Shutdown code
10h	16	1 byte	Floppy drive types
11h	17	1 byte	Advanced BIOS Setup options
12h	18	1 byte	Hard disk 0/1 types (0–15)
13h	19	1 byte	Keyboard typematic rate and delay
14h	20	1 byte	Installed equipment
15h	21	1 byte	Base memory in 1K multiples, LSB

Table 5.6 Continued

Offset (hex)	Offset (dec)	Field Size	Function
16h	22	1 byte	Base memory in 1K multiples, MSB
17h	23	1 byte	Extended memory in 1K multiples, LSB
18h	24	1 byte	Extended memory in 1K multiples, MSB
19h	25	1 byte	Hard Disk 0 Extended Type (0–255)
1Ah	26	1 byte	Hard Disk 1 Extended Type (0–255)
1Bh	27	9 bytes	Hard Disk 0 user-defined type information
24h	36	9 bytes	Hard Disk 1 user-defined type information
2Dh	45	1 byte	Advanced BIOS Setup options
2Eh	46	1 byte	CMOS checksum MSB
2Fh	47	1 byte	CMOS checksum LSB
30h	48	1 byte	POST reported extended memory LSB
31h	49	1 byte	POST reported extended memory MSB
32h	50	1 byte	Date century in BCD (00–99)
33h	51	1 byte	POST information flag
34h	52	2 bytes	Advanced BIOS Setup options
36h	54	1 byte	Chipset-specific BIOS Setup options
37h	55	7 bytes	Power-On Password (usually encrypted)
3Eh	62	1 byte	Extended CMOS checksum MSB
3Fh	63	1 byte	Extended CMOS checksum LSB

BCD = Binary-coded decimal

MSB = Most significant byte

LSB = Least significant byte

POST = Power on self test

Note that many newer systems have extended CMOS RAM with 2KB, 4KB, or more. The extra room is used to store the Plug and Play information detailing the configuration of adapter cards and other options in the system. As such, no 100% compatible standard exists for how CMOS information is stored in all systems. You should consult the BIOS manufacturer for more information if you want the full details of how CMOS is stored because the CMOS configuration and Setup program typically are part of the BIOS. This is another example of how close the relationship is between the BIOS and the motherboard hardware.

Backup programs and utilities are available in the public domain for CMOS RAM information, which can be useful for saving and later restoring a configuration. Unfortunately, these programs are BIOS specific and function only on a BIOS for which they are designed. As such, I don't usually rely on these programs because they are too motherboard and BIOS specific and will not work on all my systems seamlessly.

Table 5.7 shows the values that might be stored by your system BIOS in a special CMOS byte called the diagnostic status byte. By examining this location with a diagnostics program, you can determine whether your system has set trouble codes, which indicate that a problem previously has occurred.

Table 5.7 CMOS RAM Diagnostic Status Byte Codes

Bit Number								Hex	Function
7	6	5	4	3	2	1	0		
1	•	•	•	•	•	•	•	80	Real-time clock (RTC) chip lost power.
•	1	•	•	•	•	•	•	40	CMOS RAM checksum is bad.
•	•	1	•	•	•	•	•	20	Invalid configuration information found at POST.
•	•	•	1	•	•	•	•	10	Memory size compare error at POST.
•	•	•	•	1	•	•	•	08	Fixed disk or adapter failed initialization.
•	•	•	•	•	•	1	•	04	Real-time clock (RTC) time found invalid.
•	•	•	•	•	•	•	1	02	Adapters do not match configuration.
•	•	•	•	•	•	•	•	01	Time-out reading an adapter ID.
•	•	•	•	•	•	•	•	00	No errors found (Normal).

If the diagnostic status byte is any value other than 0, you typically get a CMOS configuration error on bootup. These types of errors can be cleared by rerunning the setup program.

Replacing a BIOS ROM

Systems dating from 1995 or earlier usually don't have a flash ROM and instead use an EPROM. To upgrade the BIOS in one of these systems, you replace the EPROM chip with a new one preloaded with the new BIOS. As with a flash ROM upgrade, you must get this from your motherboard manufacturer. There is usually a fee for this because the manufacturer must custom-burn a chip just for you and mail it out. Most boards older than 1995 are probably not worth upgrading the BIOS, so this option might no longer be available. Even if it is available, it most likely doesn't make sense to spend up to \$50 on a new BIOS for an ancient board when a more modern board can be had for nearly the same cost—especially since that new board will include a flash BIOS and many other new features.

Tip

You can get a replacement BIOS chip identical to the motherboard manufacturer's product for many systems for around \$30 from BIOSWorld (www.biosworld.com). See its Web site for details.

The procedure for replacing the BIOS chip is also useful if you have made a backup copy of your socketed system BIOS chip and need to replace a damaged original with the backup copy. This can also be useful if you have a socketed flash ROM, which was common on motherboards without a BIOS recovery jumper.

To replace the BIOS chip, follow these steps:

1. Back up the CMOS RAM settings.
2. Power down the system and unplug the power cord.
3. Remove the cover and any other components in the way of the BIOS EPROM chip. Remember to use caution with respect to static discharges; you should wear an antistatic wrist strap for this procedure or ground yourself to the chassis before touching any internal components.
4. Using a chip puller or a thin flat-blade screwdriver, gently pry the chip out of its socket.
5. Remove the new EPROM from the antistatic packing material in which it came.
6. Install the new EPROM chip into the socket. A standard rectangular BIOS chip has a dimple at one end that corresponds to a cutout on the socket. You can install the chip in the socket backward, but if you do, you will destroy the chip.

7. Reinstall anything you removed to gain access to the chip.
8. Put the cover back on, plug in the system, and power on.
9. Enter the BIOS setup information you saved earlier.
10. Reboot and enjoy the new BIOS!

As you can see, things are much easier with a modern motherboard with a flash ROM because you usually don't even have to remove the lid (unless the flash BIOS is write-protected as discussed earlier in this chapter).

Year 2000 BIOS Issues

All systems now in use should be compliant with twenty-first century dates, either through BIOS updates or through software or hardware patches. However, if you are returning stored systems built before 1999 to service, you might want to test them for year-2000 compliance. For details, see *Upgrading and Repairing PCs, 12th Edition*, available in electronic form on the DVD packaged with this book.

Preboot Environment

Both the standard and Pro versions of the Phoenix FirstBIOS have a common preboot environment with a graphical user interface that allows a user to access the BIOS Setup, extended diagnostics, a backup/restore application, or a full recovery of the original system contents (product restoration to factory-delivered contents). All these applications (except the BIOS Setup) are stored in the HPA, a hidden area of the hard drive literally situated past the reported end of the drive. The number and type of applications accessible via the preboot environment depend on which options the OEM selected when designing the system. Figure 5.9 shows IBM's implementation of the Phoenix FirstBIOS Pro preboot environment. This environment is activated by pressing the Enter key on the keyboard during the POST.

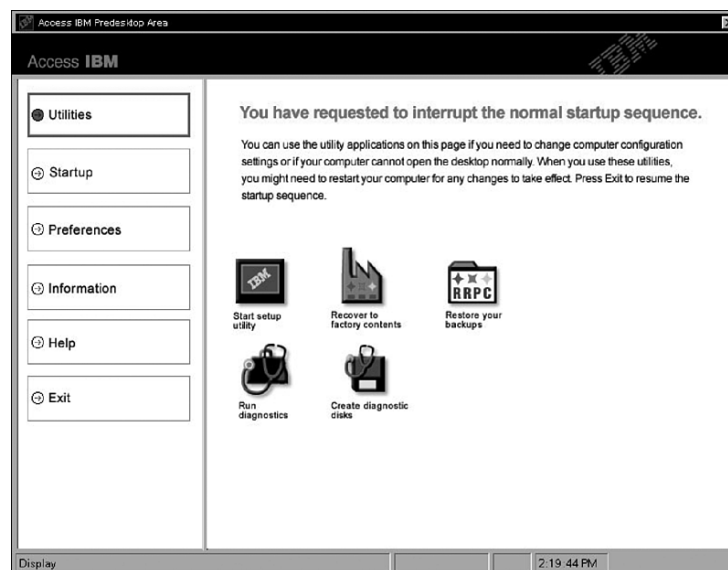

Figure 5.9 Phoenix FirstBIOS Pro preboot environment: IBM implementation shown.

A graphical preboot environment is especially useful for product recovery. For example, most of the larger system OEMs do a lot more than just install Windows on a system before they deliver it. After installing Windows, they install all the service packs and updates available at the time, as well as all

the updated drivers unique to their systems. Then they add customizations, such as special wallpapers or interface customizations, support contact information, online system documentation, and custom utilities designed to make their systems easier to use. Finally, they install applications such as DVD players, Office applications or other productivity software, and more.

This OEM customization represents a lot of work if a user were to have to duplicate this from scratch, so most manufacturers like to include the ability to easily recover the system to the factory-delivered contents, including the OS, drivers, application, and custom configuration. This is normally provided via several CDs, which could be lost or damaged by the user, are sometimes problematic to use, and which cost money to produce and deliver with the system. By using a BIOS such as the Phoenix FirstBIOS, an OEM can instead deliver the contents of the recovery CDs directly on the hard disk and make it accessible via the preboot menu in the BIOS.

Originally, this was done using a hidden partition, which unfortunately could easily be damaged or overwritten by partitioning software or other utilities. In many newer systems, the contents of the recovery CDs is instead preinstalled in the HPA, which is accessible via Protected Area Run Time Interface Extension Services (PARTIES), a standard supported on all ATA-4 or newer drives. HPA/PARTIES works by using the ATA SET MAX ADDRESS command to essentially make the drive appear to the system as a slightly smaller drive. Most manufacturers use the last 3GB of the drive for the HPA. Anything from the new max address (the newly reported end of the drive) to the true end of the drive is considered the HPA and is accessible only using PARTIES commands. Figure 5.10 shows the contents of the HPA and the relationship between the HPA and the rest of the drive.

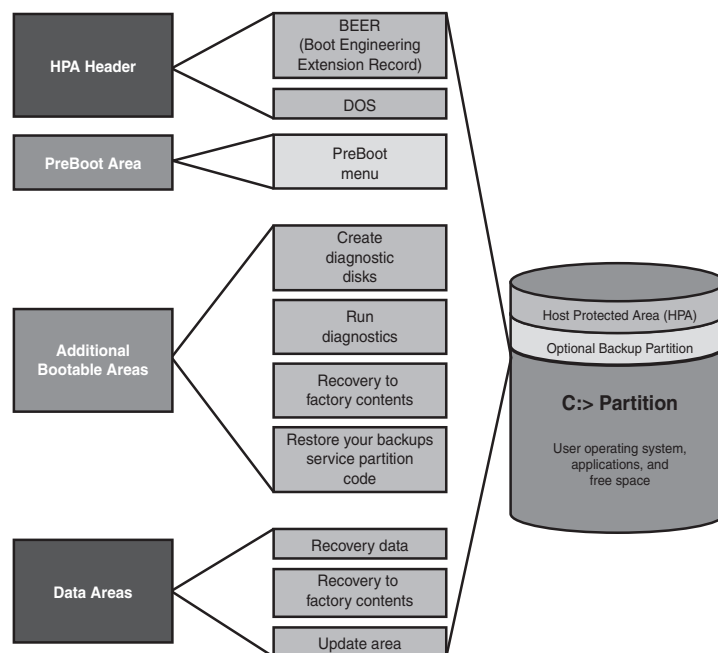

Figure 5.10 The HPA.

The HPA is more secure than a hidden partition because any data past the end of the drive simply cannot be seen by any normal application, or even a partitioning utility such as Partition Magic or Partition Commander. This makes it far more secure and immune to damage. Still, if you wanted to remove the HPA, there is a way to reset the max address, thus exposing the HPA. Then you could run something like Partition Magic or Partition Commander to resize the main partition to include the extra space that was

formerly hidden and unavailable. The only consequence is that you would lose access to the product recovery, diagnostics, and backup applications preloaded by the OEM. For some people, this might be desirable because future product recoveries could still be done via the recovery CDs (not usually shipped with the system anymore, but still available separately either free or for a minimal charge), and true hardware diagnostics can still be run via bootable floppies or CDs. Also, if you are replacing the hard disk, you can temporarily unhide the HPA on the original drive, allowing it to be copied to a new drive. Alternatively, you can use the OEM-supplied recovery CDs to install the HPA on the new drive.

Most new systems using Phoenix FirstBIOS come with their recovery software and diagnostics in the HPA because this is part of the new Phoenix FirstBIOS core managed environment (cME), which is used by a large number of OEMs (including IBM) on most desktop and laptop systems starting in 2003.

CMOS Setup Specifications

The CMOS RAM must be configured with information about your system's drives and user-selected options before you can use your computer. The Setup program provided with your system is used to select the options you want to use to start your computer.

Running or Accessing the CMOS Setup Program

If you want to run the BIOS Setup program, you usually have to reboot and press a particular key or key combination during the POST. Normally, the correct key to press is displayed onscreen momentarily during the POST. If it flashes past too quickly to read, try pressing the Pause key on the keyboard when it appears. This freezes the system, allowing you to read the display. Pressing any other key (such as the spacebar) un-pauses the system and allows the POST to continue. The major vendors have standardized the following keystrokes to enter the BIOS Setup in recent systems:

- *AMI BIOS*. Press Delete during POST.
- *Phoenix BIOS (FirstBIOS Pro)*. Press F2 during POST.
- *Award BIOS (FirstBIOS)*. Press Delete or Ctrl+Alt+Esc during POST.
- *Microid Research (MR) BIOS*. Press Esc during POST.

If your system does not respond to one of these common keystroke settings, you might have to contact the manufacturer or read the system documentation to find the correct keystrokes.

Some unique ones are as follows:

- *IBM Aptiva/Valuepoint or ThinkPad*. Press F1 during POST or while powering on the system.
- *Toshiba notebook/laptop*. Press Esc while powering on the system; then press F1 when prompted.
- *Older Phoenix BIOS*. Boot to a safe mode DOS command prompt, and then press Ctrl+Alt+Esc or Ctrl+Alt+S.
- *Compaq*. Press F10 during POST.

After you are at the BIOS Setup main screen, you'll usually find a main menu allowing access to other menus and submenus of different sections or screens. Using the Intel D875PBZ motherboard as an example (one of Intel's recent motherboards), let's go through the menus and submenus of this typical (and popular) motherboard. Although other motherboards might feature slightly different settings, most are very similar.

BIOS Setup Menus

Most modern BIOSs offer a menu bar at the top of the screen when you're in the BIOS Setup that controls navigation through the various primary menus. A typical menu bar offers the choices shown in Table 5.8.

Note

Because most common BIOSs use similar settings, I've chosen the Setup used by modern Intel motherboards as an example in the following tables. Because the BIOS is customized by the motherboard manufacturer, even the same BIOS can offer different options for different boards. The settings covered here will help you get a general idea of the type of settings to expect and how the BIOS Setup settings affect your computer.

Table 5.8 Typical BIOS Setup Menus

Setup Menu Screen	Description
Maintenance	Specifies the processor speed and clears the setup passwords. This menu is available only in Configure mode, set by a jumper on the board.
Main	Allocates resources for hardware components.
Advanced	Specifies advanced features available through the chipset.
Security	Specifies passwords and security features.
Power	Specifies power management features.
Boot	Specifies boot options and power supply controls.
Exit	Saves or discards changes to the setup program options.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Choosing each of these selections takes you to another menu with more choices. The following sections examine all the choices available in a typical motherboard, such as the Intel D875PBZ.

Maintenance Menu

The Maintenance menu is a special menu for setting the processor speed and clearing the setup passwords. Older motherboards used jumpers to configure the processor bus speed (motherboard speed) and processor multiplier. Most newer boards from Intel and others now offer this control via the BIOS Setup rather than moving jumpers. In the case of Intel, one jumper still remains on the board called the configuration jumper, and it must be set to Configure mode for the Maintenance menu to be available.

Setup displays this menu only if the system is set in Configure mode. To set Configure mode, power off the system and move the configuration jumper on the motherboard from *Normal* to *Configure* (see Figure 5.6, earlier in this chapter). Because this is the only jumper on a modern Intel board, it is pretty easy to find. When the system is powered back on, the BIOS Setup automatically runs, and you will be able to select the Maintenance menu shown in Table 5.9. After making changes and saving, power off the system and reset the jumper to Normal mode for normal operation.

Table 5.9 Typical Maintenance Menu Settings

Feature	Options	Description
Clear All Passwords	OK (default) Cancel	Clears the user and supervisor passwords
Clear BIOS	OK (default) Cancel	Clears the Wired for Management Boot Integrity Service (BIS) credentials
CPU Stepping Signature	No options	Displays CPU's stepping revision
CPU Microcode Update Revision	No options	Displays CPU's microcode update revision

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Note that most newer Intel processors are designed to allow operation only at or below their rated speeds (a feature called *speed locking*), whereas others allow higher-than-rated speeds to be selected.

If a user forgets his password, all he has to do is set the configuration jumper, enter the Maintenance menu in BIOS Setup, and use the option provided to clear the password. This function doesn't tell the user what the password was; it simply clears it, allowing a new one to be set if desired. This means the security is only as good as the lock on the system case because anybody who can get to the configuration jumper can clear the password and access the system. This is why most better cases come equipped with locks.

Extended Configuration Submenu

The Extended Configuration submenu on some Intel motherboards has memory setup options similar to those found in the section "Additional Advanced Features," later in this chapter. See this section for details.

Main Menu

The standard CMOS Setup menu dates back to the 286 days, when the complete BIOS Setup consisted of only one menu. In the standard menu, you can set the system clock and record hard disk and floppy drive parameters and the basic video type. Newer BIOSs have more complicated setups with more menus and submenus, so the main menu often is fairly sparse compared to older systems.

The main menu in a modern system reports system information such as the BIOS version, the processor type and speed, the amount of memory, and whether the memory or cache is configured for ECC functionality. The main menu also can be used to set the system date and time.

Table 5.10 shows a typical main menu.

Table 5.10 Typical Main Menu Settings

Feature	Options	Description
BIOS Version	—	Displays the version of the BIOS.
Processor Type	—	Displays the processor type.
Hyper-Threading Technology	Enabled (default); Disabled	Enables/disables Hyper-Threading Technology. This option is present only when a processor that supports Hyper-Threading Technology is installed.
Processor Speed	—	Displays the processor speed.
System Bus Speed	—	Displays the system bus speed.
System Memory Speed	—	Displays the system memory speed.
Cache RAM	—	Displays the size of the L2 cache.
Total Memory	—	Displays the total amount of RAM.
Memory Mode	—	Displays the memory mode (dual channel or single channel).
Memory Channel A Slot 0; Memory Channel A Slot 1; Memory Channel B Slot 0; Memory Channel B Slot 1	—	Displays the amount and type of RAM in the DIMM sockets.

Table 5.10 Continued

Feature	Options	Description
Memory Configuration	Non-ECC (default); ECC	ECC turns on error reporting if the system and all the memory installed supports ECC. This setting is available only when ECC memory is installed.
Language	English (default); others might be listed	Selects the current default language used by the BIOS.
System Time	Hour:minute:second	Specifies the current time.
System Date	Month/day/year	Specifies the current date.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

ECC stands for error correcting code, which is the use of extra bits on the memory modules to detect and even correct memory errors on-the-fly. For ECC to be enabled, more expensive ECC DIMMs would have to be installed in the system. Note that all DIMMs would need to be ECC versions for this to work; if even one is non-ECC, ECC can't be enabled. For mission-critical systems (such as servers), I recommend purchasing ECC memory and enabling this function because it makes the system more fault tolerant and prevents corrupted data due to soft errors in memory. Random memory errors can occur at the rate of up to 1 bit error per month for every 64–256 megabytes installed. ECC ensures that these errors don't creep into your data files, corrupt the system, or cause it to crash.

- ▶▶ See "Error Correcting Code," p. 506.

Be sure to check whether your motherboard supports ECC before purchasing ECC memory. You can install ECC memory in a non-ECC-capable board, but the ECC functionality will not be available. Also, make sure you are aware of the memory requirements for your board. Don't try to install more memory than the board supports, and be sure the modules you use meet the specifications required by the board. See the documentation for the motherboard for more information on the type and amount of memory that can be installed.

Most older BIOSs report memory as base and extended memory instead of as a single value. Base memory is typically 640KB and sometimes is called *conventional* memory. Extended memory is that which is beyond the first megabyte in the system.

You can't change any values in the memory fields; they are only for your information because they are automatically counted up by the system. If the memory count doesn't match what you have installed, a problem has likely occurred with some of the memory: It is defective, is not fully seated or properly installed, or is a type that is incompatible with your system.

Advanced Menu

The Advanced menu is a doorway to submenus for setting advanced features that are available through the motherboard chipset. This part of your BIOS setup is specific to the particular chipset the motherboard uses. Many chipsets are available on the market today, and each has unique features. The chipset setup is designed to enable the user to customize these features and control some of the chipset settings. Table 5.11 shows the typical Advanced submenus available.

Table 5.11 Typical Advanced BIOS Submenus

Submenu	Description
PCI Configuration	Configures the IRQ priority of individual PCI slots
Boot Configuration	Configures Plug and Play, resets PnP configuration data, and configures the NumLock key
Peripheral Configuration	Configures peripheral ports and devices
Drive Configuration	Configures ATA devices
Floppy Configuration	Configures the floppy drive
Event Log Configuration	Configures event logging
Video Configuration	Configures video features
USB Configuration	Configures USB support
Chipset Configuration	Configures advanced chipset features
Fan Control Configuration	Configures fan operation
Hardware Monitoring	Monitors system temperatures, voltages, and fan speeds

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

PCI Configuration Submenu

The PCI Configuration submenu is used to select the IRQ priority of add-on cards plugged into the PCI slots. Auto (the default) should be used to allow the BIOS and operating system to assign IRQs to each slot unless specific PCI cards require unique IRQs. See Table 5.12 for a typical example.

Table 5.12 Typical PCI Configuration Submenu Settings

Feature	Options	Description
PCI Slot 1 IRQ Priority	Auto (default), 3, 5, 9, 10, 11	Allows selection of the IRQ priority for PCI bus connector 1
PCI Slot 2 IRQ Priority	Auto (default), 3, 5, 9, 10, 11	Allows selection of the IRQ priority for PCI bus connector 2
PCI Slot 3 IRQ Priority	Auto (default), 3, 5, 9, 10, 11	Allows selection of the IRQ priority for PCI bus connector 3
PCI Slot 4 IRQ Priority	Auto (default), 3, 5, 9, 10, 11	Allows selection of the IRQ priority for PCI bus connector 4
PCI Slot 5 IRQ Priority	Auto (default), 3, 5, 9, 10, 11	Allows selection of the IRQ priority for PCI bus connector 5

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Additional IRQs might be available if onboard devices such as the serial and parallel ports are disabled.

Boot Configuration Submenu

The options in Table 5.13 configure the system's PnP and keyboard configuration during initial boot.

Table 5.13 Typical Boot Configuration Submenu Settings

Feature	Options	Description
Plug and Play O/S	No (default) Yes	Specifies whether a PnP operating system is being used. No lets the BIOS configure all devices. Yes lets the operating system configure plug-and-play devices. Either setting works with a PnP operating system; however, No must be selected if using a non-PnP OS.
NumLock	On (default) Off	Specifies the power-on state of the NumLock feature on the numeric keypad of the keyboard.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Additional Advanced Features

Many boards differ in the advanced chipset menus. In most cases, unless you know exactly which chipset and what type of memory and other items are found in your system, it is best to leave these settings on Auto. In that case, the modern boards use the configuration ROM found on the DIMM or RIMM memory modules to properly configure the memory settings. In fact, many newer boards no longer allow these settings to be manually adjusted because, in most cases, all that does is lead to trouble in the form of an unstable or a failing system. If you do want to play with these settings, I recommend first finding out exactly which memory modules and chipset you have and contacting the manufacturers of them to get their databooks. The databooks have all the technical information related to those devices.

Table 5.14 lists settings used by a typical motherboard's Chipset Configuration submenu.

Table 5.14 Typical Chipset Configuration Menu

Feature	Options	Description
ISA Enable Bit	Enabled (default) Disabled	When enabled, a PCI-to-PCI bridge recognizes only 16-bit I/O addresses that are not aliases of 10-bit ISA addresses (within the bridge's assigned I/O range). This helps prevent resource conflicts with ISA devices that might be present in the system (such as serial or parallel ports) and allows VGA-compatible address range mapping for ISA devices.
PCI Latency Timer	32 (default) 64 96 128 160 192 224 248	Allows you to control the time (in PCI bus clock cycles) that an agent on the PC bus can hold the bus when another agent has requested the bus.
Burn-In Mode	—	Selects a submenu used to set Burn-In mode configuration options.
Extended Configuration	Default (default) User-defined	Allows the setting of extended configuration options.
SDRAM Frequency ¹	Auto (default) 266MHz 333MHz ² 400MHz ³	Allows an override of the detected memory frequency ⁴ .
SDRAM Timing Control ¹	Auto (default) Manual-Aggressive Manual-User-defined	When Auto is selected, timings are programmed according to the memory detected. Manual-Aggressive selects the most aggressive user-defined timings. Manual-User-defined allows manual override of detected SDRAM settings.
CPC Override	Auto (default) Enabled Disabled	Controls the CPC/1n rule mode. Enabled allows the DRAM controller to attempt chip select assertions in two consecutive common clocks.
SDRAM RAS Active to Precharge ⁵	8 7 6 (default) 5	Corresponds to tRAS, or the minimum page open time.
SDRAM CAS# Latency ⁵	2.0 2.5 (default) 3.0	Selects the number of clock cycles required to address a column in memory.

Table 5.14 Continued

Feature	Options	Description
SDRAM RAS# to CAS# Delay ⁵	4 3 2 (default)	Selects the number of clock cycles between addressing a row and addressing a column.
SDRAM RAS# Precharge ⁵	4 3 2 (default)	Selects the length of time required before accessing a new row.

1. This feature is displayed only if Extended Configuration is set to User-defined.
2. This option is displayed only if the installed processor has a 533MHz system bus.
3. This option is displayed only if the installed processor has an 800MHz system bus.
4. If SDRAM Frequency is changed, you must reboot for the change to take effect. After changing this setting and rebooting, the System Memory Speed parameter in the Main menu reflects the new value.
5. This feature is normally controlled by the serial presence detect (SPD) ROM in the DIMM and is displayed only if SDRAM Timing Control is set to Manual-User-defined.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Some motherboards might also have advanced chipset options similar to those described in Table 5.15.

Table 5.15 Additional Advanced Chipset Options

Setting	Description
System BIOS Cacheable	Allows caching of the system BIOS ROM at F0000h–FFFFFh, resulting in better system performance when 16-bit applications are run. If any program writes to this memory area, a system error can result.
Video BIOS Cacheable	Allows caching of the video BIOS ROM at C0000h–C7FFFh, resulting in better video performance when 16-bit applications are run. If any program writes to this memory area, a system error can result.
Video RAM Cacheable (Video Memory Cache Mode)	Selecting Enabled allows caching of the video memory (RAM) at A0000h–AFFFFh, resulting in better video performance when 16-bit applications are run. If any program writes to this memory area, a memory access error can result. Uncacheable Speculative Write-Combining (USWC) mode is the same as Enabled on some systems.
8/16 Bit I/O Recovery Time	The I/O recovery mechanism adds bus clock cycles between PCI-originated I/O cycles to the ISA bus. This delay takes place because the PCI bus is so much faster than the ISA bus.
Memory Hole at 15M–16M	Places a 1MB empty RAM area between 15MB and 16MB. Older software sometimes would not run with 16MB or more memory in the system; enabling this provides a workaround. This is not normally used.
Passive Release	When Enabled, CPU-to-PCI bus accesses are allowed during passive release. Otherwise, the arbiter accepts only another PCI master access to local DRAM.
Delayed Transaction	The chipset has an embedded 32-bit posted write buffer to support delay transaction cycles. Select Enabled to support compliance with PCI specification version 2.1.

Overclocking/Burn-in Test Features

Many motherboards include features designed to overclock the system, which enables you to set the system to run the CPU bus (and therefore the CPU itself) and possibly other buses at higher-than-normal rated speeds. These settings are especially useful for stress testing a system after initial assembly, which is often called a *burn-in* test. Table 5.16 shows typical overclock/burn-in test features found in the BIOS Setup.

Table 5.16 Overclocking/Burn-in Test Settings

Feature	Options	Description
Do you wish to continue?	No (default) Continue	Enables or disables setting of burn-in (overclocking) mode options. Burn-in Mode is an unsupported overclocking capability for use by system engineers, technicians, or experienced users for validation and test purposes.
Host and I/O Burn-In Mode	Default (default) -2.0% -1.0% +1.0% +2.0% +3.0% +4.0%	Alters the host clock (system bus) and I/O clocks (AGP and PCI) by the percentage selected. If this option is set to anything other than Default, the AGP/PCI Burn-In Mode (shown below) is automatically set to Default.
AGP/PCI Burn-In Mode	Default (default) 63.88/31.94MHz 68.05/34.02MHz 69.44/34.72MHz 70.83/35.41MHz 72.22/36.11MHz 73.60/36.80MHz	The Default settings are 66.66/33.33MHz. Using other settings enables the selection of specific AGP/PCI clock frequencies, but only if the host clock (system bus speed) is not changed. If this option is set to anything other than Default, the Host and I/O Burn-In Mode (shown above) is automatically set to Default.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

These settings can be used to speed up the processor and interconnected buses such as PCI and AGP by a specified percentage. For specifically testing AGP video or PCI adapter cards, some motherboards allow the AGP/PCI bus speed to be set independently of the CPU bus. If you intend to use these settings to speed up a system, beware that—depending on the specific hardware and software you have—running faster than default clock speeds can reduce system stability and shorten the useful life of the processor, and it might not be covered under warranty. If any problems occur, return the settings to the default values.

Peripheral Configuration

The Peripheral Configuration menu is used to configure the devices built into the motherboard, such as serial ports, parallel ports, and built-in audio and USB ports.

Table 5.17 shows a typical Peripheral Configuration menu and choices.

Table 5.17 Typical Peripheral Configuration Menu

Feature	Options	Description
Serial Port A	Auto (default) Disabled Enabled	Configures serial port A. Auto assigns the first free COM port (normally COM 1) I/O address 3F8h and IRQ4.
Base I/O address	3F8h (default) 2F8h 3E8h 2E8h	Specifies the base I/O address for serial port A.
Interrupt	IRQ 4 (default) IRQ 3	Specifies the interrupt for serial port A.
Parallel port	Auto (default) Enabled Disabled	Configures the parallel port. Auto assigns I/O addresses 378h and IRQ7.

Table 5.17 Continued

Feature	Options	Description
Mode	Output Only Bi-directional (default) EPP ECP	Selects the mode for the parallel port. EPP is Extended Parallel Port mode, a high-speed, bidirectional mode. ECP is Enhanced Capabilities Port mode, another high-speed, bidirectional mode.
Base I/O address	378 (default) 278	Specifies the base I/O address for the parallel port.
Interrupt	IRQ 7 (default) IRQ 5	Specifies the interrupt for the parallel port.
DMA	DMA 3 (default) DMA 1	Specifies the DMA channel for the parallel port.
Audio	Enabled (default) Disabled	Enables or disables the onboard audio subsystem.
Onboard LAN	Enabled (default) Disabled	Enables or disables the onboard LAN (network card) device.

An asterisk (*) displayed next to an address indicates a conflict with another device.

(EPP and ECP are IEEE-1284-compliant modes and require the use of an IEEE-1284-compliant printer cable.)

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

I recommend disabling the serial and parallel ports if they are not being used because this frees up those resources for other devices.

ATA Configuration Submenu

The ATA Configuration submenu is for configuring ATA devices, such as hard drives, CD-ROM drives, LS-120 (SuperDisk) drives, tape drives, and so on. Table 5.18 shows the ATA Configuration menu and options for a typical modern motherboard.

Table 5.18 Typical ATA Configuration Menu Settings

Feature	Options	Description
ATA Configuration	Enhanced (default) Disabled Legacy	Enhanced causes all Serial ATA (SATA) and Parallel ATA (PATA) resources to be enabled. Disabled causes all ATA resources to be disabled. Legacy causes up to two ATA channels to be enabled for operating systems that require legacy ATA operation.
Legacy ATA Channels	PATA Pri Only PATA Sec Only PATA Pri and Sec SATA PO/P1 Only SATA PO/P1, PATA Sec SATA PO/P1, PATA Pri	Configures PATA and SATA resources for operating systems that require legacy ATA operation. This feature is present only when the ATA configuration option is set to Legacy.
PCI ATA Bus Master	Enabled (default) Disabled	Enables/disables the use of DMA for hard drive BIOS INT13 reads and writes.

Table 5.18 Continued

Feature	Options	Description
Hard Disk Pre-Delay	Disabled (default) 3 Seconds 6 Seconds 9 Seconds 12 Seconds 15 Seconds 21 Seconds 30 Seconds	Specifies the hard disk drive predelay.
SoftRAID Support	Disabled (default) Enabled	Configures SoftRAID support.
SATA Port-0	—	Select this to display a submenu (if a device is attached).
SATA Port-1	—	Select this to display a submenu (if a device is attached).
PATA Primary Master	—	Select this to display a submenu (if a device is attached).
PATA Primary Slave	—	Select this to display a submenu (if a device is attached).
PATA Secondary Master	—	Select this to display a submenu (if a device is attached).
PATA Secondary Slave	—	Select this to display a submenu (if a device is attached).

PATA = Parallel ATA

SATA = Serial ATA

Pri = Primary

Sec = Secondary

P0 = Serial ATA connector 0

P1 = Serial ATA connector 1

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

The hard disk pre-delay function is to delay accessing drives that are slow to spin up. Some drives aren't ready when the system begins to look for them during boot, causing the system to display Fixed Disk Failure messages and fail to boot. Setting this delay allows time for the drive to become ready before continuing the boot. Of course, this slows down the boot process, so if your drives don't need this delay, it should be disabled.

ATA Configuration Submenus

These submenus are for configuring each ATA device. Of all the BIOS Setup menus, the hard disk settings are by far the most important. In fact, they are the most important of all the BIOS settings. Most modern motherboards incorporate two ATA controllers that support up to four drives. Most modern BIOSs have an autodetect feature that enables automatic configuration of the drives. If this is available, in most cases you should use it because it will prevent confusion in the future. With the Auto setting, the BIOS sends a special Identify Drive command to the drive, which responds with information about the correct settings. From this, the BIOS can automatically detect the specifications and optimal operating mode of almost all ATA hard drives. When you select Auto for a hard drive, the BIOS redetects the drive specifications during POST, every time the system boots. You could swap drives with the power off, and the system would automatically detect the new drive the next time it was turned on.

In addition to the Auto setting, most older BIOSs offered a standard table of up to 47 drive types with specifically prerecorded parameters. Each defined drive type has a specified number of cylinders, number of heads, write precompensation factor, landing zone, and number of sectors. This often was used many years ago, but it is rarely used today because virtually no drives conform to the parameters on these drive type lists.

Another option is to select a setting called User or User Defined, which is where you can enter the specific drive CHS (Cylinder, Head, and Sector) parameters into the proper fields. These parameters are saved in the CMOS RAM and reloaded every time the system is powered up.

Most BIOSs today offer control over the drive translation settings if the type is set to User and not Auto. Usually, two translation settings are available, called Standard and LBA. Standard or LBA-disabled is used only for drives of 528MB or less, where the maximum number of cylinders, heads, and sectors are 1,024, 16, and 63, respectively. Because most drives today are larger, this setting is rarely used.

LBA (logical block addressing) is used for virtually all ATA drives that are larger than 528MB. Note that systems dating from 1997 and earlier usually are limited to a maximum drive size of 8.4GB unless they have a BIOS upgrade. Systems from 1998 and later usually support drives up to 136.9GB; systems dating from 2002 and beyond usually support drives beyond 137GB (48-bit LBA support), although a BIOS upgrade might be necessary. During drive access, the ATA controller transforms the data address described by sector, head, and cylinder number into a physical block address, significantly improving data transfer rates.

Table 5.19 shows the ATA drive settings found in a typical modern motherboard BIOS.

Table 5.19 Typical ATA Drive Settings

Feature	Options	Description
Drive Installed	—	Displays the type of drive installed.
Type	Auto (default) User	Specifies the ATA configuration mode for ATA devices. Auto reads settings from the ATA/ATAPI device. User allows settings to be changed.
Maximum Capacity	—	Displays the drive capacity.
LBA/Large Mode	Auto (default) Disabled	Displays whether automatic translation mode is enabled for the hard disk.
Block Mode	Auto (default) Disabled	Displays whether automatic multiple sector data transfers are enabled.
PIO Mode	Auto (default) 0 1 2 3 4	Sets the Programmed I/O mode.
DMA Mode	Auto (default) SWDMAx MWDMAx UDMAx	Specifies the DMA mode for the drive. SWDMA = SingleWord DMA; MWDMA = MultiWord DMA; UDMA = Ultra DMA.
SMART	Auto (default) Disabled Enabled	Enables/disables Self-Monitoring, Analysis, and Reporting Technology (SMART). Auto enables SMART if it's supported by the drive.
Cable Detected	—	Displays the type of cable connected to the Parallel ATA interface: 40-conductor or 80-conductor.
ARMD (ATAPI Removable Media Device) Emulation Type	Floppy	This is displayed only when an LS-120 SuperDisk drive is connected.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Setting the drive type to Auto causes the other values to be automatically configured correctly. I recommend this for virtually all standard system configurations. When set to Auto, the BIOS sends an Identify command to the drive, causing it to report back all the options and features found on that drive. Using this information, the BIOS then automatically configures all the settings on this menu for maximum performance with that drive, including selecting the fastest possible transfer modes and other features.

For hard drives, the only option available other than Auto is User. When set to User, the other choices are made available and are not automatically set. This can be useful for somebody who wants to “play” with these settings, but in most cases, all you will get by doing so is lower performance and possibly even trouble in the form of corrupted data or a nonfunctional drive. User should be used only if a drive was originally prepared with a set of values different from those recognized automatically with the default Auto configuration setting.

Floppy Configuration Submenu

The Floppy Configuration submenu is for configuring the floppy drive and interface. Table 5.20 shows the options in a typical BIOS Setup.

Table 5.20 Typical Diskette Configuration Settings

Feature	Options	Description
Diskette Controller	Enabled (default) Disabled	Disables or enables the integrated diskette controller
Diskette A:	Disabled 360KB, 5 1/4" 1.2MB, 5 1/4" 1.44MB, 3 1/2" (default) 720KB, 3 1/2" 2.88MB, 3 1/2"	Specifies the capacity and physical size of floppy disk drive A:
Diskette Write Protect	Disabled (default) Enabled	Disables or enables write protect for floppy disk drive A:

Settings based on the BIOS used by the Intel D845PEBT2 motherboard. Used by permission of Intel Corporation.

By enabling the write-protect feature, you can disallow writing to floppy disks. This can help prevent the theft of data as well as help to prevent infecting disks with viruses should they be on the system.

Event Logging

The Event Logging menu is for configuring the System Management (SMBIOS) event logging features. SMBIOS is a DMI-compliant method for managing computers on a managed network. DMI stands for Desktop Management Interface, a special protocol that software can use to communicate with the motherboard.

Using SMBIOS, a system administrator can remotely obtain information about a system. Applications such as the LANDesk Client Manager (originally developed by Intel but now sold by LANDesk Software) can use SMBIOS to report the following DMI information:

- BIOS data, such as the BIOS revision level
- System data, such as installed peripherals, serial numbers, and asset tags
- Resource data, such as memory size, cache size, and processor speed
- Dynamic data such as event detection, including event detection and error logging

Table 5.21 shows a typical Event Logging menu in BIOS Setup.

Table 5.21 Typical Event Logging Menu

Feature	Options	Description
Event Log	—	Indicates whether space is available in the event log
View Event Log	[Enter]	Displays the event log
Clear Event Log	OK (default) Cancel	Clears the event log after rebooting
Event Logging	Enabled (default) Disabled	Enables/disables logging of Desktop Management Interface events
ECC Event Logging	Enabled (default) Disabled	Enables/disables logging of ECC events
Mark Events As Read	OK (default) Cancel	Marks all events as read

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Some motherboards with ECC memory also support log ECC events. I find event logging particularly useful for tracking errors such as ECC errors. Using the View Log feature, you can see whether any errors have been detected (and corrected) by the system.

Video Configuration

The Video Configuration menu is for configuring video features. Table 5.22 shows the functions of this menu in a typical modern motherboard BIOS.

Table 5.22 Typical Video Configuration Menu

Feature	Options	Description
AGP Aperture Size	4MB 8MB 16MB 32MB 64MB (default) 128MB 256MB	Specifies the aperture size for the AGP video controller
Primary Video Adapter	AGP (default) PCI	Selects the type of video card used for the boot display device

Settings based on the BIOS used by the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Other motherboards might also include features such as those shown in Table 5.23.

Table 5.23 Additional Video Configuration Menu Options

Feature	Options	Description
Palette Snooping	Disabled (default) Enabled	Controls the capability of a primary PCI graphics controller to share a common palette with an ISA add-in video card
AGP Hardware Detected	No options	Indicates whether a 1x, 2x, or 4x AGP card is installed; disables onboard graphics subsystem

The most common use of this menu is to change the primary video device. This is useful under Windows 98 and later versions, which support dual-monitor configurations. Using this feature, you can set either the AGP or PCI video card to be the primary boot device.

USB Configuration Submenu

The USB Configuration submenu is used for configuring the USB ports on the system. Table 5.24 shows the functions of this menu in a typical modern motherboard BIOS.

Table 5.24 Typical USB Configuration Menu

Feature	Options	Description
High-Speed USB	Enabled (default) Disabled	Set to Disabled when a USB 2.0 driver is not available
Legacy USB Support	Enabled (default) Disabled	Enables/disables legacy USB support
USB 2.0 Legacy Support	FullSpeed (default) HiSpeed	Configures the USB 2.0 Legacy support: HiSpeed = 480Mbps; FullSpeed = 12Mbps

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Some motherboards that have separate USB 1.1 and USB 2.0 ports might offer additional configuration options.

Legacy USB support means support for USB keyboards and mice. If you are using USB keyboards and mice, you will find that the keyboard is not functional until a USB-aware operating system is loaded. This can be a problem when running DOS; diagnostics software; or other applications that run outside of USB-aware operating systems, such as Windows 98, Windows Me, Windows XP, and Windows 2000. In that case, you should enable the USB legacy support via this menu.

Even with legacy support disabled, the system still recognizes a USB keyboard and enables it to work during the POST and BIOS Setup. If USB legacy support is disabled (the default on some systems), the system operates as follows:

1. When you power up the computer, USB legacy support is disabled.
2. POST begins.
3. USB legacy support is temporarily enabled by the BIOS. This enables you to use a USB keyboard to enter the setup program or Maintenance mode.
4. POST completes and disables USB legacy support (unless it was set to *Enabled* while in Setup).
5. The operating system loads. While the operating system is loading, USB keyboards and mice are not recognized. After the operating system loads the USB drivers, the USB devices are recognized.

To install an operating system that supports USB, enable USB legacy support in BIOS Setup and follow the operating system's installation instructions. After the operating system is installed and the USB drivers are configured, USB legacy support is no longer used and the operating system USB drivers take over. However, I recommend that you leave legacy support enabled so the USB keyboard functions in DOS while running self-booting or DOS-based diagnostics or when running other non-USB-aware operating systems.

If USB legacy support is enabled, you shouldn't mix USB and PS/2 port keyboards and mice. For example, don't use a PS/2 keyboard with a USB mouse or a USB keyboard and a PS/2 mouse. Also remember that this legacy support is for keyboards and mice only; it won't work for USB hubs or other USB devices. For devices other than keyboards or mice to work, you need a USB-aware operating system with the appropriate USB drivers.

Fan Control Configuration Submenu

Most systems have one or more chassis fans to help cool the system. Table 5.25 shows the function of the Fan Control Configuration submenu on a typical high-performance PC.

Table 5.25 Fan Control Configuration Submenu

Feature	Options	Description
Fan Control	Enabled (default) Disabled	Enables or disables fan control.
Lowest Fan Speed	Slow (default) Off	Defines the lower limit of chassis fan speed operation. When set to <i>Slow</i> , at low system temperatures the fans will continue to run at slow speed. When set to <i>Off</i> , at low system temperatures the fans will turn off.

These options do not take effect until AC power has been completely removed from the system. After saving the BIOS settings and turning off the system, unplug the power cord from the system and wait at least 30 seconds before reapplying power and turning the system back on.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Many newer boards have built-in monitor chips that can read temperature, voltage, and fan speeds. Those that do often include a screen in the BIOS Setup that allows you to view the readings from the monitor chip. Usually such boards also include a hardware monitor program that runs under Windows for more convenient monitoring while the system is in use (see Table 5.26).

Table 5.26 Hardware Monitoring Display

Feature	Description
Processor Zone Temperature	Displays temperature near the CPU in Celsius and Fahrenheit
System Zone 1 Temperature	Displays temperature of Zone 1 in Celsius and Fahrenheit
System Zone 2 Temperature	Displays temperature of Zone 2 in Celsius and Fahrenheit
Processor Fan Speed	Displays CPU fan speed in RPM
Rear Fan Speed	Displays chassis rear fan speed in RPM
Front Fan Speed	Displays chassis front fan speed in RPM
Voltage Regulator Fan Speed	Displays VR fan speed in RPM
+1.5V in	Displays voltage level of +1.5V supply
Vccp	Displays voltage level of CPU core supply
+3.3V in	Displays voltage level of +3.3V supply
+5V in	Displays voltage level of +5V supply
+12V in	Displays voltage level of +12V supply

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Resource Configuration/PnP Configuration Menu

If you have a motherboard with one or more ISA slots, you need to use the Resource Configuration or PnP Configuration menu to determine which IRQs and memory addresses are available for ISA devices. This is not necessary on motherboards that have only PCI or PCI and AGP slots. For more information about this menu, see *Upgrading and Repairing PCs, 12th Edition*, included in electronic form on the DVD packaged with this book.

Security Menu

Most BIOSs include two passwords for security, called the supervisor and user passwords. These passwords help control who is allowed to access the BIOS Setup program and who is allowed to boot the computer. The supervisor password is also called a setup password because it controls access to the setup program. The user password is also called a system password because it controls access to the entire system.

If a supervisor password is set, a password prompt is displayed when an attempt is made to enter the BIOS Setup menus. When entered correctly, the supervisor password gives unrestricted access to view and change all the Setup options in the Setup program. If the supervisor password is not entered or is entered incorrectly, access to view and change Setup options in the Setup program is restricted.

If the user password is set, the password prompt is displayed before the computer boots up. The password must be entered correctly before the system is allowed to boot. Note that if only the supervisor password is set, the computer boots without asking for a password because the supervisor password controls access only to the BIOS Setup menus. If both passwords are set, the password prompt is displayed at boot time, and either the user or the supervisor password can be entered to boot the computer. In most systems, the password can be up to seven or eight characters long.

If you forget the password, most systems have a jumper on the board that allows all passwords to be cleared. This means that for most systems, the password security also requires that the system case be locked to prevent users from opening the cover and accessing the password-clear jumper. This jumper is often not labeled on the board for security reasons, but it can be found in the motherboard or system documentation.

Provided you know the password and can get into the BIOS Setup, a password can also be cleared by entering the BIOS Setup and selecting the Clear Password function. If no Clear function is available, you can still clear the password by selecting the Set Password function and pressing Enter (for no password) at the prompts.

Table 5.27 shows the security functions in a typical BIOS Setup.

Table 5.27 Typical Security Settings

Feature	Options	Description
Supervisor Password	—	Reports if a supervisor password is set.
User Password	—	Reports if a user password is set.
Set Supervisor Password ¹	—	Specifies the supervisor password.
User Access Level ²	Full (default) No Access View Only Limited	Sets the user access rights to the BIOS Setup Utility. Full allows the user to change all fields except the supervisor password. No Access prevents user access to the BIOS Setup Utility. View Only allows the user to view but not change the BIOS Setup Utility fields. Limited allows the user to change some fields.
Set User Password ¹	—	Specifies the user password.
Clear User Password ³	OK (default) Cancel	Clears the user password.
Chassis Intrusion	Disabled (default) Log Log, notify once Log, notify until cleared	Disabled disables chassis intrusion; Log logs the intrusion in the event log. Log, notify once halts the system during POST, the user must press F4 to continue, the intrusion flag is cleared, and the event log is updated. Log, notify until cleared halts the system during POST and the user must enter the BIOS Setup Security menu and select Clear Chassis Intrusion Status to clear the chassis intrusion flag.

1. Passwords can be up to seven alphanumeric characters, including A–Z, a–z, and 1–9.

2. This feature is displayed only if a supervisor password has been set.

3. This feature is displayed only if a user password has been set.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

To clear passwords if the password is forgotten, most motherboards have a password-clear jumper or switch. Intel motherboards require that you set the configuration jumper, enter the Maintenance menu in BIOS Setup, and select the Clear Password feature. If you can't find the documentation for your board and aren't sure how to clear the passwords, you can try removing the battery for 15 minutes or so—it clears the CMOS RAM. It can take that long for the CMOS RAM to clear on some systems because they have capacitors in the circuit that retain a charge. Note that this also erases all other BIOS settings, including the hard disk settings, so they should be recorded beforehand.

Power Menu

Power management is defined as the capability of the system to automatically enter power-conserving modes during periods of inactivity. Two main classes of power management exist; the original standard was called Advanced Power Management (APM) and was supported by most systems since the 386 and 486 processors. More recently, a new type of power management called Advanced Configuration and Power Interface (ACPI) has been developed and began appearing in systems during 1998. Most systems sold in 1998 or later support the more advanced ACPI type of power management. In APM, the hardware does the actual power management, and the operating system or other software had little control. With ACPI, the power management is now done by the operating system and BIOS, and not the hardware. This makes the control more centralized and easier to access and enables applications to work with the power management. Instead of using the BIOS Setup options, you merely ensure that ACPI is enabled in the BIOS Setup and then manage all the power settings through Windows 98/Me, 2000/XP, or later.

Tables 5.28 and 5.29 show the typical power settings found in a managed system.

Table 5.28 Typical Power Settings for a Managed System

Feature	Options	Description
ACPI	—	Selects a submenu that sets the ACPI power management options.
After Power Failure	Last State (default) Stay Off Power On	Specifies the mode of operation if an AC power loss occurs. Last State restores the computer to the power state it was in before the power loss. Stay Off keeps the computer powered off until the power button is pressed. Power On boots the computer when power is restored.
Wake on PCI PME	Stay Off (default) Power On	Specifies how the computer responds when system power is off and a PCI power management event occurs.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Table 5.29 ACPI Submenu

Feature	Options	Description
ACPI Suspend State	S3 State (default) S1 State	S3 consumes less power, but some drivers might not support this state. S1 is the safest mode but consumes more power.
Wake on LAN from S5	Stay Off (default) Power On	In ACPI stay-off mode only, it determines how the system responds to a LAN wake-up event.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

When in Standby mode, the BIOS reduces power consumption by spinning down hard drives and reducing power to or turning off monitors that comply with Video Electronics Standards Organization (VESA) and Display Power Management Signaling (DPMS). While in Standby mode, the system can still respond to external interrupts, such as those from keyboards, mice, fax/modems, or network

adapters. For example, any keyboard or mouse activity brings the system out of Standby mode and immediately restores power to the monitor.

In most systems, the operating system takes over most of the power management settings, and in some cases, it can even override the BIOS settings. This is definitely true if the operating system and motherboard both support ACPI.

Some systems feature additional power management settings in their BIOS. These options are listed in “Additional Power Management Settings” in the Technical Reference section of the DVD packaged with this book.

Boot Menu (Boot Sequence, Order)

The Boot menu is used for setting the boot features and the boot sequence (through submenus). If your operating system includes a bootable CD—Windows XP, for example—use this menu to change the boot drive order to check your CD before your hard drive. Table 5.30 shows the functions and settings available on a typical motherboard.

Table 5.30 Typical Boot Menu Settings

Feature	Options	Description
Silent Boot	Enabled (default) Disabled	Enabled displays the OEM graphic instead of POST messages. Disabled displays normal POST messages.
Add-On ROM Display Mode	Enabled (default) Disabled	Enables/disables the splash screen for add-in cards.
Intel Rapid BIOS Boot	Enabled (default) Disabled	Enables the computer to boot with or without running certain POST tests.
PXE Boot to LAN	Disabled (default) Enabled	Disables/enables PXE boot from LAN. When set to Enabled, you must reboot for the Intel Boot Agent device to be available in the boot Device menu.
USB Boot	Enabled (default) Disabled	Enables/disables booting from USB devices.
Boot Device Priority	—	Selects a submenu that specifies the boot sequence from the available types of boot devices.
Hard Disk Drives*	—	Selects a submenu that specifies the boot sequence from the available hard disk drives.
Removable Devices*	—	Selects a submenu that specifies the boot sequence from the available removable devices.
ATAPI CD-ROM Drives*	—	Selects a submenu that specifies the boot sequence from the available ATAPI CD-ROM drives.

**This feature is displayed only if this type of device is present.*

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

Using this menu, you can configure which devices your system boots from and in which order the devices are sequenced. From this menu, you also can access Hard Drive and Removable Devices submenus, which enable you to configure the ordering of these devices in the boot sequence. For example, you can set hard drives to be the first boot choice, and then in the hard drive submenu, decide to boot from the secondary drive first and the primary drive second. Normally, the default with two drives would be the other way around.

Some recent systems also enable you to boot from external USB drives, such as Zip or LS-120 SuperDisk drives.

Boot Device Priority Submenu

This submenu is used to select the order in which boot devices will be read to start the system. Table 5.31 shows the options found on a typical motherboard.

Table 5.31 Boot Device Priority Submenu

Feature	Options	Description
1st Boot Device	Removable (Floppy)	Specifies the boot sequence according to the device type. The default settings for the first through fourth boot devices are: 1. Removable, 2. Hard Drive, 3. ATAPI CD-ROM, 4. Disabled
2nd Boot Device	Hard Drive device	
3rd Boot Device	ATAPI CD-ROM device	
4th Boot Device	Disabled	

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation. If more than four boot devices are available, they are also displayed in this submenu.

The Hard Disk Drives submenu (not shown) for the D875PBZ motherboard lists up to 12 hard disks, enabling you to choose the preferred boot device; older systems usually list only primary and secondary master and slave (four) drives. This BIOS option enables you to install more than 1 bootable hard disk in your computer and select which one you want to boot from at a BIOS level, rather than by using a boot manager program. If you need to work with multiple operating systems, this menu can be very useful.

The Removable Devices and ATAPI CD-ROM Drives submenus (not shown) list up to four devices of each type, enabling you to select from which removable device or ATAPI drive to boot. On older systems, these options might be included in the boot sequence menu. Some motherboards also list Zip and SCSI drives as bootable drives.

Exit Menu

The Exit menu is for exiting the Setup program, saving changes, and loading and saving defaults. Table 5.32 shows the typical selections found in most motherboard BIOSs.

Table 5.32 Typical Exit Menu Settings

Feature	Description
Exit Saving Changes	Exits and saves the changes in CMOS RAM.
Exit Discarding Changes	Exits without saving any changes made in the BIOS Setup.
Load Optimal Defaults	Loads the factory (optimal) default values for all the Setup options.
Load Custom Defaults	Loads the custom defaults for Setup options.
Save Custom Defaults	Saves the current values as custom defaults in CMOS RAM. Normally, the BIOS reads the saved Setup values from CMOS RAM. If this memory is corrupted, the BIOS reads the custom defaults. If no custom defaults are set, the BIOS reads the factory defaults from the flash ROM.
Discard Changes	Discards changes without exiting Setup. The option values present when the computer was turned on are used.

Settings based on the BIOS used in the Intel D875PBZ motherboard. Used by permission of Intel Corporation.

After you have selected an optimum set of BIOS Setup settings, you can save them using the Save Custom Defaults option. This enables you to quickly restore your settings if they are corrupted or lost. All BIOS settings are stored in the CMOS RAM memory, which is powered by a battery attached to the motherboard.

Additional BIOS Setup Features

Some systems have additional features in their BIOS Setup screens, which might not be found in all BIOSs. Some of the more common features you might see are listed in Table 5.33.

Table 5.33 Additional BIOS Setup Features

Feature	Description
CPU Hyper-threading	Displayed on motherboards designed for use with the Intel Pentium 4 3.06GHz and faster processors with HT Technology when such processors are installed. When enabled, this feature enables hyper-threading for faster performance when multiple applications are running.
PC Health (menu)	This menu can display information such as CPU Vcore; 3.3V, 5V, and 12V actual voltage values; chassis and processor temperature; and fan speeds. The information can be used by system management programs to warn you of problems or shut down the computer automatically.
Serial ATA Controller	When enabled, Serial ATA (SATA) drives can be used.
IEEE-1394a Port	When enabled, you can use IEEE-1394a ports for DV camcorders, external hard drives, and other IEEE-1394a devices.
ATA RAID Controller	When enabled, additional ATA ports provided for RAID or individual ATA drives can be used.
Virus Warning	When enabled, you receive a warning message if a program attempts to write to the boot sector or the partition table of the hard disk drive. If you get this warning during normal operation, you should run an antivirus program to see whether an infection has occurred. This feature protects only the master boot sector, not the entire hard drive. Note that programs that usually write to the master boot sector, such as FDISK, can trigger the virus warning message.
CPU Internal Cache/ External Cache	This allows you to disable the L1 (internal) and L2 (external) CPU caches. This is often used when testing memory, in which case you don't want the cache functioning. For normal operation, both caches should be enabled.
Quick Power On Self Test	When enabled, this reduces the amount of time required to run the POST. A quick POST skips certain steps, such as the memory test. If you trust your system, you can enable the quick POST, but in most cases I recommend leaving it disabled so you get the full-length POST version.
Swap Floppy Drive	This field is functional only in systems with two floppy drives. Selecting Enabled assigns physical drive B: to logical drive A: and physical drive A: to logical drive B:.
Boot Up Floppy Seek	When enabled, the BIOS tests (seeks) floppy drives to determine whether they have 40 or 80 tracks. Only 360KB floppy drives have 40 tracks; drives with 720KB, 1.2MB, and 1.44MB capacity all have 80 tracks. Because very few modern PCs have 40-track floppy drives, you can disable this function to save time.
Boot Up System Speed	Select High to boot at the default CPU speed; select Low to boot at a simulated 8MHz speed. The 8MHz option often was used in the past with certain copy-protected programs, which would fail the protection scheme if booted at full speed. This option is not used today.
Gate A20 Option	Gate A20 refers to the way the system addresses memory above 1MB (extended memory). When set to Fast, the system chipset controls Gate A20. When set to Normal, a pin in the keyboard controller controls Gate A20. Setting Gate A20 to Fast improves system speed, particularly with protected-mode operating systems such as Windows 9x and Windows 2000/XP.

Table 5.33 Continued

Feature	Description
Typematic Rate Setting	When disabled, the following two items (Typematic Rate and Typematic Delay) are irrelevant. Keystrokes repeat at a rate determined by the keyboard controller in your system. When enabled, you can select a typematic rate and typematic delay.
Typematic Rate (Chars/Sec)	When the typematic rate setting is enabled, you can select a typematic rate (the rate at which characters repeat when you hold down a key) of 6, 8, 10, 12, 15, 20, 24, or 30 characters per second.
Typematic Delay (Msec)	When the typematic rate setting is enabled, you can select a typematic delay (the delay before key strokes begin to repeat) of 250, 500, 750, or 1,000 milliseconds.
Security Option	If you have set a password, select whether the password is required every time the system boots or only when you enter Setup.
PS/2 Mouse Function Control	If your system has a PS/2 (motherboard) mouse port and you install a serial or USB pointing device, select Disabled.
HDD SMART Capability	SMART is an acronym for Self-Monitoring Analysis and Reporting Technology system. SMART is a hard drive self-diagnostic feature available on some ATA hard drives. Enabling this option is recommended if you use diagnostic software that can monitor SMART-compatible drives to warn you of impending failures.
Report No FDD for WIN 95	Select Yes to release IRQ6 when the system contains no floppy drive, for compatibility with Windows 95 logo certification. In the Integrated Peripherals screen, select Disabled for the Onboard FDC Controller field.
ROM Shadowing	ROM chips typically are very slow, around 150ns (nanoseconds), and operate only 8 bits at a time, whereas RAM runs 60ns or even 10ns or less and is either 32 bits or 64 bits wide in most systems. Shadowing is the copying of BIOS code from ROM into RAM, where the CPU can read the BIOS drivers at the higher speed of RAM.
Operating Frequency	Some motherboards enable you to select the FSB (front-side bus) and CPU clock multiplier speeds within the BIOS rather than through the normal motherboard-based DIP switches or jumper blocks. Select this option to enable customized settings for the CPU Clock Multiplier and CPU Frequency options.
CPU Frequency	This option enables you to vary the CPU FSB frequency from the default 66MHz, 100MHz, or 133MHz to higher values, enabling you to overclock your system.
CPU Clock Multiplier	This option enables you to vary the CPU clock multiplier from its default values to higher values <i>if</i> the CPU is not multiplier-locked. Recent and current Intel CPUs ignore nonstandard CPU clock multiplier settings, but AMD Athlon and Duron CPUs can be overclocked with this option.
CPU Vcore Setting	This option enables you to vary the core voltage of the CPU to improve the stability of your system during overclocking or to install CPUs not specifically supported by the default Automatic voltage settings.

Plug and Play BIOS

Traditionally, installing and configuring devices in PCs has been a difficult process. During installation, the user is faced with the task of configuring the new card by selecting the IRQ, I/O ports, and DMA channel. In the past, users were required to move jumpers or set switches on the add-in cards to control these settings. They needed to know exactly which resources were already in use so they could find a set of resources that did not conflict with the devices already in the system. If a conflict existed, the system might not boot and the device might fail or cause the conflicting hardware to fail.

PnP is technology designed to prevent configuration problems and provide users with the capability to easily expand a PC. With PnP, the user simply plugs in the new card and the system configures it automatically for proper operation.

PnP is composed of three principal components:

- Plug and Play BIOS
- Extended System Configuration Data (ESCD)
- Plug and Play operating system

The PnP BIOS initiates the configuration of the PnP cards during the bootup process. If the cards previously were installed, the BIOS reads the information from ESCD, initializes the cards, and boots the system. During the installation of new PnP cards, the BIOS consults the ESCD to determine which system resources are available and needed for the add-in card. If the BIOS is capable of finding sufficient available resources, it configures the card. However, if the BIOS is incapable of locating sufficient available resources, the Plug and Play routines in the operating system complete the configuration process. During the configuration process, the configuration registers (in flash BIOS) on the card and the ESCD are updated with the new configuration data.

PnP Device IDs

All Plug and Play devices must contain a Plug and Play device ID to enable the operating system to uniquely recognize the device so it can load the appropriate driver software. Each device manufacturer is responsible for assigning the Plug and Play ID for each product and storing it in the hardware.

Each manufacturer of Plug and Play devices must be assigned an industry-unique, three-character vendor ID. Then, the device manufacturer is responsible for assigning a unique product ID to each individual product model. After an ID is assigned to a product model, it must not be assigned to any other product model manufactured by the same company (that is, one that uses the same vendor ID).

Note

For a comprehensive, printable list of PnP device IDs, see "PnP Device IDs" on pages 401–408 in *Upgrading and Repairing PCs, 11th Edition*, included in the Previous Editions section of the disc accompanying this book.

ACPI

ACPI stands for Advanced Configuration and Power Interface, which defines a standard method for integrating power management as well as system configuration features throughout a PC, including the hardware, operating system, and application software. ACPI goes far beyond the previous standard, called Advanced Power Management (APM), which consists mainly of processor, hard disk, and display control. ACPI controls not only power, but also all the Plug and Play hardware configuration throughout the system. With ACPI, system configuration (Plug and Play) as well as power management configuration is no longer controlled via the BIOS Setup; it is controlled entirely within the operating system instead.

ACPI enables the system to automatically turn peripherals on and off (such as CD-ROMs, network cards, hard disk drives, and printers), as well as external devices connected to the PC (such as VCRs, televisions, telephones, and stereos). ACPI technology also enables peripherals to turn on or activate the PC. For example, inserting a tape into a VCR can turn on the PC, which could then activate a large-screen television and high-fidelity sound system.

ACPI enables system designers to implement a range of power management features with various hardware designs while using the same operating system driver. ACPI also uses the Plug and Play BIOS data structures and takes control over the Plug and Play interface, providing an operating-system-independent interface for configuration and control. ACPI is supported in Windows 98/Me, Windows 2000, XP, and later versions.

During the system setup and boot process, Windows versions supporting ACPI perform a series of checks and tests to see whether the system hardware and BIOS supports ACPI. If support for ACPI is either not detected or found to be faulty, the system typically reverts to standard Advanced Power Management control, but problems can also cause a lockup with either a red or blue screen with an ACPI error code.

Red screens indicate that the problem is probably related to hardware or the BIOS. Blue screens, on the other hand, indicate that the problem is probably related to software or is an obscure problem. The ACPI error codes are described in Table 5.34.

Table 5.34 ACPI Error Codes

Error Code	Description
1xxx -	Indicates an error during the initialization phase of the ACPI driver and usually means the driver can't read one or more of the ACPI tables
2xxx -	Indicates an ACPI machine language (AML) interpreter error
3xxx -	Indicates an error within the ACPI driver event handler
4xxx -	Indicates thermal management errors
5xxx -	Indicates device power management errors

Virtually all these errors are the result of partial or incomplete ACPI implementations or incompatibilities in either the BIOS or device drivers. If you encounter any of these errors, contact your motherboard manufacturer for an updated BIOS or the device manufacturers for updated drivers.

Initializing a PnP Device

One responsibility of a Plug and Play BIOS during POST is to isolate and initialize all Plug and Play cards and assign them a valid Card Select Number (CSN). After a CSN is assigned, the system BIOS can then designate resources to the cards. The BIOS is responsible only for the configuration of boot devices; all the remaining Plug and Play devices can be configured dynamically by the operating system software.

The following steps outline a typical flow of a Plug and Play BIOS during the POST:

1. Disable all configurable devices.
2. Identify all Plug and Play devices.
3. Construct a resource map of resources that are statically allocated to devices in the system.
4. Enable input and output devices.
5. Perform ISA ROM scan.
6. Configure the boot device.
7. Enable Plug and Play ISA and other configurable devices.
8. Start the bootstrap loader.

If the loaded operating system is Plug and Play compliant, it takes over management of the system resources. Any unconfigured Plug and Play devices are configured by the appropriate system software or the Plug and Play operating system.

At this point, the operating system is loaded and takes control over Plug and Play system resources. Using the Device Manager in the operating system (such as Windows), the user can now control any Plug and Play devices.

BIOS Error Messages

When a PC system is first powered on, the system runs a POST. If errors are encountered during the POST, you usually see a text error message displayed onscreen. Errors that occur very early in the POST might happen before the video card is initialized. These types of errors can't be displayed, so the system uses two other alternatives for communicating the error message. One is beeping—the system beeps the speaker in a specific pattern that indicates which error has occurred.

- ▶▶ For detailed lists of the BIOS POST beep codes, see Chapter 24, “PC Diagnostics, Testing, and Maintenance,” p. 1285.

The other alternative is to send a hexadecimal error code to I/O port address 80h, which can be read by a special card in one of the bus slots. When the ROM BIOS is performing the POST, in most systems the results of these tests are continuously sent to I/O Port 80h so they can be monitored by special diagnostics cards called POST cards (see Figure 5.11). These tests sometimes are called *manufacturing tests* because they were designed into the system for testing systems on the assembly line without a video display attached.

Figure 5.11 A typical POST card with two-digit hexadecimal code display (left) and a POST card in operation (right).

The POST cards have a two-digit hexadecimal display used to report the number of the currently executing test routine. Before executing each test, a hexadecimal numeric code is sent to the port and then the test is run. If the test fails and locks up the machine, the hexadecimal code of the last test being executed remains on the card's display.

Note

The DVD accompanying this book contains an exhaustive listing of additional error codes, error messages, and BIOS POST codes for BIOSs from Phoenix, AMI, Award, Microid Research, and IBM.

Many tests are executed in a system before the video display card is enabled, especially if the display is EGA or VGA. Therefore, many errors can occur that would lock up the system before the system could possibly display an error code through the video system. Because not all these errors generate beep codes, to most normal troubleshooting procedures, a system with this type of problem (such as a memory failure in Bank 0) would appear completely “dead.” By using one of the commercially available POST cards, however, you can often diagnose the problem.

These codes are completely BIOS dependent because the card does nothing but display the codes sent to it. Some BIOSs have more detailed POST procedures and therefore send more informative codes. POST cards can be purchased from JDR Microdevices or other sources and are available in both ISA and PCI bus versions.

For simple but otherwise fatal errors that can't be displayed onscreen, most of the BIOS versions also send audio codes that can be used to help diagnose such problems. The audio codes are similar to POST codes, but they are read by listening to the speaker beep rather than by using a special card.

The following section details the text error codes for all the popular BIOS versions. For detailed lists of the BIOS POST beep codes, see Chapter 24, “PC Diagnostics, Testing, and Maintenance.”

General BIOS Boot Text Error Messages

During the boot process, the bootstrap loader routine in the motherboard ROM BIOS reads the first physical sector of each of the bootable drives or devices, which is cylinder 0, head 0, sector 1 in CHS mode or logical block address 0 in LBA mode. The code from the first sector is loaded into RAM, and the last two bytes are checked to see whether they match a signature value of 55AAh. If the signature bytes match, that tells the ROM that the first sector contains a valid MBR and that the ROM can continue by transferring control to the MBR code.

If the last two bytes of the first physical sector do not match 55AAh, the ROM continues by checking the first physical sector of the next bootable device in the boot sequence until it either finds one with a valid MBR or runs out of devices to check. If after checking all the drives or devices in the boot sequence, none are found to have the proper signature bytes indicating a valid MBR, the ROM invokes an interrupt 18h that calls a subroutine that displays an error message. The specific text or wording of the message varies according to the ROM manufacturer and version. The messages are detailed in the following section.

ROM BIOS Messages Indicating Boot Failure (No Valid MBR Found)

With no valid MBR or bootable device found, systems with a very old IBM BIOS display the infamous ROM BASIC interpreter, which looks like this:

```
The IBM Personal Computer Basic
Version C1.10 Copyright IBM Corp 1981
62940 Bytes free
Ok
```

IBM ROM BASIC

The ROMs of most PCs are similar to the original IBM systems with which they are compatible—with the exception of the ROM BASIC interpreter (also called Cassette BASIC). It might come as a surprise to some PC users, but the original IBM PC actually had a jack on the rear of the system for connecting a cassette tape recorder. This was to be used for loading programs and data to or from a cassette tape. IBM included the cassette port because cassette tapes were used by several early personal computers (including the Apple) because floppy drives were very expensive and hard disks were not even an option yet. However, floppy drives came down in price quickly right at the time the PC was first released, and the cassette port never appeared on any subsequent IBM systems. The cassette port also never appeared on any PC-compatible systems because floppy drives were cheap by the time they came out.

The reason for having BASIC in ROM was so the original PC could come standard with only 16KB of memory and no floppy drives in the base configuration. Many computer users at the time either wrote their own programs in the BASIC language or ran BASIC programs written by others. The BASIC language interpreter built in to the ROM BIOS of these early IBM systems was designed to access the cassette port on the back of the system, and by having the interpreter in ROM, all the 16KB of RAM could be used to store a program.

Even after the cassette port was eliminated, IBM left the BASIC code in the motherboard ROM until the early 1990s! I liken this to our having an appendix. The ROM BASIC in those IBM systems is sort of like a vestigial organ—a leftover that had some use in prehistoric evolutionary ancestors but has no function today.

You can catch a glimpse of this ROM BASIC on older IBM systems that have it by disabling all the disk drives in the system. In that case, with nothing to boot from, those systems unceremoniously dump you into the strange (vintage 1981) ROM BASIC screen.

People used to dread seeing this because it usually meant that the floppy disk or hard disk they were trying to boot from had become corrupted or had failed. Because no compatible systems ever had the BASIC interpreter in ROM, they came up with different messages to display for the same situations in which an IBM system would invoke this BASIC. The most confusing of these was the message from AMI BIOS, which simply said **NO ROM BASIC - SYSTEM HALTED**, which really meant that the system was incapable of booting.

With no valid MBR or bootable device found, systems with a more recent IBM BIOS display a screen using text graphic characters that look similar to Figure 5.12.

Figure 5.12 When the PC can't find the master boot record on a modern IBM BIOS, you are confronted with this graphic.

The meaning here is, "Insert a bootable floppy disk into the A: drive and press the F1 key."

With no valid MBR or bootable device found, systems with an AMI BIOS display the following message:

```
NO ROM BASIC - SYSTEM HALTED
```

This message is confusing to some because it seems to point to a problem with ROM BASIC, which of course is not what it really means! The AMI ROM does not include a BASIC interpreter in the ROM (neither do any other ROMs except those found in very old IBM machines), so instead of jumping into BASIC or displaying a useful message indicating there are no bootable devices, it displays this confusing message. The real meaning is the same as for all these messages, which is to say that none of the bootable devices in the boot sequence were found to contain signature bytes indicating a valid MBR in their first physical sectors.

With no valid MBR or bootable device found, systems with a Compaq BIOS display the following message:

```
Non-System disk or disk error
replace and strike any key when ready
```

This is another confusing message because this very same (or similar) error message is contained in the DOS/Windows 9X/Me VBR and normally is displayed if the system files are missing or corrupted. So, if you see this message on a Compaq system, you can't be sure whether the problem is in the MBR, VBR, or the system files, which makes tracking down and solving the problem more difficult.

With no valid MBR or bootable device found, systems with an Award BIOS display the following message:

```
DISK BOOT FAILURE, INSERT SYSTEM DISK AND PRESS ENTER
```

So far, that appears to be the least confusing of these messages. You don't need a secret decoder ring to figure out what it is really trying to say.

With no valid MBR or bootable device found, systems with a Phoenix BIOS display either this message:

```
No boot device available -
strike F1 to retry boot, F2 for setup utility
```

or this one:

```
No boot sector on fixed disk -
strike F1 to retry boot, F2 for setup utility
```

Which of these two messages you see depends on whether no boot devices were found or readable, or a boot sector could be read but was found not to have the proper signature bytes.

Although the message displayed varies from BIOS to BIOS, the causes are the same for all of them. Several things can cause these messages to be displayed, and many of them relate to the MBR.

The primary causes are disks that are new (have never been partitioned) or that have had the MBR corrupted.

The MBR, including the signature bytes, is written to the hard disk by the FDISK, DISKPART, or Disk Management program. When a drive is new or freshly low-level formatted, all the sectors are initialized with a default pattern of bytes. At that point, the first sector contains a test pattern or all 0s and the last two bytes of the sector do not contain the 55AAh signature. In other words, these ROM error messages are exactly what you see if you attempt to boot from a new hard disk or one that has been low-level formatted but not yet partitioned.

Now consider another situation that can cause these messages. If the signature bytes are correct, the BIOS executes the MBR code, which performs a test of the Boot Indicator bytes in each of the four partition table entries. These bytes are at offset 446 (1BEh), 462 (1CEh), 478 (1DEh), and 494 (1EEh), respectively. They are used to indicate which of the four possible primary partition table entries contains an active (bootable) partition. A value of 80h at any of these byte offsets indicates that the particular table contains the active partition, whereas all other values must be 00h. If more than one of these bytes is 80h (indicating multiple active partitions), or any of the byte values is anything other than 80h or 00h, you see the following error message:

Invalid partition table

If all these four boot indicator bytes are 00h—which indicates that no active (bootable) partitions exist—then the MBR returns control to the motherboard ROM. Also, if no other bootable devices exist, interrupt 18h is called and displays the same error messages as listed earlier.

- ▶▶ See “Master Boot Record,” p. 1355.

This is exactly what occurs if you were to remove the existing partitions from a drive but had not created new partitions on the drive, or if you had failed to make one of the partitions Active (bootable) during partitioning before rebooting your system.

- ▶▶ For more information on repairing or restoring the master boot sector (MBR), see Chapter 25, “File Systems and Data Recovery,” p. 1353.

Another cause for these errors can occur with hard disks that are 8.4GB in size or less, which run in CHS mode. The problem is caused by tampering with the translation mode in the system BIOS for drives less than 8.4GB in size. Translation is used by drives between 528MB and 8.4GB, which alters the reported CHS geometry of the drive into a format that enables the entire disk (up to 8.4GB) to be used by DOS and Windows. Typically, three settings exist for translation: It can be disabled (often indicated by a setting of normal) or enabled using either CHS or LBA values. Translation using CHS values is often indicated by a setting of large, and translation using LBA values is indicated by a setting of LBA. If a drive is partitioned and formatted with LBA translation and the setting is later changed to CHS (often indicated as large), the bootstrap loader in the BIOS translates drive sector locations differently and might not properly load the MBR or make the proper jump from the MBR to the VBR of the bootable volume. This can cause one of the previously discussed error messages to appear, or it can cause the MBR to display the following message:

Missing operating system

Thus, if you see such errors on a system with a hard drive between 528MB (504MiB) and 8.4GB (7.9GiB), be sure to check the translation settings for the drive. On some of the older AMI BIOS Hi-Flex and WinBIOS (graphical) versions, the translation mode setting is not on the same screen as the hard disk setup but is buried in the Advanced or Built-in Peripherals setup screens where it can be turned off by autoconfiguring BIOS setup options.

CHAPTER 6

Memory

Memory Basics

This chapter discusses memory from both a physical and logical point of view. First, we'll examine what memory is, where it fits into the PC architecture, and how it works. Then we'll look at the various types of memory, speeds, and packaging of the chips and memory modules you can buy and install.

This chapter also covers the logical layout of memory, defining the various areas and their uses from the system's point of view. Because the logical layout and uses are within the "mind" of the processor, memory mapping and logical layout remain perhaps the most difficult subjects to grasp in the PC universe. This chapter contains useful information that removes the mysteries associated with memory and enables you to get the most out of your system.

Memory is the workspace for the computer's processor. It is a temporary storage area where the programs and data being operated on by the processor must reside. Memory storage is considered temporary because the data and programs remain there only as long as the computer has electrical power or is not reset. Before being shut down or reset, any data that has been changed should be saved to a more permanent storage device (usually a hard disk) so it can be reloaded into memory in the future.

Memory often is called *RAM*, for *random access memory*. Main memory is called RAM because you can randomly (as opposed to sequentially) access any location in memory. This designation is somewhat misleading and often misinterpreted. Read-only memory (ROM), for example, is also randomly accessible, yet is usually differentiated from the system RAM because it maintains data without power and can't normally be written to. Disk memory is also randomly accessible, but we don't consider that RAM either.

Over the years, the definition of RAM has changed from a simple acronym to become something that means the primary memory workspace the processor uses to run programs, which usually is constructed of a type of chip called dynamic RAM (DRAM). One of the characteristics of DRAM chips (and therefore RAM in general) is that they store data dynamically, which really has two meanings. One meaning is that the information can be written to RAM repeatedly at any time. The other has to do with the fact that DRAM requires the data to be refreshed (essentially rewritten) every 15ms (milliseconds) or so. A type of RAM called static RAM (SRAM) does not require the periodic refreshing. An important characteristic of RAM in general is that data is stored only as long as the memory has electrical power.

When we talk about a computer's memory, we usually mean the RAM or physical memory in the system, which is mainly the memory chips or modules the processor uses to store primary active programs and data. This often is confused with the term *storage*, which should be used when referring to things such as disk and tape drives (although they can be used as a form of RAM called virtual memory).

RAM can refer to both the physical chips that make up the memory in the system and the logical mapping and layout of that memory. *Logical mapping* and *layout* refer to how the memory addresses are mapped to actual chips and what address locations contain which types of system information.

People new to computers often confuse main memory (RAM) with disk storage because both have capacities that are expressed in similar megabyte or gigabyte terms. The best analogy to explain the relationship between memory and disk storage I've found is to think of an office with a desk and a file cabinet.

In this popular analogy, the file cabinet represents the system's hard disk, where both programs and data are stored for long-term safekeeping. The desk represents the system's main memory, which allows the person working at the desk (acting as the processor) direct access to any files placed on it. Files represent the programs and documents you can "load" into the memory. To work on a particular file, it must first be retrieved from the cabinet and placed on the desk. If the desk is large enough, you might be able to have several files open on it at one time; likewise, if your system has more memory, you can run more or larger programs and work on more or larger documents.

Adding hard disk space to a system is similar to putting a bigger file cabinet in the office—more files can be permanently stored. And adding more memory to a system is like getting a bigger desk—you can work on more programs and data at the same time.

One difference between this analogy and the way things really work in a computer is that when a file is loaded into memory, it is a copy of the file that is actually loaded; the original still resides on the hard disk. Because of the temporary nature of memory, any files that have been changed after being loaded into memory must then be saved back to the hard disk before the system is powered off (which erases the memory). If the changed file in memory is not saved, the original copy of the file on the hard disk remains unaltered. This is like saying that any changes made to files left on the desktop are discarded when the office is closed, although the original files are still preserved in the cabinet.

Memory temporarily stores programs when they are running, along with the data being used by those programs. RAM chips are sometimes termed *volatile storage* because when you turn off your computer or an electrical outage occurs, whatever is stored in RAM is lost unless you saved it to your hard drive. Because of the volatile nature of RAM, many computer users make it a habit to save their work frequently. (Some software applications can do timed backups automatically.)

Launching a computer program brings files into RAM, and as long as they are running, computer programs reside in RAM. The CPU executes programmed instructions in RAM and also stores results in RAM. RAM stores your keystrokes when you use a word processor and also stores numbers used in calculations. Telling a program to save your data instructs the program to store RAM contents on your hard drive as a file.

Physically, the *main memory* in a system is a collection of chips or modules containing chips that are usually plugged into the motherboard. These chips or modules vary in their electrical and physical designs and must be compatible with the system into which they are being installed to function properly. This chapter discusses the various types of chips and modules that can be installed in different systems.

Next to the processor and motherboard, memory can be one of the more expensive components in a modern PC, although the total amount spent on memory for a typical system has declined over the past few years. Before the big memory price crash in mid-1996, memory had maintained a fairly consistent price for many years of about \$40 per megabyte. A typical configuration back then of 16MB cost more than \$600. In fact, memory was so expensive at that time that it was worth more than its weight in gold. These high prices caught the attention of criminals and memory module manufacturers were robbed at gunpoint in several large heists. These robberies were partially induced by the fact that memory was so valuable, the demand was high, and stolen chips or modules were virtually impossible to trace. After the rash of armed robberies and other thefts, memory module manufacturers began posting armed guards and implementing beefed-up security procedures.

By the end of 1996, memory prices had cooled considerably to about \$4 per megabyte—a tenfold price drop in less than a year. Prices continued to fall after the major crash until they were at or below 50 cents per megabyte in 1997. All seemed well, until events in 1998 conspired to create a spike in memory prices, increasing them by four times their previous levels. The main culprit was Intel, who had driven the industry to support a then-new type of memory called Rambus DRAM (RDRAM) and then failed to deliver the supporting chipsets on time. The industry was caught in a bind by shifting production to a type of memory for which there were no chipsets or motherboards to plug into, which then created a shortage of the existing (and popular) SDRAM memory. An earthquake in Taiwan during that year served as the icing on the cake, disrupting production and furthering the spike in prices.

Since then, things have cooled considerably, and memory prices have dropped to all-time lows, with actual prices of under 20 cents per megabyte. In particular, 2001 was a disastrous year in the semiconductor industry, prompted by the dot-com crash as well as worldwide events, and sales dropped well below that of previous years. This conspired to bring memory prices down further than they had ever been and even forced some companies to merge or go out of business.

Memory is less expensive now than ever, but its useful life has become much shorter. New types of memory are being adopted more quickly than before, and any new systems you purchase now most likely will not accept the same memory as your existing ones. In an upgrade or a repair situation, that means you often have to change the memory if you change the motherboard. The chance that you can reuse the memory in an existing motherboard when upgrading to a new one is slim.

Because of this, you should understand all the various types of memory on the market today, so you can best determine which types are required by which systems, and thus more easily plan for future upgrades and repairs.

To better understand physical memory in a system, you should see where and how it fits into the system. Three main types of physical memory are used in modern PCs:

- *ROM*. Read-only memory
- *DRAM*. Dynamic random access memory
- *SRAM*. Static RAM

ROM

Read-only memory, or ROM, is a type of memory that can permanently or semipermanently store data. It is called read-only because it is either impossible or difficult to write to. ROM also is often referred to as *nonvolatile memory* because any data stored in ROM remains there, even if the power is turned off. As such, ROM is an ideal place to put the PC's startup instructions—that is, the software that boots the system.

Note that ROM and RAM are not opposites, as some people seem to believe. Both are simply types of memory. In fact, ROM could be classified as technically a subset of the system's RAM. In other words, a portion of the system's random access memory address space is mapped into one or more ROM chips. This is necessary to contain the software that enables the PC to boot up; otherwise, the processor would have no program in memory to execute when it was powered on.

◀◀ For more information on ROM, see "Motherboard BIOS," p. 402.

The main ROM BIOS is contained in a ROM chip on the motherboard, but there are also adapter cards with ROMs on them as well. ROMs on adapter cards contain auxiliary BIOS routines and drivers needed by the particular card, especially for those cards that must be active early in the boot process, such as video cards. Cards that don't need drivers active at boot time typically don't have a ROM because those drivers can be loaded from the hard disk later in the boot process.

Most systems today use a type of ROM called electrically erasable programmable ROM (EEPROM), which is a form of Flash memory. Flash is a truly nonvolatile memory that is rewritable, enabling users to easily update the ROM or firmware in their motherboards or any other components (video cards, SCSI cards, peripherals, and so on).

DRAM

Dynamic RAM (DRAM) is the type of memory chip used for most of the main memory in a modern PC. The main advantages of DRAM are that it is very dense, meaning you can pack a lot of bits into a very small chip, and it is inexpensive, which makes purchasing large amounts of memory affordable.

The memory cells in a DRAM chip are tiny capacitors that retain a charge to indicate a bit. The problem with DRAM is that it is dynamic. Also, because of the design, it must be constantly refreshed; otherwise, the electrical charges in the individual memory capacitors will drain and the data will be lost. Refresh occurs when the system memory controller takes a tiny break and accesses all the rows of data in the memory chips. Most systems have a memory controller (normally built into the North Bridge portion of the motherboard chipset), which is set for an industry-standard refresh rate of 15ms (milliseconds). This means that every 15ms, all the rows in the memory are automatically read to refresh the data.

◀◀ See "Chipsets," p. 239.

Refreshing the memory unfortunately takes processor time away from other tasks because each refresh cycle takes several CPU cycles to complete. In older systems, the refresh cycling could take up to 10% or more of the total CPU time, but with modern systems running in the multi-gigahertz range, refresh

overhead is now on the order of a fraction of a percent or less of the total CPU time. Some systems allow you to alter the refresh timing parameters via the CMOS Setup, but be aware that increasing the time between refresh cycles to speed up your system can allow some of the memory cells to begin draining, which can cause random soft memory errors to appear. A *soft error* is a data error that is not caused by a defective chip. It is usually safer to stick with the recommended or default refresh timing. Because refresh consumes less than 1% of modern system overall bandwidth, altering the refresh rate has little effect on performance. It is almost always best to use default or automatic settings for any memory timings in the BIOS Setup. Many modern systems don't allow changes to memory timings and are permanently set to automatic settings. On an automatic setting, the motherboard reads the timing parameters out of the serial presence detect (SPD) ROM found on the memory module and sets the cycling speeds to match.

DRAMs use only one transistor and capacitor pair per bit, which makes them very dense, offering more memory capacity per chip than other types of memory. Currently, DRAM chips are available with densities of up to 1Gb or more. This means that DRAM chips are available with one billion or more transistors! Compare this to a Pentium 4, which has 55 million transistors, and it makes the processor look wimpy by comparison. The difference is that in a memory chip, the transistors and capacitors are all consistently arranged in a (normally square) grid of simple repetitive structures, unlike the processor, which is a much more complex circuit of different structures and elements interconnected in a highly irregular fashion.

The transistor for each DRAM bit cell reads the charge state of the adjacent capacitor. If the capacitor is charged, the cell is read to contain a 1; no charge indicates a 0. The charge in the tiny capacitors is constantly draining, which is why the memory must be refreshed constantly. Even a momentary power interruption, or anything that interferes with the refresh cycles, can cause a DRAM memory cell to lose the charge and therefore the data. If this happens in a running system, it can lead to blue screens, global protection faults, corrupted files, and any number of system crashes.

DRAM is used in PC systems because it is inexpensive and the chips can be densely packed, so a lot of memory capacity can fit in a small space. Unfortunately, DRAM is also slow, typically much slower than the processor. For this reason, many types of DRAM architectures have been developed to improve performance. These architectures are covered later in the chapter.

Cache Memory: SRAM

Another distinctly different type of memory exists that is significantly faster than most types of DRAM. SRAM stands for static RAM, which is so named because it does not need the periodic refresh rates like DRAM. Because of how SRAMs are designed, not only are refresh rates unnecessary, but SRAM is much faster than DRAM and much more capable of keeping pace with modern processors.

SRAM memory is available in access times of 2ns or less, so it can keep pace with processors running 500MHz or faster. This is because of the SRAM design, which calls for a cluster of six transistors for each bit of storage. The use of transistors but no capacitors means that refresh rates are not necessary because there are no capacitors to lose their charges over time. As long as there is power, SRAM remembers what is stored. With these attributes, why don't we use SRAM for all system memory? The answers are simple.

Compared to DRAM, SRAM is much faster but also much lower in density and much more expensive (see Table 6.1). The lower density means that SRAM chips are physically larger and store fewer bits overall. The high number of transistors and the clustered design mean that SRAM chips are both physically larger and much more expensive to produce than DRAM chips. For example, a DRAM module might contain 64MB of RAM or more, whereas SRAM modules of the same approximate physical size would have room for only 2MB or so of data and would cost the same as the 64MB DRAM module. Basically, SRAM is up to 30 times larger physically and up to 30 times more expensive than DRAM. The high cost and physical constraints have prevented SRAM from being used as the main memory for PC systems.

Table 6.1 Comparing DRAM and SRAM

Type	Speed	Density	Cost
DRAM	Slow	High	Low
SRAM	Fast	Low	High

Even though SRAM is too expensive for PC use as main memory, PC designers have found a way to use SRAM to dramatically improve PC performance. Rather than spend the money for all RAM to be SRAM memory, which can run fast enough to match the CPU, designing in a small amount of high-speed SRAM memory, called cache memory, is much more cost-effective. The cache runs at speeds close to or even equal to the processor and is the memory from which the processor usually directly reads from and writes to. During read operations, the data in the high-speed cache memory is resupplied from the lower-speed main memory or DRAM in advance. Up until recently, DRAM was limited to about 60ns (16MHz) in speed. To convert access time in nanoseconds to MHz, use the following formula:

$$1 / \text{nanoseconds} \times 1000 = \text{MHz}$$

Likewise, to convert from MHz to nanoseconds, use the following inverse formula:

$$1 / \text{MHz} \times 1000 = \text{nanoseconds}$$

When PC systems were running 16MHz and less, the DRAM could fully keep pace with the motherboard and system processor and there was no need for cache. However, as soon as processors crossed the 16MHz barrier, DRAM could no longer keep pace, and that is exactly when SRAM began to enter PC system designs. This occurred back in 1986 and 1987 with the debut of systems with the 386 processor running at speeds of 16MHz and 20MHz or faster. These were among the first PC systems to employ what's called *cache memory*, a high-speed buffer made up of SRAM that directly feeds the processor. Because the cache can run at the speed of the processor, the system is designed so that the cache controller anticipates the processor's memory needs and preloads the high-speed cache memory with that data. Then, as the processor calls for a memory address, the data can be retrieved from the high-speed cache rather than the much lower-speed main memory.

Cache effectiveness is expressed as a hit ratio. This is the ratio of cache hits to total memory accesses. A *hit* occurs when the data the processor needs has been preloaded into the cache from the main memory, meaning the processor can read it from the cache. A *cache miss* is when the cache controller did not anticipate the need for a specific address and the desired data was not preloaded into the cache. In that case the processor must retrieve the data from the slower main memory, instead of the faster cache. Anytime the processor reads data from main memory, the processor must wait longer because the main memory cycles at a much slower rate than the processor. If the processor with integral on-die cache is running at 3400MHz (3.4GHz), both the processor and the integral cache would be cycling at 0.29ns, while the main memory would most likely be cycling 8.5 times more slowly at 2.5ns (200MHz DDR). Therefore, the memory would be running at only a 400MHz equivalent rate. So, every time the 3.4GHz processor reads from main memory, it would effectively slow down 8.5-fold to only 400MHz! The slowdown is accomplished by having the processor execute what are called *wait states*, which are cycles in which nothing is done; the processor essentially cools its heels while waiting for the slower main memory to return the desired data. Obviously, you don't want your processors slowing down, so cache function and design become more important as system speeds increase.

To minimize the processor being forced to read data from the slow main memory, two or three stages of cache usually exist in a modern system, called Level 1 (L1), Level 2 (L2), and Level 3 (L3). The L1 cache is also called *integral* or *internal cache* because it has always been built directly into the processor as part of the processor die (the raw chip). Because of this, L1 cache always runs at the full speed of the processor core and is the fastest cache in any system. All 486 and higher processors incorporate integral L1 cache, making them significantly faster than their predecessors. L2 cache was originally called *external cache* because it was external to the processor chip when it first appeared. Originally, this meant it was

installed on the motherboard, as was the case with all 386, 486, and Pentium systems. In those systems, the L2 cache runs at motherboard and CPU bus speed because it is installed on the motherboard and is connected to the CPU bus. You typically find the L2 cache directly next to the processor socket in Pentium and earlier systems.

◀◀ See “How Cache Works,” p. 68.

In the interest of improved performance, later processor designs from Intel and AMD included the L2 cache as a part of the processor. In all processors since late 1999 (and some earlier models), the L2 cache is directly incorporated as a part of the processor die just like the L1 cache. In chips with on-die L2, the cache runs at the full core speed of the processor and is much more efficient. By contrast, most processors from 1999 and earlier with integrated L2 had the L2 cache in separate chips that were external to the main processor core. The L2 cache in many of these older processors ran at only half or one-third the processor core speed. Cache speed is very important, so systems having L2 cache on the motherboard were the slowest. Including L2 inside the processor made it faster, and including it directly on the processor die (rather than as chips external to the die) is the fastest yet. Any chip that has on-die full core speed L2 cache has a distinct performance advantage over any chip that doesn't.

Processors with built-in L2 cache, whether it's on-die or not, still run the cache more quickly than any found on the motherboard. Thus, most motherboards designed for processors with built-in cache don't have any cache on the board; all the cache is contained in the processor module instead.

L3 cache has been present in high-end workstation and server processors such as the Xeon and Itanium families since 2001. The first desktop PC processor with L3 cache was the Pentium 4 Extreme Edition, a high-end chip introduced in late 2003 with 2MB of on-die L3 cache. In the future you can expect L3 cache to become more commonplace in mainstream processors because more levels of cache help mitigate the speed differential between the fast processor core and the relatively slow motherboard and main memory.

The key to understanding both cache and main memory is to see where they fit in the overall system architecture.

See Chapter 4, “Motherboards and Buses,” for diagrams showing recent systems with different types of cache memory. Table 6.2 illustrates the need for and function of cache memory in modern systems.

Cache designs originally were *asynchronous*, meaning they ran at a clock speed that was not identical or in sync with the processor bus. Starting with the 430FX chipset released in early 1995, a new type of synchronous cache design was supported. It required that the chips now run in sync or at the same identical clock timing as the processor bus, further improving speed and performance. Also added at that time was a feature called *pipeline burst mode*, which reduces overall cache latency (wait states) by allowing single-cycle accesses for multiple transfers after the first one. Because both synchronous and pipeline burst capability came at the same time in new modules, specifying one usually implies the other. Synchronous pipeline burst cache allowed for about a 20% improvement in overall system performance, which was a significant jump.

The cache controller for a modern system is contained in either the North Bridge of the chipset, as with Pentium and lesser systems, or within the processor, as with the Pentium Pro/II and newer systems. The capabilities of the cache controller dictate the cache's performance and capabilities. One important thing to note is that most external cache controllers have a limitation on the amount of memory that can be cached. Often, this limit can be quite low, as with the 430TX chipset-based Pentium systems. Most original Pentium class chipsets such as the 430FX/VX/TX can cache data only within the first 64MB of system RAM. If you add more memory than that, you will see a noticeable slowdown in system performance because all data outside the first 64MB is never cached and is always accessed with all the wait states required by the slower DRAM. Depending on what software you use and where data is stored in memory, this can be significant. For example, 32-bit operating systems such as Windows load from the top down, so if you had 96MB of RAM, the operating system and applications would load directly into the upper 32MB (past 64MB), which is not cached. This results in a dramatic slowdown in overall system use. Removing the additional memory to bring the system total down to the cacheable limit of 64MB is the solution. In short, it is unwise to install more main RAM memory than your system (CPU or chipset) can cache.

Table 6.2 The Relationship Between L1 (Internal) Cache, L2 (External) Cache, and Main Memory in Modern Systems

CPU Type	Pentium	Pentium Pro	Pentium II	AMD K6-2	AMD K6-3	Duron
CPU speed	233MHz	200MHz	450MHz	550MHz	450MHz	1.3GHz
L1 cache speed	4.3ns (233MHz)	5.0ns (200MHz)	2.2ns (450MHz)	1.8ns (550MHz)	2.2ns (450MHz)	0.77ns (1.3GHz)
L1 cache size	16K	32K	32K	64K	64K	128K
L2 cache type	onboard	on-chip	on-chip	onboard	on-die	on-die
CPU/L2 speed ratio	—	1/1	1/2	—	1/1	1/1
L2 cache speed	15ns (66MHz)	5ns (200MHz)	4.4ns (225MHz)	10ns (100MHz)	2.2ns (450MHz)	0.77ns (1.3GHz)
L2 cache size	varies ¹	256K ²	512K	varies ¹	256K	64K
CPU bus speed	66MHz	66MHz	100MHz	100MHz	100MHz	200MHz
Memory bus speed	60ns (16MHz)	60ns (16MHz)	10ns (100MHz)	10ns (100MHz)	10ns (100MHz)	5ns (200MHz)

1. The L2 cache is on the motherboard, and the amount depends on which board is chosen and how much is installed.
2. The Pentium Pro also was available with 512KB and 1024KB L2 cache.

Chipsets made for the Pentium Pro/II and later processors did not control the L2 cache because it was moved into the processor instead. So, with the Pentium Pro/II and beyond, the processor sets the cacheability limits. The Pentium Pro and some of the earlier Pentium IIs can address up to 64GB but only cache up to 512MB. The later Pentium IIs and all Pentium III and Pentium 4 processors can cache up to 4GB. Most desktop chipsets for those processors allow only up to 1GB, 2GB, or 4GB of RAM anyway, making cacheability limits moot. All the server-oriented Xeon processors can cache up to 64GB. This is beyond the maximum RAM support of any of the chipsets.

In any case, it is important not to install more memory than the cache controller can support. If you want to know the cacheability limit for your system, consult the chipset documentation if you have a Pentium class or older system (or any system with cache on the motherboard), or check the processor documentation if you have a Pentium II class or newer system (or any system with all the cache integrated into the CPU).

RAM Types

The speed and performance issue with memory is confusing to some because memory speed is usually expressed in ns (nanoseconds) and processor speed has always been expressed in MHz (megahertz). Recently, however, some newer and faster types of memory have speeds expressed in MHz, adding to the confusion. Fortunately, you can translate one to the other.

A *nanosecond* is defined as one billionth of a second—a very short time indeed. To put some perspective on that, the speed of light is 186,282 miles (299,792 kilometers) per second in a vacuum. In one billionth of a second, a beam of light travels a mere 11.80 inches or 29.98 centimeters—less than the length of a typical ruler!

Chip and system speed has been expressed in megahertz (MHz), which is millions of cycles per second, or gigahertz (GHz), which is billions of cycles per second. During 2005, systems will exceed 5GHz or 5 billion cycles per second.

Because it is confusing to speak in these different terms for speeds, I thought it would be interesting to see how they compare. Earlier in this chapter I listed formulas you could use to mathematically convert these values. Table 6.3 shows the relationship between common nanosecond (ns) and megahertz (MHz) speeds associated with PCs from yesterday to today and tomorrow.

Athlon	Athlon XP	Pentium III	Celeron/370	Celeron/478	Pentium 4
1.4GHz	2.2GHz	1.4GHz	1.4GHz	2.4GHz	3.6GHz
0.71ns (1.4GHz)	0.45ns (2.2GHz)	0.71ns (1.4GHz)	0.71ns (1.4GHz)	0.42ns (2.4GHz)	0.28ns (3.6GHz)
128K	128K	32K	32K	20K	20K
on-die	on-die	on-die	on-die	on-die	on-die
1/1	1/1	1/1	1/1	1/1	1/1
0.71ns (1.4GHz)	0.45ns (2.2GHz)	0.71ns (1.4GHz)	0.71ns (1.4GHz)	0.42ns (2.4GHz)	0.28ns (3.6GHz)
256K	512K	512K	256K	128K	1M
266MHz	400MHz	133MHz	100MHz	400MHz	800MHz
3.8ns (266MHz)	2.5ns (400MHz)	7.5ns (133MHz)	10ns (100MHz)	2.5ns (400MHz)	1.25ns (800MHz)

Table 6.3 The Relationship Between Megahertz (MHz) and Cycle Times in Nanoseconds (ns)

Clock Speed	Cycle Time	Clock Speed	Cycle Time	Clock Speed	Cycle Time	Clock Speed	Cycle Time
4.77MHz	210ns	250MHz	4.0ns	850MHz	1.18ns	2,700MHz	0.37ns
6MHz	167ns	266MHz	3.8ns	866MHz	1.15ns	2,800MHz	0.36ns
8MHz	125ns	300MHz	3.3ns	900MHz	1.11ns	2,900MHz	0.34ns
10MHz	100ns	333MHz	3.0ns	933MHz	1.07ns	3,000MHz	0.333ns
12MHz	83ns	350MHz	2.9ns	950MHz	1.05ns	3,100MHz	0.323ns
16MHz	63ns	366MHz	2.7ns	966MHz	1.04ns	3,200MHz	0.313ns
20MHz	50ns	400MHz	2.5ns	1,000MHz	1.00ns	3,300MHz	0.303ns

33MHz	30ns	450MHz	2.2ns	1,133MHz	0.88ns	3,500MHz	0.286ns
40MHz	25ns	466MHz	2.1ns	1,200MHz	0.83ns	3,600MHz	0.278ns
50MHz	20ns	500MHz	2.0ns	1,300MHz	0.77ns	3,700MHz	0.270ns
60MHz	17ns	533MHz	1.88ns	1,400MHz	0.71ns	3,800MHz	0.263ns
66MHz	15ns	550MHz	1.82ns	1,500MHz	0.67ns	3,900MHz	0.256ns
75MHz	13ns	566MHz	1.77ns	1,600MHz	0.63ns	4,000MHz	0.250ns
80MHz	13ns	600MHz	1.67ns	1,700MHz	0.59ns	4,100MHz	0.244ns
100MHz	10ns	633MHz	1.58ns	1,800MHz	0.56ns	4,200MHz	0.238ns
120MHz	8.3ns	650MHz	1.54ns	1,900MHz	0.53ns	4,300MHz	0.233ns
133MHz	7.5ns	666MHz	1.50ns	2,000MHz	0.50ns	4,400MHz	0.227ns
150MHz	6.7ns	700MHz	1.43ns	2,100MHz	0.48ns	4,500MHz	0.222ns
166MHz	6.0ns	733MHz	1.36ns	2,200MHz	0.45ns	4,600MHz	0.217ns
180MHz	5.6ns	750MHz	1.33ns	2,300MHz	0.43ns	4,700MHz	0.213ns
200MHz	5.0ns	766MHz	1.31ns	2,400MHz	0.42ns	4,800MHz	0.208ns
225MHz	4.4ns	800MHz	1.25ns	2,500MHz	0.40ns	4,900MHz	0.204ns
233MHz	4.3ns	833MHz	1.20ns	2,600MHz	0.38ns	5,000MHz	0.200ns

As you can see from Table 6.3, as clock speeds increase, cycle time decreases proportionately.

If you examine Table 6.3, you can clearly see that the 60ns DRAM memory used in the original Pentium and Pentium II PCs up until 1998 works out to be 16.7MHz! This super-slow 16MHz memory had been installed in systems running up to 300MHz or faster, and you can see that a large mismatch existed between processor and main memory performance. The dominant standard in 2000 was to have 100MHz and even 133MHz memory, called PC100 and PC133, respectively. Starting in early 2001, double data rate (DDR) memory of 200MHz and 266MHz become popular, along with 800MHz RDRAM. In 2002 standard 333MHz DDR memory arrived, and in 2003, the speeds increased to 400MHz. During 2004, we saw the introduction of DDR2 first at 400MHz and then at 533MHz.

System memory timing is a little more involved than simply converting nanoseconds to megahertz. The transistors for each bit in a memory chip are most efficiently arranged in a grid, using a row and column scheme to access each transistor. All memory accesses involve selecting a row address and then a column address and then transferring the data. The initial setup for a memory transfer where the row and column addresses are selected is a necessary overhead referred to as *latency*. The access time for memory is the cycle time plus latency for selecting the row and column addresses. For example, SDRAM memory rated at 133MHz (7.5ns) typically takes five cycles to set up and complete the first transfer ($5 \times 7.5\text{ns} = 37.5\text{ns}$) and then perform three additional transfers with no additional setup. Thus, four transfers take a total of eight cycles, or an average of about two cycles per transfer.

Over the development life of the PC, memory has had a difficult time keeping up with the processor, requiring several levels of high-speed cache memory to intercept processor requests for the slower main memory. Table 6.4 shows the progress and relationship between system board (motherboard) speeds in PCs and the various types and speeds of main memory or RAM used and how these changes have affected total bandwidth. Many of the faster specifications listed in this table are only proposed future standards and not yet officially released.

Table 6.4 DRAM Memory Module and Bus Standards/Bandwidth (Past, Current, and Future)

Module Standard	Module Format	Chip Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Transfer Rate (MBps)
FPM	SIMM	60ns	22	1	22	8	177
EDO	SIMM	60ns	33	1	33	8	266
PC66	SDR DIMM	10ns	66	1	66	8	533
PC100	SDR DIMM	8ns	100	1	100	8	800
PC133	SDR DIMM	7/7.5ns	133	1	133	8	1,066
PC1600	DDR DIMM	DDR200	100	2	200	8	1,600
PC2100	DDR DIMM	DDR266	133	2	266	8	2,133
PC2400	DDR DIMM	DDR300	150	2	300	8	2,400
PC2700	DDR DIMM	DDR333	166	2	333	8	2,667
PC3000	DDR DIMM	DDR366	183	2	366	8	2,933
PC3200	DDR DIMM	DDR400	200	2	400	8	3,200

PC2-4300	DDR2 DIMM	DDR2-533	266	2	533	8	4,266

Table 6.4 Continued

Module Standard	Module Format	Chip Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Transfer Rate (MBps)
PC2-5400	DDR2 DIMM	DDR2-667	333	2	667	8	5,333
PC2-6400	DDR2 DIMM	DDR2-800	400	2	800	8	6,400
RIMM1200	RIMM-16	PC600	300	2	600	2	1,200
RIMM1400	RIMM-16	PC700	350	2	700	2	1,400
RIMM1600	RIMM-16	PC800	400	2	800	2	1,600
RIMM2100	RIMM-16	PC1066	533	2	1,066	2	2,133
RIMM2400	RIMM-16	PC1200	600	2	1,200	2	2,400
RIMM3200	RIMM-32	PC800	400	2	800	4	3,200
RIMM4200	RIMM-32	PC1066	533	2	1,066	4	4,266
RIMM4800	RIMM-32	PC1200	600	2	1,200	4	4,800

MT/s = Megatransfers per second

MBps = Megabytes per second

ns = Nanoseconds (billionths of a second)

FPM = Fast Page Mode

EDO = Extended data out

SIMM = Single inline memory module

DIMM = Dual inline memory module

RIMM = Rambus inline memory module

SDR = Single data rate

DDR = Double data rate

Generally, things work best when the throughput of the memory bus matches the throughput of the processor bus. Compare the memory bus transfer speeds (bandwidth) to the speeds of the processor bus as shown in Table 6.5, and you'll see that some of the memory bus rates match that of some of the processor bus rates. In most cases the type of memory that matches the CPU bus transfer rate is the best type of memory for systems with that type of processor.

Table 6.5 Processor Bus Bandwidth

CPU Bus Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Bandwidth (MBps)
33MHz 486 FSB	33	1	33	4	133
66MHz Pentium I/II/III FSB	66	1	66	8	533
100MHz Pentium I/II/III FSB	100	1	100	8	800
133MHz Pentium I/II/III FSB	133	1	133	8	1,066
200MHz Athlon FSB	100	2	200	8	1,600
266MHz Athlon FSB	133	2	266	8	2,133
333MHz Athlon FSB	166	2	333	8	2,667
400MHz Athlon FSB	200	2	400	8	3,200
400MHz Pentium 4 FSB	100	4	400	8	3,200
533MHz Pentium 4 FSB	133	4	533	8	4,266
800MHz Pentium 4 FSB	200	4	800	8	6,400

FSB = Front side bus

MBps = Megabytes per second

MT/s = Megatransfers per second

Because the processor is fairly well insulated from directly dealing with main memory by the L1 and L2 cache, memory performance has often lagged behind the performance of the processor bus. More recently, however, systems using SDRAM, DDR SDRAM, and RDRAM have memory bus performance equaling that of the processor bus. When the speed of the memory bus equals the speed of the processor bus, memory performance is optimum for that system.

Fast Page Mode DRAM

Standard DRAM is accessed through a technique called *paging*. Normal memory access requires that a row and column address be selected, which takes time. Paging enables faster access to all the data within a given row of memory by keeping the row address the same and changing only the column. Memory that uses this technique is called *Page Mode* or *Fast Page Mode* memory. Other variations on Page Mode were called *Static Column* or *Nibble Mode* memory.

Paged memory is a simple scheme for improving memory performance that divides memory into pages ranging from 512 bytes to a few kilobytes long. The paging circuitry then enables memory locations in a page to be accessed with fewer wait states. If the desired memory location is outside the current page, one or more wait states are added while the system selects the new page.

To improve further on memory access speeds, systems have evolved to enable faster access to DRAM. One important change was the implementation of burst mode access in the 486 and later processors. Burst mode cycling takes advantage of the consecutive nature of most memory accesses. After setting up the row and column addresses for a given access, using burst mode, you can then access the next three adjacent addresses with no additional latency or wait states. A burst access usually is limited to four total accesses. To describe this, we often refer to the timing in the number of cycles for each access. A typical burst mode access of standard DRAM is expressed as x - y - y - y ; x is the time for the first access (latency plus cycle time), and y represents the number of cycles required for each consecutive access.

Standard 60ns DRAM normally runs 5-3-3-3 burst mode timing. This means the first access takes a total of five cycles (on a 66MHz system bus, this is about 75ns total or 5×15 ns cycles), and the consecutive cycles take three cycles each (3×15 ns = 45ns). As you can see, the actual system timing is somewhat less than the memory is technically rated for. Without the bursting technique, memory access would be 5-5-5-5 because the full latency is necessary for each memory transfer.

DRAM memory that supports paging and this bursting technique is called Fast Page Mode (FPM) memory. The term comes from the capability of memory accesses to data on the same page to be done with less latency. Most 486 and Pentium systems from 1995 and earlier use FPM memory.

Another technique for speeding up FPM memory was called *interleaving*. In this design, two separate banks of memory are used together, alternating access from one to the other as even and odd bytes. While one is being accessed, the other is being precharged, when the row and column addresses are being selected. Then, by the time the first bank in the pair is finished returning data, the second bank in the pair is finished with the latency part of the cycle and is now ready to return data. While the second bank is returning data, the first bank is being precharged, selecting the row and column address of the next access. This overlapping of accesses in two banks reduces the effect of the latency or precharge cycles and allows for faster overall data retrieval. The only problem is that to use interleaving, you must install identical pairs of banks together, doubling the amount of SIMMs or DIMMs required. This method was popular on 32-bit wide memory systems on 486 processors but fell out of favor on Pentiums because of their 64-bit wide memory widths. To perform interleaving on a Pentium machine, you would need to install memory 128 bits at a time, meaning four 72-pin SIMMs or two DIMMs at a time.

Extended Data Out RAM

In 1995, a newer type of memory called extended data out (EDO) RAM became available for Pentium systems. EDO, a modified form of FPM memory, is sometimes referred to as *Hyper Page mode*. EDO was invented and patented by Micron Technology, although Micron licensed production to many other memory manufacturers.

EDO memory consists of specially manufactured chips that allow a timing overlap between successive accesses. The name *extended data out* refers specifically to the fact that unlike FPM, the data output drivers on the chip are not turned off when the memory controller removes the column address to begin the next cycle. This enables the next cycle to overlap the previous one, saving approximately 10ns per cycle.

The effect of EDO is that cycle times are improved by enabling the memory controller to begin a new column address instruction while it is reading data at the current address. This is almost identical to what was achieved in older systems by interleaving banks of memory, but unlike interleaving, with EDO you didn't need to install two identical banks of memory in the system at a time.

EDO RAM allows for burst mode cycling of 5-2-2-2, compared to the 5-3-3-3 of standard fast page mode memory. To do four memory transfers, then, EDO would require 11 total system cycles, compared to 14 total cycles for FPM. This is a 22% improvement in overall cycling time, but in actual testing, EDO typically increases overall system benchmark speed by about 5%. Even though the overall system improvement might seem small, the important thing about EDO was that it used the same basic DRAM chip design as FPM, meaning that there was practically no additional cost over FPM. In fact, in its heyday, EDO cost less than FPM and yet offered higher performance.

EDO RAM generally comes in 72-pin SIMM form. Figure 6.3 (later in this chapter) shows the physical characteristics of these SIMMs.

To actually use EDO memory, your motherboard chipset must support it. Most motherboard chipsets on the market from 1995 (Intel 430FX) through 1997 (Intel 430TX) offered support for EDO. Because EDO memory chips cost the same to manufacture as standard chips, combined with Intel's support of EDO in all its chipsets, the PC market jumped on the EDO bandwagon full force.

- ◀◀ See "Fifth-Generation (P5 Pentium Class) Chipsets," p. 249, and "Sixth-Generation (P6 Pentium Pro/Pentium II/III Class) Chipsets," p. 254.

EDO RAM was ideal for systems with bus speeds of up to 66MHz, which fit perfectly with the PC market up through 1997. However, since 1998 with the advent of faster system bus speeds (100MHz and above), the market for EDO has rapidly declined as the newer and faster SDRAM architecture has become the standard for new PC system memory.

A variation of EDO is burst EDO (BEDO). *BEDO* is basically EDO memory with special burst features for even speedier data transfers than standard EDO. Unfortunately, the technology was owned by Micron and not a free industry standard, so only one chipset (Intel 440FX Natoma) ever supported it. *BEDO* was therefore quickly overshadowed by industry-standard SDRAM, which was favored among PC system chipset and system designers over proprietary designs. As such, *BEDO* never really saw the light of production, and to my knowledge no systems ever really used it.

SDRAM

SDRAM is short for *synchronous DRAM*, a type of DRAM that runs in synchronization with the memory bus. *SDRAM* delivers information in very high-speed bursts using a high-speed, clocked interface. *SDRAM* removes most of the latency involved in asynchronous DRAM because the signals are already in synchronization with the motherboard clock.

Like EDO RAM, your chipset must support this type of memory for it to be usable in your system. Starting in 1996 with the 430VX and 430TX, most of Intel's chipsets began to support industry-standard *SDRAM*, making it the most popular type of memory for new systems through 2000 and even into 2001.

SDRAM performance is dramatically improved over that of FPM or EDO RAM. Because *SDRAM* is still a type of DRAM, the initial latency is the same, but overall cycle times are much faster than with FPM or EDO. *SDRAM* timing for a burst access would be 5-1-1-1, meaning that four memory reads would complete in only eight system bus cycles, compared to eleven cycles for EDO and fourteen cycles for FPM. This makes *SDRAM* almost 20% faster than EDO.

Besides being capable of working in fewer cycles, SDRAM is also capable of supporting up to 133MHz (7.5ns) system bus cycling. As such, most new PC systems sold from 1998 to 2000 have included SDRAM memory.

SDRAM is sold in DIMM form and is often rated by megahertz speed rather than nanosecond cycling time, which was confusing during the change from FPM and EDO DRAM. Figure 6.4 (later in this chapter) shows the physical characteristics of DIMMs.

To meet the stringent timing demands of its chipsets, Intel created specifications for SDRAM called PC66, PC100, and PC133. To meet the PC100 specification, 8ns chips usually are required. Normally, you would think 10ns would be considered the proper rating for 100MHz operation, but the PC100 specification calls for faster memory to ensure all timing parameters are met.

In May 1999, the Joint Electron Device Engineering Council (JEDEC) created a specification called PC133. They achieved this 33MHz speed increase by taking the PC100 specification and tightening up the timing and capacitance parameters. The faster PC133 quickly caught on as the most popular version of SDRAM for any systems running a 133MHz processor bus. The original chips used in PC133 modules were rated for exactly 7.5ns or 133MHz; later ones were rated at 7.0ns or 143MHz. These faster chips were still used on PC133 modules, but they allowed for improvements in column address strobe latency (abbreviated as CAS or CL), which somewhat improves overall memory cycling time.

Note

JEDEC is the semiconductor engineering standardization body of the Electronic Industries Alliance (EIA), a trade association that represents all areas of the electronics industry. JEDEC was originally created in 1960 and governs the standardization of all types of semiconductor devices, integrated circuits, and modules. JEDEC has about 300 member companies, including memory, chipset, and processor manufacturers as well as practically any company involved in manufacturing computer equipment using industry-standard components.

The idea behind JEDEC is simple: For example, if one company were to create a proprietary memory technology, other companies who wanted to manufacture components compliant with that memory would have to pay license fees, assuming the company that owned it was interested in licensing at all! Parts would be more proprietary in nature, causing problems with interchangeability or sourcing reasonably priced replacements. In addition, those companies licensing the technology would have no control over future changes or evolution made by the owner company.

The idea behind JEDEC is to prevent this type of scenario for things such as memory by getting all the memory manufacturers to work together to create shared industry standards covering memory chips and modules. JEDEC-approved standards for memory can then be freely shared by all the member companies, and no one single company has control over a given standard, or any of the companies producing compliant components. FPM, SDRAM, DDR SDRAM, and DDR2 SDRAM are examples of JEDEC memory standards used in PCs, whereas EDO and RDRAM are proprietary examples. You can find out more about JEDEC standards for memory and other semiconductor technology at www.jedec.org.

Table 6.6 shows the timing, rated chip speeds, and standard module speeds for various SDRAM DIMMs.

Table 6.6 SDRAM Timing, Actual Speed, and Rated Speed

Timing	Rated Chip Speed	Standard Module Speed
15ns	66MHz	PC66
10ns	100MHz	PC66
8ns	125MHz	PC100
7.5ns	133MHz	PC133
7.0ns	143MHz	PC133

Note that several module manufacturers sell modules they claim are “PC150” or “PC166” even though those speeds do not exist as official JEDEC or Intel standards and no chipsets or processors officially support these speeds. Normally, these modules actually use hand-picked 7.5ns (133MHz) or 7.0ns (143MHz) rated chips that can run overclocked at 150MHz or 166MHz speeds. In essence, PC150 or PC166 memory would more accurately be called PC133 memory that has been tested to run at overclocked speeds not supported by the original chip manufacturer. This specially selected overclockable memory is sold at a premium to enthusiasts who want to overclock their motherboard chipsets, thereby increasing the speed of the processor and memory bus. Table 6.7 shows the standard SDRAM module types and resulting bandwidths.

Table 6.7 SDRAM Module Types and Bandwidths

Module Standard	Module Format	Chip Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Transfer Rate (MBps)
PC66	SDR DIMM	10ns	66	1	66	8	533
PC100	SDR DIMM	8ns	100	1	100	8	800
PC133	SDR DIMM	7/7.5ns	133	1	133	8	1,066

MT/s = Megatransfers per second

MBps = Megabytes per second

ns = Nanoseconds (billionths of a second)

DIMM = Dual inline memory module

SDR = Single data rate

►► See “SIMMs, DIMMs, and RIMMS,” p. 477.

DDR SDRAM

Double data rate (DDR) SDRAM memory is a JEDEC-created standard that is an evolutionary upgrade of standard SDRAM in which data is transferred twice as quickly. Instead of doubling the actual clock rate, DDR memory achieves the doubling in performance by transferring twice per transfer cycle: once at the leading (falling) edge and once at the trailing (rising) edge of the cycle (see Figure 6.1). This effectively doubles the transfer rate, even though the same overall clock and timing signals are used.

Figure 6.1 SDR (single data rate) versus DDR (double data rate) cycling.

DDR found initial support in the graphics card market and since then has become the mainstream PC memory standard. As such, DDR SDRAM is supported by all the major processor, chipset, and memory manufacturers.

DDR SDRAM first came to market during 2000, but it didn't really catch on until 2001 with the advent of mainstream motherboards and chipsets supporting it. DDR SDRAM uses a new DIMM module design with 184 pins. Figure 6.5 (later in this chapter) shows the DDR SDRAM DIMM.

DDR DIMMs come in a variety of speed or throughput ratings and normally run on 2.5 volts. They are basically an extension of the standard SDRAM DIMMs redesigned to support double clocking, where data is sent on each clock transition (twice per cycle) rather than once per cycle as with standard SDRAM. To eliminate confusion with DDR, regular SDRAM is often called single data rate (SDR). Table 6.8 compares the various types of standard DDR SDRAM modules. As you can see, the raw chips are designated by their speed in megatransfers per second, whereas the modules are designated by their approximate throughput in megabytes per second.

Table 6.8 DDR SDRAM Module Types and Bandwidths

Module Standard	Module Format	Chip Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Transfer Rate (MBps)
PC1600	DDR DIMM	DDR200	100	2	200	8	1,600
PC2100	DDR DIMM	DDR266	133	2	266	8	2,133
PC2400	DDR DIMM	DDR300	150	2	300	8	2,400
PC2700	DDR DIMM	DDR333	166	2	333	8	2,667
PC3000	DDR DIMM	DDR366	183	2	366	8	2,933
PC3200	DDR DIMM	DDR400	200	2	400	8	3,200
PC3500	DDR DIMM	DDR433	216	2	433	8	3,466
PC3700	DDR DIMM	DDR466	233	2	466	8	3,733
PC4000	DDR DIMM	DDR500	250	2	500	8	4,000
PC4300	DDR DIMM	DDR533	266	2	533	8	4,266

MT/s = Megatransfers per second

MBps = Megabytes per second

DIMM = Dual inline memory module

DDR = Double data rate

The bandwidths listed in these tables are per module. Many recent chipsets support dual-channel DDR memory—a technique in which two DDR DIMMs are installed at one time and function as a single bank with double the bandwidth of a single module. For example, the Intel 865 and 875 family chipsets use dual-channel DDR memory. They support the 800MHz Pentium 4 processor front-side bus (FSB), which transfers 8 bytes (64 bits) at a time for a bandwidth of 6,400MBps ($800 \times 8 = 6400$). With an 800MHz FSB processor installed, these boards use standard PC3200 modules, installed two at a time (dual-channel), for a total bandwidth of 6,400MBps ($3,200\text{MBps} \times 2 = 6,400\text{MBps}$). This design allows the memory bus throughput to match the CPU bus throughput exactly, resulting in the best possible performance. You can optimize PC design by ensuring that the CPU bus and memory bus both run at exactly the same speeds (meaning bandwidth, not MHz), so that data can move synchronously between the buses without delays.

DDR2 SDRAM

JEDEC and its members began working on the DDR2 specification in April 1998, and published the standard in September 2003. DDR2 chip and module production actually began in mid-2003 (mainly samples and prototypes), and the first chipsets, motherboards, and systems supporting DDR2 appeared in mid-2004.

DDR2 SDRAM is simply a faster version of conventional DDR-SDRAM memory: It achieves higher throughput by using differential pairs of signal wires to allow faster signaling without noise and interference problems. DDR2 is still double data rate just as with DDR, but the modified signaling method enables higher speeds to be achieved with more immunity to noise and cross-talk between the signals. The additional signals required for differential pairs add to the pin count—DDR2 DIMMs have

240 pins, which is more than the 184 pins of DDR. The original DDR specification tops out at 400MHz, whereas DDR2 starts at 400MHz and goes up to 533MHz, 800MHz, and beyond. Table 6.9 shows the various DDR2 module types and bandwidth specifications.

Table 6.9 DDR2 SDRAM Module Types and Bandwidths

Module Standard	Module Format	Chip Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Transfer Rate (MBps)
PC2-3200	DDR2 DIMM	DDR2-400	200	2	400	8	3,200
PC2-4300	DDR2 DIMM	DDR2-533	266	2	533	8	4,266
PC2-5400	DDR2 DIMM	DDR2-667	333	2	667	8	5,333
PC2-6400	DDR2 DIMM	DDR2-800	400	2	800	8	6,400

MT/s = Megatransfers per second

MBps = Megabytes per second

DIMM = Dual inline memory module

DDR = Double data rate

In addition to providing greater speeds and bandwidth, DDR2 has other advantages. It uses lower voltage than conventional DDR (1.8V versus 2.5V), so power consumption and heat generation are reduced. Because of the greater number of pins required on DDR2 chips, the chips typically use fine-pitch ball grid array (FBGA) packaging rather than the thin small outline package (TSOP) chip packaging used by most DDR and conventional SDRAM chips. FPGA chips are connected to the substrate (meaning the memory module in most cases) via tightly spaced solder balls on the base of the chip.

Volume production of DDR2 chips and modules started in the latter part of 2003, with supporting chipsets and motherboards arriving in mid-2004. Variations of DDR2 such as G-DDR2 (Graphics DDR2) are being used in some of the higher-end graphics cards as well. Because all the major memory and chipset manufacturers are supporting DDR2, there is little doubt that DDR2 will quickly become the most popular form of memory after conventional DDR.

DDR2 DIMMs resemble conventional DDR DIMMs but have more pins and slightly different notches to prevent confusion or improper application. For example, the different physical notches prevent you from plugging a DDR2 module in to a conventional DDR (or SDR) socket. DDR2 memory module designs incorporate 240 pins, significantly more than conventional DDR or standard SDRAM DIMMs.

RDRAM

Rambus DRAM (RDRAM) is a fairly radical memory design found in high-end PC systems from late 1999 through 2002. Intel signed a contract with Rambus in 1996 ensuring it would support RDRAM into 2001. After 2001, Intel continued to support RDRAM in existing systems, but new chipsets and motherboards primarily shifted to DDR SDRAM, and all future Intel chipsets and motherboards are being designed for either conventional DDR or the new DDR2 standard. RDRAM standards had been proposed that will support faster processors through 2006; however, without Intel's commitment to future chipset development and support, very few RDRAM-based systems were sold in 2003, and almost none after that. Due to the lack of industry support from chipset and motherboard manufacturers, RDRAM will most likely not play a big part in future PCs.

With RDRAM, Rambus developed what is essentially a chip-to-chip memory bus, with specialized devices that communicate at very high rates of speed. What might be interesting to some is that this technology was first developed for game systems and first made popular by the Nintendo 64 game system, and it subsequently was used in the Sony Playstation 2.

Conventional memory systems that use FPM/EDO or SDRAM are known as *wide-channel systems*. They have memory channels as wide as the processor's data bus, which for the Pentium and up is 64 bits. The dual inline memory module (DIMM) is a 64-bit wide device, meaning data can be transferred to it 64 bits (or 8 bytes) at a time.

RDRAMs, on the other hand, are narrow-channel devices. They transfer data only 16 bits (2 bytes) at a time (plus 2 optional parity bits), but at much faster speeds. This is a shift away from a more parallel to a more serial design and is similar to what is happening with other evolving buses in the PC.

16-bit single channel RIMMs originally ran at 800MHz, so the overall throughput is 800×2 , or 1.6GB per second for a single channel—the same as PC1600 DDR SDRAM. Pentium 4 systems typically used two banks simultaneously, creating a dual-channel design capable of 3.2GBps, which matches the bus speed of the original Pentium 4 processors. The RDRAM design features less latency between transfers because they all run synchronously in a looped system and in only one direction.

Newer RIMM versions run at 1,066MHz or 1,200MHz in addition to the original 800MHz rate and are available in single-channel, 16-bit versions as well as multiple-channel, 32-bit versions for throughputs up to 4.8GBps per module.

A single Rambus memory channel can support up to 32 individual RDRAM devices (the RDRAM chips), and more if buffers are used. Each individual chip is serially connected to the next on a package called a Rambus inline memory module (RIMM), but all memory transfers are done between the memory controller and a single device, not between devices. The individual RDRAM chips are contained on RIMMs, and a single channel typically has three RIMM sockets. The RDRAM memory bus is a continuous path through each device and module on the bus, with each module having input and output pins on opposite ends. Therefore, any RIMM sockets not containing a RIMM must then be filled with a continuity module to ensure that the path is completed. The signals that reach the end of the bus are terminated on the motherboard.

Each RDRAM chip on a RIMM1600 essentially operates as a standalone module sitting on the 16-bit data channel. Internally, each RDRAM chip has a core that operates on a 128-bit wide bus split into eight 16-bit banks running at 100MHz. In other words, every 10ns (100MHz), each RDRAM chip can transfer 16 bytes to and from the core. This internally wide yet externally narrow high-speed interface is the key to RDRAM.

Other improvements to the design include separating control and data signals on the bus. Independent control and address buses are split into two groups of pins for row and column commands, while data is transferred across the 2-byte wide data bus. The actual memory bus clock runs at 400MHz; however, data is transferred on both the falling and rising edges of the clock signal, or twice per clock pulse. The falling edge is called an *even cycle*, and the rising edge is called an *odd cycle*. Complete memory bus synchronization is achieved by sending packets of data beginning on an even cycle interval. The overall wait before a memory transfer can begin (latency) is only one cycle, or 2.5ns maximum.

Figure 6.1 (shown earlier) depicts the relationship between clock and data cycles; you can see the DDR clock and data cycles used by RDRAM and DDR SDRAM. An RDRAM data packet always begins on an even (falling) transition for synchronization purposes.

The architecture also supports multiple, simultaneous interleaved transactions in multiple separate time domains. Therefore, before a transfer has even completed, another can begin.

Another important feature of RDRAM is that it is a low-power memory system. The RIMMs themselves as well as the RDRAM devices run on only 2.5 volts and use low-voltage signal swings from 1.0V to 1.8V, a swing of only 0.8V total. RDRAMs also have four power-down modes and can automatically transition into standby mode at the end of a transaction, which offers further power savings.

As discussed, RDRAM chips are installed in modules called RIMMs. A RIMM is similar in size and physical form to current DIMMs, but they are not interchangeable. RIMMs are available in module sizes up to 1GB or more and can be added to a system one at a time because each individual RIMM technically represents multiple banks to a system. They have to be added in pairs if your motherboard implements dual-channel RDRAM and you are using 16-bit wide RIMMs.

An RDRAM memory controller with a single Rambus channel supports up to three RIMM modules according to the design. However, most motherboards implement only two modules per channel to avoid problems with signal noise.

RIMMs are available in three primary speed grades, with three different width versions in each grade. The 16-bit versions are usually run in a dual-channel environment, so they have to be installed in pairs, with each one of the pairs in a different set of sockets. Each set of RIMM sockets on such boards is a channel. The 32-bit version incorporates multiple channels within a single device and, as such, is designed to be installed individually, eliminating the requirement for matched pairs. Table 6.10 compares the various types of RDRAM modules. Note that the once-common names for RIMM modules, such as PC800, have been replaced by names that reflect the actual bandwidth of the module to avoid confusion with DDR memory.

Table 6.10 RDRAM Module Types and Bandwidth

Module Standard	Module Format	Chip Type	Clock Speed (MHz)	Cycles per Clock	Bus Speed (MT/s)	Bus Width (Bytes)	Transfer Rate (MBps)
RIMM1200	RIMM-16	PC600	300	2	600	2	1,200
RIMM1400	RIMM-16	PC700	350	2	700	2	1,400
RIMM1600	RIMM-16	PC800	400	2	800	2	1,600
RIMM2100	RIMM-16	PC1066	533	2	1,066	2	2,133
RIMM2400	RIMM-16	PC1200	600	2	1,200	2	2,400
RIMM3200	RIMM-32	PC800	400	2	800	4	3,200
RIMM4200	RIMM-32	PC1066	533	2	1,066	4	4,266
RIMM4800	RIMM-32	PC1200	600	2	1,200	4	4,800

MT/s = Megatransfers per second

MBps = Megabytes per second

RIMM = Rambus inline memory module

When Intel initially threw its weight behind the Rambus memory, it seemed destined to be a sure thing for success. Unfortunately, technical delays in the chipsets caused the supporting motherboards to be significantly delayed, and with few systems to support the RIMMs, most memory manufacturers went back to making SDRAM or shifted to DDR SDRAM instead. This caused the remaining available RIMMs being manufactured to be originally priced three or more times that of a comparatively sized DIMM. More recently the cost for RDRAM RIMMs has come down to approximately that of DDR SDRAM, but by the time that happened, Intel had shifted all future chipset development to support only DDR and DDR2 memory.

As I've stated many times, one of the main considerations for memory is that the throughput of the memory bus should match the throughput of the processor bus, and in that area RDRAM RIMMs were

originally more suited to the initial Pentium 4 processor systems. However, with the increases in speed of the Pentium 4 processor bus from 400MHz to 533MHz and then 800MHz and the advent of chipsets supporting dual-channel DDR memory, DDR and DDR2 are currently the best match for the CPU bus speeds of both Intel and AMD processors. In short, the advent of newer chipsets supporting dual-channel DDR in 2002 and DDR2 in 2004 has rendered DDR and DDR2 as the best choices for modern systems, offering the maximum memory performance possible.

Note

Unfortunately for the memory chip manufacturers, Rambus has claimed patents that cover both standard and DDR SDRAM designs. So, regardless of whether these companies manufacture SDRAM, DDR, or RDRAM, it is the contention of Rambus that these memory manufacturers must pay the company royalties. Several court cases are ongoing with companies challenging these patents, and a lot is riding on the outcome. Most of the cases that have gone to trial have so far ruled against Rambus, essentially invalidating its patents and claims on DDR and SDRAM. Many appeals are pending, and it will likely be a long time before the patent issues are resolved.

Memory Modules

The CPU and motherboard architecture (chipset) dictates a particular computer's physical memory capacity and the types and forms of memory that can be installed. Over the years, two main changes have occurred in computer memory—it has gradually become faster and wider. The CPU and the memory controller circuitry indicate the speed and width requirements. The memory controller in a modern PC resides in the motherboard chipset. Even though a system might physically support a given amount of memory, the type of software you run could dictate whether all the memory can be used.

The 8088 and 8086 CPUs, with 20 address lines, can use as much as 1MB (1,024KB) of RAM. The 286 and 386SX CPUs have 24 address lines and can keep track of as much as 16MB of memory. The 386DX, 486, Pentium, and Pentium-MMX CPUs have a full set of 32 address lines, so they can keep track of 4GB of memory; the Pentium Pro, Pentium II/III, and 4, as well as the AMD Athlon and Duron, have 36 address lines and can manage an impressive 64GB. The Itanium processor, on the other hand, has 44-bit addressing, which allows for up to 16TB (terabytes) of physical RAM!

◀◀ See "Processor Specifications," p. 41.

When the 286 and higher chips emulate the 8088 chip (as they do when running 16-bit software, such as DOS or Windows 3.x), they implement a hardware operating mode called *real mode*. Real mode is the only mode available on the 8086 and 8088 chips used in PC and XT systems. In real mode, all Intel processors—even the mighty Pentium family—are restricted to using only 1MB of memory, just as their 8086 and 8088 ancestors were, and the system design reserves 384KB of that amount. Only in protected mode can the 286 or better chips use their maximum potentials for memory addressing.

◀◀ See "Processor Modes," p. 49.

P5 class systems can address as much as 4GB of memory, and P6/P7 class systems can address up to 64GB. To put these memory-addressing capabilities into perspective, 64GB (65,536MB) of memory would cost nearly \$20,000! Even if you could afford all this memory, some of the largest memory modules available today are 1GB DIMMs. Installing 64GB of RAM would require 64 of the largest 1GB DIMMs available, and most systems today support up to only four DIMM sockets.

Most motherboards have a maximum of only three to six DIMM sockets, which allows a maximum of 1.5GB–3GB if all the sockets are filled. These limitations are from the chipset, not the processor. Although some processors can address 64GB, there isn't a chipset on the market that will allow that! Most of the chipsets today are limited to 2GB of memory, although some handle up to 4GB or more.

Some systems have even more limitations. P5 class systems have been available since 1993, but only those built in 1997 or later use a motherboard chipset that supports SDRAM DIMMs. Even those using the most recent P5 class chipset from Intel, such as the 430TX, do not support more than 256MB of total memory and should not have more than 64MB actually installed because of memory-caching limitations. Don't install more than 64MB of RAM in one of these older systems unless you are sure the motherboard and chipset will allow the L2 cache to function with the additional memory.

Note

See the "Chipsets" section in Chapter 4 for the maximum cacheable limits on all the Intel and other motherboard chipsets.

SIMMs, DIMMs, and RIMMs

Originally, systems had memory installed via individual chips. They are often referred to as *dual inline package (DIP)* chips because of their designs. The original IBM XT and AT had 36 sockets on the motherboard for these individual chips; then more of them were installed on the memory cards plugged into the bus slots. I remember spending hours populating boards with these chips, which was a tedious job.

Besides being a time-consuming and labor-intensive way to deal with memory, DIP chips had one notorious problem—they crept out of their sockets over time as the system went through thermal cycles. Every day, when you powered the system on and off, the system heated and cooled, and the chips gradually walked their way out of the sockets. Eventually, good contact was lost and memory errors resulted. Fortunately, reseating all the chips back in their sockets usually rectified the problem, but that method was labor intensive if you had a lot of systems to support.

The alternative to this at the time was to have the memory soldered into either the motherboard or an expansion card. This prevented the chips from creeping and made the connections more permanent, but it caused another problem. If a chip did go bad, you had to attempt desoldering the old one and resoldering a new one or resort to scrapping the motherboard or memory card on which the chip was installed. This was expensive and made memory troubleshooting difficult.

A chip was needed that was both soldered and removable, and that is exactly what was found in the module called a *SIMM*. For memory storage, most modern systems have adopted the single inline memory module (SIMM), DIMM, or RIMM as an alternative to individual memory chips. These small boards plug into special connectors on a motherboard or memory card. The individual memory chips are soldered to the module, so removing and replacing them is impossible. Instead, you must replace the entire module if any part of it fails. The module is treated as though it were one large memory chip.

Two main types of SIMMs, three main types of DIMMs, and so far one type of RIMM are used in desktop systems. The various types are often described by their pin count, memory row width, or memory type.

SIMMs, for example, are available in two main physical types—30-pin (8 bits plus an option for 1 additional parity bit) and 72-pin (32 bits plus an option for 4 additional parity bits)—with various capacities and other specifications. The 30-pin SIMMs are physically smaller than the 72-pin versions, and either version can have chips on one or both sides. SIMMs were widely used from the late 1980s to the late 1990s but have become obsolete.

DIMMs are also available in three main types. DIMMs usually hold standard SDRAM or DDR SDRAM chips and are distinguished by different physical characteristics. Standard DIMMs have 168 pins, one notch on either side, and two notches along the contact area. DDR DIMMs, on the other hand, have 184 pins, two notches on each side, and only one offset notch along the contact area. DDR2 DIMMs have 240 pins, two notches on each side, and one in the center of the contact area. All DIMMs are either 64-bits (non-ECC/parity) or 72-bits (parity or error correcting code [ECC]) wide (data paths). The main physical difference between SIMMs and DIMMs is that DIMMs have different signal pins on each side of the module. That is why they are called *dual* inline memory modules, and why with only 1" of additional length, they have many more pins than a SIMM.

Note

There is confusion among users and even in the industry over regarding the terms single-sided or double-sided with respect to memory modules. In truth, the single- or double-sided designation actually has *nothing* to do with whether chips are physically located on one or both sides of the module, and it has *nothing* to do with whether the module is a SIMM or DIMM (meaning whether the connection pins are single- or double-inline). Instead the terms *single-sided* and *double-sided* are used to indicate whether the module has one or two banks of memory chips installed. A double-banked DIMM module has two complete 64-bit-wide banks of chips logically stacked so that the module is twice as deep (has twice as many 64-bit rows). In most (but not all) cases, this requires chips to be on both sides of the module; therefore, the term *double-sided* has often been used to indicate that a module has two banks, even though the term is technically incorrect. Single-banked modules (incorrectly referred to as *single-sided*) can have chips physically mounted on both sides of the module, and double-banked modules (incorrectly referred to as *double-sided*) can have chips physically mounted on only one side. I recommend using the terms *single-banked* and *double-banked* instead because they are much more accurate and easily understood.

RIMMs also have different signal pins on each side. Three different physical types of RIMMs are available: a 16/18-bit version with 184 pins, a 32/36-bit version with 232 pins, and a 64/72-bit version with 326 pins. Each of these plugs into the same sized connector, but the notches in the connectors and RIMMs are different to prevent a mismatch. A given board will accept only one type. By far the most common type is the 16/18-bit version. The 32-bit version was introduced in late 2002, and the 64-bit version was introduced in 2004.

The standard 16/18-bit RIMM has 184 pins, one notch on either side, and two notches centrally located in the contact area. 16-bit versions are used for non-ECC applications, whereas the 18-bit versions incorporate the additional bits necessary for ECC.

Figures 6.2–6.7 show a typical 30-pin (8-bit) SIMM, 72-pin (32-bit) SIMM, 168-pin SDRAM DIMM, 184-pin DDR SDRAM (64-bit) DIMM, 240-pin DDR2 DIMM, and 184-pin RIMM, respectively. The pins are numbered from left to right and are connected through to both sides of the module on the SIMMs. The pins on the DIMM are different on each side, but on a SIMM, each side is the same as the other and the connections carry through. Note that all dimensions are in both inches and millimeters (in parentheses), and modules are generally available in error correcting code (ECC) versions with 1 extra ECC (or parity) bit for every 8 data bits (multiples of 9 in data width) or versions that do not include ECC support (multiples of 8 in data width).

1,024MB	512MB×16	512MB×18

SIMMs, DIMMs, DDR/DDR2 DIMMs, and RIMMs of each type and capacity are available in various speed ratings. Consult your motherboard documentation for the correct memory speed and type for your system. It is usually best for the memory speed (also called throughput or bandwidth) to match the speed of the processor data bus (also called the front side bus or FSB).

If a system requires a specific speed, you can almost always substitute faster speeds if the one specified is not available. Generally, no problems occur in mixing module speeds, as long as you use modules equal to or faster than what the system requires. Because there's little price difference between the various speed versions, I often buy faster modules than are necessary for a particular application. This might make them more usable in a future system that could require the faster speed.

Because DIMMs and RIMMs have an onboard serial presence detect (SPD) ROM that reports their speed and timing parameters to the system, most systems run the memory controller and memory bus at the speed matching the slowest DIMM/RIMM installed. Most DIMMs are SDRAM memory, which means they deliver data in very high-speed bursts using a clocked interface. DDR DIMMs are also SDRAM, but they transfer data two times per clock cycle and thus are twice as fast.

Note

A *bank* is the smallest amount of memory needed to form a single row of memory addressable by the processor. It is the minimum amount of physical memory that is read or written by the processor at one time and usually corresponds to the data bus width of the processor. If a processor has a 64-bit data bus, a bank of memory also is 64 bits wide. If the memory is interleaved or runs dual-channel, a virtual bank is formed that is twice the absolute data bus width of the processor.

You can't always replace a module with a higher-capacity unit and expect it to work. Systems might have specific design limitations for the maximum capacity of module they can take. A larger-capacity module works only if the motherboard is designed to accept it in the first place. Consult your system documentation to determine the correct capacity and speed to use.

Registered Modules

SDRAM and DDR DIMMs are available in buffered, unbuffered, and registered versions. A *buffered* module has additional buffer circuits between the memory chips and the connector to condition or buffer the signals. Virtually all PC motherboards designed to use SDRAM or DDR require unbuffered or registered modules instead. In fact, no PCs that I am aware of use plain buffered modules. Some of the early PowerPC Macs might have used buffered SDRAM, but no PCs do. Because so few systems ever used them, you will not find buffered modules available for sale.

Most PC motherboards are designed to use *unbuffered* modules, which allow the memory controller signals to pass directly to the memory chips on the module with no interference. This is not only the cheapest design, but also the fastest and most efficient. The only drawback is that the motherboard designer must place limits on how many modules (meaning module sockets) can be installed on the board, and possibly also limit how many chips can be on a module. So-called double-sided modules that really have two banks of chips (twice as many as normal) onboard might be restricted on some systems in certain combinations.

Systems designed to accept extremely large amounts of RAM often require registered modules. A registered module uses an architecture which has register chips on the module that act as an interface between the actual RAM chips and the chipset. The registers temporarily hold data passing to and from the memory chips and enable many more RAM chips to be driven or otherwise placed on the module than the chipset could normally support. This allows for motherboard designs that can support many modules and enables each module to have a larger number of chips. In general, registered modules are required by server or workstation motherboards designed to support more than 1GB or 2GB of RAM. The important thing to note is that you can use only the type of module your motherboard (or chipset) is designed to support. For most, that is standard unbuffered modules or, in some cases, registered modules.

SIMM Pinouts

Table 6.12 shows the interface connector pinouts for standard 72-pin SIMMs. They also include a special presence detect table that shows the configuration of the presence detect pins on various 72-pin SIMMs. The motherboard uses the presence detect pins to detect exactly what size and speed SIMM is installed. Industry-standard 30-pin SIMMs do not have a presence detect feature, but IBM did add this capability to its modified 30-pin configuration. Note that all SIMMs have the same pins on both sides of the module. SIMM pins are usually tin plated. The plating on the module pins must match the socket pins because corrosion will result otherwise.

Table 6.12 Standard 72-Pin SIMM Pinout

Pin	SIMM Signal Name	Pin	SIMM Signal Name	Pin	SIMM Signal Name
1	Ground	25	Data Bit 22	49	Data Bit 8
2	Data Bit 0	26	Data Bit 7	50	Data Bit 24
3	Data Bit 16	27	Data Bit 23	51	Data Bit 9
4	Data Bit 1	28	Address Bit 7	52	Data Bit 25
5	Data Bit 17	29	Address Bit 11	53	Data Bit 10
6	Data Bit 2	30	+5 Vdc	54	Data Bit 26
7	Data Bit 18	31	Address Bit 8	55	Data Bit 11
8	Data Bit 3	32	Address Bit 9	56	Data Bit 27
9	Data Bit 19	33	Address Bit 12	57	Data Bit 12
10	+5 Vdc	34	Address Bit 13	58	Data Bit 28
11	Presence Detect 5	35	Parity Data Bit 2	59	+5 Vdc
12	Address Bit 0	36	Parity Data Bit 0	60	Data Bit 29
13	Address Bit 1	37	Parity Data Bit 1	61	Data Bit 13
14	Address Bit 2	38	Parity Data Bit 3	62	Data Bit 30
15	Address Bit 3	39	Ground	63	Data Bit 14
16	Address Bit 4	40	Column Address Strobe 0	64	Data Bit 31
17	Address Bit 5	41	Column Address Strobe 2	65	Data Bit 15
18	Address Bit 6	42	Column Address Strobe 3	66	EDO
19	Address Bit 10	43	Column Address Strobe 1	67	Presence Detect 1
20	Data Bit 4	44	Row Address Strobe 0	68	Presence Detect 2
21	Data Bit 20	45	Row Address Strobe 1	69	Presence Detect 3
22	Data Bit 5	46	Reserved	70	Presence Detect 4
23	Data Bit 21	47	Write Enable	71	Reserved
24	Data Bit 6	48	ECC Optimized	72	Ground

Notice that the 72-pin SIMMs use a set of four or five pins to indicate the type of SIMM to the motherboard. These presence detect pins are either grounded or not connected to indicate the type of SIMM to the motherboard. Presence detect outputs must be tied to the ground through a 0-ohm resistor or jumper on the SIMM—to generate a high logic level when the pin is open or a low logic level when the motherboard grounds the pin. This produces signals the memory interface logic can decode. If the motherboard uses presence detect signals, a power on self test (POST) procedure can determine the size and speed of the installed SIMMs and adjust control and addressing signals automatically. This enables autodetection of the memory size and speed.

Note

In many ways, the presence detect pin function is similar to the industry-standard DX coding used on modern 35mm film rolls to indicate the ASA (speed) rating of the film to the camera. When you drop the film into the camera, electrical contacts can read the film's speed rating via an industry-standard configuration.

Table 6.13 shows the Joint Electronic Devices Engineering Council (JEDEC) industry-standard presence detect configuration listing for the 72-pin SIMM family. JEDEC is an organization of U.S. semiconductor manufacturers and users that sets semiconductor standards.

Table 6.13 Presence Detect Pin Configurations for 72-Pin SIMMs

Size	Speed	Pin 67	Pin 68	Pin 69	Pin 70	Pin 11

32MB	50ns	—	Gnd	Gnd	Gnd	Gnd

— = No connection (open)

Gnd = Ground

Pin 67 = Presence detect 1

Pin 68 = Presence detect 2

Pin 69 = Presence detect 3

Pin 70 = Presence detect 4

Pin 11 = Presence detect 5

Unfortunately, unlike the film industry, not everybody in the computer industry follows established standards. As such, presence detect signaling is not a standard throughout the PC industry. Different system manufacturers sometimes use different configurations for what is expected on these four pins.

Compaq, IBM (mainly PS/2 systems), and Hewlett-Packard are notorious for this type of behavior. Many of the systems from these vendors require special SIMMs that are basically the same as standard 72-pin SIMMs, except for special presence detect requirements. Table 6.14 shows how IBM defines these pins.

Table 6.14 Presence Detect Pins for IBM 72-Pin SIMMs

67	68	69	70	SIMM Type	IBM Part Number
—	—	—	—	Not a valid SIMM	n/a
Gnd	—	—	—	1MB 120ns	n/a
—	Gnd	—	—	2MB 120ns	n/a
Gnd	Gnd	—	—	2MB 70ns	92F0102
—	—	Gnd	—	8MB 70ns	64F3606
Gnd	—	Gnd	—	Reserved	n/a
—	Gnd	Gnd	—	2MB 80ns	92F0103
Gnd	Gnd	Gnd	—	8MB 80ns	64F3607
—	—	—	Gnd	Reserved	n/a
Gnd	—	—	Gnd	1MB 85ns	90X8624
—	Gnd	—	Gnd	2MB 85ns	92F0104
Gnd	Gnd	—	Gnd	4MB 70ns	92F0105
—	—	Gnd	Gnd	4MB 85ns	79F1003 (square notch) L40-SX
Gnd	—	Gnd	Gnd	1MB 100ns	n/a
Gnd	—	Gnd	Gnd	8MB 80ns	79F1004 (square notch) L40-SX
—	Gnd	Gnd	Gnd	2MB 100ns	n/a
Gnd	Gnd	Gnd	Gnd	4MB 80ns	87F9980
Gnd	Gnd	Gnd	Gnd	2MB 85ns	79F1003 (square notch) L40SX

— = No connection (open)

Pin 67 = Presence detect 1

Pin 69 = Presence detect 3

Gnd = Ground

Pin 68 = Presence detect 2

Pin 70 = Presence detect 4

Because these pins can have custom variations, you often must specify IBM, Compaq, HP, or generic SIMMs when you order memory.

DIMM Pinouts

Table 6.15 shows the pinout configuration of a 168-pin standard unbuffered SDRAM DIMM. Note again that the pins on each side of the DIMM are different. All pins should be gold plated.

Table 6.15 168-Pin SDRAM DIMM Pinouts

Gnd = Ground*SPD* = Serial presence detect*NC* = No connection

The DIMM uses a completely different type of presence detect than a SIMM, called *serial presence detect* (*SPD*). It consists of a small EEPROM or Flash memory chip on the DIMM that contains specially formatted data indicating the DIMM's features. This serial data can be read via the serial data pins on the DIMM, and it enables the motherboard to autoconfigure to the exact type of DIMM installed.

DIMMs can come in several varieties, including unbuffered or buffered and 3.3V or 5V. Buffered DIMMs have additional buffer chips on them to interface to the motherboard. Unfortunately, these buffer chips slow down the DIMM and are not effective at higher speeds. For this reason, all PC systems use unbuffered DIMMs. The voltage is simple—DIMM designs for PCs are almost universally

3.3V. If you install a 5V DIMM in a 3.3V socket, it would be damaged, but fortunately, keying in the socket and on the DIMM prevents that.

Modern PC systems use only unbuffered 3.3V DIMMs. Apple and other non-PC systems can use the buffered 5V versions. Fortunately, the key notches along the connector edge of a DIMM are spaced differently for buffered/unbuffered or 3.3V/5V DIMMs, as shown in Figure 6.8. This prevents inserting a DIMM of the wrong type into a given socket.

Figure 6.8 168-pin DRAM DIMM notch key definitions.

DDR DIMM Pinouts

Table 6.16 shows the pinout configuration of a 184-pin DDR SDRAM DIMM. Note again that the pins on each side of the DIMM are different. All pins should be gold plated.

Table 6.16 184-Pin DDR DIMM Pinouts

DDR DIMMs use a single key notch to indicate voltage, as shown in Figure 6.9.

**Figure 6.9** 184-pin DDR SDRAM DIMM keying.

184-pin DDR DIMMs use two notches on each side to enable compatibility with both low- and high-profile latched sockets. Note that the key position is offset with respect to the center of the DIMM to prevent inserting it backward in the socket. The key notch is positioned to the left, centered, or to the right of the area between pins 52 and 53. This is used to indicate the I/O voltage for the DDR DIMM and to prevent installing the wrong type into a socket that might damage the DIMM.

DDR2 DIMM Pinouts

Table 6.17 shows the pinout configuration of a 240-pin DDR2 SDRAM DIMM. Pins 1–120 are on the front side, and pins 121–240 are on the back. All pins should be gold plated.

240-pin DDR2 DIMMs use two notches on each side to enable compatibility with both low- and high-profile latched sockets. The connector key is offset with respect to the center of the DIMM to prevent inserting it backward in the socket. The key notch is positioned in the center of the area between pins 64 and 65 on the front (184/185 on the back), and there is no voltage keying because all DDR2 DIMMs run on 1.8V.

RIMM Pinouts

RIMM modules and sockets are gold-plated and designed for 25 insertion/removal cycles. Each RIMM has 184 pins, split into two groups of 92 pins on opposite ends and sides of the module. The pinout of the RIMM is shown in Table 6.18.

16/18-bit RIMMs are keyed with two notches in the center. This prevents a backward insertion and prevents the wrong type (voltage) RIMM from being used in a system. Currently, all RIMMs run on 2.5V, but future 64-bit versions will run on only 1.8V. To allow for changes in the RIMMs, three keying options are possible in the design (see Figure 6.10). The left key (indicated as “DATUM A” in Figure 6.10) is fixed in position, but the center key can be in three different positions spaced 1mm or 2mm to the right, indicating different types of RIMMs. The current default is option A, as shown in Figure 6.10 and Table 6.19, which corresponds to 2.5V operation.

Figure 6.10 RIMM keying options.

Table 6.19 Possible Keying Options for RIMMs

Option	Notch Separation	Description
A	11.5mm	2.5V RIMM
B	12.5mm	Reserved
C	13.5mm	Reserved

RIMMs incorporate an SPD device, which is essentially a Flash ROM onboard. This ROM contains information about the RIMM’s size and type, including detailed timing information for the memory controller. The memory controller automatically reads the data from the SPD ROM to configure the system to match the RIMMs installed.

Figure 6.11 shows a typical PC RIMM installation. The RDRAM controller and clock generator are typically in the motherboard chipset North Bridge component. As you can see, the Rambus memory channel flows from the memory controller through each of up to three RIMM modules in series. Each module contains 4, 8, 16, or more RDRAM devices (chips), also wired in series, with an onboard SPD ROM for system configuration. Any RIMM sockets without a RIMM installed must have a continuity module, shown in the last socket in Figure 6.11. This enables the memory bus to remain continuous from the controller through each module (and, therefore, each RDRAM device on the module) until the bus finally terminates on the motherboard. Note how the bus loops from one module to another. For timing purposes, the first RIMM socket must be 6" or less from the memory controller, and the entire length of the bus must not be more than it would take for a signal to go from one end to another in four data clocks, or about 5ns.

Figure 6.11 Typical RDRAM bus layout showing a RIMM and one continuity module.

Interestingly, Rambus does not manufacture the RDRAM devices (the chips) or the RIMMs; that is left to other companies. Rambus is merely a design company, and it has no chip fabs or manufacturing facilities of its own. It licenses its technology to other companies who then manufacture the devices and modules.

Physical RAM Capacity and Organization

Several types of memory chips have been used in PC system motherboards. Most of these chips are single-bit-wide chips and are available in several capacities.

Note that chip capacity typically goes up by factors of four because the dies that make up the chips are square. When they increase capacity, this results in four times more transistors and four times more capacity. Most modern SIMMs and DIMMs use 16Mb–256Mb chips onboard.

Figure 6.12 shows the markings on a typical memory chip from Micron Technologies, one of the most popular chip and module manufacturers. Many memory manufacturers use similar schemes for numbering their chips; however, if you are really trying to identify a particular chip, you should consult the manufacturer catalog for more information.

The -75 marking corresponds to the chip speed in nanoseconds—in this case, a 7.5-nanosecond or 133MHz designation.

The part number usually contains a clue about the chip's type and capacity. The chip here is MT48LC8M8A2TG-75L. This decodes as

- MT = Micron Technologies
- 48 = SDRAM
- LC = 3.3V CMOS
- 8M8 = 8 million rows deep × 8 bits wide
- A2 = Device version
- TG = TSOP (thin small outline package)
- 75 = 7.5ns (133MHz) rating
- L = Low power

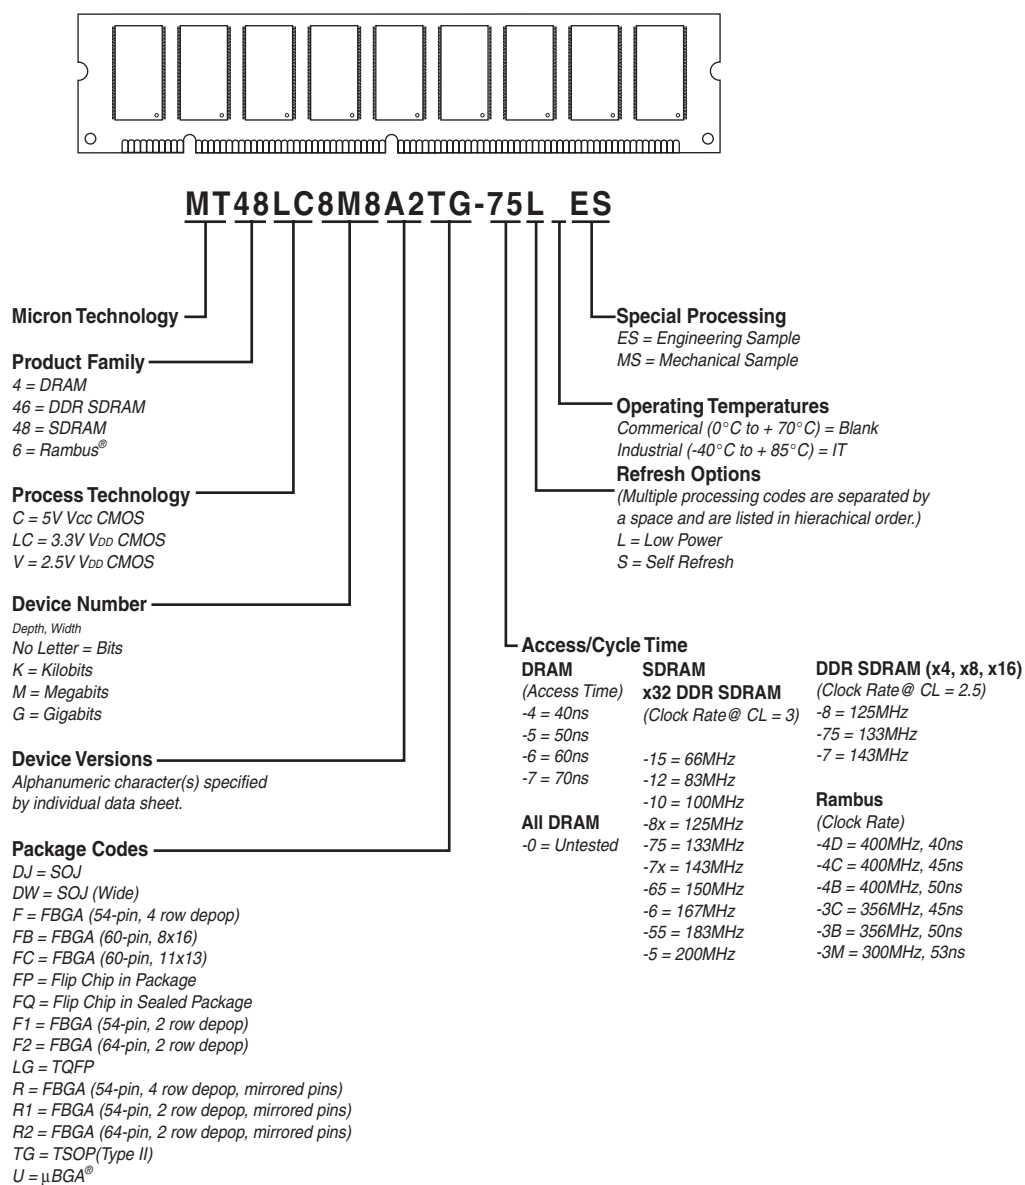

Figure 6.12 The markings on a typical memory chip (Micron shown).

Note

Markings vary from manufacturer to manufacturer. The example shown here is for illustrative purposes only.

Because this chip is 8 bits wide, I'd expect to see either 8 or 16 of them on a DIMM to make up the 64 bits of width for the complete DIMM. If 16 chips were used, this would be known as a *double-sided DIMM* and the chips would be arranged in a logically stacked form in which the two banks of 8MB×8 chips work together as if they were a single bank of 16MB×8 chips. If 8 of these chips were on a

DIMM, it would be 8MB×64 bits, which is the same as saying 8MB×8 bytes, which is the same as calling it a 64MB DIMM. If there were 16 of these chips, it would be a 128MB double-sided DIMM, and if there were either 9 or 18 of these chips, it would be a 72-bit wide DIMM with parity/ECC support.

Most chips also feature a four-digit number separate from the part number that indicates the date of manufacture by week and day. For example, 0021 indicates the chip was made in the 21st week of 2000. To further decode the chip, contact the manufacturer or chip vendor for its catalog information.

SIMMs and DIMMs also have part numbers that can be difficult to decode. Unfortunately, no industry standard exists for numbering these modules, so you must contact the manufacturer if you want to decode the numbers.

Sometimes you can't find any writing on the module that tells you the capacity or other information. In that case, just look up the chip part numbers on the chip manufacturer's Web site, and from there you should be able to figure out what it is (see Figure 6.13).

Figure 6.13 DIMM front/rear view with indecipherable markings indicating part number, capacity, or speed.

The fact that I can't decipher the information on the stickers about the DIMM is not a problem, as long as I can read the chip part numbers.

The chips carry the Hyundai (HY) logo, with a part number of HY57V651620-TC10. I found the data sheet for these chips at the Hyundai Memory Web site. I can't tell who made the actual DIMM; at first I suspected Hyundai might have made it because of the HY-3U1606 number on the left side, but I can't find any corresponding information in the Hyundai catalog that matches this designation. No matter; I can still deduce all the information I need about this module by looking at the chip information.

According to the data sheet for the chips on this DIMM, these are 10ns chips, which, although technically rated 100MHz, would classify this as a 66MHz SDRAM DIMM (PC66). If they were 8ns (125MHz) chips, this would be a PC100 DIMM, and if they were 7.5ns, this would be a PC133 DIMM. These are 64Mb chips, organized as 4MB×16 (rows by columns). Four chips are on one side, resulting in a full 64-bit wide bank of 4MB×64 bits (4MB×8 bytes or 32MB total). The other side contains the same number of chips, which would be electronically or logically "stacked" to double the depth (number of rows). This is because DIMMs can be only 64 bits wide, resulting in a total of 8MB×64 bits, which is 8MB×8 bytes, which is 64MB total. The additional tiny Atmel brand chip on the right side is the serial EEPROM, which contains the data about this DIMM that can be read by the motherboard to configure the chipset memory controllers. Because there are no additional memory chips, this DIMM lacks the additional 8 bits of width to make it a 72-bit wide ECC DIMM.

So, by deciphering the chip part numbers and adding things up, I have figured out that this is a 64MB, double-sided, non-ECC, PC66 SDRAM DIMM.

Tip

If you are unable to decipher the chip part number, you can use the HWinfo or SiSoftware Sandra program to identify your memory module as well as many other facts about your computer, including chipset, processor, empty memory sockets, and much more. You can download shareware versions of HWinfo from www.hwinfo.com or SiSoft Sandra from www.sisoftware.net.

Memory Banks

Memory chips (DIPs, SIMMs, SIPP, and DIMMs) are organized in banks on motherboards and memory cards. You should know the memory bank layout and position on the motherboard and memory cards.

You need to know the bank layout when adding memory to the system. In addition, memory diagnostics report error locations by byte and bit addresses, and you must use these numbers to locate which bank in your system contains the problem.

The banks usually correspond to the data bus capacity of the system's microprocessor. Table 6.20 shows the widths of individual banks based on the type of PC.

Table 6.20 Memory Bank Widths on Various Systems

Processor	Data Bus	Memory Bank Size (No Parity)	Memory Bank Size (Parity/ECC)	30-Pin SIMMs per Bank	72-Pin SIMMs per Bank	168-Pin DIMMs per Bank
8088	8-bit	8 bits	9 bits	1	n/a	n/a
8086	16-bit	16 bits	18 bits	2	n/a	n/a
286	16-bit	16 bits	18 bits	2	n/a	n/a
386SX, SL, SLC	16-bit	16 bits	18 bits	2	n/a	n/a
486SLC, SLC2	16-bit	16 bits	18 bits	2	n/a	n/a
386DX	32-bit	32 bits	36 bits	4	1	n/a
486SX, DX, DX2, DX4, 5x86	32-bit	32 bits	36 bits	4	1	n/a
Pentium, K6 series	64-bit	64 bits	72 bits	8*	2	1
PPro, PII, Celeron, PIII, P4, Athlon/Duron, Athlon XP	64-bit	64 bits	72 bits	8*	2	1

*Very few if any motherboards using this type of memory were made for these processors.

The number of bits for each bank can be made up of single chips, SIMMs, or DIMMs. Modern systems don't use individual chips; instead, they use only SIMMs or DIMMs. If the system has a 16-bit processor, such as a 386SX, it probably uses 30-pin SIMMs and has two SIMMs per bank. All the SIMMs in a single bank must be the same size and type.

A 486 system requires four 30-pin SIMMs or one 72-pin SIMM to make up a bank. A single 72-pin SIMM is 32 bits wide, or 36 bits wide if it supports parity. You can often tell whether a SIMM supports parity by counting its chips. To make a 32-bit SIMM, you could use 32 individual 1-bit-wide chips, or you could use eight individual 4-bit-wide chips to make up the data bits. If the system uses parity, four extra bits are required (36 bits total), so you would see one more 4-bit-wide or four individual 1-bit-wide chips added to the bank for the parity bits.

As you might imagine, 30-pin SIMMs are less than ideal for 32-bit or 64-bit systems (that is, 486 or Pentium) because you must use them in increments of four or eight per bank. Because these SIMMs are currently available in 1MB, 4MB, and 16MB capacities, a single bank of 30-pin SIMMs in a 486 system

would be 4MB, 16MB, or 64MB; for a Pentium system, this would be 8MB, 32MB, or 128MB of memory, with no in-between amounts. Using 30-pin SIMMs in 32- and 64-bit systems artificially constrains memory configurations, and such systems are not recommended. If a 32-bit system (such as any PC with a 486 processor) uses 72-pin SIMMs, each SIMM represents a separate bank and the SIMMs can be added or removed on an individual basis rather than in groups of four, as would be required with 30-pin SIMMs. This makes memory configuration much easier and more flexible. In 64-bit systems that use SIMMs, two 72-pin SIMMs are required per bank.

DIMMs are ideal for Pentium and higher systems because the 64-bit width of the DIMM exactly matches the 64-bit width of the Pentium processor data bus. Therefore, each DIMM represents an individual bank, and they can be added or removed one at a time.

The physical orientation and numbering of the SIMMs or DIMMs used on a motherboard is arbitrary and determined by the board's designers, so documentation covering your system or card comes in handy. You can determine the layout of a motherboard or an adapter card through testing, but that takes time and might be difficult, particularly after you have a problem with a system.

Memory Module Speed

When you replace a failed memory module or install a new module as an upgrade, you typically must install a module of the same type and speed as the others in the system. You can substitute a module with a different (faster) speed but only if the replacement module's speed is equal to or faster than that of the other modules in the system.

Some people have had problems when "mixing" modules of different speeds. With the wide variety of motherboards, chipsets, and memory types, few ironclad rules exist. When in doubt as to which speed module to install in your system, consult the motherboard documentation for more information.

Substituting faster memory of the same type doesn't result in improved performance if the system still operates the memory at the same speed. Systems that use DIMMs or RIMMs can read the speed and timing features of the module from a special SPD ROM installed on the module and then set chipset (memory controller) timing accordingly. In these systems, you might see an increase in performance by installing faster modules, to the limit of what the chipset will support.

To place more emphasis on timing and reliability, there are Intel and JEDEC standards governing memory types that require certain levels of performance. Intel, for example, has created the PC66, PC100, and PC133 standards supported by many newer chipsets. These standards certify that memory modules perform within Intel's timing and performance guidelines. At 100MHz or higher, there is not much "forgiveness" or slop allowed in memory timing.

The same common symptoms result when the system memory has failed or is simply not fast enough for the system's timing. The usual symptoms are frequent parity check errors or a system that does not operate at all. The POST might report errors, too. If you're unsure of which chips to buy for your system, contact the system manufacturer or a reputable chip supplier.

Gold Versus Tin

Many people don't understand the importance of the memory module electrical contacts in a computer system. Modules (SIMMs, DIMMs, and RIMMs) are available in gold- or tin-plated contact form. I initially thought that gold contact modules were the best way to go for reliability in all situations, but that is not true. To have the most reliable system, you must install modules with gold-plated contacts into gold-plated sockets and modules with tin-plated contacts into tin-plated sockets only.

If you don't heed this warning and install memory with gold-plated contacts into tin sockets or vice versa, you will have problems with memory errors and reliability in the long run. In my experiences, they occur six months to one year after installation. I have encountered this problem several times in my own systems

and in several systems I have serviced. I have even been asked to assist one customer in a lawsuit as an expert witness. The customer had bought several hundred machines from a vendor, and severe memory failures began appearing in most of the machines approximately a year after delivery. The cause was traced to dissimilar metals between the memory modules and sockets (gold-plated contact SIMMs in tin-plated contact sockets, in this case). The vendor refused to replace the SIMMs with tin-plated versions, hence the lawsuit.

Most systems using 72-pin SIMMs have tin-plated sockets, so they must have tin-plated SIMM memory installed. Studies done by the connector manufacturers, such as AMP, show that a type of corrosion called *fretting* occurs when tin comes in pressure contact with gold or any other metal. With fretting corrosion, tin oxide transfers to the harder gold surface, eventually causing a high-resistance connection. This happens whenever gold comes into contact with tin, no matter how thick or thin the gold coating is. Over time, depending on the environment, fretting corrosion can and will cause high resistance at the contact point and thus cause memory errors.

You might think tin makes a poor connector material because it readily oxidizes. Even so, electrical contact is easily made between two tin surfaces under pressure because the oxides on the softer tin surfaces bend and break, ensuring contact. In most memory modules, the contacts are under fairly high pressure when the modules are installed.

When tin and gold come into contact, because one surface is hard, the oxidation builds up and does not break easily under pressure. Increased contact resistance ultimately results in memory failures.

The connector manufacturer AMP has published several documents from the AMP Contact Physics Research Department that discuss this issue, but two are the most applicable. One is titled “Golden Rules: Guidelines for the Use of Gold on Connector Contacts,” and the other is called “The Tin Commandments: Guidelines for the Use of Tin on Connector Contacts.” Both can be downloaded in PDF form from the AMP Web site. Commandment Number Seven from the Tin Commandments specifically states “7. Mating of tin-coated contacts to gold-coated contacts is not recommended.” For further technical details, you can contact Intel or AMP.

Certainly, the best type of arrangement is having gold-plated modules installed in gold-plated sockets. Most systems using DIMMs or RIMMs are designed this way.

If you have mixed metals in your memory now, the correct solution is to replace the memory modules with the appropriate contact type to match the socket. Another much less desirable solution is to wait until problems appear (about six months to a year, in my experience) and then remove the modules, clean the contacts, reinstall, and repeat the cycle. This is probably fine if you are an individual with one or two systems, but it is not fine if you are maintaining hundreds of systems. If your system does not feature parity or ECC memory (most systems sold today do not), when the problems do occur, you might not be able to immediately identify them as memory related (General Protection Faults, crashes, file and data corruption, and so on).

One problem with cleaning is that the hard tin oxide deposits that form on the gold surface are difficult to remove and often require abrasive cleaning (by using an eraser or a crocus cloth, for example). This should never be done dry because it generates static discharges that can damage the chips. Instead, use a contact cleaner to lubricate the contacts; wet contacts minimize the potential for static discharge damage when rubbing the eraser or other abrasive on the surface.

To further prevent this problem from occurring, I highly recommend using a liquid contact enhancer and lubricant called Stabilant 22 from D.W. Electrochemicals when installing SIMMs or DIMMs. Its Web site has a detailed application note on this subject if you are interested in more technical details; see the Vendor List on the disc accompanying this book.

Some people have accused me of being too picky by insisting that the memory match the socket. On several occasions, I have returned either memory or motherboards because the vendor putting them together did not have a clue that this is a problem. When I tell some people about it, they tell me they have a lot of PCs with mixed metal contacts that run fine and have been doing so for many years.

Of course, that is certainly a poor argument against sound engineering practices. Many people are running SCSI buses that are way too long, with improper termination, and they say they run “fine.” Parallel port cables are by the spec limited to 10 feet, yet I see many that have longer cables, which people claim work “fine.” The IDE cable limit is 18”; that spec is violated and people get away with it, saying their drives run just “fine.” I see cheap, crummy power supplies that put out noise, ripple, and loosely regulated voltages, and I have even measured up to 69 volts AC of ground leakage, and yet the systems appeared to be running “fine.” I have encountered numerous systems without proper CPU heatsinks, or in which the active heatsink (fan) was seized, and the system ran “fine.” This reminds me of when Johnny Carson would interview 100-year-old people and often got them to admit that they drank heavily and smoked cigarettes every day, as if those are good practices that ensure longevity!

The truth is I am often amazed at how poorly designed or implemented some systems are, and yet they do seem to work...for the most part. The occasional lockup or crash is just written off by the user as “that’s the way they all are.” All, except *my* systems, of course. In my systems, I adhere to proper design and engineering practices. In fact, I am often guilty of engineering or specifying overkill into things. Although it adds to the cost, they do seem to run better because of it.

In other words, what one individual can “get away” with does not change the laws of physics. It does not change the fact that for those supporting many systems or selling systems where the maximum in reliability and service life is desired, the gold/tin issue does matter.

Another issue that was brought to my attention was the thickness of the gold on the contacts; people are afraid that it is so thin that it will wear off after one or two insertions. Certainly, the choice of gold coating thickness depends on the durability required by the application; because of gold’s high cost, it is prudent to keep the gold coating thickness as low as is appropriate for the durability requirements.

To improve durability, a small amount of cobalt or nickel added to the gold usually hardens the gold coatings. Such coatings are defined as “hard gold” and produce coatings with a low coefficient of friction and excellent durability characteristics. Hard gold-coated contacts can generally withstand hundreds to thousands of durability cycles without failing. Using an underlayer with a hardness value greater than that of gold alone that provides additional mechanical support can enhance the durability of hard gold coatings. Nickel is generally recommended as an underlayer for this purpose. Special electronic contact lubricants or enhancers, such as Stabilant 22 from D.W. Electrochemicals, are also effective at increasing the durability of gold coatings. Generally, lubrication can increase the durability of a gold contact by an order of magnitude. These and other chemicals are discussed in more detail in Chapter 24, “PC Diagnostics, Testing, and Maintenance.”

Increasing the thickness of a hard gold coating increases durability. AMP obtained the laboratory results in Table 6.21 for the wear-through of a hard gold coating to the 1.3 micron (50 micro-inch) thick nickel underplate. The following data is for a 0.635cm (0.250”) diameter ball wiped a distance of 1.27cm (0.500”) under a normal force of 100 grams for each cycle.

Table 6.21 Plating Thickness for Gold-Plated Contacts

Thickness Microns	Thickness Micro-inch	Cycles to Failure
0.4	15	200
0.8	30	1000
1.3	50	2000

As you can see from this table, an 0.8 micron (30 micro-inches) coating of hard gold results in durability that is more than adequate for most connector applications because it allows 1,000 insertion and removal cycles before wearing through. I studied the specification sheets for DIMM and SIMM sockets produced by AMP and found that its gold-plated sockets come mostly as .000030 (30 micro-inches) thick gold

over .000050 (50 micro-inches) thick nickel in the contact area. As far as I can determine, the coating on virtually all memory module contacts would be similar in thickness, allowing for the same durability.

AMP also has a few gold-plated sockets with specifications of .001020-thick (1,020 micro-inches) gold over .001270-thick (1,270 micro-inches) nickel. I'd guess that the latter sockets were for devices such as SIMM testers, in which many insertions were expected over the life of the equipment. They could also be used in high-vibration or high-humidity environments.

For reference, all its tin-contact SIMM and DIMM sockets have the following connector plating specifications: .000030 (30 micro-inches) minimum thick tin on mating edge over .000050 (50 micro-inches) minimum thick nickel on entire contact.

The bottom line is that the thickness of the coating in current module sockets and modules is not an issue for the expected use of these devices. The thickness of the plating used is also not relevant to the tin versus gold compatibility issue. The only drawback to a thinner gold plating is that it will wear after fewer insertion/removal cycles, exposing the nickel underneath and allowing the onset of fretting corrosion.

In my opinion, this tin/gold issue is even more important for those using DIMMs and RIMMs, for two reasons. With SIMMs, you really have two connections for each pin (one on each side of the module), so if one of them goes high resistance, it will not matter; there is a built-in redundancy. With DIMMs and RIMMs, you have many, many more connections (168 or 184 versus 72) and no redundant connections. The chance for failure is much greater. Also, DIMMs and RIMMs run much faster, at speeds of up to 800MHz or faster, where the timing is down in the single-digit nanosecond range. At these speeds, the slightest additional resistance in the connection causes problems.

Bottom line: Definitely don't mix metal types, but for the utmost in reliability for systems using DIMMs or RIMMs, be sure both the motherboard sockets as well as the modules themselves have gold-plated contacts. You usually can tell easily because tin is silver-colored, whereas gold is, well, gold-colored.

Parity and ECC

Part of the nature of memory is that it inevitably fails. These failures are usually classified as two basic types: hard fails and soft errors.

The best understood are *hard fails*, in which the chip is working and then, because of some flaw, physical damage, or other event, becomes damaged and experiences a permanent failure. Fixing this type of failure normally requires replacing some part of the memory hardware, such as the chip, SIMM, or DIMM. Hard error rates are known as *HERs*.

The other more insidious type of failure is the *soft error*, which is a nonpermanent failure that might never recur or could occur only at infrequent intervals. (Soft fails are effectively "fixed" by powering the system off and back on.) Soft error rates are known as *SERs*.

About 20 years ago, Intel made a discovery about soft errors that shook the memory industry. It found that alpha particles were causing an unacceptably high rate of soft errors or single event upsets (SEUs, as they are sometimes called) in the 16KB DRAMs that were available at the time. Because alpha particles are low-energy particles that can be stopped by something as thin and light as a sheet of paper, it became clear that for alpha particles to cause a DRAM soft error, they would have to be coming from within the semiconductor material. Testing showed trace elements of thorium and uranium in the plastic and ceramic chip packaging materials used at the time. This discovery forced all the memory manufacturers to evaluate their manufacturing processes to produce materials free from contamination.

Today, memory manufacturers have all but totally eliminated the alpha-particle source of soft errors. Many people believed that was justification for the industry trend to drop parity checking. The argument is that, for example, a 16MB memory subsystem built with 4MB technology would experience a soft error caused by alpha particles only about once every 16 years! The real problem with this thinking is that it is seriously flawed, and many system manufacturers and vendors were coddled into removing parity and other memory fault-tolerant techniques from their systems even though soft

errors continue to be an ongoing problem. More recent discoveries prove that alpha particles are now only a small fraction of the cause of DRAM soft errors.

As it turns out, the biggest cause of soft errors today are cosmic rays. IBM researchers began investigating the potential of terrestrial cosmic rays in causing soft errors similar to alpha particles. The difference is that cosmic rays are very high-energy particles and can't be stopped by sheets of paper or other more powerful types of shielding. The leader in this line of investigation was Dr. J.F. Ziegler of the IBM Watson Research Center in Yorktown Heights, New York. He has produced landmark research into understanding cosmic rays and their influence on soft errors in memory.

One example of the magnitude of the cosmic ray soft-error phenomenon demonstrated that with a certain sample of non-IBM DRAMs, the SER at sea level was measured at 5950 FIT (failures in time, which is measured at 1 billion hours) per chip. This was measured under real-life conditions with the benefit of millions of device hours of testing. In an average system, this would result in a soft error occurring every six months or less. In power-user or server systems with a larger amount of memory, it could mean one or more errors per month! When the exact same test setup and DRAMs were moved to an underground vault shielded by more than 50 feet of rock, thus eliminating all cosmic rays, absolutely no soft errors were recorded. This not only demonstrates how troublesome cosmic rays can be, but it also proves that the packaging contamination and alpha-particle problem has indeed been solved.

Cosmic-ray-induced errors are even more of a problem in SRAMs than DRAMs because the amount of charge required to flip a bit in an SRAM cell is less than is required to flip a DRAM cell capacitor. Cosmic rays are also more of a problem for higher-density memory. As chip density increases, it becomes easier for a stray particle to flip a bit. It has been predicted by some that the soft error rate of a 64MB DRAM will be double that of a 16MB chip, and a 256MB DRAM will have a rate four times higher.

Unfortunately, the PC industry has largely failed to recognize this cause of memory errors. Electrostatic discharge, power surges, or unstable software can much more easily explain away the random and intermittent nature of a soft error, especially right after a new release of an operating system or major application.

Studies have shown that the soft error rate for ECC systems is on the order of 30 times greater than the hard error rate. This is not surprising to those familiar with the full effects of cosmic-ray-generated soft errors. The number of errors experienced varies with the density and amount of memory present. Studies show that soft errors can occur from once a month or less to several times a week or more!

Although cosmic rays and other radiation events are the biggest cause of soft errors, soft errors can also be caused by the following:

- *Power glitches or noise on the line.* This can be caused by a defective power supply in the system or by defective power at the outlet.
- *Incorrect type or speed rating.* The memory must be the correct type for the chipset and match the system access speed.
- *RF (radio frequency) interference.* Caused by radio transmitters in close proximity to the system, which can generate electrical signals in system wiring and circuits. Keep in mind that the increased use of wireless networks, keyboards, and mice can lead to a greater risk of RF interference.
- *Static discharges.* Causes momentary power spikes, which alter data.
- *Timing glitches.* Data doesn't arrive at the proper place at the proper time, causing errors. Often caused by improper settings in the BIOS Setup, by memory that is rated slower than the system requires, or by overclocked processors and other system components.

Most of these problems don't cause chips to permanently fail (although bad power or static can damage chips permanently), but they can cause momentary problems with data.

How can you deal with these errors? Just ignoring them is certainly not the best way to deal with them, but unfortunately that is what many system manufacturers and vendors are doing today. The

best way to deal with this problem is to increase the system's fault tolerance. This means implementing ways of detecting and possibly correcting errors in PC systems. Three basic levels and techniques are used for fault tolerance in modern PCs:

- Nonparity
- Parity
- ECC

Nonparity systems have no fault tolerance at all. The only reason they are used is because they have the lowest inherent cost. No additional memory is necessary, as is the case with parity or ECC techniques. Because a parity-type data byte has 9 bits versus 8 for nonparity, memory cost is approximately 12.5% higher. Also, the nonparity memory controller is simplified because it does not need the logic gates to calculate parity or ECC check bits. Portable systems that place a premium on minimizing power might benefit from the reduction in memory power resulting from fewer DRAM chips. Finally, the memory system data bus is narrower, which reduces the amount of data buffers. The statistical probability of memory failures in a modern office desktop computer is now estimated at about one error every few months. Errors will be more or less frequent depending on how much memory you have.

This error rate might be tolerable for low-end systems that are not used for mission-critical applications. In this case, the extreme market sensitivity to price probably can't justify the extra cost of parity or ECC memory, and such errors then must be tolerated.

At any rate, having no fault tolerance in a system is simply gambling that memory errors are unlikely. You further gamble that if they do occur, memory errors will result in an inherent cost less than the additional hardware necessary for error detection. However, the risk is that these memory errors can lead to serious problems. A memory error in a calculation could cause the wrong value to go into a bank check. In a server, a memory error could force a system to hang and bring down all LAN-resident client systems with subsequent loss of productivity. Finally, with a nonparity or non-ECC memory system, tracing the problem is difficult, which is not the case with parity or ECC. These techniques at least isolate a memory source as the culprit, thus reducing both the time and cost of resolving the problem.

Parity Checking

One standard IBM set for the industry is that the memory chips in a bank of nine each handle 1 bit of data: 8 bits per character plus 1 extra bit called the *parity bit*. The parity bit enables memory-control circuitry to keep tabs on the other 8 bits—a built-in cross-check for the integrity of each byte in the system. If the circuitry detects an error, the computer stops and displays a message informing you of the malfunction. If you are running a GUI operating system, such as Windows or OS/2, a parity error generally manifests itself as a locked system. When you reboot, the BIOS should detect the error and display the appropriate error message.

SIMMs and DIMMs are available both with and without parity bits. Originally, all PC systems used parity-checked memory to ensure accuracy. Starting in 1994, a disturbing trend developed in the PC-compatible marketplace. Most vendors began shipping systems without parity checking or any other means of detecting or correcting errors! These systems can use cheaper nonparity SIMMs, which saves about 10%–15% on memory costs for a system. Parity memory results in increased initial system cost, primarily because of the additional memory bits involved. Parity can't correct system errors, but because parity can detect errors, it can make the user aware of memory errors when they happen. This has two basic benefits:

- Parity guards against the consequences of faulty calculations based on incorrect data.
- Parity pinpoints the source of errors, which helps with problem resolution, thus improving system serviceability.

PC systems can easily be designed to function using either parity or nonparity memory. The cost of implementing parity as an option on a motherboard is virtually nothing; the only cost is in actually purchasing

the parity SIMMs or DIMMs. This enables a system manufacturer to offer its system purchasers the choice of parity if the purchasers feel the additional cost is justified for their particular applications.

Unfortunately, several of the big names began selling systems without parity to reduce their prices, and they did not make it well known that the lower cost meant parity memory was no longer included as standard. This began happening mostly in 1994 and 1995, and it has continued until recently, with few people understanding the full implications. After one or two major vendors did this, most of the others were forced to follow to remain price-competitive.

Because nobody wanted to announce this information, it remained sort of a dirty little secret within the industry. Originally, when this happened you could still specify parity memory when you ordered a system, even though the default configurations no longer included it. There was a 10%–15% surcharge on the memory, but those who wanted reliable, trustworthy systems could at least get them, provided they knew to ask, of course. Then a major bomb hit the industry, in the form of the Intel Triton 430FX Pentium chipset, which was the first major chipset on the market that did not support parity checking at all! It also became the most popular chipset of its time and was found in practically all Pentium motherboards sold in the 1995 timeframe. This set a disturbing trend for the next few years. All but one of Intel's Pentium processor chipsets after the 430FX did not support parity-checked memory; the only one that did was the 430HX Triton II.

Since then, Intel and other chipset manufacturers have put support for parity and ECC memory in most of their chipsets (especially so in their higher-end models). The low-end chipsets, however, typically do lack support for either parity or ECC. If more reliability is important to you, make sure the systems you purchase have this support. In Chapter 4, you can learn which recent chipsets support parity and ECC memory and which ones do not.

Let's look at how parity checking works, and then examine in more detail the successor to parity checking, called ECC, which can not only detect but correct memory errors on-the-fly.

How Parity Checking Works

IBM originally established the odd parity standard for error checking. The following explanation might help you understand what is meant by odd parity. As the 8 individual bits in a byte are stored in memory, a parity generator/checker, which is either part of the CPU or located in a special chip on the motherboard, evaluates the data bits by adding up the number of 1s in the byte. If an even number of 1s is found, the parity generator/checker creates a 1 and stores it as the ninth bit (parity bit) in the parity memory chip. That makes the sum for all 9 bits (including the parity bit) an odd number. If the original sum of the 8 data bits is an odd number, the parity bit created would be a 0, keeping the sum for all 9 bits an odd number. The basic rule is that the value of the parity bit is always chosen so that the sum of all 9 bits (8 data bits plus 1 parity bit) is stored as an odd number. If the system used even parity, the example would be the same except the parity bit would be created to ensure an even sum. It doesn't matter whether even or odd parity is used; the system uses one or the other, and it is completely transparent to the memory chips involved. Remember that the 8 data bits in a byte are numbered 0 1 2 3 4 5 6 7. The following examples might make it easier to understand:

Data bit number:	0	1	2	3	4	5	6	7	Parity bit
Data bit value:	1	0	1	1	0	0	1	1	0

In this example, because the total number of data bits with a value of 1 is an odd number (5), the parity bit must have a value of 0 to ensure an odd sum for all 9 bits.

Here is another example:

Data bit number:	0	1	2	3	4	5	6	7	Parity bit
Data bit value:	1	1	1	1	0	0	1	1	1

In this example, because the total number of data bits with a value of 1 is an even number (6), the parity bit must have a value of 1 to create an odd sum for all 9 bits.

When the system reads memory back from storage, it checks the parity information. If a (9-bit) byte has an even number of bits, that byte must have an error. The system can't tell which bit has changed or whether only a single bit has changed. If 3 bits changed, for example, the byte still flags a parity-check error; if 2 bits changed, however, the bad byte could pass unnoticed. Because multiple bit errors (in a single byte) are rare, this scheme gives you a reasonable and inexpensive ongoing indication that memory is good or bad.

The following examples show parity-check messages for three types of older systems:

For the IBM PC:	PARITY CHECK x	
For the IBM XT:	PARITY CHECK x	yyyyy (z)
For the IBM AT and late model XT:	PARITY CHECK x	yyyyy

where x is 1 or 2:

- 1 = Error occurred on the motherboard
- 2 = Error occurred in an expansion slot

In this example, yyyyy represents a number from 00000 through FFFFF that indicates, in hexadecimal notation, the byte in which the error has occurred.

Where (z) is (S) or (E):

- (S) = Parity error occurred in the system unit
- (E) = Parity error occurred in an optional expansion chassis

Note

An expansion chassis was an option IBM sold for the original PC and XT systems to add more expansion slots.

When a parity-check error is detected, the motherboard parity-checking circuits generate a nonmaskable interrupt (NMI), which halts processing and diverts the system's attention to the error. The NMI causes a routine in the ROM to be executed. On some older IBM systems, the ROM parity-check routine halts the CPU. In such a case, the system locks up, and you must perform a hardware reset or a power-off/power-on cycle to restart the system. Unfortunately, all unsaved work is lost in the process.

Most systems do not halt the CPU when a parity error is detected; instead, they offer you the choice of rebooting the system or continuing as though nothing happened. Additionally, these systems might display the parity error message in a different format from IBM, although the information presented is basically the same. For example, most systems with a Phoenix BIOS display one of these messages:

```
Memory parity interrupt at xxxx:xxxx
Type (S)hut off NMI, Type (R)eboot, other keys to continue
```

or

```
I/O card parity interrupt at xxxx:xxxx
Type (S)hut off NMI, Type (R)eboot, other keys to continue
```

The first of these two messages indicates a motherboard parity error (Parity Check 1), and the second indicates an expansion-slot parity error (Parity Check 2). Notice that the address given in the form xxxx:xxxx for the memory error is in a segment:offset form rather than a straight linear address, such as with IBM's error messages. The segment:offset address form still gives you the location of the error to a resolution of a single byte.

You have three ways to proceed after viewing this error message:

- You can press S, which shuts off parity checking and resumes system operation at the point where the parity check first occurred.
- You can press R to force the system to reboot, losing any unsaved work.
- You can press any other key to cause the system to resume operation with parity checking still enabled.

If the problem occurs, it is likely to cause another parity-check interruption. It's usually prudent to press S, which disables the parity checking so you can then save your work. In this case, it's best to save your work to a floppy disk to prevent the possible corruption of the hard disk. You should also avoid overwriting any previous (still good) versions of whatever file you are saving because you could be saving a bad file caused by the memory corruption. Because parity checking is now disabled, your save operations will not be interrupted. Then, you should power the system off, restart it, and run whatever memory diagnostics software you have to try to track down the error. In some cases, the POST finds the error on the next restart, but you usually need to run a more sophisticated diagnostics program—perhaps in a continuous mode—to locate the error.

Systems with an AMI BIOS display the parity error messages in the following forms:

ON BOARD PARITY ERROR ADDR (HEX) = (xxxxx)

or

OFF BOARD PARITY ERROR ADDR (HEX) = (xxxxx)

These messages indicate that an error in memory has occurred during the POST, and the failure is located at the address indicated. The first one indicates that the error occurred on the motherboard, and the second message indicates an error in an expansion slot adapter card. The AMI BIOS can also display memory errors in the following manners:

Memory Parity Error at xxxxx

or

I/O Card Parity Error at xxxxx

These messages indicate that an error in memory has occurred at the indicated address during normal operation. The first one indicates a motherboard memory error, and the second indicates an expansion slot adapter memory error.

Although many systems enable you to continue processing after a parity error and even allow disabling further parity checking, continuing to use your system after a parity error is detected can be dangerous. The idea behind letting you continue using either method is to give you time to save any unsaved work before you diagnose and service the computer, but be careful how you do this.

Note that these messages can vary depending not only on the ROM BIOS but also on your operating system. Protected mode operating systems, such as most versions of Windows, trap these errors and run their own handler program that displays a message different from what the ROM would have displayed. The message might be associated with a blue screen or might be a trap error, but it usually indicates that it is memory or parity related. For example, Windows 98 displays a message indicating *Memory parity error detected. System halted.* when such an error has occurred.

Caution

When you are notified of a memory parity error, remember the parity check is telling you that memory has been corrupted. Do you want to save potentially corrupted data over the good file from the last time you saved? Definitely not! Be sure you save your work with a different filename. In addition, after a parity error, save only to a floppy disk if possible and avoid writing to the hard disk; there is a slight chance that the hard drive could become corrupt if you save the contents of corrupted memory.

After saving your work, determine the cause of the parity error and repair the system. You might be tempted to use an option to shut off further parity checking and simply continue using the system as though nothing were wrong. Doing so is like unscrewing the oil pressure warning indicator bulb on a car with an oil leak so the oil pressure light won't bother you anymore!

A few years ago, when memory was more expensive, a few companies marketed SIMMs with bogus parity chips. Instead of actually having the extra memory chips needed to store the parity bits, these “logic parity” or parity “emulation” SIMMs used an onboard parity generator chip. This chip ignored any parity the system was trying to store on the SIMM, but when data was retrieved, it always ensured that the correct parity was returned, thus making the system believe all was well even though there might have been a problem.

These bogus parity modules were used because memory was much more expensive and a company could offer a “parity” SIMM for only a few dollars more with the fake chip. Unfortunately, identifying them can be difficult. The bogus parity generator doesn’t look like a memory chip and has different markings from the other memory chips on the SIMM. Most of them had a “GSM” logo, which indicated the original manufacturer of the parity logic device, not necessarily the SIMM itself.

One way to positively identify these bogus fake parity SIMMs is by using a hardware SIMM test machine, such as those by Tanisys (www.tanisys.com), CST (www.simmtester.com), or Innoventions (www.memorytest.com). I haven’t seen DIMMs or RIMMs with fake parity/ECC bits, and memory prices have come down far enough that it probably isn’t worth the trouble anymore.

Error Correcting Code

ECC goes a big step beyond simple parity-error detection. Instead of just detecting an error, ECC allows a single bit error to be corrected, which means the system can continue without interruption and without corrupting data. ECC, as implemented in most PCs, can only detect, not correct, double-bit errors. Because studies have indicated that approximately 98% of memory errors are the single-bit variety, the most commonly used type of ECC is one in which the attendant memory controller detects and corrects single-bit errors in an accessed data word (double-bit errors can be detected but not corrected). This type of ECC is known as *single-bit error-correction double-bit error detection (SEC-DED)* and requires an additional 7 check bits over 32 bits in a 4-byte system and an additional 8 check bits over 64 bits in an 8-byte system. ECC in a 4-byte (32-bit, such as a 486) system obviously costs more than nonparity or parity, but in an 8-byte-wide bus (64-bit, such as Pentium/Athlon) system, ECC and parity costs are equal because the same number of extra bits (8) is required for either parity or ECC. Because of this, you can purchase parity SIMMs (36-bit), DIMMs (72-bit), or RIMMs (18-bit) for 32-bit systems and use them in an ECC mode if the chipset supports ECC functionality. If the system uses SIMMs, two 36-bit (parity) SIMMs are added for each bank (for a total of 72 bits), and ECC is done at the bank level. If the system uses DIMMs, a single parity/ECC 72-bit DIMM is used as a bank and provides the additional bits. RIMMs are installed in singles or pairs, depending on the chipset and motherboard. They must be 18-bit versions if parity/ECC is desired.

ECC entails the memory controller calculating the check bits on a memory-write operation, performing a compare between the read and calculated check bits on a read operation, and, if necessary, correcting bad bits. The additional ECC logic in the memory controller is not very significant in this age of inexpensive, high-performance VLSI logic, but ECC actually affects memory performance on writes. This is because the operation must be timed to wait for the calculation of check bits and, when the system waits for corrected data, reads. On a partial-word write, the entire word must first be read, the affected byte(s) rewritten, and then new check bits calculated. This turns partial-word write operations into slower read-modify writes. Fortunately, this performance hit is very small, on the order of a few percent at maximum, so the tradeoff for increased reliability is a good one.

Most memory errors are of a single-bit nature, which ECC can correct. Incorporating this fault-tolerant technique provides high system reliability and attendant availability. An ECC-based system is a good choice for servers, workstations, or mission-critical applications in which the cost of a potential memory error outweighs the additional memory and system cost to correct it, along with ensuring that it does not detract from system reliability. If you value your data and use your system for important (to you) tasks, you’ll want ECC memory. No self-respecting manager would build or run a network server, even a lower-end one, without ECC memory.

By designing a system that allows the user to make the choice of ECC, parity, or nonparity, users can choose the level of fault tolerance desired, as well as how much they want to gamble with their data.

Installing RAM Upgrades

Adding memory to a system is one of the most useful upgrades you can perform and also one of the least expensive—especially when you consider the increased capabilities of Windows 9x/Me, Windows NT/2000/XP, and OS/2 when you give them access to more memory. In some cases, doubling the memory can practically double the speed of a computer.

The following sections discuss adding memory, including selecting memory chips, installing memory chips, and testing the installation.

Upgrade Options and Strategies

Adding memory can be an inexpensive solution; at this writing, the cost of memory has fallen to about 12 cents per megabyte or less. A small dose can give your computer's performance a big boost.

How do you add memory to your PC? You have two options, listed in order of convenience and cost:

- Adding memory in vacant slots on your motherboard
- Replacing your current motherboard's memory with higher-capacity memory

If you decide to upgrade to a more powerful computer system or motherboard, you usually can't salvage the memory from your previous system. Most of the time it is best to plan on equipping a new board with the optimum type of memory that it supports.

Be sure to carefully weigh your future needs for computing speed and a multitasking operating system (OS/2, Windows 9x, Windows NT, Windows 2000, or Linux, for example) against the amount of money you spend to upgrade current equipment.

Before you add RAM to a system (or replace defective RAM chips), you must determine the memory chips required for your system. Your system documentation has this information.

If you need to replace a defective memory module and do not have the system documentation, you can determine the correct module for your system by inspecting the ones that are already installed. Each module has markings that indicate the module's capacity and speed. RAM capacity and speed are discussed in detail earlier in this chapter.

If you do not have the documentation for your system and the manufacturer does not offer technical support, open your system case and carefully write down the markings that appear on your memory chips. Then contact a local computer store or module vendor, such as Kingston, Micron (Crucial), PNY, or others, for help in determining the proper RAM chips for your system. Adding the wrong modules to a system can make it as unreliable as leaving a defective module installed and trying to use the system in that condition.

Note

Before upgrading an older Pentium (P5 class) system beyond 64MB of RAM, be sure your chipset supports caching more than 64MB. Adding RAM beyond the amount supported by your L2 cache slows performance rather than increases it. See the section "Cache Memory: SRAM," earlier in this chapter, and the discussion of chipsets in Chapter 4 for a more complete explanation of this common system limitation. This limitation was mostly with Pentium (P5) class chipsets. Pentium II and later processors, including the AMD Athlon and Duron, have the L2 cache controller integrated in the processor (not the chipset), which supports caching up to 1GB, or 4GB on most newer models. With the higher price of older SIMM-type memory modules per megabyte compared to SDRAM and DDR-SDRAM, you might find it more cost-effective to replace your motherboard, processor, and memory with new components than to add memory to an older system that uses SIMMs.

Selecting and Installing Memory

If you are upgrading a motherboard by adding memory, follow the manufacturer's guidelines on which memory chips or modules to buy. As you learned earlier, memory comes in various form factors, including SIMMs, DIMMs, and RIMMs.

No matter which type of memory modules you have, the chips are installed in memory banks. A *memory bank* is a collection of memory chips that make up a complete row of memory. Your processor reads each row of memory in one pass. A memory bank does not work unless the entire row is filled with memory chips. (Banks are discussed in more detail earlier in this chapter in the section "Memory Banks.")

Installing extra memory on your motherboard is an easy way to add memory to your computer. Most systems have at least one vacant memory bank where you can install extra memory at a later time and speed up your computer.

If your system requires dual-channel memory, as some high-performance systems do, you must use two identical memory modules (same size, speed, and type).

Purchasing Memory

When purchasing memory, there are some issues you need to consider. Some are related to the manufacturing and distribution of memory, whereas others depend on the type of memory you are purchasing. This section covers some of the issues you should consider when purchasing memory.

Suppliers

Many companies sell memory, but only a few companies actually *make* memory. Additionally, only a few companies make memory chips, but many more companies make memory modules such as SIMMs, DIMMs, and RIMMs. Most of the companies that make the actual RAM chips also make modules containing their own chips. Other companies, however, strictly make modules; these companies purchase memory chips from several chip makers and then produce modules with these chips. Finally, some companies don't make either the chips or modules. Instead, they purchase modules made by other companies and relabel them.

I refer to memory modules made by the chip manufacturers as first-party modules, whereas those made by module (but not chip) manufacturers I call second-party modules. Finally, those that are simply relabeled first- or second-party modules under a different name are called third-party modules. I always prefer to purchase first- or second-party modules if I can because they are better documented. In essence they have a better pedigree and their quality is generally more assured. Not to mention that purchasing from the first or second party eliminates one or more middlemen in the distribution process as well.

First-party manufacturers (where the same company makes the chips and the modules) include Micron (<http://www.crucial.com>), Infineon (formerly Siemens), Samsung, Mitsubishi, Toshiba, NEC, and others. Second-party companies that make the modules (but not the chips) include Kingston, Viking, PNY, Simple Tech, Smart, Mushkin, and OCZ Technologies.

At the third-party level you are not purchasing from a manufacturer but from a reseller or remarketer instead. Although I call this third-party memory, some people call these modules *major on third*, which is British slang used to indicate that the memory modules are sourced from a third-party manufacturer (which might be unspecified) even though they are using name brand chips. It is derived from saying that a given memory module is made from memory chips supplied by a "major" memory chip manufacturer "on third"-party manufactured SIMM/DIMM boards. That particular slang term is not often used in the United States.

Most of the large manufacturers don't sell small quantities of memory to individuals, but some have set up factory outlet stores where individuals can purchase as little as a single module. Two of the largest memory manufacturers in the world, Samsung and Micron, both have factory outlet stores you can use. Because you are buying direct, the pricing is often highly competitive with the second- and third-party suppliers. Micron's factory outlet store is <http://www.crucial.com>.

SIMMs

When purchasing SIMMs, the main things to consider are as follows:

- Do you need FPM (Fast Page Mode) or EDO (extended data out) versions?
- Do you need ECC or non-ECC?
- What speed grade do you need?

Most Pentium systems after 1995 used EDO SIMMs that were non-ECC and rated for 60ns access time. If your system is older than that, you might need regular FPM versions. The FPM and EDO types are interchangeable in many systems, but some older systems do not accept the EDO type. If your system is designed for high-reliability using ECC, you might need (or want) ECC versions; otherwise, standard non-ECC types are typically used. You can mix the two, but in that case the system defaults to non-ECC mode.

Unfortunately, FPM and EDO SIMMs are obsolete by today's standards, so they are much more expensive than newer, better, and faster types of memory. This can make adding memory to older systems cost prohibitive.

Tip

Instead of buying new SIMM memory for older systems, check with computer repair shops or other users who might have a collection of old parts.

DIMMs

When purchasing DIMMs, the main things to consider are as follows:

- Do you need SDR or DDR versions?
- Do you need ECC or non-ECC?
- Do you need registered or unbuffered versions?
- What speed grade do you need?
- Do you need a specific column address strobe (CAS) latency?

Currently, DIMMs come in single data rate (SDR) and double data rate (DDR) versions, with most newer systems using the DDR type; look for the first DDR2 modules and systems in late 2003. They are not interchangeable because they use completely different signaling and have different notches to prevent a mismatch. High-reliability systems such as servers can use ECC versions, although most systems use the less-expensive non-ECC types. Most systems use standard unbuffered DIMMs, but file server or workstation motherboards designed to support very large amounts of memory might require registered DIMMs. Registered DIMMs contain their own memory registers, enabling the module to hold more memory than a standard DIMM. DIMMs come in a variety of speeds, with the rule that you can always substitute a faster one for a slower one, but not vice versa. As an example, if your system requires PC2100 DDR DIMMs, you can install faster PC2700 DDR DIMMs but not slower PC1600 versions.

Another speed-related issue is the column address strobe (CAS) latency. Sometimes this specification is abbreviated CAS or CL and is expressed in a number of cycles, with lower numbers indicating higher speeds (fewer cycles). The lower CAS latency shaves a cycle off a burst mode read, which marginally improves memory performance. Single data rate DIMMs are available in CL3 or CL2 versions, with the CL2 being faster. DDR DIMMs are available in CL2.5 or CL2 versions, with CL2 being the faster and better version in that case. You can mix DIMMs with different CAS latency ratings, but the system usually defaults to cycling at the slower speeds of the lowest common denominator.

RIMMs

When purchasing RIMMs, the main things to consider are as follows:

- Do you need 184-pin (16/18-bit) or 232-pin (32/36-bit) versions?
- Do you need ECC or non-ECC?
- What speed grade do you need?

RIMMs are available in 184-pin and 232-pin versions, and although they appear to be the same size, they are not interchangeable. Differences exist in the notches that prevent a mismatch. High-reliability systems might want or need ECC versions, which have extra ECC bits. As with other memory types, you can mix ECC and non-ECC types, but systems can't use the ECC capability.

Replacing Modules with Higher-Capacity Versions

If all the memory module slots on your motherboard are occupied, your best option is to remove an existing bank of memory and replace it with higher-capacity modules. For example, if you have a motherboard that supports two DIMM modules (each representing one bank on a processor with a 64-bit data bus), you could remove one of them and replace it with a higher-capacity version. For example, if you have two 64MB modules giving a total of 128MB, you could remove one of the 64MB modules and replace it with a 128MB unit, in which case you'd then have a total of 192MB of RAM.

However, just because higher-capacity modules are available that are the correct pin count to plug into your motherboard, don't automatically assume the higher-capacity memory will work. Your system's chipset and BIOS set limits on the capacity of the memory you can use. Check your system or motherboard documentation to see which size modules work with it before purchasing the new RAM. You should make sure you have the latest BIOS for your motherboard when installing new memory.

Installing Memory

This section discusses installing memory—specifically, new SIMM or DIMM modules. It also covers the problems you are most likely to encounter and how to avoid them. You also get information on configuring your system to use new memory.

When you install or remove memory, you are most likely to encounter the following problems:

- Electrostatic discharge
- Improperly seated modules
- Incorrect memory configuration settings in the BIOS Setup

To prevent electrostatic discharge (ESD) when you install sensitive memory chips or boards, you shouldn't wear synthetic-fiber clothing or leather-soled shoes because these promote the generation of static charges. Remove any static charge you are carrying by touching the system chassis before you begin, or better yet, wear a good commercial grounding strap on your wrist. You can order one from

any electronics parts store. A grounding strap consists of a conductive wristband grounded at the other end through a 1-meg ohm resistor by a wire clipped to the system chassis. Be sure the system you are working on is unplugged.

Caution

Be sure to use a properly designed commercial grounding strap; do not make one yourself. Commercial units have a 1-meg ohm resistor that serves as protection if you accidentally touch live power. The resistor ensures that you do not become the path of least resistance to the ground and therefore become electrocuted. An improperly designed strap can cause the power to conduct through you to the ground, possibly killing you.

Each memory chip or module must be installed in a specific orientation. Interference fit notches and tangs are designed to prevent improper installation of the module into the socket. As long as you are observant and don't try to force anything, the proper orientation should be fairly easy to figure out. As you insert the module, be sure the notches align with the appropriate tangs on the socket.

I would hope it goes without saying, but before installing memory, be sure the system power is off! You should make sure the system is unplugged from any power outlets just to be sure. If you were to install memory while the power was on (even if the system was in a sleep mode), you would probably fry not only the memory but possibly the entire motherboard as well. Most newer systems incorporate standby power connections, so they are partially powered on even when the system is powered off. The only way to ensure such systems are really powered off completely is to unplug them from the wall socket.

You remove SIMMs, DIMMs, or RIMMs by releasing the locking tabs and either pulling or rolling them out of their sockets. The installation is exactly the opposite.

After adding the memory and putting the system back together, you might have to run the BIOS Setup and resave with the new amount of memory being reported. Most newer systems automatically detect the new amount of memory and reconfigure the BIOS Setup settings for you. Most newer systems also don't require setting any jumpers or switches on the motherboard to configure them for your new memory.

After configuring your system to work properly with the additional memory, you might want to run a memory-diagnostics program to ensure that the new memory works properly. Some are run automatically for you. At least two and sometimes three memory-diagnostic programs are available for all systems. In order of accuracy, these programs are as follows:

- POST (power on self test)
- Disk-based advanced diagnostics software

The POST is used every time you power up the system.

Many additional diagnostics programs are available from aftermarket utility software companies. More information on aftermarket testing facilities can be found in Chapter 24.

Installing SIMMs

SIMM memory is oriented by a notch on one side of the module that is not present on the other side, as shown in Figure 6.14. The socket has a protrusion that must fit into this notched area on one side of the module. This protrusion makes installing a SIMM backward impossible unless you break the connector or the module. Figure 6.15 details the notch and locking clip.

Figure 6.14 The notch on this SIMM is shown on the left side. Insert the SIMM at a 45° angle and then tilt it forward until the locking clips snap into place.

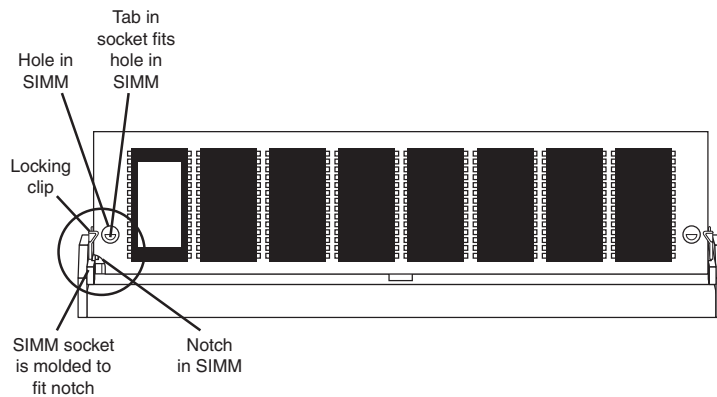

Figure 6.15 This figure shows the SIMM inserted in the socket with the notch aligned, the locking clip locked, and the hole in the SIMM aligned with the tab in the socket.

Installing DIMMs and RIMMs

Similarly, DIMMs and RIMMs are keyed by notches along the bottom connector edge that are offset from the center so they can be inserted in only one direction, as shown in Figure 6.16.

The DIMM/RIMM ejector tab locks into place in the notch on the side of the DIMM when it is fully inserted. Some DIMM sockets have ejector tabs on both ends. Take care not to force the module into the socket. If the module does not slip easily into the slot and then snap into place, the module is probably not oriented or aligned correctly. Forcing the module could break the module or the socket. If the retaining clips on the socket break, the memory isn't held firmly in place, and you likely will get random memory errors because the module can't make consistent electrical contact if it is loose.

Figure 6.16 DIMM keys match the protrusions in the DIMM sockets. DDR DIMM and RIMM keys are similar but not exactly the same.

Installing RIMMs

RIMMs install in exactly the same manner as DIMMs, although in different sockets. The ejector tabs on the sides are similar, and they go in at a straight 90° angle just like DIMMs. The key notches on the RIMM prevent backward installation and aid alignment when inserting them.

You'll also need to fill any empty RIMM sockets with a continuity module. Refer to Figure 6.11 for details on this module.

Troubleshooting Memory

Memory problems can be difficult to troubleshoot. For one thing, computer memory is still mysterious to people because it is a kind of “virtual” thing that can be hard to grasp. The other difficulty is that memory problems can be intermittent and often look like problems with other areas of the system, even software. This section shows simple troubleshooting steps you can perform if you suspect you are having a memory problem.

To troubleshoot memory, you first need some memory-diagnostics testing programs. You already have several, and might not know it. Every motherboard BIOS has a memory diagnostic in the POST that runs when you first turn on the system. In most cases, you also receive a memory diagnostic on a utility disk that came with your system. Many commercial diagnostics programs are on the market, and almost all of them include memory tests.

When the POST runs, it not only tests memory, but also counts it. The count is compared to the amount counted the last time BIOS Setup was run; if it is different, an error message is issued. As the POST runs, it writes a pattern of data to all the memory locations in the system and reads that pattern back to verify that the memory works. If any failure is detected, you see or hear a message. Audio messages (beeping) are used for critical or “fatal” errors that occur in areas important for the system’s operation. If the system can access enough memory to at least allow video to function, you see error messages instead of hearing beep codes.

See the disc accompanying this book for detailed listings of the BIOS beep and other error codes, which are specific to the type of BIOS you have. These BIOS codes are found in the Technical Reference section of the disc in printable PDF format for your convenience. For example, most Intel motherboards use the Phoenix BIOS. Several beep codes are used in that BIOS to indicate fatal memory errors.

If your system makes it through the POST with no memory error indications, there might not be a hardware memory problem, or the POST might not be able to detect the problem. Intermittent memory errors are often not detected during the POST, and other subtle hardware defects can be hard for the POST to catch. The POST is designed to run quickly, so the testing is not nearly as thorough as it could be. That is why you often have to boot from a DOS or diagnostic disk and run a true hardware diagnostic to do more extensive memory testing. These types of tests can be run continuously and be left running for days if necessary to hunt down an elusive intermittent defect.

Still, even these programs do only pass/fail type testing; that is, all they can do is write patterns to memory and read them back. They can't determine how close the memory is to failing—only whether it worked. For the highest level of testing, the best thing to have is a dedicated memory test machine, usually called a *SIMM/DIMM/RIMM module tester*. These devices enable you to insert a module and test it thoroughly at a variety of speeds, voltages, and timings to let you know for certain whether the memory is good or bad. Versions of these testers are available to handle all types of memory from older SIMMs to the latest DDR DIMMs or RIMMs. I have defective modules, for example, that work in some systems (slower ones) but not others. What I mean is that the *same* memory test program fails the module in one machine but passes it in another. In the module tester, it is always identified as bad right down to the individual bit, and it even tells me the actual speed of the device, not just its rating. Companies that offer memory module testers include Tanisys (www.tanisys.com), CST (www.simmtester.com), and Innoventions (www.memorytest.com). They can be expensive, but for a professional in the PC repair business, using one of these SIMM/DIMM testers is the only way to go.

After your operating system is running, memory errors can still occur, typically identified by error messages you might receive. These are the most common:

- **Parity errors.** Indicates that the parity-checking circuitry on the motherboard has detected a change in memory since the data was originally stored. (See the “How Parity Checking Works” section earlier in this chapter.)
- **General or global protection faults.** A general-purpose error indicating that a program has been corrupted in memory, usually resulting in immediate termination of the application. This can also be caused by buggy or faulty programs.
- **Fatal exception errors.** Error codes returned by a program when an illegal instruction has been encountered, invalid data or code has been accessed, or the privilege level of an operation is invalid.
- **Divide error.** A general-purpose error indicating that a division by 0 was attempted or the result of an operation does not fit in the destination register.

If you are encountering these errors, they could be caused by defective or improperly configured memory, but they can also be caused by software bugs (especially drivers), bad power supplies, static discharges, close proximity radio transmitters, timing problems, and more.

If you suspect the problems are caused by memory, there are ways to test the memory to determine whether that is the problem. Most of this testing involves running one or more memory test programs.

I am amazed that most people make a critical mistake when they run memory test software. The biggest problem I see is that people run memory tests with the system caches enabled. This effectively invalidates memory testing because most systems have what is called a *write-back cache*. This means that data written to main memory is first written to the cache. Because a memory test program first writes data and then immediately reads it back, the data is read back from the cache, not the main memory. It makes the memory test program run very quickly, but all you tested was the cache. The bottom line is that if you test memory with the cache enabled, you aren't really writing to the

SIMM/DIMMs, but only to the cache. Before you run any memory test programs, be sure your cache is disabled. The system will run very slowly when you do this, and the memory test will take much longer to complete, but you will be testing your actual RAM, not the cache.

The following steps enable you to effectively test and troubleshoot your system RAM. Figure 6.17 provides a boiled-down procedure to help you step through the process quickly.

First, let's cover the memory testing and troubleshooting procedures.

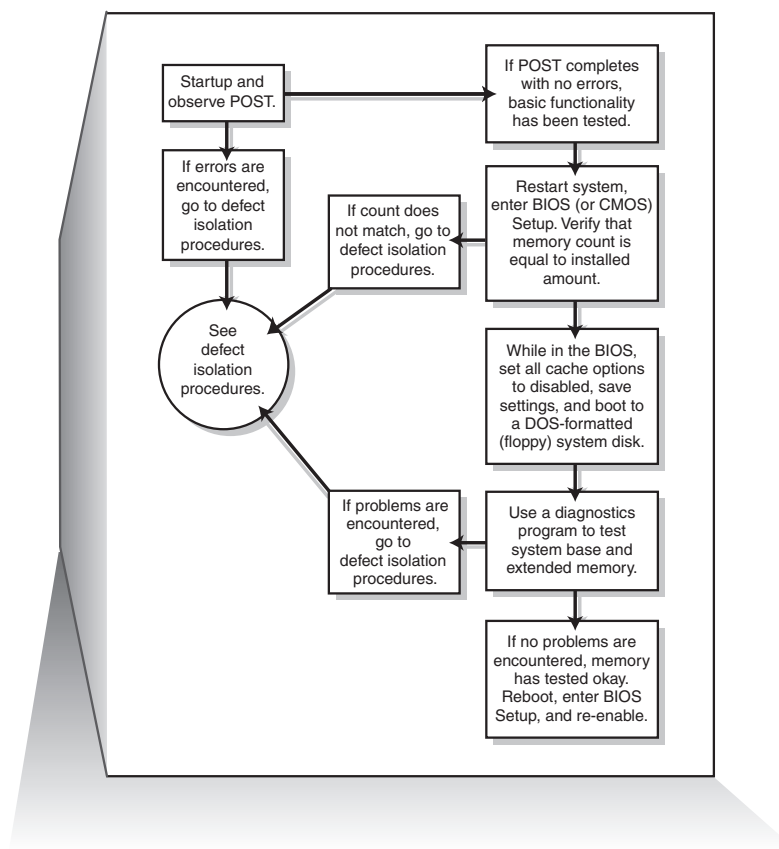

Figure 6.17 Testing and troubleshooting memory.

1. Power up the system and observe the POST. If the POST completes with no errors, basic memory functionality has been tested. If errors are encountered, go to the defect isolation procedures.
2. Restart the system, and enter your BIOS (or CMOS) Setup. In most systems, this is done by pressing the F2 key during the POST but before the boot process begins. Once in BIOS Setup, verify that the memory count is equal to the amount that has been installed. If the count does not match what has been installed, go to the defect isolation procedures.
3. Find the BIOS Setup options for cache, and set all cache options to disabled. Save the settings and reboot to a DOS-formatted system disk (floppy) containing the diagnostics program of your choice. If your system came with a diagnostics disk, you can use that, or you can use one of the many commercial PC diagnostics programs on the market, such as PC-Technician by Windsor Technologies (which comes in self-booting form), the Norton Utilities by Symantec, or others.

4. Follow the instructions that came with your diagnostic program to have it test the system base and extended memory. Most programs have a mode that enables them to loop the test—that is, to run it continuously, which is great for finding intermittent problems. If the program encounters a memory error, proceed to the defect isolation procedures.
5. If no errors are encountered in the POST or in the more comprehensive memory diagnostic, your memory has tested okay in hardware. Be sure at this point to reboot the system, enter the BIOS Setup, and re-enable the cache. The system will run very slowly until the cache is turned back on.
6. If you are having memory problems yet the memory still tests okay, you might have a problem undetectable by simple pass/fail testing, or your problems could be caused by software or one of many other defects or problems in your system. You might want to bring the memory to a SIMM/DIMM tester for a more accurate analysis. Most PC repair shops have such a tester. I would also check the software (especially drivers, which might need updating), power supply, and system environment for problems such as static, radio transmitters, and so forth.

Memory Defect Isolation Procedures

To use these steps, I am assuming you have identified an actual memory problem that is being reported by the POST or disk-based memory diagnostics. If this is the case, see the following steps and Figure 6.18 for the steps to identify or isolate which SIMM or DIMM in the system is causing the problem.

1. Restart the system and enter the BIOS Setup. Under a menu usually called Advanced or Chipset Setup might be memory timing parameters. Select BIOS or Setup defaults, which are usually the slowest settings. Save the settings, reboot, and retest using the testing and troubleshooting procedures listed earlier. If the problem has been solved, improper BIOS settings were the problem. If the problem remains, you likely do have defective memory, so continue to the next step.
2. Open the system for physical access to the SIMM/DIMM/RIMMs on the motherboard. Identify the bank arrangement in the system. For example, Pentium systems use 64-bit banks, which means two SIMMs or one DIMM per bank. Pentium 4 systems require two 184-pin RIMMs at a time (in separate channels) or a single 232-pin RIMM if the system uses that type. Using the manual or the legend silk-screened on the motherboard, identify which modules correspond to which banks.
3. Remove all the memory except the first bank, and retest using the troubleshooting and testing procedures listed earlier. If the problem remains with all but the first bank removed, the problem has been isolated to the first bank, which must be replaced.
4. Replace the memory in the first bank, preferably with known good spare modules, but you can also swap in others that you have removed and retest. If the problem *still* remains after testing all the memory banks (and finding them all to be working properly), it is likely the motherboard itself is bad (probably one of the memory sockets). Replace the motherboard and retest.
5. At this point, the first (or previous) bank has tested good, so the problem must be in the remaining modules that have been temporarily removed. Install the next bank of memory and retest. If the problem resurfaces now, the memory in that bank is defective. Continue testing each bank until you find the defective module.
6. Repeat the preceding step until all remaining banks of memory are installed and have been tested. If the problem has not resurfaced after removing and reinstalling all the memory, the problem was likely intermittent or caused by poor conduction on the memory contacts. Often simply removing and replacing memory can resolve problems because of the self-cleaning action between the module and the socket during removal and installation.

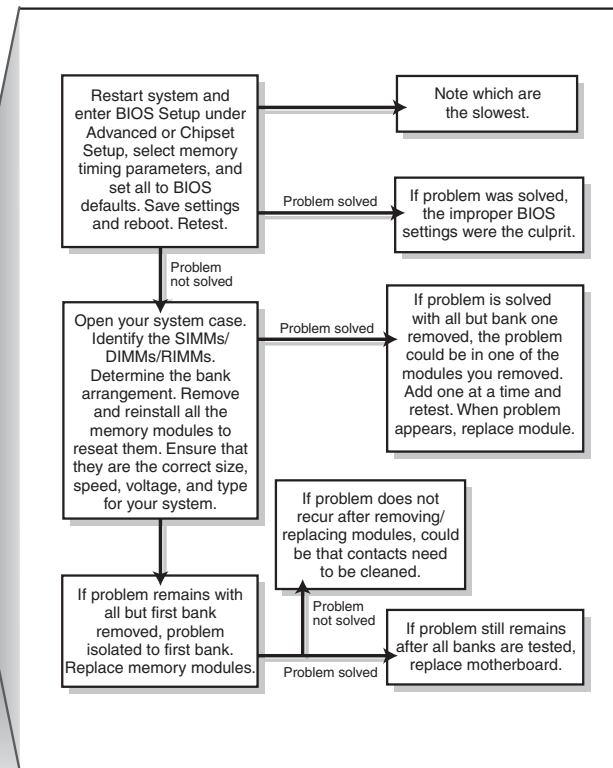

Figure 6.18 Follow these steps if you are still encountering memory errors after completing the steps in Figure 6.17.

The System Logical Memory Layout

The original PC had a total of 1MB of addressable memory, and the top 384KB of that was reserved for use by the system. Placing this reserved space at the top (between 640KB and 1024KB instead of at the bottom, between 0KB and 640KB) led to what is often called the *conventional memory barrier*. The constant pressures on system and peripheral manufacturers to maintain compatibility by never breaking from the original memory scheme of the first PC has resulted in a system memory structure that is (to put it kindly) a mess. Almost two decades after the first PC was introduced, even the newest Pentium 4-based systems are limited in many important ways by the memory map of the first PCs.

What we end up with is a PC with a split personality. There are two primary modes of operation that are very different from each other. The original PC used an Intel 8088 processor that could run only 16-bit instructions or code, which ran in what was called the real mode of the processor. These early processors had only enough address lines to access up to 1MB of memory, and the last 384KB of that was reserved for use by the video card as video RAM, other adapters (for on-card ROM BIOS), and finally the motherboard ROM BIOS.

The 286 processor brought more address lines, enough to allow up to 16MB of RAM to be used, and a new mode called *protected mode* that you had to be in to use it. Unfortunately, all the operating systems software at the time was designed to run only within the first 1MB, so extender programs were

added and other tricks performed to eventually allow DOS and Windows 3.x access up to the first 16MB. One area of confusion was that RAM was now noncontiguous; that is, the operating system could use the first 640KB and the last 15MB, but not the 384KB of system reserved area that sat in between.

When Intel released the first 32-bit processor in 1985 (the 386DX), the memory architecture of the system changed dramatically. There were now enough address lines for the processor to use 4GB of memory, but this was accessible only in a new 32-bit *protected mode* in which only 32-bit instructions or code could run. This mode was designed for newer, more advanced operating systems, such as Windows 9x, NT, 2000, XP, OS/2, Linux, Unix, and so forth. With the 386 came a whole new memory architecture in which this new 32-bit software could run. Unfortunately, it took 10 years for the mainstream user to upgrade to 32-bit operating systems and applications, which shows how stubborn we are! From a software instruction perspective, all the 32-bit processors since the 386 are really just faster versions of the same. Other than the more recent additions of MMX and SSE (or AMD's 3DNow) instructions to the processor, for all intents and purposes, a Pentium 4 or Athlon is just a "turbo" 386. Even more advanced server-oriented, 64-bit instruction set processors such as the Intel Itanium and AMD Opteron processors fit into this category because they can also run 32-bit software.

The real problem now is that the 32-bit processors have two distinctly different modes, with different memory architectures in each. For backward compatibility, you could still run the 32-bit processors in real mode, but only 16-bit software could run in that mode, and such software could access only the first 1MB or 16MB, depending on how it was written. For example, 16-bit drivers could load into and access only the first 1MB. Also, it is worth noting that the system ROM BIOS, including the POST, BIOS configuration, boot code, and all the internal drivers, is virtually all 16-bit software. This is because all Intel-compatible PC processors begin operation in 16-bit real mode when they are powered on. When a 32-bit operating system loads, it is that operating system code that instructs the processor to switch into 32-bit protected mode.

When an operating system such as Windows is loaded, the processor is switched into 32-bit protected mode early in the loading sequence. Then, 32-bit drivers for all the hardware can be loaded, and then the rest of the operating system can load. In 32-bit protected mode, the operating systems and applications can access all the memory in the system, up to the maximum limit of the processor (64GB for most of the Pentium II and later chips).

Unfortunately, one problem with protected mode is just that: It is protected. The name comes from the fact that only driver programs are allowed to talk directly to the hardware in this mode; programs loaded by the operating system, such as by clicking an icon in Windows, are not allowed to access memory or other hardware directly. This protection is provided so that a single program can't crash the machine by doing something illegal. You might have seen the error message in Windows indicating this, and that the program will be shut down.

Diagnostics software by nature must talk to the hardware directly. This means that little intensive diagnostics testing can be done while a protected mode operating system such as Windows 9x, NT, 2000, XP, Linux, and so forth is running. For system testing, you usually have to boot from a DOS floppy or interrupt the loading of Windows (press the F8 key when Starting Windows appears during the boot process) and select Command Prompt Only, which boots you into DOS. In Windows 9x (but not Me), you can execute a shutdown and select Restart the Computer in MS-DOS mode. Many of the higher-end hardware diagnostics programs include their own special limited 16-bit operating systems so they can more easily access memory areas even DOS would use. With Windows 2000 and XP, you can format a floppy disk with MS-DOS startup files by selecting that option from the Format menu in My Computer.

For example, when you boot from a Windows 9x startup disk, you are running 16-bit DOS, and if you want to access your CD-ROM drive to install Windows, you must load a 16-bit CD-ROM driver program from that disk as well. In this mode, you can do things such as partition and format your hard disk, install Windows, or test the system completely. OEM versions of Windows 98 and all versions of Windows Me and newer come on bootable CDs, so if your system supports booting from a CD-ROM drive, be sure to set that option in the BIOS Setup to eliminate the need for a formatted floppy disk.

The point of all this is that although you might not be running DOS very much these days, at least for system configuration and installation, as well as for high-level hardware diagnostics testing, data recovery, and so forth, you might still have to boot to a 16-bit OS occasionally. When you are in that mode, the system's architecture changes, less memory is accessible, and some of the software you are running (16-bit drivers and most application code) must fight over the first 1MB or even 640KB for space.

The system memory areas discussed in this chapter, including the 384KB at the top of the first megabyte, which is used for video, adapter BIOS, and motherboard BIOS, as well as the remaining extended memory, are all part of the PC hardware design. They exist whether you are running 16-bit or 32-bit software; however, the limitations on their use in 16-bit (real) mode are much more severe. Because most people run 32-bit operating systems, such as Windows 9x, 2000, XP, Linux, and so on, these operating systems automatically manage the use of RAM, meaning you don't have to interact with and manage this memory yourself as you often did with the 16-bit operating systems.

The following sections are intended to give you an understanding of the PC hardware memory layout, which is consistent no matter which operating system you use. The only things that change are how your operating system uses these areas and how they are managed by the OS.

The following sections detail the various types of memory installed on a modern PC. The kinds of memory covered in the following sections include

- Conventional (base) memory
- Upper memory area (UMA)
- High memory area (HMA)
- Extended memory (XMS)
- Expanded memory (obsolete)
- Video RAM memory (part of UMA)
- Adapter ROM and special-purpose RAM (part of UMA)
- Motherboard ROM BIOS (part of UMA)

Figure 6.19 shows the logical address locations for a 16-bit or higher system. If the processor is running in real mode, only the first megabyte is accessible. If the processor is in protected mode, the full 16MB, 4096MB, or 65536MB are accessible. Each symbol is equal to 1KB of memory, and each line or segment is 64KB. This map shows the first two megabytes of system memory.

◀◀ See "Processor Modes," p. 49.

Note

To save space, this map stops after the end of the second megabyte. In reality, this map continues to the maximum of addressable memory.

Figure 6.19 The logical memory map of the first 2MB.

Conventional (Base) Memory

The original PC/XT-type system was designed to use 1MB of RAM. This 1MB of RAM is divided into several sections, some of which have special uses. DOS can read and write to the entire megabyte but can manage the loading of programs only in the portion of RAM space called *conventional memory*, which was 512KB at the time the first PC was introduced. The other 512KB was reserved for use by the system, including the motherboard and adapter boards plugged into the system slots.

After introducing the system, IBM decided that only 384KB was needed for these reserved uses, and the company began marketing PCs with 640KB of user memory. Therefore, 640KB became the standard for memory that can be used by DOS for running programs and often is termed the 640KB memory barrier. The remaining memory after 640KB was reserved for use by the graphics boards, other adapters, and the motherboard ROM BIOS.

This barrier largely affects 16-bit software, such as DOS and Windows 3.1, and is much less of a factor with 32-bit software and operating systems, such as Windows 9x, NT/2000/XP, and so on.

Upper Memory Area

The term *Upper Memory Area (UMA)* describes the reserved 384KB at the top of the first megabyte of system memory on a PC/XT and the first megabyte on an AT-type system. This memory has the addresses from A0000 through FFFFF. The way the 384KB of upper memory is used breaks down as follows:

- *The first 128KB after conventional memory is called video RAM.* It is reserved for use by video adapters. When text and graphics are displayed onscreen, the data bits that make up those images reside in this space. Video RAM is allotted the address range A0000–BFFFF.
- *The next 128KB is reserved for the adapter BIOS that resides in read-only memory chips on some adapter boards plugged into the bus slots.* Most VGA-compatible video adapters use the first 32KB of this area for their onboard BIOS. Any other adapters installed can use the rest. Many network adapters also use this area for special-purpose RAM called *shared memory*. Adapter ROM and special-purpose RAM is allotted the address range C0000–DFFFF.
- *The last 128KB of memory is reserved for motherboard BIOS (the basic input/output system, which is stored in read-only RAM chips or ROM).* The POST and bootstrap loader, which handles your system at boot-up until the operating system takes over, also reside in this space. Most systems use only the last 64KB (or less) of this space, leaving the first 64KB or more free for remapping with memory managers. Some systems also include the CMOS Setup program in this area. The motherboard BIOS is allotted the address range E0000–FFFFF.

Not all the 384KB of reserved memory is fully used on most 16-bit and higher systems. For example, according to the PC standard, reserved video RAM begins at address A0000, which is right at the 640KB boundary. Normally, it is used for VGA graphics modes, whereas the monochrome and color text modes use B0000–B7FFF and B8000–BFFFF, respectively. Older non-VGA adapters used memory only in the B0000 segment. Different video adapters use varying amounts of RAM for their operations, depending mainly on the mode they are in. To the processor, however, it always appears as the same 128KB area, no matter how much RAM is really on the video card. This is managed by bank switching areas of memory on the card in and out of the A0000–BFFFF segments.

Although the top 384KB of the first megabyte was originally termed *reserved memory*, it is possible to use previously unused regions of this memory to load 16-bit device drivers (such as the ANSI.SYS screen driver that comes with DOS) and memory-resident programs (such as MOUSE.COM, the DOS mouse driver), which frees up the conventional memory they would otherwise require. Note that this does not affect 32-bit device drivers such as those used with Windows 9x, NT/2000/XP, and so forth because they load into extended memory with no restrictions. The amount of free UMA space varies from system to system, depending mostly on the adapter cards installed on the system. For example, most video adapters, SCSI adapters, and some network adapters require some of this area for built-in ROMs or special-purpose RAM use.

Segment Addresses and Linear Addresses

See the “General Troubleshooting and Diagnostics,” section in the Technical Reference section of the disc accompanying this book for a discussion of segment and linear addressing.

Video RAM Memory

A video adapter installed in your system uses a portion of your system’s first megabyte of memory to hold graphics or character information for display, but this typically is used or active only when in basic VGA mode.

Note that even though a modern video card can have 64MB or more of onboard memory, only 128KB of this memory appears available to the system in the video RAM area. The rest of the memory is accessible only by the video processor (on the video card) directly, or by your system processor via a memory aperture positioned near the 4GB top of the system address space. Because this aperture can be configured differently by various cards, you should consult the technical documentation for your

Some systems incorporate the video adapter into the motherboard or even directly in the motherboard chipset. In these systems, even though the video BIOS and motherboard BIOS might be from the same manufacturer, they are always set up to emulate a standard VGA-type adapter card. In other words, the video BIOS appears in the first 32KB of segment C000 just as though a standalone VGA-type card were plugged into a slot. The built-in video circuit in these systems can in many cases be disabled with a switch or jumper or sometimes by simply plugging in a video card. By having the built-in VGA act exactly as though it were a separate card, disabling it allows a new adapter to be installed with no compatibility problems that might arise if the video drivers had been incorporated into the motherboard BIOS.

Adapter ROM and Special-Purpose RAM Memory

The second 128KB of upper memory beginning at segment C000 is reserved for the software programs, or BIOS, on the adapter boards plugged into the system slots. These BIOS programs are stored on special chips known as ROM. Most adapters today use EEPROM or Flash ROM, which can be erased and reprogrammed right in the system without removing the chip or card. Updating the Flash ROM is as simple as running the update program you get from the manufacturer and following the directions onscreen. It pays to check periodically with your card manufacturers to see whether they have Flash ROM updates for their cards.

ROM is useful for semipermanent programs that must always be present while the system is running, and especially for booting. Graphics boards, hard disk controllers, communications boards, and expanded memory boards, for example, are adapter boards that might have adapter ROM. These adapter ROMs are in an area of memory separate from the VGA video RAM and motherboard ROM areas.

On systems based on the 386 CPU chip or higher, memory managers that are included with DOS 6 or third-party programs can load device drivers and memory-resident programs into unused regions in the UMA.

To actually move the RAM usage on any given adapter requires that you consult the documentation for the card. Most older cards require that specific switches or jumpers be changed, and the settings will probably not be obvious without the manual. Plug and Play cards allow these settings to be changed by software that comes with the card or the Device Manager program included in Windows.

Video Adapter BIOS

The video adapter ROM BIOS controls the video card during the boot sequence and anytime the system is in basic VGA modes (such as when running DOS). You also are using the video ROM BIOS code whenever you are running Windows in safe mode. All modern video adapters (even AGP cards) use 32KB for their onboard BIOS, from addresses C0000–C7FFF.

Depending on the basic VGA mode selected (color text, monochrome text, or VGA graphics), the video card uses some or all of the 128KB of upper memory beginning at segment C000. In addition, graphics cards can contain up to 64MB or more of onboard memory for use in their native high-resolution modes in which to store currently displayed data and more quickly fetch new screen data for display.

Hard Disk Controller and SCSI Host Adapter BIOS

The upper memory addresses C0000–DFFFF are also used for the built-in BIOS contained on many hard drive and SCSI controllers. Table 6.22 lists the amount of memory and the addresses commonly used by the BIOS contained on hard drive adapter cards.

Motherboard BIOS Memory

The last 128KB of reserved memory is used by the motherboard BIOS. The BIOS programs in ROM control the system during the boot-up procedure and remain as drivers for various hardware in the system during normal operation. Because these programs must be available immediately, they can't be loaded from a device such as a disk drive.

◀◀ See Chapter 5, "BIOS," p. 397.

Both segments E000 and F000 in the memory map are considered reserved for the motherboard BIOS, but only some systems actually use this entire area. Older 8-bit systems require only segment F000 and enable adapter card ROM or RAM to use segment E000. Most 16-bit or greater systems use all F000 for the BIOS and might decode but not use any of segment E000. By decoding an area, the motherboard essentially grabs control of the addresses, which precludes installing any other hardware in this region. In other words, configuring adapter cards to use this area isn't possible. That is why you will find that most adapters that use memory simply do not allow any choices for memory use in segment E000. Although this might seem like a waste of 64KB of memory space, any 386 or higher system can use the powerful MMU in the processor to map RAM from extended memory into segment E000 as an upper memory block. The system can subsequently load 16-bit driver software in this UMB if necessary. This is a nice solution to what otherwise would be wasted memory, although it is not important if you use 32-bit drivers.

Figure 6.23 shows the motherboard ROM BIOS memory use of most 16-bit or greater systems.

.	=	Empty Addresses
R	=	Standard Motherboard ROM BIOS
	:	0---1---2---3---4---5---6---7---8---9---A---B---C---D---E---F---
0E000:	:
0F000:	:	AA

Figure 6.23 Motherboard ROM BIOS memory use of most systems.

Note that the standard system BIOS uses only segment F000 (64KB). In almost every case, the remainder of the BIOS area (segment E000) is completely free and can be used as UMA block space.

Extended Memory

As mentioned previously in this chapter, the memory map on a system based on the 286 or higher processor can extend beyond the 1MB boundary that exists when the processor is in real mode. On a 286 or 386SX system, the extended memory limit is 16MB (24-bit addressing); on a 386DX, 486, Pentium, or Pentium MMX system, the extended memory limit is 4GB (4,096MB using 32-bit addressing). Systems based on the Pentium Pro, Pentium II, and newer processors have a limit of 64GB (65,536MB using 36-bit addressing).

Note

36-bit memory addressing is enabled through a method called physical address extension (PAE). PAE is an Intel-provided memory address extension that enables support of up to 64GB of physical memory for applications running on most 32-bit Intel Pentium Pro and later processors. PAE enables the processor to expand the number of bits that can be used to address physical memory from 32 bits to 36 bits, but it requires operating system support as well. Support for PAE is provided only in server-oriented operating systems such as Windows 2000 and later versions of the Advanced Server and Datacenter Server operating systems. Without PAE support, memory addressing is limited to 32 bits or 4GB of physical RAM.

For a system to address memory beyond the first megabyte, the processor must be in protected mode—the native mode of 286 and higher processors. On a 286, only programs designed to run in protected mode can take advantage of extended memory; 386 and higher processors offer another mode, called virtual real mode, which enables extended memory to be, in effect, chopped into 1MB pieces (each its own real-mode session). Virtual real mode also enables several of these sessions to be running simultaneously in

protected areas of memory. They can be seen as DOS prompt sessions or windows within Windows 9x/Me, NT, 2000, XP, or OS/2. Although several DOS programs can be running at once, each is still limited to a maximum of 640KB of memory because each session simulates a real-mode environment, right down to the BIOS and Upper Memory Area. Running several programs at once in virtual real mode, called *multitasking*, requires software that can manage each program and keep them from crashing into one another. OS/2; Windows 9x/Me; and Windows NT, 2000, and XP all do this.

The 286 and higher CPU chips also run in what is termed *real mode*, which enables full compatibility with the 8088 CPU chip installed on the PC/XT-type computer. Real mode enables you to run DOS programs one at a time on an AT-type system just as you would on a PC/XT. However, an AT-type system running in real mode, particularly a system based on the 386 through Pentium 4 or Athlon, is really functioning as little more than a turbo PC. In real mode, these processors can emulate the 8086 or 8088, but they can't operate in protected mode at the same time. For that reason, the 386 and above also provide a virtual real mode that operates under protected mode. This enables real-mode programs to execute under the control of a protected-mode operating system, such as Win9x/Me or NT/2000/XP.

Note

Extended memory is basically all memory past the first megabyte, which can be accessed only while the processor is in protected mode.

XMS Memory

Microsoft, Intel, AST Corp., and Lotus Development developed the extended memory specification (XMS) in 1987 to specify how programs would use extended memory. The XMS specification functions on systems based on the 286 or higher and enables real-mode programs (those designed to run in DOS) to use extended memory and another block of memory usually out of the reach of DOS.

Before XMS, there was no way to ensure cooperation between programs that switched the processor into protected mode and used extended memory. There was also no way for one program to know what another had been doing with the extended memory because none of them could see that memory while in real mode. HIMEM.SYS becomes an arbitrator of sorts that first grabs all the extended memory for itself and then doles it out to programs that know the XMS protocols. In this manner, several programs that use XMS memory can operate together under DOS on the same system, switching the processor into and out of protected mode to access the memory. XMS rules prevent one program from accessing memory that another has in use. Because Windows 3.x is a program manager that switches the system to and from protected mode in running several programs at once, it has been set up to require XMS memory to function. Windows 9x/Me operates mostly in protected mode, but still calls on real mode for access to many system components. Windows NT, 2000, and XP are true protected-mode operating systems, as is OS/2.

Extended memory can be made to conform to the XMS specification by installing a device driver in the CONFIG.SYS file. The most common XMS driver is HIMEM.SYS, which is included with Windows 3.x and later versions of DOS, starting with 4.0 and up. Windows 9x/Me and NT/2000/XP automatically allow XMS functions in DOS prompt sessions, and you can configure full-blown DOS-mode sessions to allow XMS functions as well.

Note

To learn more about the high memory area and expanded memory, see Chapter 5 of *Upgrading and Repairing PCs, 10th Anniversary Edition*, on the disc.

Preventing ROM BIOS Memory Conflicts and Overlap

As explained previously, C000 and D000 are reserved for use by adapter-board ROM and RAM. If two adapters have overlapping ROM or RAM addresses, usually neither board operates properly. Each board functions if you remove or disable the other one, but they do not work together.

With many adapter boards, you can change the actual memory locations to be used with jumpers, switches, or driver software, which might be necessary to allow two boards to coexist in one system. This type of conflict can cause problems for troubleshooters. You must read the documentation for each adapter to find out which memory addresses the adapter uses and how to change the addresses to allow coexistence with another adapter. Most of the time, you can work around these problems by reconfiguring the board or by changing jumpers, switch settings, or software-driver parameters. This change enables the two boards to coexist and stay out of each other's way.

Additionally, you must ensure that adapter boards do not use the same IRQ, DMA channel, or I/O port address. You can easily avoid adapter board memory, IRQ, DMA channel, and I/O port conflicts by creating a chart or template to mock up the system configuration by penciling on the template the resources already used by each installed adapter. You end up with a picture of the system resources and the relationship of each adapter to the others.

If you are running a Plug and Play operating system, such as Windows 9x/Me or 2000/XP, you can use the Device Manager to view and optionally print all the device settings. I highly recommend you use this to print out all the settings in your system before and after you make modifications to see what has been changed. This will help you anticipate conflicts and ensures that you configure each adapter board correctly the first time. The template also becomes important documentation when you consider new adapter purchases. New adapters must be configurable to use the available resources in your system.

◀◀ See "System Resources," p. 367.

If your system has Plug and Play capabilities, and you use PnP adapters, it can resolve conflicts between the adapters by moving the memory usage on any conflict. Unfortunately, this routine is not intelligent and still requires human intervention—that is, manual specification of addresses to achieve the most optimum location for the adapter memory.

ROM Shadowing

Virtually all 386 and higher systems enable you to use what is termed *shadow memory* for the motherboard and possibly some adapter ROMs as well. Shadowing essentially moves the programming code from slow ROM chips into fast 32-bit system memory. Shadowing slower ROMs by copying their contents into RAM can greatly speed up these BIOS routines—sometimes making them four to five times faster.

Note that shadowing ROMs is not very important when running a 32-bit operating system, such as Win9x/Me or NT/2000/XP. This is because those operating systems use the 16-bit BIOS driver code only during booting; then they load 32-bit replacement drivers into faster extended memory and use them. Therefore, shadowing normally affects only DOS or other 16-bit software and operating systems. Because of this, some people are tempted to turn off the Video BIOS shadowing feature in the BIOS setup. Unfortunately, it won't gain you any memory back (you've lost it anyway) and will make the system slightly slower to boot up and somewhat slower when in Windows safe mode. The 16-bit BIOS video driver code is used at those times.

Note

To learn more about ROM shadowing, see Chapter 5 of *Upgrading and Repairing PCs, 10th Anniversary Edition*, on the disc accompanying this book.

Total Installed Memory Versus Total Usable Memory

Most people don't realize that not all the RAM you purchase and install in a system is available. Because of some quirks in system design, the system usually has to "throw away" up to 384KB of RAM to make way for the Upper Memory Area.

For example, most systems with 16MB of RAM (which is 16,384KB) installed show a total of only 16,000KB installed during the POST or when running Setup. This indicates that $16,384\text{KB} - 16,000\text{KB} = 384\text{KB}$ of missing memory! Some systems might show 16,256KB with the same 16MB installed, which works out to $16,384\text{KB} - 16,256\text{KB} = 128\text{KB}$ missing.

If you run your Setup program and check out your base and extended memory values, you will find more information than just the single figure for the total shown during the POST. In most systems with 4,096KB (4MB), you have 640KB base and 3,072KB extended. In some systems, Setup reports 640KB base and 3,328KB extended memory, which is a bonus. In other words, most systems come up 384KB short, but some come up only 128KB short.

This shortfall is not easy to explain, but it is consistent from system to system. Say that you have a 486 system with two installed 72-pin (32-bit) 16MB SIMMs. This results in a total installed memory of 32MB in two separate banks because the processor has a 32-bit data bus. Each SIMM is a single bank in this system. The first bank (or SIMM, in this case) starts at address 0000000h (the start of the first megabyte), and the second starts at 1000000 (the start of the seventeenth megabyte).

One of the cardinal rules of memory is that you absolutely cannot have two hardware devices wired to the same address. This means that 384KB of the first memory bank in this system would be in direct conflict with the video RAM (segments A000 and B000), any adapter card ROMs (segments C000 and D000), and of course the motherboard ROM (segments E000 and F000). This means all SIMM RAM that occupies these addresses must be shut off; otherwise, the system will not function! Actually, a motherboard designer can do three things with the SIMM memory that would overlap from A0000–FFFFF:

- Use the faster RAM to hold a copy of any slow ROMs (shadowing), disabling the ROM in the process
- Turn off any RAM not used for shadowing, eliminating any UMA conflicts
- Remap any RAM not used for shadowing, adding to the stack of currently installed extended memory

Most systems shadow the motherboard ROM (usually 64KB) and the video ROM (32KB) and simply turn off the rest. Some motherboard ROMs allow additional shadowing to be selected between C8000 and DFFFF, usually in 16KB increments.

Note

You can shadow only ROM, never RAM, so if any card (such as a network card) has a RAM buffer in the C8000–DFFFF area, you must not shadow the RAM buffer addresses; otherwise, the card will not function. For the same reason, you can't shadow the A0000–BFFFF area because it is the video adapter RAM buffer.

Most motherboards do not do any remapping, which means that any of the 384KB not shadowed is simply turned off. That is why enabling shadowing does not seem to use any memory. The memory used for shadowing would otherwise be discarded in most systems. These systems would appear to be short by 384KB compared to what is physically installed in the system. For example, in a system with 32MB, no remapping would result in 640KB of base memory and 31,744KB of extended memory, for a total of 32,384KB of usable RAM—384KB short of the total (32,768KB–384KB).

Systems that show 384KB of “missing” memory do not do remapping. If you want to determine whether your system has any missing memory, all you need to know are three things. One is the total physical memory actually installed. Running your Setup program can discover the other two items. You want to know the total base and extended memory numbers recognized by the system. Then simply subtract the base and extended memory from the total installed to determine the missing memory. You usually will find that your system is missing 384KB, but you could be lucky and have a system that remaps 256KB of what is missing and thus shows only 128KB of memory missing.

Virtually all systems use some of the missing memory for shadowing ROMs, especially the motherboard and video BIOS, so what is missing is not completely wasted. Systems missing 128KB will find that it is being used to shadow your motherboard BIOS (64KB from F0000 to FFFFF) and video BIOS (32KB from C0000 to C8000). The remainder of segment C0000 (32KB from C8000 to CFFFF) is simply being turned off. All other segments (128KB from A0000 to BFFFF and 128KB from D0000 to EFFFF) are being remapped to the start of the fifth megabyte (400000–43FFFF). Most systems simply disable these remaining segments rather than take the trouble to remap them.

Note that with the relatively large amount of memory in modern PCs, losing a paltry 384KB hardly has an impact on performance. Also, because shadowing has a performance benefit only when running under a 16-bit OS such as DOS, systems running Windows aren't affected by any changes to the shadowing settings. If these settings are present in your BIOS Setup, I usually recommend they be left at default settings.

Adapter Memory Configuration and Optimization

Adapter boards use upper memory for their BIOS and as working RAM. If two boards attempt to use the same BIOS area or RAM area of upper memory, a conflict occurs that can keep your system from booting. In most cases, the plug-and-play software in the operating system ensures that such cards are automatically reconfigured so that they are not in conflict; however, sometimes problems can occur and you must step in and manually resolve a conflict. The following sections cover ways to avoid these potential unresolved conflicts and how to troubleshoot if they do occur. In addition, these sections discuss moving adapter memory to resolve conflicts and provide some ideas on optimizing adapter memory use.

How to Determine What Adapters Occupy the UMA

You can determine which adapters are using space in upper memory in the following two ways:

- Study the documentation for each adapter on your system to determine the memory addresses they use.
- Use a software utility or the Device Manager in your operating system to determine which upper memory areas your adapters are using.

The simplest way (although by no means always the most foolproof) is to use a software utility to determine the upper memory areas used by the adapters installed on your system. One such utility, Microsoft Diagnostics (MSD), comes with Windows 3.x and DOS 6 or higher versions. The Device Manager in the Windows 9x/Me and 2000/XP Control Panel also supplies this information in much more detail than MSD, as does the new System Information utility that comes with Windows 98 and later. These utilities examine your system configuration and determine not only the upper memory used by your adapters, but also the IRQs used by each of these adapters.

True plug-and-play systems also shut down one of the cards involved in a conflict to prevent a total system lockup. This could cause Windows to boot in safe mode.

After you run MSD, Device Manager, or another utility to determine your system's upper memory configuration, make a printout of the memory addresses used. Thereafter, you can quickly refer to the printout when you are adding a new adapter to ensure that the new board does not conflict with any devices already installed on your system.

Moving Adapter Memory to Resolve Conflicts

After you identify a conflict or potential conflict using one of the two methods discussed in the previous section, you might have to reconfigure one or more of your adapters to move the upper memory space used by a problem adapter.

Most adapter boards make moving adapter memory a somewhat simple process, enabling you to change a few jumpers or switches to reconfigure the board. With plug-and-play cards, use the configuration program that comes with the board or the Windows Device Manager to make the changes. The following steps help you resolve most problems that arise because adapter boards conflict with one another:

1. Determine the upper memory addresses currently used by your adapter boards and write them down.
2. Determine whether any of these addresses are overlapping, which results in a conflict.
3. Consult the documentation for your adapter boards to determine which boards can be reconfigured so that all adapters have access to unique memory addresses.
4. Configure the affected adapter boards so that no conflict in memory addresses occurs.

For example, if one adapter uses the upper memory range C8000–CBFFF and another adapter uses the range CA000–CCFFF, you have a potential address conflict. One of them must be changed. Note that plug-and-play cards allow these changes to be made directly from the Windows Device Manager.

CHAPTER 7

The ATA/IDE Interface

An Overview of the IDE Interface

The interface used to connect hard disk and optical drives to a modern PC is typically called IDE (Integrated Drive Electronics); however, I always like to point out that the true name of this interface is ATA (AT Attachment). The ATA designation refers to the fact that this interface was originally designed to connect a combined drive and controller directly to the 16-bit bus found in the 1984 vintage IBM AT (Advanced Technology) and compatible computers. The AT bus is otherwise known as the ISA (Industry Standard Architecture) bus. Although ATA is the official name of the interface, *IDE* is a marketing term originated by some of the drive manufacturers to describe the drive/controller combination used in drives with the ATA interface. *Integrated Drive Electronics* refers to the fact that the interface electronics or controller is built in to the drive and is not a separate board, as with earlier drive interfaces. Although the correct name for the particular IDE interface we most commonly use is technically ATA, many persist in using the IDE designation today. If you are being picky, you could say that *IDE* refers generically to any drive interface in which the controller is built in to the drive, whereas *ATA* refers to the specific implementation of IDE that is used in most PCs.

ATA is used to connect not only hard disks, but also optical (CD and DVD) drives, high-capacity SuperDisk or Zip floppy drives, and tape drives. Even so, ATA is still thought of primarily as a hard disk interface, and it evolved directly from the separate controller and hard drive interfaces that were used prior to ATA. This chapter covers the standard parallel version of ATA as well as the newer Serial ATA interfaces in detail; it also briefly mentions the original interfaces from which ATA evolved. Because the ATA interface is directly integrated into virtually all motherboard chipsets, ATA is the primary storage device interface used by most PCs.

Note

Even Apple recognized the value of ATA and began incorporating it into virtually all modern Macintosh systems released from 1995 to the present (before that, Apple used a semiproprietary version of SCSI). In fact, Apple has quietly adopted many other industry standards taken directly from the PC, including PCI, AGP, USB, and both SDR and DDR SDRAM, to name a few.

►► See “SuperDisk LS-120 and LS-240,” p. 710.

Precursors to IDE

A variety of hard disk interfaces has been used for PC hard disks over the years. As time has passed, the number of choices has increased; however, many of the older interface standards are obsolete and no longer viable in newer systems.

The primary job of the hard disk controller or interface is to transmit and receive data to and from the drive. The various interface types limit how fast data can be moved from the drive to the system and offer different features as well as levels of performance. If you are putting together a system in which performance is a primary concern, you need to know how these various interfaces affect performance and what you can expect from them. Many statistics that appear in technical literature are not indicative of the real performance figures you will see in practice. I will separate the myths presented by some of these overly optimistic figures from the reality of what you will actually see.

Several types of hard disk interfaces have been used in PCs over the years, as shown in Table 7.1.

Table 7.1 PC Drive Interfaces

Interface	When Used	Interface	When Used
ST-506/412	1978–1989 (obsolete)	SCSI	1986–present
ESDI	1983–1991 (obsolete)	ATA (IDE)	1986–present
Non-ATA IDE	1987–1993 (obsolete)	Serial ATA	2003–present

Of these interfaces, only ST-506/412 and ESDI are what you could call true disk-controller-to-drive interfaces, and they are obsolete. Non-ATA versions of IDE were used primarily in the IBM PS/2 systems and are also obsolete. Current SCSI, ATA, and Serial ATA are system-level interfaces that usually internally incorporate a chipset-based controller interface. For example, many SCSI, parallel ATA, and Serial ATA drives incorporate the same basic controller circuitry inside the actual drive. The SCSI interface then adds another layer that connects between the drive controller and the PCI (or ISA) bus, whereas PATA and Serial ATA have a more direct connection from the controller to the AT bus attachment interface. Despite their differences, we call a SCSI, ATA, or Serial ATA card a *host interface adapter* instead of a controller card because the actual controllers are inside the drives. Virtually all modern disk drives use parallel ATA, Serial ATA, or SCSI interfaces to connect to a system.

IDE Origins

Any drive with an integrated controller could be called an IDE drive, although normally when we say *IDE*, we really mean the specific version of IDE called ATA. No matter what you call it, combining the drive and controller greatly simplifies installation because there are no separate power or signal cables that run from the controller to the drive. Also, when the controller and drive are assembled as a unit, the number of total components is reduced, signal paths are shorter, and the electrical connections are more noise-resistant. This results in a more reliable and less expensive design than is possible when a separate controller, connected to the drive by cables, is used.

Placing the controller, including the digital-to-analog encoder/decoder (endec), on the drive offers an inherent reliability advantage over interfaces with separate controllers such as ST506 and ESDI. Reliability is increased because the data encoding, from digital to analog, is performed directly on the drive in a tight noise-free environment. The timing-sensitive analog information does not have to travel along crude ribbon cables that are likely to pick up noise and insert propagation delays into the signals. The integrated configuration enables increases in the clock rate of the encoder and the storage density of the drive.

Integrating the controller and drive also frees the controller and drive engineers from having to adhere to the strict guidelines imposed by the earlier interface standards. Engineers can design what essentially are custom drive and controller implementations because no other controller will ever have to be connected to the drive. The resulting drive and controller combinations can offer higher performance than earlier standalone controller and drive setups. IDE drives sometimes are called drives with embedded controllers.

The earliest IDE drives were called hardcards and were nothing more than hard disks and controllers bolted directly together and plugged into a slot as a single unit. Companies such as the Plus Development Division of Quantum took small 3 1/2" drives (either ST-506/412 or ESDI) and attached them directly to a standard controller. The drive/controller assembly then was plugged into an ISA bus slot as though it were a normal disk controller card. Unfortunately, the mounting of a heavy, vibrating hard disk in an expansion slot with nothing but a single screw to hold it in place left a lot to be desired—not to mention the physical interference with adjacent cards because many of these units were much thicker than a controller card alone.

Several companies got the idea to redesign the controller to replace the logic board assembly on a standard hard disk and then mount it in a standard drive bay just like any other drive. Because the built-in controller in these drives still needed to plug directly into the expansion bus just like any other controller, a cable was run between the drive and one of the slots. This is the origin of IDE.

IDE Variations

There have been four main types of IDE interfaces based on three bus standards:

- Serial AT Attachment (SATA)
- Parallel AT Attachment (ATA, based on the 16-bit AT-bus, also called ISA)
- XT IDE (based on 8-bit ISA, obsolete)
- MCA IDE (based on 16-bit Micro Channel, obsolete)

Of these, only the parallel and Serial ATA versions are used today. ATA and Serial ATA have evolved with newer, faster, and more powerful versions. The newer versions of parallel ATA are referred to as ATA-2 and higher. They are also sometimes called EIDE (Enhanced IDE), Fast-ATA, Ultra-ATA, or Ultra-DMA. Even though parallel ATA has hit the end of the evolutionary road with ATA-7, Serial ATA picks up where parallel ATA leaves off and offers greater performance, higher reliability, easier installation, lower cost, and an established roadmap for future upgrades.

In 1987, IBM developed its own Micro Channel Architecture (MCA) IDE drives for systems such as the PS/2 Model 70, and connected them to the bus through a bus adapter device called an *interposer card*. These bus adapters (sometimes called *paddle boards* or *angle boards*) needed only a few buffer chips and did not require any real circuitry because the drive-based controller was designed to plug directly into the bus. The *paddle board* nickname came from the fact that they resemble game paddle or joystick adapters, which do not have much circuitry on them. MCA IDE uses a non-standard 72-pin connector, and was designed for MCA bus systems only.

An 8-bit variation of IDE appeared in 8-bit ISA systems such as the PS/2 Model 30. The XT IDE interface used a 40-pin connector similar to, but not compatible with, the 16-bit version. Neither MCA nor XT versions of IDE became very popular, and they have been off the market for several years.

Note

It is important to note that only the ATA IDE interface has been standardized by the industry. The XT and MCA IDE interfaces never were adopted as industry-wide standards and never became very popular. These interfaces were only used from 1987 to 1993 and only in IBM PS/2 (and some early ThinkPad) systems.

In most modern systems you will find at least two ATA connectors on the motherboard, and systems that offer ATA RAID have two additional ATA connectors which can be used for an ATA RAID array or for additional ATA drives running as independent devices. If your motherboard does not have one of these connectors and you want to attach an ATA drive to your system, you can purchase an adapter card that adds an ATA interface (or two) to a system via the ISA or PCI bus slots. Some of the cards offer additional features, such as an onboard ROM BIOS or cache memory.

Because only the parallel and serial ATA versions of IDE are in use today, they are what this chapter focuses on.

Origins of ATA

Control Data Corporation (CDC; its disk drive division was later called Imprimis), Western Digital, and Compaq actually created what could be called the first ATA IDE interface drive and were the first to establish the 40-pin ATA connector pinout. The first ATA IDE drive was a 5 1/4" half-height CDC Wren II 40MB drive with an integrated WD controller and was initially used in the first Compaq 386 systems in 1986. I remember seeing this drive for the first time in 1986 at the fall Comdex show, and besides the (at the time) unique 40-pin ribbon cable, I remember being surprised by the green activity LED on the front bezel (most drives up until then used red LEDs).

Compaq was the first to incorporate a special bus adapter in its system to adapt the 98-pin AT-bus (also known as ISA) edge connector on the motherboard to a smaller 40-pin, header-style connector into which the drive would plug. The 40-pin connectors were all that was necessary because it was known that a disk controller never would need more than 40 of the ISA bus lines. Smaller 2 1/2" ATA drives found in notebook computers use a superset 44-pin or 50-pin connection, which includes additional pins for power and configuration. The pins from the original ISA bus used in ATA are the only signal pins required by a standard-type AT hard disk controller. For example, because a primary AT-style disk controller uses only interrupt request (IRQ) line 14, the primary motherboard ATA connector supplies only that IRQ line; no other IRQ lines are necessary. Even if your ATA interface is integrated within the motherboard chipset South Bridge or I/O Controller Hub chip (as it would be in

newer systems) and runs at higher bus speeds, the pinout and functions of the pins are still the same as the original design taken right off the ISA bus.

- ◀◀ See "Motherboard Connectors," p. 330.
- ◀◀ See "The ISA Bus," p. 350.

Note

Many people who use systems with ATA connectors on the motherboard believe that a hard disk controller is built in to their motherboards, but in a technical sense the controller is actually in the drive. Although the integrated ATA ports on a motherboard often are referred to as *controllers*, they are more accurately called *host adapters* (although you'll rarely hear this term). A host adapter can be thought of as a device that connects a controller to a bus.

Eventually, the 40-pin ATA connector and drive interface design was placed before one of the ANSI standards committees that, in conjunction with drive manufacturers, ironed out some deficiencies, tied up some loose ends, and then published what was known as the CAM ATA (Common Access Method AT Attachment) interface. The CAM ATA Committee was formed in October 1988, and the first working document of the AT Attachment interface was introduced in March 1989. Before the CAM ATA standard, many companies, such as Conner Peripherals (which later merged with Seagate Technology), made proprietary changes to the original interface as designed by CDC. As a result, many older ATA drives from the late 1980s are very difficult to integrate into a dual-drive setup because minor differences in the interfaces can cause compatibility problems among the drives. By the early 1990s, most drive manufacturers brought their drives into full compliance with the official standard, which eliminated many of these compatibility problems.

Some areas of the ATA standard have been left open for vendor-specific commands and functions. These vendor-specific commands and functions are the main reason it is so difficult to low-level format ATA drives. To work to full capability, the format program you are using typically must know the specific vendor-unique commands for remapping defects. Unfortunately, these and other specific drive commands differ from OEM to OEM, clouding the "standard" somewhat. Most ATA drive manufacturers publish their drive formatting/initialization software on their Web sites.

Note

Many people are confused about 16- versus 32-bit bus connections and 16- versus 32-bit hard drive connections. A PCI bus connection allows for a 32-bit (and possibly 64-bit in some versions) connection between the bus and the ATA host interface, which is typically in the motherboard chipset South Bridge or I/O Controller Hub (ICH) chip. However, the actual parallel ATA interface between the host connector on the motherboard and the drive (or drives) itself is only a 16-bit interface. Thus, in a parallel ATA drive configuration, you are still getting only 16-bit transfers between the drive and the motherboard-based host interface. Even so, the clock speeds of the ATA interface are high enough that one or two hard drives normally can't supply the controller enough data to saturate even a 16-bit channel. The same is true with Serial ATA, which—although it transmits only 1 bit at a time—does so at extremely high speeds.

Parallel ATA is a 16-bit parallel interface, meaning that 16 bits are transmitted simultaneously down the interface cable. A serial interface called Serial ATA was officially introduced in late 2000 and began appearing in systems starting in 2003. Serial ATA (SATA) sends 1 bit down the cable at a time, enabling thinner and smaller cables to be used and providing higher performance due to the higher cycling speeds allowed. SATA is a completely new and updated physical interface design, while remaining compatible on the software level with parallel ATA. Throughout this book, *ATA* refers to both the parallel and serial versions, whereas parallel ATA (PATA) and Serial ATA (SATA) refer to the specific version as indicated. Figure 7.1 shows how the power and data cables used by SATA compare in size to those used by parallel ATA.

Figure 7.1 Serial ATA data cables (lower right) are much smaller than those used by parallel ATA (upper right), whereas the power cables (left) are similar in size.

The primary advantage of ATA drives over the older, separate controller-based interfaces and newer host bus interface alternatives, such as USB, SCSI, and IEEE 1394 (i.LINK or FireWire), is cost. Because the separate controller or host adapter is eliminated and the cable connections are simplified, ATA drives cost much less than a standard controller and drive combination.

- ▶▶ See “Small Computer System Interface,” p. 584.
- ▶▶ See “USB and IEEE 1394 (i.LINK or FireWire),” p. 982.

In terms of performance, ATA drives are often some of the highest performance drives available—but they can also be among the lowest performance drives. This apparent contradiction is a result of the fact that all ATA drives are different. You can’t make a blanket statement about the performance of ATA drives because each drive is unique. The high-end models, however, offer performance equal or superior to that of any other type of drive on the market for a single-user, single-tasking operating system.

ATA Standards

Today, the ATA interface is controlled by an independent group of representatives from major PC, drive, and component manufacturers. This group is called Technical Committee T13 (<http://www.t13.org>) and is responsible for all standards relating to the parallel and Serial AT Attachment storage interfaces. T13 is a part of the International Committee on Information Technology Standards (INCITS), which operates under rules approved by the American National Standards Institute (ANSI), a governing body that sets rules that control nonproprietary standards in the computer industry as well as many other industries. A second group called the Serial ATA Working Group (<http://www.serialata.org>) was formed to initially create the Serial ATA standards, which are then passed on to the T13 Committee for refinement and official publication under ANSI. The ATA-7 standard incorporates both parallel and serial standards and represents the end of the road for parallel ATA because ATA-8 and beyond will contain only serial versions.

The rules these committees operate under are designed to ensure that voluntary industry standards are developed by the consensus of people and organizations in the affected industry. INCITS specifically develops Information Processing System standards, whereas ANSI approves the process under which they are developed and then publishes them. Because T13 is essentially a public organization, all the working drafts, discussions, and meetings of T13 are open for all to see.

Copies of any of the published standards can be purchased from ANSI or Global Engineering Documents (see the Vendor List on the disc that accompanies this book). Draft versions of the standards can be downloaded from the T13 Committee or Serial ATA Working Group Web site.

The parallel ATA interface has evolved into several successive standard versions, introduced as follows:

- ATA-1
- ATA-2 (also called Fast-ATA, Fast-ATA-2, or EIDE)
- ATA-3
- ATA-4 (Ultra-ATA/33)
- ATA-5 (Ultra-ATA/66)
- ATA-6 (Ultra-ATA/100)
- ATA-7 (Ultra-ATA/133 or Serial ATA)
- SATA-8 (Serial ATA II)

Since ATA-1, newer versions of the ATA interface and complementary BIOS support larger and faster drives, as well as different types of devices other than hard disks. ATA-2 and later have improved the original ATA interface in five main areas:

- Secondary two-device channel
- Increased maximum drive capacity
- Faster data transfer
- ATAPI (ATA Program Interface)
- SATA (Serial ATA)

Each newer version of ATA is backward-compatible with the previous versions. In other words, older ATA-1 or ATA-2 devices work fine on ATA-6 and ATA-7 interfaces. ATA-7 includes both parallel and Serial ATA, but SATA-8 is serial only. Newer versions of ATA are normally built on older versions and with few exceptions can be thought of as extensions of the previous versions. This means that ATA-7, for example, is generally considered equal to ATA-6 with the addition of some features.

Table 7.2 breaks down the various ATA standards. The following sections describe all the ATA versions in more detail.

Table 7.2 ATA Standards

Standard	Proposed	Published	Withdrawn	PIO Modes	DMA Modes	UDMA Modes	Parallel Speed (MBps) ¹	Serial Speed (MBps)	Features
ATA-1	1988	1994	1999	0-2	0	—	8.33	—	Drives support up to 136.9GB; BIOS issues not addressed
ATA-2	1993	1996	2001	0-4	0-2	—	16.67	—	Faster PIO modes; CHS/LBA BIOS translation defined up to 8.4GB; PC-Card
ATA-3	1995	1997	2002	0-4	0-2	—	16.67	—	SMART; improved signal integrity; LBA support mandatory; eliminated single-word DMA modes
ATA-4	1996	1998	—	0-4	0-2	0-2	33.33	—	Ultra-DMA modes; ATAPI Packet Interface; BIOS support up to 136.9GB
ATA-5	1998	2000	—	0-4	0-2	0-4	66.67	—	Faster UDMA modes; 80-pin cable with autodetection
ATA-6	2000	2002	—	0-4	0-2	0-5	100	—	100MBps UDMA mode; extended drive and BIOS support up to 144PB

Table 7.2 Continued

Standard	Proposed	Published	Withdrawn	PIO Modes	DMA Modes	UDMA Modes	Parallel Speed (MBps) ¹	Serial Speed (MBps)	Features
ATA-7	2001	2004	—	0–4	0–2	0–6	133	150	133MBps UDMA mode; Serial ATA
SATA-8	2004	—	—	—	—	—	—	300	Serial ATA II

SMART = Self-Monitoring, Analysis, and Reporting Technology

ATAPI = AT Attachment Packet Interface

MB = Megabyte; million bytes

GB = Gigabyte; billion bytes

PB = Petabyte; quadrillion bytes

CHS = Cylinder, Head, Sector

LBA = Logical block address

PIO = Programmed I/O

DMA = direct memory access

UDMA = Ultra DMA (direct memory access)

ATA-1 (AT Attachment Interface for Disk Drives)

ATA-1 defined the original AT Attachment interface, which was an integrated bus interface between disk drives and host systems based on the ISA (AT) bus. These major features were introduced and documented in the ATA-1 specification:

- 40/44-pin connectors and cabling
- Master/slave or cable select drive configuration options
- Signal timing for basic Programmed I/O (PIO) and direct memory access (DMA) modes
- Cylinder, head, sector (CHS) and logical block address (LBA) drive parameter translations supporting drive capacities up to $2^{28}-2^{20}$ (267,386,880) sectors, or 136.9GB

Although ATA-1 had been in use since 1986, work on turning it into an official standard began in 1988 under the Common Access Method (CAM) committee. The ATA-1 standard was finished and officially published in 1994 as ANSI X3.221-1994, AT Attachment Interface for Disk Drives. ATA-1 was officially withdrawn as a standard on August 6, 1999.

Although ATA-1 supported theoretical drive capacities up to 136.9GB ($2^{28}-2^{20} = 267,386,880$ sectors), it did not address BIOS limitations that stopped at 528MB ($1024 \times 16 \times 63 = 1,032,192$ sectors). The BIOS limitations would be addressed in subsequent ATA versions because, at the time, no drives larger than 528MB had existed.

ATA-2 (AT Attachment Interface with Extensions-2)

ATA-2 first appeared in 1993 and was a major upgrade to the original ATA standard. Perhaps the biggest change was almost a philosophical one. ATA-2 was updated to define an interface between host systems and storage devices in general and not only disk drives. The major features added to ATA-2 as compared to the original ATA standard include

- Faster PIO and DMA transfer modes
- Support for power management
- Support for removable devices
- PCMCIA (PC Card) device support
- Identify Drive command that reports more information
- Defined standard CHS/LBA translation methods for drives up to 8.4GB in capacity

The most important additions in ATA-2 were the support for faster PIO and DMA modes, as well as methods to enable BIOS support up to 8.4GB. The BIOS support was necessary because, although ATA-1 was designed to support drives of up to 136.9GB in capacity, the PC BIOS could originally handle drives of up to 528MB. Adding parameter-translation capability now allowed the BIOS to handle drives up to 8.4GB. This is discussed in more detail later in this chapter.

ATA-2 also featured improvements in the Identify Drive command that enabled a drive to tell the software exactly what its characteristics are; this is essential for both Plug and Play (PnP) and compatibility with future revisions of the standard.

ATA-2 was also known by unofficial marketing terms such as fast-ATA or fast-ATA-2 (Seagate/Quantum) and EIDE (Enhanced IDE, Western Digital).

Although work on ATA-2 began in 1993, the standard was not officially published until 1996 as ANSI X3.279-1996 AT Attachment Interface with Extensions. ATA-2 was officially withdrawn in 2001.

ATA-3 (AT Attachment Interface-3)

First appearing in 1995, ATA-3 was a comparatively minor revision to the ATA-2 standard that preceded it. It consisted of a general cleanup of the specification and had mostly minor clarifications and revisions. The most major changes included the following:

- Eliminated single-word (8-bit) DMA transfer protocols.
- Added SMART (Self-Monitoring, Analysis, and Reporting Technology) support for prediction of device performance degradation.
- LBA mode support was made mandatory (previously it had been optional).
- Added ATA Security mode, allowing password protection for device access.
- Recommendations for source and receiver bus termination to solve noise issues at higher transfer speeds.

ATA-3 built on ATA-2, adding improved reliability, especially of the faster PIO mode 4 transfers; however, ATA-3 did not define any faster modes. ATA-3 did add a simple password-based security scheme, more sophisticated power management, and SMART. This enables a drive to keep track of problems that might result in a failure and therefore avoid data loss. SMART is a reliability prediction technology that was initially developed by IBM.

Work on ATA-3 began in 1995, and the standard was finished and officially published in 1997 as ANSI X3.298-1997, AT Attachment 3 Interface. ATA-3 was officially withdrawn in 2002.

ATA/ATAPI-4 (AT Attachment with Packet Interface Extension-4)

First appearing in 1996, ATA-4 included several important additions to the standard. It included the Packet Command feature known as the AT Attachment Packet Interface (ATAPI), which allowed devices such as CD-ROM and CD-RW drives, LS-120 SuperDisk floppy drives, Zip drives, tape drives, and other types of storage devices to be attached through a common interface. Until ATA-4 came out, ATAPI was a separately published standard. ATA-4 also added the 33MB per second (MBps) transfer mode known as Ultra-DMA or Ultra-ATA. ATA-4 is backward-compatible with ATA-3 and earlier definitions of the ATAPI.

Work on ATA-4 began in 1996, and the standard was finished and officially published in 1998 as ANSI NCITS 317-1998, AT Attachment - 4 with Packet Interface Extension.

The major revisions added in ATA-4 were as follows:

- Ultra-DMA (UDMA) transfer modes up to Mode 2, which is 33MBps (called UDMA/33 or Ultra-ATA/33)
- Integral ATAPI support

- Advanced power management support
- Defined an optional 80-conductor, 40-pin cable for improved noise resistance
- Host protected area (HPA) support
- Compact Flash Adapter (CFA) support
- Introduced enhanced BIOS support for drives over 9.4ZB (zettabytes or trillion gigabytes) in size (even though ATA was still limited to 136.9GB)

The speed and level of ATA support in your system is mainly dictated by your motherboard chipset. Most motherboard chipsets come with a component called either a South Bridge or an I/O Controller Hub that provides the ATA interface (as well as other functions) in the system. Check the specifications for your motherboard or chipset to see whether yours supports the faster ATA/33, ATA/66, ATA/100, or ATA/133 mode. One indication is to enter the BIOS Setup, put the hard disk on manual parameter settings (user defined), and see which (if any) Ultra-DMA modes are listed. Most boards built during 1998 support ATA/33; in 2000 they began to support ATA/66; and by late 2000 most started supporting ATA/100. ATA/133 support became widespread in mid-2002.

◀◀ See “Chipsets,” p. 254.

ATA-4 made ATAPI support a full part of the ATA standard, and thus ATAPI was no longer an auxiliary interface to ATA but merged completely within it. Thus, ATA-4 promoted ATA for use as an interface for many other types of devices. ATA-4 also added support for new Ultra-DMA modes (also called Ultra-ATA) for even faster data transfer. The highest-performance mode, called UDMA/33, had 33MBps bandwidth—twice that of the fastest programmed I/O mode or DMA mode previously supported. In addition to the higher transfer rate, because UDMA modes relieve the load on the processor, further performance gains were realized.

An optional 80-conductor cable (with cable select) is defined for UDMA/33 transfers. Although this cable was originally defined as optional, it would later be required for the faster ATA/66, ATA/100, and ATA/133 modes in ATA-5 and later. Many hard drives purchased in retail kits include the 80-conductor cable, although other types of devices, such as optical drives, include only a 40-conductor cable.

Support for a reserved area on the drive called the host protected area (HPA) was added via an optional `SET MAX ADDRESS` command. This enables an area of the drive to be reserved for recovery software.

Also included was support for queuing commands, which is similar to that provided in SCSI-2. This enabled better multitasking as multiple programs make requests for ATA transfers.

▶▶ See “SCSI Versus ATA,” p. 585.

Another standard approved by the T13 committee in 1998 is “ANSI NCITS 316-1998 1394 to AT Attachment - Tailgate,” which is a bridge protocol between the IEEE 1394 (i.LINK/FireWire) bus and ATA that enables ATA drives to be adapted to FireWire. A *tailgate* is an adapter device (basically a small circuit board) that converts IEEE 1394 (i.LINK or FireWire) to ATA, essentially allowing ATA drives to be plugged into a FireWire bus. This has enabled vendors such as Maxtor, Western Digital, and others to quickly develop IEEE 1394 (FireWire) external drives for backup and high-capacity removable data storage. Inside almost any external FireWire drive enclosure you will find the tailgate device and a standard ATA drive.

▶▶ See “IEEE 1394,” p. 992.

ATA/ATAPI-5 (AT Attachment with Packet Interface-5)

ATA-5 first appeared in 1998 and built on the previous ATA-4 interface. ATA-5 includes Ultra-ATA/66 (also called Ultra-DMA or UDMA/66), which doubles the Ultra-ATA burst transfer rate by reducing setup times and increasing the clock rate. The faster clock rate increases interference, which causes problems with the standard 40-pin cable used by ATA and Ultra-ATA. To eliminate noise and interference, the newer 40-pin, 80-conductor cable has now been made mandatory for drives running in

UDMA/66 or faster modes. This cable was first announced in ATA-4 but is now mandatory in ATA-5 to support the Ultra-ATA/66 mode. This cable adds 40 additional ground lines between each of the original 40 ground and signal lines, which helps shield the signals from interference. Note that this cable works with older, non-Ultra-ATA devices as well because it still has the same 40-pin connectors.

Work on ATA-5 began in 1998, and the standard was finished and officially published in 2000 as ANSI NCITS 340-2000, AT Attachment - 5 with Packet Interface.

The major additions in the ATA-5 standard include the following:

- Ultra-DMA (UDMA) transfer modes up to Mode 4, which is 66MBps (called UDMA/66 or Ultra-ATA/66).
- 80-conductor cable now mandatory for UDMA/66 operation.
- Added automatic detection of 40- or 80-conductor cables.
- UDMA modes faster than UDMA/33 are enabled only if an 80-conductor cable is detected.

The 40-pin, 80-conductor cables will support the cable select feature and have color-coded connectors. The blue (end) connector should be connected to the ATA host interface (usually the motherboard). The black (opposite end) connector is known as the *master position*, which is where the primary drive plugs in. The gray (middle) connector is for slave devices.

To use either the UDMA/33 or UDMA/66 mode, your ATA interface, drive, BIOS, and cable must be capable of supporting the mode you want to use. The operating system also must be capable of handling direct memory access. Windows 95 OSR2 or later, Windows 98/Me, and Windows 2000/XP are ready out of the box, but older versions of Windows 95 and NT (prior to Service Pack 3) require additional or updated drivers to fully exploit these faster modes. Contact the motherboard or system vendor for the latest drivers.

For reliability, Ultra-DMA modes incorporate an error-detection mechanism known as *cyclical redundancy checking (CRC)*. CRC is an algorithm that calculates a checksum used to detect errors in a stream of data. Both the host (controller) and the drive calculate a CRC value for each Ultra-DMA transfer. After the data is sent, the drive calculates a CRC value, and this is compared to the original host CRC value. If a difference is reported, the host might be required to select a slower transfer mode and retry the original request for data.

ATA/ATAPI-6 (AT Attachment with Packet Interface-6)

ATA-6 began development during 2000 and includes Ultra-ATA/100 (also called Ultra-DMA or UDMA/100), which increases the Ultra-ATA burst transfer rate by reducing setup times and increasing the clock rate. As with ATA-5, the faster modes require the improved 80-conductor cable. Using the ATA/100 mode requires both a drive and motherboard interface that supports that mode.

Work on ATA-6 began in 2000, and the standard was finished and officially published in 2002 as ANSI NCITS 361-2002, AT Attachment - 6 with Packet Interface.

The major changes or additions in the standard include the following:

- Ultra-DMA (UDMA) Mode 5 added, which allows 100MBps (called UDMA/100, Ultra-ATA/100, or just ATA/100) transfers.
- Sector count per command increased from 8-bits (256 sectors or 131KB) to 16-bits (65,536 sectors or 33.5MB), allowing larger files to be transferred more efficiently.
- LBA addressing extended from 2^{28} to 2^{48} (281,474,976,710,656) sectors supporting drives up to 144.12PB (petabytes = quadrillion bytes). This feature is often referred to as *48-bit LBA* or *greater than 137GB* support by vendors; Maxtor refers to this feature as *Big Drive*.
- CHS addressing made obsolete; drives must use 28-bit or 48-bit LBA addressing only.

Besides adding the 100MBps UDMA Mode 5 transfer rate, ATA-6 also extended drive capacity greatly, and just in time. ATA-5 and earlier standards supported drives of up to only 137GB in capacity, which became a limitation as larger drives were becoming available. Commercially available 3 1/2" drives exceeding 137GB were introduced during 2001, but they were originally available only in SCSI versions because SCSI doesn't share the same limitations as ATA. With ATA-6, the sector addressing limit has been extended from (2^{28}) sectors to (2^{48}) sectors. What this means is that LBA addressing previously could use only 28-bit numbers, but with ATA-6, LBA addressing can use larger 48-bit numbers if necessary. With 512 bytes per sector, this raises maximum supported drive capacity to 144.12PB. That is equal to more than 144.12 quadrillion bytes! Note that the 48-bit addressing is optional and necessary only for drives larger than 137GB. Drives 137GB or smaller can use either 28-bit or 48-bit addressing.

ATA/ATAPI-7 (AT Attachment with Packet Interface-7)

Work on ATA-7 began late in 2001 and, as with the earlier ATA standards, ATA-7 was built on the previous standard (ATA-6)—with some additions.

The primary addition in ATA-7 is another transfer mode for parallel ATA, called UDMA Mode 6, that allows for data transfers up to 133MBps. As with the UDMA Mode 5 (100MBps) and UDMA Mode 4 (66MBps), the use of an 80-conductor cable is required. Slower speeds don't require the 80-conductor cable, although they will work and are always preferred over the 40-conductor type.

Another major change in the specification was the inclusion of the Serial ATA 1.0 specification into ATA-7. This makes SATA an official part of the ATA standard. Work on ATA-7 began in 2001, and the standard was finished and officially published in 2004.

Note that although the throughput has been increased from the drive controller (on the drive) to the motherboard via the UDMA modes, most ATA drives—even those capable of UDMA Mode 6 (133MBps) from the drive to the motherboard—still have an average maximum sustained transfer rate while reading data of under 60MBps. This means that although newer ATA drives can transfer at speeds up to 133MBps from the circuit board on the drive to the motherboard, data from the drive media (platters) through the heads to the circuit board on the drive moves at less than half that rate. For that reason, running a drive capable of UDMA Mode 6 (133MBps) on a motherboard capable of only UDMA Mode 5 (100MBps) really doesn't slow things down much, if at all. Likewise, upgrading your ATA host adapter from one that does 100MBps to one that can do 133MBps won't help much if your drive reads data off the disk platters at only half that speed. Always remember that the media transfer rate is far more important than the interface transfer rate when selecting a drive because the media transfer rate is the limiting factor.

As a historical note, ATA-7 is the last revision of the venerable parallel ATA standard. ATA is evolving into Serial ATA, which was incorporated into the ATA-7 specification and is covered in detail later in this chapter.

SATA/ATAPI-8

In 2004, work began on SATA-8, which is a new ATA standard based on ATA-7 that will carry forward the development of Serial ATA while removing parallel ATA from the standard entirely. The main features of SATA-8 include

- The removal of parallel ATA from the standard
- The replacement of read long/write long functions
- Improved HPA management

The most dramatic change is the removal of parallel ATA from the SATA-8 standard. This is not intended to make parallel ATA obsolete, but instead is designed to allow new features and functions to be made available in SATA-8-compliant Serial ATA drives, while also allowing parallel ATA drives to continue to be manufactured in compliance with ATA-7. In other words, parallel drives will continue to be compliant with ATA-7 and earlier, and Serial ATA drives will be compliant with ATA-7 and later. Simplifying the ATA standard in this manner allows obsolete parallel ATA features to be removed,

resulting in a clearer and more concise description of the Serial ATA interface for future standards. It is expected that SATA-8 will be finalized and officially published in 2006.

Parallel ATA

Parallel ATA has unique specifications and requirements regarding the physical interface, cabling, and connectors as compared to Serial ATA. The following sections detail the unique features of parallel ATA.

Parallel ATA I/O Connector

The parallel ATA interface connector is normally a 40-pin header-type connector with pins spaced 0.1" (2.54mm) apart, and generally it is keyed to prevent the possibility of installing it upside down (see Figures 7.2 and 7.3). To create a keyed connector, the manufacturer usually removes pin 20 from the male connector and blocks pin 20 on the female cable connector, which prevents the user from installing the cable backward. Some cables also incorporate a protrusion on the top of the female cable connector that fits into a notch in the shroud surrounding the mating male connector on the device. The use of keyed connectors and cables is highly recommended. Plugging an ATA cable in backward normally doesn't cause any permanent damage; however, it can lock up the system and prevent it from running.

Figure 7.2 Typical parallel ATA (IDE) hard drive connectors.

Figure 7.3 Parallel ATA (IDE) 40-pin interface connector detail.

Table 7.3 shows the standard 40-pin parallel ATA (IDE) interface connector pinout.

Table 7.3 40-Pin Parallel ATA Connector

Signal Name	Pin	Pin	Signal Name
-RESET	1	2	GROUND
Data Bit 7	3	4	Data Bit 8
Data Bit 6	5	6	Data Bit 9
Data Bit 5	7	8	Data Bit 10
Data Bit 4	9	10	Data Bit 11
Data Bit 3	11	12	Data Bit 12
Data Bit 2	13	14	Data Bit 13

Data Bit 0	17	18	Data Bit 15
GROUND	19	20	KEY (pin missing)
DRQ 3	21	22	GROUND
-IOW	23	24	GROUND
-IOR	25	26	GROUND
I/O CH RDY	27	28	CSEL:SPSYNC ¹
-DACK 3	29	30	GROUND
IRQ 14	31	32	Reserved ²
Address Bit 1	33	34	-PDIAG
Address Bit 0	35	36	Address Bit 2
-CS1FX	37	38	-CS3FX
-DA/SP	39	40	GROUND
+5V (Logic)	41	42	+5V (Motor)
GROUND	43	44	Reserved

1. Pin 28 is usually cable select, but some older drives could use it for spindle synchronization between multiple drives.

2. Pin 32 was defined as -IOCS16 in ATA-2 but is no longer used.

Note that "-" preceding a signal name (such as with -RESET) indicates the signal is "active low."

The 2 1/2" drives found in notebook/laptop-size computers typically use a smaller unitized 50-pin header connector with pins spaced only 2.0mm (0.079") apart. The main 40-pin part of the connector is the same as the standard parallel ATA connector (except for the physical pin spacing), but there are added pins for power and jumpering. The cable that plugs into this connector typically has 44 pins, carrying power as well as the standard ATA signals. The jumper pins usually have a jumper on them (the jumper position controls cable select, master, or slave settings). Figure 7.4 shows the unitized 50-pin connector used on the 2 1/2" parallel ATA drives in laptop or notebook computers.

Note the jumper pins at positions A–D and that the pins at positions E and F are removed. A jumper usually is placed between positions B and D to set the drive for cable select operation. On this connector, pin 41 provides +5V power to the drive logic (circuit board), pin 42 provides +5V power to the motor (2 1/2" drives use 5V motors, unlike larger drives that typically use 12V motors), and pin 43 provides a power ground. The last pin (44) is reserved and not used.

Table 7.4 shows the 50-pin unitized parallel ATA interface connector pinout as used on most 2 1/2" (laptop or notebook computer) drives.

Figure 7.4 50-pin unitized parallel ATA connector detail (used on 2 1/2" notebook/laptop parallel ATA drives with a 44-pin cable).

Table 7.4 50-Pin Unitized Parallel ATA 2 1/2" (Notebook/Laptop Drive) Connector Pinout

Not All Cables and Connectors Are Keyed

Many lower-cost board and cable manufacturers leave out the keying. Cheaper motherboards often don't have pin 20 removed on their ATA connectors; consequently they don't supply a cable with pin 20 blocked. If they don't use a shrouded connector with a notch and a corresponding protrusion on the cable connector, no keying exists and the cables can be inserted backward. Fortunately, the only consequence of this in most cases is that the device won't work until the cable is attached with the correct orientation.

Note that some systems do not display any video until the ATA drives respond to a spin-up command, which they can't receive if the cable is connected backward. So, if you connect an unkeyed ATA drive to your computer, turn on the computer, and it seems as if the system is locked up (you don't see anything on the screen), check the ATA cable. (See Figure 7.6 for examples of unkeyed and keyed ATA cables.)

In rare situations in which you are mixing and matching items, you might encounter a cable with pin 20 blocked (as it should be) and a board with pin 20 still present. In that case, you can break off pin 20 from the board—or for the more squeamish, remove the block from the cable or replace the cable with one without the blocked pin. Some cables have the block permanently installed as a part of the connector housing, in which case you must break off pin 20 on the board or device end or use a different cable.

The simple rule of thumb is that pin 1 should be oriented toward the power connector on the device, which normally corresponds to the stripe on the cable.

Parallel ATA I/O Cable

A 40-conductor ribbon cable is specified to carry signals between the bus adapter circuits and the drive (controller). To maximize signal integrity and eliminate potential timing and noise problems, the cable should not be longer than 18" (0.46 meters), although testing shows that 80-conductor cables can be used reliably up to 27" (0.69 meters) in length.

Note that ATA drives supporting the higher-speed transfer modes, such as PIO Mode 4 or any of the Ultra-DMA (UDMA) modes, are especially susceptible to cable integrity problems and cables that are too long. If the cable is too long, you can experience data corruption and other errors that can be maddening. This is manifested in problems reading from or writing to the drive. In addition, any drive using UDMA Mode 5 (66MBps transfer rate), Mode 6 (100MBps transfer rate), or Mode 7 (133MBps transfer rate) must use a special, higher-quality 80-conductor cable (the extra conductors are grounds to reduce noise). I also recommend this type of cable if your drive is running at UDMA Mode 2 (33MBps) or slower because it can't hurt and can only help. I always keep a high-quality 80-conductor ATA cable in my toolbox for testing drives where I suspect cable integrity or cable length problems. Figure 7.5 shows the typical ATA cable layout and dimensions.

Figure 7.5 Parallel ATA (IDE) cable, with 40-pin connectors and either 40- or 80-conductor cables (additional wires are grounded in 80-conductor versions).

Note

Most 40-conductor cables do not color-code the connectors, whereas all 80-conductor cables do color-code the connectors.

Two primary variations of parallel ATA cables are used today: one with 40 conductors and the other with 80 conductors (see Figure 7.6). Both use 40-pin connectors, and the additional wires in the 80-conductor version are simply wired to ground. The additional conductors are designed to reduce noise and interference and are required when setting the interface to run at 66MBps (ATA/66) or faster. The drive and host adapter are designed to disable the higher-speed ATA/66, ATA/100, or ATA/133 modes if an 80-conductor cable is not detected. In such cases, you might see a warning message when you start your computer if an ATA/66 or faster drive is connected to a 40-conductor cable. The 80-conductor cable can also be used at lower speeds; although this is unnecessary, it improves the signal integrity. Therefore, it is the recommended version no matter which drive you use.

I once had a student ask me how to tell an 80-conductor cable from a 40-conductor cable. I thought to myself, “Is this a trick question?” Perhaps they didn’t know that each conductor in a ribbon cable can be seen as a rib or ridge in the cable. The simple answer is to count the ridges (conductors) in the cable. If you count only 40, it must be a 40-conductor cable, and if you count to 80, well...you get the idea! If you observe them side by side, the difference is clear: The 80-conductor cable has an obviously smoother, less ridged appearance than the 40-conductor cable.

Figure 7.6 40-conductor (left) and 80-conductor (right) parallel ATA cables.

Note the keying on the 80-conductor cable that is designed to prevent backward installation, but note also that the poorly constructed 40-conductor cable shown in this example lacks keying. Most good 40-conductor cables include the keying; however, because it is optional, many cheaply constructed versions do not include it. Keying was made mandatory for all 80-conductor cables as part of the standard.

Longer or Rounded Cables

The official parallel ATA standard limits cable length to 18" (0.46 meters); however, many of these cables that are sold are longer, up to even 36" (0.91 meters) or more in length. I’ve had many readers write me questioning the length, asking, “Why would people sell cables longer than 18" if the standard doesn’t allow it?” Well, just because something is for sale doesn’t mean it conforms to the standards and will work properly! I see improperly designed, poorly manufactured, and nonconforming items for sale all the time. Still, many people have used the longer cables and yet their systems seem to work fine, but I’ve also documented numerous cases where using longer cables has caused problems, so I decided to investigate this issue more thoroughly.

What I’ve discovered is that you can use longer 80-conductor cables reliably up to 27" (0.69 meters) in length, but 40-conductor cables should remain limited to 18" just as the standard indicates.

In fact, an attempt was made to change the parallel ATA standard to allow 27" cables. If you read www.t13.org/technical/e00151r0.pdf, you’ll see data from a proposal that shows “negligible differences in Ultra DMA Mode 5 signal integrity between a 27", 80-conductor cable and an 18", 80-conductor cable.” This extended cable design was actually proposed back in October 2000, but it was never incorporated into the standard. Even though it was never officially approved, I take the information presented in this proposal as empirical evidence for allowing the use of 80-conductor cables up to 27" in length without problems.

To that, I would add another recommendation, which is that in general I do not recommend “rounded” ATA cables. A rounded design has not been approved in the ATA standard, and there is some evidence that they can cause problems with crosstalk and noise. The design of 80-conductor cables is such that a ground wire is interspersed between each data wire in the ribbon, and *rounding* the cable causes some of the data lines to run parallel or adjacent to each other at random, thereby causing crosstalk and noise and resulting in signal errors.

In support of this, I read an interview with Rahul Sood in the March 2004 issue of *CPU* (www.computerpoweruser.com). Sood is the chief technology officer of a popular builder of high-end systems, called Voodoo PC (www.voodoopc.com). In the *CPU* interview, he said, “I don’t agree with rounded cables, I never have. SATA cables are great, of course, but rounded [parallel ATA] cables are a different story because there is potential for noise. Any benchmarks that I’ve run on any of the rounded cables that we’ve tested show either errors generating over time or they’re slower than good quality flat IDE cables.”

Of course, many people are using rounded cables with success, but my knowledge of electrical engineering as well as the ATA standard has always made me somewhat uncomfortable with their use. Although I cannot offer any specific test data to corroborate the findings of Sood, I do prefer to stick with 80-conductor ribbon cables of 27" or less in length in my own systems.

Parallel ATA Signals

This section describes some of the most important parallel ATA signals having to do with drive configuration and installation in more detail. This information can help you understand how the cable select feature works, for example.

Pin 20 is used as a key pin for cable orientation and is not connected to the interface. This pin should be missing from any ATA connectors, and the cable should have the pin-20 hole in the connector plugged off to prevent the cable from being plugged in backward.

Pin 39 carries the drive active/slave present (DASP) signal, which is a dual-purpose, time-multiplexed signal. During power-on initialization, this signal indicates whether a slave drive is present on the interface. After that, each drive asserts the signal to indicate that it is active. Early drives could not multiplex these functions and required special jumper settings to work with other drives. Standardizing this function to allow for compatible dual-drive installations is one of the features of the ATA standard. This is why some drives require a slave present (SP) jumper whereas others do not.

Pin 28 carries the cable select signal (CSEL). In some older drives, it could also carry a spindle synchronization signal (SPSYNC), but that is not commonly found on newer drives. The CSEL function is the most widely used and is designed to control the designation of a drive as master (drive 0) or slave (drive 1) without requiring jumper settings on the drives. If a drive sees the CSEL as being grounded, the drive is a master; if CSEL is open, the drive is a slave.

You can install special cabling to ground CSEL selectively. This installation usually is accomplished through a Y-cable arrangement, with the ATA bus connector in the middle and each drive at opposite ends of the cable. One leg of the Y has the CSEL line connected through, indicating a master drive; the other leg has the CSEL line open (conductor interrupted or removed), making the drive at that end the slave.

Parallel ATA Dual-Drive Configurations

Dual-drive parallel ATA installations can be problematic because each drive has its own controller and both controllers must function while being connected to the same bus. There has to be a way to ensure that only one of the two controllers will respond to a command at a time.

The ATA standard provides the option of operating on the AT bus with two drives in a daisy-chained configuration. The primary drive (drive 0) is called the *master*, and the secondary drive (drive 1) is called the *slave*. You designate a drive as being master or slave by setting a jumper or switch on the

drive or by using a special line in the interface called the *cable select (CS) pin* and setting the CS jumper on the drive.

When only one drive is installed, the controller responds to all commands from the system. When two drives (and, therefore, two controllers) are installed, both controllers receive all commands from the system. Each controller then must be set up to respond only to commands for itself. In this situation, one controller must be designated as the master and the other as the slave. When the system sends a command for a specific drive, the controller on the other drive must remain silent while the selected controller and drive are functioning. Setting the jumper to master or slave enables discrimination between the two controllers by setting a special bit (the DRV bit) in the drive/head register of a command block.

Configuring ATA drives can be simple, as is the case with most single-drive installations. Or it can be troublesome, especially when it comes to mixing two older drives from different manufacturers on a single cable.

Most ATA drives can be configured with four possible settings:

- Master (single-drive)
- Slave (dual-drive)
- Master (dual-drive)
- Cable select

Many drives simplify this to three settings: master, slave, and cable select. Because each ATA drive has its own controller, you must specifically tell one drive to be the master and the other to be the slave. No functional difference exists between the two, except that the drive that's specified as the slave will assert a signal called DASP after a system reset informs the master that a slave drive is present in the system. The master drive then pays attention to the drive select line, which it otherwise ignores. Telling a drive that it's the slave also usually causes it to delay its spinup for several seconds to allow the master to get going and thus to lessen the load on the system's power supply.

Until the ATA specification, no common implementation for drive configuration was in use. Some drive companies even used different master/slave methods for different models of drives. Because of these incompatibilities, some drives work together only in a specific master/slave or slave/master order. This situation mostly affects older IDE drives introduced before the ATA specification.

Most drives that fully follow the ATA specification now need only one jumper (master/slave) for configuration. A few also need a slave present jumper, as well. Table 7.5 shows the jumper settings required by most ATA drives.

Table 7.5 Jumper Settings for Most ATA-Compatible Drives on Standard (Non-Cable Select) Cables

Jumper Name	Single-Drive	Dual-Drive Master	Dual-Drive Slave
Master (M/S)	On	On	Off
Slave Present (SP)	Off	On	Off
Cable Select (CS)	Off	Off	Off

Note

If a cable select cable is used, the CS jumper should be set On and all others should be Off. The cable connector then determines which drive will be master or slave.

Figure 7.7 shows the jumpers on a typical ATA drive.

Figure 7.7 Parallel ATA (IDE) drive jumpers for most drives.

The master jumper indicates that the drive is a master or a slave. Some drives also require a slave present jumper, which is used only in a dual-drive setup and then installed only on the master drive—which is somewhat confusing. This jumper tells the master that a slave drive is attached. With many parallel ATA drives, the master jumper is optional and can be left off. Installing this jumper doesn't hurt in these cases and can eliminate confusion; I recommend that you install the jumpers listed here.

Note

Note that some drives have these jumpers on the drive circuit board on the bottom of the drive, and as such they might not be visible on the rear.

To eliminate confusion over master/slave settings, most newer systems now use the cable select option. This involves two things. The first is having a special parallel ATA cable that has all the wires except pin 28 running from the motherboard connector to both drive connectors. Pin 28 is used for cable select and is connected to one of the drive connectors (labeled master) and not to the other (labeled slave). Both drives are then configured in cable select mode via the CS jumper on each drive.

With cable select, the drive that receives signals on pin 28 automatically becomes the master, and the other becomes the slave. Most cables implement this by removing the metal insulation displacement bit from the pin-28 hole, which can be difficult to see at a glance. Other cables have a section of pin 28 visibly cut from the cable somewhere along the ribbon. Because this is such a minor modification

to the cable and can be difficult to see, cable select cables typically have the connectors labeled master, slave, and system, indicating that the cable controls these options rather than the drive. All 80-conductor UltraATA cables are designed to use cable select.

With cable select, you simply set the CS jumper on all drives and then plug the drive you want to be the master into the connector labeled master on the cable and the drive you want to be the slave into the connector labeled slave.

The only downside I see to using cable select is that it can restrict how the cable is routed or where you mount the drive that is to be master versus slave because they must be plugged in to specific cable connector positions.

Parallel ATA PIO Transfer Modes

ATA-2 and ATA-3 defined the first of several higher-performance modes for transferring data over the parallel ATA interface, to and from the drive. These faster modes were the main part of the newer specifications and were the main reason they were initially developed. The following section discusses these modes.

The PIO (programmed I/O) mode determines how fast data is transferred to and from the drive using PIO transfers. In the slowest possible mode—PIO Mode 0—the data cycle time can't exceed 600 nanoseconds (ns). In a single cycle, 16 bits are transferred into or out of the drive, making the theoretical transfer rate of PIO Mode 0 (600ns cycle time) 3.3MBps, whereas PIO Mode 4 (120ns cycle time) achieves a 16.6MBps transfer rate.

Table 7.6 shows the PIO modes, with their respective transfer rates.

Table 7.6 PIO Modes and Transfer Rates

PIO Mode	Bus Width (Bits)	Cycle Speed (ns)	Bus Speed (MHz)	Cycles per Clock	Transfer Rate (MBps)	ATA Specification
0	16	600	1.67	1	3.33	ATA-1
1	16	383	2.61	1	5.22	ATA-1
2	16	240	4.17	1	8.33	ATA-1
3	16	180	5.56	1	11.11	ATA-2
4	16	120	8.33	1	16.67	ATA-2

ATA-2 was also referred to as EIDE (Enhanced IDE) or Fast-ATA.

ns = nanoseconds (billionths of a second)

MB = million bytes

Most motherboards with ATA-2 or greater support have dual ATA connectors on the motherboard. Most of the motherboard chipsets include the ATA interface in their South Bridge components, which in most systems is tied into the PCI bus.

Older 486 and some early Pentium boards have only the primary connector running through the system's PCI local bus. The secondary connector on those boards usually runs through the ISA bus and therefore supports up to Mode 2 operation only.

When interrogated with an Identify Drive command, a hard disk returns, among other things, information about the PIO and DMA modes it is capable of using. Most enhanced BIOSs automatically set the correct mode to match the capabilities of the drive. If you set a mode faster than the drive can handle, data corruption results.

ATA-2 and newer drives also perform Block Mode PIO, which means they use the Read/Write Multiple commands that greatly reduce the number of interrupts sent to the host processor. This lowers the overhead, and the resulting transfers are even faster.

Parallel ATA DMA Transfer Modes

ATA drives also support *direct memory access (DMA)* transfers. DMA means that the data is transferred directly between drive and memory without using the CPU as an intermediary, as opposed to PIO. This has the effect of offloading much of the work of transferring data from the processor, in effect allowing the processor to do other things while the transfer is taking place.

There are two distinct types of direct memory access: singleword (8-bit) and multiword (16-bit) DMA. Singleword DMA modes were removed from the ATA-3 and later specifications and are obsolete. DMA modes are also sometimes called *busmaster* ATA modes because they use a host adapter that supports bus-mastering. Ordinary DMA relies on the legacy DMA controller on the motherboard to perform the complex task of arbitration, grabbing the system bus and transferring the data. In the case of busmastering DMA, all this is done by a higher-speed logic chip in the host adapter interface (which is also on the motherboard).

Systems using the Intel PIIX (PCI IDE ISA eXcelerator) and later South Bridge chips (or equivalent) have the capability of supporting busmaster ATA. The singleword and doubleword busmaster ATA modes and transfer rates are shown in Tables 7.7 and 7.8.

Table 7.7 Singleword (8-bit) DMA Modes and Transfer Rates

8-bit DMA Mode	Bus Width (Bits)	Cycle Speed (ns)	Bus Speed (MHz)	Cycles per Clock	Transfer Rate (MBps)	ATA Specification
0	16	960	1.04	1	2.08	ATA-1*
1	16	480	2.08	1	4.17	ATA-1*
2	16	240	4.17	1	8.33	ATA-1*

*Singleword (8-bit) DMA modes were removed from the ATA-3 and later specifications.

Table 7.8 Multiword (16-bit) DMA Modes and Transfer Rates

16-bit DMA Mode	Bus Width (Bits)	Cycle Speed (ns)	Bus Speed (MHz)	Cycles per Clock	Transfer Rate (MBps)	ATA Specification
0	16	480	2.08	1	4.17	ATA-1
1	16	150	6.67	1	13.33	ATA-2*
2	16	120	8.33	1	16.67	ATA-2*

*ATA-2 was also referred to as EIDE (Enhanced IDE) or Fast-ATA.

Note that doubleword DMA modes are also called busmaster DMA modes by some manufacturers. Unfortunately, even the fastest doubleword DMA Mode 2 results in the same 16.67MBps transfer speed as PIO Mode 4. However, even though the transfer speed is the same as PIO, because DMA offloads much of the work from the processor, overall system performance is higher. Even so, multiword DMA modes were never very popular and have been superseded by the newer Ultra-DMA modes supported in devices that are compatible with ATA-4 through ATA-7.

Table 7.9 shows the Ultra-DMA modes now supported in the ATA-4 through ATA-7 specifications. Note that you need to install the correct drivers for your host adapter and version of Windows to use this feature.

Table 7.9 Ultra-DMA Support in ATA-4 Through ATA-7

Ultra DMA Mode	Bus Width	Cycle Speed (Bits)	Bus Speed (ns)	Cycles per (MHz)	Transfer Rate Clock	ATA Specification (MBps)
0	16	240	4.17	2	16.67	ATA-4
1	16	160	6.25	2	25.00	ATA-4
2	16	120	8.33	2	33.33	ATA-4
3	16	90	11.11	2	44.44	ATA-5
4	16	60	16.67	2	66.67	ATA-5
5	16	40	25.00	2	100.00	ATA-6
6	16	30	33.00	2	133.00	ATA-7

ATA-4 UDMA Mode 2 is sometimes called Ultra-ATA/33 or ATA-33.

ATA-5 UDMA Mode 4 is sometimes called Ultra-ATA/66 or ATA-66.

ATA-6 UDMA Mode 5 is sometimes called Ultra-ATA/100 or ATA-100.

ATA-7 UDMA Mode 6 is sometimes called Ultra-ATA/133 or ATA-133.

Serial ATA

With the release of ATA-7, it seems that the parallel ATA standard that has been in use for more than 10 years has finally reached the end of the line. Sending data at rates faster than 133MBps down a parallel ribbon cable is fraught with all kinds of problems because of signal timing, electromagnetic interference (EMI), and other integrity problems. The solution is called Serial ATA, which is an evolutionary replacement for the venerable parallel ATA physical storage interface. Serial ATA is software-compatible with parallel ATA, which means it fully emulates all the commands, registers, and controls so existing software will run on the new architecture without any changes. In other words, the existing BIOSs, operating systems, and utilities that work on parallel ATA also work on Serial ATA.

Of course, they do differ physically—that is, you can't plug parallel ATA drives into Serial ATA host adapters and vice versa, although signal converters make that possible. The physical changes are all for the better because Serial ATA uses much smaller and thinner cables with only seven conductors that are easier to route inside the PC and easier to plug in with smaller, redesigned cable connectors. The interface chip designs also are improved with far fewer pins and lower voltages. These improvements are all designed to eliminate the design problems inherent in parallel ATA.

Figure 7.8 shows the official Serial ATA working group logo used to identify most Serial ATA devices.

Figure 7.8 Serial ATA official logo, which is used to identify SATA devices.

Although Serial ATA won't immediately replace parallel ATA, most new systems include Serial ATA interfaces alongside parallel ATA interfaces. Eventually, SATA will replace parallel ATA as the de facto standard internal storage device interface found in PCs. As current motherboard designs indicate, the transition from ATA to SATA is a gradual one, and during this transition parallel ATA capabilities

will continue to be available. I also expect that, with more than a 10-year history, parallel ATA devices will continue to be available even after most PCs have gone to SATA.

Development for Serial ATA started when the Serial ATA Working Group effort was announced at the Intel Developer Forum in February 2000. The initial members of the Serial ATA Working Group included APT Technologies, Dell, IBM, Intel, Maxtor, Quantum, and Seagate. The first Serial ATA 1.0 draft specification was released in November 2000 and was officially published as a final specification in August 2001. The Serial ATA II extensions to this specification, which make Serial ATA suitable for network storage, were released in October 2002. Both can be downloaded from the Serial ATA Working Group Web site at <http://www.serialata.org>. Since forming, the group has added more than 150 Contributor and Adopter companies to the membership from all areas of industry. Systems using Serial ATA were first released in late 2002 using discrete PCI interface boards and chips. SATA was finally integrated directly into the motherboard chipset in April 2003 with the introduction of the Intel ICH5 (I/O controller hub) chipset component. Since then, most new motherboard chipsets have included Serial ATA.

The performance of SATA is impressive, although current hard drive designs can't fully take advantage of its bandwidth. Three variations of the standard have been proposed that all use the same cables and connectors; they differ only in transfer rate performance. Currently, only the first two speeds are available, with higher speeds coming in the future. Table 7.10 shows the specifications for the current and future proposed SATA versions; the next-generation 300MBps version is not expected until 2005, whereas the 600MBps version is expected in 2007.

Table 7.10 Serial ATA Transfer Modes

Serial ATA Type	Signal Rate (Gbps)	Bus Width (Bits)	Bus Speed (MHz)	Data Cycles per Clock	Bandwidth (MBps)
SATA-150	1.5	1	1500	1	150
SATA-300	3.0	1	3000	1	300
SATA-600	6.0	1	6000	1	600

From Table 7.10, you can see that Serial ATA sends data only a single bit at a time. The cable used has only seven wires (four signal and three ground) and is a very thin design, with keyed connectors only 14mm (0.55") wide on each end. This eliminates problems with airflow compared to the wider parallel ATA ribbon cables. Each cable has connectors only at each end, and each cable connects the device directly to the host adapter (typically on the motherboard). There are no master/slave settings because each cable supports only a single device. The cable ends are interchangeable—the connector on the motherboard is the same as on the device, and both cable ends are identical. Maximum SATA cable length is 1 meter (39.37"), which is considerably longer than the 18" maximum for parallel ATA. Even with this thinner, longer, and less-expensive cable, you initially get transfer rates of 150MBps (nearly 13% greater than parallel ATA/133). Serial ATA-II supports 300MBps, and even 600MBps is possible.

Serial ATA uses a special encoding scheme called 8B/10B to encode and decode data sent along the cable. The 8B/10B transmission code originally was developed (and patented) by IBM in the early 1980s for use in high-speed data communications. This encoding scheme is now used by many high-speed data transmission standards, including Gigabit Ethernet, Fibre Channel, FireWire, and others. The main purpose of the 8B/10B encoding scheme is to guarantee that there are never more than four 0s (or 1s) transmitted consecutively. This is a form of run length limited (RLL) encoding called RLL 0,4, in which the 0 represents the minimum and the 4 represents the maximum number of consecutive 0s in each encoded character.

8B/10B encoding also ensures that there are never more than six or fewer than four 0s (or 1s) in a single encoded 10-bit character. Because 1s and 0s are sent as voltage changes on a wire, this ensures that the spacing between the voltage transitions sent by the transmitter is fairly balanced, with a more

regular and steady stream of pulses. This presents a steadier load on the circuits, increasing reliability. The conversion from 8-bit data to 10-bit encoded characters for transmission leaves several 10-bit patterns unused. Many of these additional patterns are used to provide flow control, delimit packets of data, perform error checking, or perform other special functions.

Serial ATA Cables and Connectors

The physical transmission scheme for SATA uses *differential NRZ (nonreturn to zero)*. This uses a balanced pair of wires, each carrying +0.25V (one-quarter volt). The signals are sent differentially: If one wire in the pair carries +0.25V, the other wire carries -0.25V, where the differential voltage between the two wires is always 0.5V (one-half volt). So, for a given voltage waveform, the opposite voltage waveform is sent along the adjacent wire. Differential transmission minimizes electromagnetic radiation and makes the signals easier to read on the receiving end.

A 15-pin power cable and power connector is optional with SATA, providing 3.3V power in addition to the 5V and 12V provided via the industry-standard 4-pin device power connectors. Although it has 15 pins, this new power connector design is only 24mm (0.945"). With 3 pins designated for each of the 3.3V, 5V, and 12V power levels, enough capacity exists for up to 4.5 amps of current at each voltage, which is plenty for even the most power-hungry drives. For compatibility with existing power supplies, SATA drives can be made with the original, standard 4-pin device power connector or the new 15-pin SATA power connector—or both. If the drive doesn't have the type of connector you need, adapters are available to convert from one type to the other.

Figure 7.9 shows what the new SATA signal and power connectors look like.

Figure 7.9 SATA (Serial ATA) signal and power connectors on a typical SATA hard drive.

Figure 7.10 shows SATA and parallel ATA host adapters on a typical motherboard.

Figure 7.10 A motherboard with Serial and parallel ATA host adapters.

The pinouts for the Serial ATA data and optional power connectors are shown in Tables 7.11 and 7.12, respectively.

Table 7.11 Serial ATA Data Connector Pinout

Signal Pin	Signal	Description
S1	Gnd	First mate
S2	A+	Host Transmit +
S3	A-	Host Transmit -
S4	Gnd	First mate
S5	B-	Host Receive -
S6	B+	Host Receive +
S7	Gnd	First mate

All pins are in a single row spaced 1.27mm (.050") apart.

All ground pins are longer so they will make contact before the signal/power pins to allow hot plugging.

Table 7.12 Serial ATA Optional Power Connector Pinout

Power Pin	Signal	Description
P1	+3.3V	3.3V power
P2	+3.3V	3.3V power
P3	+3.3V	3.3V power
P4	Gnd	First mate
P5	Gnd	First mate
P6	Gnd	First mate
P7	+5V	5V power
P8	+5V	5V power
P9	+5V	5V power
P10	Gnd	First mate
P11	Gnd	First mate
P12	Gnd	First mate
P13	+12V	12V power
P14	+12V	12V power
P15	+12V	12V power

All pins are in a single row spaced 1.27mm (.050") apart.

All ground pins are longer so they will make contact before the signal/power pins to allow hot plugging.

Three power pins are used to carry 4.5 amps, a maximum current for each voltage.

Serial ATA Configuration

Configuration of Serial ATA devices is also much simpler because the master/slave or cable select jumper settings used with parallel ATA are no longer necessary.

BIOS setup for Serial ATA drives is also quite simple. Because Serial ATA is based on ATA, autodetection of drive settings on systems with Serial ATA connectors is performed in the same way as on parallel ATA systems. Depending on the system, Serial ATA interfaces might be enabled by default or might need to be enabled in the BIOS setup program (see Chapter 5, “BIOS,” for details).

Because Serial ATA is based on parallel ATA, you can adapt ATA-100 and ATA-133 hard disks to a Serial ATA host adapter with a converter such as the HighPoint RocketHead 100 device shown in Figure 7.11. This converter is included with HighPoint Serial ATA RAID host adapters, and similar devices can be purchased from aftermarket vendors.

Figure 7.11 Two views of the HighPoint RocketHead 100 converter.

If you want to use Serial ATA drives but don't want to install a new motherboard with Serial ATA host adapters already included, you can install a separate Serial ATA host adapter into a PCI expansion slot (see Figure 7.12). Most of these adapters include ATA RAID functions.

Some of the first Serial ATA host adapters, such as models from HighPoint and 3Ware, use a parallel-to-Serial ATA bridge technology that consumes as much as half of the available bandwidth. Other adapters, such as those made by Promise Technology, use native Serial ATA controller chips, which is a better solution in theory because it preserves all the bandwidth for use by the drive. However, current Serial ATA drives, like their parallel ATA siblings, cannot transfer data at anything close to the 150MBps rate of the host adapter; 40MBps–50MBps is the typical range for average transfer speeds of 7200rpm Serial ATA drives.

Serial ATA II

As with parallel ATA, Serial ATA was designed to be the primary storage interface used inside a PC and was not initially designed to be used as an external interface. However, with Serial ATA II (SATA-8, under development), Serial ATA will evolve to include external connections, storage enclosures with multiple drives, and port multipliers that allow up to 15 SATA drives to be connected to a single SATA port. The external connection is designed to support four lanes, with 300MBps per lane, for a total of 1200MBps. This competes with external SCSI for RAID enclosures but most likely won't compete with general-purpose high-speed external device interfaces such as USB 2.0 and IEEE 1394 (i.LINK/FireWire). Because of the lower cost and smaller size of the internal cabling, there is little doubt that Serial ATA will replace parallel ATA inside both desktop and laptop systems over the next few years.

Figure 7.12 Typical two-channel (top) and four-channel (bottom) Serial ATA RAID host adapters. The two-channel adapter also includes a parallel ATA host adapter.

Advanced Host Controller Interface

Serial ATA was designed not only as a replacement for parallel ATA, but also as an interface that would evolve into something with many more capabilities and features than its predecessor. Initially, compatibility with parallel ATA was one of the most important features of Serial ATA because it enabled a smooth and easy transition from one to the other. This compatibility extends to the driver level, allowing Serial ATA devices to use the same BIOS-level drivers and software as legacy parallel ATA devices.

Although the intent of Serial ATA was to allow an easy transition from parallel ATA, it was also designed to allow future growth and expansion of capabilities. To accomplish this, an enhanced software interface called the Advanced Host Controller Interface (AHCI) was initially developed by the AHCI Contributor Group, a group chaired by Intel and originally consisting of AMD, Dell, Marvell, Maxtor, Microsoft, Red Hat, Seagate, and StorageGear. The AHCI Contributor Group released a preliminary version of AHCI v0.95 in May 2003 and released the final specification in 2004.

AHCI provides a standard, high-performance interface to system driver/OS software for discovering and implementing such advanced SATA features as command queuing, hot plugging, and power management. AHCI was integrated into Serial ATA-supporting chipsets in 2004 and is supported by AHCI drivers for Windows.

Serial ATA Transfer Modes

Serial ATA transfers data in a completely different manner from parallel ATA. As indicated previously, the transfer rates are 150MBps, 300MBps, and 600MBps, with most drives today using the 150MBps rate. However, because SATA is designed to be backward-compatible with parallel ATA, some confusion can result because SATA drives can report and emulate parallel ATA mode settings for backward compatibility. This means that the drive is merely lying for backward compatibility with existing software.

For example, many motherboards detect and report a Serial ATA drive as supporting Ultra DMA Mode 5 (ATA/100), which is a parallel ATA mode operating at 100MBps. This is obviously incorrect because even the slowest Serial ATA mode (SATA-150) is 150MBps and Ultra DMA modes simply do not apply to Serial ATA drives.

Parallel and Serial ATA are completely different electrical and physical specifications, but Serial ATA does *emulate* parallel ATA in a way that makes it completely software transparent. In fact, the parallel ATA emulation in Serial ATA specifically conforms to the ATA-5 specification.

This is especially apparent in the IDENTIFY DEVICE command used by the autodetect routines in the BIOS to read the drive parameters. The Serial ATA specification indicates that many of the items returned by IDENTIFY DEVICE are to be “set as indicated in ATA/ATAPI-5,” including available UDMA modes and settings.

The SATA 1 specification also says, “Emulation of parallel ATA device behavior as perceived by the host BIOS or software driver, is a cooperative effort between the device and the Serial ATA host adapter hardware. The behavior of Command and Control Block registers, PIO and DMA data transfers, resets, and interrupts are all emulated. The host adapter contains a set of registers that shadow the contents of the traditional device registers, referred to as the Shadow Register Block. All Serial ATA devices behave like Device 0 devices. Devices shall ignore the DEV bit in the Device/Head field of received Register FISs, and it is the responsibility of the host adapter to gate transmission of Register FISs to devices, as appropriate, based on the value of the DEV bit.”

This means the shadow register blocks are “fake” parallel ATA registers, allowing all ATA commands, modes, and so on to be emulated. Serial ATA was designed to be fully software compatible with ATA/ATAPI-5, which is why a Serial ATA drive can report in some ways as if it were parallel ATA or running in parallel ATA modes, even though it isn't.

ATA Features

The ATA standards have gone a long way toward eliminating incompatibilities and problems with interfacing IDE drives to ISA/PCI bus systems. The ATA specifications define the signals on the 40-pin connector, the functions and timings of these signals, cable specifications, and so on. The following section lists some of the elements and functions defined by the ATA specifications.

ATA Commands

One of the best features of the ATA interface is the enhanced command set. The ATA interface was modeled after the WD1003 controller IBM used in the original AT system. All ATA drives must support the original WD command set (eight commands) with no exceptions, which is why ATA drives are so easy to install in systems today. All IBM-compatible systems have built-in ROM BIOS support for the WD1003, so they essentially support ATA as well.

In addition to supporting all the WD1003 commands, the ATA specification added numerous other commands to enhance performance and capabilities. These commands are an optional part of the ATA interface, but several of them are used in most drives available today and are very important to the performance and use of ATA drives in general.

Perhaps the most important is the IDENTIFY DRIVE command. This command causes the drive to transmit a 512-byte block of data that provides all details about the drive. Through this command, any program (including the system BIOS) can find out exactly which type of drive is connected, including the

drive manufacturer, model number, operating parameters, and even the serial number of the drive. Many modern BIOSs use this information to automatically receive and enter the drive's parameters into CMOS memory, eliminating the need for the user to enter these parameters manually during system configuration. This arrangement helps prevent mistakes that can later lead to data loss when the user no longer remembers what parameters he used during setup.

The Identify Drive data can tell you many things about your drive, including the following:

- Number of logical block addresses available using LBA mode
- Number of physical cylinders, heads, and sectors available in P-CHS mode
- Number of logical cylinders, heads, and sectors in the current translation L-CHS mode
- Transfer modes (and speeds) supported
- Manufacturer and model number
- Internal firmware revision
- Serial number
- Buffer type/size, indicating sector buffering or caching capabilities

Several public-domain programs can execute this command to the drive and report the information onscreen. In the past, I've used the IDEINFO program available at <http://www.tech-pro.co.uk/ideinfo.html>. However, because this program was created almost a decade ago, it doesn't provide the best information about recent drives. For more up-to-date information, use IDEDIAG, which is available from <http://www.penguin.cz/~mhi/idediag>, or HWINFO, which is available from <http://www.hwinfo.com>. (I find these programs especially useful when I am trying to install ATA drives on a system that has a user-defined drive type but doesn't support autodetection and I need to know the correct parameters for a user-definable BIOS type. These programs get the information directly from the drive.)

Two other important commands are the Read Multiple and Write Multiple commands. These commands permit multiple-sector data transfers and, when combined with block-mode PIO capabilities in the system, can result in incredible data-transfer rates many times faster than single-sector PIO transfers. Some older systems require you to select the correct number of sectors supported by the drive, but most recent systems automatically determine this information for you.

Many other enhanced commands are available, including room for a given drive manufacturer to implement what are called *vendor-unique* commands. Certain vendors often use these commands for features unique to that vendor. Often, vendor-unique commands control features such as low-level formatting and defect management. This is why low-level format programs can be so specific to a particular manufacturer's ATA drives and why many manufacturers make their own LLF programs available.

ATA Security Mode

Support for hard disk passwords (called ATA Security Mode) was added to the ATA-3 specification during 1995. The proposal adopted in the ATA specification was originally from IBM, which had developed this capability and which had already begun incorporating it into ThinkPad systems and IBM 2.5" drives. Because it was then incorporated into the official ATA-3 standard (finally published in 1997), most other drive and system manufacturers have also adopted this, especially for laptop systems and 2.5" drives. Note that these passwords are *very* secure. Also, if you lose or forget them, they usually cannot be recovered and you will never be able to access the drive. More on that later...

Hard disk security passwords are set via the BIOS Setup, and not all systems support this feature. Most laptops support hard disk security, but most desktops do not. If supported, two types of hard disk passwords can be set, called user and master. The user password locks and unlocks the disk, whereas the master password is used to only unlock. You can set only a user password, or you can set user+master, but you cannot set a master password alone.

When a user password is set (with no master), or when both user+master passwords are set, access to the drive is prevented (even if the drive is moved to a different system) unless the user (or master) password is entered upon system startup.

The master password is designed to be an alternative or backup password for system administrators as a master unlock. With both master and user passwords set, the user is told the user password but not the master password. Subsequently, the user can change the user password as desired; however, a system administrator can still gain access by using the master password.

If a user or user+master password is set, the disk must be unlocked at boot time via a BIOS-generated password prompt. The appearance of the prompt varies from system to system, but in IBM systems the prompt is graphical. An icon consisting of a cylinder with a number above it (indicating the drive number) next to a padlock appears onscreen. If the hard disk password prompt appears, you must enter it; otherwise, you will be denied access to the drive and the system will not boot.

As I said earlier, if you forget the user password (with no master) or both the user and master passwords (if both are set), you will not be able to gain access to the drive, even if you move it to another system and even if the other system does not support ATA Security Mode. The drive will have essentially become a paper weight.

As with many security features, a workaround might be possible if you forget your password. In this case, at least one company can either restore the drive to operation (with all the data lost) or restore the drive and the data. That company is Nortek (see <http://www.nortek.on.ca> for more information). The password removal procedure costs \$85–\$295, and you must provide proof of ownership when you send in the drive. As you can see, the cost is generally more than the cost of a new drive, so it is worthwhile only if you absolutely need the data back.

Hard disk passwords are not preset on a brand-new drive, but they might be preset if you are buying a used drive or if the people or company you purchased the drive or system from entered them. This is a common ploy when selling drives or systems on eBay—for example, the seller might set supervisor or hard disk passwords and hold them until payment is received. Or he might be selling used product “as-is” for which he doesn’t have the passwords, which renders them useless to the purchaser. Because of this, I *never* recommend purchasing a laptop or hard drive used unless you are certain that no supervisor or hard disk passwords are set.

Most systems also support other power-on or supervisor passwords in the BIOS Setup. In most systems, when you set a supervisor password, it automatically sets the hard disk password to the same value as well. In most cases, if a supervisor password is set and it matches the hard disk user or master password, when you enter the supervisor password, the BIOS automatically enters the hard disk password at the same time. This means that even though a hard disk password is set, you might not even know it because the hard disk password is entered automatically at the same time as you enter the supervisor password; therefore, you won’t see a separate prompt for the hard disk password. However, if the drive is later separated from the system, it will not work on another system until the correct hard disk password is entered. Without the services of a company such as Nortek, you can remove a hard disk password only if you know the password to begin with.

Host Protected Area

Most PCs sold on the market today include some form of automated product recovery or restoration feature that allows a user to easily restore the operating system and other software on the system to the state it was in when the system was new. Originally, this was accomplished via one or more product recovery CDs containing automated scripts that reinstalled all the software that came preinstalled on the system when it was new.

Unfortunately, the CDs could be lost or damaged, they were often problematic to use, and including them by default cost manufacturers a lot of money. This prompted PC manufacturers to move the recovery software to a hidden partition of the boot hard drive. Although this wastes some space on the drive, the recovery software normally fits on from one to four CDs, which occupies 1GB–3GB of

drive space. With 60GB or larger drives, this amounts to 5% or less of the total space. Still, even the hidden partition was less than satisfactory because the partition could easily be damaged or overwritten by partitioning software or other utilities, so there was no way to make it secure.

In 1996, Gateway proposed a change to the ATA-4 standard under development that would allow a space called the host protected area to be reserved on a drive. This change was ratified, and the HPA feature set was incorporated into the ATA-4 specification that was finally published in 1998. A separate BIOS firmware interface specification called Protected Area Run Time Interface Extension Services (PARTIES) was initiated in 1999 that defined services an operating system could use to access the HPA. The PARTIES standard was completed and published in 2001 as NCITS 346-2001, Protected Area Run Time Interface Extension Services.

The HPA works by using the optional ATA SET MAX ADDRESS command to make the drive appear to the system as a slightly smaller drive. Anything from the new max address (the newly reported end of the drive) to the true end of the drive is considered the HPA and is accessible only using PARTIES commands. This is more secure than a hidden partition because any data past the end of the drive simply cannot be seen by any normal application, or even a partitioning utility such as PartitionMagic or Partition Commander. Still, if you want to remove the HPA, you can use some options in the BIOS Setup or separate commands to reset the max address, thus exposing the HPA. At that point, you can run something such as PartitionMagic or Partition Commander to resize the adjacent partition to include the extra space that was formerly hidden and unavailable.

Most new systems using Phoenix FirstBIOS come with their recovery software and diagnostics in the HPA because this is part of the new Phoenix FirstBIOS core managed environment (cME), which is used by a large number of OEMs (including IBM) on most desktop and laptop systems starting in 2003.

◀◀ For more information on the HPA and what might be stored there, see "Preboot Environment," p. 428.

ATA Packet Interface

ATA Packet Interface (ATAPI) is a standard designed to provide the commands necessary for devices such as CD-ROMs, removable media drives such as SuperDisk and Zip, and tape drives that plug in to an ordinary ATA (IDE) connector. The principal advantage of ATAPI hardware is that it's cheap and works on your current adapter. For CD-ROMs, it has a somewhat lower CPU usage compared to proprietary adapters, but there's no performance gain otherwise. For tape drives, ATAPI has the potential for superior performance and reliability compared to the popular floppy controller attached tape devices. Although ATAPI CD-ROMs use the hard disk interface, this does not mean they look like ordinary hard disks. To the contrary, from a software point of view, they are a completely different kind of animal. They most closely resemble a SCSI device. All modern ATA CD-ROMs support the ATAPI protocols, and generally the terms are synonymous. In other words, an ATAPI CD-ROM is an ATA CD-ROM, and vice versa.

Caution

Most systems starting in 1998 began supporting the Phoenix El Torito specification, which enables booting from ATAPI CD or DVD drives. Systems without El Torito support in the BIOS can't boot from an ATAPI CD or DVD drive. Even with ATAPI support in the BIOS, you still must load a driver to use ATAPI under DOS or Windows. Windows 95 and later (including 98 and Me) and Windows NT (including Windows 2000 and XP) have native ATAPI support. Some versions of the Windows 98 and Me CD-ROMs are bootable, whereas all NT, 2000, and XP CD-ROMs are directly bootable on those systems, greatly easing installation.

I normally recommend keeping ATA devices you will be accessing simultaneously on separate channels. Because ATA does not typically support overlapping access, when one drive is being accessed on a given channel, the other drive on the same channel can't be accessed. By keeping the CD-ROM and hard disk on separate channels, you can more effectively overlap accessing between them. One other caveat is that a parallel ATA device such as a hard drive might be incapable of functioning if another parallel ATAPI device (CD or DVD drive) is master. Therefore, in most cases you should try to set parallel ATA hard drives as master (device 0) and parallel ATAPI drives as slave (device 1) on a given cable.

ATA Drive Capacity Limitations

ATA interface versions up through ATA-5 suffered from a drive capacity limitation of about 137GB (billion bytes). Depending on the BIOS used, this limitation can be further reduced to 8.4GB, or even as low as 528MB (million bytes). This is due to limitations in both the BIOS and the ATA interface, which when combined create even further limitations. To understand these limits, you have to look at the BIOS (software) and ATA (hardware) interfaces together.

Note

In addition to the BIOS/ATA limitations discussed in this section, various operating system limitations also exist. These are described later in this chapter.

The limitations when dealing with ATA drives are those of the ATA interface itself as well as the BIOS interface used to talk to the drive. A summary of the limitations is shown in Table 7.13.

This section details the differences between the various sector addressing methods and the limitations incurred by using them.

Prefixes for Decimal and Binary Multiples

Many readers are unfamiliar with the MiB (mebibyte), GiB (gibibyte), and so on designations I am using in this section and throughout the book. These are part of a standard designed to eliminate confusion between decimal- and binary-based multiples, especially in computer systems. Standard SI (system international or metric system) units are based on multiples of 10. This worked well for most things, but not for computers, which operate in a binary world where most numbers are based on powers of 2. This has resulted in different meanings being assigned to the same prefix—for example 1KB (kilobyte) could mean either 1,000 (10^3) bytes or 1,024 (2^{10}) bytes. To eliminate confusion, in December 1998 the International Electrotechnical Commission (IEC) approved as an international standard the prefix names and symbols for binary multiples used in data processing and transmission. Some of these prefixes are shown in Table 7.14.

Under this standard terminology, an MB (megabyte) would be 1,000,000 bytes, whereas an MiB (mebibyte) would be 1,048,576 bytes.

Note

For more information on these industry-standard decimal and binary prefixes, check out the National Institute for Standards and Technology (NIST) Web site at physics.nist.gov/cuu/Units/prefixes.html.

Table 7.13 ATA/IDE Capacity Limitations for Various Sector Addressing Methods

Sector Addressing Method	Total Sectors Calculation	Max. Total Sectors
CHS: BIOS w/o TL	1024×16×63	1,032,192
CHS: BIOS w/bit-shift TL	1024×240×63	15,482,880
CHS: BIOS w/LBA-assist TL	1024×255×63	16,450,560
CHS: BIOS INT13h	1024×256×63	16,515,072
CHS: ATA-1/ATA-5	65536×16×255	267,386,880
LBA: ATA-1/ATA-5	2 ²⁸	268,435,456
LBA: ATA-6+	2 ⁴⁸	281,474,976,710,655
LBA: EDD BIOS	2 ⁶⁴	18,446,744,073,709,551,616

BIOS = Basic input output system

w/ = with

ATA = AT Attachment (IDE)

w/o = without

CHS = Cylinder head sector

TL = Translation

LBA = Logical block (sector) address

INT13h = Interrupt 13 hex

Table 7.14 Standard Prefix Names and Symbols for Binary Multiples

Decimal Prefixes:			
Factor	Symbol	Name	Value
10 ³	k	Kilo	1,000
10 ⁶	M	Mega	1,000,000
10 ⁹	G	Giga	1,000,000,000
10 ¹²	T	Tera	1,000,000,000,000
10 ¹⁵	P	Peta	1,000,000,000,000,000
10 ¹⁸	E	Exa	1,000,000,000,000,000,000
10 ²¹	Z	Zetta	1,000,000,000,000,000,000,000

Note that the symbol for kilo (k) is in lowercase (which is technically correct according to the SI standard), whereas all other decimal prefixes are uppercase.

BIOS Limitations

Motherboard ROM BIOSs have been updated throughout the years to support larger and larger drives. Table 7.15 shows the most important relative dates when drive capacity limits were changed.

Table 7.15 Dates of Changes to Drive Capacity Limitations in the ROM BIOS

BIOS Date	Capacity Limit
August 1994	528MB
January 1998	8.4GB
September 2002	137GB

These are when the limits were broken, such that BIOSs older than August 1994 are generally limited to drives of up to 528MB, whereas BIOSs older than January 1998 are generally limited to 8.4GB. Most BIOSs dated 1998 or newer support drives up to 137GB, and those dated September 2002 or

Maximum Capacity (Bytes)	Capacity (Decimal)	Capacity (Binary)
528,482,304	528.48MB	504.00MiB
7,927,234,560	7.93GB	7.38GiB
8,422,686,720	8.42GB	7.84GiB
8,455,716,864	8.46GB	7.88GiB
136,902,082,560	136.90GB	127.50GiB
137,438,953,472	137.44GB	128.00GiB
144,115,188,075,855,872	144.12PB	128.00PiB
9,444,732,965,739,290,427,392	9.44ZB	8.00ZiB

EDD = Enhanced Disk Drive specification
(Phoenix/ATA)

MB = megabyte (million bytes)

MiB = mebibyte

GB = gigabyte (billion bytes)

GiB = gibibyte

PB = petabyte (quadrillion bytes)

PiB = pebibyte

ZB = zettabyte (sextillion bytes)

ZiB = zebibyte

Binary Prefixes:

Factor	Symbol	Name	Derivation	Value
2 ¹⁰	Ki	Kibi	Kilobinary	1,024
2 ²⁰	Mi	Mebi	Megabinary	1,048,576
2 ³⁰	Gi	Gibi	Gigabinary	1,073,741,824
2 ⁴⁰	Ti	Tebi	Terabinary	1,099,511,627,776
2 ⁵⁰	Pi	Pebi	Petabinary	1,125,899,906,842,624
2 ⁶⁰	Ei	Exbi	Exabinary	1,152,921,504,606,846,976
2 ⁷⁰	Zi	Zebi	Zettabinary	1,180,591,620,717,411,303,424

newer should support drives larger than 137GB. These are only general guidelines, though; to accurately determine this for a specific system, you should check with your motherboard manufacturer. You can also use the BIOS Wizard utility from <http://www.unicore.com/bioswiz/index2.html>, which will tell you the BIOS date from your system and specifically whether your system supports the Enhanced Hard Disk Drive specification (which means drives over 8.4GB).

If your BIOS does not support EDD (drives over 8.4GB), the three possible solutions are

- Upgrade your motherboard BIOS to a 1998 or newer version that supports >8.4GB.
- Install a BIOS upgrade card, such as the Ultra ATA 133 PCI card from www.maxtordirect.com.
- Install a software patch to add >8.4GB support.

Of these, the first one is the most desirable because it is usually free. Visit your motherboard manufacturer's Web site to see whether it has any newer BIOSs available for your motherboard that will support large drives. If it doesn't, the next best thing is to use a card such as the ATA Pro Flash from Micro Firmware or the Ultra ATA 133 PCI card from Maxtor. I almost never recommend the last solution because it merely installs a software patch in the boot sector area of the hard drive, which can result in numerous problems when booting from different drives, installing new drives, or recovering data.

CHS Versus LBA

There are two primary methods to address (or number) sectors on an ATA drive. The first method is called CHS (cylinder head sector) after the three respective coordinate numbers used to address each sector of the drive. The second method is called LBA (logical block address) and uses a single number to address each sector on a drive. CHS was derived from the physical way drives were constructed (and is how they work internally), whereas LBA evolved as a simpler and more logical way to number the sectors regardless of the internal physical construction.

- ▶▶ For more information on cylinders, heads, and sectors as they are used internally within the drive, see “Hard Disk Drive Operation,” p. 645.

When reading a drive sequentially in CHS mode, the process starts with cylinder 0, head 0, and sector 1 (which is the first sector on the disk). Next, all the remaining sectors on that first track are read; then the next head is selected; and then all the sectors on that track are read—and so on until all the heads on the first cylinder are read. Then the next cylinder is selected, and the sequence starts again. Think of CHS as an odometer of sorts: The sector numbers must roll over before the head number can change, and the head numbers must roll over before the cylinder can change.

When reading a drive sequentially in LBA mode, the process starts with sector 0, then read 1, then 2, and so on. The first sector on the drive in CHS mode would be 0,0,1, and the same sector in LBA mode would be 0.

As an example, imagine a drive with one platter, two heads (both sides of the platter are used), two tracks on each platter (cylinders), and two sectors on each track. We would say the drive has two cylinders (tracks per side), two heads (sides), and two sectors per track. This would result in a total capacity of eight (2×2×2) sectors. Noting that cylinders and heads begin numbering from 0—whereas physical sectors on a track number from 1—using CHS addressing, we would say the first sector on the drive is cylinder 0, head 0, sector 1 (0,0,1); the second sector is 0,0,2; the third sector is 0,1,1; the fourth sector is 0,1,2; and so on until we get to the last sector, which would be 1,1,2.

Now imagine that we could take the eight sectors and, rather than refer directly to the physical cylinder, head, and sector, number the sectors in order from 0 to 7. Thus, if we wanted to address the fourth sector on the drive, we could reference it as sector 0,1,2 in CHS mode or as sector 3 in LBA mode. Table 7.16 shows the correspondence between CHS and LBA sector numbers for this eight-sector imaginary drive.

Table 7.16 CHS and LBA Sector Numbers for an Imaginary Drive with Two Cylinders, Two Heads, and Two Sectors per Track (Eight Sectors Total)

Mode	Equivalent Sector Numbers							
CHS:	0,0,1	0,0,2	0,1,1	0,1,2	1,0,1	1,0,2	1,1,1	1,1,2
LBA:	0	1	2	3	4	5	6	7

As you can see from this example, using LBA numbers is simpler and generally easier to handle; however, when the PC was first developed, all BIOS and ATA drive-level addressing was done using CHS addressing.

CHS/LBA and LBA/CHS Conversions

You can address the same sectors in either CHS or LBA mode. The conversion from CHS to LBA is always consistent in that for a given drive, a particular CHS address always converts to a given LBA address, and vice versa. The ATA-1 document specifies a simple formula that can be used to convert CHS parameters to LBA:

$$\text{LBA} = (((C \times \text{HPC}) + H) \times \text{SPT}) + S - 1$$

By reversing this formula, you can convert the other way—that is, from LBA back to CHS:

$$C = \text{int}(\text{LBA} / \text{SPT} / \text{HPC})$$

$$H = \text{int}((\text{LBA} / \text{SPT}) \bmod \text{HPC})$$

$$S = (\text{LBA} \bmod \text{SPT}) + 1$$

For these formulae, the acronyms are defined as follows:

LBA = Logical block address

C = Cylinder

H = Head

S = Sector

HPC = Heads per cylinder (total number of heads)

SPT = Sectors per track

int X = Integer portion of X

X mod Y = Modulus (remainder) of X/Y

Using these formulas you can calculate the LBA for any given CHS address, and vice versa. Given a drive of 16,383 cylinders, 16 heads, and 63 sectors per track, Table 7.17 shows the equivalent CHS and LBA addresses.

Table 7.17 Equivalent CHS and LBA Sector Numbers for a Drive with 16,383 Cylinders, 16 Heads, and 63 Sectors per Track (16,514,064 Sectors Total)

Cylinder	Head	Sector	LBA
0	0	1	0
0	0	63	62
0	1	0	63
999	15	63	1,007,999
1,000	0	1	1,008,000
9,999	15	63	10,079,999
10,000	0	1	10,080,000
16,382	15	63	16,514,063

BIOS Commands Versus ATA Commands

In addition to the two methods of sector addressing (CHS or LBA), there are two levels of interface where sector addressing occurs. One interface is where the operating system talks to the BIOS (using BIOS commands); the other is where the BIOS talks to the drive (using ATA commands). The specific commands at these levels are different, but both support CHS and LBA modes. Figure 7.13 illustrates the two interface levels.

When the operating system talks to the BIOS to read or write sectors, it issues commands via software interrupt (not the same as an IRQ) INT13h, which is how the BIOS subroutines for disk access are called. Various INT13h subfunctions allow sectors to be read or written using either CHS or LBA addressing. The BIOS routines then convert the BIOS commands into ATA hardware-level commands, which are sent over the bus I/O ports to the drive controller. Commands at the ATA hardware level can also use either CHS or LBA addressing, although the limitations are different. Whether your BIOS and drive use CHS or LBA addressing depends on the drive capacity, age of the BIOS and drive, BIOS Setup settings used, and operating system used.

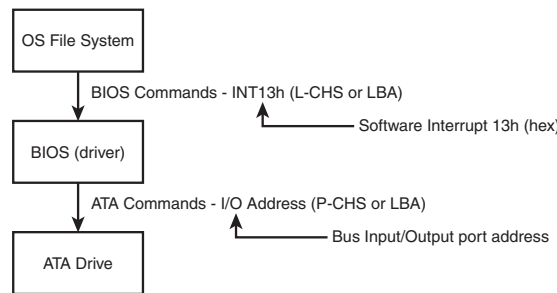

Figure 7.13 The relationship between BIOS and physical sector addressing. (In this figure, L-CHS stands for Logical CHS and P-CHS stands for Physical CHS.)

CHS Limitations (the 528MB Barrier)

The original BIOS-based driver for hard disks is accessed via software interrupt 13h (13 hex) and offers functions for reading and writing drives at the sector level. Standard INT13h functions require that a particular sector be addressed by its cylinder, head, and sector location—otherwise known as *CHS addressing*. This interface is used by the operating system and low-level disk utilities to access the drive. IBM originally wrote the INT13h interface for the BIOS on the PC XT hard disk controller in 1983, and in 1984, incorporated it into the AT motherboard BIOS. This interface used numbers to define the particular cylinder, head, and sector being addressed. Table 7.18, which shows the standard INT13h BIOS CHS parameter limits, includes the maximum values for these numbers.

Table 7.18 INT13h BIOS CHS Parameter Limits

Field	Field Size	Maximum Value	Range	Total Usable
Cylinder	10 bits	1024	0–1023	1024
Head	8 bits	256	0–255	256
Sector	6 bits	64	1–63	63

The concept of a maximum value given a number of digits is simple: If you had, for example, a hotel with two-digit decimal room numbers, you could have only 100 (10^2) rooms, numbered 0–99. The CHS numbers used by the standard BIOS INT13h interface are binary, and with a 10-bit number being used to count cylinders, you can have only 1,024 (2^{10}) maximum, numbered 0–1023. Because the head is identified by an 8-bit number, the maximum number of heads is 256 (2^8), numbered 0–255. Finally, with sectors per track there is a minor difference. Sectors on a track are identified by a 6-bit number, which would normally allow a maximum of 64 (2^6) sectors; however, because sectors are numbered starting with 1 (instead of 0), the range is limited to 1–63, which means a total of 63 sectors per track is the maximum the BIOS can handle.

These BIOS limitations are true for all BIOS versions or programs that rely on CHS addressing. Using the maximum numbers possible for CHS at the BIOS level, you can address a drive with 1,024 cylinders, 256 heads, and 63 sectors per track. Because each sector is 512 bytes, the math works out as follows:

Max. Values	
Cylinders	1,024
Heads	256
Sectors/Track	63

```

Total Sectors    16,515,072
-----
Total Bytes     8,455,716,864
Megabytes (MB)      8,456
Mebibytes (MiB)    8,064
Gigabytes (GB)     8.4
Gibibytes (GiB)   7.8

```

From these calculations, you can see that the maximum capacity drive addressable via the standard BIOS INT13h interface is about 8.4GB (where GB equals roughly 1 billion bytes), or 7.8GiB (where GiB means *gigabinarybytes*).

Unfortunately, the BIOS INT13h limits are not the only limitations that apply. Limits also exist in the ATA interface itself. The ATA CHS limits are shown in Table 7.19.

Table 7.19 Standard ATA CHS Parameter Limitations

Field	Field Size	Maximum Value	Range	Total Usable
Cylinder	16 bits	65536	0-65535	65536
Head	4 bits	16	0-15	16
Sector	8 bits	256	1-255	255

As you can see, the ATA interface uses different sized fields to store CHS values. Note that the ATA limits are higher than the BIOS limits for cylinders and sectors but lower than the BIOS limit for heads. The CHS limits for capacity according to the ATA-1 through ATA-5 specification are as follows:

```

Max. Values
-----
Cylinders      65,536
Heads          16
Sectors/Track  255
=====
Total Sectors  267,386,880
-----
Total Bytes   136,902,082,560
Megabytes (MB) 136,902
Mebibytes (MiB) 130,560
Gigabytes (GB)  136.9
Gibibytes (GiB) 127.5

```

When you combine the limitations of the BIOS and ATA CHS parameters, you end up with the situation shown in Table 7.20.

Table 7.20 Combined BIOS and ATA CHS Parameter Limits

Field	BIOS CHS Parameter Limits	ATA CHS Parameter Limits	Combined CHS Parameter Limits
Cylinder	1,024	65,536	1,024
Head	256	16	16
Sector	63	255	63
Total Sectors	16,515,072	267,386,880	1,032,192
Maximum Capacity	8.4GB	136.9GB	528MB

As you can see, the lowest common denominator of the combined CHS limits results in maximum usable parameters of 1,024 cylinders, 16 heads, and 63 sectors, which results in a maximum drive capacity of 528MB. This became known as the 528MB barrier (also called the 504MiB barrier), and it affects virtually all PCs built in 1993 or earlier.

CHS Translation (Breaking the 528MB Barrier)

Having a barrier limiting drive capacity to 528MB or less wasn't a problem when the largest drives available were smaller than that. But by 1994, drive technology had developed such that making drives larger than what the combined BIOS and ATA limitations could address was possible. Clearly a fix for the problem was needed.

Starting in 1993, the BIOS developer Phoenix Technologies began working on BIOS extensions to work around the combined CHS limits. In January 1994, it released the BIOS Enhanced Disk Drive (EDD) Specification, which was later republished by the T13 committee (also responsible for ATA) as "BIOS Enhanced Disk Drive Services (EDD)." The EDD documents detail several methods for circumventing the limitations of previous BIOSs without causing compatibility problems with existing software. These include

- BIOS INT13h extensions supporting 64-bit LBA
- Bit-shift geometric CHS translation
- LBA-assist geometric CHS translation

The method for dealing with the CHS problem was called *translation* because it enabled additional subroutines in the BIOS to translate CHS parameters from ATA maximums to BIOS maximums (and vice versa). In an effort to make its methods standard among the entire PC industry, Phoenix released the EDD document publicly and allowed the technology to be used free of charge, even among its competitors such as AMI and Award. The T13 committee in charge of ATA subsequently adopted the EDD standard and incorporated it into official ATA documents.

Starting in 1994, most BIOSs began implementing the Phoenix-designed CHS translation methods, which enabled drives up to the BIOS limit of 8.4GB to be supported. The fix involved what is termed *parameter translation* at the BIOS level, which adapted or translated the cylinder, head, and sector numbers to fit within the allowable BIOS parameters. There are two types of translation: One works via a technique called CHS bit-shift (usually called "Large" or "Extended CHS" in the BIOS Setup), and the other uses a technique called LBA-assist (usually called "LBA" in the BIOS Setup). These refer to the different mathematical methods of doing essentially the same thing: converting one set of CHS numbers to another.

CHS bit-shift translation manipulates the cylinder and head numbers but does not change the sector number. It begins with the physical (drive reported) cylinders and heads and, using some simple division and multiplication, comes up with altered numbers for the cylinders and heads. The sectors per track value is not translated and is passed unaltered. The term *bit-shift* is used because the division and multiplication math is actually done in the BIOS software by shifting bits in the CHS address.

With CHS bit-shift translation, the drive reported (physical) parameters are referred to as P-CHS and the BIOS altered logical parameters are referred to as L-CHS. After the settings are made in the BIOS Setup, L-CHS addresses are automatically translated to P-CHS at the BIOS level. This enables the operating system to send commands to the BIOS using L-CHS parameters, which the BIOS automatically converts to P-CHS when it talks to the drive using ATA commands. Table 7.21 shows the rules for calculating CHS bit-shift translation.

CHS bit-shift translation is based on dividing the physical cylinder count by a power of 2 to bring it under the 1,024 cylinder BIOS INT13h limit and then multiplying the heads by the same power of 2, leaving the sector count unchanged. The power of 2 used depends on the cylinder count, as indicated in Table 7.21.

Table 7.21 CHS Bit-Shift Translation Rules

Physical (Drive Reported) Cylinders	Physical Heads	Logical Cylinders	Logical Heads	Max. Capacity
$1 < C \leq 1,024$	$1 < H \leq 16$	$C = C$	$H = H$	528MB
$1,024 < C \leq 2,048$	$1 < H \leq 16$	$C = C/2$	$H = H \times 2$	1GB
$2,048 < C \leq 4,096$	$1 < H \leq 16$	$C = C/4$	$H = H \times 4$	2.1GB
$4,096 < C \leq 8,192$	$1 < H \leq 16$	$C = C/8$	$H = H \times 8$	4.2GB
$8,192 < C \leq 16,384$	$1 < H \leq 16$	$C = C/16$	$H = H \times 16$	8.4GB

The drive reported sector count is not translated.

The logical heads value can't exceed 255 with some operating systems, such as DOS/Win9x/Me.

Here is an example of CHS bit-shift translation:

	P-CHS Parameters	Bit-shift L-CHS Parameters
Cylinders	8,000	1,000
Heads	16	128
Sectors/Track	63	63
=====		
Total Sectors	8,064,000	8,064,000

Total Bytes	4,128,768,000	4,128,768,000
Megabytes (MB)	4,129	4,129
Mebibytes (MiB)	3,938	3,938
Gigabytes (GB)	4.13	4.13
Gibibytes (GiB)	3.85	3.85

This example shows a drive with 8,000 cylinders and 16 heads. The physical cylinder count is way above the BIOS limit of 1,024, so if CHS bit-shift translation is selected in the BIOS Setup, the BIOS then divides the cylinder count by 2, 4, 8, or 16 to bring it below 1,024. In this case it would divide by 8, which results in a new logical cylinder count of 1,000—which is below the 1,024 maximum. Because the cylinder count is divided by 8, the head count is then multiplied by the same number, resulting in 128 logical heads, which is also below the limit the BIOS can handle.

So, although the drive reports having 8,000 cylinders and 16 heads, the BIOS and all software (including the operating system) instead see the drive as having 1,000 cylinders and 128 heads. Note that the 63 sectors/track figure is simply carried over without change. The result is that by using the logical parameters, the BIOS can see the entire 4.13GB drive and won't be limited to just the first 528MB.

When you install a drive, you don't have to perform the translation math to convert the cylinders and heads; the BIOS does that for you automatically. All you have to do is allow the BIOS to autodeTECT the P-CHS parameters and then enable the translation in the BIOS Setup. Selecting Large or ECHS translation in the BIOS Setup enables the CHS bit-shift. The BIOS does the rest of the work for you.

CHS bit-shift is a simple and fast (code-wise) scheme that can work with all drives, but unfortunately it can't properly translate all theoretically possible drive geometries for drives under 8.4GB. To solve this, an addendum was added to the ATA-2 specification to specifically require drives to report certain ranges of geometries to allow bit-shift translation to work. Thus, all drives that conform to the ATA-2 specification (or higher) can be translated using this method.

The 2.1GB Barrier

Some BIOSs incorrectly allocated only 12 bits for the P-CHS cylinder field, thereby allowing a maximum of 4,096 cylinders. Combined with the standard 16-head and 63-sector limits, this resulted in the inability to support any drives over 2.1GB in capacity. Fortunately, this BIOS defect affected only a limited number of systems with BIOS dates prior to about mid-1996.

The 4.2GB Barrier

Even so, some problems still existed with bit-shift translation. Because of the way DOS and Windows 9x/Me were written, they could not properly handle a drive with 256 heads. This was a problem for drives larger than 4.2GB because the CHS bit-shift translation rules typically resulted in 256 heads as a logical value, as seen in the following example:

	P-CHS Parameters	Bit-shift L-CHS Parameters
Cylinders	12,000	750
Heads	16	256
Sectors/Track	63	63
=====		
Total Sectors	12,096,000	12,096,000

Total Bytes	6,193,152,000	6,193,152,000
Megabytes (MB)	6,193	6,193
Mebibytes (MiB)	5,906	5,906
Gigabytes (GB)	6.19	6.19
Gibibytes (GiB)	5.77	5.77

This scheme failed when you tried to install Windows 9x/Me (or DOS) on a drive larger than 4.2GB because the L-CHS parameters included 256 heads. Any BIOS that implemented this scheme essentially had a 4.2GB barrier, so installing a drive larger than that and selecting CHS bit-shift translation caused the drive to fail. Note that this was not a problem for Windows NT/2000/XP.

Note

It is interesting to note that the BIOS is not actually at fault here; the problem instead lies with the DOS/Win9x/Me file system code, which stores the sector per track number as an 8-bit value. The number 256 causes a problem because $256 = 100000000b$, which takes 9 bits to store. The value $255 = 11111111b$ is the largest value that can fit in an 8-bit binary register and is therefore the maximum number of heads those operating systems can support.

To solve this problem, CHS bit-shift translation was revised by adding a rule such that if the drive reported 16 heads and more than 8,192 cylinders (which would result in a 256-head translation), the P-CHS head value would be assumed to be 15 (instead of 16) and the P-CHS cylinder value would be multiplied by 16/15 to compensate. These adjusted cylinder and head values would then be translated. The following example shows the results:

	P-CHS Parameters	Bit-shift L-CHS Parameters	Revised Bit- shift L-CHS Parameters
Cylinders	12,000	750	800
Heads	16	256	240
Sectors/Track	63	63	63
=====			

Total Sectors	12,096,000	12,096,000	12,096,000

Total Bytes	6,193,152,000	6,193,152,000	6,193,152,000
Megabytes (MB)	6,193	6,193	6,193
Mebibytes (MiB)	5,906	5,906	5,906
Gigabytes (GB)	6.19	6.19	6.19
Gibibytes (GiB)	5.77	5.77	5.77

As you can see from this example, a drive with 12,000 cylinders and 16 heads translates to 750 cylinders and 256 heads using the standard CHS bit-shift scheme. The revised CHS bit-shift scheme rule does a double translation in this case, first changing the 16 heads to 15 and then multiplying the 12,000 cylinders by 16/15, resulting in 12,800 cylinders. Then, the new cylinder value is CHS bit-shift translated by dividing it by 16, resulting in 800 logical cylinders. Likewise, the 15 heads are multiplied by 16, resulting in 240 logical heads. If the logical cylinder count calculates to over 1,024 then it is truncated to 1,024. In this case, what started out as 12,000 cylinders and 16 heads P-CHS becomes 800 cylinders and 240 heads (instead of 750 cylinders and 256 heads) L-CHS, which works around the bug in the DOS/Win9x/Me operating systems.

So far, all my examples have been very clean—that is, the L-CHS parameters have calculated to the same capacity as the P-CHS parameters. Unfortunately, it doesn't always work out that way. The following example shows a more typical example in the real world. Several 8.4GB drives from Maxtor, Quantum, Seagate, and others report 16,383 cylinders and 16 heads P-CHS. For those drives, the translations would work out as follows:

	P-CHS Parameters	Bit-shift L-CHS Parameters	Revised Bit- shift L-CHS Parameters

Cylinders	16,383	1,023	1,024
Heads	16	256	240
Sectors/Track	63	63	63
=====			
Total Sectors	16,514,064	16,498,944	15,482,880

Total Bytes	8,455,200,768	8,447,459,328	7,927,234,560
Megabytes (MB)	8,455	8,447	7,927
Mebibytes (MiB)	8,064	8,056	7,560
Gigabytes (GB)	8.46	8.45	7.93
Gibibytes (GiB)	7.87	7.87	7.38

Note that the revised CHS bit-shift translation rules result in supporting only 7.93GB of the 8.46GB total on the drive. In fact, the parameters shown (with 240 heads) are the absolute maximum that revised CHS bit-shift supports. Fortunately, another translation mode is available that improves this situation.

LBA-Assist Translation

The LBA-assist translation method places no artificial limits on the reported drive geometries, but it works only on drives that support LBA addressing at the ATA interface level. Fortunately, though, virtually all ATA drives larger than 2GB support LBA. LBA-assist translation takes the CHS parameters the drive reports, multiplies them together to get a calculated LBA maximum value (total number of sectors), and then uses this calculated LBA number to derive the translated CHS parameters. Table 7.22 shows the rules for LBA-assist translation.

Table 7.22 LBA-Assist Translation Rules

Total Sectors	Logical Cylinders	Logical Heads	Logical Sectors
$1 < T \leq 1,032,192$	$T/1,008$	16	63
$1,032,192 < T \leq 2,064,384$	$T/2,016$	32	63
$2,064,384 < T \leq 4,128,768$	$T/4,032$	64	63
$4,128,768 < T \leq 8,257,536$	$T/8,064$	128	63
$8,257,536 < T \leq 16,450,560$	$T/16,065$	255	63

T = Total sectors, calculated by multiplying the drive-reported P-CHS parameters ($C \times H \times S$)

LBA-assist translation fixes the sectors at 63 no matter what and divides and multiplies the cylinders and heads by predetermined values depending on the total number of sectors. This results in a set of L-CHS parameters the operating system uses to communicate with the BIOS. The L-CHS numbers are then translated to LBA numbers at the ATA interface level. Because LBA mode is more flexible at translating, it should be used in most cases instead of CHS bit-shift.

Normally, both the CHS bit-shift and LBA-assist translations generate the same L-CHS geometry for a given drive. This should always be true if the drive reports 63 sectors per track and 4, 8, or 16 heads. In the following example both translation schemes result in identical L-CHS values:

	P-CHS Parameters	Revised bit- shift L-CHS Parameters	LBA-assist L-CHS Parameters
Cylinders	8,192	1,024	1,024
Heads	16	128	128
Sectors/Track	63	63	63
=====			
Total Sectors	8,257,536	8,257,536	8,257,536

Total Bytes	4,227,858,432	4,227,858,432	4,227,858,432
Megabytes (MB)	4,228	4,228	4,228
Mebibytes (MiB)	4,032	4,032	4,032
Gigabytes (GB)	4.23	4.23	4.23
Gibibytes (GiB)	3.94	3.94	3.94

However, if the drive reports a value other than 63 sectors per track or has other than 4, 8, or 16 heads, LBA-assist translation does not result in the same parameters as CHS bit-shift translation. In the following example, different translations result:

	P-CHS Parameters	Revised bit- shift L-CHS Parameters	LBA-assist L-CHS Parameters
Cylinders	16,383	1,024	1,024
Heads	16	240	255
Sectors/Track	63	63	63
=====			
Total Sectors	16,514,064	15,482,880	16,450,560

Total Bytes	8,455,200,768	7,927,234,560	8,422,686,720
Megabytes (MB)	8,455	7,927	8,423
Mebibytes (MiB)	8,064	7,560	8,033
Gigabytes (GB)	8.46	7.93	8.42
Gibibytes (GiB)	7.87	7.38	7.84

The LBA-assist translation supports 8.42GB, which is nearly 500MB more than the revised CHS bit-shift translation. More importantly, these translations are different, which can result in problems if you change translation modes with data on the drive. If you were to set up and format a drive using CHS bit-shift translation and then change to LBA-assist translation, the interpreted geometry could change and the drive could then become unreadable until it is repartitioned and reformatted (which would destroy all the data). Bottom line: After you select a translation method, don't plan on changing it unless you have your data securely backed up.

Virtually all PC BIOSs since 1994 have translation capability in the BIOS Setup, and virtually all offer both translation modes as well as an option to disable translation entirely. If both CHS bit-shift and LBA-assist translation modes are offered, you should probably choose the LBA method of translation because it is the more efficient and flexible of the two. LBA-assist translation also gets around the 4.2GB operating system bug because it is designed to allow a maximum of 255 logical heads no matter what.

You usually can tell whether your BIOS supports translation by the capability to specify more than 1,024 cylinders in the BIOS Setup, although this can be misleading. The best clue is to look for the translation setting parameters in the ATA/IDE drive setup page in the BIOS Setup. See Chapter 5, "BIOS," for more information on how to enter the BIOS Setup on your system. If you see drive-related settings, such as LBA or ECHS (sometimes called Large or Extended), these are telltale signs of a BIOS with translation support. Most BIOSs with a date of 1994 or later include this capability, although some AMI BIOS versions from the mid-1990s locate the LBA setting on a screen different from the hard drive configuration screen. If your system currently does not support parameter translation, you might be able to get an upgrade from your motherboard manufacturer or install a BIOS upgrade card with this capability, such as the ATA Pro Flash by Micro Firmware (see the Vendor List on the disc that accompanies this book). Another option for drives larger than 137GB is the Ultra ATA/133 PCI Adapter Card from Maxtor. This card also supports the ATA/133 transfer rate of the fastest ATA drives.

Table 7.23 summarizes the four ways today's BIOSs can handle addressing sectors on the drive: Standard CHS (no translation), Extended CHS translation, LBA translation, and pure LBA addressing.

Table 7.23 Drive Sector Addressing Methods

BIOS Mode	OS to BIOS	BIOS to Drive
Standard (Normal) - No Translation	P-CHS	P-CHS
CHS Bit-Shift (ECHS) Translation	L-CHS	P-CHS
LBA-Assist (LBA) Translation	L-CHS	LBA
Pure LBA (EDD BIOS)	LBA	LBA

In Standard CHS, there is only one possible translation step internal to the drive. The drive's actual physical geometry is completely invisible from the outside with all zoned recorded ATA drives today. The cylinders, heads, and sectors printed on the label for use in the BIOS Setup are purely logical geometry and do not represent the actual physical parameters. Standard CHS addressing is limited to 16 heads and 1,024 cylinders, which provides a limit of 504MiB (528MB).

This is often called "Normal" in the BIOS Setup and causes the BIOS to behave like an old-fashioned one without translation. Use this setting if your drive has fewer than 1,024 cylinders or if you want to use the drive with a non-DOS operating system that doesn't understand translation.

ECHS or Large in the BIOS Setup is CHS bit-shift, and most BIOSs from 1997 and later use the revised method (240 logical heads maximum).

LBA, as selected in the BIOS Setup, indicates LBA-assist translation, not pure LBA mode. This enables software to operate using L-CHS parameters while the BIOS talks to the drive in LBA mode.

The only way to select a pure LBA mode, from the OS to the BIOS as well as from the BIOS to the drive, is with a drive that is over 8.4GB. All drives over 137GB must be addressed via LBA at both the BIOS and drive levels, and most PC BIOSs automatically address any drive over 8.4GB in that manner, as well. In that case no special BIOS Setup settings are necessary, other than setting the type to auto or autodetect.

Caution

A word of warning with these BIOS translation settings: If you have a drive 8.4GB or less in capacity and switch between Standard CHS, ECHS, or LBA, the BIOS can change the (translated) geometry. The same thing can happen if you transfer a disk that has been formatted on an old, non-LBA computer to a new one that uses LBA. This causes the logical CHS geometry seen by the operating system to change and the data to appear in the wrong location from where it actually is! This can cause you to lose access to your data if you are not careful. I always recommend recording the CMOS Setup screens associated with the hard disk configuration so you can properly match the setup of a drive to the settings to which it was originally set. This does not affect drives over 8.4GB because in those cases pure LBA is automatically selected.

The 8.4GB Barrier

Although CHS translation breaks the 528MB barrier, it runs into another barrier at 8.4GB. Supporting drives larger than 8.4GB requires leaving CHS behind and changing from CHS to LBA addressing at the BIOS level. The ATA interface had always supported LBA addressing, even in the original ATA-1 specification. One problem was that LBA support at the ATA level originally was optional, but the main problem was that there was no LBA support at the BIOS interface level. You could set LBA-assist translation in the BIOS Setup, but all that did was convert the drive LBA numbers to CHS numbers at the BIOS interface level.

Phoenix Technologies recognized that the BIOS interface needed to move from CHS to LBA early on and, beginning in 1994, published the “BIOS Enhanced Disk Drive Specification (EDD),” which addressed this problem with new extended INT13h BIOS services that worked with LBA rather than CHS addresses.

To ensure industry-wide support and compatibility for these new BIOS functions, in 1996 Phoenix turned this document over to the InterNational Committee on Information Technology Standards (INCITS) T13 technical committee for further enhancement and certification as a standard called the “BIOS Enhanced Disk Drive Specification (EDD).” Starting in 1998, most of the other BIOS manufacturers began installing EDD support in their BIOSs, enabling BIOS-level LBA mode support for ATA drives larger than 8.4GB. Coincidentally (or not), this support arrived just in time because ATA drives of that size and larger became available that same year.

The EDD document describes new extended INT13h BIOS commands that allow LBA addressing up to 2^{64} sectors, which results in a theoretical maximum capacity of more than 9.44ZB (zettabytes, or quadrillion bytes). That is the same as saying 9.44 trillion GB: 9.44×10^{21} bytes or, to be more precise, 9,444,732,965,739,290,427,392 bytes! I say theoretical capacity because even though by 1998 the BIOS could handle up to 2^{64} sectors, ATA drives were still using only 28-bit addressing (2^{28} sectors) at the ATA interface level. This limited an ATA drive to 268,435,456 sectors, which was a capacity of 137,438,953,472 bytes, or 137.44GB. Thus, the 8.4GB barrier had been broken, but another barrier remained at 137GB because of the 28-bit LBA addressing used in the ATA interface. The numbers work out as follows:

	Max. Values
-----	-----
Total Sectors	268,435,456
-----	-----
Total Bytes	137,438,953,472
Megabytes (MB)	137,439
Mebibytes (MiB)	131,072
Gigabytes (GB)	137.44
Gibibytes (GiB)	128.00

By using the new extended INT13h 64-bit LBA mode commands at the BIOS level, as well as the existing 28-bit LBA mode commands at the ATA level, no translation would be required and the LBA

numbers would be passed unchanged. The combination of LBA at the BIOS as well as the ATA interface levels meant that the clumsy CHS addressing could finally die. This also means that when you install an ATA drive larger than 8.4GB in a PC that has an EDD-capable BIOS (1998 or newer), both the BIOS and the drive are automatically set to use LBA mode.

An interesting quirk is that to allow backward-compatibility when you boot an older operating system that doesn't support LBA mode addressing (DOS or the original release of Win95, for example), most drives larger than 8.4GB report 16,383 cylinders, 16 heads, and 63 sectors per track, which is 8.4GB. For example, this enables a 120GB drive to be seen as an 8.4GB drive by older BIOSs or operating systems. That sounds strange, but I guess having a 120GB drive being recognized as an 8.4GB is better than not having it work at all. If you did want to install a drive larger than 8.4GB into a system dated before 1998, the recommended solution is either a motherboard BIOS upgrade or an add-on BIOS card with EDD support (available from Micro Firmware and others).

The 137GB Barrier and Beyond

By 2001, the 137GB barrier had become a problem because 3 1/2" hard drives were poised to breach that capacity level. The solution came in the form of ATA-6, which was being developed during that year. To enable the addressing of drives of greater capacity, ATA-6 upgraded the LBA functions from using 28-bit numbers to using larger 48-bit numbers.

The ATA-6 specification extends the LBA interface such that it can use 48-bit sector addressing. This means that the maximum capacity is increased to 2^{48} (281,474,976,710,656) total sectors. Because each sector stores 512 bytes, this results in a maximum drive capacity of

Max. Values	
Total Sectors	281,474,976,710,656
Total Bytes	144,115,188,075,855,872
Megabytes (MB)	144,115,188,076
Mebibytes (MiB)	137,438,953,472
Gigabytes (GB)	144,115,188
Gibibytes (GiB)	134,217,728
Terabytes (TB)	144,115
Tebibytes (TiB)	131,072
Petabytes (PB)	144.12
Pebibytes (PiB)	128.00

As you can see, the 48-bit LBA in ATA-6 allows a capacity of just over 144PB (petabytes = quadrillion bytes)!

Because the EDD BIOS functions use a 64-bit LBA number, they have a much larger limit:

Max. Values	
Total Sectors	18,446,744,073,709,551,616
Total Bytes	9,444,732,965,739,290,427,392
Megabytes (MB)	9,444,732,965,739,290
Mebibytes (MiB)	9,007,199,254,740,992
Gigabytes (GB)	9,444,732,965,739
Gibibytes (GiB)	8,796,093,022,208
Terabytes (TB)	9,444,732,966
Tebibytes (TiB)	8,589,934,592
Petabytes (PB)	9,444,733
Pebibytes (PiB)	8,388,608
Exabytes (EB)	9,445
Exbibytes (EiB)	8,192
Zettabytes (ZB)	9.44
Zebibytes (ZiB)	8.00

Although the BIOS services use 64-bit LBA (allowing up to 2^{64} sectors) for even greater capacity, the 144 petabyte ATA-6 limitation is the lower of the two that applies. Still, that should hold us for some time to come.

Because hard disk drives have been doubling in capacity every 1.5–2 years (Moore's Law), and considering that 200GB+ ATA drives were available in late 2003, I estimate that it will take us until between the years 2031 and 2041 before we reach the 144PB barrier (assuming hard disk technology hasn't been completely replaced by then). Similarly, I estimate that the 9.44ZB EDD BIOS barrier won't be reached until between the years 2055 and 2073! Phoenix originally claimed that the EDD specification would hold us until 2020, but it seems they were being quite conservative.

The 137GB barrier has proven a bit more complicated than previous barriers because, in addition to BIOS issues, operating system issues must also be considered.

Internal ATA drives larger than 137GB require 48-bit LBA (logical block address) support. This support absolutely needs to be provided in the OS, but it can also be provided in the BIOS. It is best if both OS and BIOS support it, but it can be made to work if only the OS has the support.

To have 48-bit LBA support in the OS requires one of the following:

- Windows XP with Service Pack 1 (SP1) or later.
- Windows 2000 with Service Pack 4 (SP4) or later.
- Windows 98/98SE/Me or NT 4.0 with the Intel Application Accelerator (IAA) loaded. This solution works only if your motherboard has an IAA-supported chipset. See www.intel.com/support/chipsets/IAA/instruct.htm for more information.

To have 48-bit LBA support in the BIOS requires either

- A motherboard BIOS with 48-bit LBA support (most of those dated September 2002 or later)
- An ATA host adapter card with onboard BIOS that includes 48-bit LBA support

If your motherboard BIOS does not have the support and an update is not available from your motherboard manufacturer, you can use a card. Cards that offer 48-bit LBA support include the LBA Pro ISA card from eSupport (www.esupport.com) and the Maxtor Ultra ATA/133 PCI card (www.maxtor.com). The Maxtor card has two additional ATA-133 ports you can use to connect up to four additional drives, whereas the eSupport card has only a BIOS with no ports. In both cases, you could continue to use your existing motherboard ports; the BIOS on the cards would allow 48-bit LBA support for both motherboard-based and card-based ports.

Note that if you have both BIOS and OS support as well, you can simply install and use the drive like any other. If you have no BIOS support, but you do have OS support, portions of the drive past 137GB are not recognized or accessible until the OS is loaded. If you are installing the OS to a blank hard drive and booting from an original XP (pre-SP1) CD or earlier, you need to partition and install up to the first 137GB of the drive at installation time. After installing the OS and then the SP1 update, you can either partition the remainder of the drive using standard partitioning software or use a third-party partitioning program such as PartitionMagic or Partition Commander to resize the first partition to use the full drive. If you are booting from an XP SP1 or later CD, you can recognize and access the entire drive during the OS installation and partition the entire drive as a single partition greater than 137GB, if you want.

Finally, keep in mind that the original version of Windows XP, as well as Windows 2000/NT or Windows 95/98/Me, does not currently provide native support for ATA hard drives that are larger than 137GB. You will therefore need to use XP and ensure you have Service Pack 1 or later installed.

Operating System and Other Software Limitations

Note that if you use older software including utilities, applications, or even operating systems that rely exclusively on CHS parameters, they will see all drives over 8.4GB as 8.4GB only. You will need not only a newer BIOS, but also newer software designed to handle the direct LBA addressing to work with drives over 8.4GB.

Operating system limitations with respect to drives over 8.4GB are shown in Table 7.24.

Table 7.24 Operating System Limitations

Operating System	Limitations for Hard Drive Size
DOS/Windows 3x	DOS 6.22 or lower can't support drives greater than 8.4GB. DOS 7.0 or higher (included with Windows 95 or later) is required to recognize a drive over 8.4GB.
Windows 9x/Me	Windows 95a (original version) does support the INT13h extensions, which means it does support drives over 8.4GB; however, due to limitations of the FAT16 file system, the maximum individual partition size is limited to 2GB. Windows 95B/OSR2 or later (including Windows 98/Me) supports the INT13h extensions, which allows drives over 8.4GB, and also supports FAT32, which allows partition sizes up to the maximum capacity of the drive. However, Windows 95 doesn't support hard drives larger than 32GB because of limitations in its design. Windows 98 requires an update to FDISK to partition drives larger than 64GB.
Windows NT	Windows NT 3.5x does not support drives greater than 8.4GB. Windows NT 4.0 does support drives greater than 8.4GB; however, when a drive larger than 8.4GB is being used as the primary bootable device, Windows NT will not recognize more than 8.4GB. Microsoft has released Service Pack 4, which corrects this problem.
Windows 2000/XP	Windows 2000/XP supports drives greater than 8.4GB.
OS/2 Warp	Some versions of OS/2 are limited to a boot partition size of 3.1GB or 4.3GB. IBM has a Device Driver Pack upgrade that enables the boot partition to be as large as 8.4GB. The HPFS file system in OS/2 will support drives up to 64GB.
Novell	NetWare 5.0 or later supports drives greater than 8.4GB.

In the case of operating systems that support drives over 8.4GB, the maximum drive size limitations are dependent on the BIOS and hard drive interface standard, not the OS. Instead, other limitations come into play for the volumes (partitions) and files that can be created and managed by the various operating systems. These limitations are dependent on not only the operating system involved, but also the file system that is used for the volume. Table 7.25 shows the minimum and maximum volume (partition) size and file size limitations of the various Windows operating systems. As noted in the previous section, the original version of XP, as well as Windows 2000/NT or Windows 95/98/Me, does not currently provide native support for ATA hard drives that are larger than 137GB. You will need to use XP and ensure you have Service Pack 1 or later installed to use an ATA drive over 137GB. This does not affect drives interfaced via USB, FireWire, SCSI, or other interfaces.

Table 7.25 Operating System Volume/File Size Limitations by File System

OS Limitations by File System	FAT16	FAT32	NTFS
Min. Volume Size (9x/Me)	2.092MB	33.554MB	—
Max. Volume Size (95)	2.147GB	33.554MB	—
Max. Volume Size (98)	2.147GB	136.902GB	—
Max. Volume Size (Me)	2.147GB	8.796TB	—
Min. Volume Size (NT/2000/XP)	2.092MB	33.554MB	1.000MB
Max. Volume Size (NT/2000/XP)	4.294GB	8.796GB	281.475TB
Max. File Size (all)	4.294GB	4.294GB	16.384TB

— = not applicable

MB = megabyte = 1,000,000 bytes

GB = gigabyte = 1,000,000,000 bytes

TB = terabyte = 1,000,000,000,000 bytes

ATA RAID

RAID is an acronym for redundant array of independent (or inexpensive) disks and was designed to improve the fault tolerance and performance of computer storage systems. RAID was first developed at the University of California at Berkeley in 1987, and was designed so that a group of smaller, less expensive drives could be interconnected with special hardware and software to make them appear as a single larger drive to the system. By using multiple drives to act as one drive, increases in fault tolerance and performance could be realized.

Initially, RAID was conceived to simply enable all the individual drives in the array to work together as a single, larger drive with the combined storage space of all the individual drives added up. However, this actually reduced reliability and didn't do much for performance, either. For example, if you had four drives connected in an array acting as one drive, you would be four times as likely to experience a drive failure than if you used just a single larger drive. To improve the reliability and performance, the Berkeley scientists proposed six levels (corresponding to different methods) of RAID. These levels provide varying emphasis on either fault tolerance (reliability), storage capacity, performance, or a combination of the three.

An organization called the RAID Advisory Board (RAB) was formed in July 1992 to standardize, classify, and educate on the subject of RAID. The RAB has developed specifications for RAID, a conformance program for the various RAID levels, and a classification program for RAID hardware.

Currently, seven standard RAID levels are defined by the RAID Advisory Board, called RAID 0–6. RAID typically is implemented by a RAID controller board, although software-only implementations are possible (but not recommended). The levels are as follows:

- **RAID Level 0—Striping.** File data is written simultaneously to multiple drives in the array, which act as a single larger drive. Offers high read/write performance but very low reliability. Requires a minimum of two drives to implement.
- **RAID Level 1—Mirroring.** Data written to one drive is duplicated on another, providing excellent fault tolerance (if one drive fails, the other is used and no data lost), but no real increase in performance as compared to a single drive. Requires a minimum of two drives to implement (same capacity as one drive).
- **RAID Level 2—Bit-level ECC.** Data is split one bit at a time across multiple drives, and error correction codes (ECCs) are written to other drives. Intended for storage devices that do not incorporate ECC internally (all SCSI and ATA drives have internal ECC). Provides high data rates with good fault tolerance, but large numbers of drives are required, and no commercial RAID 2 controllers or drives without ECC, that I am aware of, are available on the market.
- **RAID Level 3—Striped with parity.** Combines RAID Level 0 striping with an additional drive used for parity information. This RAID level is really an adaptation of RAID Level 0 that sacrifices some capacity, for the same number of drives. However, it also achieves a high level of data integrity or fault tolerance because data usually can be rebuilt if one drive fails. Requires a minimum of three drives to implement (two or more for data and one for parity).
- **RAID Level 4—Blocked data with parity.** Similar to RAID 3 except data is written in larger blocks to the independent drives, offering faster read performance with larger files. Requires a minimum of three drives to implement (two or more for data and one for parity).
- **RAID Level 5—Blocked data with distributed parity.** Similar to RAID 4 but offers improved performance by distributing the parity stripes over a series of hard drives. Requires a minimum of three drives to implement (two or more for data and one for parity).
- **RAID Level 6—Blocked data with double distributed parity.** Similar to RAID 5 except parity information is written twice using two different parity schemes to provide even better fault tolerance in case of multiple drive failures. Requires a minimum of four drives to implement (two or more for data and two for parity).

Additional RAID levels exist that are not supported by the RAID Advisory Board but which are instead custom implementations by specific companies. Note that a higher number doesn't necessarily mean increased performance or fault tolerance; the numbered order of the RAID levels was entirely arbitrary.

At one time virtually all RAID controllers were SCSI based, meaning they used SCSI drives. For a professional setup, SCSI RAID is definitely the best choice because it combines the advantages of RAID with the advantages of SCSI—an interface that already was designed to support multiple drives. Now, however, ATA RAID controllers are available that allow for even less expensive RAID implementations. These ATA RAID controllers typically are used in single-user systems for performance rather than reliability increases.

Most ATA RAID implementations are much simpler than the professional SCSI RAID adapters used on network file servers. ATA RAID is designed more for the individual who is seeking performance or simple drive mirroring for redundancy. When set up for performance, ATA RAID adapters run RAID Level 0, which incorporates data striping. Unfortunately, RAID 0 also sacrifices reliability such that if one drive fails, all data is lost. With RAID 0, performance scales up with the number of drives you add in the array. If you use four drives, you won't necessarily have four times the performance of a single drive, but it can be close to that for sustained transfers. Some overhead is still involved in the controller performing the striping and issues still exist with latency—that is, how long it takes to find the data—but performance will be higher than any single drive can normally achieve.

When set up for reliability, ATA RAID adapters generally run RAID Level 1, which is simple drive mirroring. All data written to one drive is written to the other. If one drive fails, the system can continue to work on the other drive. Unfortunately, this does not increase performance at all, and it also means you get to use only half of the available drive capacity. In other words, you must install two drives, but you get to use only one (the other is the mirror). However, in an era of high capacities and low drive prices, this is not a significant issue. If you want to eliminate a lot of bulky cabling, consider Serial ATA RAID, which uses the narrow Serial ATA cables shown earlier in this chapter.

Combining performance with fault tolerance requires using one of the other RAID levels, such as 3 or 5. For example, virtually all professional RAID controllers used in network file servers are designed to use RAID Level 5. Controllers that implement RAID Level 5 are more expensive, and at least three drives must be connected. To improve reliability, but at a lower cost, many of the ATA RAID controllers enable combinations of the RAID levels—such as 0 and 1 combined. This usually requires four drives, two of which are striped together in a RAID Level 0 arrangement, which is then redundantly written to a second set of two drives in a RAID Level 1 arrangement. This enables you to have approximately double the performance of a single drive, and you have a backup set should one of the primary sets fail.

Today, you can get parallel or Serial ATA RAID controllers from companies such as Arco Computer Products, Iwill, Promise Technology, HighPoint, and more. A typical low-cost ATA RAID controller enables up to four drives to be attached, and you can run them in RAID Level 0, 1, or 0+1 mode. Remember that performance suffers somewhat when running two drives (master/slave) on a single parallel ATA channel because only one drive can transfer on the cable at a time, which cuts performance in half. Four-channel parallel ATA RAID cards are available, but most new RAID cards are moving to Serial ATA, which doesn't have the master/slave channel sharing problems of parallel ATA. Serial ATA RAID cards use a separate Serial ATA data channel (cable) for each drive, allowing maximum performance. I recommend Serial ATA RAID cards for best performance.

If you are looking for an ATA RAID controller (or a motherboard with an integrated ATA RAID controller), things to look for include

- RAID levels supported (most support 0, 1, and 0+1 combined, although some ATA RAID 5 card products are now available)
- Two or four channels (I recommend four channels for best performance with four devices using parallel ATA)

- Support for ATA/100 or ATA/133 speeds for parallel ATA
- Support for 33MHz or 66MHz PCI slots (some servers have 66MHz slots)
- Serial ATA RAID implementations for maximum performance, ease of installation, and reliability

If you want to experiment with RAID inexpensively, you can implement RAID without a custom controller when using certain higher-end (often server-based) operating systems. For example, Windows NT/2000 and XP or Server 2003 operating systems provide a software implementation for RAID using both striping and mirroring. In these operating systems, the Disk Administrator tool is used to set up and control the RAID functions, as well as to reconstruct the volume when a failure has occurred. Normally, though, if you are building a server in which the ultimate in performance and reliability is desired, you should look for Serial ATA or SCSI RAID controllers that support RAID Level 3 or 5.

CHAPTER 8

The SCSI Interface

Small Computer System Interface

SCSI (pronounced “scuzzy”) stands for Small Computer System Interface and is a general-purpose interface used for connecting many types of devices to a PC. This interface has its roots in SASI, the Shugart Associates System Interface. SCSI is a popular interface for attaching high-speed disk drives to higher-performance PCs, such as workstations or especially to high-end network servers. SCSI is also very flexible; it is not just a disk interface, but is a systems-level interface allowing many types of devices to be connected, including scanners and printers. SCSI is a bus that supports as many as 7 or 15 total devices. Multichannel adapters exist that can support up to 7 or 15 devices per channel.

The SCSI card, called the *host adapter*, functions as the gateway between the SCSI bus and the PC system bus. Each device on the bus has a SCSI controller chip built in. The SCSI host adapter does not talk directly with actual devices such as hard disks; instead, it talks to the SCSI interface controller that is built into the drive.

A single SCSI bus can support as many as 8 or 16 physical units, usually called SCSI *IDs*. One of these units is the SCSI host adapter card in your PC; the other 7 or 15 can be other peripherals. You could have hard disks, tape drives, CD-ROM drives, a graphics scanner, or other devices attached to a single SCSI host adapter. Most systems can support up to four host adapters, each with up to 15 devices, for a total of 60 devices! There are even dual-channel adapters that could double that figure.

SCSI is a fast interface, generally suited to high-performance workstations, servers, or anywhere the ultimate in performance for a storage system interface is needed. The latest Ultra5 (Ultra640) SCSI version supports transfer speeds of up to 640MB per second (MBps)! By comparison, parallel ATA (also known as IDE) transfers at speeds up to 133MBps, and Serial ATA transfers at 150MBps. Note that these figures are raw interface transfer speeds; the speeds of individual devices are normally much lower. The higher speeds of the SCSI bus are utilized when multiple devices share the bus, in which case they can overlap reads and writes and more fully utilize the higher bandwidth available. The slower ATA buses allow only one or two devices, making higher throughputs unnecessary because they would be unusable.

When you purchase a SCSI device such as a SCSI hard disk, you usually are purchasing the device, device controller, and SCSI interface controller in one circuit; as such the device is ready to connect directly to the SCSI bus. This type of drive usually is called an *embedded SCSI device*—the SCSI interface is built in. For example, most SCSI hard drives are technically the same or similar as compared to their ATA counterparts except for the addition of the SCSI interface controller circuits (normally a single chip) added to the logic board. Your system cannot talk directly to the device controller as though it were plugged into the system bus, like on a standard ATA drive. Instead, communications go through the SCSI host adapter installed in the system bus, then to the SCSI interface controller on the drive logic board, and finally to the device controller (also on the logic board) and disk drive. You can access the drive only through the SCSI protocols.

Apple originally rallied around SCSI as being an inexpensive way out of the bind in which it put itself with the Macintosh. When the engineers at Apple realized their mistake in making the Macintosh a closed system (no expansion slots!), they decided that the easiest way to gain expandability was to build a SCSI port into the system, which is how external peripherals were originally added to the slotless Macs. Of course, in keeping with Apple tradition of proprietary designs, they used a nonstandard SCSI connector. Now that Apple is designing systems with expansion slots, Universal Serial Bus (USB), and FireWire (also known as iLink or IEEE 1394), the nonstandard Apple SCSI interface has been dropped from most Macs as a built-in option. Because PC systems have always been expandable, the push toward SCSI was not as urgent. With up to eight or more bus slots supporting various devices in PC-compatible systems, it seemed as though SCSI was not as necessary for system expansion. In fact, with modern PCs sporting inexpensive built-in USB and FireWire ports for external expansion, in most cases SCSI devices are necessary only when top performance or reliability (using hot-swappable drive arrays) is a critical issue. However, USB 2.0 as well as IEEE 1394a/b (FireWire) offer performance comparable to many of the lower-speed versions of SCSI and should be considered as an alternative for devices such as external hard drives and scanners. In fact, for most anything except server-oriented drive arrays, you should probably choose one of the other interfaces over SCSI.

SCSI originally became popular in the PC-based workstation and server market because of the performance and expandability it offers. One block that stalled acceptance of SCSI in the early PC marketplace was the lack of a complete standard; the SCSI standard originally was designed by one company and then turned into a committee-controlled public standard where it eventually became comprehensive and complete. Since then, no single manufacturer has controlled it.

Note

Most SCSI host adapters bundled with hardware, such as graphics scanners or SCSI CD-RW drives, do not include all the features necessary to support multiple SCSI devices or bootable SCSI hard drives. This has nothing to do with any limitations in the SCSI specification. The situation is simply that the manufacturer has included the most stripped-down version of a SCSI host adapter available to save money. It has all the functionality necessary to support the device it came with, but usually lacks the onboard ROM BIOS chip with drivers necessary for booting SCSI drives. Fortunately, with the right adapter and drivers, one SCSI card could support all the SCSI devices in a system from hard drives to optical drives, scanners, tape drives, and more.

In the beginning, SCSI adapters lacked the capability to boot from hard disks on the SCSI bus. Booting from these drives and using a variety of operating systems was a problem that resulted from the lack of a software interface standard. The standard BIOS software in PC systems is designed to talk to ST-506/412, ESDI, or ATA hard disks and devices. SCSI is so different from ATA that a new set of ROM BIOS routines is necessary to support the system so it can self-boot. Also, this BIOS support is unique to the SCSI host adapter you are using; so, unless the host adapter is built in to your motherboard, this support won't be found in your motherboard BIOS. Instead, SCSI host adapters are available with BIOS support for SCSI hard disk drives right on the SCSI host adapter itself.

Note

For more information about the ancient ST-506/412 and ESDI Interfaces, see "ST-506/412 Interface" and "ESDI Interface," respectively, in the Technical Reference section of the disc accompanying this book. Although PCs have not used these interfaces since the early '90s, several current interfaces evolved from them, so I include the information for historical reasons.

Because of the lead taken by Apple in developing systems software (operating systems and ROM) support for SCSI, peripherals connect to Apple systems in fairly standard ways. Until recently, this type of standard-setting leadership was lacking for SCSI in the PC world. This situation changed dramatically with Windows 95 and later versions, which include drivers for most popular SCSI adapters and peripherals on the market. These days, Windows 98/Me, Windows NT/2000/XP includes even more drivers and support for SCSI adapters and devices built in.

Many system manufacturers have standardized SCSI for high-end workstation or server systems. In these systems, a SCSI host adapter card is placed in one of the slots, or the system has a SCSI host adapter built in to the motherboard. This arrangement is similar in appearance to the ATA interface because a single cable runs from the motherboard to the SCSI drive. SCSI supports as many as 7 or 15 additional devices per bus (some of which might not be hard disks), whereas ATA supports only 4 devices (2 per host adapter). Additionally, SCSI supports more types of devices other than hard disks than ATA supports. ATA devices must be a hard disk, an ATA-type CD-ROM drive, a tape drive, an LS-120 or LS-240 SuperDisk drive, a Zip drive, and so on. Systems with SCSI drives are easy to upgrade because virtually any third-party SCSI drive will plug in and function.

SCSI Versus ATA

When you compare the performance and capabilities of ATA (AT attachment, sometimes also known as IDE for integrated drive electronics) interface and SCSI interface drives, you must consider several factors. These two types of drives are the most popular drives used in PC systems today, and a single manufacturer might make seemingly identical drives in both interfaces. Deciding which drive type is best for your system is a difficult decision that depends on many factors.

In most cases, you will find that an ATA drive using the same head-disk assembly as a SCSI drive from the same manufacturer performs about the same or outperforms the equivalent SCSI drive at a given task or benchmark. This is particularly true when using a single disk drive with a single-user operating system, such as Windows 9x/Me. More powerful operating systems, such as Windows NT, Windows 2000, or Windows XP, can more effectively use the command queuing and other features of SCSI, thus improving performance over ATA—especially when supporting multiple drives.

It is interesting to see that SCSI really evolved from ATA, or you could say that both evolved from the ST-506/412 and ESDI interfaces that were once used.

◀◀ See “Precursors to IDE,” p. 532.

SCSI Hard Disk Evolution and Construction

SCSI is not a disk interface, but a bus that supports SCSI bus interface controllers connected to disk and other device controllers. The first SCSI drives for PCs were standard ST-506/412 or ESDI drives with a separate SCSI bus interface controller card (sometimes called a *bridge controller*) that converted the ST-506/412 or ESDI interfaces to SCSI. This interface originally was in the form of a secondary logic board, and the entire assembly often was mounted in an external case.

The next step was to build the SCSI bus interface controller directly into the drive’s own logic board. Today, we call these drives *embedded* SCSI drives because the SCSI interface is built in.

At that point, there was no need to conform to the absolute specifications of ST-506/412 or ESDI on the internal disk interface because the only other device the interface ever would have to talk to was built in as well. Thus, the disk controller chipset manufacturers began to develop more customized chipsets that were based on the ST-506/412 or ESDI chipsets already available but offered more features and higher performance.

Today, if you look at a typical SCSI drive logic board, you often can identify the chip that serves as the disk controller on the board as being the same kind that would be used on an ATA drive.

Consider some examples. An ATA drive must fully emulate the system-level disk-controller interface introduced with the Western Digital WD1003 controller series IBM used in the original 1984 AT system. Most of these built-in controllers have more capabilities than the original WD1003 series (usually in the form of additional commands), but they must at least respond to all the original commands that were used with the WD1003.

In some cases a manufacturer makes ATA and SCSI drives with the same capacity and specifications, which use the same head disk assembly (HDA). If you study these virtually identical drives, the only major difference you will find is an additional chip on the logic board of the SCSI version, called a SCSI Bus Adapter Chip (SBAC) or SCSI controller chip.

Figures 8.1 and 8.2 show the logic-block diagrams of an ATA and a SCSI drive from the same manufacturer. These drives use the same HDA; they differ only in their logic boards, and even the logic boards are the same except for the addition of an SBIC on the SCSI drive’s logic board.

Notice that even the circuit designs of these two drives are almost identical. Both drives use an LSI (large scale integrated circuit) chip called the WD42C22 Disk Controller and Buffer Manager chip. In the ATA drive, this chip is connected through a DMA control chip directly to the AT bus. In the SCSI version, a WD33C93 SCSI bus interface controller chip is added to interface the disk-controller logic to the SCSI bus. In fact, the logic diagrams of these two drives differ only in the fact that the SCSI version has a complete subset of the ATA drive, with the SCSI bus interface controller logic added. This essentially is a very condensed version of the separate drive and bridge controller setups that were used in the early days of PC SCSI.

◀◀ See “Parallel ATA DMA Transfer Modes,” p. 552.

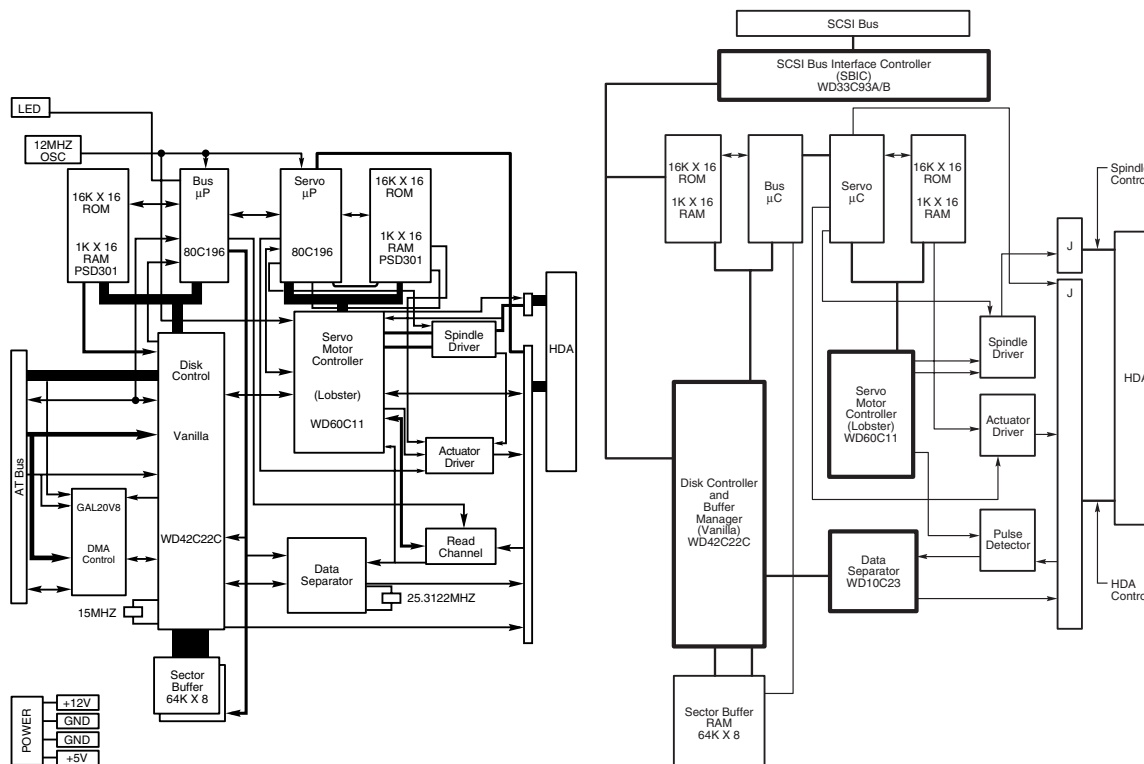

Figure 8.1 Typical ATA (also called IDE) drive logic board block diagram.

To top off this example, study the logic diagram in Figure 8.3 for the WD 1006V-MM1, which is an old ST-506/412 controller used in early AT-compatible computers.

You can clearly see that the main LSI chip onboard is the same WD42C22 disk controller chip used in the ATA and SCSI drives. Here is what the technical reference literature says about that chip:

The WD42C22 integrates a high-performance, low-cost Winchester controller's architecture. The WD42C22 integrates the central elements of a Winchester controller subsystem such as the host interface, buffer manager, disk formatter/controller, encoder/decoder, CRC/ECC (Cyclic Redundancy Check/Error Correction Code) generator/checker, and drive interface into a single 84-pin PQFP (Plastic Quad Flat Pack) device.

You can now see that many SCSI drives are "regular" ATA drives with a SCSI bus interface controller chip added to the logic board. This fact will come up again later in this chapter in the section "SCSI Versus ATA Performance: Advantages and Limitations," which discusses performance and other issues differentiating these interfaces.

For another example, I have several old IBM 320MB and 400MB embedded SCSI-2 hard disks; each of these drives has onboard a WD-10C00 Programmable Disk Controller in the form of a 68-pin Plastic Leaded Chip Carrier (PLCC) chip. The technical literature states

This chip supports ST412, ESDI, SMD, and Optical interfaces. It has 27Mbps maximum transfer rate and an internal, fully programmable 48- or 32-bit ECC, 16-bit CRC-CCITT or external user-defined ECC polynomial, fully programmable sector sizes, and 1.25 micron low power CMOS design.

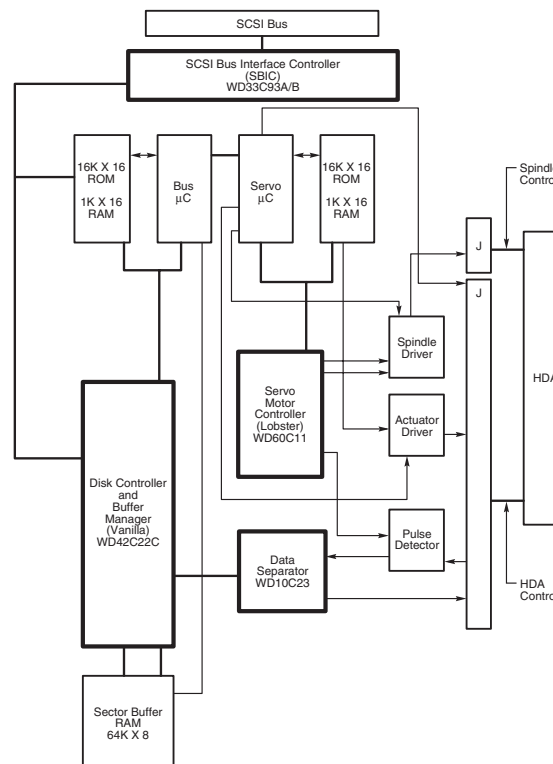

Figure 8.2 Typical SCSI drive logic board block diagram.

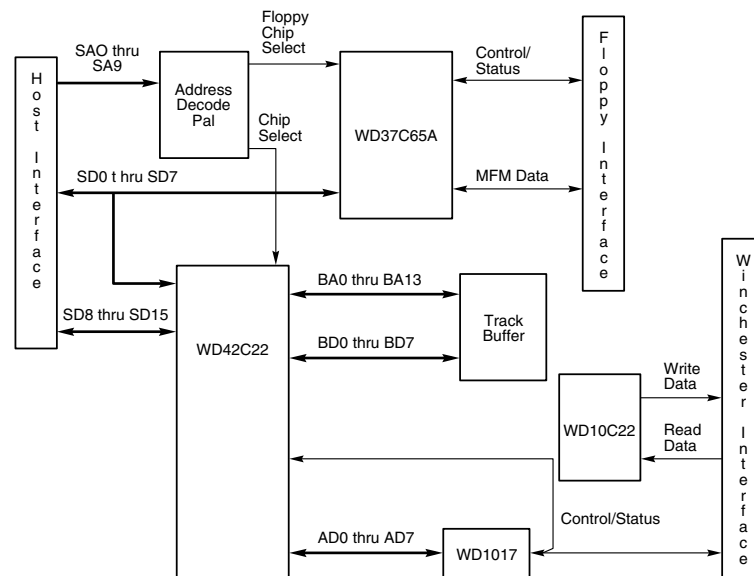

Figure 8.3 Western Digital WD1006V-MM1 ST-506/412 Disk Controller block diagram.

In addition, these particular embedded SCSI drives include the 33C93 SCSI Bus Interface Controller chip, which also is used in the other SCSI drive that I mentioned. Again, there is a distinctly separate disk controller, and the SCSI interface controller is added on top of that.

So again, most embedded SCSI drives have a built-in disk controller (usually based on previous ST-506/412 or ESDI designs) and additional logic to interface that controller to the SCSI bus (a built-in bridge controller, if you like). Now think about this from a performance standpoint. If SCSI drives really are ATA drives with a SCSI Bus Interface Controller chip added, what conclusions can you draw?

First, no drive can perform sustained data transfers faster than the data can actually be read from the disk platters. In other words, the HDA limits performance to whatever it is capable of achieving. Drives can transmit data in short bursts at very high speeds because they often have built-in cache or read-ahead buffers that store data. Many of the newer high-performance SCSI and ATA drives have 8MB or more of cache memory onboard. No matter how big or intelligent the cache is, however, sustained data transfer is still limited by the HDA.

◀◀ See "ATA Standards," p. 536.

Data from the HDA must pass through the disk controller circuits, which, as you have seen, are virtually identical between similar SCSI and ATA drives. In the ATA drive, this data then is presented directly to the system bus. In the SCSI drive, however, the data must pass through a SCSI bus interface controller chip on the drive, travel through the SCSI bus, and then pass through another SCSI bus interface controller chip in the SCSI host adapter card in your system. The longer route a SCSI transfer must take makes this type of transfer slower than the much more direct ATA transfer, when communicating with a single device.

The conventional wisdom has been that SCSI always is much faster than ATA; unfortunately, this wisdom is usually wrong. One cannot compare ATA and SCSI by merely looking at the raw ATA and SCSI bus performance capabilities. An Ultra4 SCSI drive can transfer data at an interface transfer rate of 320MBps, whereas an UltraATA/133 drive can transfer data at an interface transfer rate of 133MBps. Based on these raw transfer rates, SCSI seems to be much faster, but the raw transfer rate of the interface is not the limiting factor. As discussed previously, the actual HDA and disk-controller circuitry place limits on this performance of each drive. The key figure to check is what is reported as the internal or media transfer rate for the drive itself. For example, here are the specs on two similar drives (one ATA and one SCSI):

ATA Drive		SCSI Drive	
Drive	Maxtor DiamondMax+60 ATA	Drive	IBM Ultrastar 73LZX SCSI
Interface	UltraATA/100	Interface	Ultra4 (Ultra320) SCSI
Platters	3	Platters	6
Data heads	6	Data heads	12
Capacity	60GB	Capacity	73.4GB
Areal density (max)	15.4Gb/sq. in.	Areal density (max)	13.2Gb/sq. in.
Rotational speed	7,200rpm	Rotational speed	10,000rpm
Internal cache buffer	2MB	Internal cache buffer	4MB
Interface transfer rate	Up to 100MBps	Interface transfer rate	Up to 320MBps
Media transfer rate	Up to 57MBps	Media transfer rate	Up to 58MBps
Sustained data transfer rate	28.5MBps–57MBps	Sustained data transfer rate	29.8MBps–58MBps
Average sustained transfer rate	42.75MBps	Average sustained transfer rate	43.9MBps

Note that although the SCSI drive can claim a much higher external transfer rate of 320MBps as compared to the ATA drive's 100MBps, in actuality these drives are almost identical performers. The real specs to look at are in the last two lines of the tables, which detail how fast data can actually be read from the drive. In particular, the sustained transfer rates are the true transfer rates for reading data from these drives; as you can see, they are very close indeed. The rotational speed, track density, and things such as internal buffers or caches mainly influence the true transfer rate of a drive.

Then you have to factor in that the SCSI drive would cost 50%–100% more than the ATA counterpart. Not to mention the cost of springing for an Ultra4 SCSI host adapter to plug the drive into. Decent SCSI adapters, especially Ultra-SCSI versions, can easily cost \$300 or more, which is 2 or 3 times the cost of most desktop PC motherboards. When you consider that UltraATA and/or Serial ATA interfaces are built in to modern motherboards for free, you can see that, depending on your needs, spending a ton of extra cash for SCSI can be a significant waste of money.

Now to present the counterpoint: Although these two drives are basically equivalent, the ATA version was one of the top ATA drives offered at the time, whereas the SCSI drive listed was only a middle-of-the-pack performer. Hitachi and others make SCSI drives that have rotational speeds of 15,000rpm; increased track density; and larger buffers. Of course, these drives cost even more. So, the bottom line is that if you must have the absolute best-performing drives, by all means get the top-of-the-line SCSI drives and Ultra SCSI Wide adapters. However, if you want something that is literally one third or one fourth the cost and three-fourths or more the performance, stick with ATA.

ANSI SCSI Standards

The SCSI standard defines the physical and electrical parameters of a parallel I/O bus used to connect computers and peripheral devices in daisy-chain fashion. The standard supports devices such as disk drives, tape drives, and CD-ROM drives. The original SCSI standard (ANSI X3.131-1986) was approved in 1986, SCSI-2 was approved in January 1994, and the first portions of SCSI-3 were approved in 1995. Note that SCSI-3 has evolved into an enormous standard with numerous sections and is an evolving, growing standard still very much under development. Because it has been broken down into multiple standards, there really is no single SCSI-3 standard.

The SCSI interface is defined as a standard by ANSI (the American National Standards Institute), specifically by a committee currently known as T10. T10 is a technical committee of the InterNational Committee on Information Technology Standards (INCITS, pronounced "insights"). INCITS is accredited by ANSI and operates under rules approved by ANSI. These rules are designed to ensure that voluntary standards are developed by the consensus of industry groups. INCITS develops information-processing system standards,

whereas ANSI approves the processes under which they are developed and publishes them. Working draft copies of all SCSI-related standards can be downloaded from the T10 Technical Committee site (www.t10.org).

One problem with the original SCSI-1 document was that many of the commands and features were optional, and there was little or no guarantee that a particular peripheral would support the expected commands. This problem caused the industry as a whole to define a set of 18 basic SCSI commands called the Common Command Set (CCS) to become the minimum set of commands supported by all peripherals. SCSI-1 plus the CCS became the basis for the SCSI-2 specification.

Along with formal support for CCS, SCSI-2 provided additional definitions for commands to access CD-ROM drives (and their sound capabilities), tape drives, removable drives, optical drives, and several other peripherals. In addition, an optional higher-speed version called Fast SCSI-2 and a 16-bit version called Wide SCSI-2 were defined. Another feature of SCSI-2 is *command queuing*, which enables a device to accept multiple commands and execute them in the order that the device deems to be most efficient. This feature is most beneficial when you are using a multitasking operating system that could be sending several requests on the SCSI bus at the same time.

The X3T9 group approved the SCSI-2 standard as X3.131-1990 in August 1990, but the document was recalled in December 1990 for changes before final ANSI publication. Final approval for the SCSI-2 document was made in January 1994, although it changed little from the original 1990 release. The SCSI-2 document is now called ANSI X3.131-1994. The official document is available from Global Engineering Documents and the ANSI committee—both are listed in the Vendor List on the disc packaged with this book. You can also download the final working drafts of these documents from the T10 Technical Committee home page, as listed previously.

Most companies indicate that their host adapters follow both the ANSI X3.131-1986 (SCSI-1) and the X3.131-1994 (SCSI-2) standards. Note that because virtually all parts of SCSI-1 are supported in SCSI-2, most SCSI-1 devices are also considered SCSI-2 by default. Many manufacturers advertise that their devices are SCSI-2, but this does not mean they support any of the additional optional features that were incorporated in the SCSI-2 revision.

For example, an optional part of the SCSI-2 specification includes a fast synchronous mode that doubles the standard synchronous transfer rate from 5MBps to 10MBps. This Fast SCSI transfer mode can be combined with 16-bit Wide SCSI for transfer rates of up to 20MBps. An optional 32-bit version was defined in SCSI-2, but component manufacturers have shunned this as too expensive. In essence, 32-bit SCSI was a stillborn specification, as it was withdrawn from the SCSI-3 standard. Most SCSI implementations are 8-bit standard SCSI or 16-bit Fast/Wide SCSI. Even devices that support none of the Fast or Wide modes can still be considered SCSI-2.

SCSI-3 is broken down into a number of standards. The SCSI Parallel Interface (SPI) standard controls the parallel interconnection between SCSI devices, which is mostly what we are talking about here. So far, five versions of SPI have been created, including SPI, SPI-2, SPI-3, SPI-4, and SPI-5.

What can be confusing is that several terms can be used to describe the newer SPI standards, as shown in Table 8.1.

Table 8.1 SPI (SCSI Parallel Interface) Standards

SCSI-3 Standard	Also Known As	Speed	Throughput
SPI	Ultra SCSI	Fast-20	20/40MBps
SPI-2	Ultra2 SCSI	Fast-40	40/80MBps
SPI-3	Ultra3 SCSI or Ultra160(+)	Fast-80DT	160MBps
SPI-4	Ultra4 SCSI or Ultra320	Fast-160DT	320MBps
SPI-5	Ultra5 SCSI or Ultra640	Fast-320DT	640MBps

To add to the confusion, SPI-3 or Ultra3 SCSI is also called Ultra160 or Ultra160+, SPI-4 or Ultra4 SCSI is also called Ultra320, and SPI-5 or Ultra5 SCSI is also called Ultra640. The Ultra160 designation refers to any device that includes the first three of the five main features from the Ultra3 SCSI specification. Ultra160+ refers to any device that supports all five main features of Ultra3 SCSI. Ultra320 and Ultra640 includes all the features of Ultra160+, as well as several additional features.

Table 8.2 shows the maximum transfer rates for the SCSI bus at various speeds and widths and the cable type required for the specific transfer widths.

Note

The A cable listed in Table 8.2 is the standard 50-pin SCSI cable, whereas the P cable is a 68-pin cable designed for 16-bit transfers. High Voltage Differential (HVD) signaling was never popular and is now considered obsolete. Low Voltage Differential (LVD) signaling is used in the Ultra2 and Ultra3 modes to increase performance and cabling lengths. Pinouts for the cable connections are listed in this chapter in Tables 8.3–8.6, and you can see the connectors in Figures 8.8–8.10.

SCSI is both forward and backward compatible, meaning one can run faster devices on buses with slower host adapters or vice versa. In each case, the entire bus runs at the lowest common-denominator speed. Thus, although you can mix and match different speeds of devices on the same bus, you should place fast devices on a separate SCSI adapter (or connector, if you use dual-bus adapters) from slower devices. In fact, as was stated earlier, virtually any SCSI-1 device can also legitimately be called SCSI-2 (or even SCSI-3) because most of the improvements in the later versions are optional. Of course, you can't take advantage of the faster modes on an older, slower host adapter. By the same token, you can purchase an Ultra3-capable SCSI host adapter and still run older standard SCSI devices. You can even mix standard 8-bit and wide 16-bit devices on the same bus using cable adapters.

SCSI-1

SCSI-1 was the first implementation of SCSI and was officially known as ANSI X3.131-1986. The major features of SCSI-1 were as follows:

- 8-bit parallel bus
- 5MHz asynchronous or synchronous operation
- 4MBps (asynchronous) or 5MBps (synchronous) throughput
- 50-pin cables with low-density pin-header internal and Centronics-style external connectors
- Single-ended (SE) unbalanced transmission
- Passive termination
- Optional bus parity

SCSI-1 is now considered obsolete; in fact, the standard has been withdrawn by ANSI and replaced by SCSI-2.

SCSI-2

SCSI-2 is officially known as ANSI X3.131-1994. The SCSI-2 specification is essentially an improved version of SCSI-1 with some parts of the specification tightened and several new features and options added. Normally, SCSI-1 and SCSI-2 devices are compatible, but SCSI-1 devices ignore the additional features in SCSI-2.

Some of the changes in SCSI-2 are very minor. For example, SCSI-1 allowed SCSI bus parity to be optional, whereas parity must be implemented in SCSI-2. Parity is an extra bit that is sent as a verification bit to ensure that the data is not corrupted. Another requirement is that initiator devices, such as host adapters, provide terminator power to the interface; most devices already did so, though.

Table 8.2 SCSI Types, Data-Transfer Rates, and Cables

SCSI Standard	SCSI Technology	Marketing Term	Clock Speed (MHz)	Transfer Width	ST/DT
SCSI-1	Async	Asynchronous	5	8-bit	ST
SCSI-1	Fast-5	Synchronous	5	8-bit	ST
SCSI-2	Fast-5/Wide	Wide	5	16-bit	ST
SCSI-2	Fast-10	Fast	10	8-bit	ST
SCSI-2	Fast-10/Wide	Fast/Wide	10	16-bit	ST
SCSI-3/SPI	Fast-20	Ultra	20	8-bit	ST
SCSI-3/SPI	Fast-20/Wide	Ultra/Wide	20	16-bit	ST
SCSI-3/SPI-2	Fast-40	Ultra2	40	8-bit	ST
SCSI-3/SPI-2	Fast-40/Wide	Ultra2/Wide	40	16-bit	ST
SCSI-3/SPI-3	Fast-80DT	Ultra3 (Ultra160)	40 ^s	16-bit	DT
SCSI-3/SPI-4	Fast-160DT	Ultra4 (Ultra320)	80 ^s	16-bit	DT
SCSI-3/SPI-5	Fast-320DT	Ultra5 (Ultra640)	160 ^s	16-bit	DT

Cable lengths are in meters: 25M = 80ft., 12M = 40ft., 6M = 20ft., 3M = 10ft., 1.5M = 5ft.

SE = Single-ended signaling.

HVD = High Voltage Differential signaling; obsolete.

LVD = Low Voltage Differential signaling.

SPI = SCSI Parallel Interface; part of SCSI-3.

ST = Single transition, or one transfer per clock cycle.

DT = Double transition, or two transfers per clock cycle; 16-bit only.

SCSI-2 also added several optional features:

- Fast SCSI (10MHz)
- Wide SCSI (16-bit transfers)
- Command queuing
- New commands
- High-density, 50-pin cable connectors
- Active (Alternative 2) termination for improved single-ended (SE) transmission
- High Voltage Differential transmission (incompatible with SE on the same bus) for longer bus lengths

Wide SCSI enables parallel data transfers at a bus width of 16 bits. The wider connection requires a new cable design. The standard 50-conductor, 8-bit cable is called the A cable. SCSI-2 originally defined a special 68-conductor B cable that was supposed to be used in conjunction with the A cable for 32-bit wide transfers. However, because of a lack of industry support and the added expenses involved, 32-bit SCSI was never actually implemented and was finally removed as part of the SCSI-3 specifications. Therefore, two different types of SCSI cables are now available, called the A cable and the P cable. A cables are any SCSI cables with 50-pin connectors, whereas P cables are any SCSI cables with 68-pin connectors. You need a P cable if you are connecting a Wide SCSI device and want it to work in 16-bit mode. The P cable was not officially included in the standard until SCSI-3.

Fast SCSI refers to high-speed synchronous transfer capability. Fast SCSI achieves a 10MBps transfer rate on the standard 8-bit SCSI cabling. When combined with a 16-bit Wide SCSI interface, this configuration results in data-transfer rates of 20MBps (called Fast/Wide).

The high-density connectors enable smaller, more efficient connector and cable designs.

Transfer Speed (MB/s)	Max. No. of Devices ¹	Cable Type	Max. Length (SE)	Max. Length (HVD)	Max. Length (LVD)
4	7	A (50-pin)	6M	25M	-
5	7	A (50-pin)	6M	25M	-
10	15	P (68-pin)	6M	25M	-
10	7	A (50-pin)	3M	25M	-
20	15	P (68-pin)	3M	25M	-
20	7	A (50-pin)	3/1.5M ²	25M	-
40	7	P (68-pin)	3/1.5M ²	25M	-
40	7	A (50-pin)	-	-	12M ³
80	15	P (68-pin)	-	-	12M ³
160	15	P (68-pin)	-	-	12M ³
320	15	P (68-pin)	-	-	12M ³
640	15	P (68-pin)	-	-	10M ⁴

1 = Not including the host adapter.

2 = Ultra SCSI cable total length is restricted to 1.5M if more than three devices exist on the bus (not including the host adapter). A maximum of seven devices is allowed.

3 = A 25M cable can be used if only one device exists (point-to-point interconnect).

4 = For Ultra5 (Ultra640) only, cable length is restricted to 2M using ribbon cable, and a 20M cable can be used if only one device exists (point-to-point interconnect).

5 = Ultra3 (Ultra160), Ultra4 (Ultra320), and Ultra5 (Ultra640) SCSI transfer twice per clock cycle and are 16-bit only.

In SCSI-1, an initiator device, such as a host adapter, was limited to sending one command per device. In SCSI-2, the host adapter can send as many as 256 commands to a single device, which will store and process those commands internally before responding on the SCSI bus. The target device can even resequence the commands to enable the most efficient execution or performance possible. This is especially useful in multitasking environments, such as OS/2 and Windows NT, which can take advantage of this feature.

SCSI-2 took the Common Command Set that was being used throughout the industry and made it an official part of the standard. The CCS was designed mainly for disk drives and did not include specific commands designed for other types of devices. In SCSI-2, many of the old commands are reworked, and several new commands have been added. New command sets have been added for CD-ROMs, optical drives, scanners, communications devices, and media changers (jukeboxes).

The single-ended SCSI bus depends on very tight termination tolerances to function reliably. Unfortunately, the original 132-ohm passive termination defined in the SCSI-1 document was not designed for use at the higher synchronous speeds now possible. These passive terminators, which are sometimes built in to SCSI devices, can cause signal reflections to generate errors when transfer rates increase or when more devices are added to the bus. SCSI-2 defines an active (voltage-regulated) terminator that lowers termination impedance to 110 ohms and improves system integrity. Note that LVD SCSI requires special LVD terminators. If you use SE terminators on a bus with LVD devices, they either won't work or, if they are multimode devices, will default to SE operation.

These features are not required; they are optional under the SCSI-2 specification. If you connect a standard SCSI host adapter to a Fast SCSI drive, for example, the interface will work, but only at standard SCSI speeds.

SCSI-3

SCSI-3 is a term used to describe a set of standards currently being developed. Simply put, it is the next generation of documents a product conforms to. Unlike SCSI-1 and SCSI-2, SCSI-3 is not one document that covers all the layers and interfaces of SCSI, but is instead a collection of documents that covers the primary commands, specific command sets, and electrical interfaces and protocols. The command sets include hard disk interface commands, commands for tape drives, commands for redundant array of inexpensive drives (RAID), and other commands. Additionally, an overall SCSI Architectural Model (SAM) exists for the physical and electrical interfaces, as does a SCSI Parallel Interface (SPI) standard that controls the form of SCSI most commonly used. Each document within the standard is now a separate publication with its own revision level—for example, within SCSI-3, five versions of the SCSI Parallel Interface have been published. Usually, we don't refer to SCSI-3 anymore as a specific interface and instead refer to the specific subsets of SCSI-3, such as SPI-3 (Ultra3 SCSI).

The main additions to SCSI-3 include

- Ultra2 (Fast-40) SCSI
- Ultra3 (Fast-80DT) SCSI
- Ultra4 (Fast-160DT) SCSI
- Ultra5 (Fast-320DT) SCSI
- New Low Voltage Differential signaling
- Elimination of High Voltage Differential signaling

Breaking SCSI-3 into many smaller individual standards has enabled the standard as a whole to develop more quickly. The individual standards can now be published more quickly rather than waiting for an entire large standard to be approved.

Figure 8.4 shows the main parts of SCSI today.

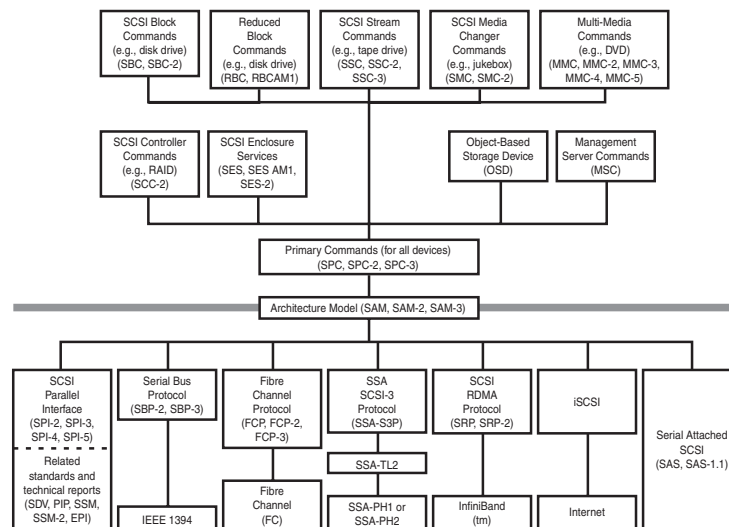

Figure 8.4 SCSI architecture.

The most recent changes or additions to SCSI include the Ultra320 (Ultra4) and Ultra640 (Ultra5) SCSI standards, which have taken the performance of SCSI up to 320MBps or 640MBps. Ultra2 SCSI and beyond also include the LVD (low-voltage differential) electrical interface standard, which enables greater cable lengths. The older high-voltage differential signaling has also been removed from the standard.

A number of people are confused over the speed variations in SCSI. Part of the problem is that speeds are quoted as either clock speeds (MHz) or transfer speeds. With 8-bit transfers, you get 1 byte per transfer, so if the clock is 40MHz (Fast-40 or Ultra2 SCSI), the transfer speed is 40MBps. On the other hand, if you are using a Wide (16-bit) interface, the transfer speed doubles to 80MBps, even though the clock speed remains at 40MHz. With Fast-80DT, the bus speed technically remains at 40MHz; however, two transfers are made per cycle, resulting in a throughput speed of 160MBps. The same is true for Ultra4 SCSI, which runs at 80MHz, transfers 2 bytes at a time, and has two transfers per cycle, for a throughput of 320MBps. Ultra5 doubles the clock speed again, running at 160MHz, transferring 2 bytes at a time, two times per cycle, for a throughput of 640MBps.

Finally, confusion exists because SCSI speeds or modes are often discussed using either the official terms—such as Fast-10, Fast-20, Fast-40, Fast-80DT, Fast-160DT—or the equivalent marketing terms, such as Fast, Ultra, Ultra2, Ultra3 (also called Ultra160) and Ultra4 (Ultra320). Refer to Table 8.2 for a complete breakdown of SCSI official terms, marketing terms, and speeds.

The further evolution of the most commonly used form of SCSI is defined under the SPI standards within SCSI-3. The SPI standards are detailed in the following sections.

SPI or Ultra SCSI

The SCSI Parallel Interface standard was published on January 1, 1995, and is the first SCSI standard that fell under the SCSI-3 designation. The SPI standard is officially known as ANSI/INCITS 253-1995 (formerly ANSI X3.253-1995). SPI is also called Ultra SCSI by most marketing departments and defines the parallel bus electrical connections and signals. A separate document called the SCSI Interlock Protocol (SIP) defines the parallel command set. SIP was included in the later SPI-2 and SPI-3 revisions and is no longer carried as a separate document. The main features added in SPI or Ultra SCSI are

- Fast-20 (Ultra) speeds (20MBps or 40MBps)
- 68-pin P-cable and connectors defined for Wide SCSI

SPI initially included speeds up to Fast SCSI (10MHz), which enabled transfer speeds up to 20MBps using a 16-bit wide bus. Later, Fast-20 (20MHz), commonly known as Ultra SCSI, was added through an addendum document (ANSI/INCITS 253-1995 Amendment 1), allowing a throughput of 40MBps on a 16-bit wide bus (commonly called Ultra/Wide).

SPI-2 or Ultra2 SCSI

SPI-2 is also called Ultra2 SCSI and was officially published on April 14, 1998 as ANSI/INCITS 302-1998 (formerly ANSI X3.302-1998). SPI-2 or Ultra2 SCSI adds several features to the prior versions:

- Fast-40 (Ultra2) speeds (40MBps or 80MBps)
- Single Connector Attachment (SCA-2) connectors
- Low-voltage differential (LVD) signaling
- 68-pin Very High Density Connector (VHDC)

The most notable of these is a higher speed called Fast-40, which is commonly called Ultra2 SCSI and runs at 40MHz. On a narrow (8-bit) bus, this results in 40MBps throughput, whereas on a wide bus (16-bit), this results in 80MBps throughput and is commonly referred to as Ultra2/Wide.

To achieve these speeds, a new electrical interface called LVD must be used. The slower single-ended electrical interface is only good for speeds up to Fast-20; Fast-40 mode requires LVD operation. The LVD signaling also enables longer cable lengths up to 12 meters with multiple devices or 25 meters with only one device. LVD and SE devices can share the same cable, but in that case, the bus runs in SE mode and is restricted in length to as little as 1.5 meters in Fast-20 mode. LVD operation requires special LVD-only or LVD/SE multimode terminators. If multimode terminators are used, the same terminators work on either SE or LVD buses.

The SPI-2 standard also includes SCSI Interlink Protocol (SIP) and defines the Single Connector Attachment (SCA-2) 80-pin connector for hot-swappable drive arrays. There is also a new 68-pin Very High Density Connector (VHDC), which is smaller than the previous types.

SCSI Signaling

“Normal,” or standard, SCSI uses a signaling technique called *single-ended (SE)* signaling. SE signaling is a low-cost technique, but it also has performance and noise problems.

Single-ended signaling is also called *unbalanced* signaling. Each signal is carried on a pair of wires, usually twisted to help reduce noise. With SE, one of the pair is grounded—often to a common ground for all signals—and the other carries the actual voltage transitions. It is up to a receiver at the other end of the cable to detect the voltage transitions, which are really just changes in voltage.

Unfortunately, this type of unbalanced signaling is very prone to problems with noise, electromagnetic interference, and ground leakage; these problems get worse the longer the cable is. This is why Ultra SCSI was limited to such short maximum bus lengths—as little as 1.5 meters, or 5 feet.

When SCSI was first developed, a signaling technique called High Voltage Differential signaling was also introduced into the standard. Differential signaling, also known as *balanced signaling*, is still done with a pair of wires. In fact, the first in the pair carries the same type of signal that single-ended SCSI carries. The second in the pair, however, carries the logical inversion of that signal. The receiving device detects the difference between the pair (hence the name differential). By using the wires in a balanced pair, the receiver no longer needs to detect voltage magnitude, only the differential between voltages in two wires. This is much easier for circuits to do reliably, which makes them less susceptible to noise and enables greater cable length. Because of this, differential SCSI can be used with cable lengths of up to 25 meters, whereas single-ended SCSI is good only for 6 meters maximum, or as little as 1.5 meters in the faster modes.

Figure 8.5 shows the circuit differences between balanced (differential) and unbalanced (single-ended) transmission lines.

Figure 8.5 Balanced (differential) versus unbalanced (single-ended) signaling.

Unfortunately, the original standard for HVD signaling called for high-voltage differentials between the two wires. This meant that small, low-power, single-chip interfaces using HVD signaling could not be developed. Instead, circuits using several chips were required. This worked at both ends, meaning both the host adapter and device circuitry had to be larger and more expensive.

Another problem with HVD SCSI is that although the cables and connectors look (and are) exactly the same as for SE SCSI, both types of devices can't be mixed on the same bus. If they are, the high voltage from the HVD device burns out the receiver circuits on all SE devices attached to the bus. In other words, the result is smoked hardware—not a pretty sight.

Because SE SCSI worked well enough for the speeds that were necessary up until recently, HVD SCSI signaling never really caught on. It was used only in minicomputers and very rarely, if at all, in PCs. Because of this fact, the extra cost of this interface, and the fact that it is electrically incompatible with standard SE SCSI devices, HVD signaling was removed from the SCSI specification in the latest SCSI-3 documents. So, as far as we are concerned, it is obsolete.

Still, a need existed for a more reliable signaling technique that would allow for longer cable lengths. The answer came in the form of LVD signaling. By designing a new version of the differential interface, it can be made to work with inexpensive and low-power SCSI chips. Another advantage of LVD is that because it uses low voltage, if you plug an LVD device into an SE SCSI bus, nothing will be damaged. In fact, as an optional part of the LVD standard, the LVD device can be designed as a multimode device, which means it works on both SE and LVD buses. In the case of installing a multimode LVD device into an SE bus, the device detects that it is installed in an SE bus and defaults to SE mode.

Therefore, all multimode LVD/SE SCSI devices can be used on either LVD or SE SCSI buses. However, when on a bus with even one other SE device, all the LVD devices on the bus run only in SE mode. Because SE mode supports only SCSI speeds of up to 20MHz (Fast-20 or UltraSCSI) and cable lengths of up to 1.5 or 3 meters, the devices also work only at that speed or lower; you also might have problems with longer cables. Although you can purchase an Ultra3 SCSI multimode LVD/SE drive and install it on a SCSI bus along with single-ended devices, you will certainly be wasting the capabilities of the faster device.

Note that all Ultra2 and Ultra3 devices support LVD signaling because that is the only way they can be run at the Ultra2 (40MHz) or Ultra3 (80MHz) speeds. Ultra SCSI (20MHz) or slower devices can support LVD signaling, but in most cases, LVD is synonymous with Ultra2 or Ultra3 only.

Table 8.2, shown earlier, lists all the SCSI speeds and maximum lengths for each speed using the supported signaling techniques for that speed.

Because the connectors are the same for SE, HVD, LVD, or multimode SE/LVD devices, and because putting an HVD device on any bus with SE or LVD devices causes damage, it would be nice to be able to tell them apart. One way is to look for a special symbol on the unit; the industry has adopted different universal symbols for single-ended and differential SCSI. Figure 8.6 shows these symbols.

Figure 8.6 Universal symbol icons identifying SE, LVD, multimode LVD/SE, and HVD devices.

If you do not see such symbols, you can tell whether you have a High Voltage Differential device by using an ohmmeter to check the resistance between pins 21 and 22 on the device connector:

- On a single-ended or Low Voltage Differential device, the pins should be tied together and also tied to the ground.
- On a High Voltage Differential device, the pins should be open or have significant resistance between them.

Although you will blow up stuff if you plug HVD devices into LVD or SE buses, this generally should not be a problem because virtually all devices used in the PC environment are SE, LVD, or LVD/SE. HVD has essentially been rendered obsolete because it has been removed from the SCSI standard with Ultra3 SCSI (SPI-3).

SPI-3 or Ultra3 SCSI (Ultra160)

SPI-3—also known as Ultra3 or Ultra160 SCSI—was published on November 1, 2000, and built on the previous standard primarily by doubling the speed to Fast-80DT (double transition). This results in a maximum throughput of 160MBps. The main features added to SPI-3 (Ultra3) are

- DT (double transition) clocking
- Packetization
- Cyclic redundancy checking (CRC)
- Quick Arbitrate and Select (QAS)
- Domain validation

Double transition clocking sends data on both the rising and falling edges of the REQ/ACK clock. This enables Ultra3 SCSI to transfer data at 160MBps, while still running at a bus clock rate of 40MHz. This mode is defined for 16-bit wide bus use only.

Cyclic redundancy checking (CRC) is a form of error checking incorporated into Ultra3 SCSI. Previous versions of SCSI used simple parity checking to detect transmission errors. CRC is a much more robust form of error-detection capability that is far superior for operation at higher speeds.

Domain validation allows better negotiation of SCSI transfer speeds and modes. With prior SCSI versions, when the bus is initialized, the host adapter sends an `INQUIRY` command at the lowest 5MHz speed to each device to determine which data-transfer rate the device can use. The problem is that, even though both the host adapter and device might support a given speed, there is no guarantee that the interconnection between the devices will reliably work at that speed. If a problem occurs, the device becomes inaccessible. With domain validation, after a maximum transfer speed is negotiated between the host and device, it is then tested at that rate. If errors are detected, the rate is stepped down until the connection tests error-free. This is similar to how modems negotiate transmission speeds before communicating and really improves the flexibility and perceived reliability of SCSI.

Packetization is a protocol that enables information to be transferred between SCSI devices in a much more efficient manner. Traditional parallel SCSI uses multiple bus phases to communicate different types of information between SCSI devices: one for command information, two for messages, one for status, and two for data. In contrast, packetized SCSI communicates all this information by using only two phases: one for each direction. This dramatically reduces the command and protocol overhead, especially as higher and higher speeds are used.

Packetized SCSI is fully compatible with traditional parallel SCSI, which means packetized SCSI devices can reside on the same bus as traditional SCSI devices. As long as the host adapter supports the packetization, it can communicate with one device using packets and another using traditional protocol. Not all Ultra3 or Ultra160 SCSI devices include packetization support, however. Ultra3 devices that support packetization typically are referred to as Ultra160+ SCSI.

Quick Arbitrate and Select (QAS) is a feature in Ultra3 SCSI that reduces arbitration time by eliminating bus free time. QAS enables a device to transfer control of the bus to another device without an intervening `BUS FREE` phase. SCSI devices that support QAS report that capability in the `INQUIRY` command.

Ultra160 and Ultra160+

Because the five main new features of Ultra3 SCSI are optional, drives could claim Ultra3 capability and not have a consistent level of functionality. To ensure truth in advertising and a minimum level of performance, a group of manufacturers got together and created a substandard within Ultra3 SCSI that requires a minimum set of features. These are called Ultra160 and Ultra160+ because both indicate 160MBps throughput. These are technically not an official part of the SPI-3 standard. Even so, they do guarantee that certain specifications will be met and certain performance levels will be attained.

Ultra160 is a specific implementation of Ultra3 (SPI-3) SCSI that includes the first three additional features of Ultra3 SCSI:

- Fast-80DT clocking for 160MBps operation
- CRC
- Domain validation

Ultra160 SCSI runs in LVD mode and is backward compatible with all Ultra2 SCSI (LVD) devices. The only caveat is that no SE devices must be on the bus. When Ultra2 and Ultra160 (Ultra3) devices are mixed, each device can operate at its full-rated speed independent of the other. The bus will dynamically switch from single- to double-transition mode to support the differences in speeds.

Ultra160+ adds the other two features, ensuring a full implementation of Ultra3:

- Packetization
- Quick Arbitrate and Select

With Ultra160 and Ultra160+, a known level of functionality ensures that a minimum level of performance will be met. Ultra160+ SCSI is the highest-performance PC-level storage interface and is best suited for high-traffic environments, such as high-end network servers or workstations. The adaptability and scalability of the interface enables high performance with high reliability.

SPI-4 or Ultra4 SCSI (Ultra320)

SPI-4, also known as Ultra4 or Ultra320 SCSI was published on December 1, 2002, as ANSI/INCITS 362-2002, and has all the same features as the previous Ultra3 (Ultra160) SCSI plus several new features to ensure reliable data transmission at twice the speed.

Ultra320 SCSI integrates both the Packetization and Quick Arbitrate and Select features from Ultra160+ SCSI as mandatory features.

Ultra320 SCSI then adds the following new features:

- *Transfer speed.* Ultra320 transfers data 2 bytes (16 bits) at a time at 80MHz using double-transition (DT) cycling, meaning it transfers twice per cycle (hertz). This results in a burst transfer rate of 320MBps.
- *Read/write data streaming.* This minimizes the overhead for queued data transfers by enabling a device to send one data stream queue-tag packet followed by multiple data packets. Previously, only one data packet could be sent with each queue-tag packet. Write performance is also increased because there are fewer bus turnarounds from data in to data out.
- *Flow control.* This allows a target device to indicate when the last packet of a data stream will be transferred, which enables the initiator to terminate the data prefetch or begin flushing data buffers sooner than previously possible.

At the high 80MHz DT (dual transition) signaling speeds used with Ultra320, problems were discovered with high-frequency roll-off (signal degradation) and skew (timing variations) in the cables and logic boards. To compensate for this, Ultra320 can use one of two methods: write precompensation (WPC) in the transmitters or adjustable active filters (AAF) in the receivers. Write precompensation alters the transmitted signals by driving the first bit after a clock transition harder than the subsequent bits. Write precompensation can be turned off if receivers with AAF are used instead, which are capable of compensating for roll-off and skew problems in the transmission line at the receiving end. When using AAF, a special training pattern with low- and high-frequency signals is sent before each data transfer to allow the receiver to dynamically adjust for the high-frequency roll-off and skew problems. AAF is considered the best method because it is dynamic and automatically adjusts to compensate for the particular conditions in the bus at the time of each data transfer. Because of this, the faster Ultra640 standard requires AAF and WPC is not an option.

SPI-5 or Ultra5 SCSI (Ultra640)

SPI-5 (also known as Ultra5 or Ultra640 SCSI) was published on July 10, 2003, as ANSI/INCITS 367-2003 and is twice as fast as the previous Ultra4 (Ultra320) standard. Most importantly, SPI-5 or Ultra640 is being promoted as the last of the parallel SCSI standards according to Technical Committee T10. With the announcement of Ultra640, the new Serial Attached SCSI (SAS) standard was mentioned for the future as picking up where parallel SCSI leaves off.

Ultra640 includes all the same features of Ultra320 SCSI, with the following additional features or requirements:

- Signal and clock speeds double (160MHz, 2 bytes per transfer, and two transfers per cycle).
- Write precompensation (WPC) is no longer allowed.
- Adjustable active filters (AAF) are required.
- The AAF receiver adjusts the clocking for both the rising and falling edges of the signal.

- The AAF training pattern is changed to compensate for crosstalk effects.
- Cable length is restricted to 2M using a multidrop ribbon cable, or up to 20M for a shielded cable if only one device exists (point-to-point interconnect).

With Ultra640 SCSI, ribbon cables are restricted to 2M in total length. This is because ribbon cable has high crosstalk, or signal noise transfer, between adjacent wires. The maximum length for a shielded cable bus is 10M, or 20M if a single device is connected.

SPI-5 (Ultra640) SCSI will almost certainly be the last generation of the parallel SCSI physical interface. In fact, currently there are no Ultra640 products on the market. Additionally, because SAS has been released and is being touted as the future of SCSI, there might never be any Ultra640 products. Because SAS uses the same basic physical layer and connections as Serial ATA, SAS is expected to be the next step in both SCSI and high-end SATA solutions.

Serial Attached SCSI

With parallel SCSI reaching the end of the road with the development of Ultra320 and Ultra640, and future upgrades in speed to the parallel bus both extremely difficult and expensive to engineer, it was deemed that serial architectures should be investigated by the T10 committee as possible solutions for future SCSI implementations. Starting in April 2002, the committee began work on a future serial SCSI standard. Rather than reinvent the wheel, it was decided to adopt the same signaling, cable, and connector designs as used in SATA and combine the SCSI command protocol with a somewhat modified SATA physical layer design. The result was called Serial Attached SCSI and was officially published on October 30, 2003, as ANSI/INCITS 376-2003. An extension featuring incremental enhancements and fixes is called Serial Attached SCSI 1.1 and is currently under development.

SAS was designed to leverage the cost economies of the SATA physical interface, cable, and connector designs while preserving the robust software and reliability of SCSI. SAS was designed as an extendable standard with future increases in speed and performance in mind. As with SATA, the serial interface is self-clocking, which allows data rates to be more easily pushed higher and higher. The main features of Serial Attached SCSI include

- 300MBps point-to-point connections with up to 1200MBps with future backward-compatible enhancements.
- Wide-port devices will allow multiple serial connections, multiplying the bandwidth available by the number of connections.
- SAS utilizes the robust and refined (20 years in development) SCSI protocol.
- SAS supports both 300MBps SAS and 150MBps SATA drives, enabling a motherboard or host adapter with SAS connectors to support both SAS and SATA drives.

The most important feature of SAS is that it will actually support two types of drives. SATA drives can be attached for low-cost storage, and true SAS drives can be attached for higher-performance systems. The SAS connector design enables both SAS and SATA drives to be plugged in; however, it is impossible to plug an SAS drive into a SATA interface. Because the SATA connector signals are a subset of SAS signals, SATA drives will operate on SAS host adapters. SAS drives, on the other hand, will not operate on SATA adapters. The SAS connectors are specially keyed to prevent plugging them into SATA host adapters.

SAS uses three protocols, each for transferring different types of data depending on which type of device is being accessed:

- *Serial SCSI Protocol (SSP)*. Sends SCSI commands to SAS devices
- *SCSI Management Protocol (SMP)*. Sends management information to expanders
- *SATA Tunneled Protocol (STP)*. Sends SATA commands to SATA devices

By including these protocols, SAS provides full compatibility with existing SCSI devices and applications software as well as SATA devices and software. Combined with the backward compatibility of SAS and SATA physical connections, this enables SAS to operate as a universal interconnection for both SAS and SATA devices. If SAS is onboard, a user could upgrade her system from SATA to SAS by either replacing the SATA drive with an SAS drive or by keeping the SATA drive and adding the SAS drive to the system and using both simultaneously. To further ensure compatibility, in January 2003, the SCSI Trade Association (STA) and the Serial ATA (SATA) II Working Group announced a partnership to enable system-level compatibility with SAS and SATA hard drives.

Serial Attached SCSI is designed for extremely high bandwidth. Data transfer rates start at 3Gbps (300Mbps) with a roadmap enabling increases up to 12Gbps (1200Mbps), which is nearly four times that of Ultra320 SCSI. Additionally, Serial Attached SCSI is a point-to-point connection that allows full bandwidth to each drive, rather than sharing it among multiple drives as with parallel SCSI. Devices can also use Wide-Port connections, meaning they can have multiple connections to a single device. The total bandwidth available in that case is multiplied by the total number of connections to the device.

Internal connections use cables up to 1 meter long; these are similar to SATA cables except for a modified connector key. External connections, on the other hand, use Infiniband-type cables supporting four physical connections, along with an adapter allowing four internal connections to be mated to the external cable via an open expansion slot. The device connector looks a lot like the connector on a SATA drive; however, it also features a key and optional secondary signals for Wide-Port device connections. The design of the host connector enables both SATA and SAS cables to be attached. The pinout of each connection uses seven pins, and the pinout is identical to SATA.

Figure 8.7 shows the icon used to identify SAS devices and connections compliant with the SAS standard.

Figure 8.7 Serial Attached SCSI (SAS) icon.

A key feature of SAS is expandability. Devices called *expanders* enable SAS to be scaled up to connect large numbers of drives. Expanders are essentially low-cost switches that enable up to 128 individual point-to-point connections to be made—a total of up to 16,384 SAS devices can be connected via multiple expanders to a single host. By contrast, parallel SCSI imposes a limit of 15 devices per SCSI chain and severely limits total cable length.

Although the SAS specification was released in October 2003, prototype SAS adapters and drives were first demonstrated by Seagate and HP in March 2003. Retail SAS products (including host adapters and drives) are expected to be available to the public in the second half of 2004. All the major disk drive manufacturers have announced plans to develop SAS disk drives, and SAS allows existing SATA drives to be used as well.

RAID Arrays

Most servers, especially at levels above the workgroup, use SCSI drives rather than ATA drives because of their superior performance. You can enhance performance and data reliability further by creating a drive array. RAID (redundant array of inexpensive/independent disks) technologies are used by both SCSI and ATA drives. Current SCSI-based RAID products primarily support Ultra320 and Ultra160 drives and are used in traditional servers and rack-mounted computers. For a complete description of RAID levels and terminologies, see Chapter 7, “The ATA/IDE Interface.”

Fibre Channel SCSI

Fibre Channel (FC) SCSI is a specification for a serial interface using a fibre channel physical and protocol characteristic, with a SCSI command set. It can achieve 200MBps or 400MBps over either fiber or coaxial cable of several kilometers in length. Fibre Channel is designed for long-distance connectivity (such as several kilometers) and connecting multiple systems, and it has become a popular choice for storage area networks (SANs) and server clusters. Fibre Channel SCSI complements, rather than replaces, Ultra160 and Ultra320 SCSI, which are designed for direct connection to servers.

200MBps versions of Fibre Channel SCSI use the gigabit interface connector (GBIC), whereas 400MBps versions use either the small form factor pluggable (SFP) connector for optical connections or the high-speed serial data connector (HSSDC) for copper cable (these connectors are shown later in this chapter, in Figures 8.13–8.15).

Because SAS and iSCSI will offer much the same performance and benefits of FC at a much lower cost, it is expected that SAS and iSCSI will replace FC in many high-end server applications.

iSCSI

Another variation on SCSI, iSCSI, combines the performance of SCSI drives with Ethernet networking up to gigabit speeds. Because iSCSI uses Ethernet to transport data between systems, iSCSI storage can be located anywhere an Ethernet network can reach, including Internet access. In addition, iSCSI storage enables secure remote storage for computers that could be hundreds of kilometers away. Because iSCSI data can be routed the same way any other type of Ethernet data can be routed, it enables data to be transported even when some connections between the server and the storage devices are unavailable.

Eventually, iSCSI is expected to replace Fibre Channel in uses such as network attached storage (NAS), SANs, and storage clusters. Similar to Fibre Channel, iSCSI cards can be purchased in both copper-wire and fiber-optic versions to match the Ethernet network already in use. The first iSCSI devices were produced by Adaptec and Cisco Systems in mid-2002.

SCSI Cables and Connectors

The SCSI standards are very specific when it comes to cables and connectors. The most common connectors specified in this standard are the 50-position unshielded pin header connector for internal SCSI connections and the 50-position shielded Centronics latch-style connectors for external connections. The shielded Centronics-style connector also is called Alternative 2 in the official specification. Passive or Active termination (Active is preferred) is specified for both single-ended and differential buses. The 50-conductor bus configuration is defined in the SCSI-2 standard as the A cable.

Older narrow (8-bit) SCSI adapters and external devices use a full-size Centronics-type connector. Figure 8.8 shows what the low-density, 50-pin SCSI connector looks like.

Figure 8.8 Low-density, 50-pin SCSI device connector.

The SCSI-2 revision added a high-density, 50-position, D-shell connector option for the A-cable connectors. This connector now is called Alternative 1. Figure 8.9 shows the 50-pin, high-density SCSI connector.

Figure 8.9 High-density, 50-pin SCSI device connector.

The Alternative 2 Centronics latch-style connector remains unchanged from SCSI-1. A 68-conductor B-cable specification was added to the SCSI-2 standard to provide for 16- and 32-bit data transfers; the connector, however, had to be used in parallel with an A cable. The industry did not widely accept the B-cable option, which has been dropped from the SCSI-3 standard.

To replace the ill-fated B cable, a new 68-conductor P cable was developed as part of the SCSI-3 specification. Shielded and unshielded high-density D-shell connectors are specified for both the A and P cables. The shielded high-density connectors use a squeeze-to-release latch rather than the wire latch used on the Centronics-style connectors. Active termination for single-ended buses is specified, providing a high level of signal integrity. Figure 8.10 shows the 68-pin, high-density SCSI connector.

Figure 8.10 High-density, 68-pin SCSI device connector.

Drive arrays normally use special SCSI drives with what is called an 80-pin Alternative-4 connector, which is capable of Wide SCSI and also includes power signals. Drives with the 80-pin connector are usually *hot-swappable*—they can be removed and installed with the power on—in drive arrays. The 80-pin Alt-4 connector is shown in Figure 8.11.

Figure 8.11 80-pin Alt-4 SCSI device connector.

Apple and some other nonstandard implementations from other vendors used a 25-pin cable and connector for SCSI devices. They did this by eliminating most of the grounds from the cable, which unfortunately results in a noisy, error-prone connection. These 25-pin connectors and cables are not compliant with any SCSI standard; you should avoid them if possible. The connector used in these cases was a standard female DB-25 connector, which looks exactly like a PC parallel port (printer) connector.

Unfortunately, you can damage equipment by plugging printers into DB-25 SCSI connectors or by plugging SCSI devices into DB-25 printer connectors. So, if you use this type of SCSI connection, be sure it is well marked because there is no way to tell DB-25 SCSI from DB-25 parallel printer connectors by looking at them. The nonstandard DB-25 SCSI connector is shown in Figure 8.12.

Again, I recommend avoiding making SCSI connections using this type of nonstandard cable or connector.

Fibre Channel SCSI devices running at 200MBps can connect to various types of devices, depending on the gigabit interface connector (GBIC) module installed in the host adapter. The module could use a subscriber connector (SC) for fiber-optic cable, a high-speed serial data connector (HSSDC) for

copper cable, or a DB-9 connector for copper cable. The GBIC module can be removed from the host adapter, as shown in Figure 8.13. 400MBps devices can connect to the HSSDC connector shown in Figure 8.14 if copper wire is used, or they can connect to the modular small form factor pluggable (SFP) connector shown in Figure 8.15 if fiber-optic cable is used.

Figure 8.12 Nonstandard DB-25 SCSI device connector.

Parallel SCSI Cable and Connector Pinouts

The following section details the pinouts of the various SCSI cables and connectors. Two electrically different versions of SCSI exist: single-ended and differential. These two versions are electrically incompatible and must not be interconnected; otherwise, damage will result. Fortunately, very few differential SCSI applications are available in the PC industry, so you will rarely (if ever) encounter one. Within each electrical type (single-ended or differential), there are basically two SCSI cable types:

- A cable (Standard 8-bit SCSI)
- P cable (16-bit Wide SCSI)

The 50-pin A-cable is used in most SCSI-1 and SCSI-2 installations and is the most common cable you will encounter. SCSI-2 Wide (16-bit) applications use a P cable instead, which has 68 pins. You can intermix standard and Wide SCSI devices on a single SCSI bus by interconnecting A and P cables with special adapters. SCSI-3 applications that are 32-bit wide would have used an additional Q cable, but this was finally dropped from the SCSI-3 standard after it was never implemented in actual products.

SCSI cables are specially shielded with the most important high-speed signals carried in the center of the cable and less important, slower ones in two additional layers around the perimeter. A typical SCSI cable is constructed as shown in Figure 8.16.

Figure 8.16 Cross section of a typical SCSI cable.

This specialized construction is what makes SCSI cables so expensive, as well as thicker than other types of cables. Note this specialized construction is necessary only for external SCSI cables. Cables used to connect devices inside a shielded enclosure (such as inside a PC) can use much less expensive ribbon cables.

The A cables can have pin-header-type (internal) connectors or external shielded connectors, each with a different pinout. The P cables feature the same connector pinout on either internal or external cable connections.

Single-Ended SCSI Cables and Connectors

The single-ended electrical interface is the most popular type for PC systems. Tables 8.3 and 8.4 show all the possible single-ended cable and connector pinouts. The A cable is available in both internal unshielded and external shielded configurations. A hyphen preceding a signal name indicates the signal is Active Low. The RESERVED lines have continuity from one end of the SCSI bus to the other. In an A cable bus, the RESERVED lines should be left open in SCSI devices (but may be connected to ground) and are connected to ground in the bus terminator assemblies. In the P and Q cables, the RESERVED lines are left open in SCSI devices and the bus terminator assemblies.

IBM used the SCSI interface in virtually all PS/2 systems introduced after 1990. These systems use a Micro-Channel SCSI adapter or have the SCSI Host Adapter built in to the motherboard. In either case, IBM's SCSI interface uses a special 60-pin, mini-Centronics-type external shielded connector that is unique in the industry.

A special IBM cable is required to adapt this connector to the standard 50-pin Centronics-style connector used on most external SCSI devices. The pinout of the IBM 60-pin, mini-Centronics-style external shielded connector is shown in Table 8.5. Notice that although the pin arrangement is unique, the pin-number-to-signal designations correspond with the standard unshielded internal pin header type of SCSI connector. IBM has discontinued this design in all its systems because after the PS/2 series, all have used conventional SCSI connectors.

The P cable (single-ended) and connectors are used in 16-bit Wide SCSI-2 applications (see Table 8.6 for the pinout).

High-Voltage Differential SCSI Signals

High Voltage Differential SCSI is not normally used in a PC environment but is very popular with minicomputer installations because of the very long bus lengths that are allowed. This has changed with the introduction of Low Voltage Differential signaling for SCSI, bringing the benefits of differential signaling to lower-end and more mainstream SCSI products.

Differential signaling uses drivers on both the initiator and target ends of the bus and makes each signal work in a push/pull arrangement, rather than a signal/ground arrangement as with standard single-ended SCSI. This enables much greater cable lengths and eliminates some of the problems with termination.

Almost all PC peripherals produced since the beginning of SCSI have been SE types. These are incompatible with HVD devices, although HVD devices can be used on an SE bus with appropriate (and expensive) adapters. The LVD devices, on the other hand, can be used on an SE bus if they are multi-mode devices, in which case they switch into SE mode. If all devices—including the host adapter—support LVD mode, all the devices switch into that mode and much longer cable lengths and higher speeds can be used. The normal limit for an SE SCSI bus is 1.53 meters maximum (about 5–10 feet) and up to 20MHz. If run in LVD mode, the maximum bus length goes up to 12 meters (about 40 feet) and speeds can go up to 80MHz. HVD SCSI supports bus lengths of up to 25 meters (about 80 feet).

Note that almost all modern SCSI hard disks are Ultra2 or Ultra3 devices, which means by default they are also LVD or multimode LVD/SE devices.

Expanders

SCSI expanders separate a SCSI bus into more than one physical segment, each of which can have the full SCSI cable length for that type of signaling. They provide a complete regeneration of the SCSI bus signals, allowing greater cable lengths and incompatible devices to essentially share the same bus. An expander also can be used to separate incompatible parts of a SCSI bus—for example, to keep SE and HVD SCSI devices in separate domains.

Expanders are transparent to the software and firmware on the bus, and they don't take up a device ID. They are usually capable of providing termination if located at the end of a bus segment, or they can have termination disabled if they are in the middle of a bus segment.

Because of their expense, expanders are not normally used except in extreme situations in which no other alternative remains. In most cases, it is better to stick within the recommended cable and bus length requirements and keep incompatible devices, such as HVD devices, off a standard SE or LVD bus.

Termination

Because a SCSI bus carries high-speed electrical signals, it can be affected by electrical reflections that might occur within any transmission line system. A terminator is designed to minimize the potential for reflections or noise on the bus, as well as to create the proper load for the bus transmitter circuits. Terminators are placed at each end of the bus to minimize these problems.

Despite the simple rules that only two terminators must be on the bus and they must be at each end, I still see improper termination as the most common cause of problems in SCSI installations.

Several types of SCSI terminators are available, dependent on the bus signaling and speed requirements:

- Passive
- Active (also called Alternative 2)
- Forced Perfect Termination (FPT): FPT-3, FPT-18, and FPT-27
- HVD termination
- LVD termination

The first three are used on single-ended SCSI buses only. Passive terminators use a passive network of 220-ohm and 330-ohm resistors to control bus termination. They should be used only in narrow

(8-bit) SCSI buses running at 5MHz. Passive terminators allow signal fluctuations in relation to the terminator power signal on the bus. Usually, passive terminating resistors suffice over short distances, such as 2 or 3 feet, but for longer distances or higher speeds, active termination is a real advantage. Active termination is required with Fast SCSI.

Passive terminators can be plugged in to the unused SCSI port or be built in to many low-speed SCSI devices such as scanners, optical drives, and removable-media drives. On such devices, you can activate or deactivate built-in passive termination with jumper blocks, a toggle switch, or some other form of selector switch—depending on the device.

Active terminators use built-in voltage regulator ICs combined with 110-ohm resistors. An active terminator actually has one or more voltage regulators to produce the termination voltage, rather than resistor voltage dividers alone. This arrangement helps ensure that the SCSI signals always are terminated to the correct voltage level. Active terminators often have some type of LED indicating the termination activity. The SCSI-2 specification recommends active termination on both ends of the bus and requires active termination whenever Fast or Wide SCSI devices are used. Most high-performance host adapters have an “auto-termination” feature, so if it is the end of a chain, it terminates itself.

A variation on active termination is available for single-ended buses: *forced perfect termination (FPT)*. Forced perfect termination is an even better form of active termination in which diode clamps are added to eliminate signal overshoot and undershoot. The trick is that instead of clamping to +5 and ground, these terminators clamp to the output of two regulated voltages. This arrangement enables the clamping diodes to eliminate signal overshoot and undershoot, especially at higher signaling speeds and over longer distances. Forced perfect termination is technically not found in the SCSI specifications but is the superior type of termination for single-ended applications that experience high levels of electrical noise.

FPT terminators are available in several versions. FPT-3 and FPT-18 versions are available for 8-bit standard SCSI, whereas the FPT-27 is available for 16-bit (Wide) SCSI. The FPT-3 version forces perfect the three most highly active SCSI signals on the 8-bit SCSI bus, whereas the FPT-18 forces perfect all the SCSI signals on the 8-bit bus except grounds. FPT-27 also forces perfect all the 16-bit Wide SCSI signals except grounds.

HVD buses require HVD terminators, constructed using a passive network of 330-ohm/150-ohm/330-ohm resistors. The only choice is that the terminator matches your cable or device connection.

The same is true for Low Voltage Differential buses. They require LVD terminators for the bus to function properly. One twist is that special LVD/SE (active) multimode terminators are available. These function as LVD types on an LVD bus and as active types on an SE bus. Note that if any SE devices are on the bus, it functions in SE mode and never uses LVD mode, severely limiting bus length and performance. If any SE-only terminators or SE devices are on the bus, the bus defaults into SE mode.

Schematic diagrams of passive, active, and FPT terminators can be found in *Upgrading and Repairing PCs, 15th Edition*, which is included on the disc packaged with this book.

- ▶▶ See “SCSI Drive Configuration,” p. 610.

Note

Several companies make high-quality terminators for the SCSI bus, including East/West Manufacturing Enterprises, Inc. (formerly Aeronics) and the Data/Mate division of Methode. Both companies make a variety of terminators. EVE is well noted for some unique FPT versions that are especially suited to problem configurations that require longer cable runs or higher signal integrity. One of the best investments you can make in any SCSI installation is in high-quality cables and terminators. Contact information for both of these companies is in the Vendor List on the accompanying disc.

Special terminators also are required for LVD and HVD SCSI, so if you are using those interfaces, be sure your terminators are compatible.

With LVD or HVD buses, you don't have much choice in terminator types, but for single-ended buses, you have at least three choices.

Tip

The best rule for terminators, as well as for cables, is to get the best you can. My recommendation is to *never* use passive terminators; instead, use active or, if you want the best in reliability and integrity, use only FPT.

SCSI Drive Configuration

SCSI drives are not too difficult to configure, but they are more complicated than ATA drives. The SCSI standard controls the way the drives must be set up. You need to set up two or three items when you configure a SCSI drive:

- SCSI ID setting (0–7 or 0–15)
- Terminating resistors

The SCSI ID setting is very simple. Up to 7 SCSI devices can be used on a single narrow SCSI bus or up to 15 devices on a Wide SCSI bus, and each device must have a unique SCSI ID address. There are 8 or 16 addresses respectively, and the host adapter takes 1 address, so the rest are free for up to 7 or 15 SCSI peripherals. Most SCSI host adapters are factory-set to ID 7 or 15, which is the highest-priority ID. All other devices must have unique IDs that do not conflict with one another. Some host adapters boot only from a hard disk set to a specific ID. Older Adaptec host adapters required the boot hard disk to be ID 0; newer ones can boot from any ID.

Setting the ID usually involves changing jumpers on the drive. If the drive is installed in an external chassis, the chassis might have an ID selector switch that is accessible at the rear. This selector makes ID selection a simple matter of pressing a button or rotating a wheel until the desired ID number appears. If no external selector is present, you must open the external device chassis and set the ID via the jumpers on the drive.

Three jumpers are required to set the SCSI ID; the particular ID selected actually is derived from the binary representation of the jumpers themselves. One example is setting all three ID jumpers to off, resulting in a binary number of 000b, which translates to an ID of 0. A binary setting of 001b equals ID 1, 010b equals 2, 011b equals 3, and so on. (Notice that as I list these values, I append a lowercase b to indicate binary numbers.)

Unfortunately, the jumpers can appear either forward or backward on the drive, depending on how the manufacturer set them up. To keep things simple, I have recorded all the various ID jumper settings in the following tables. Table 8.7 shows the settings for drives that order the jumpers with the most significant bit (MSB) to the left; Table 8.8 shows the settings for drives that have the jumpers ordered so that the MSB is to the right.

Table 8.7 SCSI ID Jumper Settings with the Most Significant Bit to the Left

SCSI	ID	Jumper	Settings
0	0	0	0
1	0	0	1
2	0	1	0

SCSI termination is very simple. Termination is required at both ends of the bus; there are no exceptions. If the host adapter is at one end of the bus, it must have termination enabled. If the host adapter is in the middle of the bus, and if both internal and external bus links are present, the host adapter must have its termination disabled and the devices at each end of the bus must have terminators installed. Unfortunately, the majority of problems I see with SCSI installations are the result of improper termination.

Figure 8.17 shows a representation of a SCSI bus with several devices attached. In this case, the host adapter is at one end of the bus and a CD-ROM drive is at the other. For the bus to work properly, those devices must be terminated, whereas the others do not have to be.

Figure 8.17 SCSI bus daisy-chain connections; the first and last devices must be terminated.

When installing an external SCSI device, you usually find the device in a storage enclosure with both input and output SCSI connectors, so you can use the device in a daisy-chain. If the enclosure is at the end of the SCSI bus, an external terminator module most likely will have to be plugged into the second (outgoing) SCSI port to provide proper termination at that end of the bus (see Figure 8.18).

Figure 8.18 External SCSI device terminator.

External terminator modules are available in a variety of connector configurations, including pass-through designs, which are necessary if only one port is available. Pass-through terminators also are commonly used in internal installations in which the device does not have built-in terminating resistors. Many hard drives use pass-through terminators for internal installations to save space on the logic-board assembly (see Figure 8.19).

Figure 8.19 Internal pin-header connector pass-through SCSI terminator.

The pass-through models are required when a device is at the end of the bus and only one SCSI connector is available.

Other configuration items on a SCSI drive can be set via jumpers. Following are several of the most common additional settings:

- Start on Command (delayed start)
- Terminator Power
- SCSI Parity
- Synchronous Negotiation

These configuration items are described in the following sections.

Start on Command (Delayed Start)

If you have multiple drives installed in a system, it is wise to set them up so that not all the drives start to spin immediately when the system is powered on. A hard disk drive can consume three or four times more power during the first few seconds after power-on than during normal operation. The motor requires this additional power to get the platters spinning quickly. If several drives are drawing all this power at the same time, the power supply can be overloaded, which can cause the system to hang or have intermittent startup problems.

Nearly all SCSI drives provide a way to delay drive spinning so this problem does not occur. When most SCSI host adapters initialize the SCSI bus, they send out a command called Start Unit to each of the ID addresses in succession. By setting a jumper on the hard disk, you can prevent the disk from spinning until it receives the Start Unit command from the host adapter. Because the host adapter sends this command to all the ID addresses in succession, from the highest-priority address (ID 7) to the lowest (ID 0), the higher-priority drives can be made to start first, with each lower-priority drive spinning up sequentially. Because some host adapters do not send the Start Unit command, some drives might simply delay spin-up for a fixed number of seconds rather than wait for a command that never will arrive.

If drives are installed in external chassis with separate power supplies, you need not implement the delayed-start function. This function is best applied to internal drives that must be run from the same power supply that runs the system. For internal installations, I recommend setting Start on Command (delayed start) even if you have only one SCSI drive; this setting eases the load on the power supply by spinning the drive up after the rest of the system has full power. This method is especially good for portable systems and other systems in which the power supply is limited.

SCSI Parity

SCSI Parity is a limited form of error checking that helps ensure that all data transfers are reliable. Virtually all host adapters support SCSI parity checking, so this option should be enabled on every device. The only reason it exists as an option is that some older host adapters do not work with SCSI parity, so the parity must be turned off.

Terminator Power

The terminators at each end of the SCSI bus require power from at least one device on the bus. In most cases, the host adapter supplies this terminator power; in some cases, however, it does not. For example, parallel port SCSI host adapters typically do not supply terminator power. It is not a problem if more than one device supplies terminator power because each source is diode-protected. For simplicity's sake, many people often configure all devices to supply terminator power. If no device supplies terminator power, the bus is not terminated correctly and will not function properly.

SCSI Synchronous Negotiation

The SCSI bus can run in two modes: asynchronous (the default) and synchronous. The bus actually switches modes during transfers through a protocol called *synchronous negotiation*. Before data is transferred across the SCSI bus, the sending device (called the *initiator*) and the receiving device (called the *target*) negotiate how the transfer will take place. If both devices support synchronous transfers, they will discover this fact through the negotiation and the transfer will take place at the faster synchronous rate.

Unfortunately, some older devices do not respond to a request for synchronous transfer and can actually be disabled when such a request is made. For this reason, both host adapters and devices that support synchronous negotiation often have a jumper that can be used to disable this negotiation so it can work with older devices. By default, all devices today should support synchronous negotiation, and this function should be enabled.

Plug and Play SCSI

Plug and Play (PnP) SCSI originally was released in April 1994. This specification enables SCSI device manufacturers to build PnP peripherals that are automatically configured when used with a PnP operating system. This enables you to easily connect or reconfigure external peripherals, such as hard disk drives, backup tapes, and CD-ROMs.

To connect SCSI peripherals to the host PC, the specification requires a PnP SCSI host adapter. PnP add-in cards enable a PnP operating system to automatically configure software device drivers and system resources for the host bus interface.

The PnP SCSI specification includes these technical highlights:

- A single cable connector configuration
- Automatic termination of the SCSI bus
- SCAM (SCSI Configured AutoMagically*) automatic ID assignment
- Full backward compatibility of PnP SCSI devices with the installed base of SCSI systems

Note

"AutoMagically" is not a misspelling. The word is actually used in the official name for the original specification, which the X3T9.2 committee designated X3T9.2/93-109r5.

This helps make SCSI easier to use for the average user.

Each SCSI peripheral you add to your SCSI bus (other than hard disk drives) requires an external driver to make the device work. Hard disks are the exception; driver support for them typically is provided as part of the SCSI host adapter BIOS. These external drivers are specific not only to a particular device, but also to the host adapter.

Recently, two types of standard host adapter interface drivers have become popular, greatly reducing this problem. By having a standard host adapter driver to write to, peripheral makers can more quickly create new drivers that support their devices and then talk to the universal host adapter driver. This arrangement eliminates dependence on one particular type of host adapter. These primary or universal drivers link the host adapter and operating system.

The Advanced SCSI Programming Interface (ASPI) currently is the most popular universal driver, with most peripheral makers writing their drivers to talk to ASPI. The *A* in ASPI used to stand for Adaptec, the company that introduced it, but other SCSI device vendors have licensed the right to use ASPI with their products. DOS does not support ASPI directly, but it does when the ASPI driver is loaded. Windows 9x/Me, Windows NT/2000/XP, and OS/2 2.1 and later versions provide automatic ASPI support for several SCSI host adapters.

Future Domain (now merged into Adaptec) and NCR created another interface driver called the Common Access Method (CAM). CAM is an ANSI-approved protocol that enables a single driver to control several host adapters. CAM is widely used by Linux and Unix operating systems for SCSI device interfacing using open-source drivers.

SCSI Configuration Troubleshooting

When you are installing a chain of devices on a single SCSI bus, the installation can get complicated very quickly. If you have a problem during installation, check these items first:

- Make sure you are using the latest BIOS from your motherboard manufacturer. Some have had problems with their PCI bus slots not working properly.
- Make sure that all SCSI devices attached to the bus are powered on.
- Make sure all SCSI cables and power cables are properly connected. Try removing and reseating all the connectors to be sure.
- Check that the host adapter and each device on each SCSI bus channel have a unique SCSI ID setting.
- Make sure the SCSI bus is terminated properly. Remember there should be only two terminators on the bus, one at each end. All other terminations should be removed or disabled.
- If your system BIOS setup has settings for controlling PCI bus configuration, make sure the PCI slot containing the SCSI adapter is configured for an available interrupt. If your system is Plug and Play, use the Windows Device Manager to check and possibly change the resource configuration.
- Make sure the host adapter is installed in a PCI slot that supports bus mastering. Some older motherboards (mainly old 486 processor boards) did not allow bus mastering to work in all PCI slots. Check your motherboard documentation and try moving the SCSI host adapter to a different PCI slot. This should not be an issue on any Pentium or newer boards.
- If you have a SCSI hard disk installed and your system will not boot from the SCSI drive, there can be several causes for this problem. Note that if both SCSI and non-SCSI disk drives are installed in your computer, in almost all cases the non-SCSI drive is the boot device. If you want to boot from a SCSI drive, check the boot sequence configuration in your BIOS. If your system allows it, change the boot sequence to allow SCSI devices to boot first. If not, try removing the non-SCSI drives from your system.

If the system has only SCSI disk drives and still won't boot, check the following items:

- Be sure your computer's BIOS Setup drive configuration is set to No Drives Installed. The PC BIOS supports only ATA (also called IDE) drives; by setting this to no drives, the system will then try to boot from another device, such as SCSI.
- Make sure the drive is partitioned and that a primary partition exists. Use FDISK from DOS or Windows 9x/Me or the Windows Disk Management tool in Windows 2000/XP to check.

- Make sure the boot partition of the boot hard disk is set to active. This can be checked or changed with the FDISK or Disk Management program.
- Finally as a last resort, you can try backing up all data on the SCSI hard disk and then perform a low-level format with the Format utility built in to or included with the host adapter.

Here are some tips for getting your setup to function quickly and efficiently:

- *Start by adding one device at a time.* Rather than plugging numerous peripherals into a single SCSI card and then trying to configure them at the same time, start by installing the host adapter and a single hard disk. Then, you can continue installing devices one at a time, checking to ensure that everything works before moving on.
- *Keep good documentation.* When you add a SCSI peripheral, write down the SCSI ID address and any other switch and jumper settings, such as SCSI Parity, Terminator Power, and Delayed or Remote Start. For the host adapter, record the BIOS addresses, Interrupt, DMA channel, and I/O Port addresses used by the adapter, and any other jumper or configuration settings (such as termination) that might be important to know later. If you use the System Configuration Template provided in Chapter 4, "Motherboards and Buses," to record information about your system, attach the SCSI information sheet to the System Configuration Template to provide more complete information about your system.
- *Use proper termination.* Each end of the bus must be terminated, preferably with active or forced perfect terminators. If you are using any Fast SCSI-2 device, you must use active terminators rather than the cheaper passive types. Even with standard (slow) SCSI devices, active termination is highly recommended. If you have only internal or external devices on the bus, the host adapter and last device on the chain should be terminated. If you have external and internal devices on the chain, you generally will terminate the first and last of these devices, but not the SCSI host adapter (which is in the middle of the bus).
- *Use high-quality shielded SCSI cables.* Be sure your cable connectors match your devices. Use high-quality shielded cables, and observe the SCSI bus-length limitations. Use cables designed for SCSI use, and, if possible, stick to the same brand of cable throughout a single SCSI bus. Different brands of cables have different impedance values; this situation sometimes causes problems, especially in long or high-speed SCSI implementations.

Following these simple tips will help minimize problems and leave you with a trouble-free SCSI installation.

SCSI Versus ATA Performance: Advantages and Limitations

Modern operating systems are multitasking, and SCSI devices (with all their additional controller circuitry) function independently of one another, unlike ATA. Therefore, data can be read and written to any of the SCSI devices simultaneously. This enables smoother multitasking and increased overall data throughput. The most advanced operating systems, such as Windows NT/2000/XP, even allow drive striping. A *striped drive set* is two or more drives that appear to the user as one drive. Data is split between the drives equally, again increasing overall throughput. Increased fault tolerance and performance are readily implemented and supported in SCSI drive arrays.

Ultra4 (Ultra320) SCSI drives offer advantages when compared with ATA. Ultra320 SCSI is 140% faster than UltraATA/133, which has a maximum data rate of 133MBps. Ultra320 SCSI also fully supports multitasking and can significantly improve system performance in workstations and servers running Windows NT, 2000, or XP. ATA limits cable lengths to 18 inches, effectively eliminating the ability to connect remote or external devices, whereas Ultra4 (Ultra320) SCSI allows external connections of up to 12 meters or more in length. Also note that ATA allows only 2 devices per cable, whereas Ultra320 SCSI can connect up to 15 devices. Finally, the domain validation feature of Ultra320 SCSI enables noise and other problems on the bus to be handled properly, whereas with ATA, if a problem occurs with the connection (and that is more common at the UltraATA/100 and 133 speeds), the ATA drives simply fail.

ATA drives have much less command overhead for a given sector transfer than do SCSI drives. In addition to the drive-to-controller command overhead that both ATA and SCSI must perform, a SCSI transfer involves negotiating for the SCSI bus; selecting the target drive; requesting data; terminating the transfer over the bus; and finally converting the logical data addresses to the required cylinder, head, and sector addresses. This arrangement gives ATA an advantage in sequential transfers handled by a single-tasking operating system. In a multitasking system that can take advantage of the extra intelligence of the SCSI bus, SCSI can have the performance advantage.

SCSI drives offer significant architectural advantages over ATA and other drives. Because each SCSI drive has its own embedded disk controller that can function independently from the system CPU, the computer can issue simultaneous commands to every drive in the system. Each drive can store these commands in a queue and then perform the commands simultaneously with other drives in the system. The data could be fully buffered on the drive and transferred at high speed over the shared SCSI bus when a time slot was available.

Although ATA drives also have their own controllers, they do not normally operate simultaneously, and command queuing is not supported. In effect, the dual controllers in a dual-drive ATA installation work one at a time so as not to step on each other.

ATA does not fully support overlapped, multitasked I/O, which enables a device to take on multiple commands and work on them independently and in an order different from which they were received, releasing the bus for other devices to use. The ATA bus instead waits for each command to be completed before the next one can be sent.

As you can see, SCSI has some advantages over ATA, especially where expansion is concerned, and also with regard to support for multitasking operating systems. Unfortunately, it also costs more to implement.

One final advantage of SCSI is in the portability of external devices. It is easy to take an external SCSI CD-ROM, tape drive, scanner, or even a hard disk and quickly move it to another system. This allows moving peripherals more freely between systems and can be a bonus if you have several systems with which you might want to share a number of peripherals. Installing a new external SCSI device on a system is easier because you normally will not need to open it up.

Of course, moving an external SCSI device from one system to another is not nearly as easy as it would be with a USB or FireWire (IEEE-1394) device, which is one reason the latter two (especially USB) are catching on in the mainstream market. USB and FireWire devices are Plug and Play and hot-swappable, allowing you to attach or remove the device with the power on. Plus, no device ID or other configuration is necessary. Narrow and Wide SCSI devices must normally be attached with the device and system power turned off; they also must be configured to use a unique device ID and have proper termination set for existing and new devices.

Recommended SCSI Host Adapters, Cables, and Terminators

For SCSI host adapters, I usually recommend Adaptec. Its adapters work well and come with the necessary formatting and operating software. Windows 9x/Me, Windows NT/2000/XP, and even OS/2 have built-in support for Adaptec SCSI adapters. This support is a consideration in many cases because it frees you from having to deal with additional drivers.

Standard or Fast SCSI is adequately supported by the now-obsolete ISA bus, but if you are going to install a Wide SCSI bus—or especially an Ultra, Ultra2, or Ultra160/320 bus—you should consider a PCI host adapter. This is because ISA supports a maximum transfer speed of only about 8MBps, whereas a Fast-Wide SCSI bus runs up to 20MBps. Even faster versions such as Ultra3 (Ultra160) or

Ultra4 (Ultra320) SCSI run up to a blazing 320MBps! In virtually every case, a local bus SCSI adapter would be a PCI bus version, which is supported in all current PC systems. For maximum performance, you should use a 64-bit-wide, 66MHz version of the PCI slot if your host adapter supports this version of the PCI standard.

- ◀◀ See "The ISA Bus," p. 350.
- ◀◀ See "The PCI Bus," p. 358.

Like all modern PCI adapters, plug and play is supported, meaning virtually all functions on the card can be configured and set through software. No more digging through manuals or looking for interrupt, DMA, I/O port, and other jumper settings—everything is controlled by software and saved in a flash memory module on the card. Following are some features found on recent SCSI cards:

- Complete configuration utility built in to the adapter's ROM
- Software-configurable IRQ, ROM addresses, DMA, I/O port addresses, SCSI parity, SCSI ID, and other settings
- Software-selectable automatic termination (no resistors to pull out!)
- Enhanced BIOS support for up to 15 drives
- No drivers required for more than two hard disks
- Drive spin-up on a per-drive basis available
- Boots from any SCSI ID

Adaptec has full PnP support on all its SCSI adapters. These adapters either are automatically configured in any PC that supports the PnP specification or can be configured manually through supplied software in non-PnP systems. The PnP SCSI adapters are highly recommended because they can be configured without opening up the PC! All functions are set by software, and there are no jumpers or switches to attend to. Most peripheral manufacturers write drivers for Adaptec's cards first, so you will not have many compatibility or driver-support problems with any Adaptec card.

For SCSI cables, I recommend CS Electronics (<http://www.scsi-cables.com>), which can supply or custom manufacture virtually any SCSI cable or adapter. It can also supply a wide range of terminators, as can a company called East/West Manufacturing Enterprises, Inc. (formerly Aeronics), which is also worth a look. Visit its Web site at <http://www.ewme.com>.

CHAPTER 9

Magnetic Storage Principles

Magnetic Storage

Permanent or semipermanent computer data storage works by either optical or magnetic principles—or, in some cases, a combination of the two. In the case of magnetic storage, a stream of binary computer data bits (0s and 1s) is stored by magnetizing tiny pieces of metal embedded on the surface of a disk or tape in a pattern that represents the data. Later, this magnetic pattern can be read and converted back into the exact same stream of bits you started with. This is the principle of magnetic storage and the subject of this chapter.

Magnetic storage is often difficult for people to understand because magnetic fields can't be seen by the human eye. This chapter explains the principles, concepts, and techniques behind modern computer magnetic storage, enabling you to understand what happens behind the scenes. This information is designed for those who have an insatiable curiosity about how these things work; it is not absolutely necessary to know this to use a PC or perform routine troubleshooting, maintenance, or upgrades. Because the data I store on my hard drives, tape drives, floppy drives, and other magnetic storage devices happens to be far more important to me than the devices themselves, knowing how my data is handled makes me feel much more comfortable with the system in general. Having an understanding of the underlying technology does help when it comes to dealing with problems that might arise.

This chapter covers magnetic storage principles and technology and can be considered an introduction to several other chapters in the book, including the following:

- Chapter 10, “Hard Disk Storage”
- Chapter 11, “Floppy Disk Storage”
- Chapter 12, “High-Capacity Removable Storage”
- Chapter 13, “Optical Storage”
- Chapter 14, “Physical Drive Installation and Configuration”

Consult these chapters for more specific information on various types of magnetic and optical storage, as well as drive installation and configuration.

History of Magnetic Storage

Before there was magnetic storage for computers, the primary storage medium was punch cards (paper cards with holes punched in to indicate character or binary data), originally invented by Herman Hollerith for use in the 1890 Census. What amazes me is that I missed contact with punch cards by about a year; the college I went to discontinued using them during my freshman year, before I was able to take any computer-related courses. I have to believe that this was more a reflection on their budget and lack of focus on current technology at the time (in 1979, there really weren't many punch-card readers being used in the field) than it is on my age! Although long obsolete in computer use, punch cards in various forms are still used in older voting equipment.

The history of magnetic storage dates back to June 1949, when a group of IBM engineers and scientists began working on a new storage device. What they were working on was the first magnetic storage device for computers, and it revolutionized the industry. On May 21, 1952, IBM announced the IBM 726 Tape Unit with the IBM701 Defense Calculator, marking the transition from punched-card calculators to electronic computers.

Four years later, on September 13, 1956, a small team of IBM engineers in San Jose, California, introduced the first computer disk storage system as part of the 305 RAMAC (Random Access Method of Accounting and Control) computer.

The 305 RAMAC drive could store 5 million characters (that's right, only 5MB!) of data on 50 disks, each a whopping 24" in diameter. Unlike tape drives, RAMAC's recording heads could go directly to any location on a disk surface without reading all the information in between. This random accessibility had a profound effect on computer performance at the time, enabling data to be stored and retrieved significantly faster than if it were on tape.

From these beginnings, the magnetic storage industry has progressed such that today you can store 75GB or more on tiny 3 1/2" drives that fit into a single computer drive bay.

IBM's contributions to the history and development of magnetic storage are incredible; in fact, most have either come directly from IBM or as a result of IBM research. Not only did IBM invent computer magnetic tape storage as well as the hard disk drive, but it also invented the floppy drive. The same San Jose facility where the hard drive was created introduced the first floppy drive, then using 8" diameter floppy disks, in 1971. The team that developed the drive was led by Alan Shugart, a now legendary figure in computer storage.

Since then, IBM has pioneered advanced magnetic data encoding schemes, such as Modified Frequency Modulation (MFM) and Run Length Limited (RLL); drive head designs, such as Thin Film, magneto-resistive (MR), and giant magneto-resistive (GMR) heads; and drive technologies, such as Partial Response Maximum Likelihood (PRML), No-ID recording, and Self-Monitoring Analysis and Reporting Technology (S.M.A.R.T.). Today, the combined hard disk drive operations of IBM and Hitachi (called Hitachi Global Storage Technology) is arguably the leader in developing and implementing new drive technology and is second in sales only to Seagate Technology in PC hard drives.

How Magnetic Fields Are Used to Store Data

All magnetic storage devices read and write data by using electromagnetism. This basic principle of physics states that as an electric current flows through a conductor (wire), a magnetic field is generated around the conductor (see Figure 9.1). Note that electrons actually flow from negative to positive as shown in the figure, although we normally think of current flowing in the other direction.

Figure 9.1 A magnetic field is generated around a wire when current is passed through it.

Electromagnetism was discovered in 1819 by Danish physicist Hans Christian Oersted, when he found that a compass needle would deflect away from pointing north when brought near a wire conducting an electric current. When the current was shut off, the compass needle resumed its alignment with the Earth's magnetic field and again pointed north.

The magnetic field generated by a wire conductor can exert an influence on magnetic material in the field. When the direction of the flow of electric current or polarity is reversed, the magnetic field's polarity also is reversed. For example, an electric motor uses electromagnetism to exert pushing and pulling forces on magnets attached to a rotating shaft.

Another effect of electromagnetism was discovered by Michael Faraday in 1831. He found that if a conductor is passed through a moving magnetic field, an electrical current is generated. As the polarity of the magnetic field changes, so does the direction of the electric current's flow (see Figure 9.2).

Figure 9.2 Current is induced in a wire when passed through a magnetic field.

For example, an alternator, which is a type of electrical generator used in automobiles, operates by rotating electromagnets on a shaft past coils of stationary wire conductors, which consequently generates large amounts of electrical current in those conductors. Because electromagnetism works two ways, a motor can become a generator and vice versa. When applied to magnetic storage devices, this two-way operation of electromagnetism makes recording data on a disk and reading that data back later possible. When recording, the head changes electrical impulses to magnetic fields, and when reading, the head changes magnetic fields back into electrical impulses.

The read/write heads in a magnetic storage device are U-shaped pieces of conductive material, with the ends of the U situated directly above (or next to) the surface of the actual data storage medium. The U-shaped head is wrapped with coils or windings of conductive wire, through which an electric current can flow (see Figure 9.3). When the drive logic passes a current through these coils, it generates a magnetic field in the drive head. Reversing the polarity of the electric current causes the polarity of the generated field to change also. In essence, the heads are electromagnets whose voltage can be switched in polarity very quickly.

Figure 9.3 A magnetic read/write head.

The disk or tape that constitutes the actual storage medium consists of some form of substrate material (such as Mylar for floppy disks or aluminum or glass for hard disks) on which a layer of magnetizable material has been deposited. This material usually is a form of iron oxide with various other elements added. Each of the individual magnetic particles on the storage medium has its own magnetic field. When the medium is blank, the polarities of those magnetic fields are normally in a state of random disarray. Because the fields of the individual particles point in random directions, each tiny magnetic field is canceled out by one that points in the opposite direction; the cumulative effect of this is a surface with no observable field polarity. With many randomly oriented fields, the net effect is no observable unified field or polarity.

When a drive's read/write head generates a magnetic field, the field jumps the gap between the ends of the U shape. Because a magnetic field passes through a conductor much more easily than through the air, the field bends outward from the gap in the head and actually uses the adjacent storage medium as the path of least resistance to the other side of the gap. As the field passes through the medium directly under the gap, it polarizes the magnetic particles it passes through so they are aligned with the field. The field's polarity or direction—and, therefore, the polarity or direction of the field induced in the magnetic medium—is based on the direction of the flow of electric current through the coils. A change in the direction of the current flow produces a change in the direction of the magnetic field. During the development of magnetic storage, the distance between the read/write head and the media has decreased dramatically. This enables the gap to be smaller and also makes the size of the recorded magnetic domain smaller. The smaller the recorded magnetic domain, the higher the density of data that can be stored on the drive.

When the magnetic field passes through the medium, the particles in the area below the head gap are aligned in the same direction as the field emanating from the gap. When the individual magnetic domains of the particles are in alignment, they no longer cancel one another out, and an observable magnetic field exists in that region of the medium. This local field is generated by the many magnetic particles that now are operating as a team to produce a detectable cumulative field with a unified direction.

The term *flux* describes a magnetic field that has a specific direction or polarity. As the surface of the medium moves under the drive head, the head can generate what is called a *magnetic flux* of a given polarity over a specific region of the medium. When the flow of electric current through the coils in the head is reversed, so is the magnetic field polarity or flux in the head gap. This flux reversal in the head causes the polarity of the magnetized particles on the disk medium to reverse.

The flux reversal or flux transition is a change in the polarity of the aligned magnetic particles on the surface of the storage medium. A drive head creates flux reversals on the medium to record data. For each data bit (or bits) that a drive writes, it creates a pattern of positive-to-negative and negative-to-positive flux reversals on the medium in specific areas known as *bit cells* or *transition cells*. A bit cell or transition cell is a specific area of the medium—controlled by the time and speed at which the medium travels—in which the drive head creates flux reversals. The particular pattern of flux reversals within the transition cells used to store a given data bit (or bits) is called the *encoding method*. The drive logic or controller takes the data to be stored and encodes it as a series of flux reversals over a period of time, according to the pattern dictated by the encoding method it uses.

Note

The two most popular encoding methods for magnetic media are Modified Frequency Modulation and Run Length Limited. All floppy disk drives and some older hard disk drives use the MFM scheme. Today's hard disk drives use one of several variations on the RLL encoding method. These encoding methods are described in more detail later in this chapter in the section "Data Encoding Schemes."

During the write process, voltage is applied to the head. As the polarity of this voltage changes, the polarity of the magnetic field being recorded also changes. The flux transitions are written precisely at the points where the recording polarity changes. Strange as it might seem, during the read process, a head does not generate exactly the same signal that was written. Instead, the head generates a voltage pulse or spike only when it crosses a flux transition. When the transition changes from positive to negative, the pulse that the head detects is a negative voltage. When the transition changes from negative to positive, the pulse is a positive voltage spike. This effect occurs because current is generated in a conductor only when passing through lines of magnetic force at an angle. Because the head moves parallel to the magnetic fields it created on the media, the only time the head generates voltage when reading is when passing through a polarity or flux transition (flux reversal).

In essence, while reading from the medium, the head becomes a flux transition detector, emitting voltage pulses whenever it crosses a transition. Areas of no transition generate no pulse. Figure 9.4 shows the relationship between the read and write waveforms and the flux transitions recorded on a storage medium.

Figure 9.4 Magnetic write and read processes.

You can think of the write pattern as being a square waveform that is at a positive or negative voltage level. When the voltage is positive, a field is generated in the head, which polarizes the magnetic media in one direction. When the voltage changes to negative, the magnetic field induced in the media also changes direction. Where the waveform actually transitions from positive to negative voltage, or vice versa, the magnetic flux on the disk also changes polarity. During a read, the head senses these flux transitions and generates a pulsed positive or negative waveform, rather than the continuously positive or negative waveform used during the original recording. In other words, the signal when reading is 0 volts unless the head detects a magnetic flux transition, in which case it generates a positive or negative pulse accordingly. Pulses appear only when the head is passing over flux transitions on the medium. By knowing the clock timing the drive uses, the controller circuitry can determine whether a pulse (and therefore a flux transition) falls within a given transition cell time period.

The electrical pulse currents generated in the head while it is passing over the storage medium in read mode are very weak and can contain significant noise. Sensitive electronics in the drive and controller assembly amplify the signal above the noise level and decode the train of weak pulse currents back into binary data that is (theoretically) identical to the data originally recorded.

As you can see, hard disk drives and other storage devices read and write data by means of basic electromagnetic principles. A drive writes data by passing electrical currents through an electromagnet (the drive head), generating a magnetic field that is stored on the medium. The drive reads data by passing the head back over the surface of the medium. As the head encounters changes in the stored magnetic field, it generates a weak electrical current that indicates the presence or absence of flux transitions in the signal as it was originally written.

Read/Write Head Designs

As disk drive technology has evolved, so has the design of the read/write head. The earliest heads were simple iron cores with coil windings (electromagnets). By today's standards, the original head designs were enormous in physical size and operated at very low recording densities. Over the years, head designs have evolved from the first simple ferrite core designs into the several types and technologies available today. This section discusses the various types of heads found in PC hard disk drives, including the applications and relative strengths and weaknesses of each.

Five main types of heads have been used in hard disk drives over the years:

- Ferrite
- Magneto-resistive (MR)
- Thin-Film (TF)
- Giant magneto-resistive (GMR)
- Metal-In-Gap (MIG)

A sixth type, perpendicular, is in the experimental stage and is expected to be introduced in 2004 or later. It is discussed at the end of this section.

Ferrite

Ferrite heads, the traditional type of magnetic-head design, evolved from the original IBM 30-30 Winchester drive. These heads have an iron-oxide core wrapped with electromagnetic coils. The drive produces a magnetic field by energizing the coils or passing a magnetic field near them. This gives the heads full read/write capability. Ferrite heads are larger and heavier than thin-film heads and therefore require a larger floating height to prevent contact with the disk while it is spinning.

Manufacturers have made many refinements to the original (monolithic) ferrite head design. One type of ferrite head, called a composite ferrite head, has a smaller ferrite core bonded with glass in a ceramic housing. This design permits a smaller head gap, which enables higher track densities. These heads are less susceptible to stray magnetic fields than the older monolithic design heads.

During the 1980s, composite ferrite heads were popular in many low-end drives, such as the Seagate ST-225. As density demands grew, the competing MIG and thin-film head designs came to be used in place of ferrite heads, which are virtually obsolete today. Ferrite heads can't write to the higher coercivity media necessary for high-density disk designs and have poor frequency response with higher noise levels. The main advantage of ferrite heads is that they are the cheapest type available.

Metal-In-Gap

Metal-In-Gap heads are a specially enhanced version of the composite ferrite design. In MIG heads, a metal substance is applied to the head's recording gap. Two versions of MIG heads are available: single-sided and double-sided. Single-sided MIG heads are designed with a layer of magnetic alloy placed along the trailing edge of the gap. Double-sided MIG designs apply the layer to both sides of the gap. The metal alloy is applied through a vacuum-deposition process called sputtering.

This magnetic alloy has twice the magnetization capability of raw ferrite and enables the head to write to the higher coercivity thin-film media needed at the higher densities. MIG heads also produce a sharper gradient in the magnetic field for a better-defined magnetic pulse. Double-sided MIG heads offer even higher coercivity capability than the single-sided designs.

Because of these increases in capabilities through improved designs, MIG heads were for a time the most popular head design and were used in many hard disk drives in the late '80s and early '90s. They are still used today in LS-120 (SuperDisk) drives.

Thin Film

Thin-film heads are manufactured much the same way as a semiconductor chip—through a photolithographic process. This process creates many thousands of heads on a single circular wafer and produces a very small, high-quality product.

TF heads have an extremely narrow and controlled head gap that is created by sputtering a hard aluminum material. Because this material completely encloses the gap, the area is very well protected, minimizing the chance of damage from contact with the spinning disk. The core is a combination of iron and nickel alloy that has two to four times more magnetic power than a ferrite head core.

TF heads produce a sharply defined magnetic pulse that enables them to write at extremely high densities. Because they do not have a conventional coil, TF heads are more immune to variations in coil impedance. These small, lightweight heads can float at a much lower height than the ferrite and MIG heads; in some designs, the floating height is 2 micro-inches or less. Because the reduced height enables the heads to pick up and transmit a much stronger signal from the platters, the signal-to-noise ratio increases and improves accuracy. At the high track and linear densities of some drives, a standard ferrite head would not be capable of picking out the data signal from the background noise. Another advantage of TF heads is that their small size enables the platters to be stacked closer together, enabling more platters to fit into the same space.

When first introduced, TF heads were relatively expensive compared with older technologies, such as ferrite and MIG. Better manufacturing techniques and the need for higher densities, however, have driven the market to TF heads. The widespread use of these heads has also made them cost-competitive with, if not cheaper than, MIG heads.

Many of the drives in the 100MB–2GB range used TF heads, especially in the smaller form factors. TF heads displaced MIG heads as the most popular head design, but they have now themselves been displaced by newer magneto-resistive heads.

Magneto-Resistive Heads

A more recent development in magnetic recording—or more specifically, the read phase of magnetic recording—is the magneto-resistive head, sometimes also referred to as the anisotropic magneto-resistant (AMR) head. In the last few years, virtually all modern hard disk designs have shifted to using MR heads. MR heads are capable of increasing density four times or greater as compared to the previous inductive-only heads. IBM introduced the first commercially available drive with MR heads in 1991, in a 1GB 3 1/2" model.

All heads are detectors; that is, they are designed to detect the flux transitions in the media and convert them back to electrical signals that can be interpreted as data. One problem with magnetic recording is the ever-increasing desire for more and more density, which is putting more information (flux transitions) in a smaller and smaller space. As the magnetic domains on the disk get smaller, the signal from the heads during reading operations becomes weaker; distinguishing the true signal from the random noise or stray fields present becomes difficult. A more efficient read head, which is a more efficient way to detect these transitions on the disk, is therefore necessary.

Another magnetic effect that is well known today is being used in modern drives. When a wire is passed through a magnetic field, not only does the wire generate a small current, but the resistance of the wire also changes. Standard read heads use the head as a tiny generator, relying on the fact that the heads will generate a pulsed current when passed over magnetic flux transitions. A newer type of head design pioneered by IBM instead relies on the fact that the resistance in the head wires will also change.

Rather than use the head to generate tiny currents, which must then be filtered, amplified, and decoded, a magneto-resistive head uses the head as a resistor. A circuit passes a voltage through the head and watches for the voltage to change, which will occur when the resistance of the head changes as it passes through the flux reversals on the media. This mechanism for using the head results in a much stronger and clearer signal of what was on the media and enables the density to be increased.

MR heads rely on the fact that the resistance of a conductor changes slightly when an external magnetic field is present. Rather than put out a voltage by passing through a magnetic-field flux reversal—as a normal head would—the MR head senses the flux reversal and changes resistance. A small current flows through the heads, and this sense current measures the change in resistance. This design provides an output that is three or more times more powerful than a TF head during a read. In effect, MR heads are power-read heads, acting more like sensors than generators.

MR heads are more costly and complex to manufacture than other types of heads because several special features or steps must be added:

- Additional wires must be run to and from the head to carry the sense current.
- Four to six more masking steps are required.
- Because MR heads are so sensitive, they are very susceptible to stray magnetic fields and must be shielded.

Because the MR principle can only read data and is not used for writing, MR heads are really two heads in one. The assembly includes a standard inductive TF head for writing data and an MR head for reading. Because two separate heads are built into one assembly, each head can be optimized for its task. Ferrite, MIG, and TF heads are known as single-gap heads because the same gap is used for both reading and writing, whereas the MR head uses a separate gap for each operation.

The problem with single-gap heads is that the gap length is always a compromise between what is best for reading and what is best for writing. The read function needs a thinner gap for higher resolution; the write function needs a thicker gap for deeper flux penetration to switch the medium. In a dual-gap MR head, the read and write gaps can be optimized for both functions independently. The write (TF) gap writes a wider track than the read (MR) gap reads. Thus, the read head is less likely to pick up stray magnetic information from adjacent tracks.

A typical IBM-designed MR head is shown in Figure 9.5. This figure first shows the complete MR head-and-slider assembly on the end of an actuator arm. This is the part you would see if you opened up a drive. The slider is the block device on the end of the triangular-shaped arm that carries the head. The actual head is the tiny piece shown magnified at the end of the slider, and then the MR read sensor in the head is shown further magnified.

The read element, which is the actual magneto-resistive sensor, consists of a nickel-ferrite (NiFe) film separated by a spacer from a magnetically soft layer. The NiFe film layer changes resistance in the presence of a magnetic field. Layers of shielding protect the MR sensor read element from being corrupted by adjacent or stray magnetic fields. In many designs, the second shield also functions as one pole of the write element, resulting in what is called a *merged* MR head. The write element is not of MR design but is instead a traditional thin film inductive head.

IBM's MR head design employs a Soft Adjacent Layer (SAL) structure, consisting of the MR NiFe film, as well as a magnetically soft alloy layer separated by a film with high electrical resistance. In this design, a resistance change occurs in the NiFe layer as the MR sensor passes through a magnetic field.

As areal densities have increased, heads have been designed with narrower and thinner MR elements. The newest heads have reduced the film width between the side contacts to as little as half a micron or less.

Figure 9.5 Cross section of a magneto-resistive head.

Giant Magneto-Resistive Heads

In the quest for even more density, IBM introduced a new type of MR head in 1997. Called giant magneto-resistive heads, they are physically smaller than standard MR heads but are so named for the GMR effect on which they are based. The design is very similar; however, additional layers replace the single NiFe layer in a conventional MR design. In MR heads, a single NiFe film changes resistance in response to a flux reversal on the disk. In GMR heads, two films (separated by a very thin copper conducting layer) perform this function.

The GMR effect was first discovered in 1988 in crystal samples exposed to high-powered magnetic fields (1,000 times the fields used in HDDs). Scientists Peter Gruenberg of Julich, Germany, and Albert Fert of Paris discovered that large resistance changes were occurring in materials comprised of alternating very thin layers of various metallic elements. The key structure in GMR materials is a spacer layer of a nonmagnetic metal between two layers of magnetic metals. One of the magnetic layers is *pinned*, which means it has a forced magnetic orientation. The other magnetic layer is *free*, which means it is free to change orientation or alignment. Magnetic materials tend to align themselves in the same direction. So if the spacer layer is thin enough, the free layer takes on the same orientation as the pinned layer. What was discovered was that the magnetic alignment of the free magnetic layer would periodically swing back and forth from being aligned in the same magnetic direction as the pinned layer to being aligned in opposite magnetic directions. The overall resistance is relatively low when the layers are in the same alignment and relatively high when in opposite magnetic alignment.

Figure 9.6 shows a GMR read element.

Figure 9.6 Cross section of a giant magneto-resistive head.

When a weak magnetic field, such as that from a bit on a hard disk, passes beneath a GMR head, the magnetic orientation of the free magnetic layer rotates relative to that of the other and generates a significant change in electrical resistance due to the GMR effect. Because the physical nature of the resistance change was determined to be caused by the relative spin of the electrons in the different layers, GMR heads are often referred to as *spin-valve heads*.

IBM announced the first commercially available drive using GMR heads (a 16.8GB 3 1/2" drive) in December 1997. Since then, GMR heads have become the standard in most drives of 20GB and beyond. GMR enables drives to store up to 20Gb of data per square inch of disk surface, enabling drives with capacities exceeding 100GB to be produced in the standard 3 1/2" wide, 1" high form factor.

Perpendicular

Virtually all hard drives and other types of magnetic media record data using longitudinal recording, which stores magnetic bits horizontally across the surface of the media. However, perpendicular recording, which aligns magnetic signals vertically on the media surface, has the potential to achieve higher data densities because vertically oriented magnetic bits use less space than longitudinally stored bits (see Figure 9.7). Professor Shun-ich Iwasaki was the first to propose this method of magnetic storage in 1976. However, until recently, the only major product to use this recording method was the short-lived 2.88MB floppy drive introduced in 1989 by Toshiba and first used in IBM PS/2 systems starting in 1991. Currently, major drive vendors such as Seagate and Maxtor are experimenting with perpendicular recording as a way to achieve signal density surpassing that achievable even with AFC pixie dust media (see the section "Increasing Areal Density with Pixie Dust," later in this chapter).

Figure 9.7 Longitudinal recording (left) compared to perpendicular recording (right).

In April 2002, Read-Rite Corporation, a major maker of read/write heads, reached areal densities of 130Gb per square inch in a prototype drive using media provided by Maxtor subsidiary MMC Technology. In November 2002, Seagate Technology announced it had achieved areal densities of more than 100Gb per square inch in a prototype drive using this technology as well. According to two independent studies published in 2000, perpendicular recording could enable densities of 500Gb–1000Gb (1 terabit) per square inch in the future.

Unlike GMR heads and AFC media (discussed later in this chapter), which can be added relatively easily to existing drive technologies, perpendicular recording requires entirely new read/write head designs. Because of the cost of such a changeover, and because GMR and AFC technologies are sufficient for the present, drives using perpendicular recording are not expected to reach the market until 2004 or later.

Head Sliders

The term *slider* is used to describe the body of material that supports the actual drive head itself. The slider is what actually floats or slides over the surface of the disk, carrying the head at the correct distance from the medium for reading and writing. Older sliders resemble a trimaran, with two outboard pods that float along the surface of the disk media and a central “hull” portion that actually carries the head and read/write gap. Figure 9.8 shows a typical mini slider. Note that the actual head, with the read/write gap, is on the trailing end of the slider.

Figure 9.8 The underside of a typical head mini slider.

The trend toward smaller and smaller form factor drives has forced sliders to become smaller as well. The typical Mini-Winchester slider design was about 4mm × 3.2mm × 0.86mm in size. Most head manufacturers have since shifted to smaller Micro, Nano, Pico, or Femto sliders. The Femto sliders in use today are extremely small—about the size of the ball in the tip of a ballpoint pen. Pico and Femto sliders are assembled by using flex interconnect cable (FIC) and chip on ceramic (COC) technology that enables the process to be completely automated.

Table 9.1 shows the characteristics of the various types of sliders used in hard disk drives.

Table 9.1 Hard Disk Drive Slider Types

Slider Type	Year Introduced	Relative Size	Dimensions			Mass (mg)
			L (mm)	W (mm)	H (mm)	
Mini	1980	100%	4.00	3.20	0.86	55.0
Micro	1986	70%	2.80	2.24	0.60	16.2
Nano (+ Pressure)	1991	62%	2.50	1.70	0.43	7.8
Nano (- Pressure)	1994	50%	2.00	1.60	0.43	5.9
Pico	1997	30%	1.25	1.00	0.30	1.6
Femto	2003	20%	0.85	0.70	0.23	0.6

Smaller sliders reduce the mass carried at the end of the head actuator arms, which provides increased acceleration and deceleration leading to faster seek times. The smaller sliders also require less surface area, allowing the head to track closer to the outer and inner diameters, thus increasing the usable area of the disk platters. Further, the smaller slider contact area reduces the slight wear on the platter surface that occurs during normal startup and spindown of the drive platters. Figure 9.9 shows a magnified photo of a Femto slider mounted on the head gimbal assembly, which is on the end of the head actuator arm.

Figure 9.9 Magnified head gimbal assembly featuring a Femto slider (photo courtesy Hitachi Global Storage Technologies).

The newer slider designs also have specially modified surface patterns that are designed to maintain the same floating height above the disk surface, whether the slider is positioned above the inner or outer cylinders. Conventional sliders would increase or decrease their floating heights considerably according to the velocity of the disk surface traveling beneath them. Above the outer cylinders, the velocity and floating height would be higher. This arrangement is undesirable in newer drives that use zoned bit recording, in which the bit density is the same on all the cylinders. When the bit density is uniform throughout the drive, the head floating height should also be relatively constant for maximum performance. Special textured surface patterns and manufacturing techniques enable the sliders to float at a much more consistent height, making them ideal for zoned bit recording drives. For more information on zoned recording, see the section “Disk Formatting” in Chapter 10.

A typical Femto air-bearing slider surface design is shown in Figure 9.10.

Figure 9.10 Femto air-bearing slider surface design.

A Femto slider has three distinct areas with complex shapes designed to achieve a consistent head-to-disk floating height across the disk as well as minimal height loss under high-altitude (low-pressure) conditions. The shallow etch area creates a stepped air inlet allowing airflow to create a positive pressure under the air-bearing surface that lifts the slider away from the disk. The deep etch area creates an opposite negative pressure pocket that simultaneously pulls the slider closer to the disk surface. The combination of positive and negative pressures is designed to balance the force of the suspension arm pushing the slider toward the disk, while keeping the slider at the desired floating height away from the disk surface. The balance of positive and negative pressures stabilizes and reduces the floating height variations commonly found in older slider designs. The first drive using the Femto slider design was the Hitachi 7K60 2 1/2" drive released in May 2003.

Data Encoding Schemes

Magnetic storage is essentially an analog medium. The data a PC stores on it, however, is digital information—that is, 1s and 0s. When the drive sends digital information to a magnetic recording head, the head creates magnetic domains on the storage medium with specific polarities corresponding to the positive and negative voltages the drive applies to the head. The flux reversals form the boundaries between the areas of positive and negative polarity that the drive controller uses to encode the digital data onto the analog medium. During a read operation, each flux reversal the drive detects generates a positive or negative pulse that the device uses to reconstruct the original binary data.

To optimize the placement of flux transitions during magnetic storage, the drive passes the raw digital input data through a device called an encoder/decoder (endec), which converts the raw binary information to a waveform designed to optimally place the flux transitions (pulses) on the media. During a read operation, the endec reverses the process and decodes the pulse train back into the original binary data. Over the years, several schemes for encoding data in this manner have been developed; some are better or more efficient than others, which you see later in this section.

Other descriptions of the data encoding process might be much simpler, but they omit the facts that make some of the issues related to hard drive reliability so critical—namely, timing. Engineers and designers are constantly pushing the envelope to stuff more and more bits of information into the limited quantity of magnetic flux reversals per inch. What they've come up with, essentially, is a design in which the bits of information are decoded not only from the presence or absence of flux reversals, but from the timing between them. The more accurately they can time the reversals, the more information that can be encoded (and subsequently decoded) from that timing information.

In any form of binary signaling, the use of timing is significant. When interpreting a read or write waveform, the timing of each voltage transition event is critical. Timing is what defines a particular bit or transition cell—that is, the time window within which the drive is either writing or reading a

transition. If the timing is off, a given voltage transition might be recognized at the wrong time as being in a different cell, which would throw the conversion or encoding off, resulting in bits being missed, added, or misinterpreted. To ensure that the timing is precise, the transmitting and receiving devices must be in perfect synchronization. For example, if recording a 0 is done by placing no transition on the disk for a given time period or cell, imagine recording ten 0 bits in a row—you would have a long period of ten time periods or cells with no transitions.

Imagine now that the clock on the encoder was slightly off time while reading data as compared to when it was originally written. If it were fast, the encoder might think that during this long stretch of 10 cells with no transitions, only 9 cells had actually elapsed. Or if it were slow, it might think that 11 cells had elapsed instead. In either case, this would result in a read error, meaning the bits that were originally written would not be read as being the same. To prevent timing errors in drive encoding/decoding, perfect synchronization is necessary between the reading and writing processes. This synchronization often is accomplished by adding a separate timing signal, called a *clock signal*, to the transmission between the two devices. The clock and data signals also can be combined and transmitted as a single signal. Most magnetic data encoding schemes use this type of combination of clock and data signals.

Adding a clock signal to the data ensures that the communicating devices can accurately interpret the individual bit cells. Each bit cell is bounded by two other cells containing the clock transitions. By sending clock information along with the data, the clocks remain in sync, even if the medium contains a long string of identical 0 bits. Unfortunately, the transition cells used solely for timing take up space on the medium that could otherwise be used for data.

Because the number of flux transitions a drive can record in a given space on a particular medium is limited by the physical nature or density of the medium and the head technology, drive engineers have developed various ways of encoding the data by using a minimum number of flux reversals (taking into consideration the fact that some flux reversals used solely for clocking are required). Signal encoding enables the system to make the maximum use of a given drive hardware technology.

Although various encoding schemes have been tried, only a few are popular today. Over the years, these three basic types have been the most popular:

- Frequency Modulation
- Modified Frequency Modulation
- Run Length Limited

The following sections examine these codes, how they work, where they are used, and any advantages or disadvantages that apply to them. It will help to refer to Figure 9.9 (later in the chapter) as you read the descriptions of each of these encoding schemes because this figure depicts how each of these schemes would store an “X” on the same media.

FM Encoding

One of the earliest techniques for encoding data for magnetic storage is called Frequency Modulation encoding. This encoding scheme—sometimes called Single-Density encoding—was used in the earliest floppy disk drives installed in PC systems. The original Osborne portable computer, for example, used these Single-Density floppy disk drives, which stored about 80KB of data on a single disk. Although it was popular until the late 1970s, FM encoding is no longer used.

MFM Encoding

Modified Frequency Modulation encoding was devised to reduce the number of flux reversals used in the original FM encoding scheme and, therefore, to pack more data onto the disk. MFM encoding minimizes the use of clock transitions, leaving more room for the data. It records clock transitions only when a stored 0 bit is preceded by another 0 bit; in all other cases, a clock transition is not required. Because MFM minimizes the use of clock transitions, it can double the clock frequency used by FM encoding, enabling it to store twice as many data bits in the same number of flux transitions.

Because MFM encoding writes twice as many data bits by using the same number of flux reversals as FM, the clock speed of the data is doubled and the drive actually sees the same number of total flux reversals as with FM. This means a drive using MFM encoding reads and writes data at twice the speed of FM, even though the drive sees the flux reversals arriving at the same frequency as in FM.

Because it is twice as efficient as FM encoding, MFM encoding also has been called Double-Density recording. MFM is used in virtually all PC floppy disk drives today and was used in nearly all PC hard disks for a number of years. Today, virtually all hard disks use variations of RLL encoding, which provides even greater efficiency than MFM.

Table 9.2 shows the data bit-to-flux reversal translation in MFM encoding.

Table 9.2 MFM Data-to-Flux Transition Encoding

Data Bit Value	Flux Encoding
1	NT
0 preceded by 0	TN
0 preceded by 1	NN

T = Flux transition

N = No flux transition

RLL Encoding

Today's most popular encoding scheme for hard disks, called Run Length Limited, packs up to twice the information on a given disk than MFM does and three times as much information as FM. In RLL encoding, the drive combines groups of bits into a unit to generate specific patterns of flux reversals. By combining the clock and data signals in these patterns, the clock rate can be further increased while maintaining the same basic distance between the flux transitions on the storage medium.

IBM invented RLL encoding and first used the method in many of its mainframe disk drives. During the late 1980s, the PC hard disk industry began using RLL encoding schemes to increase the storage capabilities of PC hard disks. Today, virtually every drive on the market uses some form of RLL encoding.

Instead of encoding a single bit, RLL typically encodes a group of data bits at a time. The term *Run Length Limited* is derived from the two primary specifications of these codes, which are the minimum number (the run length) and maximum number (the run limit) of transition cells allowed between two actual flux transitions. Several variations of the scheme are achieved by changing the length and limit parameters, but only two have achieved any real popularity: RLL 2,7 and RLL 1,7.

You can even express FM and MFM encoding as a form of RLL. FM can be called RLL 0,1 because as few as zero and as many as one transition cells separate two flux transitions. MFM can be called RLL 1,3 because as few as one and as many as three transition cells separate two flux transitions. (Although these codes can be expressed as variations of RLL form, it is not common to do so.)

RLL 2,7 was initially the most popular RLL variation because it offers a high-density ratio with a transition detection window that is the same relative size as that in MFM. This method provides high storage density and fairly good reliability. In very high-capacity drives, however, RLL 2,7 did not prove to be reliable enough. Most of today's highest capacity drives use RLL 1,7 encoding, which offers a density ratio 1.27 times that of MFM and a larger transition detection window relative to MFM. Because of the larger relative timing window or cell size within which a transition can be detected, RLL 1,7 is a more forgiving and more reliable code, which is important when media and head technology are being pushed to their limits.

Another little-used RLL variation called RLL 3,9—sometimes also called Advanced RLL (ARLL)—allows an even higher density ratio than RLL 2,7. Unfortunately, reliability suffered too greatly under the RLL 3,9 scheme; the method was used by only a few now-obsolete controllers and has all but disappeared.

Understanding how RLL codes work is difficult without looking at an example. Within a given RLL variation, such as RLL 2,7 or 1,7, you can construct many flux transition encoding tables to demonstrate how particular groups of bits are encoded into flux transitions.

In the conversion table shown in Table 9.3, specific groups of data that are 2, 3, and 4 bits long are translated into strings of flux transitions 4, 6, and 8 transition cells long, respectively. The selected transitions for a particular bit sequence are designed to ensure that flux transitions do not occur too closely together or too far apart.

Limiting how close two flux transitions can be is necessary because of the fixed resolution capabilities of the head and storage medium. Limiting how far apart two flux transitions can be ensures that the clocks in the devices remain in sync.

Table 9.3 RLL 2,7 Data-to-Flux Transition Encoding

Data Bit Values	Flux Encoding
10	NTNN
11	TNNN
000	NNNTNN
010	TNNTNN
011	NNTNNN
0010	NNTNNTNN
0011	NNNNTNNN

T = Flux transition

N = No flux transition

In studying Table 9.3, you might think that encoding a byte value such as 00000001b would be impossible because no combinations of data bit groups fit this byte. Encoding this type of byte is not a problem, however, because the controller does not transmit individual bytes; instead, the controller sends whole sectors, making encoding such a byte possible by including some of the bits in the following byte. The only real problem occurs in the last byte of a sector if additional bits are necessary to complete the final group sequence. In these cases, the endec in the controller adds excess bits to the end of the last byte. These excess bits are then truncated during any reads so the controller always decodes the last byte correctly.

Encoding Scheme Comparisons

Figure 9.11 shows an example of the waveform written to store the ASCII character X on a hard disk drive by using three different encoding schemes.

In each of these encoding scheme examples, the top line shows the individual data bits (01011000b, for example) in their bit cells separated in time by the clock signal, which is shown as a period (.). Below that line is the actual write waveform, showing the positive and negative voltages as well as head voltage transitions that result in the recording of flux transitions. The bottom line shows the transition cells, with T representing a transition cell that contains a flux transition and N representing a transition cell that is empty.

The FM encoding example shown in Figure 9.11 is easy to explain. Each bit cell has two transition cells: one for the clock information and one for the data itself. All the clock transition cells contain flux transitions, and the data transition cells contain a flux transition only if the data is a 1 bit. No transition is present when the data is a 0 bit. Starting from the left, the first data bit is 0, which decodes as a flux transition pattern of TN. The next bit is a 1, which decodes as TT. The next bit is 0, which decodes as TN, and so on.

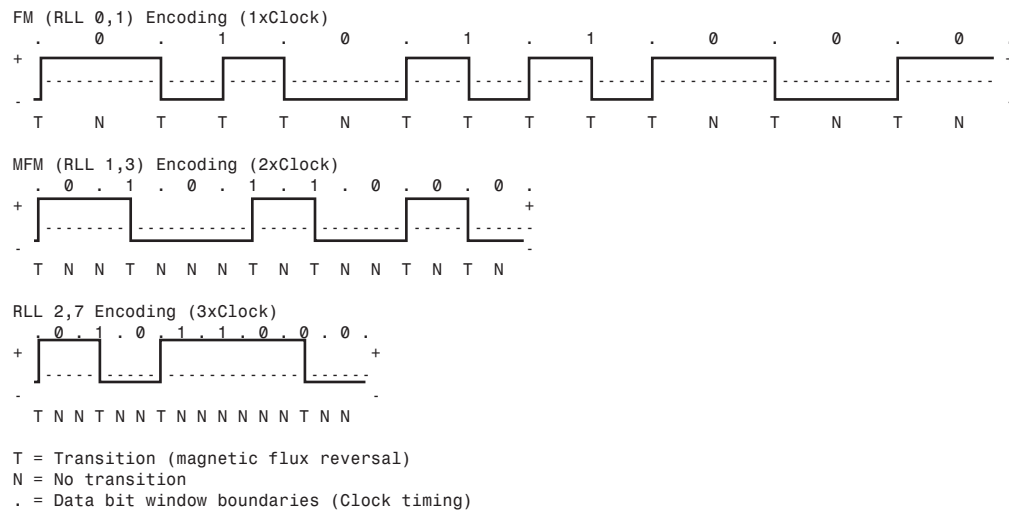

Figure 9.11 ASCII character X write waveforms using FM; MFM; and RLL 2,7 encoding.

The MFM encoding scheme also has clock and data transition cells for each data bit to be recorded. As you can see, however, the clock transition cells carry a flux transition only when a 0 bit is stored after another 0 bit. Starting from the left, the first bit is a 0, and the preceding bit is unknown (assume 0), so the flux transition pattern is TN for that bit. The next bit is a 1, which always decodes to a transition-cell pattern of NT. The next bit is 0, which was preceded by 1, so the pattern stored is NN. By using Table 9.2 (shown earlier), you easily can trace the MFM encoding pattern to the end of the byte. You can see that the minimum and maximum numbers of transition cells between any two flux transitions are one and three, respectively, which explains why MFM encoding can also be called RLL 1,3.

The RLL 2,7 pattern is more difficult to see because it encodes groups of bits rather than individual bits. Starting from the left, the first group that matches the groups listed in Table 9.3 is the first three bits, 010. These bits are translated into a flux transition pattern of TNNTNN. The next two bits, 11, are translated as a group to TNNN; and the final group, 000 bits, is translated to NNNTNN to complete the byte. As you can see in this example, no additional bits are needed to finish the last group.

Notice that the minimum and maximum numbers of empty transition cells between any two flux transitions in this example are 2 and 6, although a different example could show a maximum of seven empty transition cells. This is where the RLL 2,7 designation comes from. Because even fewer transitions are recorded than in MFM, the clock rate can be increased to three times that of FM or 1.5 times that of MFM, thus storing more data in the same space. Notice, however, that the resulting write waveform itself looks exactly like a typical FM or MFM waveform in terms of the number and separation of the flux transitions for a given physical portion of the disk. In other words, the physical minimum and maximum distances between any two flux transitions remain the same in all three of these encoding scheme examples.

Partial-Response, Maximum-Likelihood Decoders

Another feature often used in modern hard disk drives involves the disk read circuitry. Read channel circuits using Partial-Response, Maximum-Likelihood (PRML) technology enable disk drive manufacturers to increase the amount of data stored on a disk platter by up to 40%. PRML replaces the standard “detect one peak at a time” approach of traditional analog peak-detect, read/write channels with digital signal processing.

As the data density of hard drives increases, the drive must necessarily record the flux reversals closer together on the medium. This makes reading the data on the disk more difficult because the adjacent magnetic peaks can begin to interfere with each other. PRML modifies the way the drive reads the data from the disk. The controller analyzes the analog data stream it receives from the heads by using digital signal sampling, processing, and detection algorithms (this is the partial response element) and predicts the sequence of bits the data stream is most likely to represent (the maximum likelihood element). PRML technology can take an analog waveform, which might be filled with noise and stray signals, and produce an accurate reading from it.

This might not sound like a very precise method of reading data that must be bit-perfect to be usable, but the aggregate effect of the digital signal processing filters out the noise efficiently enough to enable the drive to place the flux change pulses much more closely together on the platter, thus achieving greater densities. Most drives with capacities of 2GB or above use PRML technology in their endec circuits.

Capacity Measurements

In December 1998, the International Electrotechnical Commission (IEC)—the leading international organization for worldwide standardization in electrotechnology—approved as an IEC International Standard names and symbols for prefixes for binary multiples for use in the fields of data processing and data transmission. Prior to this, a lot of confusion had existed as to whether a megabyte stood for 1 million bytes (10^6) or 1,048,576 bytes (2^{20}). Even so, these new prefixes have yet to be widely adopted and confusion still reigns. The industry-standard abbreviations for the units used to measure the capacity of magnetic (and other) drives are shown in Table 9.4.

Table 9.4 Standard Abbreviations and Meanings

Abbreviation	Description	Power	Value
K	Kilo	10^3	1,000
Ki	Kibi	2^{10}	1,024
M	Mega	10^6	1,000,000
Mi	Mebi	2^{20}	1,048,576
G	Giga	10^9	1,000,000,000
Gi	Gibi	2^{30}	1,073,741,824
T	Tera	10^{12}	1,000,000,000,000
Ti	Tebi	2^{40}	1,099,511,627,776
P	Peta	10^{15}	1,000,000,000,000,000
Pi	Pebi	2^{50}	1,125,899,906,842,624

According to the new prefix standard, 1 mebibyte (1 MiB = 2^{20} B = 1,048,576 B) and 1 megabyte (1MB = 10^6 B = 1,000,000 B) are not equal. Because the new prefixes are not in widespread use (and they might never be), M in most cases can indicate both decimal *millions of bytes* and binary *megabytes*. Similarly, G is often used to refer to decimal *billions of bytes* and binary *gigabytes*. In general, memory values are expressed by using the binary values, although disk capacities can go either way. This often leads to confusion in reporting disk capacities because many manufacturers tend to use whichever value makes their products look better. For example, drive capacities are often rated in decimal billions (G - Giga), whereas most BIOS chips and operating system utilities, such as the Windows FDISK, rate the same drive in binary gigabytes (Gi - Gibi). Note also that when bits and bytes are used as part of some other measurement, the difference between bits and bytes is often distinguished by the use of a lower- or uppercase B. For example, megabits are typically abbreviated with a lowercase *b*, resulting in the abbreviation *Mbps* for *megabits per second*, whereas *MBps* indicates *megabytes per second*.

Areal Density

Areal density is often used as a technology growth-rate indicator for the hard disk drive industry. *Areal density* is defined as the product of the linear bits per inch (BPI), measured along the length of the tracks around the disk, multiplied by the number of tracks per inch (TPI), measured radially on the disk (see Figure 9.12). The results are expressed in units of megabits or gigabits per square inch (Mbit/sq. inch or Gbit/sq. inch) and are used as a measure of efficiency in drive recording technology. Current high-end 3 1/2" drives record at areal densities exceeding 60Gbit/sq. inch (such as the 400GB Hitachi 7K400, which records at 61.7Gbit/sq. inch), whereas 2 1/2" drives such as the 80GB Hitachi 5K80 record at areal densities of 70Gbit/sq. inch or more. Prototype drives with densities of 130Gbit/sq. inch or more now exist, which will enable 3 1/2" drives with capacities of 1 terabyte (TB) or more in the next few years.

Figure 9.12 Areal density, combining tracks per inch and bits per inch.

Drives record data in tracks, which are circular bands of data on the disk. Each track is divided into sectors. Figure 9.13 shows an actual floppy disk sprayed with magnetic developer (powdered iron) such that an image of the actual tracks and sectors can be clearly seen. The disk shown is a 5 1/4" 360KB floppy, which has 40 tracks per side, with each track divided into 9 sectors. Note that each sector is delineated by gaps in the recording, which precede and postcede the track and sector headers (where ID and address information resides). You can clearly see the triple gap preceding the first sector, which includes the track and sector headers. Then following in a counterclockwise direction, you see each subsequent sector, preceded by gaps delineating the header for that sector. The area between the headers is where the sector data is written.

Notice that sector 9 is longer than the others; this is to enable rotational speed differences between drives, so that all the data can be written before running into the start of the track. Also notice that a good portion of the disk surface isn't used because it is simply impractical to have the heads travel in and out that far, and the difference in length between the sectors on the inner and outer tracks becomes more of a problem.

Areal density has been rising steadily since the first magnetic storage drive (IBM RAMAC) was introduced in 1956, initially at a growth rate of about 25% per year (doubling every four years), and since the early 1990s at a growth rate of about 60% per year (doubling every year and a half). The development and introduction of magneto-resistive heads in 1991, giant magneto-resistive heads in 1997, and AFC pixie dust media in 2001 have propelled the increase in the areal density growth rate. In the 47+ years since the RAMAC drive was introduced, the areal density of magnetic storage has increased more than 17 million fold.

At the current growth rate, within the next three years or so, drive manufacturers will achieve areal densities of approximately 100Gbit/sq. inch, which is considered near the point at which the super-paramagnetic effect takes place. This is an effect in which the magnetic domains become so small that they are intrinsically unstable at room temperature. Techniques such as extremely high coercivity media and vertical polarity recording are projected to enable magnetic storage densities of

400Gbit/sq. inch or more, but beyond that, scientists and engineers will have to look toward other technologies. One such technology being considered for the future is holographic storage, in which a laser writes data three-dimensionally in a crystal plate or cube.

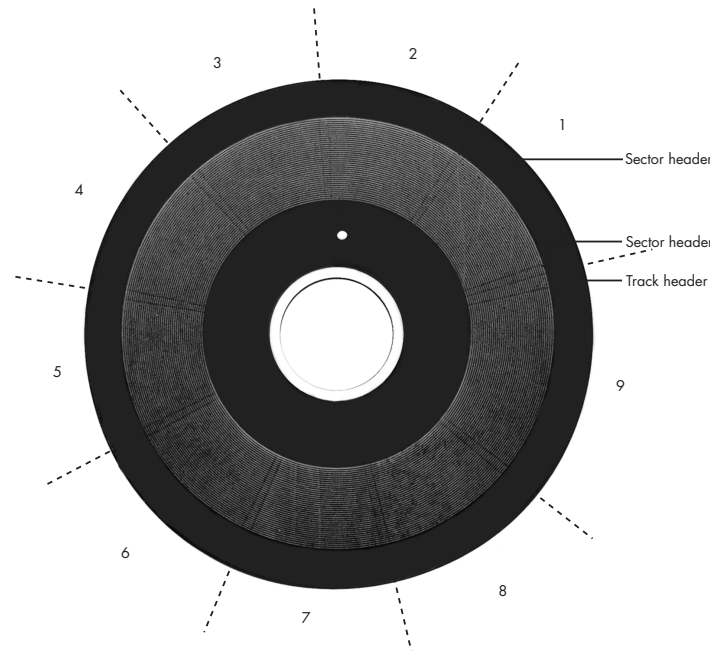

Figure 9.13 360KB floppy disk media sprayed with magnetic developer (powdered iron) showing the actual track and sector images.

Figure 9.14 shows how areal density has increased from when magnetic storage was first developed (1956 RAMAC) through the present time.

To increase areal density while maintaining the same external drive form factors, drive manufacturers have developed media and head technologies to support these higher areal densities, such as ceramic/glass platters, GMR heads, pseudo-contact recording, and PRML electronics, as discussed earlier in this chapter. The primary challenge in achieving higher densities is manufacturing drive heads and disks to operate at closer tolerances. Improvements in tolerances and the use of more platters in a given form factor continue to fuel improvements in drive capacity, but drive makers continue to seek even greater capacity increases, both by improving current technologies and by developing new ones.

To fit more data on a platter of a given size, the tracks must be placed more closely together and the heads must be capable of achieving greater precision in their placements over the tracks. This also means that as hard disk capacities increase, heads must float ever closer to the disk surface during operation. The gap between the head and disk is as close as 10 nanometers (0.01 microns) in some drives, which is approximately the thickness of a cell membrane. By comparison, a human hair is typically 80 microns in diameter, which is 8,000 times thicker than the gap between the head and disk in some drives. The prospect of actual contact or near contact recording is being considered for future drives to further increase density.

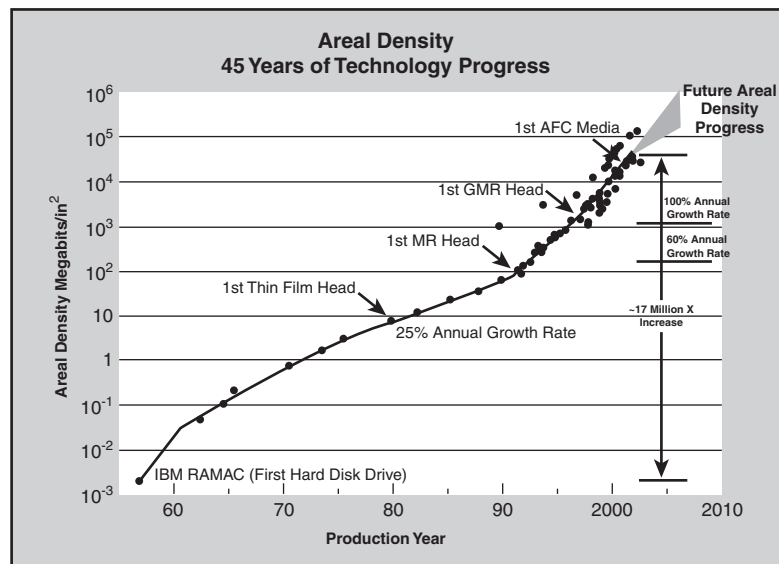

Figure 9.14 Evolution of areal density in magnetic disk storage.

Increasing Areal Density with Pixie Dust

In 1990, IBM scientists discovered that a thin layer of the element ruthenium was the most effective nonmagnetic element that could be used for spacers in devices such as GMR heads. However, more than a decade passed before the first commercially available application of this principle was used to increase disk drive storage densities by improving the storage density of the drives' platters.

In May 2001, IBM began to produce drives using "pixie dust" technology in its Travelstar 2 1/2" hard drive series for notebook computers. In November 2001, Deskstar GXP drives using the same technology were introduced, and these drives had capacities of 80GB and 120GB.

These drives achieved data densities exceeding 25Gb per square inch through the use of a thin (three-atom-thick) layer of ruthenium used to separate two magnetic surfaces on each side of the drive's platters. Traditional drives use platters with a single magnetic surface per side. Media using the ruthenium coating, commonly referred to as pixie dust, is technically known as antiferromagnetically coupled (AFC) media. IBM continues to use AFC media in its latest drives for notebook, desktop, and server computers and has licensed AFC media to other drive and media vendors.

AFC media was developed because achieving greater and greater densities of magnetic storage requires individual magnetic areas on the media to become smaller and smaller. However, when magnetic areas become too small, a problem called the superparamagnetic effect (which causes magnetic areas to lose their magnetism over time) can occur.

When a thin layer of ruthenium is placed between two magnetic layers, the layers are forced to orient themselves magnetically in opposite directions to each other. Although the three-layer structure is physically thicker than a conventional magnetic surface, the opposing magnetic orientations make the layers appear to be thinner than a conventional surface. As a result, disk drive read/write heads can record smaller, high-density signals, increasing the storage capacity of a given platter size without the risk of the signal degrading. Figure 9.15 compares a normal single-layer disk platter to a disk platter using pixie dust AFC media technology.

Figure 9.15 Conventional media uses a single magnetic surface, whereas AFC media uses two magnetic surfaces separated by a thin layer of ruthenium, a process IBM refers to as *pixie dust*.

Just as GMR heads use two layers separated by a thin conductive layer to increase data storage density, AFC media uses a similar principle. In essence, AFC media represents an extension of GMR principles from the read/write heads to the media's data recording surfaces. Over time, AFC media is expected to quadruple the storage capacity of magnetic media, enabling drives to reach capacities of 100Gb per square inch or more. In practical terms, such capacity could result in desktop 3 1/2" hard drives of up to 1TB, 2 1/2" notebook hard drives of up to 300GB, and IBM Microdrives (which have a 1" wide platter) of 8GB or more.

CHAPTER 10

Hard Disk Storage

Definition of a Hard Disk

To many users, the hard disk drive is the most important and yet the most mysterious part of a computer system. A *hard disk drive* is a sealed unit that a PC uses for nonvolatile data storage. *Nonvolatile*, or semipermanent, storage means that the storage device retains the data even when no power is supplied to the computer. Because the hard disk drive is expected to retain data until deliberately erased or overwritten, the hard drive is used to store crucial programming and data. As a result, when the hard disk fails, the consequences are usually very serious. To maintain, service, and upgrade a PC system properly, you must understand how the hard disk functions.

A hard disk drive contains rigid, disk-shaped platters, usually constructed of aluminum or glass (see Figure 10.1). Unlike floppy disks, the platters can't bend or flex—hence the term *hard disk*. In most hard disk drives, you can't remove the platters, which is why they are sometimes called *fixed* disk drives. Removable hard disk drives are also available. Usually, this term refers to a device in which the entire drive unit (that is, the disk unit containing the platters as well as the rest of the drive) is removable, but it can also refer to cartridge drives, where the platters are contained in a removable cartridge.

Figure 10.1 Hard disk heads and platters.

Note

Hard disk drives are sometimes referred to as *Winchester drives*. This term dates back to 1973, when IBM introduced the model 3340 drive, which had 30MB of fixed platter and 30MB of removable platter storage on separate spindles. The drive was codenamed Winchester by project leader Ken Haughton because the original capacity designation (30-30) sounded like the popular .30-30 (caliber-grains of charge) cartridge used by the Winchester 94 rifle introduced in 1895. The original 3340 “Winchester” drive was the first to use a sealed head/disk assembly, and the name has since been applied to all subsequent drives with similar technology.

Hard Drive Advancements

In 1957, Cyril Northcote Parkinson published his famous compilation of essays titled *Parkinson's Law*, which begins with the statement, “Work expands so as to fill the time available for its completion.” A corollary of Parkinson's most famous “law” can be applied to hard drives: “Data expands so as to fill the space available for its storage.” This, of course, means that no matter how big a drive you get, you *will* find a way to fill it. I know that I have lived by that dictum since purchasing my first hard disk drive 20 years ago.

Even though I am well aware of the exponential growth of everything associated with computers, I am still amazed at how large and fast modern drives have become. The first hard drive I purchased in

1983 was a 10MB (that's 10 megabyte, *not* gigabyte) Miniscribe model 2012, which was a 5 1/4" (platter) drive that was 203.2mm×146mm×82.6mm or 8"×5.75"×3.25" (L×W×H) in overall size and weighed 2.5kg (5.5 lb., which is more than some laptop computers)! By comparison, the 400GB Hitachi Deskstar 7K400 drive (currently the highest-capacity 3 1/2" hard drive) uses smaller 3 1/2" platters, is about 147mm×101.6mm×26.1mm or 5.8"×4"×1" in overall size and weighs only 0.7kg (1.54 lb.). It stores a whopping 400GB, which is 40,000 times more storage in a package that is less than one-sixth the size and about one-fourth the weight. That's a pretty large step in just over 20 years' time!

Note

The book *Parkinson's Law* (ISBN: 1-5684-9015-1) is still in print and is in fact considered one of the essential tomes of business and management study even today.

To give you an idea of how far hard drives have come in the 20+ years they have been used in PCs, I've outlined some of the more profound changes in PC hard disk storage:

- Maximum storage capacities have increased from the 5MB and 10MB 5 1/4" full-height drives available in 1982 to 300GB or more for even smaller 3 1/2" half-height drives (Maxtor MaXLine II) and 80GB or more for notebook system 2 1/2" drives (Hitachi Travelstar 5K80) that are 9.5mm (or less) in height. Hard drives smaller than 30GB are rare in today's desktop personal computers.
- Data transfer rates to and from the media (sustained transfer rates) have increased from between 85KBps and 102KBps for the original IBM XT in 1983 to an average of 62MBps or more for some of the fastest drives today (Seagate Cheetah X15.3).
- Average seek times (how long it takes to move the heads to a particular cylinder) have decreased from more than 85ms (milliseconds) for the 10MB drives used by IBM in the 1983 vintage PC-XT to 3.6ms or less for some of the fastest drives today. The Maxtor Atlas 15K features an average seek time of just 3.2ms.
- In 1982–1983, a 10MB drive and controller cost more than \$2,000 (\$200 per megabyte), which would be more than double that in today's dollars. Today, the cost of hard drives (with integrated controllers) has dropped to one-eighth of a cent per megabyte or less, or about 80GB for \$100!

Note

In a rather stunning move, IBM sold its Hard Disk Drive operations division to Hitachi on January 6, 2003. The resulting new company is called Hitachi Global Storage Technologies (www.hitachigst.com); comprises the hard disk drive operations of Hitachi and IBM; and is headquartered in San Jose, California. Hitachi Global Storage Technologies now manufactures, sells, and supports the former IBM Travelstar, Microdrive, Ultrastar, and Deskstar product lines. The new company is 70% owned by Hitachi, with the remaining shares held by IBM. Hitachi will assume full ownership at the end of 2005, and IBM has no involvement in the management of the new company. What is stunning about this is that IBM invented the hard drive, so it is sad to see it exit the business.

Hard Disk Drive Operation

The basic physical construction of a hard disk drive consists of spinning disks with heads that move over the disks and store data in tracks and sectors. The heads read and write data in concentric rings called *tracks*, which are divided into segments called *sectors*, which typically store 512 bytes each (see Figure 10.2).

Hard disk drives usually have multiple disks, called *platters*, that are stacked on top of each other and spin in unison, each with two sides on which the drive stores data. Most drives have two or three platters, resulting in four or six sides, but some PC hard disks have up to 12 platters and 24 sides with 24 heads to read them (Seagate Barracuda 180). The identically aligned tracks on each side of every

platter together make up a cylinder (see Figure 10.3). A hard disk drive usually has one head per platter side, with all the heads mounted on a common carrier device or rack. The heads move radially across the disk in unison; they can't move independently because they are mounted on the same carrier or rack, called an *actuator*.

Figure 10.2 The tracks and sectors on a disk.

Figure 10.3 Hard disk cylinders.

Originally, most hard disks spun at 3,600rpm—approximately 10 times faster than a floppy disk drive. For many years, 3,600rpm was pretty much a constant among hard drives. Now, however, most drives spin even faster. Although speeds can vary, modern drives typically spin the platters at either 4,200rpm; 5,400rpm; 7,200rpm; 10,000rpm; or 15,000rpm. Most standard-issue drives found in PCs today spin at 5,400rpm, with high-performance models spinning at 7,200rpm. Some of the small 2 1/2" notebook drives run at only 4,200rpm to conserve power, and the 10,000rpm or 15,000rpm drives are usually found only in very high-performance workstations or servers, where their higher prices, heat generation, and noise can be more easily dealt with. High rotational speeds combined with a fast head-positioning mechanism and more sectors per track are what make one hard disk faster overall than another.

The heads in most hard disk drives do not (and should not!) touch the platters during normal operation. However, on most drives, the heads do rest on the platters when the drive is powered off. In most drives, when the drive is powered off, the heads move to the innermost cylinder, where they land on the platter surface. This is referred to as *contact start stop* (CSS) design. When the drive is powered on, the heads slide on the platter surface as they spin up, until a very thin cushion of air builds up between the heads and platter surface, causing the heads to lift off and remain suspended a short distance above or below the platter. If the air cushion is disturbed by a particle of dust or a shock, the head can come into contact with the platter while it is spinning at full speed. When contact with the spinning platters is forceful enough to do damage, the event is called a *head crash*. The result of a head crash can be anything from a few lost bytes of data to a completely ruined drive. Most drives have special lubricants on the platters and hardened surfaces that can withstand the daily “takeoffs and landings” as well as more severe abuse.

Some newer drives do not use CSS design and instead use a load/unload mechanism that does not allow the heads to contact the platters, even when the drive is powered off. First used in the 2 1/2" form factor notebook or laptop drives where resistance to mechanical shock is more important, traditional load/unload mechanisms use a ramp positioned just off the outer part of the platter surface, whereas some newer designs position the ramp near the spindle. When the drive is powered off or in a power-saving mode, the heads ride up on the ramp. When powered on, the platters are allowed to come up to full speed before the heads are released down the ramp, allowing the airflow (air bearing) to prevent any head/platter contact.

Because the platter assemblies are sealed and nonremovable, the track densities on the disk can be very high. Hard drives today have up to 96,000 or more tracks per inch (TPI) recorded on the media (Hitachi Travelstar 5K80). Head disk assemblies (HDAs), which contain the platters, are assembled and sealed in clean rooms under absolutely sanitary conditions. Because few companies repair HDAs, repair or replacement of the parts inside a sealed HDA can be expensive. Every hard disk ever made eventually fails. The only questions are when the failure will occur and whether your data is backed up.

Caution

It is strongly recommended that you do not even attempt to open a hard disk drive's HDA unless you have the equipment and expertise to make repairs inside. Most manufacturers deliberately make the HDA difficult to open to discourage the intrepid do-it-yourselfer. Opening the HDA voids the drive's warranty.

Many PC users know that hard disks are fragile, and comparatively speaking, they are certainly one of the more fragile components in your PC. That being the case, it comes as somewhat of a surprise to the students in some of my PC Hardware and Troubleshooting or Data Recovery seminars when I run various hard disks with the covers removed—and in some cases I've even removed and installed the covers while the drives were operating! Those drives continue to store data perfectly to this day with their lids either on or off. Of course, I do not recommend that you try this with your own drives.

The Ultimate Hard Disk Drive Analogy

There is an old analogy that compares the interaction of the heads and the medium in a typical hard disk drive as being similar in scale to a 747 Jumbo Jet flying a few feet off the ground at cruising speed (500+ mph). I have heard this analogy used repeatedly for years, and in the past I even used it myself without checking to see whether the analogy is technically accurate with respect to modern hard drives. It isn't.

Perhaps the most inaccurate aspect of the 747 analogy is the use of an airplane of any type to describe the head-and-platter interaction. This analogy implies that the heads fly very low over the surface of the disk, but technically, this is not true. The heads do not fly at all in the traditional aerodynamic sense; instead, they float or ski on a cushion of air that is being dragged around by the platters.

A much better analogy would use a hovercraft instead of an airplane; the action of a hovercraft much more closely emulates the action of the heads in a hard disk drive. Like a hovercraft, the drive heads rely somewhat on the shape of the bottom of the head to capture and control the cushion of air that keeps them floating over the disk. By nature, the cushion of air on which the heads float forms only in very close proximity to the platter and is often called an *air bearing* by those in the disk drive industry.

I thought it was time to come up with a new analogy that more correctly describes the dimensions and speeds at which a hard disk drive operates today. I looked up the specifications on a specific modern hard disk drive and then magnified and rescaled all the dimensions involved by a factor of more than 300,000. For my example, I use an IBM Deskstar 75GXP drive, which is a 75GB (formatted capacity), 3 1/2" ATA (AT Attachment interface) drive. The head sliders (called *pico* sliders) in this drive are about 0.049" long, 0.039" wide, and 0.012" high. They float on a cushion of air about 15 nanometers (nm or billionths of a meter) over the surface of the disk while traveling at an average true speed of 53.55 miles per hour (figuring an average track diameter of about 2 1/2"). These heads read and write individual bits spaced only 2.56 micro-inches (millionths of an inch) apart, along tracks separated by only 35.27 micro-inches. The heads can move from one track to another in 8.5 milliseconds during an average seek.

To create my analogy, I magnified the scale to make the head floating height equal to 5 millimeters (about 0.2"). Because 5 millimeters is about 333,333 times greater than 15 nanometers (nm), I scaled up everything else by the same amount.

Magnified to such a scale, the heads in this typical hard disk would be about 1,361 feet long, 1,083 feet wide, and 333 feet high (the length and height would be about equal to the Sears Tower if it were tipped over sideways). These skyscraper-sized heads would float on a cushion of air that to scale would be only 5mm thick (about 0.2") while traveling at a speed of 17.8 million miles per hour (4,958 miles per second), all while reading data bits spaced a mere 0.85" apart on tracks separated by only 0.98 feet!

The proportionate forward speed of this imaginary head is difficult to comprehend, so I'll elaborate. The diameter of the Earth at the equator is 7,926 miles, which means a circumference of about 24,900 miles. At 4,958 miles per second, this imaginary skyscraper-sized head would circle the earth once every 5 seconds (at only two-tenths of an inch over the surface)! It would also read 231.33MB in one lap around this equatorial track.

There is also sideways velocity to consider. Because the average seek time of 8.5 milliseconds is defined as the time it takes to move the heads over one-third of the total tracks (about 9,241 tracks in this example), the heads could move sideways within a scale distance of 1.71 miles in that short time. This results in a scale seek velocity of more than 726,321mph, or 202 miles per second!

This analogy should give you a new appreciation of the technological marvel that the modern hard disk drive actually represents. It makes the old Jumbo Jet analogy look rather pathetic (not to mention grossly inaccurate), doesn't it?

Tracks and Sectors

A *track* is a single ring of data on one side of a disk. A disk track is too large to manage data effectively as a single storage unit. Many disk tracks can store 100,000 or more bytes of data, which would be very inefficient for storing small files. For that reason, tracks are divided into several numbered divisions known as sectors. These sectors represent arc-shaped pieces of the track.

Various types of disk drives split their disk tracks into different numbers of sectors, depending on the density of the tracks. For example, floppy disk formats use 8–36 sectors per track, although hard disks usually store data at a higher density and today can have 900 or more sectors per track physically. The sectors created by the standard formatting procedure on a PC system have a capacity of 512 bytes, which has been one constant throughout the history of the PC. One interesting phenomenon of the

PC standard is that to be compatible with most older BIOSs and drivers, drives usually perform an internal translation so that they pretend to have 63 sectors per track when addressed in CHS (cylinder, head, sector) mode.

The sectors on a track are numbered starting with 1, unlike the heads or cylinders that are numbered starting with 0. For example, a 1.44MB floppy disk contains 80 cylinders numbered 0–79 and two heads numbered 0 and 1, whereas each track on each cylinder has 18 sectors numbered 1–18.

When a disk is formatted, the formatting program creates ID areas before and after each sector's data that the disk controller uses for sector numbering and identifying the start and end of each sector. These areas precede and follow each sector's data area and consume some of the disk's total storage capacity. This accounts for the difference between a disk's unformatted and formatted capacities. Note that most modern hard drives are sold preformatted and advertise only the formatted capacity. The unformatted capacity is usually not mentioned anymore. Another interesting development is that many new drives use what is called No-ID sector formatting, which means the sectors are recorded without ID marks before and after each sector. Therefore, more of the disk can be used for actual data.

Each sector on a disk usually has a prefix portion, or header, that identifies the start of the sector and contains the sector number, as well as a suffix portion, or trailer, that contains a checksum (which helps ensure the integrity of the data contents). Many newer drives omit this header and have what is called a No-ID recording, allowing more space for actual data. With a No-ID recording, the start and end of each sector are located via predetermined clock timing.

Each sector contains 512 bytes of data. The low-level formatting process typically fills the data bytes with some specific value, such as F6h (hex), or some other repeating test pattern used by the drive manufacturer. Some patterns are more difficult for the electronics on the drive to encode/decode, so these patterns are used when the manufacturer is testing the drive during initial formatting. A special test pattern might cause errors to surface that a normal data pattern would not show. This way, the manufacturer can more accurately identify marginal sectors during testing.

Note

The type of disk formatting discussed here is a physical or low-level format, not the high-level format you perform when you use a Windows DOS-based FORMAT program. See the section "Disk Formatting," later in this chapter, to learn about the difference between these two types of formatting.

The sector headers and trailers are independent of the operating system, file system, and files stored on the drive. In addition to the headers and trailers, gaps exist within the sectors, between the sectors on each track, and between tracks, but none of these gaps contain usable data space. The gaps are created during the low-level format process when the recording is turned off momentarily. They serve the same function as having gaps of no sound between the songs recorded on a cassette tape. The prefix, suffix, and gaps account for the lost space between the unformatted capacity of a disk and the formatted capacity. For example, a 4MB (unformatted) floppy disk (3 1/2") has a capacity of 2.88MB when it is formatted, a 2MB (unformatted) floppy has a formatted capacity of 1.44MB, and an older 38MB unformatted capacity (for instance, Seagate ST-4038) hard disk has a capacity of only 32MB when it is formatted. Because the ATA/IDE and SCSI hard drives you purchase today are low-level formatted at the factory, the manufacturers now advertise only the formatted capacity. Even so, nearly all drives use some reserved space for managing the data that will be stored on the drive. Thus, although I stated earlier that each disk sector is 512 bytes in size, this statement is technically untrue. Each sector does allow for the storage of 512 bytes of data, but the data area is only a portion of the sector. Each sector on a disk typically occupies up to 571 bytes of the disk, of which only 512 bytes are available for the storage of user data. The actual number of additional bytes required for the sector header and trailer can vary from drive to drive. As mentioned earlier, though, many modern drives now use a No-ID recording scheme that virtually eliminates the storage overhead of the sector header information.

You might find it helpful to think of each disk sector as being a page in a book. In a book, each page contains text, but the entire page is not filled with text; rather, each page has top, bottom, left, and right margins. Information such as chapter titles (track and cylinder numbers) and page numbers (sector numbers) is placed in the margins. The “margin” areas of a sector are created during the low-level formatting process. Formatting also fills the data area of each sector with dummy values. After you perform a high-level format on the disk, the PC’s file system can write to the data area of each sector, but the sector header and trailer information can’t be altered during normal write operations unless the disk is low-level formatted again.

Table 10.1 shows the format for each track and sector on a typical hard disk drive with 17 sectors per track.

Table 10.1 Typical Disk Track/Sector Format Using ID Marks

Bytes	Name	Description
16	POST INDEX GAP	All 4Eh, at the track beginning after the Index mark.
The following sector data (shown between the lines in this table) is repeated as many times as there are sectors on the track.		
13	ID VFO LOCK	All 00h; synchronizes the VFO for the sector ID.
1	SYNC BYTE	A1h; notifies the controller that data follows.
1	ADDRESS MARK	FEh; defines that ID field data follows.
2	CYLINDER NUMBER	A value that defines the head actuator position.
1	HEAD NUMBER	A value that defines the particular head selected.
1	SECTOR NUMBER	A value that defines the sector.
2	CRC	Cyclic Redundancy Check to verify ID data.
3	WRITE TURN-ON GAP	00h written by format to isolate the ID from DATA.
13	DATA SYNC VFO LOCK	All 00h; synchronizes the VFO for the DATA.
1	SYNC BYTE	A1h; notifies the controller that data follows.
1	ADDRESS MARK	F8h; defines that user DATA field follows.
512	DATA	The area for user DATA.
2	CRC	Cyclic Redundancy Check to verify DATA.
3	WRITE TURN-OFF GAP	00h; written by DATA update to isolate DATA.
15	INTER-RECORD GAP	All 00h; a buffer for spindle speed variation.
693	PRE-INDEX GAP	All 4Eh, at track end before Index mark.

571 = Total bytes per sector; 512 = Data (usable) bytes per sector

Note: “All XXh” indicates that field will be filled with XXh bytes.

As you can see, the usable space for data on each track is about 15% less than its total unformatted capacity. This is true for most disks, although the percentage can vary slightly, depending on how many sectors exist per track. The following paragraphs detail each piece of the sector data listed in Table 10.1.

The POST INDEX GAP provides a head-switching recovery period, so when switching from one track to another, the heads can read sequential sectors without waiting for an additional revolution of the disk. Because the disk is continuously spinning and the heads take some small amount of time to move radially from track to track, reading consecutive sectors on two different tracks, one right after the other, is not possible. By the time the head moves to the new track, the beginning of the second sector has already spun past it. Leaving a gap between sectors provides the heads with time to move to another track.

In some drives, this gap does not provide sufficient time for the heads to move. When this is the case, a drive can gain additional time by skewing the sectors on different tracks so the arrival of the first sector is delayed. In other words, the low-level formatting process offsets the sector numbering, so instead of the same numbered sectors on each track being adjacent to each other, Sector 9 on one track might be next to Sector 8 of the next track, which is next to Sector 7 on the next, and so forth. The optimum skew value is based on the rotational speed of the disk as compared to the lateral speed of the heads.

Note

At one time, the head skew was a parameter you could set yourself while low-level formatting a drive. Today's ATA/IDE and SCSI drives are low-level formatted at the factory with the optimum skew values.

The Sector ID data consists of the Cylinder, Head, and Sector Number fields, as well as a CRC field used to verify the ID data. Most controllers use bit 7 of the Head Number field to mark a sector as bad during a low-level format or surface analysis. This convention is not absolute, however. Some controllers use other methods to mark a bad sector, but the mark usually involves one of the ID fields.

The WRITE TURN-ON GAP follows the ID field's CRC bytes and provides a pad to ensure a proper recording of the user data area that follows, as well as to enable full recovery of the ID CRC.

The user DATA field consists of all 512 bytes of data stored in the sector. This field is followed by a CRC field to verify the data. Although many controllers use two bytes of CRC here, the controller might implement a longer error correction code (ECC) that requires more than two CRC bytes to store. The ECC data stored here provides the possibility of correcting errors in the DATA field as well as detecting them. The correction/detection capabilities depend on the ECC code the drive uses and its implementation by the controller. The WRITE TURN-OFF GAP is a pad that enables the ECC (CRC) bytes to be fully recovered.

The INTER-RECORD GAP provides a means to accommodate variances in drive spindle speeds. A track might have been formatted while the disk was running slightly more slowly than normal and then written to while the disk was running slightly more quickly than normal. In such cases, this gap prevents the accidental overwriting of any information in the next sector. The actual size of this padding varies, depending on the speed of the DATA disk's rotation when the track was formatted and each time the DATA field is updated.

The PRE-INDEX GAP enables speed tolerance over the entire track. This gap varies in size, depending on the variances in disk rotation speed and write-frequency tolerance at the time of formatting.

This sector prefix information is extremely important because it contains the numbering information that defines the cylinder, head, and sector. So this information, except the DATA field, DATA CRC bytes, and WRITE TURN-OFF GAP, is written only during a low-level format.

Disk Formatting

Two formatting procedures are required before you can write user data to a disk:

- Physical, or low-level formatting
- Logical, or high-level formatting

When you format a blank floppy disk, the Windows Explorer or DOS `FORMAT` command performs both types of formats simultaneously. If the floppy was already formatted, DOS and Windows will default to doing only a high-level format.

A hard disk, however, requires two separate formatting operations. Moreover, a hard disk requires a third step, between the two formatting procedures, to write the partitioning information to the disk. Partitioning is required because a hard disk is designed to be used with more than one operating system. Using multiple operating systems on one hard drive is possible by separating the physical formatting in

a procedure that is always the same, regardless of the operating system used and the high-level format (which is different for each operating system). Partitioning enables a single hard disk drive to run more than one type of operating system, or it can enable a single operating system to use the disk as several volumes or logical drives. A *volume* or *logical drive* is any section of the disk to which the operating system assigns a drive letter or name.

Consequently, preparing a hard disk drive for data storage involves three steps:

1. Low-level formatting (LLF)
2. Partitioning
3. High-level formatting (HLF)

Low-Level Formatting

During a low-level format, the formatting program divides the disk's tracks into a specific number of sectors, creating the intersector and intertrack gaps and recording the sector header and trailer information. The program also fills each sector's data area with a dummy byte value or a pattern of test values. For floppy disks, the number of sectors recorded on each track depends on the type of disk and drive. For hard disks, the number of sectors per track depends on the drive and the controller interface.

Originally, PC hard disk drives used a separate controller that took the form of an expansion card or was integrated into the motherboard. Because the controller could be used with various disk drives and might even have been made by a different manufacturer, some uniformity had to exist in the communications between the controller and the drive. For this reason, the number of sectors written to a track tended to be relatively consistent.

The original ST-506/412 MFM controllers always placed 17 sectors per track on a disk, although ST-506/412 controllers with RLL encoding increased the number of sectors to 25 or 26 per track; ESDI drives had 32 or more sectors per track. The ATA/IDE and SCSI drives found in PCs today can have anywhere from 17 to 900 or more sectors per track.

Virtually all ATA and SCSI drives use a technique called *zoned-bit recording (ZBR)*, sometimes shortened to *zoned recording*, which writes a variable number of sectors per track. Without zoned recording, the number of sectors, and therefore bits, on each track is a constant. This means the actual number of bits per inch will vary. More bits per inch will exist on the inner tracks, and fewer will exist on the outer. The data rate and rotational speed will remain constant, as will the number of bits per track. Figure 10.4 shows a drive recorded with the same number of sectors per track.

Figure 10.4 Standard recording, where the same number of sectors comprise every track.

A standard recording wastes capacity on the outer tracks because it is longer and yet holds the same amount of data (more loosely spaced) as the inner tracks. One way to increase the capacity of a hard drive during the low-level format is to create more sectors on the disks' outer cylinders than on the inner ones. Because they have a larger circumference, the outer cylinders can hold more data. Drives without zoned recording store the same amount of data on every cylinder, even though the tracks of

the outer cylinders might be twice as long as those of the inner cylinders. The result is wasted storage capacity because the disk medium must be capable of storing data reliably at the same density as on the inner cylinders. When the number of sectors per track is fixed, as in older controllers, the drive capacity is limited by the density of the innermost (shortest) track.

Drives that use zoned recording split the cylinders into groups called *zones*, with each successive zone having more sectors per track as you move outward from the center of the disk. All the cylinders in a particular zone have the same number of sectors per track. The number of zones varies with specific drives, but most drives have 10 or more zones.

Figure 10.5 shows a drive with zoned-bit recording.

Figure 10.5 Zoned recording, where the number of sectors per track increases within each zone, moving out from the center.

Another effect of zoned recording is that transfer speeds vary depending on which zone the heads are in. A drive with zoned recording still spins at a constant speed. Because more sectors exist per track in the outer zones, however, data transfer is fastest there. Consequently, data transfer is slowest when reading or writing to the inner zones. That is why virtually all drives today report minimum and maximum sustained transfer rates, which depend on where on the drive you are reading from or writing to.

As an example, see Table 10.2, which shows the zones defined for a Hitachi Travelstar 7K60 2 1/2" notebook drive, the sectors per track for each zone, and the resulting data transfer rate. This is one of the fastest laptop hard drives on the market.

Table 10.2 Zoned Recording Information for the Hitachi Travelstar 7K60 2 1/2" Hard Disk Drive

Zone	Sectors per Track	Bytes per Track	Transfer Rate (MBps)
0	720	368640	44.24
1	704	360448	43.25
2	696	356352	42.76
3	672	344064	41.29
4	640	327680	39.32
5	614	314368	37.72
6	592	303104	36.37
7	556	284672	34.16
8	528	270336	32.44
9	480	245760	29.49

Table 10.2 Continued

Zone	Sectors per Track	Bytes per Track	Transfer Rate (MBps)
10	480	245760	29.49
11	456	233472	28.02
12	432	221184	26.54
13	416	212992	25.56
14	384	196608	23.59
15	360	184320	22.12

This drive has a total of 54,288 cylinders, which are divided into 16 zones averaging 3,393 cylinders each. Zone 0 consists of the outermost cylinders, which are the longest and contain the most sectors: 720 for each track. Because each sector is 512 bytes, each track in the outer zone contains 368,640 bytes of data. The inner zone has only 360 sectors per track, which means each track in the inner zone holds 184,320 bytes.

With zoned recording, this drive averages 545.63 sectors per track. Without zoned recording, the number of sectors per track would be limited to 360 for all tracks. The use of zoned recording therefore provides nearly a 52% increase in the storage capacity of this particular drive.

Also notice the difference in the data transfer rates for each of the zones. Because the drive spins at 7,200 rpm, it completes a single revolution every 1/120 of a second, or every 8.33 milliseconds. Therefore, the data transfer speed varies depending on which zone you are reading and writing. In the outer zone, the data transfer rate is 44.24MBps, whereas in the inner zone it is only 22.12MBps. The average transfer rate for this drive is 33.52MBps. This is one reason you might notice huge discrepancies in the results produced by disk drive benchmark programs. A test that reads or writes files on the outer tracks of the disk naturally yields far better results than one conducted on the inner tracks. It might appear as though your drive is running more slowly when the problem is actually that the test results you are comparing stem from disk activity on different zones.

Another thing to note is that this drive conforms to the ATA-6 specification and is capable of running in Ultra-ATA/100 mode (also called UDMA-100), which implies a transfer speed of 100MBps. As you can see, that is entirely theoretical because the true media transfer speed of this drive varies between about 22MBps and 44MBps, averaging about 33MBps overall. The interface transfer rate is just that: what the interface is capable of. It has little bearing on the actual capabilities of the drive.

Drives with separate controllers used in the past could not handle zoned recording because no standard way existed to communicate information about the zones from the drive to the controller.

With SCSI and ATA disks, however, formatting individual tracks with different numbers of sectors became possible because these drives have the disk controller built in. The built-in controllers on these drives are fully aware of the zoning algorithm and can translate the physical cylinder, head, and sector numbers to logical cylinder, head, and sector numbers so the drive appears to have the same number of sectors on each track. Because the PC BIOS is designed to handle only a single number of sectors per track throughout the entire drive, a zoned drive must run by using a sector translation scheme.

The use of zoned recording enables drive manufacturers to increase the capacity of their hard drives by 20%–50% or more when compared with a fixed-sector-per-track arrangement. All modern drives use zoned recording.

Partitioning

Creating a partition on a hard disk drive enables it to support separate file systems, each in its own partition.

Each file system can then use its own method to allocate file space in logical units called *clusters* or *allocation units*. Every hard disk drive must have at least one partition on it and can have up to four partitions, each of which can support the same or different type file systems. Three common file systems are used by PC operating systems today:

- **FAT (file allocation table).** The standard file system supported by DOS and Windows 9x/Me. FAT partitions support filenames of 11 characters maximum (8 characters + a 3-character extension) under DOS, and 255 characters under Windows 9x (or later). The standard FAT file system uses 12- or 16-bit numbers to identify clusters, resulting in a maximum volume size of 2GB.
Using FDISK, you can create only two physical FAT partitions on a hard disk drive—primary and extended—but you can subdivide the extended partition into as many as 25 logical volumes. Alternative partitioning programs, such as Partition Magic, can create up to four primary partitions or three primary and one extended.
- **FAT32 (file allocation table, 32-bit).** An optional file system supported by Windows 95 OSR2 (OEM Service Release 2), Windows 98, Windows Me, and Windows 2000/XP.
FAT32 uses 32-bit numbers to identify clusters, resulting in a maximum single volume size of 2TB or 2,048GB.
- **NTFS (Windows NT File System).** The native file system for Windows NT/2000/XP that supports filenames up to 256 characters long and partitions up to (a theoretical) 16 exabytes. NTFS also provides extended attributes and file system security features that do not exist in the FAT file system.

Up until the release of XP, FAT32 was by far the most popular file system. Because NTFS is native to XP, NTFS is now becoming more popular in newer systems. Still, the FAT file system is accessible by nearly every operating system, which makes it the most compatible in a mixed OS environment. FAT32 and NTFS provide additional features but are not universally accessible by other operating systems.

▶▶ See “FAT32,” p. 1373.

Partitioning normally is accomplished by running the disk partitioning program that comes with your operating system. The name and exact operation of the disk partitioning program varies with the operating system. For example, FDISK is used by DOS and Windows 9x/Me for this task, whereas the DISKPART command or the Disk Management snap-in component of the Computer Management service are used with Windows XP. FDISK, DISKPART, and other disk partitioning tools enable you to select the amount of space on the drive to use for a partition, from a single megabyte (or 1%) of the drive up to the entire capacity of the drive or as much as the particular file system will allow. You usually should have as few partitions as possible, and many people (myself included) try to stick with only one or two at the most. This was more difficult before FAT32 because the maximum partition size for a FAT16 partition was only 2GB. With FAT32, though, the maximum partition size can be up to 2048GB.

Caution

FDISK, DISKPART, and other disk partitioning tools included in operating systems can't be used to change the size of a partition; all they can do is remove or create partitions. The act of removing or creating a partition destroys and loses access to data that was contained in the partition or that was on that part of the disk. To manipulate partitions without destroying data, you can use third-party utility programs, such as Partition Magic from PowerQuest or Partition Commander from V-Communications.

After a drive is partitioned, each partition must then be high-level formatted by the operating system that will use it.

High-Level Formatting

During the high-level format, the operating system writes the structures necessary for managing files and data on the disk. For example, FAT partitions have a Volume Boot Sector (VBS), two copies of a file allocation table (FAT), and a root directory on each formatted logical drive. These data structures enable the operating system to manage the space on the disk, keep track of files, and even manage defective areas so they do not cause problems.

High-level formatting is not really a physical formatting of the drive, but rather the creation of a table of contents for the disk. In low-level formatting, which is the real physical formatting process, tracks and sectors are written on the disk. As mentioned, the DOS and Windows 9x/Me `FORMAT` command can perform both low-level and high-level format operations on a floppy disk, but it performs only the high-level format for a hard disk. Low-level formats of ATA and SCSI hard disk drives are performed by the manufacturer and should almost never be performed by the end user. The only time I low-level format ATA or SCSI drives is when I am attempting to repair a format that has become damaged (parts of the disk become unreadable) or in some cases when I want to wipe away all data on the drive.

Basic Hard Disk Drive Components

Many types of hard disk drives are on the market, but nearly all share the same basic physical components. Some differences might exist in the implementation of these components (and in the quality of the materials used to make them), but the operational characteristics of most drives are similar. The basic components of a typical hard disk drive are as follows (see Figure 10.6):

- Disk platters
- Read/write heads
- Head actuator mechanism
- Spindle motor (inside platter hub)
- Logic board (controller or Printed Circuit Board)
- Cables and connectors
- Configuration items (such as jumpers or switches)

Figure 10.6 Typical hard disk drive components.

The platters, spindle motor, heads, and head actuator mechanisms usually are contained in a sealed chamber called the head disk assembly (HDA). The HDA is usually treated as a single component; it is rarely opened. Other parts external to the drive's HDA, such as the logic boards, bezel, and other configuration or mounting hardware, can be disassembled from the drive.

Hard Disk Platters (Disks)

A hard disk drive has one or more platters, or disks. Hard disks for PC systems have been available in several form factors over the years. Normally, the physical size of a drive is expressed as the size of the platters. Following are the platter sizes that have been associated with PC hard disk drives:

- 5 1/4" (actually 130mm, or 5.12")
- 3 1/2" (actually 95mm, or 3.74")
- 2 1/2" (actually 65mm, or 2.56")
- 1.8" (actually 48mm, or 1.89")
- 1" (actually 34mm, or 1.33")
- 0.85" (actually 21.5mm)

Larger hard disk drives that have 8", 14", or even larger platters are available, but these drives are not used with PC systems. Currently, the 3 1/2" drives are the most popular for desktop and some portable systems, whereas the 2 1/2" and smaller drives are very popular in portable or notebook systems.

During 1998, IBM introduced a drive called the MicroDrive (now manufactured by Hitachi Global Storage Technologies), which currently can store up to 4GB or more on a single platter about the size of a quarter. These drives are in the physical and electrical format of a Type II Compact Flash (CF) card, which means they can be used in any device that takes CF cards, including digital cameras, personal digital assistants (PDAs), MP3 players, and anywhere else Compact Flash memory cards can be used.

In 2004, Toshiba followed with an even smaller drive, the 0.85" drive, which is about the size of a postage stamp and stores up to 4GB. This drive is not really designed for PCs but will be used in cell phones, digital audio players, PDAs, digital still cameras, camcorders, and more.

Several companies have introduced 1.8" drives over the years, most notably HP, Calluna, Toshiba, and Hitachi. Of those, only Toshiba and Hitachi continue to manufacture drives in that format. In 2000, Toshiba introduced its 1.8" drives, which are available in the physical format of a Type II PC Card, or in a format designed to be mounted internally in a device. Hitachi introduced its 1.8" drives in 2003. These drives are available in capacities of up to 40GB or more and can be used in extremely thin and light laptop computers as well as PDAs, MP3 players, or other small digital devices.

Most hard disk drives have two or more platters, although some of the smaller drives used in portable systems and some entry-level drives for desktop computers have only one. The number of platters a drive can have is limited by the drive's vertical physical size. The maximum number of platters I have seen in any 3 1/2" drive is 12; however, most drives have 6 or fewer.

Platters have traditionally been made from an aluminum/magnesium alloy, which provides both strength and light weight. However, manufacturers' desire for higher and higher densities and smaller drives has led to the use of platters made of glass (or, more technically, a glass-ceramic composite). One such material, produced by the Dow Corning Corporation, is called MemCor. MemCor is composed of glass with ceramic implants, enabling it to resist cracking better than pure glass. Glass platters offer greater rigidity than metal (because metal can be bent and glass can't) and can therefore be machined to one-half the thickness of conventional aluminum disks—sometimes less. Glass platters are also much more thermally stable than aluminum platters, which means they do not expand or contract very much with changes in temperature. Several hard disk drives made by companies such as Hitachi, Seagate, Toshiba, Areal Technology, and Maxtor currently use glass or glass-ceramic platters; in fact, Hitachi Global Storage Technologies (Hitachi and IBM's joint hard disk venture) is designing all its new drives with only glass platters. For most other manufacturers as well, glass disks will probably replace the standard aluminum/magnesium substrate over the next few years.

Recording Media

No matter which substrate is used, the platters are covered with a thin layer of a magnetically retentive substance, called the *medium*, on which magnetic information is stored. Three popular types of magnetic media are used on hard disk platters:

- Oxide media
- Thin-film media
- AFC (antiferromagnetically coupled) media

Oxide Media

The oxide medium is made of various compounds, containing iron oxide as the active ingredient. The magnetic layer is created on the disk by coating the aluminum platter with a syrup containing iron-oxide particles. This syrup is spread across the disk by spinning the platters at high speed; centrifugal force causes the material to flow from the center of the platter to the outside, creating an even coating of the material on the platter. The surface is then cured and polished. Finally, a layer of material that protects and lubricates the surface is added and burnished smooth. The oxide coating is usually about 30 millionths of an inch thick. If you could peer into a drive with oxide-coated platters, you would see that the platters are brownish or amber.

As drive density increases, the magnetic medium needs to be thinner and more perfectly formed. The capabilities of oxide coatings have been exceeded by most higher-capacity drives. Because the oxide medium is very soft, disks that use it are subject to head-crash damage if the drive is jolted during operation. Most older drives, especially those sold as low-end models, use oxide media on the drive platters. Oxide media, which have been used since 1955, remained popular because of their relatively low cost and ease of application. Today, however, very few drives use oxide media.

Thin-Film Media

The thin-film medium is thinner, harder, and more perfectly formed than oxide medium. Thin film was developed as a high-performance medium that enabled a new generation of drives to have lower head-floating heights, which in turn made increases in drive density possible. Originally, thin-film media were used only in higher-capacity or higher-quality drive systems, but today, virtually all drives use thin-film media.

The thin-film medium is aptly named. The coating is much thinner than can be achieved by the oxide-coating method. Thin-film media are also known as plated, or sputtered, media because of the various processes used to deposit the thin film on the platters.

Thin-film plated media are manufactured by depositing the magnetic medium on the disk with an electroplating mechanism, in much the same way that chrome plating is deposited on the bumper of a car. The aluminum/magnesium or glass platter is immersed in a series of chemical baths that coat the platter with several layers of metallic film. The magnetic medium layer itself is a cobalt alloy about 1 μ -inch thick.

Thin-film sputtered media are created by first coating the aluminum platters with a layer of nickel phosphorus and then applying the cobalt-alloy magnetic material in a continuous vacuum-deposition process called *sputtering*. This process deposits magnetic layers as thin as 1 μ -inch or less on the disk, in a fashion similar to the way that silicon wafers are coated with metallic films in the semiconductor industry. The same sputtering technique is again used to lay down an extremely hard, 1 μ -inch protective carbon coating. The need for a near-perfect vacuum makes sputtering the most expensive of the processes described here.

The surface of a sputtered platter contains magnetic layers as thin as 1 μ -inch. Because this surface also is very smooth, the head can float more closely to the disk surface than was previously possible. Floating

heights as small as 10nm (nanometers, or about 0.4 μ -inch) above the surface are possible. When the head is closer to the platter, the density of the magnetic flux transitions can be increased to provide greater storage capacity. Additionally, the increased intensity of the magnetic field during a closer-proximity read provides the higher signal amplitudes necessary for good signal-to-noise performance.

Both the sputtering and plating processes result in a very thin, hard film of magnetic medium on the platters. Because the thin-film medium is so hard, it has a better chance of surviving contact with the heads at high speed. In fact, modern thin-film media are virtually uncrashable. If you could open a drive to peek at the platters, you would see that platters coated with the thin-film medium look like mirrors.

AFC Media

The latest advancement in drive media is called antiferromagnetically coupled (AFC) media and is designed to allow densities to be pushed beyond previous limits. Anytime density is increased, the magnetic layer on the platters must be made thinner and thinner. Areal density (tracks per inch times bits per inch) has increased in hard drives to the point where the grains in the magnetic layer used to store data are becoming so small that they become unstable over time, causing data storage to become unreliable. This is referred to as the *superparamagnetic limit*, and it has been determined to be between 30Gb/sq. in. and 50Gb/sq. in. Drives today have already reached 35Gb/sq. in., which means the superparamagnetic limit is now becoming a factor in drive designs.

AFC media consists of two magnetic layers separated by a very thin 3-atom (6 angstrom) film layer of the element ruthenium. IBM has coined the term “pixie dust” to refer to this ultra-thin ruthenium layer. This sandwich produces an antiferromagnetic coupling of the top and bottom magnetic layers, which causes the apparent magnetic thickness of the entire structure to be the difference between the top and bottom magnetic layers. This allows the use of physically thicker magnetic layers with more stable larger grains, so they can function as if they were really a single layer that was much thinner overall.

IBM has introduced AFC media into several drives, starting with the 2 1/2" Travelstar 30GN series of notebook drives introduced in 2001; they were the first drives on the market to use AFC media. In addition, IBM has introduced AFC media in desktop 3 1/2" drives starting with the Deskstar 120 GXP. AFC media is also used by Hitachi Global Storage Technologies, which owns the former IBM hard drive lines. I expect other manufacturers to introduce AFC media into their drives as well. The use of AFC media is expected to allow areal densities to be extended to 100Gb/sq. in. and beyond.

- ▶▶ For more information about AFC media and other advanced storage technologies, see Chapter 9, “Magnetic Storage Principles,” p. 619.

Read/Write Heads

A hard disk drive usually has one read/write head for each platter surface (meaning that each platter has two sets of read/write heads—one for the top side and one for the bottom side). These heads are connected, or ganged, on a single movement mechanism. The heads, therefore, move across the platters in unison.

Mechanically, read/write heads are simple. Each head is on an actuator arm that is spring-loaded to force the head into contact with a platter. Few people realize that each platter actually is “squeezed” by the heads above and below it. If you could open a drive safely and lift the top head with your finger, the head would snap back down into the platter when you released it. If you could pull down on one of the heads below a platter, the spring tension would cause it to snap back up into the platter when you released it.

Figure 10.7 shows a typical hard disk head-actuator assembly from a voice coil drive.

When the drive is at rest, the heads are forced into direct contact with the platters by spring tension, but when the drive is spinning at full speed, air pressure develops below the heads and lifts them off the surface of the platter. On a drive spinning at full speed, the distance between the heads and the platter can be anywhere from 0.5 μ -inches to 5 μ -inches or more in a modern drive.

Figure 10.7 Read/write heads and rotary voice coil actuator assembly.

In the early 1960s, hard disk drive recording heads operated at floating heights as large as 200 μ -inches–300 μ -inches; today's drive heads are designed to float as low as 10nm (nanometers) or 0.4 μ -inches above the surface of the disk. To support higher densities in future drives, the physical separation between the head and disk is expected to drop even further, such that on some drives there will even be contact with the platter surface. New media and head designs will be required to make full or partial contact recording possible.

Caution

The small size of the gap between the platters and the heads is why you should never open the disk drive's HDA except in a clean-room environment. Any particle of dust or dirt that gets into this mechanism could cause the heads to read improperly or possibly even to strike the platters while the drive is running at full speed. The latter event could scratch the platter or the head, causing permanent damage.

To ensure the cleanliness of the interior of the drive, the HDA is assembled in a class-100 or better clean room. This specification means that a cubic foot of air can't contain more than 100 particles that measure up to 0.5 microns (19.7 μ -inches). A single person breathing while standing motionless spews out 500 such particles in a single minute! These rooms contain special air-filtration systems that continuously evacuate and refresh the air. A drive's HDA should not be opened unless it is inside such a room.

Although maintaining a clean-room environment might seem to be expensive, many companies manufacture tabletop or bench-size clean rooms that sell for only a few thousand dollars. Some of these devices operate like a glove box; the operator first inserts the drive and any tools required, closes the box, and then turns on the filtration system. Inside the box, a clean-room environment is maintained, and a technician can use the built-in gloves to work on the drive.

In other clean-room variations, the operator stands at a bench where a forced-air curtain maintains a clean environment on the bench top. The technician can walk in and out of the clean-room field by walking through the air curtain. This air curtain is very similar to the curtain of air used in some stores and warehouses to prevent heat from escaping in the winter while leaving a passage wide open.

Because the clean environment is expensive to produce, few companies except those that manufacture the drives are properly equipped to service hard disk drives.

Read/Write Head Designs

As disk drive technology has evolved, so has the design of the read/write head. The earliest heads were simple iron cores with coil windings (electromagnets). By today's standards, the original head designs were enormous in physical size and operated at very low recording densities. Over the years, head designs have evolved from the first simple ferrite core designs into the magneto-resistive and giant magneto-resistive types available today.

For more information on the various head designs, see Chapter 9.

Head Actuator Mechanisms

Possibly more important than the heads themselves is the mechanical system that moves them: the head actuator. This mechanism moves the heads across the disk and positions them accurately above the desired cylinder. Many variations on head actuator mechanisms are in use, but all fall into one of two basic categories:

- Stepper motor actuators
- Voice coil actuators

The use of one or the other type of actuator has profound effects on a drive's performance and reliability. The effects are not limited to speed; they also include accuracy, sensitivity to temperature, position, vibration, and overall reliability. The head actuator is the single most important specification in the drive, and the type of head actuator mechanism in a drive tells you a great deal about the drive's performance and reliability characteristics. Table 10.3 shows the two types of hard disk drive head actuators and the affected performance characteristics.

Table 10.3 Characteristics of Stepper Motor Versus Voice Coil Drives

Characteristic	Stepper Motor	Voice Coil
Relative access speed	Slow	Fast
Temperature sensitive	Yes (very)	No
Positionally sensitive	Yes	No
Automatic head parking	Not usually	Yes
Preventive maintenance	Periodic reformat	None required
Relative reliability	Poor	Excellent

Stepper motor actuators were commonly used on hard drives made during the 1980s and early 1990s with capacities of 100MB or less. All the drives I've seen with greater storage capacity use a voice coil actuator.

Floppy disk drives position their heads by using a stepper motor actuator. The accuracy of the stepper mechanism is suited to a floppy disk drive because the track densities usually are nowhere near those of a hard disk. The track density of a 1.44MB floppy disk is 135 tracks per inch, whereas hard disk drives have densities of more than 5,000 tracks per inch. All hard disk drives being manufactured today use voice coil actuators because stepper motors can't achieve the degree of accuracy necessary.

Stepper Motor Actuators

A stepper motor is an electrical motor that can "step," or move from position to position, with mechanical detents or click-stop positions. If you were to grip the spindle of one of these motors and spin it manually, you would hear a clicking or buzzing sound as the motor passed each detent position with a soft click.

Stepper motors can't position themselves between step positions; they can stop only at the predetermined detent positions. The motors are small (between 1" and 3") and can be square, cylindrical, or flat. Stepper motors are outside the sealed HDA, although the spindle of the motor penetrates the HDA through a sealed hole.

Stepper motor mechanisms are affected by a variety of problems, but the greatest problem is temperature. As the drive platters heat and cool, they expand and contract, and the tracks on the platters move in relation to a predetermined track position. The stepper mechanism can't move in increments of less than a single track to correct for these temperature-induced errors. The drive positions the heads to a particular cylinder according to a predetermined number of steps from the stepper motor, with no room for nuance.

Figure 10.8 shows a common stepper motor design, in which a split metal band is used to transfer the movement from the rotating motor shaft to the head actuator itself.

Figure 10.8 A stepper motor actuator.

Voice Coil Actuators

The voice coil actuators used in virtually all hard disk drives made today—unlike stepper motor actuators—use a feedback signal from the drive to accurately determine the head positions and adjust them, if necessary. This arrangement provides significantly greater performance, accuracy, and reliability than traditional stepper motor actuator designs.

A voice coil actuator works by pure electromagnetic force. The construction of the mechanism is similar to that of a typical audio speaker, from which the term *voice coil* is derived. An audio speaker uses a stationary magnet surrounded by a voice coil, which is connected to the speaker's paper cone. Energizing the coil causes it to move relative to the stationary magnet, which produces sound from the cone. In a typical hard disk drive's voice coil system, the electromagnetic coil is attached to the end of the head rack and placed near a stationary magnet. No physical contact occurs between the coil and the magnet; instead, the coil moves by pure magnetic force. As the electromagnetic coils are energized, they attract or repulse the stationary magnet and move the head rack. Systems like these are extremely quick, efficient, and usually much quieter than systems driven by stepper motors.

Unlike a stepper motor, a voice coil actuator has no click-stops or detent positions; rather, a special guidance system stops the head rack above a particular cylinder. Because it has no detents, the voice coil actuator can slide the heads in and out smoothly to any position desired. Voice coil actuators use a guidance mechanism called a *servo* to tell the actuator where the heads are in relation to the cylinders and to place the heads accurately at the desired positions. This positioning system often is called a *closed loop feedback mechanism*. It works by sending the index (or servo) signal to the positioning

electronics, which return a feedback signal that is used to position the heads accurately. The system also is called *servo-controlled*, which refers to the index or servo information that is used to dictate or control head-positioning accuracy.

A voice coil actuator with servo control is not affected by temperature changes, as a stepper motor is. When temperature changes cause the disk platters to expand or contract, the voice coil system compensates automatically because it never positions the heads in predetermined track positions. Rather, the voice coil system searches for the specific track, guided by the prewritten servo information, and then positions the head rack precisely above the desired track, wherever it happens to be. Because of the continuous feedback of servo information, the heads adjust to the current position of the track at all times. For example, as a drive warms up and the platters expand, the servo information enables the heads to “follow” the track. As a result, a voice coil actuator is sometimes called a *track following system*.

The two main types of voice-coil positioner mechanisms are

- Linear voice-coil actuators
- Rotary voice-coil actuators

The two types differ only in the physical arrangement of the magnets and coils.

Linear Actuators

A linear actuator moves the heads in and out over the platters in a straight line (see Figure 10.9). The coil moves in and out on a track surrounded by the stationary magnets. The primary advantage of the linear design is that it eliminates the head azimuth variations that occur with rotary positioning systems. (*Azimuth* refers to the angular measurement of the head position relative to the tangent of a given cylinder.) A linear actuator does not rotate the head as it moves from one cylinder to another, thus eliminating this problem.

Figure 10.9 A linear voice coil actuator.

Although the linear actuator seems to be a good design, it has one fatal flaw: The devices are much too heavy. As drive performance has increased, the desire for lightweight actuator mechanisms has become very important. The lighter the mechanism, the faster it can accelerate and decelerate from one cylinder to another. Because they are much heavier than rotary actuators, linear actuators were popular only for a short time; they are virtually nonexistent in drives manufactured today.

Rotary actuators also use stationary magnets and a movable coil, but the coil is attached to the end of an actuator arm. As the coil moves relative to the stationary magnet, it swings the head arms in and out over the surface of the disk. The primary advantage of this mechanism is its light weight, which means the heads can accelerate and decelerate very quickly, resulting in very fast average seek times. Because of the lever effect on the head arm, the heads move faster than the actuator, which also helps to improve access times. (Refer to Figure 10.7, which shows a rotary voice coil actuator.)

The disadvantage of a rotary system is that as the heads move from the outer to the inner cylinders, they rotate slightly with respect to the tangent of the cylinders. This rotation results in an azimuth error and is one reason the area of the platter in which the cylinders are located is somewhat limited. By limiting the total motion of the actuator, the azimuth error is contained to within reasonable specifications. Virtually all voice coil drives today use rotary actuator systems.

Servo Mechanisms

Three servo mechanism designs have been used to control voice coil positioners over the years:

- Wedge servo
- Embedded servo
- Dedicated servo

The three designs are slightly different, but they accomplish the same basic task: They enable the head positioner to adjust continuously so it is precisely positioned above a given cylinder on the disk. The main difference between these servo designs is where the gray code information is actually written on the drive.

All servo mechanisms rely on special information that is written to the disk when it is manufactured. This information is usually in the form of a special code called a *gray code*. A gray code is a special binary notational system in which any two adjacent numbers are represented by a code that differs in only one bit place or column position. This system enables the head to easily read the information and quickly determine its precise position.

At the time of manufacture, a special machine called a servowriter writes the servo gray code on the disk. The servowriter is basically a jig that mechanically moves the heads to a given reference position and then writes the servo information at that position. Many servowriters are themselves guided by a laser-beam reference that calculates its own position by calculating distances in wavelengths of light. Because the servowriter must be capable of moving the heads mechanically, the process requires either that the lid of the drive be removed or that access be available through special access ports in the HDA. After the servowriting is complete, these ports are usually covered with sealing tape. You often see these tape-covered holes on the HDA, usually accompanied by warnings that you will void the warranty if you remove the tape. Because servowriting exposes the interior of the HDA, it requires a clean-room environment.

A servowriter is an expensive piece of machinery, costing up to \$50,000 or more, and often must be custom-made for a particular make or model of drive. Some drive-repair companies have servowriting capability, which means they can rewrite the servo information on a drive if it becomes damaged. If a servowriter is not available, a drive with servo-code damage must be sent back to the drive manufacturer for the servo information to be rewritten.

Fortunately, damaging the servo information through disk read and write processes is impossible. Drives are designed so the heads can't overwrite the servo information, even during a low-level format. One myth that has been circulating (especially with respect to ATA drives) is that you can damage the servo information by improper low-level formatting. This is not true. An improper low-level format can compromise the performance of the drive, but the servo information is totally protected and can't be overwritten. Even so, the servo information on some drives can be damaged by a strong adjacent magnetic field or by jarring the drive while it is writing, which causes the heads to move off track.

The track-following capabilities of a servo-controlled voice coil actuator eliminate the positioning errors that occur over time with stepper motor drives. Voice coil drives are not affected by conditions such as

thermal expansion and contraction of the platters. In fact, many voice coil drives today perform a special thermal-recalibration procedure at predetermined intervals while they run. This procedure usually involves seeking the heads from cylinder 0 to some other cylinder one time for every head on the drive. As this sequence occurs, the control circuitry in the drive monitors how much the track positions have moved since the last time the sequence was performed, and a thermal-recalibration adjustment is calculated and stored in the drive's memory. This information is then used every time the drive positions the heads to ensure the most accurate positioning possible.

Most drives perform the thermal-recalibration sequence every 5 minutes for the first 30 minutes that the drive is powered on and then once every 25 minutes after that. With some drives, this thermal-recalibration sequence is very noticeable; the drive essentially stops what it is doing, and you hear rapid ticking for a second or so. Some people think this is an indication that their drive is having a problem reading something and perhaps is conducting a read retry, but this is not true. Most drives today (ATA and SCSI) employ this thermal-recalibration procedure to maintain positioning accuracy.

As multimedia applications grew in popularity, thermal recalibration became a problem with some manufacturers' drives. The thermal-recalibration sequence sometimes interrupted the transfer of a large data file, such as an audio or a video file, which resulted in audio or video playback jitter. Some companies released special A/V (audio visual) drives that hide the thermal-recalibration sequences so they never interrupt a file transfer. Most of the newer ATA and SCSI drives are A/V capable, which means the thermal-recalibration sequences will not interrupt a transfer such as a video playback. A/V-capable ATA drives are also used in set-top boxes that are utilized for digital recording, such as the popular TiVo and ReplayTV devices.

While we are on the subject of automatic drive functions, most of the drives that perform thermal-recalibration sequences also automatically perform a function called a *disk sweep*. Also called *wear leveling* by some manufacturers, this procedure is an automatic head seek that occurs after the drive has been idle for a period of time. The disk-sweep function moves the heads to a cylinder in the outer portion of the platters, which is where the head float-height is highest (because the head-to-platter velocity is highest). Then, if the drive continues to remain idle for another period, the heads move to another cylinder in this area, and the process continues indefinitely as long as the drive is powered on.

The disk-sweep function is designed to prevent the head from remaining stationary above one cylinder in the drive for too long, where friction between the head and platter eventually would dig a trench in the medium. Although the heads are not in direct contact with the medium, they are so close that the constant air pressure from the head floating above a single cylinder could cause friction and excessive wear. Figure 10.10 shows both a wedge and an embedded servo.

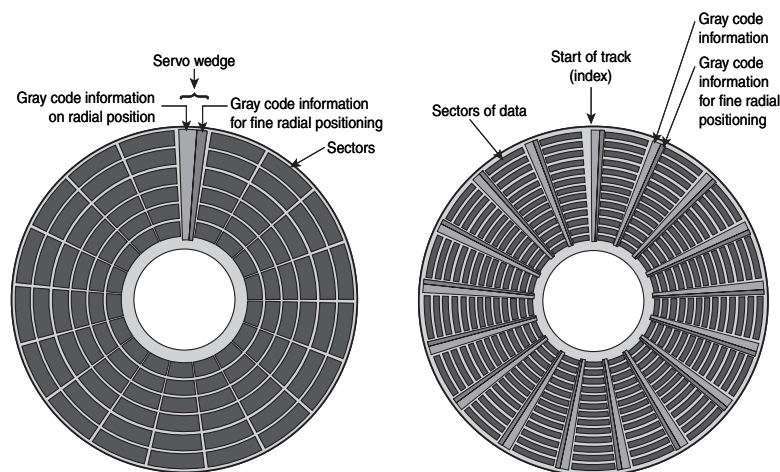

Figure 10.10 A wedge and an embedded servo.

Wedge Servo

Early servo-controlled drives used a technique called a *wedge servo*. In these drives, the gray-code guidance information is contained in a “wedge” slice of the drive in each cylinder immediately preceding the index mark. The index mark indicates the beginning of each track, so the wedge-servo information was written in the PRE-INDEX GAP, which is at the end of each track. This area is provided for speed tolerance and normally is not used by the controller.

Some controllers had to be notified that the drive was using a wedge servo so they could shorten the sector timing to allow for the wedge-servo area. If they were not correctly configured, these controllers would not work properly with the drive.

Another problem was that the servo information appears only one time every revolution, which means that the drive often needed several revolutions before it could accurately determine and adjust the head position. Because of these problems, the wedge servo never was a popular design; it no longer is used in drives.

Embedded Servo

An embedded servo is an enhancement of the wedge servo. Instead of placing the servo code before the beginning of each cylinder, an embedded servo design writes the servo information before the start of each sector. This arrangement enables the positioner circuits to receive feedback many times in a single revolution, making the head positioning much faster and more precise. Another advantage is that every track on the drive has its own positioning information, so each head can quickly and efficiently adjust position to compensate for any changes in the platter or head dimensions, especially for changes due to thermal expansion or physical stress.

Most drives today use an embedded servo to control the positioning system. As in the wedge servo design, the embedded servo information is protected by the drive circuits and any write operations are blocked whenever the heads are above the servo information. Thus, it is impossible to overwrite the servo information with a low-level format, as some people incorrectly believe.

Although the embedded servo works much better than the wedge servo because the servo feedback information is made available several times in a single disk revolution, a system that offered continuous servo feedback information would be better.

Dedicated Servo

A dedicated servo is a design in which the servo information is written continuously throughout the entire track, rather than just once per track or at the beginning of each sector. Unfortunately, if this procedure were used on the entire drive, no room would be left for data. For this reason, a *dedicated servo* uses one side of one of the platters exclusively for the servo-positioning information. The term “dedicated” comes from the fact that this platter side is completely dedicated to the servo information and can’t contain any data.

When building a dedicated servo drive, the manufacturer dedicates one side of one platter from normal read/write usage and records a special set of gray-code data there that indicates the proper track positions. Because the head that rests above this surface can’t be used for normal reading and writing, the gray code can never be erased and the servo information is protected—as in the other servo designs. No low-level format or other procedure can possibly overwrite the servo information. Figure 10.11 shows a dedicated servo mechanism. Typically, the head on top or one in the center is dedicated for servo use.

When the drive moves the heads to a specific cylinder, the internal drive electronics use the signals received by the servo head to determine the position of the read/write heads. As the heads move, the track counters are read from the dedicated servo surface. When the servo head detects the requested track, the actuator stops. The servo electronics then fine-tune the position so the heads are precisely above the desired cylinder before any writing is permitted. Although only one head is used for servo tracking, the other heads are attached to the same rack so that if one head is above the desired cylinder, all the others are as well.

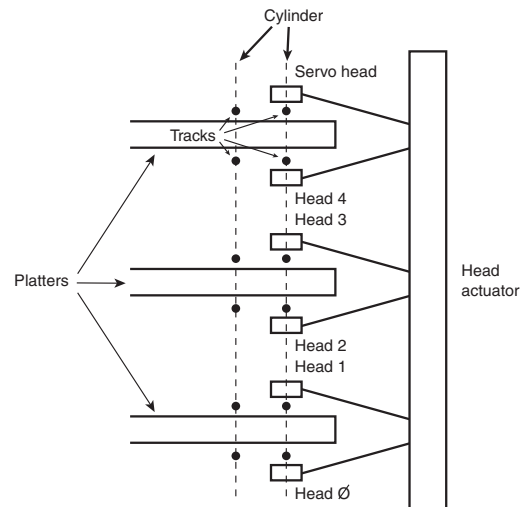

Figure 10.11 A dedicated servo, showing one entire head/side used for servo reading.

One way of telling whether a drive uses a dedicated servo platter is if it has an odd number of heads. For example, the Toshiba MK-538FB 1.2GB drive that I used to have in one of my systems had eight platters, but only 15 read/write heads. That drive uses a dedicated servo positioning system, and the 16th head is the servo head. The advantage of the dedicated servo concept is that the servo information is continuously available to the drive, making the head positioning process faster and more precise.

The drawback to a dedicated servo is that dedicating an entire platter surface for servo information is wasteful. Virtually all drives today use a variation on the embedded servo technique instead. Some drives combined a dedicated servo with an embedded servo, but this type of hybrid design is rare. Regardless of whether the servo mechanism is dedicated or embedded, it is far more accurate than the stepper motor mechanisms of the past.

Of course, as mentioned earlier, today's ATA and SCSI drives have head, track, and sector-per-track parameters that are translated from the actual physical numbers. Therefore, you usually can't tell from the published numbers exactly how many heads or platters are contained within a drive.

Automatic Head Parking

When you power off a hard disk drive using CSS (contact start stop) design, the spring tension in each head arm pulls the heads into contact with the platters. The drive is designed to sustain thousands of takeoffs and landings, but it is wise to ensure that the landing occurs at a spot on the platter that contains no data. Older drives required manual head parking; you had to run a program that positioned the drive heads to a landing zone—usually the innermost cylinder—before turning off the system. Modern drives automatically park the heads, so park programs are no longer necessary.

Some amount of abrasion occurs during the landing and takeoff process, removing just a “micro puff” from the magnetic medium, but if the drive is jarred during the landing or takeoff process, real damage can occur. Newer drives that use load/unload designs incorporate a ramp positioned outside the outer surface of the platters to prevent any contact between the heads and platters, even if the drive is powered off. Load/unload drives automatically park the heads on the ramp when the drive is powered off.

One benefit of using a voice coil actuator is automatic head parking. In a drive that has a voice coil actuator, the heads are positioned and held by magnetic force. When the power to the drive is removed, the magnetic field that holds the heads stationary over a particular cylinder dissipates, enabling the head rack to skitter across the drive surface and potentially cause damage. In the voice

coil design, the head rack is attached to a weak spring at one end and a head stop at the other end. When the system is powered on, the spring is overcome by the magnetic force of the positioner. When the drive is powered off, however, the spring gently drags the head rack to a park-and-lock position before the drive slows down and the heads land. On some drives, you could actually hear the “ting...ting...ting...ting” sound as the heads literally bounce-parked themselves, driven by this spring.

On a drive with a voice coil actuator, you activate the parking mechanism by turning off the computer; you do not need to run a program to park or retract the heads, as was necessary with early hard disk designs. In the event of a power outage, the heads park themselves automatically. (The drives unpark automatically when the system is powered on.)

Air Filters

Nearly all hard disk drives have two air filters. One is called the recirculating filter, and the other is called either a barometric or breather filter. These filters are permanently sealed inside the drive and are designed never to be changed for the life of the drive, unlike many older mainframe hard disks that had changeable filters.

A hard disk on a PC system does not circulate air from inside to outside the HDA or vice versa. The recirculating filter permanently installed inside the HDA is designed to filter only the small particles scraped off the platters during head takeoffs and landings (and possibly any other small particles dislodged inside the drive). Because PC hard disk drives are permanently sealed and do not circulate outside air, they can run in extremely dirty environments (see Figure 10.12).

Figure 10.12 Air circulation in a hard disk.

The HDA in a hard disk drive is sealed but not airtight. The HDA is vented through a barometric or breather filter element that enables pressure equalization (breathing) between the inside and outside of the drive. For this reason, most hard drives are rated by the drive’s manufacturer to run in a specific range of altitudes, usually from 1,000 feet below to 10,000 feet above sea level. In fact, some hard drives are not rated to exceed 7,000 feet while operating because the air pressure would be too low inside the drive to float the heads properly. As the environmental air pressure changes, air bleeds into or out of the drive so internal and external pressures are identical. Although air does bleed through a vent, contamination usually is not a concern because the barometric filter on this vent is designed to filter out all particles larger than 0.3 microns (about 12 μ -inches) to meet the specifications for cleanliness inside the drive. You can see the vent holes on most drives, which are covered internally by this breather filter. Some drives use even finer grade filter elements to keep out even smaller particles.

I conducted a seminar in Hawaii several years ago, and several of the students were from one of the astronomical observatories atop Mauna Kea. They indicated that virtually all the hard disk drives they had tried to use at the observatory site had failed very quickly, if they worked at all. This was no surprise because the observatories are at the 13,796-foot peak of the mountain, and at that altitude, even people don't function very well! At the time, they had to resort to solid-state (RAM) disks, tape drives, or even floppy disk drives as their primary storage medium. IBM's Adstar division, which made all IBM hard drives before the creation of the Hitachi Global Storage Technologies joint venture, developed a line of rugged 3 1/2" drives that are hermetically sealed (airtight), although they do have air inside the HDA. Because they carry their own internal air under pressure, these drives can operate at any altitude and can withstand extremes of shock and temperature. The drives are designed for military and industrial applications, such as systems used aboard aircraft and in extremely harsh environments. They are, of course, more expensive than typical hard drives that operate under ambient pressures. Other vendors, such as MBM Rugged Systems Ltd. (www.lago.co.uk), have also introduced hermetically sealed drives.

Hard Disk Temperature Acclimation

Because most hard drives have a filtered port to bleed air into or out of the HDA, moisture can enter the drive, and after some period of time, it must be assumed that the humidity inside any hard disk is similar to that outside the drive. Humidity can become a serious problem if it is allowed to condense—and especially if you power up the drive while this condensation is present. Most hard disk manufacturers have specified procedures for acclimating a hard drive to a new environment with different temperature and humidity ranges, and especially for bringing a drive into a warmer environment in which condensation can form. This situation should be of special concern to users of laptop or portable systems. If you leave a portable system in an automobile trunk during the winter, for example, it could be catastrophic to bring the machine inside and power it up without allowing it to acclimate to the temperature indoors.

The following text and Table 10.4 are taken from the factory packaging that Control Data Corporation (later Imprimis and eventually Seagate) used to ship with its hard drives:

If you have just received or removed this unit from a climate with temperatures at or below 50°F (10°C) do not open this container until the following conditions are met, otherwise condensation could occur and damage to the device and/or media may result. Place this package in the operating environment for the time duration according to the temperature chart.

Table 10.4 Hard Disk Drive Environmental Acclimation Table

Previous Climate Temperature	Acclimation Time	Previous Climate Temperature	Acclimation Time
+40°F (+4°C)	13 hours	-10°F (-23°C)	20 hours
+30°F (-1°C)	15 hours	-20°F (-29°C)	22 hours
+20°F (-7°C)	16 hours	-30°F (-34°C) or less	27 hours
+10°F (-12°C)	17 hours		
0°F (-18°C)	18 hours		

As you can see from this table, you must place a hard disk drive that has been stored in a colder-than-normal environment into its normal operating environment for a specified amount of time to allow it to acclimate before you power it on.

Spindle Motors

The motor that spins the platters is called the spindle motor because it is connected to the spindle around which the platters revolve. Spindle motors in hard disk drives are always connected directly; no belts or gears are involved. The motor must be free of noise and vibration; otherwise, it can transmit a rumble to the platters, which can disrupt reading and writing operations.

The spindle motor also must be precisely controlled for speed. The platters in hard disk drives revolve at speeds ranging from 3,600rpm to 15,000rpm (60–250 revolutions per second) or more, and the motor has a control circuit with a feedback loop to monitor and control this speed precisely. Because the speed control must be automatic, hard drives do not have a motor-speed adjustment. Some diagnostics programs claim to measure hard drive rotation speed, but all these programs do is estimate the rotational speed by the timing at which sectors pass under the heads.

There is actually no way for a program to measure the hard disk drive's rotational speed; this measurement can be made only with sophisticated test equipment. Don't be alarmed if some diagnostics program tells you that your drive is spinning at an incorrect speed; most likely, the program is wrong, not the drive. Platter rotation and timing information is not provided through the hard disk controller interface. In the past, software could give approximate rotational speed estimates by performing multiple sector read requests and timing them, but this was valid only when all drives had the same number of sectors per track and spun at the same speed. Zoned-bit recording—combined with the many various rotational speeds used by modern drives, not to mention built-in buffers and caches—means that these calculation estimates can't be performed accurately by software.

On most drives, the spindle motor is on the bottom of the drive, just below the sealed HDA. Many drives today, however, have the spindle motor built directly into the platter hub inside the HDA. By using an internal hub spindle motor, the manufacturer can stack more platters in the drive because the spindle motor takes up no vertical space.

Note

Spindle motors, particularly on the larger form-factor drives, can consume a great deal of 12-volt power. Most drives require two to three times the normal operating power when the motor first spins the platters. This heavy draw lasts only a few seconds or until the drive platters reach operating speed. If you have more than one drive, you should try to sequence the start of the spindle motors so the power supply does not have to provide such a large load to all the drives at the same time. Most SCSI and some ATA drives have a delayed spindle-motor start feature.

Fluid Dynamic Bearings

Traditionally, spindle motors have used ball bearings in their design, but limitations in their performance have now caused drive manufacturers to look for alternatives. The main problem with ball bearings is that they have approximately 0.1 micro-inch (millionths of an inch) of runout, which is lateral side-to-side play in the bearings. Even though that might seem small, with the ever increasing density of modern drives, it has become a problem. This runout allows the platters to move randomly that distance from side to side, which causes the tracks to wobble under the heads. Additionally, the runout plus the metal-to-metal contact nature of ball bearings allows an excessive amount of mechanical noise and vibration to be generated, and that is becoming a problem for drives that spin at higher speeds.

The solution is a new type of bearing called a fluid dynamic bearing, which uses a highly viscous lubricating fluid between the spindle and sleeve in the motor. This fluid serves to dampen vibrations and movement, allowing runout to be reduced to 0.01 micro-inches or less. Fluid dynamic bearings also allow for better shock resistance, improved speed control, and reduced noise generation. Several of the more advanced drives on the market today already incorporate fluid dynamic bearings, especially those designed for very high spindle speeds, high areal densities, or low noise. Over the next few years, I expect to see fluid dynamic bearings become standard issue in most hard drives.

Logic Boards

All hard disk drives have one or more logic boards mounted on them. The logic boards contain the electronics that control the drive's spindle and head actuator systems and present data to the controller in some agreed-upon form. On ATA drives, the boards include the controller itself, whereas SCSI drives include the controller and the SCSI bus adapter circuit.

Many disk drive failures occur in the logic board, not in the mechanical assembly. (This statement does not seem logical, but it is true.) Therefore, you sometimes can repair a failed drive by replacing the logic board rather than the entire drive. Replacing the logic board, moreover, enables you to regain access to the data on the drive—something that replacing the entire drive does not provide. Unfortunately, none of the drive manufacturers sell logic boards separately. The only way to obtain a replacement logic board for a given drive is to purchase a functioning identical drive and then cannibalize it for parts. Of course, it doesn't make sense to purchase an entire new drive just to repair an existing one except in cases in which data recovery from the old drive is necessary.

If you have an existing drive that contains important data, and the logic board fails, you will be unable to retrieve the data from the drive unless the board is replaced. Because the value of the data in most cases far exceeds the cost of the drive, a new drive that is identical to the failed drive can be purchased and cannibalized for parts such as the logic board, which can be swapped onto the failed drive. This method is common among companies that offer data recovery services. They stock a large number of popular drives they can use for parts to allow data recovery from defective customer drives they receive.

Most of the time the boards are fairly easy to change with nothing more than a screwdriver. Merely removing and reinstalling a few screws as well as unplugging and reconnecting a cable or two are all that is required to remove and replace a typical logic board.

Cables and Connectors

Hard disk drives typically have several connectors for interfacing to the computer, receiving power, and sometimes grounding to the system chassis. Most drives have at least these three types of connectors:

- Interface connector(s)
- Power connector
- Optional ground connector (tab)

Of these, the interface connectors are the most important because they carry the data and command signals between the system and the drive. In most cases, the drive interface cables can be connected in a daisy-chain or bus-type configuration. Most interfaces support at least two devices, and SCSI (Small Computer System Interface) can support up to seven (Wide SCSI can support up to fifteen) devices in the chain, in addition to the host adapter. Older interfaces, such as ST-506/412 or ESDI (Enhanced Small Device Interface), used separate cables for data and control signals, but today's SCSI, ATA (AT Attachment), and Serial ATA drives have a single data connector on each drive.

◀◀ See "Parallel ATA I/O Connector," p. 543, and "SCSI Cables and Connectors," p. 602.

The power is supplied via the larger four-pin peripheral power connector found on all PC power supplies. Most hard disk drives use both 5- and 12-volt power, although some of the smaller drives designed for portable applications use only 5-volt power. In most cases, the 12-volt power runs the spindle motor and head actuator, and the 5-volt power runs the circuitry. Make sure your power supply can supply adequate power for the hard disk drives installed in your system.

The 12-volt power consumption of a drive usually varies with the physical size of the unit. The larger the drive is, the faster it spins. In addition, the more platters there are to spin, the more power it requires. For example, most of the 3 1/2" drives on the market today use roughly one-half to one-fourth the power (in watts) of the older 5 1/4" drives. Some of the very small (2 1/2" or 1.8") hard disks barely sip electrical power and actually use 1 watt or less!

A grounding tab provides an optional ground connection between the drive and the system's chassis. In most computers, the hard disk drive is mounted directly to the chassis using screws, or the drive is grounded via the ground wires in the power connector, so an extra ground wire is unnecessary.

Configuration Items

To configure a hard disk drive for installation in a system, you usually must set several jumpers (and, possibly, terminating resistors) properly. These items typically vary according to the type of interface the drive supports but can vary somewhat from drive to drive as well.

▶▶ See Chapter 14, “Physical Drive Installation and Configuration,” p. 831.

The Faceplate or Bezel

At one time, hard disk drive vendors offered a front faceplate, or *bezel*, as an option (see Figure 10.13). In most systems today, the bezel is a part of the case and not the drive itself.

Figure 10.13 Typical 5 1/4" and 3 1/2" hard drive bezel shown from the front (as seen on the outside of the PC case) (top) and from the back (bottom—the inside mounting and LED wiring).

Older systems had the drive installed so it was visible outside the system case. To cover the hole in the case, you would use an optional bezel or faceplate. Because today's drives are almost always mounted in an internal bay or an external bay behind a blank faceplate, you seldom need to buy a drive bezel. If you need to use one, you typically use one included with your system or case. However, drive bezels are still available from several vendors in several sizes and colors to match various PC systems. Many faceplate configurations for 3 1/2" drives are available, including bezels that fit 3 1/2" drive bays as well as 5 1/4" drive bays. You even have a choice of colors (usually black, cream, or white).

Some bezels feature a light-emitting diode (LED) that flickers when your hard disk is in use. The LED is mounted in the bezel; the wire hanging off the back of the LED plugs into the drive. In some drives, the LED is permanently mounted on the drive, and the bezel has a clear or colored window so you can see the LED flicker while the drive is being accessed. Most systems today have an LED indicating drive access on the case's front panel, which is connected to a hard drive LED connector on the motherboard.

In systems in which the hard disk is hidden by the unit's cover, a bezel is unnecessary. In fact, using a bezel can prevent the cover from resting on the chassis properly, in which case the bezel must be removed. If you are installing a drive that does not have a proper bezel, frame, or rails to attach to the system, check the Vendor List on the disc accompanying this book; several listed vendors offer these accessories for a variety of drives. If you are using a 7200rpm or faster hard disk, you should consider placing the drive into a drive bay with a removable cover and using a drive bay cooler, which fits on the front of an external drive bay just as a normal bezel would. It has a power connector to provide power for one or more fans used to cool the drive for greater reliability.

Hard Disk Features

To make the best decision in purchasing a hard disk for your system or to understand what distinguishes one brand of hard disk from another, you must consider many features. This section examines some of the issues you should consider when you evaluate drives:

- Capacity
- Reliability
- Performance
- Cost

Capacity

As stated earlier, a corollary of Parkinson's famous "law" can be applied to hard drives: "Data expands so as to fill the space available for its storage." This of course means that no matter how big a drive you get, you *will* find a way to fill it.

If you've exhausted the space on your current hard disk, you might be wondering, "How much storage space is enough?" Because you are more likely to run out of space than have too much, you should aim high and get the largest drive that will fit within your budget. Modern systems are used to store many space-hungry file types, including digital photos, music, video, newer operating systems, applications, and games. As an example, according to hard drive manufacturer Western Digital, storing 600 high-res photos (500KB each), 12 hours of digital music, 5 games, 20 applications, and just 90 minutes of digital video requires an estimated 43GB of space, exceeding the capacity of the typical hard drive installed in many low-end systems sold at retail.

Running out of space causes numerous problems in a modern system, mainly because Windows, as well as many newer applications, uses a large amount of drive space for temporary files and virtual memory. When Windows runs out of room, system instability, crashes, and data loss are inevitable.

Capacity Limitations

How big a hard drive you can use depends somewhat on the interface you choose. Although the ATA interface is by far the most popular interface for hard drives, SCSI interface drives are also available. Each has different limitations, but those of ATA have always been lower than those of SCSI.

When ATA was first created in 1986, it had a maximum capacity limitation of 137GB (65,536×16×255 sectors). BIOS issues further limited capacity to 8.4GB in systems earlier than 1998, and 528MB in systems earlier than 1994. Even after the BIOS problems were resolved, however, the 137GB limit of ATA remained. Fortunately, this was broken in the ATA-6 specification drafted in 2001. ATA-6 augments the addressing scheme used by ATA to allow drive capacity to grow to 144PB (petabytes, or quadrillion bytes), which is 2⁴⁸ sectors. This has opened the door allowing ATA drives over 137GB to be released. Obviously any drives larger than 137GB would by nature conform to ATA-6. However, if you are installing a drive larger than that, you should also ensure that your motherboard BIOS has ATA-6 support.

BIOS Limitations

If your current hard drive is 8GB or smaller, your system might not be capable of handling a larger drive without a BIOS upgrade because many older (pre-1998) BIOSs can't handle drives above the 8.4GB limit, and others (pre-2002) have other limits such as 137GB. Most ATA hard drives ship with a setup disk containing a software BIOS substitute such as Ontrack's Disk Manager or Phoenix Technologies' EZ-Drive (Phoenix purchased EZ-Drive creator StorageSoft in January 2002), but I don't recommend using a software BIOS replacement. Ez-Drive, Disk Manager, and their OEM offshoots (Drive Guide, MAXBlast, Data Lifeguard, and others) can cause problems if you need to boot from floppy or CD media or if you need to repair the nonstandard master boot record these products use.

If your motherboard ROM BIOS dates before 1998 and is limited to 8.4GB or dates before 2002 and is limited to 137GB, and you want to install a larger drive, I recommend you first contact your motherboard (or system) manufacturer to see whether an update is available. Virtually all motherboards incorporate a flash ROM, which allows for easy updates via a utility program.

Internal ATA drives larger than 137GB require 48-bit logical block address (LBA) support. This support *must* be provided in the operating system; it can also be provided in the BIOS, or both. It is best if both the OS and the BIOS support it, but it can be made to work if only the OS has the support.

48-bit LBA support in the OS requires

- Windows XP with Service Pack 1 (SP1) or later.
- Windows 2000 with Service Pack 4 (SP4) or later.
- Windows 98/98SE/Me or NT 4.0 with the Intel Application Accelerator (IAA) loaded. This solution works only if your motherboard has an IAA-supported chipset. See www.intel.com/support/chipsets/IAA/instruct.htm for more information.

48-bit LBA support in the BIOS requires either of the following:

- A motherboard BIOS with 48-bit LBA support (usually dated September 2002 or later)
- An adapter card with onboard BIOS that includes 48-bit LBA support, such as the LBA Pro card from eSupport (www.esupport.com)

These cards use an ISA slot and contain a flash ROM that adds 48-bit LBA support for your existing ATA host adapters. These cards are ROM only. They don't have onboard ATA interfaces, and your drives remain connected to your previously existing ATA host adapters (normally built in to the motherboard).

If you have both OS and BIOS support for 48-bit LBA, you can simply install and use the drive like any other internal drive. On the other hand, if you do not have 48-bit LBA support in the BIOS, but you do have it in the OS, portions of the drive past 137GB are not recognized or accessible until the OS is loaded. This means that if you are installing the OS to a blank hard drive and booting from an original XP (pre-SP1) CD or earlier, you need to partition up to the first 137GB of the drive at installation time. After the OS is fully installed and the service packs added, the remainder of the drive beyond 137GB is recognized. At that point, you can then either partition the remainder of the drive beyond 137GB using the XP Disk Management tools or use a third-party partitioning program such as PartitionMagic or Partition Commander to resize the first partition to use the full drive.

If you are booting from an XP SP1 or later CD (meaning a CD with Service Pack 1 already applied), you can recognize and access the entire drive during the OS installation and partition the entire drive as a single partition greater than 137GB if you like.

If you need more or faster ATA interface connections, or if you don't have ISA slots on your motherboard, you can use PCI-based add-on cards (such as the Ultra133 TX2 and Ultra100 TX2) from companies like Maxtor and Promise Technologies. These cards support drives up to and beyond the 137GB limit imposed by the ATA-5 and older standards. These cards also have two ATA host adapter interfaces onboard that support two drives each (four drives per card). These cards do support ATA-133 and ATA-100 interface speeds and are backward-compatible with older, slower ATA drives.

Maxtor and Western Digital sell drives in kits bundled with an ATA-133 PCI host adapter card that also provides BIOS support for drives beyond 137GB.

USB, FireWire, and SCSI drives don't have these capacity issues because they don't rely on the ROM BIOS for support and use OS managed drivers instead.

SCSI was designed from the beginning with fewer limitations than ATA, which is why SCSI is more commonly used in high-performance file servers, workstations, and other high-performance computer systems. Even though SCSI originated prior to ATA, the architects had the foresight to allow SCSI to address devices up to 2.2TB (terabytes, or trillion bytes) in capacity (2^{32} sectors). In 2001, the SCSI command set was further upgraded to support drives up to 9.44ZB (zettabytes, or sextillion bytes) in capacity (2^{64} sectors). Because SCSI was initially designed with fewer limitations and greater performance in

mind, manufacturers have always released their largest capacity drives in SCSI versions first. If you absolutely must have the biggest drive, it will almost always be a SCSI drive you are looking for.

Because of the changes in 2001 to both ATA and SCSI, it will be many years before the capacity limitations of either interface become a problem.

Operating System Limitations

More recent operating systems such as Windows Me, as well as Windows 2000 and XP, fortunately don't have any problems with larger drives. However, older operating systems might have limitations when it comes to using large drives.

DOS generally does not recognize drives larger than 8.4GB because those drives are accessed using LBA and DOS versions 6.x and lower use only CHS addressing.

Windows 95 has a 32GB hard disk capacity limit, and there is no way around it other than upgrading to Windows 98 or newer. Additionally, the retail or upgrade versions of Windows 95 (also called Windows 95 OSR 1 or Windows 95a) are further limited to using only the FAT16 (16-bit file allocation table) file system, which carries a maximum partition size limitation of 2GB. Therefore, if you had a 30GB drive, you would be forced to divide it into 15 2GB partitions, with each appearing as a separate drive letter (drives C:–Q: in this example). Windows 95B and 95C can use the FAT32 file system, which allows partition sizes up to 2TB. Note that because of internal limitations, no version of FDISK can create partitions larger than 512MB.

Windows 98 supports large drives, but a bug in the FDISK program included with Windows 98 reduces the reported drive capacity by 64GB for drives over that capacity. The solution is an updated version of FDISK that can be downloaded from Microsoft. Another bug appears in the `FORMAT` command with Windows 98: If you run `FORMAT` from a command prompt on a partition over 64GB, the size isn't reported correctly, although the entire partition is formatted.

Performance

When you select a hard disk drive, one of the important features you should consider is the performance (speed) of the drive. Hard drives can have a wide range of performance capabilities. As is true of many things, one of the best indicators of a drive's relative performance is its price. An old saying from the automobile-racing industry is appropriate here: "Speed costs money. How fast do you want to go?"

The speed of a disk drive is typically measured in two ways:

- Transfer rate
- Average access time

Transfer Rate

The transfer rate is probably more important to overall system performance than any other statistic, but it is also one of the most misunderstood specifications. The problem stems from the fact that several transfer rates can be specified for a given drive; however, the most important of these is usually overlooked.
